Any bacterium that is, at least occasionally, active in the soil is a potential host for phages. Commonly used approaches for detecting phages in soil have indicated that soil contains numerous phages capable of infecting many members of the diverse bacterial community. Although there has been no attempt to estimate the total concentration of phage particles in a soil sample, the limited data currently available indicate that a gram of fertile soil would contain numbers of phages in excess of the 10^9 viable counts for their bacterial hosts. Indeed, it has been suggested that phages may be the most numerous genetic object in the soil habitat.

Therefore, the ecology of phages in soil clearly merits more attention. Phages may exert some control on the many biochemical transformations of their hosts, either by direct lysis of key bacteria or indirectly as agents of genetic change. They also provide a novel opportunity to apply and test the concepts of host–parasite interactions. At a more practical level, the presence of phage in a sample that is active against bacterial taxa of interest can be a rapid means of screening large numbers of soils for the presence of selected bacteria. Also, the introduction of phages could potentially be used as a control method to limit the population size of engineered bacteria that have been introduced into soil.

This entry aims to address the current objectives, methods and problems of studying the roles of phages in soil. There will be some emphasis on phage infecting *Streptomyces*, a genus that is widespread in soil and to which most of our research has been directed.

Detection of Phages in Soil

Two basic approaches have been used to detect and isolate phages from soils. These are (1) enrichment procedures, which demonstrate the existence of one or more phage types in the sample; and (2) direct counts, which provide an estimate of the number of phages *in vivo* which are active against selected host(s).

Enrichment procedures

The most widely used enrichment procedure involves incubating a soil sample with a high concentration of the potential host cells. Within the soil, those phages that have the ability to infect this host will increase in number during this time. The period of incubation depends on the growth cycle of the host, as does the growth medium. Ideally both of these variables should be determined before attempting an enrichment procedure. Depending on the aims of the exercise, it may be appropriate to use a mixture of soil samples or a combination of putative hosts.

After incubation, the larger particles of soil and microbial material are removed by centrifugation and the supernatant is passed through a filter that excludes bacteria (e.g. 0.45 μm). The filtrate is then spotted on to a lawn of the putative host(s), preferably using the double-layer method. Any plaques or confluent lysis appearing after incubation indicates the presence of phage active against the host(s). Phages can then be purified by sequential isolation, dilution and testing against the host. High-titer stocks of specific phages can be prepared by plating them against their host, removing areas of high lysis, soaking them in a suitable nutrient medium at 4°C, filtering the supernatant and storing the suspension at 4°C. The viability of such stocks should be checked at 6-monthly intervals.

This method has proved to be both simple and effective, resulting in the isolation of phages specific to a variety of soil bacteria. A positive result also indicates that the host, or a close relative, is present in the soil sample(s) tested.

An alternative method dispenses with the addition of a high concentration of the potential host cells. Samples of soil are added to broth and incubated to stimulate growth of indigenous bacterial propagules and, hence, multiplication of their phages. Cell-free filtrates can then be spotted on to lawns of any potential hosts of interest. The rates of detection of actinophages (phage infecting actinomycetes) compare favorably with those obtained by the host enrichment method. Examples of actinophages detected in a range of soils by this method are given in **Table 1.**

Direct counts

Unlike enrichment procedures, direct counts aim to determine the concentration of phages present in a sample *in vivo*. Therefore, soil samples of known weight are suspended, diluted and filtered to remove bacteria. Dilutions of the filtrates are then plated on to lawns of putative host(s). The number of phage plaques developing indicates the number of phage particles per dry weight of soil, which are active against the host used.

Not all attempts to obtain direct counts have been successful and there are several possible reasons for

Table 1 Examples of actinophages in soils detected by nonhost enrichment

Propagation taxa	*No. of soils in which detected*
Streptomyces craterifer	37
Amycolatopsis spp.	37
Saccharopolyspora rectivirgula	17
Microtetraspora africana	11
Nocardioides albus	10
Actinomadura kijaniata	6
Saccharomonospora viridis	6
Amycolata autotrophica	4

this. Firstly, it is essential that the host strains used are known to be indigenous members of the soil or soil microhabitat used. Secondly, it is important that these strains are, or have been recently, active in the soil. It is well known that the soil mass is often relatively poor in energy sources for organotrophic bacteria and that these supplies are often concentrated in sites such as plant root regions. Also, there is much evidence to suggest that many common bacterial isolates (e.g. *Bacillus*, *Streptomyces*) are often obtained from resting spores within the sample. Consequently, the highest direct counts have been obtained from energy-rich habitats, such as garden compost and mushroom compost (10^3–10^4 PFU g^{-1} for *Streptomyces* phage (similar counts for thermophilic *Bacillus* phage)). Finally, the efficiency of the procedures used to extract phage particles from soil must be considered. Whatever the extraction method, its efficiency will be influenced by the physical nature of the soil. If a known titer of phage is added to sandy, loam and clay soils under controlled laboratory conditions, the percentages recovered usually decrease sequentially. This is probably due to the adsorption of phage particles to soil colloids. In addition, there are several variables in the extraction procedure. In our studies of the recovery of streptomycete phages added to three sterile soils, the best results were obtained by reciprocal shaking of the soil suspension in a nutrient broth with 0.1% (w/v) egg albumin at pH 8.0, followed by centrifugation of extracts at 1200*g* for 15 min. However, filter sterilization of the extracts resulted in lower recoveries of phage (34–87%) than those obtained using chloroform sterilization (93–100%). The latter method provided direct counts of phages active against selected *Streptomyces* spp. from arable and garden soils ranging from 0 to 10^3 PFU g^{-1} soil. Nevertheless there is much scope for the improvement of procedures to obtain accurate direct counts of phages in soil.

Stability of Free Phages in Soil

The methods used to detect or enumerate phages in soil are based on the assumption that phages exist as free particles in the sample. Therefore, it is pertinent to consider the factors that determine their stability in soil. Most data have been obtained by adding known titers of phages to natural and sterilized soil samples under laboratory conditions. The latter approach has the advantage of distinguishing between the survival of phages and the effect of factors on the activity of potential host bacteria (unless natural samples are incubated at low temperatures which preclude host growth). Additional information has been provided by studies on phage stability in laboratory broth suspensions. Relatively few studies of this topic have been made and many of the results have been equivocal. For example, when streptomycete phages were added to a range of soils, loss of viability was generally greater in natural soil. However, there was no significant difference in the stability of streptomycete phages added to natural and sterile sand dune soils; total inactivity of added phages occurred after 5 weeks. The half-life values of streptomycete phages added to sterilized sand dune soil stored at 4°C ranged from 1.19 to 18.9 days. Thus, it seems likely that free phage particles have a variable, but ecologically significant, capacity for stability in soil.

Various soil abiotic factors influence the stability of phage particles in soil. The presence and type of colloidal particles may have an effect on stability, but also influences the efficiency of extraction methods due to adsorption by phages. It is not always easy to differentiate between these two effects. In our experiments, four phages were added to a sand dune soil supplemented with 8% (w/w) kaolin or montmorillonite. Three phages showed increased half-lives in the presence of kaolin and one in the presence of montmorillonite. Previous data suggested that streptomycete phages were more readily adsorbed to kaolin than to montmorillonite.

Soil pH is another important factor influencing phage stability. Most studies have been conducted using typical neutrophilic hosts, active in a range from about pH 5.0 to pH 8.0. It has proved difficult to isolate phages from acidic soils (< pH 5.0) and laboratory studies on phage survival in soil tend to mirror this picture. The recovery of titers of streptomycete phages added to soils of different pH ranged from 0 (pH 3.7–4.2) to 10^3–10^4 PFU g^{-1} (pH 6.1–8.0). When four streptomycete phages were added to a sand dune soil (pH 6.8) and a pine forest soil (pH 5.9), half-lives in the former were larger in each case.

Soil temperatures vary considerably with locality, season and depth; most bacterial isolates react as

mesophiles with optimum growth at 25–30°C but phages are generally more stable at lower temperatures. The ideal storage temperature for most phages in broth suspension is 4°C, and when streptomycete phages were stored in sterile soil, half-lives were larger at 4°C than 20°C; however, the phages infecting thermophilic hosts, such as *Bacillus* spp. and *Thermoactinomyces* spp., which are active in self-heating composts, have an equivalent stability and activity at temperatures from 40 to 55°C.

Soil moisture is a continually fluctuating factor and has a major influence on bacterial growth, primarily through its effect on aeration; therefore, it clearly affects the activity of potential hosts. However, there is little evidence that moisture levels have a significant influence on free phage particles *per se*.

Phage–Host Interactions in Soil

Most studies on phage–host interactions in soil have been based on the assumption that the phages are virulent and undergo a typical lytic cycle, hence this article is mainly concerned with virulent phages. The possibility of phages forming lysogenic relationships cannot, however, be ruled out. It has been suggested that lysogeny is a mutually beneficial interaction for both host and phage. The phage can persist for long periods in the prophage state, protected from adverse environmental conditions, while the host is provided with homoimmunity to infecting phages. However, recent work has shown that the carriage of phages may be detrimental to the survival of the host as lysogens of a *Streptomyces* sp. were shown to die off in nonsterile soil, whereas the nonlysogen survived.

With regards to virulent phages, whatever the effects of environmental factors on free phages in soil their continued presence in soil depends on their chance adsorption to a suitable metabolically active host bacterium. Free phage particles presumably behave as passive entities in the soil suspension. Two factors may mitigate the randomness of phage–host encounters. Firstly, most phages are probably concentrated in microsites where their previously lysed hosts were active. Secondly, there is some evidence that both host cells and phage particles can adsorb to colloidal materials, thus increasing their proximity. If a potentially successful encounter occurs, its subsequent development will depend on the influence of environmental factors on adsorption, penetration and the level of host activity after infection.

The latter is clearly influenced by the quantity and nature of the energy supplies, temperature, aeration and pH. Information on the effect of environmental factors on reversible and irreversible adsorption is limited and confined mainly to reactions of phages added to sterile soil or broth cultures under laboratory conditions. Phage–streptomycete interactions usually have low infection efficiencies (10–50%), probably due to incomplete adsorption. The proportion of phages that is reversibly adsorbed is not dependent on host concentration (as streptomycetes are mycelial organisms, germlings are used as infectable units). Irreversible adsorption has been shown to depend on temperature, pH, time and host concentration. Increases in the latter lead to more adsorptions than those obtained by increasing phage concentrations, indicating that availability of adsorption sites may be a limiting factor. Subsequent to infection, it has been shown that the age and physiological state of the host influences the burst size, with a tenfold increase occurring in well-germinated spores (18 h) compared with newly germinated ones (4 h).

The temporal abundance of phages in soil is a reflection of the dynamics of host–phage interactions occurring within the microbial community. Such interactions reflect considerable complexity and have only recently begun to be examined in soil microcosms. Intrinsically, phage abundance is coupled to host abundance, and in turn host abundance will be a function of available resources within the soil environment. This coupling may, however, be an indirect one because hosts exhibit susceptibility to phages at specific stages in their life cycle. In single-cell bacteria, only actively growing cells are potentially infectable. In filamentous bacteria, the number of successful encounters between phage and hosts will be relative to the number of infectable host units, i.e. mycelial tips and germinating spores. In turn the abundance of infectable units will be proportional to resources for available host population growth. At the extremes, resource renewal may result in host populations being continuously available, as in bacteria at steady-state equilibrium or, when resource renewal is punctuated, periods where (1) absolute host numbers are low, and (2) where the number of infectable units are low. In actinomycetes, the abundance of infectable units as tips will be related to the resources available for filamentous vegetative growth. This abundance is increased when sporulation is triggered by resource exhaustion, with subsequent germination of spores occurring on resource renewal. Phasic fluctuation of infectable units in time, driven by resource utilization and renewal at the microsite level, is therefore a backdrop which may part regulate phage numbers over time. The extent to which a stable distribution of infectable units occurs over time will depend on the extent to which resources for growth are repetitively/continuously

renewed, which in turn may reflect the relative homogeneity of the soil environment as a whole.

Single species dynamics – phage components

Simplistically, absolute numbers of phages at a point in time will depend upon the gains arising from replication within hosts and the losses incurred through processes leading to inviability. In the absence of hosts, phages exhibit a 'type-specific' death rate that is constant within a given environment, enabling persistence of the virion bank within the soil to be quantified as a half-life. For actinophages, half-lives have been reported in the range of 1.19–18.9 days.

Burst size, the number of phages produced by a successful infection, may vary over three orders of magnitude, typically from *c.* 10 to 1000 PFU per infection. Temperature is an important determinant in phage reproduction, influencing key parameters of yield. Latent periods are shortened with elevated temperatures, whereas burst sizes are increased.

The probability of successful infection of a host by phages is a relatively rare event (10^{-5}–10^{-10}), and comparative studies suggest that infection efficiencies per unit volume are elevated in soil as opposed to broth culture. This may be a direct reflection of differences in surface area available for phage–host interaction in the two systems. The colloidal properties of soils are significant determinants of infection efficiency, as phages and bacteria may adsorb to clay colloids. The clay particles may act to concentrate phages and bacteria in the same microsite in the soil and, on the other hand, may protect bacteria from phage attack by differential adsorption.

Single species dynamics – host components

Rates of change in host numbers over time, in the absence of phages, will depend on the gains made through reproduction and the loss through death. In single-species bacterial populations, intrinsic rates of increase and carrying capacities of particular environments are common parameters in the descriptions of population dynamics. The steady-state conditions and the return times to steady state are governed by the form of the relationship between growth rate, the concentration of resource(s) limiting growth and the magnitude of the perturbations from equilibrium. Characteristically the generation times of unicellular hosts are short and population responses to resource renewal may be extremely rapid. In filamentous forms, developmental times are of longer duration and hence response times may be slower than in unicells. Filamentous hosts may also retain a bank of dormant spores at the same time as filamentous growth and sporulation is occurring. The finite rate of increase, often most conveniently measured immediately after sporulation, is therefore the sum of the contributions from the active fraction of the population (sporulating individuals) and the proportion of viable spores persisting over generations. In streptomycetes in natural soil, multiplication rates may vary up to a thousandfold. Significant variation in the proportion of spores persisting over a cycle of sporulation have been reported to range from 30 to 55%.

Experiments in which spore production has been measured from differing initial concentrations of inoculum into a constant volume of medium or soil have clearly pointed to density-dependent regulation of finite rates of increase in filamentous hosts. Such regulation is more likely to occur during spore production than in mortality of germinated spores. Although few actinomycetes have been considered in detail, in streptomycetes (1) both intra- and interspecific competition has been demonstrated, and (2) simple mixtures of streptomyces species may coexist at lowered equilibrium population densities than exhibited by individual components in monoculture. In long-term soil microcosms, streptomycete populations may persist in mixture, fluctuating in size between 10^5 and 10^6 CFU g^{-1} soil.

Host–Phage Interactions

The few empirical studies using soils have shown that prolonged coexistence between an individual host (single-cell or actinomycete) and a phage may occur, in which both components exhibit stability around an equilibrium mean density. In a bacteriophage–host association, the equilibrium density of both components is characterized by considerable constancy. In actinophage–host interactions, the host displays oscillations around a mean equilibrium with host numbers increasing during a sporulation phase in a periodic manner. Phage abundance shows a tendency to track host abundance.

In sterile soil cultures of *Bacillus subtilis* populations, the presence of a virulent phage lowered host equilibrium population size by a factor of ten, and phage densities were considerably lower than host densities. In contrast, the introduction of a temperate phage did not alter host equilibrium density from that observed when the host was cultured alone.

Streptomycete-virulent phage interactions in sterile soil also result in long-term persistence of phage, with a concomitant lowering of mean host abundance, although fluctuations in both components of at least one order of magnitude occurred around mean equilibrium levels. Also, the interaction with a

temperate phage resulted in the population density of the lysogen being lower than that of the nonlysogen counterpart.

Theoretical studies of predator–prey relations in other biological systems have pointed to the importance of the nature of the predator and prey responses in determining the outcome of a one-sided antagonistic interaction. In particular, the precise responses by phages to host density and host aggregation can have important effects (either stabilizing or destabilizing) on the interaction. The limited experimental evidence suggests that (1) the rate of phage 'predation' may increase as streptomycete density increases, and hence larger host populations suffer more mortality than smaller ones; and (2) the spatial heterogeneity of the soil environment may provide refuges for the host in which protection from phage infection may occur. In the former case there is a tendency to destabilize the interaction, leading to phage extinction. In the latter, the scale of spatial heterogeneity is important in determining stabilizing effects to provide a constant number or constant proportion of refuges. Besides these purely ecological considerations, temperature and lysogeny have been argued to be coevolutionary responses by phage to stabilize the interaction.

Experimental studies have shown that, on first introduction of phages to a host culture in soil, the phages may undergo an initial epidemic followed by a stable equilibrium. Analytical studies have indicated that phage–host interactions may be sensitive to initial starting conditions (relative abundance of the two components) but the form of dynamic behaviour (stable equilibrium, dampened oscillations, unstable fluctuations) is crucially dependent upon infection efficiency, burst size and intrinsic rate of increase of the host.

Community Dynamics

Both single-cell bacterial and streptomycete communities in soil may display considerable species richness and the role of phage and host in the maintenance of each other's diversity is yet to be unequivocally demonstrated. Laboratory studies of interspecific competition in simple (two species) mixtures of both bacteria and streptomycetes have indicated that competitive exclusion may occur, but the extent to which phage may mediate competitive interactions and ensure coexistence of competing hosts is unknown. Such a stabilizing influence will necessarily lead to phage persistence. Differential host susceptibility is another factor that may lead to long-term stability in host–phage interaction, and phages typically show wide variation in host range. The functional significance of lysogeny in the ecology of phages is still obscure but it has been suggested that prophages are much more common than free virions. If long-term phage persistence is related to lysogeny, phage diversity will be a function of host range and community interactions amongst hosts and other taxa in soil. The importance of these interactions during successional processes in soils remains to be unraveled.

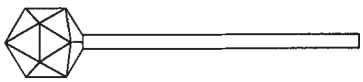
PHAGES OF *STREPTOCOCCUS THERMOPHILUS*



Harald Brüssow, Nestlé Research Center Lausanne, Lausanne, Switzerland

Industrial Background

Lactic acid bacteria are used as so-called starters to transform milk into a variety of products. *Streptococcus thermophilus* is used in the production of mozzarella cheese and in symbiosis with *Lactobacillus delbrueckii* in the production of yoghurt and Swiss-type cheese. Streptococci, lactococci, lactobacilli and the well-studied model bacterium *Bacillus subtilis* belong to an evolutionary related group of the low

temperate phage resulted in the population density of the lysogen being lower than that of the nonlysogen counterpart.

Theoretical studies of predator–prey relations in other biological systems have pointed to the importance of the nature of the predator and prey responses in determining the outcome of a one-sided antagonistic interaction. In particular, the precise responses by phages to host density and host aggregation can have important effects (either stabilizing or destabilizing) on the interaction. The limited experimental evidence suggests that (1) the rate of phage 'predation' may increase as streptomycete density increases, and hence larger host populations suffer more mortality than smaller ones; and (2) the spatial heterogeneity of the soil environment may provide refuges for the host in which protection from phage infection may occur. In the former case there is a tendency to destabilize the interaction, leading to phage extinction. In the latter, the scale of spatial heterogeneity is important in determining stabilizing effects to provide a constant number or constant proportion of refuges. Besides these purely ecological considerations, temperature and lysogeny have been argued to be coevolutionary responses by phage to stabilize the interaction.

Experimental studies have shown that, on first introduction of phages to a host culture in soil, the phages may undergo an initial epidemic followed by a stable equilibrium. Analytical studies have indicated that phage–host interactions may be sensitive to initial starting conditions (relative abundance of the two components) but the form of dynamic behaviour (stable equilibrium, dampened oscillations, unstable fluctuations) is crucially dependent upon infection efficiency, burst size and intrinsic rate of increase of the host.

Community Dynamics

Both single-cell bacterial and streptomycete communities in soil may display considerable species richness and the role of phage and host in the maintenance of each other's diversity is yet to be unequivocally demonstrated. Laboratory studies of interspecific competition in simple (two species) mixtures of both bacteria and streptomycetes have indicated that competitive exclusion may occur, but the extent to which phage may mediate competitive interactions and ensure coexistence of competing hosts is unknown. Such a stabilizing influence will necessarily lead to phage persistence. Differential host susceptibility is another factor that may lead to long-term stability in host–phage interaction, and phages typically show wide variation in host range. The functional significance of lysogeny in the ecology of phages is still obscure but it has been suggested that prophages are much more common than free virions. If long-term phage persistence is related to lysogeny, phage diversity will be a function of host range and community interactions amongst hosts and other taxa in soil. The importance of these interactions during successional processes in soils remains to be unraveled.

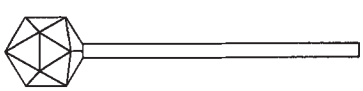
PHAGES OF *STREPTOCOCCUS THERMOPHILUS*



Harald Brüssow, Nestlé Research Center Lausanne, Lausanne, Switzerland

Industrial Background

Lactic acid bacteria are used as so-called starters to transform milk into a variety of products. *Streptococcus thermophilus* is used in the production of mozzarella cheese and in symbiosis with *Lactobacillus delbrueckii* in the production of yoghurt and Swiss-type cheese. Streptococci, lactococci, lactobacilli and the well-studied model bacterium *Bacillus subtilis* belong to an evolutionary related group of the low

GC branch of Gram-positive Eubacteria. During growth the lactic streptococci ferment milk sugar (lactose) into lactic acid. The concomitant drop in pH leads to a coagulation of the milk which creates the food matrix. The low pH also protects the product against spoilage organisms.

Phage attack has always been a major problem in the dairy industry. Bacteriophages kill the starter and thus prevent proper fermentation. There are endogenous and exogenous sources of phages in the dairy industry. The endogeneous source is intimately linked with the starter. Many valuable starter bacteria, including lactic streptococci, are lysogenic, i.e. they contain an integrated copy of a temperate bacteriophage in their genome. Between 1 to 10% of starter strains release infectious phage after induction with mitomycin C. The prophage can also be activated under conditions of physiological stress of the bacterial cell. Starters frequently experience temperature, water, sugar, salt and concentration stress under conditions of industrial production. The majority of phage problems in the dairy industry are, however, linked to virulent phages which enter the factory through airborne and waterborne transmission routes from exogenous environmental sources, most likely raw milk. Production problems in a yoghurt factory start with a phage contamination level of 10^3 PFU ml^{-1}. First signs are a slowed acidification or texture problems of the yoghurt. Loss of entire starter batches are not rare. Occasionally, the phage problem is transmitted into the production line resulting in the loss of the product. Once introduced into the production line, phages can hide out for weeks, if not months in hard-to-disinfect infection pockets. Since a larger yoghurt plant processes 50 000 liters of milk daily, the stakes are high and phage attacks can be very costly. The economical implications are even more serious in cheese production where many dairies process half a million liters of milk daily. The conditions of cheese manufacturing favor the growth of phages. Not only are the milk volumes greater, but the raw milk is heated to lower temperatures and for shorter times than in yoghurt production. In addition, cheese production is an open process; during separation of the cheese whey large quantities of phage-loaden aerosols and liquids are created which contaminate the whole factory. In contrast, during yoghurt production the fermented milk is contained in a closed tubing system with minimal exposure to the environment. To minimize the negative effects of phage infections, the mozzarella industry uses complex starter mixes or even undefined starter blends. The yoghurt industry relies on few starter strains used in rotation to prevent the amplification of phages beyond a critical threshold.

Ecology

A longitudinal survey of *S. thermophilus* phages was conducted over several years in a mozzarella factory. The dairy used a complex, undefined mixture of starter cells and open, continuous fermentation tanks. Twelve distinct lytic groups of phages showing 11 distinct restriction patterns were observed over a two-year observation period. Multiple phage isolates from the same lytic group showed no nucleotide sequence changes over time. Dairy factories are thus not evolution machines creating new phage types. The diversity of the factory phages reflects the diversity of the phages attained in their natural environment. A direct proof of a link between factory phages and phages from the environment is, however, difficult to provide, as the phage concentration in the environment is very low compared to the infestation level of the factory (10^4–10^7 PFU ml^{-1}). To document these invasion events, an intervention study was conducted. The complex, undefined starter system of the factory was replaced by a defined starter system composed of cells which were unable to propagate the resident phage population. The intervention led to a marked decrease of the factory-specific phage population. Within a week three new phage types had colonized the factory (**Fig. 1**). Restriction analysis demonstrated that the new phages were not derivatives of the resident phage population. They were identical to phages found at low titers (10–130 PFU ml^{-1}) in the raw milk delivered to the factory during the intervention trial.

Classification of Virulent Phages

Virulent *S. thermophilus* phages from several collections have been characterized. All phages possess the same basic morphology consisting of an isometric head and long, noncontractile tail. In some phages, a thin fiber is attached to a terminal plate (**Fig. 2**). Morphologically they are classified as group B1 *Siphoviridae* (**Table 1**).

The largest collection covered 30 years of factory surveys from Italy and France. It contained about 100 distinct phage isolates. The phages differed in restriction pattern (more than 60 distinct restriction patterns were observed) or host range. Extensive DNA crosshybridization was observed between these phages. Host range analysis allowed the separation of yoghurt phages into two lytic groups, I and II. The taxonomic differentiation of these two lytic groups was biologically meaningful as it was corroborated by independent techniques (serology, protein and DNA analysis). Lytic group I phages were *cos*-site phages, whereas lytic group II phages were *pac*-site phages.

Table 1 *Streptococcus thermophilus* phages in numbers

Growth	Growth medium	Milk, M17 broth
	Growth temperature	40°C
	Eclipse period	30 min
	Rise period	20 min
	Burst size	140–200
Morphology	Head	65 nm
	Tail	230–260 nm
	Tail fiber	50–400 nm
Taxonomy	Order	*Caudavirales*
	Family	*Siphoviridae* Group B
Genome		ds DNA, 31–45 kb
Classification:	*cos*-site	
Yoghurt	Virulent	Prototype Sfi19 (lytic group I, serotype 1) DNA: 37 392 bp; 44 ORFs Proteins: minor: 155, 105, 82, 64, 55, 44 kDa major: 33, 28 kDa
	Temperate	Prototype Sfi21 (lytic group I, serotype 1) DNA: 40 739; 52 ORFs
	pac-site	
	Virulent	Prototype Sfi11 (lytic group II, serotype 2) DNA: 39 807 bp; 51 ORFs Proteins: minor: 160, 120, 82, 74, 70, 60 kDa major: 44, 27, 18 kDa
	Temperate	Prototype 01205 DNA: 43 075 bp; 57 ORFs
Cheese	Many lytic groups	

Antisera against lytic group I phages did not neutralize lytic group II phages and vice versa. In addition, DNA probes were defined that were able to differentiate phages belonging to either lytic group I or II. The *cos*-site phages showed two major structural proteins, whereas *pac*-site phages demonstrated three major proteins.

In contrast, cheese phage isolates possessed a narrow host range and consisted of many lytic groups; within 41 isolates 34 different lytic groups were observed. The limited number of lytic groups in yoghurt-derived phages may reflect the restricted number of specialized starter strains used in yoghurt production.

Genomics of Virulent Phages

Phage Sfi19 (ϕSfi19) was chosen as the type phage for virulent lytic group I *cos*-site phages. It has a genome size of 37 kb. Interestingly, all 44 predicted genes are encoded on the same DNA strand (**Fig. 3, Table 2**). In accordance with the modular theory of phage evolution, genes of related functions are found in clusters. A DNA packaging module is found around the *cos*-site at the arbitrarily defined left genome end. It is followed by a cluster of putative head genes and then a tail DNA module. Downstream of the structural gene modules, which filled up the left half of the phage genome, there is a lysis cassette, then a remnant of a lysogeny module, a DNA replication module and finally a region of unknown attribution. With one exception the closest database matches of the predicted proteins are to predicted proteins from other phages attacking Gram-positive bacteria. The exception is the first viral ClpP protease. This gene differs substantially from that encoded by the streptococcal host genome.

A remarkable feature of the ϕSfi19 genome structure is the similarity of gene clusters from ϕSfi19 to clusters of adjacent genes in other phages. The compared phage genome segments show a similar topological organization of genes and significant similarity of their predicted protein sequences. Specifically, the DNA packaging region in ϕSfi19 resembles that of *Lactobacillus casei* phage a2; the major head-to-tail region resembles that of *Leuconostoc oenos* phage L10; the lysis cassette resembles that of *Streptococcus pneumoniae* phage Dp-1 and finally the DNA replication region shows similarity to two *Lactococcus lactis* phages, BK5-T and 7-2.

ϕSfi11 was chosen as the type phage for virulent lytic group II *pac*-site phages. It has a genome size of 40 kb. Despite being longer than ϕSfi19, its overall structure is strikingly similar (**Fig. 3**). All 51 predicted ϕSfi11 genes are encoded on the same DNA strand, two similarly situated open reading frames (ORFs)

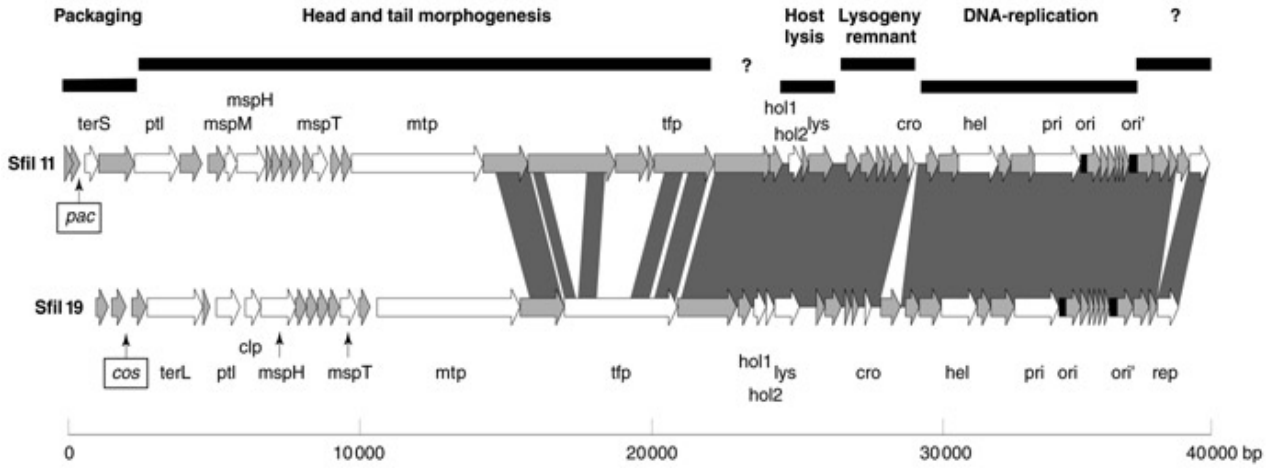

Figure 3 Alignment of the genome maps from phages Sfi11 and Sfi19. ORFs are represented by arrows and are annotated (see **Table 2** for abbreviations). Regions of sequence similarity are connected by shading.

are of unusual length for prokaryotic genes and the modular structure is exactly identical. Over the DNA replication module both phages show such a high degree of sequence similarity that one has to postulate a recent DNA exchange process between both phage types. The only exception is a gene from ϕSfi19 with a highly repetitive sequence structure (18 repeats of 18 bp), which has no complement in Sfi11. Over the DNA packaging and morphogenesis modules no sequence similarity was detected, despite a similar genetic organization. In this region, adjacent genes from phage Sfi11 demonstrated sequence similarities with adjacent genes from *Bacillus subtilis* phage SPP1 (DNA packaging) and *Lactococcus lactis* phage TP901-1 (morphogenesis module). At the end of the tail module, a transition zone was identified where regions with sequence similarity are interspersed with regions lacking any sequence similarity. When the *tfp* region was compared between phages Sfi11 and ϕ01205 a similar intermingling of short conserved and non-conserved protein domains was observed. Since both phages are otherwise so similar (see

Table 2 The genes of *Streptococcus thermophilus* phage Sfi21

Gene	*Amino acids*	*Function*	*Comments*
cos		cohesive end	15 nt 3′ overhang; dyad symmetry
terL	623	terminase, large subunit	NTP-binding motif (WalkerA)
ptl	384	portal protein	
clp	221	clpP-protease	First viral clp protease
mspH	397	major structural protein Head	Proteolytic cleavage
mspT	203	major structural protein Tail	
mtp	1560	minor tail protein	
tfp	1276	tail fiber protein	Collagen-like repeats; anti-receptor?
hol1	141	holin	Host viability loss
hol2	87	holin	Dual start site, host viability loss
lys	288	lysin	*N*-acetylmuramoyl-L-alanine amidase
attP		attachment site phage	Site of integrase action
int	359	integrase	Recombinase
imm	203	immunity	Strong antiphage element against heterologous virulent phages
mpm	122	metallo proteinase motif	
cI	127	cI repressor	Helix-turn-helix motif, antiphage element against homologous phage
cro	75	cro-repressor	Helix-turn-helix motif
ant	287	antirepressor	Helix-turn-helix motif
hel	443	helicase	DEAH-box, Walker A motif
pri	508	primase	Walker A motif
ori		origin of replication	Drives plasmid replication, very strong antiphage element

below), but differed in host range, the protein is a candidate for the streptococcal antireceptor. The antireceptor interacts with the phage receptor structure on the bacterial cell.

Temperate Phages

The prototype *cos*-site temperate phage ϕSfi21 was isolated from a French yoghurt starter. The starter spontaneously released infectious phages at a low level (10^3 PFU ml^{-1}). A number of cells could be lytically infected with ϕSfi21. The one-step growth characteristics of ϕSfi21 are similar to that of virulent *S. thermophilus* phages. A small percentage of the infected cells (<0.01%) survived the infection to yield lysogens. Phage DNA was site-specifically integrated into a tRNA gene of the host genome. The prophage DNA coexisted with unintegrated phage DNA of monomer genome size.

Extensive crosshybridization between individual restriction fragments of ϕSfi21 and a large panel of virulent *S. thermophilus* phages suggested a close relationship between temperate and virulent *S. thermophilus* phages. Crosshybridization with ϕSfi21 DNA ranged from a single restriction fragment (differing from phage to phage) to all fragments. Lytic group I phages showed the closest relationship to ϕSfi21.

The prototype *pac*-site temperate ϕO1205 was isolated from a Greek yoghurt. In contrast to ϕSfi21, ϕO1205 could only infect the cured lysogen and did not protect the lysogen against superinfection with virulent phages. A further *pac*-site temperate phage, ϕTP-J34, was isolated from a German yoghurt. The lysogenic host released mainly defective phages lacking the tail structure. The few infectious particles released could infect the cured lysogen. The presence of the prophage induced a phenotypic change in the aggregation behavior of the host cell (lysogenic conversion).

Genomics of Temperate Phages

ϕSfi21 has a genome size of 41 kb with cohesive ends. In contrast to virulent phages, not all ORFs are encoded on the same DNA strand. The exception are four adjacent genes covering the core genetic information for the lysogenic life style (**Fig. 4**). Otherwise, the genome of ϕSfi21 closely resembles the genome of the lytic group I *cos*-site ϕSfi19. In fact, over major parts of the genome the two phages show an identical gene order. The genes differ from each other only by point mutations (mainly at the third codon position) and small deletions/insertions. Overall the two phages differ by 10% bp changes. The changes are unevenly distributed; over the packaging and morphogenesis modules the change rate is high (20%), whereas over the lysis and replication modules only few (<1%) base pair changes are observed. Interestingly, both phage genomes differ only over the lysogeny module and the DNA replication modules. The virulent ϕSfi19 shows a duplication of the phage origin of replication, whereas the temperate phages ϕSfi21 and ϕO1205 possess only the origin downstream of the primase gene (see below).

ϕO1205 has a genome of 43 kb and contains a *pac*-site. It resembles ϕSfi21 in several respects: all but four genes of the core lysogeny module are coded on the same DNA strand; the lysogeny module is located at an identical genome position; the overall modular structure is identical. ϕO1205 is closely related to virulent *S. thermophilus* phages, but in contrast to ϕSfi21 the closest similarity is with *pac*-site phages of lytic group II. Major differences between ϕO1205 and lytic group II ϕSfi11 are located in three regions: the lysogeny module, the DNA replication region and the putative tail fiber gene. Over the remaining regions the two phages differed more or less uniformly by 10% base pair changes except for the highly conserved DNA replication module.

Lysogeny Module

In the lysogeny module of ϕSfi21 there is the following gene order: *int* (integrase), *imm* (superinfection immunity), *mpm* (metalloproteinase motif protein), *cI* (phage repressor) and in the opposite orientation *cro* (phage repressor), *ant* (antirepressor) (**Fig. 4**). This geometry creates a potential genetic switch structure between the two phage repressor genes. The lysogeny module is flanked on one side by the lysis cassette and on the other side by the DNA replication module. This gene constellation is found in many *Siphoviridae* infecting an evolutionarily related group of Gram-positive bacteria (*Streptococcus, Lactococcus, Lactobacillus, Bacillus*). Numerous sequence similarities link the predicted proteins of *Siphoviridae* from these bacteria suggesting a common evolutionary origin also for their phages. Recombination events have, however, reshuffled the genes of this module; sequence alignments of the lysogeny modules from different streptococcal phages reveal areas of high sequence conservation interspersed with regions of low sequence similarity. Several transition zones are found within genes. Contrary to the initial formulation of the modular theory of phage evolution the unit of the evolutionary exchange in streptococcal phages is not a group of functionally related genes, but can be as small as a single gene. Exchange reactions can even occur within

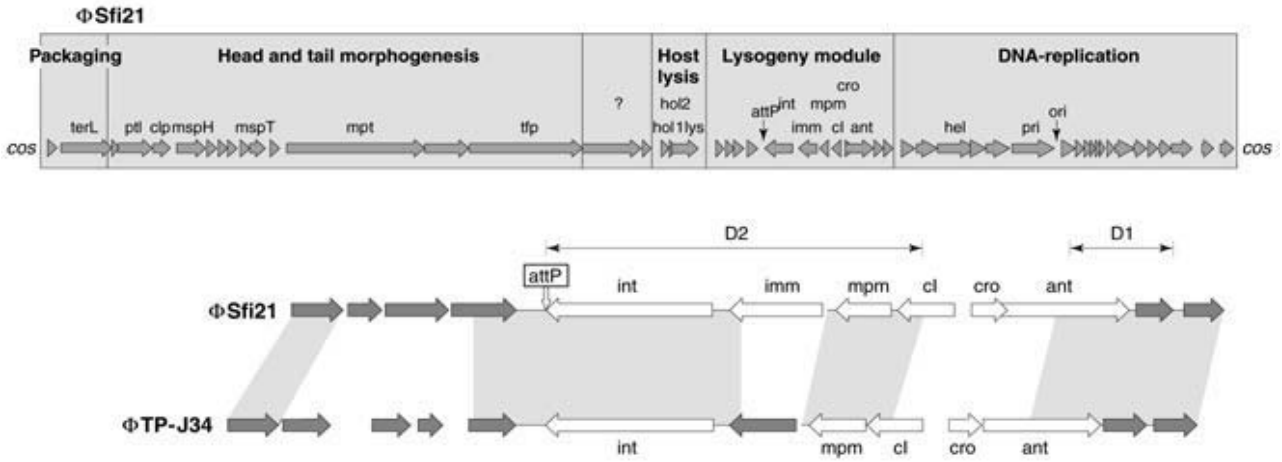

Figure 4 Genome map of the temperate *cos*-site phage Sfi21 (above). An amplified view of its lysogeny module is shown below in comparison with the *pac*-site phage TP-J34. Regions of sequence similarity are connected by shading. D1 and D2, deletions.

genes, possibly between gene segments encoding distinct protein domains. Several genes from the lysogeny module of ϕSfi21 were biologically characterized. The integrase mediates the integration of phage DNA into the chromosome of several *S. thermophilus* cells via site-specific recombination. Sequencing of the phage and bacterial attachment sites (*attP, attB, attR, attL*) identified a 40 bp identity region which, unusually, overlapped both the phage integrase gene for 18 bp and the terminal 11 bp of a host tRNA gene. A phage DNA segment covering *attP* and the phage integrase contained all the genetic information for faithful integration of a nonreplicative plasmid into the bacterial *attB* site. ϕO1205 and ϕTPJ-34 use a molecularly identical integration system.

When the indicator cell Sfi1 was lysogenized with ϕSfi21, the cell was protected against superinfection with the temperate phage and with 15 out of 19 virulent *S. thermophilus* phages (notably not ϕSfi19). The immunity functions could be attributed by cloning experiments to two phage genes. Interestingly, the two genes showed complementary activities. Transformation of an indicator cell with the cI repressor protected the cell against superinfection with the homologous temperate phage and its deletion mutants, but not against virulent phages. The CI repressor showed a helix-turn-helix DNA binding motif. Gel-shift experiments demonstrated binding to the putative genetic switch region between the *cI* and *cro* genes. Protection of the lysogenic cell against superinfection with virulent phages is achieved by the phage gene located upstream of the integrase. Transformation of the indicator cell with this gene protected the cell against 12 virulent phages, but not the homologous phage.

The Cro and Ant proteins showed both helix-turn-helix DNA binding motifs and sequence similarity to a repressor from a lambdoid coliphage 434 and an antirepressor from coliphage P1. A gene downstream of *ant* encodes a protein with a weak excisionase motif. However, a spontaneous ϕSfi21 deletion mutant (D1 in **Fig. 4**) showed that neither *ant* nor *xis*? are necessary for establishment of lysogeny or induction of the prophage.

The Lysis Cassette

Three genes constitute the lysis cassette of *S. thermophilus* phages. In contrast to other phage systems, two holins (pore-forming proteins) precede the lysin gene (**Fig. 3.**). One holin shows a dual start site suggesting a holin–antiholin control circuit. The lysin gene suggests a modular design. The N-terminal domain encoding the amidase shows similarity to other phage lysins. The C-terminal domain encoding the substrate-binding part resembles host proteins. In an infectious variant phage the lysin gene was actually split into two parts separated by 1 kb. The intervening DNA showed links to endonucleases found in self-splicing group I introns. At late, but not early times after infection both parts of the lysin messenger were rejoined. Both holin genes reduced the viability of the *Escherichia* coli host, when their expression was induced. Overexpression of the lysin gene in *E. coli* yielded a 31 kDa protein. Its specific lytic activity on streptococcal cell walls was demonstrated by an *in situ* detection assay.

Origin of Replication and Phage Resistance

Seven adjacent genes from the DNA replication module are the most conserved part of the *S. thermophilus* phage genomes. More than 70% of the phages from different collections contained this DNA segment. The very low sequence variability observed in this module makes it an attractive target for the design of engineered phage resistance mechanisms. This genome segment codes for four genes with nucleoside triphosphate binding motifs (Walker A motif), one of which is a distant member of the helicase superfamily, whereas another shows sequence similarity to DNA primases. Downstream of the putative primase gene noncoding DNA has been identified which possesses conspicious DNA repeats. This AT-rich DNA segment shows 80% sequence identity to a region following the *repA* gene of the cryptic *S. thermophilus* plasmid pST1. In fact, when cloned into a low copy number plasmid it acts as an origin of replication driven by phage infection. The inhibitory activity is plasmid copy number dependent and operates by blocking the accumulation of phage DNA during infection. Protein(s) in φSfi21-, but not in φSfi19-infected cells interact with the putative phage origin. In fact, φSfi19 is insensitive to the inhibition mediated by the φSfi21 origin. The φSfi19 origin differs in 14 nucleotide positions from the φSfi21 origin. When cloned on a plasmid the φSfi19 origin protects the indicator cell against infection with φSfi19 and five further phages insensitive to the φSfi21 origin. Together the two origins protect the indicator cell against infection with 23 out of 25 phages tested. None of the phages was able to form plaques on the starter containing the cloned phage origin. This is one of the broadest and strongest phage inhibitory activities described in the lactic acid bacteria field. In combination with the superinfection immunity gene, it might provide the basis for the development of phage resistant starters for yoghurt and mozzarella factories.

Structural Gene Cluster

The genetic organization of the DNA packaging and the head and tail morphogenesis region from φSfi21 resembles closely that of phages infecting evolutionary very unrelated hosts, the Gram-negative Eubacterium *Escherichia* and even the Archaeon *Methanobacterium* (**Fig. 5**). From the *cos*-site to the gene coding for the major tail protein, there is a surprising similarity in gene order between φSfi21 and lambdoid coliphages. Comparable genes have been found at identical positions; φSfi21 genes which could not be attributed showed a very similar size to the corresponding genes from these coliphages.

Sequence similarity of streptococcal structural phage proteins is limited to phages infecting Gram-positive bacteria. A hierarchy of sequence relatedness has been observed that correlated approximately with the evolutionary distance between the bacterial hosts (*S. thermophilus* ≫ *Lactococcus* > *Leuconostoc* ≈ *Bacillus* ≈ *Lactobacillus* ≫ *Mycobacterium* ≈ *Streptomyces*). Sequence similarity is closest to phage BK5-T infecting *Lactococcus lactis*, which is the closest evolutionary relative of *S. thermophilus* in this bacterial branch. The major head genes of these two phages could be aligned resulting in a 50% base pair sequence identity. The similarity to all other phages was only detectable at the amino acid sequence level of the predicted proteins.

No sequence similarity has been seen between φSfi21 and lambdoid phages, including φHK97. Nevertheless, striking structural similarities have been observed. Both major head proteins show a comparable length, a comparable secondary structure prediction and proteolytic cleavage at a comparable position. Both head genes are preceded by a protease gene. A possible interpretation is that *Siphoviridae* from Eubacteria (and Archaea?) share a common, although very distant ancestor for this genome region.

Phage Diversity

A number of mechanisms could theoretically create phage diversity. The classical mechanism is modular DNA exchange. Streptococcal phages have certainly exchanged their DNA replication modules. No other known mechanism can explain this high level of sequence conservation (99.8% at the bp level) over long DNA segments between otherwise clearly distinct phages. However, modular exchanges with non-*S. thermophilus* phage DNA have not been observed. The highest similarity in this category was a 50% base pair identity with a lactococcal phage. This similarity probably represents evolutionary relationships.

Genes from related *S. thermophilus* phages differ by numerous point mutations. The investigated phages demonstrated an average 10% base pair difference for phages belonging to the same subgroup. It is likely that this figure will rise when sequence data from *S. thermophilus* phages of other ecological or geographical origin become available. Accumulation of point mutations therefore seems to drive streptococcal phage evolution as it drives animal and plant virus evolution. In fact, phylogenetic trees could be constructed for individual phage proteins (e.g. integrase). These trees do not necessarily reflect the

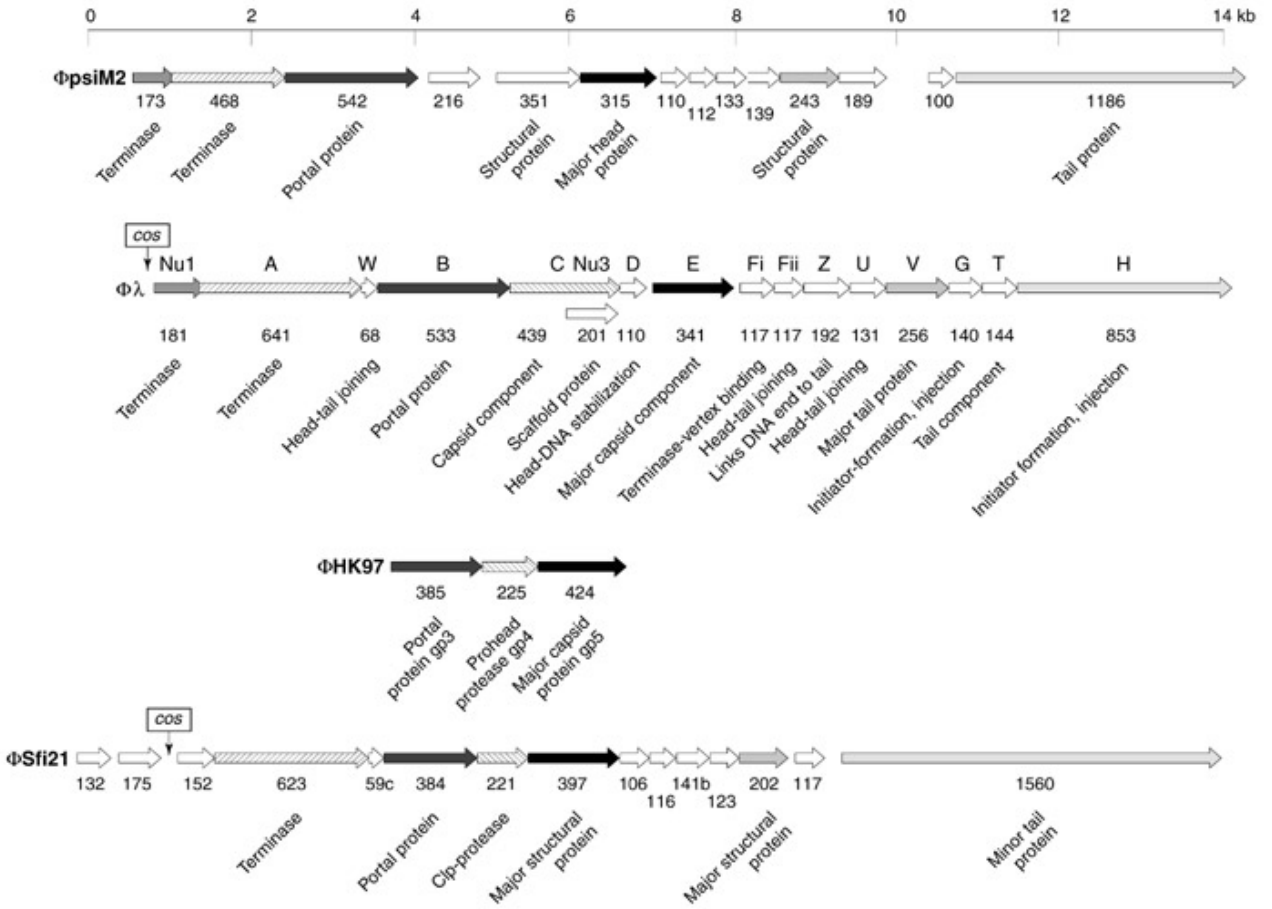

Figure 5 Comparison of the DNA packaging and morphogenesis modules from phage Sfi21, *E. coli* phages λ and HK97 and archaeavirus psiM2. Corresponding genes are marked by the same shading. Numbers give codon length.

evolutionary relationships of the corresponding phages, but only that of individual phage genes.

Genes from related *S. thermophilus* phages frequently differ by insertion/deletion events. These processes might create variability and thus the raw material for selection. Several spontaneous deletions have been observed repeatedly. One occurred in the putative tail fiber gene of φSfi21 which contains four collagen-like tripeptide GXY repeats. A 0.8 kb long DNA segment flanked by a 53 bp repeat was lost. Slippage of the DNA polymerase or unequal crossover events might have created this event. In other spontaneous deletions the phage integrase seems to be involved. During serial passage of φSfi21 a DNA segment spanning from the *attP* site to a site within the *cI* repressor gene was reproducibly lost (D2 deletion in **Fig. 4**). The latter site possesses a 4 bp repeat from one border of the attachment site. This deletion transforms the temperate φSfi21 into a virulent phage. Interestingly, wild-type virulent phages contain most of the genes surrounding this deleted region, although in a rearranged fashion, but none of the genes from the integrase to the cI repressor. It is thus tempting to speculate that the virulent *S. thermophilus* phages were created from temperate phages through recombination processes. Interestingly, the putative intron in the lysin gene of a variant streptococcal phage contained an endonuclease gene with bioinformatic links to self-mobilizing introns. This intron was near the rest of the lysogeny module which experienced extensive recombination. Recombinant phages might be produced during double infections, but such recombinants remain to be characterized molecularly. *S. thermophilus* phages are a young research field. Molecular data have only become available in the last four years. Due to its industrial importance the field will rapidly develop. *S. thermophilus* phages will also be an interesting model system to address those questions of phage evolution which can not be investigated with lambdoid coliphages.

History

Plant reoviruses are members of the family *Reoviridae*. They are distinguished by a segmented double-stranded (ds) RNA genome, a transmission mechanism that involves replication in the insect vector, and a propensity to induce tumors in infected plant hosts. Consequently, viruses within this group have attracted attention as potential model systems for studying a range of biological and molecular interactions and processes. From a historical perspective, plant reoviruses have played important roles in several significant scientific developments. Studies with rice dwarf virus (RDV) and wound tumor virus (WTV) were crucial in confirming the once controversial hypothesis that some insect-borne plant viruses actually replicate in the vector. The technique of density gradient centrifugation was developed during attempts to purify WTV. Efforts to understand the details of plant reovirus transmission led to the establishment of a continuous cell culture line from a plant virus insect vector. Several members of this group can cause considerable damage to crop plants and therefore are also of interest from an agronomic perspective.

Complete sequence data are now available for two plant-associated reoviruses and partial sequence data for several others, allowing for informed comparisons within this part of the *Reoviridae* family, and with animal-infecting reoviruses.

Taxonomy and Classification

Plant-associated reoviruses are subdivided into three genera based on particle structure, number and size of dsRNA segments, and vector. Members of the genus *Phytoreovirus* are leafhopper transmitted and have particles that contain 12 genomic segments. Members of the genus *Fijivirus* contain 10 genomic segments and are planthopper transmitted. Members of the genus *Oryzavirus* are also planthopper transmitted and have particles that contain 10 segments of dsRNA, but these differ in size and structure from those of the genus *Fijivirus*, as noted below.

The genus *Phytoreovirus* currently consists of three members: WTV, RDV and rice gall dwarf virus (RGDV). A fourth possible member that was recently identified, tobacco leaf enation virus (TLEV), would represent only the second reovirus capable of infecting

History

Plant reoviruses are members of the family *Reoviridae*. They are distinguished by a segmented double-stranded (ds) RNA genome, a transmission mechanism that involves replication in the insect vector, and a propensity to induce tumors in infected plant hosts. Consequently, viruses within this group have attracted attention as potential model systems for studying a range of biological and molecular interactions and processes. From a historical perspective, plant reoviruses have played important roles in several significant scientific developments. Studies with rice dwarf virus (RDV) and wound tumor virus (WTV) were crucial in confirming the once controversial hypothesis that some insect-borne plant viruses actually replicate in the vector. The technique of density gradient centrifugation was developed during attempts to purify WTV. Efforts to understand the details of plant reovirus transmission led to the establishment of a continuous cell culture line from a plant virus insect vector. Several members of this group can cause considerable damage to crop plants and therefore are also of interest from an agronomic perspective.

Complete sequence data are now available for two plant-associated reoviruses and partial sequence data for several others, allowing for informed comparisons within this part of the *Reoviridae* family, and with animal-infecting reoviruses.

Taxonomy and Classification

Plant-associated reoviruses are subdivided into three genera based on particle structure, number and size of dsRNA segments, and vector. Members of the genus *Phytoreovirus* are leafhopper transmitted and have particles that contain 12 genomic segments. Members of the genus *Fijivirus* contain 10 genomic segments and are planthopper transmitted. Members of the genus *Oryzavirus* are also planthopper transmitted and have particles that contain 10 segments of dsRNA, but these differ in size and structure from those of the genus *Fijivirus*, as noted below.

The genus *Phytoreovirus* currently consists of three members: WTV, RDV and rice gall dwarf virus (RGDV). A fourth possible member that was recently identified, tobacco leaf enation virus (TLEV), would represent only the second reovirus capable of infecting

dicotyledonous plants. All members of this genus are morphologically similar, e.g. they lack capsid spikes prominent on particles of other plant reoviruses, contain 12 genomic RNA segments that exhibit similar electrophoretic profiles, and are transmitted exclusively by cicadellid leafhoppers. The genus *Fijivirus*, whose name is derived from its type member Fiji disease virus (FDV), consists of three principal members: FDV, maize rough dwarf virus (MRDV) and oat sterile dwarf virus (OSDV). Several other plant-infecting reoviruses described in the literature are now considered geographical races of members of this genus. Viruses related to MRDV include rice black streaked dwarf virus (RBSDV), pangola stunt virus (PSV) and cereal tillering disease virus (CTDV). *Arrhenatherum* blue dwarf virus (ABDV) and Lolium enation viruses (LEV) are related to OSDV. Members of the genus *Fijivirus* have genomes consisting of 10 segments that exhibit a characteristic electrophoretic profile quite distinct from that exhibited by genomes of the members of the genus *Phytoreovirus* and are transmitted exclusively by delphacid planthoppers. A possible member of the genus *Fijivirus*, *Nilaparvata lugens* reovirus (NLRV), was tentatively assigned to the genus based on sequence, structure and a planthopper association. However, although NLRV may transit through rice plants as a means of transmission from planthopper to planthopper, it does not replicate in these plants. The third plant-associated genus, *Oryzavirus*, consists of the type member rice ragged stunt virus (RRSV) and the *Echinochola* ragged stunt virus (ERSV). Members of this genus resemble members of the genus *Fijivirus* in terms of number of genomic segments and transmission by delphacid planthoppers, but differ in virus particle morphology and the electrophoretic profiles of the genomic RNA segments.

Additional support for the subdivision of plant-associated reoviruses into these three genera comes from comparative sequence analysis of the terminal domains of respective genomic segments. All genomic segments of each member of the genus *Phytoreovirus* contain the conserved terminal oligonucleotide sequences (+) 5′-GGU/CA----U/CGAU-3′ (only terminal sequences of the coding strand are shown). In contrast, two confirmed members of the genus *Fijivirus*, MRDV and RBSDV, have the conserved oligonucleotide sequences (+) 5′-AAGUUUUU----GUC-3′. Terminal sequences of the possible member NLRV are (+) 5′-AGU----GUUGUC-3′. The consensus conserved terminal oligonucleotide sequence for members of the genus *Oryzavirus* is (+) 5′-GUAAA----GUGC-3′. Thus, the nature of the genomic conserved terminal oligonucleotide sequences for the plant-infecting members of the family *Reoviridae* appear to be genus specific, providing an additional taxonomic criterion.

Virion Structure

Plant reovirus particles consist of two protein shells surrounding a core composed of dsRNA genomic segments and associated proteins. For members of the genus *Phytoreovirus*, the core consists of 12 dsRNA genomic segments tightly associated with three structural proteins surrounded by a shell of well-defined capsomers. This structure is further surrounded by a less well-defined outer shell consisting of two more loosely associated proteins. The complete particle is approximately 70–80 nm in diameter. RDV was recently crystallized, and its structure is now better known. Crystallized RDV particles are 693 Å (69.3 nm) in diameter. The outer capsid contains 780 protein subunits, thought to be the 46 kDa P8 protein, that are linked by disulfide bonds to form 260 trimeric capsomers. Members of the other plant reovirus genera have a slightly different morphology, characterized by the presence of prominent spikes protruding from the inner capsid. Purified RRSV particles exhibit additional differences in that they appear to contain only one protein shell.

Several enzymatic activities are associated with the purified core structures. These include an RNA-dependent RNA polymerase responsible for mRNA synthesis, and two enzymatic activities involved in the RNA-capping reactions: an mRNA-guanyltransferase and a guanine 7-methyltransferase. An additional RNA-modifying activity, an mRNA 2′-O-methyltransferase, has also been demonstrated in purified WTV preparations. From an evolutionary perspective, this observation is interesting, since this enzymatic activity is not present in plant cells.

Genome Organization

Complete sequences are now available for one member of the genus *Phytoreovirus* (RDV) and one proposed member of the genus *Fijivirus* (NLRV). Partial sequences of several other plant reoviruses are also available. Although each of the 10 or 12 segments that constitute the viral genome is unique in terms of nucleotide sequence, most dsRNA segments of the genera *Phytoreovirus* and *Fijivirus* conform to a similar basic organizational strategy. For example, all dsRNA segments of the RDV genome and the nine sequenced segments of the WTV genome contain conserved terminal sequences. It has not yet been determined whether the 5′ terminus of the coding strand is capped with an m^7G^5 ppp structure as occurs for other members of the family *Reoviridae*. The

other terminus, however, appears to be a perfect base-paired duplex and lacks any homopolymeric stretches. Segment-specific regions of inverted complementarity (inverted repeats) from 3 to 17 residues in length are found adjacent to the conserved sequences. Most segments contain one long open reading frame (ORF). For dsRNA segments of the genus *Phytoreovirus*, the ORF is on the strand containing the conserved 5′ terminal sequence GGU/CA∼, and is flanked by a relatively short (18–63 nucleotides) 5′ noncoding region and a slightly longer (93–492 nucleotides) 3′ noncoding region. Segment 12 of both WTV and RDV contains a short ORF located downstream from the large ORF that encodes the nonstructural protein Pns12, and RDV segment S12 contains other short ORFs that may be partially duplicated and rearranged. It is unclear whether any of the smaller ORFs of WTV or RDV S12 is expressed *in vivo*. However, the expression of two small out-of-phase ORFs embedded within the main RDV S12 ORF has been reported for infected rice tissue.

In vitro expression of cloned WTV and RDV genomic dsRNAs has allowed the assignment of virally-encoded polypeptides to their cognate genomic segments. More detailed structure–function studies have recently been performed on several RDV-encoded proteins. In addition, alignment analysis of the predicted amino acid sequences of the major inner capsid protein of the three members of genus *Phytoreovirus* have provided convincing evidence that these three viruses evolved from a common ancestor.

Interestingly, both MRDV segment S6 and RBSDV segment S7 revealed coding strands that contained two large nonoverlapping ORFs consisting of 363 and 310 codons and separated by 52 nucleotide intercistronic regions. This configuration is unique among the family *Reoviridae*. Only the 5′ proximal ORF was expressed in cell-free translation systems, and it is unknown whether the 3′proximal ORF is expressed *in vivo*. The finding that the second ORF is absent in the corresponding segment of NLRV, the putative member of the genus *Fijivirus* that does not replicate in its plant host, suggests that the second ORF may be important to infection of plants. As indicated above, the genomic segments of MRDV and RBSDV, both members of the genus *Fijivirus*, contain the same conserved terminal oligonucleotide sequences (+AAGUUUUU----GUC-3′), indicating the likelihood of a common ancestor for these two viruses.

Sequence information for members of genus *Oryzavirus* is currently somewhat limited. However, it is clear from RRSV and ERSV sequence data gathered to date that the structural motif consisting of conserved terminal oligonucleotides and adjacent segment-specific inverted repeats is also a feature for this plant reovirus genus. Coding features for members of the genus *Oryzavirus* also seem to be consistent with reovirus genome organization.

Several pieces of evidence suggest that plant reovirus particles may contain one copy of each of the 10 or 12 segments that comprise the viral genome. This evidence is based primarily on studies with WTV, and includes the following observations. Genomic RNA isolated from purified virus particles contains equimolar amounts of each segment and, based on extrapolations of dilution–infectivity curves, it is predicted that an infection can be initiated by a single virus particle. The mechanisms responsible for the apparent selective packaging of one copy of each viral RNA segment into a single particle are not well understood. Molecular characterization of internally deleted defective-interfering (DI) RNAs present in some transmission-defective WTV populations clearly established that the sequence information necessary for replication and packaging of genomic segments resides within the terminal domains of the segment. It was shown further that DI RNAs displaced only the genomic segment from which they were derived and did not interfere with the replication or packaging of unrelated genomic segments. Combined, these observations suggested that each genomic segment must contain at least two operational recognition domains: one that specifies that the RNA is viral and not cellular, and a second that distinguishes one genomic RNA segment from another. It has been postulated that the initial events leading to the replication of WTV genomic segments involve the specific recognition and packaging of viral transcripts, rather than dsRNA segments, followed by subsequent synthesis of the genomic noncoding strand. It has been postulated further that the conserved terminal oligonucleotides and the segment-specific inverted repeats may serve as recognition domains, with the terminal inverted repeats serving to specify the conformational properties of the viral transcripts as a result of intramolecular base-pairing.

Gene Expression

There are numerous technical difficulties associated with studying virus replication and gene expression *in planta*. In contrast, the cultured cell lines derived from leafhopper vectors provide very convenient systems for examining these processes for the plant reoviruses. All three members of the genus *Phytoreovirus* have been shown to multiply readily in their leafhopper vector and cultured cells derived from these vectors. Infection of both the leafhopper vector and cultured

vector cells results in a productive, usually asymptomatic, persistent infection. Infection of cultured vector cells by WTV has been examined in detail and was found to have the following characteristics. Infected cultures fail to exhibit any apparent cytopathology either during the initial (acute) stages of infection or after the onset of persistence. Persistently infected cells exhibit the same morphology, pattern of cellular protein synthesis and growth rate as uninfected cells and do not suffer from periodic crises. Essentially all cells in the persistently infected culture remain infected for hundreds of cell passages. Infectious virus is recoverable from persistently infected cells and can initiate a new round of acute and persistent infection. The kinetics of viral protein and RNA synthesis has also been measured in WTV-infected vector cells. Based on distinct changes in the level of viral gene expression, the infection was divided into an acute phase (the first 5 days after inoculation) and a persistent phase (beginning with the first cell passage). Viral specific polypeptide and viral genomic RNA accumulation was observed to increase to a maximum level during the first 5 days following inoculation and then to decrease rapidly to approximately 5% of the maximum level beginning with the first cell passage. In contrast, viral specific mRNAs were present at approximately the same level in the acute phase and in the early stage of the persistent phase of infection. Moreover, viral transcripts isolated from persistently infected cells were found to be translated inefficiently *in vitro*, reflecting the situation observed in infected cells. These results were interpreted as suggesting that a form of post-translational regulation of viral gene expression operates in vector cells persistently infected with WTV. The recent successful culture of planthopper cell lines will allow similar studies with members of the other plant reovirus genera.

Plant reovirus gene structure is generally simple, with apparent monocistronic messages in most dsRNA segments. In cases of possibly more complex gene structures, expression *in vivo* of coding regions in addition to the major segment-associated polypeptide (e.g. WTV or RDV S12; MRDV S6 or RBSDV S7, all discussed elsewhere) has not been confirmed. Post-translational processing has been identified for one plant reovirus protein. Genomic segment S8 of RRSV, type member of the genus *Oryzavirus*, encodes a structural protein that has been identified serologically in virus particles. The complete 67 kDa S8 product was recently shown to be processed autocatalytically to a 46 kDa product. The 43 kDa protein identified as the major capsid protein of RRSV, P8, was thought to be the result of further proteolytic processing of the 46 kDa protein.

Epidemiology

The epidemiology of the monocot-infecting reoviruses is tied to the presence of the crop and the hopper vector. Many of the monocot-infecting reoviruses are found in tropical regions, so the cycle from the agronomically important plant host to the vector and back to the plant host is often difficult to break. Complicating this, wild grasses may serve as alternate hosts for these viruses. In tropical and subtropical regions, overwintering of the virus is often unnecessary because of the constant presence of plant and vector. However, overwintering of virus in eggs may be an important survival mechanism in temperate regions.

Prevention and Control

Several members of this genus were once responsible for serious crop losses and were expensive to control, but advances in the development of effective control measures have resulted in reduced impact of these viral diseases. The two main approaches for control of reoviruses that infect graminaceous hosts are breeding for resistance and chemical control of insect vectors. Although intensive breeding for resistance was only recently initiated, several rice varieties resistant to RDV and other reoviruses are now available. Chemical control of insect vectors has been a reasonably effective preventative measure when vector populations were otherwise low, but has not been effective under high vector pressure. Pathogen-derived resistance involving genetic engineering approaches, for example transforming plants with coat protein or other viral genes as has been successfully deployed against numerous other RNA plant viruses, have been tried to a limited extent with RDV and RRSV. None of the three structural genes transformed into rice plants to date have effectively reduced virus infection.

Geographic and Seasonal Distribution

Plant-infecting reoviruses have been isolated on every continent. Members of the genus *Phytoreovirus* have been identified only in North America (WTV), Asia (RDV and RGDV), and Africa (TLEV). WTV is of no economic significance and has been isolated only twice, in both cases serendipitously, but RDV and RGDV are commonly found infecting rice crops and have been reported to cause severe damage under certain growing conditions and when viruliferous insect vector population levels are high. Members of the genus *Fijivirus* are more widely distributed, found in the South Pacific, South America, Europe and Asia. Both confirmed members of the genus *Oryzavirus*

have been found only in Asia and are so far of limited but potential economic importance. Seasonal distribution of plant reoviruses is associated with presence of the crop and vector.

Plant Host Range and Symptom Expression

The recorded host range of plant reoviruses, with the exception of WTV and TLEV, is limited to the Gramineae. Severe stunting or dwarfing is the most common symptom of reovirus infection of graminaceous plants. Additional symptoms include distortion of the leaves, including marginal serration, flecking or streaking, or the development of abnormally dark-green coloration. These symptoms are generally accompanied by vein swelling, enations or hyperplastic growth on the abaxial leaf surface. WTV is the only confirmed reovirus known to infect dicotyledonous plants, and has a wide experimental range extending to more than 40 species in 20 plant families. The experimental host range of the other possible member found in dicotyledonous plants, TLEV, has not yet been determined. Symptoms of WTV infection include stunting and leaf distortion, but the most notable symptom is neoplastic growth of phloem tissue, the degree and duration of which are dependent on the host. For example, WTV infection of *Trifolium* spp. results in vein enlargement, whereas infection of *Melilotus* spp. results in the formation of massive stem and root tumors. Wounding of infected plants tends to promote tumor formation, thus the virus name. The molecular basis for tumor induction by plant reoviruses is unknown. Among the plant-infecting reoviruses, only RDV fails to induce neoplasia. RDV is also atypical in that its replication is not limited to the phloem tissue of infected plants.

Transmission and Tissue Tropism

Infection of plant hosts by the plant reoviruses requires the aid of an insect vector; members of this virus group are not spread by mechanical transmission. The mode of transmission is referred to as propagative because virus multiplication occurs in the insect vector as a necessary part of the transmission process. The virus is acquired during feeding on infected plants. It sequentially infects different tissues of the vector, eventually reaching the salivary gland, and is then transmitted to uninfected plants via the salivary fluid during subsequent feeding. This process can take from 13 to 30 days to complete, depending on environmental conditions.

As indicated above, members of genus *Phytoreovirus* are transmitted by leafhoppers, whereas members of the other genera are transmitted by planthoppers. Transmission of a particular plant reovirus is limited to a single or several vector species, e.g. WTV is transmitted only by *Agallia constricta* Van Duzee, *Agallia quadripunctata* Provancher and *Agalliopsis novella* (Say). In contrast to the situation in infected plants, multiplication of virus in the insect vector results in no apparent pathological consequences, although reductions in fecundity of MRDV- and RDV-infected vectors have been reported. Transovarial transmission to progeny has also been reported for several of the plant reoviruses. Continuous cell culture lines have been generated from several leafhopper species that serve as plant reovirus vectors, and recently a continuous culture was developed from embryonic cells of a planthopper. These cultured vector cells support virus multiplication, thus providing a valuable system for studying viral gene expression and replication as well as details of virus–vector interaction. Although the plant reoviruses do not form plaques on the vector cell monolayers, virus titers can be readily determined with the aid of a fluorescence focus assay.

Maintenance of plant reoviruses exclusively in a plant host can result in the generation of virus populations that are deficient or defective in their ability to be transmitted by the insect vector. This phenomenon has been studied in some detail for WTV. The loss of transmissibility was accompanied by a loss in the ability to infect cultured vector cells and the generation of internally deleted forms of specific genomic segments that acted as DI RNAs. In selected isolates, certain segments, e.g. segments S2 or S5, appeared to be missing. Although these isolates retained the ability to induce tumors in systemically infected vegetatively propagated plants, they were completely defective in insect transmissibility. It has been suggested that one or both of these segments are required for replication in the insect vector but are dispensable for replication in the plant host. This hypothesis was partially tested for RDV by selective removal of the outer capsid protein P2 (the S2 product) with carbon tetrachloride. Progressive removal of the P2 protein resulted in a progressive decrease in infectivity to insect cells. Subsequent studies demonstrated that an RDV mutant lacking P2 was transmission-defective but able to replicate in plants, confirming the importance of the S2 gene product for infection of insect cells. The S5 gene product of RDV, P5, was recently identified as a minor core protein with NTP binding properties, and not an outer coat protein as previously believed. The specific roles of P2 or P5 in infection of insect cells remains unknown.

With the exception of RDV, plant reoviruses are

confined to the phloem of infected plants. The galls or enations often associated with plant infection represent modified phloem that serves as a site of virus replication and accumulation.

Future

Many of the fascinating biological properties exhibited by the plant reoviruses remain poorly understood. Unfortunately, the lack of infectious cDNA clones of plant reoviruses prevents mechanistic studies from proceeding as fast as they might. Recent completion of plant-associated reovirus sequences, including NLRV, is providing important information for comparison of plant reoviruses with some of the more thoroughly studied animal reoviruses. Studies using expressed proteins are allowing for examination of the roles of individual dsRNA segments and their gene products in the infection process. Questions about the molecular basis of such processes as virus-induced neoplasia, viral persistence, vector range and the recognition, sorting and packaging of a segmented RNA genome will be addressed in the coming years.

PICORNAVIRUSES – INSECT (*PICORNAVIRIDAE*)

Paul D Scotti, The Horticulture and Food Research Institute of New Zealand Ltd, Mt Albert Research Centre, Auckland, New Zealand

Peter D Christian, CSIRO Division of Entomology, Canberra, Australia

Introduction

'Insect picornavirus' is often misused as a generic term for any small, spherical virus isolated from insects. This term is regularly, and often incorrectly, applied to all unenveloped particles less than 40 nm in diameter without considering the physicochemical properties of the virions. With one exception none of these have been shown to have properties that would indicate they are true picornaviruses. They will therefore be referred to as 'picorna-like' meaning they have *at least* single-stranded, positive-sense RNA genomes of about 2.5–3.0 million daltons (MDa) molecular weight and 25–30 nm diameter, nonenveloped isometric particles containing (usually) three capsid proteins present in equimolar amounts. Excluding nodaviruses and tetraviruses, there are about 60 of these small viruses. Most of these are not sufficiently well characterized to assign to any existing taxonomic group. However 20 or so have physicochemical properties that allow them to be termed picorna-like (**Table 1**). They are unassigned viruses, for genus, in the family *Picornaviridae*.

Properties of the Genome

Four of the insect picorna-like viruses have had their genome structures elucidated through determination of their complete sequence. Infectious flacherie virus

Black queen cell virus	2.8	34, 32, 29, 6	1.34	30
Egypt bee virus		41, 30, 25	1.37	30
Kashmir bee virus (all strains)		41, 37, 25, 6	1.37	30
Sacbrood virus	2.6	32, 28, 25	1.33	30
Slow bee paralysis virus		46, 29, 27	1.37	30
		Dipteran viruses (flies/mosquitoes)		
Ceratitis V virus		39, 34, 27	1.35	24
Drosophila A virus		73, 42, 32	1.37	30
Drosophila P virus		48, 29, 26	1.36	25–30
Kawino virus	2.6	33, 30, 27, 7	1.33	28
Queensland fruit fly virus	2.9	42, 37, 31	1.34	30
		Hemipteran viruses (true bugs)		
Aphid lethal paralysis virus	3.3	34, 32, 31	1.34	26–28
Himetobi P virus	2.8	37, 33, 28	1.35	29
Nezara viridula virus-1	3.1	32, 32, 31	1.34	29
Plautia stali intestine virus[a,b]	9.1 kb	33, 30, 26, 4.5		30
Rhopalosiphum padi virus	2.9 (9 kb)	31, 30, 28	1.37	27
Triatoma virus	3.0	39, 37, 33	1.39	30
		Lepidopteran viruses (moths/butterflies)		
Gonometa virus		37, 32, 29, 12	1.35	32
Infectious flacherie virus[c]	2.4 (9.7 kb)	35, 33, 31, 12	1.38	26–27
Latoia viridissima virus	2.9	31, 30	1.34	30
Lymantria ninayi virus	2.8	38, 33, 32	1.32	29

[a]Genome organization is 'calici-like' with capsid protein coding region at the 3′ end.
[b]Could also be grouped with CrPV and DCV.
[c]Genome organization suggests IFV is a 'true' picornavirus with single ORF and polymerase region located at the 3′ end.
RNA weights are in megadaltons (MDa) and/or in kilobases (kb); a blank for RNA means no value has been reported. Only major capsid proteins are listed (kDa). The densities of virions in CsCl are reported densities and have been estimated using a number of different methods and in a variety of conditions so they should not be taken as either the 'best estimates' nor are they directly comparable.

(IFV) of the silkworm has a genome structure similar to that of the mammalian picornaviruses. *Drosophila* C virus (DCV), *Plautia stali* intestinal virus (PsIV) and *Rhopalosiphum padi* virus (RhpV) have a quite different genomic organization. In contrast to the picornaviruses these viruses have the RNA-dependent RNA polymerase (RDRP) located at the 5′ end of the genome and the coat proteins at the 3′ end. Rather than producing a single polyprotein these viruses have two distinct open reading frames (ORFs) separated by an untranslated region of around 200 bases and available evidence suggests that the two ORFs are translated independently. We will refer to these viruses as 'di-cistronic picorna-like viruses' (**Fig. 1**). There are, therefore, at least two distinct groups of viruses among the insect picorna-like viruses: true picornaviruses and di-cistronic picorna-like viruses.

The CrPV/DCV Complex

Until 1997, the best characterized insect picorna-like viruses were cricket paralysis virus (CrPV) (**Fig. 2**), originally isolated from the orthopterans *Teleogryllus commodus* and *T. oceanicus* in Australia, and isolated from the dipteran *Drosophila melanogaster*. CrPV was discovered during the course of a mass-rearing program of the Australian field cricket, *T. commodus*, in the late 1960s. Young crickets became paralyzed and died and the disease, which spread rapidly and killed about 95% of the colony, was shown to be caused by the virus now called 'cricket paralysis virus'. Similar outbreaks in laboratory and commercial colonies of crickets have been observed elsewhere. DCV was isolated from laboratory populations of *D. melanogaster* in the late 1960s, during a

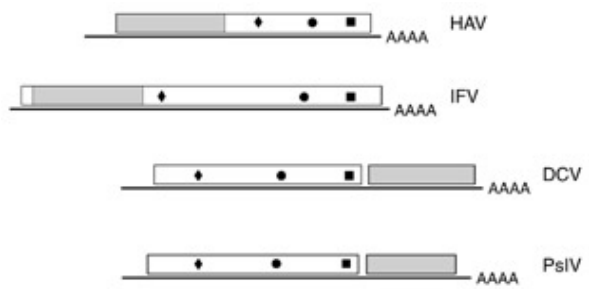

Figure 1 Genome organization of *Drosophila* C virus (DCV) and *Plautia stali* intestinal virus (PsIV) compared with that of infectious flecherie virus (IFV) and hepatitis A virus (HAV) (*Picornaviridae*: *Hepatovirus*). The capsid protein coding regions are shown by the shaded boxes and the RNA-dependent RNA polymerase (RDRP) regions by the unshaded boxes. Within the RDRP region the helicase-like domains (◆), cysteine protease domains (●) and RNA polymerase domains (■) are indicated.

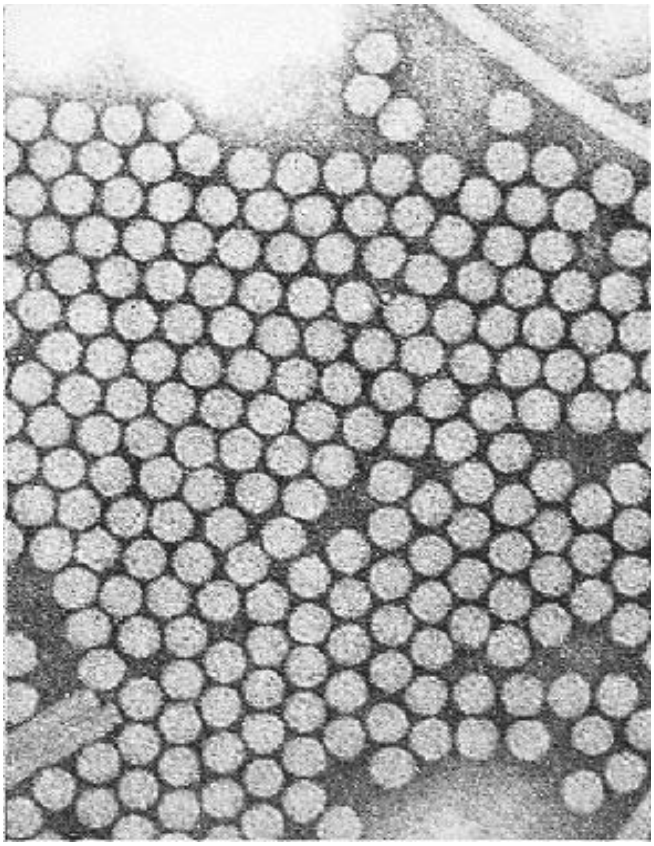

Figure 2 Electronmicrograph of cricket paralysis virus. The icosahedral virus particles are 25–27 nm in diameter; tobacco mosaic virus rods, 18 nm in diameter, were included as a reference standard.

general study of the incidence of small viruses in flies. When extracts of dead flies were injected into healthy adult *Drosophila*, the flies died within three days and the virus multiplied to higher titers than the other viruses being studied at that time. DCV has subsequently been identified in a number of species of *Drosophila*.

CrPV is a rather ubiquitous virus with a wide host range (**Table 2**) so the name is historical rather than categorical. In fact the host range of CrPV is extensive and covers over 40 species that have been tested from five orders of insects. CrPV did not multiply in the silkworm, *Bombyx mori*, or a species of cockroach nor in a locust species. CrPV has also not been shown to replicate in coleopterans, although only a few species have been tested. In insect hosts, both CrPV and DCV have frequently been found as inapparent infections, detected only by bioassay or serological tests. These infections may go completely undetected until a total population collapse occurs. Two DCV isolates that were tested multiplied in the Mediterranean fruit fly, *Ceratitis capitata*, but not in the cricket *Gryllus bimaculatus*. CrPV, however, multiplies in this cricket species. One strain of CrPV was shown to be highly infectious for *C. capitata* and killed the majority of adult flies fed with a virus suspension.

CrPV replicates in most, but not all, *D. melanogaster* cell lines tested and in several lepidopteran and mosquito cell lines. In some cultured *D. melanogaster* cell lines, CrPV causes a distinct cytopathic effect (cpe) which normally leads to cell lysis. DCV has only been observed to produce a cpe in *D. melanogaster* cells. In these cells, DCV causes cell clumping and cell detachment and in some instances results in cell lysis. DCV has also been detected as a persistent infection in several *D. melanogaster* cell lines. The fact that CrPV and DCV replicate in cultured cell lines has allowed their replicative strategies to be quite extensively studied.

CrPV and DCV show serological crossreactivity although they are not identical, a fact which is confirmed by other data. There has also been a report of crossreactivity between CrPV and the vertebrate cardiovirus (*Picornaviridae*), encephalomyocarditis virus (EMCV). CrPV antigen reacted with EMCV antibody, shown to be IgG. Since CrPV and EMCV are clearly unrelated this probably reflects a structural convergence rather than shared ancestry.

There are a number of isolates of CrPV and these can be separated into two distinct serological groups; one group consists of all the isolates from Australasia and the other group contains the two North American isolates. This correlates with differences in polyacrylamide gel electrophoresis profile of capsid polypeptides and that seen from polymerase chain reaction–restriction endonuclease digest (PCR-REN) analysis of the genomes. CrPV isolates can be distinguished serologically from DCV isolates. No serological

Some of the unclassified SRVs have been reasonably well characterized and are clearly not picorna-like; these are included for completeness.

subgrouping of DCV isolates has been observed. The general serological picture for CrPV/DCV is that of a complex of related, but not identical, virus strains. Since these isolates are often from totally different geographical regions and, in the case of CrPV, from a variety of hosts, it is not surprising that such variability exists.

Despite the serological crossreactivity, molecular data indicate that CrPV and DCV are quite distinct. For example, cDNA hybridization studies revealed essentially no homology between CrPV and DCV genomes. Sequence analysis confirmed this but showed that in the region encoding the capsid proteins CrPV and DCV have around 78% similarity (66% identity) at the amino acid level. cDNA hybridization results showed that the different isolates of DCV were 60–85% homologous at the nucleotide level whereas PCR-restriction nucleotide digest analysis indicated a higher degree of nucleotide sequence homology, around 90–95%. Similar results have been obtained among CrPV strains using the latter methodology.

Sequence analysis of the DCV genome demonstrates that it is 9264 nucleotides long and contains two large ORFs. These are separated by 191 nucleotides of untranslated sequence containing several stop codons in all three reading frames. The 5′ ORF encodes a protein with similarities to the RNA-dependent RNA polymerase, helicase and protease domains of several other small RNA viruses from plants and animals (**Fig. 1**). The ORF at the 3′ end encodes the capsid proteins. This latter ORF is unusual in that it lacks a methionine initiation codon and no subgenomic RNA is produced; this suggests that the capsid polyprotein is translated through an internal ribosome entry site. The organization of the 3′ end of CrPV appears to be the same as DCV which also has no apparent methionine initiation codon for the coat protein-containing ORF.

In *D. melanogaster* cells, CrPV shuts down virtually all host cell protein synthesis within several hours after infection. This contrasts sharply with DCV which shows less ability to shut down host cell functions. The fact that CrPV eventually results in extensive cpe whereas DCV does not may be a reflection of this ability. CrPV structural protein synthesis is similar to DCV. Processing of precursors into structural proteins is more rapid than for poliovirus, mengovirus or EMCV. The processing of precursor polypeptides is primarily by virus-induced protease(s) but *in vitro* data suggest that *Drosophila* proteases may also be involved. Coat proteins are produced in supramolar excess compared with the nonstructural proteins, supporting the model for independent initiation of the two ORFs.

A major difficulty arises in identifying reported picorna-like viruses as CrPV strains since a number of isolates of 'picorna-like viruses' or 'small RNA viruses' from insects have never been tested serologically to see if they are CrPV-related. Even if this is done, some viruses could easily be missed or misclassified. For example, $CrPV_{BRK}$, is serologically distinct from most other isolates – a feature borne out by its capsid polypeptide pattern and by PCR-REN analysis of the 3′ end of its genome. Far higher concentrations of heterologous antisera had to be used to get a detectable reaction. An isolate of CrPV from *Pseudoplusia includens*, now called $CrPV_{ARK}$ and known to be closely related to $CrPV_{BRK}$, would not have been recognized as a CrPV strain if the conditions for serological testing had not been radically adjusted.

Picorna-like Viruses of Hymenopterans (Wasps and Bees)

With its wide host range it is not surprising that CrPV has been isolated from the hymenopterans, the European honeybee, *Apis mellifera*, the common wasp, *Vespa vulgaris*, and the German wasp, *V. germanica*. However, there have been a number of other picorna-like viruses isolated from the honeybee. A 'filterable virus', identified years later as sacbrood virus (SBV), was isolated in 1913 from *A. mellifera*

and later from the Asiatic hive bee *A. cerana*. Despite their economic importance as pollinators, which far outweighs their value as honey producers, only a few laboratories worldwide have studied the bee viruses. Most of the isolations and characterization studies were carried out at the Rothamsted Experimental Station in England by Leslie 'Bill' Bailey in a 20-year period beginning in the mid-1960s. **Table 2** lists the eight viruses from a total of 15 different viruses, that have properties that merit them being designated picorna-like (see also **Table 1**).

The causative agent of sacbrood was first described in 1913 but it was not until 1964 that it was found to have picorna-like virus properties (SBV). Prior to this, in 1963, acute bee paralysis virus (ABPV) had been described as having picorna-like properties. Although capable of causing paralysis when injected into adult honeybees, ABPV was not initially reported to be associated with any naturally occurring disease symptoms in the UK. However, it has since been found to kill larvae, pupae and adult bees in colonies in other parts of the world when found in association with the parasitic mite *Varroa jacobsoni*. In the UK ABPV is most frequently detected during the late summer months when colony numbers are at their greatest but drops quickly to a low level over the autumn and winter months. ABPV particles are icosahedral, composed of four capsid proteins and contain single-stranded RNA.

Kashmir bee virus (KBV) was initially isolated from *A. cerana* in Kashmir and India. Several strains of KBV were subsequently isolated from the European honeybee in Australia and New Zealand as well as from the wasp *V. germanica* and has since been shown to be pandemic in *A. mellifera* populations. Initially it was thought to cause extensive mortality in hives. Later studies showed that KBV normally exists in a latent state but that infections with other bee pathogens such as the microsporidian *Nosema apis* and the foul brood bacterium *Melisococcus pluton* can trigger virus replication leading to death. Some data suggest that KBV has a serological relationship to ABPV. However, this may be a nonspecific reaction similar to the serological crossreactivity detected between CrPV and the mammalian picornavirus EMCV or an example of convergent evolution since they can both be transmitted through the salivary glands. Molecular studies on the genome of KBV and ABPV will likely resolve these alternatives.

Other picorna-like viruses have been reported for the European honeybee: Berkeley bee paralysis virus (BBPV), black queen cell virus (BQCV), Egypt bee virus (EBV), and slow paralysis virus (SPV). A 30 nm virus, called deformed wing virus, was isolated from *A. mellifera* in Japan but no detailed characterization has been done so this isolate is not included in **Table 1**.

Slow paralysis virus was isolated from *A. mellifera* bees in Britain during field surveys for bee virus X in the early 1970s. It has been found occasionally in honeybees in the UK and causes paralysis of adult *A. mellifera* bees approximately 12 days after injection. As the name implies this aspect of its pathology distinguishes it from the faster-acting acute and chronic paralysis viruses. BQCV is commonly found in association with *N. apis*. As the name implies it was first isolated from dead pupae found in queen cells that exhibited a dark brown to black discoloration. The virus is not particularly infectious when fed to larvae or adult bees or injected into the latter. Nevertheless it is a common infection in beehives in the UK, particularly during the early summer months. Apart from the original isolation and description, little is known of either BBPV or EBV.

Experimental manipulations such as the injection of buffer solutions or sera into pupae, or raising the incubation temperature, can induce replication of inapparent viral infections. Conversely, injections of antisera specific to a particular virus into pupae can neutralize or suppress the induction of that virus if it is present. Some experiments using such techniques have suggested a replicative hierarchy among some honeybee viruses. For instance in one series of experiments carried out in Australia, in the absence of suppression, injection with buffer induced primarily KBV. If KBV was neutralized then SBV and BQCV were induced with SBV out-replicating BQCV. If both KBV and SBV were suppressed then BQCV replicated to high levels.

Except for the $CrPV_{BEE}$ isolate, none of the bee viruses have been found to replicate in any insect cell line and no bee cell line exists. This means that detailed studies on the replication of this important class of viruses is lacking although there are substantial data on their biology and pathology.

Picorna-like Viruses of Dipterans (True Flies)

Although dipterans, such as mosquitoes, have been well studied because of their ability to transmit pathogenic viruses of humans or animals, surprisingly few viruses have been discovered which are pathogenic to the insects themselves. In addition to *Drosophila* C virus, only five other viruses merit inclusion in **Table 1**. These include Kawino virus (KV), isolated from the mosquito *Mansonia uniformis* in Kenya, and the picorna-like viruses isolated from the Mediterranean fruit fly, *Ceratitis capitata* (*Ceratitis* V virus), the Queensland fruit fly, *Dacus*

tryoni (Queensland fruit fly virus QFFV) and *D. melanogaster* (*Drosophila* P and A viruses, DPV and DAV, respectively).

KV has been relatively well characterized and shows the typical capsid protein profile of a picornavirus. However, the genome does not appear to contain a poly(A) region. It replicates in several mosquito cell lines but only produced a cpe in one *Aedes* line. Unfortunately, no studies have been made on its replication and the virus appears to be 'lost'. QFFV is relatively well characterized and the RNA shown to have a poly(A) tract. Unfortunately the virus is not infectious to the *Drosophila* cell lines 1 and 2 (in which DCV and CrPV replicate) so detailed studies on replication have not been done.

DPV was originally discovered in apparently healthy laboratory populations of *D. melanogaster* when studies showed that infected flies had a lower life expectancy and reduced fecundity and fertility. Like DPV, DAV is only mildly pathogenic to flies and frequently occurs as inapparent infections in laboratory populations. Both DPV and DAV replicate in *Drosophila* cells but neither produce the lytic cpe commonly seen with DCV. Both viruses have been commonly found in natural populations of *D. melanogaster*, and in the case of DAV it has also been found in natural populations of other *Drosophila* species.

A fourth picorna-like virus is also known from *Drosophila*, namely the virus 'iota' (DiV), originally isolated from *D. immigrans* populations collected in France in the early 1970s. DiV is serologically related to DPV but has not been well characterized physically and so has not been included in **Table 1**. DiV has been shown to confer CO_2 sensitivity to infected flies, similar to the totally unrelated insect rhabdovirus, sigma virus. Although common in *D. immigrans* populations in France in the early 1970s, within five years it seemed to have completely disappeared and could no longer be isolated from natural populations of flies.

Picorna-like Viruses of Hemipterans (True Bugs)

Hemipterans, such as aphids and leafhoppers are important as vectors of plant viruses and human or veterinary diseases. As with the dipteran viruses there have not been extensive recordings of pathogenic viruses found in them. Only five of the ten isolates of small RNA viruses or virus-like particles found in Hemipterans have been characterized sufficiently to be considered picorna-like (**Table 1**).

The first virus, RhpV, pathogenic to a hemipteran, was isolated from the aphid *Rhopalosiphum padi* in Illinois and later reported from laboratory colonies in South Africa. Another aphid virus, aphid lethal paralysis virus (ALPV) was also isolated from *R. padi* colonies but is quite distinct from RhpV in its physicochemical properties as well as being much more pathogenic, causing paralysis and eventual death of the infected aphids. RhpV has also been shown to occur in laboratory and field populations of other *Rhopalosiphum* species as well as aphid species of other genera. ALPV host range is also not limited to *R. padi*.

No cultured cell lines have been found to support the replication of Rhpv and ALPV and therefore detailed studies of their replication strategies have not been carried out. Therefore, for both viruses, little is known of their replicative strategies or affinities. However, cell-free translations of the genomic RNA of RhpV and ALPV showed that large proteins were synthesized and that for ALPV the putative polyprotein was cleaved into smaller proteins which reacted with antisera to purified virions. Recent sequence data indicate that RhpV has a genomic organization similar to DCV/CrPV, i.e. dicistronic with the coat proteins encoded at the 3′ end of the genome, although full details of the sequence are not currently available.

Recently, a virus (PsIV) was isolated from the intestines of the brown winged green bug *Plautia stali*. This virus appears to have a dicistronic genomic organization like that of DCV and CrPV. However, the two ORFs are in the same frame and separated by only one stop codon, allowing for the possibility of read-through expression of ORF 2. The putative ORF 1 contains identifiable core motifs for the RNA helicase, cysteine protease and the RNA polymerase (**Fig. 1**) but overall shows very low amino acid similarity to the RDRP region of DCV (52% similarity, 27% identity). ORF 2 contained sequences corresponding to regions of the capsid proteins and like the RDRP region has low amino acid identity with the DCV capsid proteins (51% similarity, 29% identity).

Himetobi P virus (HiPV) was originally isolated from the leafhopper *Laodelphax striatellus* (called 'himetobi' in Japan) but subsequently detected in laboratory and field populations of other species. The virus NVV-1 has been isolated from another leafhopper, *Nezara viridula*. A VP4 has not been recorded for either of these viruses nor have they apparently been tested in the several leafhopper cells lines described so, again, these viruses cannot be classified at this time.

The only recorded insect virus isolate from a hemipteran affecting vertebrates is *Triatoma* virus, which was isolated from a species in Argentina which

transmits the human protozoan parasite which causes Chagas' disease. Although some physical characters have been described there are no reports of attempts to infect cell lines.

Picorna-like Viruses of Lepidopterans (Moths and Butterflies)

Although many insect viruses affecting lepidopterans have been described, stimulated mainly by the pest status of many moth species in agriculture, horticulture and forestry, these viruses are mainly the large occluded viruses (baculoviruses, entomopoxviruses and cytoplasmic polyhedrosis viruses). Relatively few picorna-like viruses have been described although there have been numerous reports of 'virus-like particles' and electron micrographs of 'crystalline arrays' in the literature of the past 20–30 years. Some of these could well be 'CrPVs' as in the case of the virus reported from *Pseudoplusia includens* but which turned out to be $CrPV_{ARK}$. Other isolates have only been partially characterized.

The best characterized isolate is infectious flacherie virus (IFV) obtained from the silkworm *B. mori* in Japan. Besides the characteristics of IFV illustrated in **Table 1**, the ssRNA genome has been translated *in vitro* and shown to synthesize a large 130–200 kDa protein reminiscent of the precursor polypeptides seen for the true picornaviruses. The 3′ terminus is polyadenylated although the 5′ terminus appears to lack a VPg cap. Like the vertebrate picornaviruses, the genome consists of a single long ORF of 9255 nucleotides with the replicase-related proteins located at the 3′ end and the structural proteins located at the 5′ end of the genomic RNA (**Fig. 1**). Although it has a somewhat larger genome than most mammalian picornaviruses, IFV appears to be the best (and presently only) insect virus candidate for inclusion in the *Picornaviridae*.

Three other lepidopteran viruses, *Gonometa* virus (GV), *Latoia viridissima* virus (LvV) and *Lymantria ninayi* virus (LnV) are sufficiently characterized to regard them as picorna-like. GV was isolated from field populations of insects which had been devastated by an epizootic in Uganda in the 1960s and may possibly be the same as or similar to a virus found in *Pachymetana* during the same period. Although GV has long been regarded as a possible insect picornavirus because of its physical characteristics it has essentially been 'lost to science'. The few existing samples do not replicate in any of the insect cell lines tested and since the insect host is not readily available, it is not known whether the few laboratory stocks of the virus are even viable. LvV and LnV, like GV, were both isolated from insects collected during natural disease epizootics. Apart from their initial characterization little else is known about these latter three lepidopteran picorna-like viruses.

Potential as Biological Control Agents

Insect picorna-like viruses have been recorded in a number of different insect families including some, such as the hemipterans and the orthopterans (e.g. grasshoppers, locusts, crickets) where the occluded viruses do not occur frequently. The picorna-like viruses might be useful for these groups as well as others. There are several recorded examples of the picorna-like viruses being used as control agents. Infestations of the moth *Gonometa podocarpi* in pine plantations in Uganda were controlled using extracts of dead insects killed by GV and applying these to pest populations where the virus was absent. Like GV, LvV was shown to be an effective biocontrol agent when extracts of diseased cadavers were applied to apparently healthy populations of the pest insects.

Although not tested in the field, CrPV has shown itself quite capable of devastating insect populations and was originally discovered when it triggered a population collapse of crickets. CrPV has also been shown to kill adult Mediterranean fruit flies in laboratory tests where several days after feeding the flies 80% died. CrPV was also shown to be the most effective agent for killing the olive fruit fly, being superior to the other viruses tested, including two baculoviruses and an iridovirus.

Although CrPV can be grown in cultured cell lines and in large scale, most of the picorna-like viruses do not grow, or have not been tested for growth, in established insect cell lines. Although this indicates that commercial production could be difficult, recent developments in the production and assembly of viruses in nonpermissive systems may be particularly applicable to the insect picorna-like viruses. Detailed environmental impact evaluations are also essential for any bioinsecticide, not only for potential interactions between the viruses and vertebrates but also with regard to nontarget insect species, particularly with viruses like CrPV which have a demonstrated broad host range. However a wide host range could also be considered an advantage since a particular virus could be used against a range of insect pests and considering the local ecology and environment, as well as the method of application, could make the picorna-like viruses useful agents.

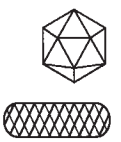
PLANT PARARETROVIRUSES (*CAULIMOVIRIDAE*)



Contents

Caulimoviruses: General Features

James E Schoelz and **June E Bourque**, Plant Pathology, University of Missouri, Columbia, Missouri, USA

History

Caulimoviruses are a group of plant viruses composed of double-stranded (ds) DNA encapsidated into an icosahedral virion. Caulimoviruses have been a subject of study because they cause economic losses in their respective hosts; in addition, they have made significant contributions to our knowledge of the molecular biology of plant viruses. The genome of cauliflower mosaic virus (CaMV), the type member of the genus, was the first of the plant viruses shown to contain DNA rather than RNA as genetic material. Furthermore, it was the first viral genome to be completely sequenced and cloned into bacterial plasmids in an infectious form. The caulimoviruses have also been extensively studied as a model for host–pathogen interactions and because their replication and expression strategies are unusual for plant viruses. For example, CaMV was the first plant virus to be shown to replicate by reverse transcription of an RNA intermediate into dsDNA.

In the early 1980s CaMV was thought to have some promise as a vector for foreign genes in plants. The effort to convert CaMV into a virus-based vector was scaled back when it was shown that the virus genome could tolerate only small insertions. A few small genes, such as dihydrofolate reductase and interferon, were eventually expressed in plants via a CaMV vector. However, other plant viruses, in particular tobacco mosaic virus, potato virus X and tomato bushy stunt virus, have been shown to be much more versatile as vectors for foreign genes.

Although CaMV has had only limited utility as a plant virus vector, the virus continues to have a great impact on plant biotechnology. The CaMV genome has served as a source for the most widely used promoter in plant genetic engineering. The 35S promoter of CaMV is capable of directing a high level of transcription in most types of plant tissues. This promoter was used to drive expression of the first transgene introduced into transgenic plants, and it is still the primary choice for expression of transgenes for both research and commercial applications.

Taxonomy and Classification

Members of the *Caulimovirus* genus, which has 11 definitive species (**Table 1**), have recently been assigned to the *Caulimoviridae* family. The virus genome is composed of circular, dsDNA approximately 8.0 kb in length that contains one or more single-stranded discontinuities. The viral DNA is encapsidated into isometric virions, 45–50 nm in diameter. In infected plants most virions are usually

Badnaviruses

Benham E. Lockhart and **Neil E. Olszewski**, Department of Plant Pathology and Department of Plant Biology, University of Minnesota, St Paul, Minnesota, USA

Taxonomy and Classification

The genus *Badnavirus* consists of plant viruses with nonenveloped bacilliform virions measuring 120–150 × 30 nm containing a circular double-stranded DNA (dsDNA) genome 7.5–8 kb in size (**Fig. 1**). The majority of badnaviruses are transmitted by mealybugs, and some are also seed-transmitted. The genus currently contains 13 definitive members: *Commelina* yellow mottle virus (CoYMV), the type member; *Aglaonema* bacilliform virus (AgBV); cacao swollen shoot virus (CSSV); rice tungro bacilliform (RTBV); banana streak virus (BSV); canna yellow mottle virus (CaYMV); citrus mosaic badnavirus (CMBV); *Kalanchoë* top-spotting virus (KTSV); *Dioscorea* bacilliform virus (DBV); pineapple bacilliform virus (PBV); *Piper* yellow mottle virus (PYMV); sugarcane bacilliform virus (ScBV); and *Schefflera* ringspot virus (SRV). Viruses with similar particle morphology occurring in *Aucuba, Colocasia, Mimosa, Rubus, Spiraea* and *Yucca* are possible additional members of the genus.

Badnaviruses differ from other bacilliform plant viruses in particle size and composition, and in genome type. The plant rhabdoviruses have significantly larger bacilliform particles surrounded by a lipid-containing envelope, and have a single-stranded RNA (ssRNA) genome. The bacilliform virions of alfalfa mosaic virus (AMV) are less than one-third the size of badnaviruses, and also contain ssRNA. Badnaviruses differ from caulimoviruses, the only other known group of dsDNA plant viruses, in particle morphology, genome size and organization, vector relationships and histopathology.

It is noteworthy that a number of clonally propagated plant hosts of badnaviruses (sugarcane, citrus, banana, black pepper, betel, taro, schefflera) have their centers of origin or diversity in southeast Asia or Australasia. This suggests, but does not provide direct evidence, that badnaviruses may have originated in this part of the world.

Virus Structure and Composition

Badnavirus particles average 120–150 × 30 nm in size, but particles ranging in size from 30 nm spheres to bacilliform particles up to 1000 nm long may occur. Some isolates of BSV, CSSV and PYMV produce significant numbers of abnormally long particles. The particles have a sedimentation coefficient of approximately 200S, and a buoyant density in CsCl of 1.31 g cm^{-3}. The virions are stable in Cs_2SO_4 but not in CsCl. Purified virus preparations sediment as a single component in both rate zonal and isopycnic density gradient centrifugation, indicating that particles of different lengths contain approximately equal ratios of nucleic acid and protein. Purified virus preparations have uncorrected A_{260}/A_{280} ratios of 1.3–1.4. There is no information on extinction coefficient values.

Badnavirus virions contain a major capsid protein of 39 kDa. Proteolysis by proteases generates a second major polypeptide of 37 kDa. Larger virus-related polypeptides are also detected by immunoblotting, and these most probably represent various fragments of the polyprotein from which the capsid protein is released by post-translational processing. The CoYMV capsid protein is not glycosylated, and there is no evidence for the presence of any other non-protein components in the capsid. Analysis of the particle structure of RTBV using optical diffraction

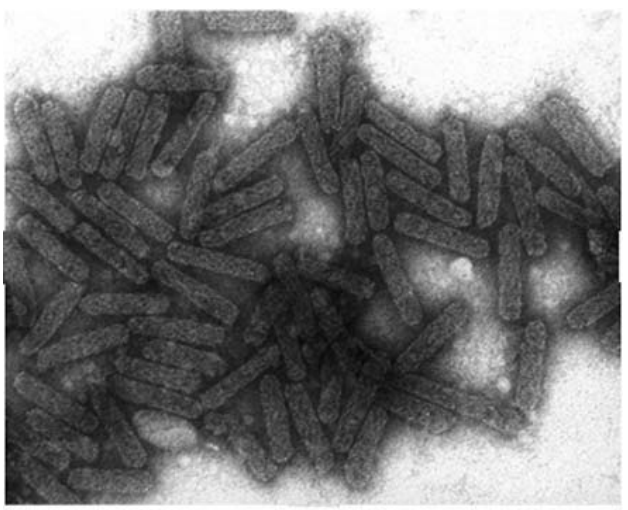

Figure 1 Particles of sugarcane bacilliform virus (ScBV) negatively stained with sodium phosphotungstate. Scale bar = 100 nm.

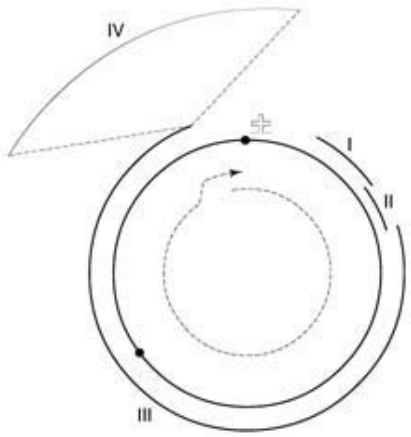

Figure 2 The generalized organization of the viral transcript, genome and open reading frames (ORFs). The dotted arrow indicates the badnavirus transcript. The solid circle indicates the DNA genome and the dots mark the locations of the site-specific discontinuities. The cloverleaf indicates the $tRNA^{Met}$ binding site. The solid arcs indicate the locations of ORFs I–III, which are present in all badnaviruses, and the thinner outermost arc indicates the relative location of ORF IV of RTBV.

of electron micrographs indicates that the tubular portion of the particle has a structure based on an icosahedron cut across its threefold axis, with a structural repeat of 10 nm and nine rings of hexamer subunits.

Badnavirus virions contain a single species of dsDNA, which has a buoyant density of 1.57 g cm^{-3} in CsCl–ethidium bromide. Under nondenaturing conditions, the DNA migrates in agarose gels as three or more bands corresponding to linear, circular and knotted configurations. Electron microscopic examination of purified virus and ultrathin sections of infected tissue reveal that the virions have an electron-translucent central core. However, there is no information on the nature of protein–DNA interaction within the nucleocapsid.

Genome Structure

The various badnaviruses encapsidate a circular dsDNA which, depending on the virus, ranges in size from 7.5 to 8.0 kb. This circular DNA molecule is relaxed, rather than supercoiled, because each strand is interrupted by a site-specific discontinuity (**Fig. 2**). The plus and minus strand discontinuities are located adjacent to the sequences that are believed to prime the synthesis of these strands, suggesting that the discontinuities are generated during replication of the genome.

Virus Replication and Multiplication

The badnaviruses are pararetroviruses that replicate by reverse transcription of a terminally redundant transcript that is longer than the genome (**Fig. 2**). This process is carried out by a virus-encoded reverse transcriptase (RT) and RNase H. Minus-strand synthesis is believed to be primed when $tRNA^{Met}$ anneals near the 5′ end of the viral transcript. In the case of CoYMV and similar to other retroelements, plus-strand synthesis appears to initiate at a polypurine-rich region. In contrast, RTBV plus-strand synthesis does not appear to initiate at a polypurine-rich region.

Molecular Biology

Only the minus strand of the genome is transcribed. Although it has not yet been demonstrated, transcription is probably similar to that of the caulimoviruses, in that it involves host RNA polymerase II and occurs on a nuclear-localized, covalently closed minichromosome. All badnaviruses examined produce a transcript that is terminally redundant and between 120 and 270 nt longer than genome length. The terminally redundant transcript is believed to serve both as a polycistronic mRNA and as the template for genome replication. In addition, a small portion of the RTBV transcript is spliced to produce an mRNA-encoding open reading frame (ORF) IV, the terminal ORF of the polycistronic mRNA. This smaller mRNA appears to be the only one capable of expressing ORF IV.

In general, the polycistronic mRNA contains three ORFs (I–III) arranged in a tight tandem array (**Fig. 2**). However, the RTBV RNA contains an additional ORF, ORF IV. In addition to the larger protein-encoding ORFs, the leader of the polycistronic RNA also contains several very small and apparently noncoding ORFs. Translation of the polycistronic mRNA employs both a translational shunt to avoid the untranslated ORFs of the leader and leaky scanning by ribosomes allowing the expression of ORFs II and III.

ORF III, which is the largest and with the exception of RTBV the last ORF of the mRNA, encodes a large polyprotein that is proteolytically processed to yield a protein involved in the cell-to-cell movement of the virus, the capsid protein, an aspartic protease, a RT and an RNase H. The polyprotein is probably processed by the aspartic protease. The cell-to-cell movement protein is a structural component of tubules extending between adjacent cells that serve as a conduit for virion movement between cells. Although the functions of the proteins encoded by the

other ORFs are unknown, the ORF I and ORF II proteins of CoYMV and RTBV are known to be associated with virions and the ORF II proteins of CSSV and RTBV bind nucleic acids *in vitro*.

Geographic Distribution and Economic Importance

Badnaviruses occur primarily in the tropics and subtropics in vegetatively propagated or perennial crops. The notable exception is RTBV, whose host, rice, is a seed-propagated annual. RTBV occurs in Asia and southeast Asia, where it may be a major yield-limiting factor in some localities. Cacao swollen shoot virus occurs in several countries in West Africa, and is also a disease of major economic importance. Banana streak virus is the most commonly occurring virus in *Musa*, and probably occurs in all banana- and plantain-growing areas of the world. Some BSV isolates cause severe damage and crop loss, and the occurrence of this virus in improved varieties has been a hindrance to movement of this germplasm. PYMV, which occurs on both black pepper (*Piper nigrum*) and betel vine (*P. betle*) in southeast Asia, has a pronounced effect on plant growth, and may have been one of the factors contributing to the decline of black pepper cultivation in the former Indochina. ScBV, some isolates of which are serologically closely related to BSV, occurs worldwide in nearly all clones of noble sugarcane (*Saccharum officinarum*), but is less prevalent in newer commercial *Saccharum* hybrids. Badnaviruses occur frequently in mixed infections with other viruses, and there is some evidence of mutually synergistic effects on virus replication and symptom development in such mixed infections.

Host Range and Symptomatology

Badnaviruses occur in both monocotyledonous (e.g. RTBV, CoYMV, ScBV) and dicotyledonous (e.g. CSSV, CMBV, PYMV, SRV) hosts. The individual viruses typically have very restricted natural and experimental host ranges, frequently limited to a few species within a single plant genus. The exceptions are CSSV and ScBV, which can infect several different genera and families. The most common symptom of badnavirus infection is a yellow foliar mottle.

A characteristic feature of badnavirus infection is seasonal variation in virus titer and symptoms expression. This periodicity of virus replication and symptom development is correlated with seasonal temperature changes.

Serology

Badnaviruses are only moderately immunogenic. Repeated immunization of rabbits yields antisera with homologous enzyme immunoassay (EIA) titers of 1:250 000. Both EIA and immunoelectron microscopy (IEM) can be used for virus detection and for studying serological relationships within and between badnavirus species.

There is a general lack of serological crossreactivity between members of the badnavirus group, and individual badnaviruses may have one or more distinct serotypes (e.g. CSSV, ScBV, BSV, KTSV, SRV). EIA and IEM tests indicate serological relationships between BSV and ScBV, and between CSSV, SRV and DBV. ScBV has the greatest degree of serological diversity among its isolates, and polyclonal antisera raised against a mixed pool of ScBV antigens crossreact with the majority of other badnaviruses.

Virus–Host Relationships

Except in the early stages of infection, badnaviruses typically occur in low concentration in host tissue. RTBV has been reported to be phloem-limited in rice, but several other badnaviruses (e.g. CoYMV, PYMV, SRV, CaYMV) are not tissue-limited, and their virions have been observed in epidermal, mesophyll and vascular cells. Virions only occur in the cytoplasm, and may appear in palisade-like arrays or in random aggregates. The particles do not occur in the proteinaceous inclusion bodies (viroplasms) typical of caulimoviruses. The absence of a proteinaceous inclusion body from badnaviruses is corroborated by the absence from the badnavirus genome of a coding region analogous to the caulimovirus ORF VI. Although badnavirus virions have not been observed in nuclei of infected cells, filamentous structures of unknown function have been observed in nuclei of ScBV-infected sugarcane. Badnavirus infection also appears to induce internal structural modifications in mitochondria. Tubular structures containing virions traverse the wall between adjacent cells in CoYMV-infected *Commelina diffusa*. These structures presumably occupy modified plasmodesmatal openings, and appear to play a role in cell-to-cell trafficking of virions.

Many *Musa* genotypes contain integrated BSV genomic sequences, and there is evidence for similar integration of badnavirus genome sequences in other plant species such as sugarcane and canna. The mechanism of integration of viral sequences has not been determined, and the number, nature and possible

biological significance of these viral sequences are not known.

Transmission

Eight of the 13 definitive members of the badnavirus group (CMBV, CSSV, CoYMV, BSV, KTSV, PYMV, ScBV, SRV) are transmitted by mealybugs (*Pseudococcidae*). The mode of transmission is semipersistent and nonpropagative. Vectors can transmit virus after brief acquisition periods (15–30 min), but the rate and duration of transmissibility increase with acquisition feeding up to 24 h. After a 24 h acquisition feeding period, mealybugs retain the ability to transmit virus for up to 72 h. Mealybug vectors of badnaviruses include *Planococcus citri, Planococcus kenyae, Planococcoides njalensis, Pseudococcus longispinus, Ferrisia virgata, Saccharicoccus saccharoides* and *Dysmicoccus boninsis*. The mealybug vectors are able to acquire and transmit badnaviruses at all stages of the life cycle.

In contrast with the majority of badnaviruses, RTBV is transmitted in a semipersistent manner by leafhopper vectors, principally *Nephotettix* spp. Leafhopper transmission of RTBV occurs only in association with a helper virus, rice tungro spherical virus (RTSV), which has an ssRNA genome. Transmission of RTBV does not require the presence of RTSV, but only the presence of a helper component coded for by the RTSV genome. Although the mealybug-transmitted badnaviruses commonly occur in nature in mixed infections with other insect-transmitted viruses, it has been clearly demonstrated that they are not dependent on these viruses for transmission by their mealybug vectors.

Three definitive or proposed members of the badnavirus group (KTSV, CoYMV and Mimosa bacilliform virus) are seed-transmitted at rates of 10–80% and KTSV is also pollen-transmitted. BSV is also seed-transmitted in banana. Except for RTSV and CaYMV, the other definitive members of the badnavirus group are transmitted by mechanical inoculation.

Epidemiology, Detection and Control

The epidemiology of plant diseases caused by badnaviruses is determined primarily by the fact that the majority of these viruses occur in vegetatively propagated crops, have restricted host ranges and are transmitted by mealybug vectors which are relatively sedentary and do not disperse rapidly or over great distances.

Clonal propagation from virus-infected stock plants therefore represents the principal means of spread of badnavirus diseases. Short-distance spread by mealybug vectors occurs when foliage contact within the crop canopy permits the vectors to crawl from infected to healthy plants. Because of their restricted host ranges, spread of badnaviruses occurs primarily within a single cultivated species, and apart from the case of CSSV in West Africa, there is little evidence that noncrop plants play an important role in the epidemiology of these diseases. There is also no evidence that badnaviruses can be spread by mechanical contact, by cutting tools, or during cultural operations.

RTBV differs fundamentally from the other badnaviruses in its epidemiology. RTBV infects a seed-propagated annual crop, and is spread by an aerial vector capable of rapid, as well as long-distance, dispersal. The practice of multiple cropping of rice in parts of Asia and southeast Asia provides a source of both virus and vector for infection of new fields.

Control of the majority of mealybug-transmitted badnaviruses occurring in clonally propagated crops can be accomplished effectively by use of virus-free propagating stock. The principal difficulty lies in developing sensitive and reliable virus-indexing methods. Badnaviruses usually occur in low concentration in their host plants, many of which contain high levels of tannins, mucilage and other compounds which may interfere with assay procedures. In addition, badnavirus-infected plants may produce symptomless, virus-free foliage for several months at a time before symptoms reappear, thereby compromising the reliability of disease detection based on visual inspection. Enzyme immunoassay EIA offers a sensitive and reliable method for detection of badnaviruses when viral antigen occurs in plant tissue. The applicability of this technique is restricted, however, by the occurrence of serologically distinct badnavirus populations within a given crop (e.g. cacao, banana, sugarcane, *Kalanchoë*). Detection and identification methods based on polymerase chain reaction (PCR) amplification of common badnavirus genomic sequences appear to offer a more reliable and sensitive indexing method for propagating stock. However, the reliability of this method may be compromised by the existence of badnavirus genomic sequences integrated into host plant DNA. Virus detection using immunocapture PCR (IC-PCR) can be used to avoid potential problems caused by the presence of integrated viral sequences. The production of virus-free plants by apical meristem culture has been used successfully with a variety of clonally propagated crop plants infected by RNA viruses. Initial results with ScBV in sugarcane suggests that this technique may not be successful in the case of badnavirus infection.

On the basis of characteristics of the host plant and

disease epidemiology, RTBV-induced disease in rice is amenable to control strategies not relevant to the other badnavirus diseases. Breeding and selection of virus- or vector-resistant varieties is a prime option in the case of rice, but is less readily accomplished in clonally propagated crop plant hosts of other badnaviruses. Control of vector populations by cultural or chemical methods is also far more relevant to RTBV than to other badnaviruses.

PLANT RESISTANCE TO VIRUSES

Contents

Natural Resistance

RSS Fraser, Society for General Microbiology, Reading, UK

Importance of Resistance in Disease Control

Plant viruses cause serious economic losses in many crops, in three main ways. Infection normally reduces yield biomass; an important example is the effect of the complex of related viruses known as barley yellow dwarf on all major cereal crops. In crops which are sold on the basis of appearance, such as ornamentals and many fruits and vegetables, blemishing and distortion as a result of virus infection can lead to complete loss of marketability, even in cases where yield biomass is only slightly reduced. Finally, costs are incurred if eradication or avoidance programs are enforced, for example in production and certification of virus-tested seed potatoes.

In contrast to the control of fungal diseases of plants, no chemical pesticides are available for routine use as direct antiviral agents. It has, therefore, been necessary to develop a number of alternative control strategies. These include control of the biotic vectors of particular plant viruses, use of virus-free seed or planting material of vegetatively propagated crops, good cultural practices to minimize transmission, and deployment of a number of different mechanisms of plant resistance. Naturally occurring resistance mechanisms, the topic of this article, have been of most use in crop protection until now, but several types of genetically engineered resistance mechanisms, using viral and nonviral genes, are now becoming available. In both types of resistance, it is important to study the mechanisms involved, to increase the effectiveness with which resistance can be used in crop protection, and to understand more fundamental questions about the molecular interactions between plants and viruses.

Types of Natural Resistance Mechanism

Plant viruses are very diverse in their structure, mode of replication and transmission, and in their pathogenic effects on their hosts. Perhaps not surprisingly,

functions alone were not responsible for the complementation.

Control

PC1SV-CVB isolate was found to be economically important in some of the peanut growing areas in the state of Andhra Pradesh. Reports on the economic importance of SoyCMV are not available. No efforts have so far been made to devise any strategies for controlling PC1SV or SoyCMV.

Rice Tungro Bacilliform Virus

Roger Hull, John Innes Centre, Norwich Research Park, Colney, Norwich, UK

General Features

Rice tungro disease was first recognized in the experimental fields at the International Rice Research Institute, The Philippines in 1963 and identified as a distinct virus disease in 1965. However, previous descriptions of disorders in rice (*Oryza sativa*) would indicate that it has been present in the Philippines, and probably elsewhere in southeast Asia from at least the 1930s. Since its recognition as a virus disease, tungro has been reported in most of the rice-growing countries of south and southeast Asia (**Fig. 1**).

Tungro is unusual in that it has a multitude of local names, there being at least 40 names including 'tungro' and 'accep na pula' in The Philippines and names such as 'penyakit merah' in Malaysia and 'mentek' in Indonesia; this plurality of names reflects the importance with which farmers regarded the disease. The disease is generally endemic but has caused periodic major outbreaks in various countries in this region. Much of the increase in impact of tungro has been attributed to the 'green revolution', which resulted in large areas of rice with high fertilizer inputs and overlapping cropping of new susceptible cultivars, conditions highly suitable to rapid spread of the viruses. Overall this disease is now considered to be one of the major constraints to rice production in this region, with annual losses in excess of \$US 1.5×10^9; this does not include the costs of insecticides to control the virus vector.

It was not until 1978 that it was realized that tungro disease is caused by a complex of two viruses, rice

Figure 1 Distribution (shaded area) of rice tungro disease in south and southeast Asia.

tungro spherical virus (RTSV), which causes few symptoms and is leafhopper transmitted, and rice tungro bacilliform virus (RTBV), which is the major contributor to symptom production. RTBV on its own is not leafhopper transmitted but is so in the presence of RTSV. Thus, RTSV confers the leafhopper transmissibility to the complex and RTBV confers most of the symptom production.

Symptoms and Host Range

The symptoms of tungro vary with rice cultivar but in many cultivars the disease causes stunting of the plant, red or orange colouring of the leaves and a reduction of tiller numbers. Early infection can cause death of some very susceptible cultivars and, in many other cultivars, results in considerable loss of yield. RTBV (and RTSV) is restricted to the vascular tissues of infected plants being found in both the phloem and xylem.

Rice is the principal host of the tungro viruses but either or both of them can infect wild rice species (e.g. *O. australiensis, O. barthii, O. brachyantha, O. eichengeri, O. fatua, O. glaberrima, O. nivara, O. officinalis, O. perennis, O. punctata, O. redleyi, O. rufipogon*) and some other graminaceous species. However, some of these reports need treating with caution as reliable confirmation of infection by either or both viruses was not available at the time the tests were conducted.

Virus Transmission

As noted above, RTBV is transmitted by leafhoppers only in the presence of RTSV. The major vector is the rice green leafhopper, *Nephotettix virescens*, and it can also be transmitted by some other leafhopper species such as *N. nigropictus, N. malayensis, N. parvus* and *Recilia dorsalis*. The relationship of both viruses with the leafhopper vector is semipersistent, with acquisition in a matter of minutes and ability to be able to transmit immediately. The retention of transmissibility increases with length of acquisition feeding. Neither of the two viruses is transmissible mechanically but cloned RTBV has been transmitted by agroinoculation (see below).

Virus Control

The major approaches to controlling tungro are cultural, use of insecticides against the vector and the deployment of resistance. Cultural techniques mainly aim at avoiding the main peaks of vector occurrence and having a crop-free period which would reduce sources of infection. There is widespread use of insecticides but, as the disease is transmitted in a semipersistent manner, and as rice is usually grown on small plots, this is not particularly effective. There are two major types of resistance, that against the insect vector and tolerance against RTBV. The initial breeding programs used the vector resistance, which did not prove to be particularly durable. Current breeding programmes are utilizing various forms of natural resistance to the two viruses. That against RTBV is tolerance, which is found in the cultivar Utri Merah. Various transgenic approaches to conferring resistance to RTBV are currently being tested.

Virus Classification

RTBV belongs to the *Badnavirus* genus of the plant pararetrovirus family, the *Caulimoviridae*. It has bacilliform particles which contain a double-stranded DNA genome of about 8.0 kb. Because of some differences in genome organization RTBV is placed in a separate group to the other badnaviruses.

Virus Particles

RTBV has bacilliform particles of 30 nm diameter and usually about 130 nm length (**Fig. 2**). However, in some isolates longer particles in excess of 300 nm are found. The structure of the particles is based on a $T = 3$ icosahedron cut across its threefold axis with the tubular portion being made up of rings of hexamer subunits and a repeat distance of about 10 nm. The particles have an s_{20w} of approximately 200 and a buoyant density in cesium chloride of approximately 1.36 g ml^{-1}.

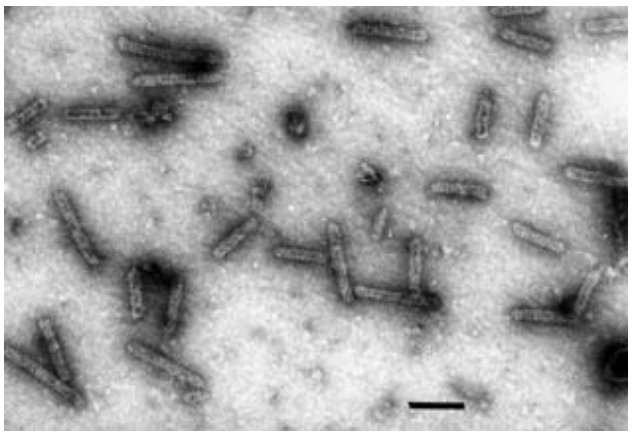

Figure 2 Electron micrograph of particles of RTBV negatively stained with uranyl acetate. Bar = 100 nm.

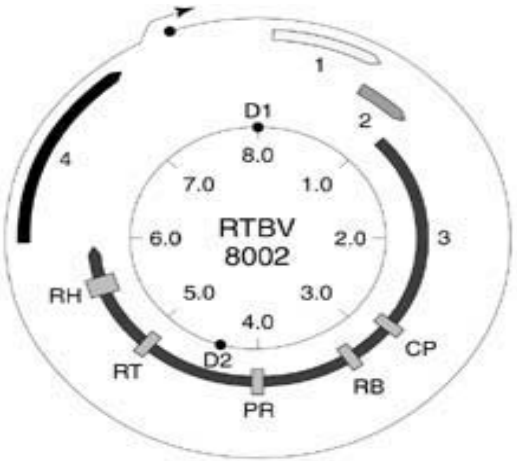

Figure 3 Genome organization of RTBV. The inner circle represents the double-stranded DNA genome with the positions of the two discontinuities, D1 and D2, indicated. The arcs show the positions of the four open reading frames (ORF 1–4). ORF 1 is shaded lighter as it does not have a conventional AUG start codon. The positions of the sequence motifs for coat protein (CP), RNA binding 'cys' sequence (RB), aspartate protease (PR), reverse transcriptase (RT) and RNase H (RH) on ORF 3 polyprotein are indicated. The outer circle represents the 35S RNA with terminal redundancy, the spot being the 5′ end and the arrow head the 3′ end.

Viral Genome

The virus particles contain a double-stranded DNA genome of 7934–8002 bp, depending on strain. As with all plant pararetroviruses, the genome has discontinuities at specific sites and, as with other badnaviruses, RTBV has one discontinuity in each strand. These discontinuities are related to the replication of the genome and are discussed further below.

Genome Organization

RTBV is similar to other retro- and pararetroviruses in that the genomic DNA is transcribed asymmetrically, with all the coding capacity being on one strand. RTBV has four open reading frames (ORFs) which potentially encode proteins of more than 10 kDa (**Fig. 3**). The first three ORFs are closely packed and interface with the sequence ATGA, the ATG being the start codon of the downstream ORF and the TGA the stop codon for the upstream ORF. ORF 4 is separated from ORF 3 by a short noncoding region and ORF 1 is separated from ORF 4 by a longer noncoding region.

ORF 1

This ORF, which follows a 666 nt leader sequence of the genome length transcript, potentially encodes a protein of 24 kDa. It is unusual in not having an AUG start codon in any of the three reading frames and using AUU as a start codon. Although no function is known for the product of this ORF, it is found within virus particles.

ORF 2

This ORF encodes a protein of 12 kDa which is located on purified virus particles. The C-terminus of this protein has a nucleic acid-binding activity but no real function has yet been ascribed to it.

ORF 3

The protein of 194 kDa encoded by ORF 3 is a polyprotein which is processed to give at least the viral coat protein, an aspartate protease, reverse transcriptase (RT) and ribonuclease H (RH). Thus, it contains the analogues of *gag* and *pol* of reverse transcribing elements. The N-terminal portion of this polyprotein is processed to give a 40 kDa protein with some sequence similarities with cell-to-cell movement proteins found in other plant viruses. However, its function is uncertain as RTBV is limited to vascular tissue and is not found in mesophyll tissue, where viral movement proteins are thought to operate. The next section of the polyprotein is processed to give two 37 kDa species which make up the viral coat protein. The C-terminal of these species contains the 'cys' motif, $CXCX_2CX_4HX_4C$, characteristic of the RNA-binding site of retroviral *gag* proteins. It also contains the additional 'cys' sequence ($CX_2CX_{11}CX_2CX_4CX_2C$) which is apparently unique to all badnaviruses. The aspartate protease is identified by its core motif, DSG, and is a protein of about 20 kDa. Similarly, the RT and RH regions are identified by their characteristic amino acid motifs. This region is processed into products of 62 and

55 kDa, both of which have RT activity but only the 55 kDa protein having RH activity.

ORF 4

This is an ORF unique to RTBV, not being found in other badnaviruses. It encodes a product of 46 kDa with a sequence motif characteristic of a leucine zipper. No function has yet been ascribed to it.

Expression of the Gene Products

The genome is transcribed to give a transcript (35S RNA) with a terminal redundancy of 215 or 216 nt which, as with most retro- and pararetroviruses, is the template for both replication (see below) and expression of the gene products. In the agroinoculation procedure mentioned above, which was used to show that the sequenced genome was biologically active, a construct was made which would express this 35S RNA. This construct was inserted into the T DNA of *Agrobacterium,* the bacteria transformed with the plasmid and the bacterial paste suspension inoculated into rice plants.

The core promoter for the 35S RNA is a characteristic TATA sequence 32 nucleotides upstream of the transcript start and has enhancing elements both upstream and downstream in the transcribed region. The transcript is terminated at a poly(A) signal sequence.

The expression of RTBV gene products from the 35S RNA has several unique features. There is strong evidence for a 'ribosome shunt' mechanism by which ribosomes bypass most of the leader sequence. The 'shunt donor' is close to the 5′ end of the RNA and the 'shunt acceptor' is between the first and second ATT sequences in ORF I. This ATT is an inefficient start codon, having only about 10% of the efficiency of an AUG codon in a good context. Thus, many of the ribosomes will bypass it in the uninitiated state. Similarly, the AUG codon at the start of ORF 2 is in a weak context and so a significant proportion of the ribosomes will leak through uninitiated. The next AUG codon, which is at the start of ORF 3, is in a good context and should recruit the rest of the ribosomes. Thus, the first three ORFs are expressed by a cascade of 'leaky' ribosomes from the same mRNA. ORF 4 is expressed from an mRNA spliced from the 35S RNA, the splice donor being close to the 5′ end of the RNA and the splice acceptor being just in ORF 4, leaving an intron of 6.3 kb. The AUG start codon for this ORF comes from a short ORF supplied by the splice donor.

One of the differences that RTBV has from most reverse transcribing elements is that the analogues of *gag* and *pol* are on the ORF 3 polyprotein. The *gag* protein is required in much higher amounts than the *pol* and in almost all reverse transcribing elements their production is regulated either by frameshift or by readthrough of a weak stop codon. The *copia* retroelement has a polyprotein containing both *gag* and *pol* but these are differentially expressed by a splicing mechanism. No such mechanism has been found for RTBV and it is possible that the second 'cys' sequence may control the expression of these two gene products.

Viral Replication

The replication mechanism of RTBV closely resembles that of other plant pararetroviruses, such as cauliflower mosaic virus (CaMV), with transcription of a supercoiled form of the viral genome by host DNA-dependent RNA polymerase II in the nucleus, to give the 35S RNA and reverse transcription of the 35S RNA by virus-encoded reverse transcriptase in the cytoplasm. Replication intermediates have been found which have features very similar to those of CaMV. As with nearly all plant reverse transcribing elements the (−)-strand DNA synthesis on the RTBV 35S RNA transcript is primed by $tRNA^{met}_{init}$ but the priming of the (+)-strand DNA synthesis is not at a polypurine-rich region. The discontinuities in the viral genome are at these priming sites.

Virus Variation

Many of the early descriptions of variants of tungro were before it was recognized that the disease was caused by two viruses and did not distinguish between RTBV and RTSV. There are few characterized biological variants of RTBV but molecular studies have shown both local microvariation and regional variants. The microvariation is of the order of 1–2% at the nucleotide level and is that expected from a replication system that does not have proofreading. At the regional level there are two distinct strains of the virus, one from southeast Asia and the other from the Indian subcontinent. The nucleotide sequences of these two strains are about 75% similar and at the amino acid level the similarity varies from 88% (ORF 2) to 56% (ORF 4). The Indian strain is characterized by a deletion of 68 nucleotides in the non-coding region when compared with the southeast Asian strain. No serological differences can be detected between these strains.

Badnaviruses

Benham E. Lockhart and **Neil E. Olszewski**, Department of Plant Pathology and Department of Plant Biology, University of Minnesota, St Paul, Minnesota, USA

Taxonomy and Classification

The genus *Badnavirus* consists of plant viruses with nonenveloped bacilliform virions measuring 120–150 × 30 nm containing a circular double-stranded DNA (dsDNA) genome 7.5–8 kb in size (**Fig. 1**). The majority of badnaviruses are transmitted by mealybugs, and some are also seed-transmitted. The genus currently contains 13 definitive members: *Commelina* yellow mottle virus (CoYMV), the type member; *Aglaonema* bacilliform virus (AgBV); cacao swollen shoot virus (CSSV); rice tungro bacilliform (RTBV); banana streak virus (BSV); canna yellow mottle virus (CaYMV); citrus mosaic badnavirus (CMBV); *Kalanchoë* top-spotting virus (KTSV); *Dioscorea* bacilliform virus (DBV); pineapple bacilliform virus (PBV); *Piper* yellow mottle virus (PYMV); sugarcane bacilliform virus (ScBV); and *Schefflera* ringspot virus (SRV). Viruses with similar particle morphology occurring in *Aucuba, Colocasia, Mimosa, Rubus, Spiraea* and *Yucca* are possible additional members of the genus.

Badnaviruses differ from other bacilliform plant viruses in particle size and composition, and in genome type. The plant rhabdoviruses have significantly larger bacilliform particles surrounded by a lipid-containing envelope, and have a single-stranded RNA (ssRNA) genome. The bacilliform virions of alfalfa mosaic virus (AMV) are less than one-third the size of badnaviruses, and also contain ssRNA. Badnaviruses differ from caulimoviruses, the only other known group of dsDNA plant viruses, in particle morphology, genome size and organization, vector relationships and histopathology.

It is noteworthy that a number of clonally propagated plant hosts of badnaviruses (sugarcane, citrus, banana, black pepper, betel, taro, schefflera) have their centers of origin or diversity in southeast Asia or Australasia. This suggests, but does not provide direct evidence, that badnaviruses may have originated in this part of the world.

Virus Structure and Composition

Badnavirus particles average 120–150 × 30 nm in size, but particles ranging in size from 30 nm spheres to bacilliform particles up to 1000 nm long may occur. Some isolates of BSV, CSSV and PYMV produce significant numbers of abnormally long particles. The particles have a sedimentation coefficient of approximately 200S, and a buoyant density in CsCl of 1.31 g cm^{-3}. The virions are stable in Cs_2SO_4 but not in CsCl. Purified virus preparations sediment as a single component in both rate zonal and isopycnic density gradient centrifugation, indicating that particles of different lengths contain approximately equal ratios of nucleic acid and protein. Purified virus preparations have uncorrected A_{260}/A_{280} ratios of 1.3–1.4. There is no information on extinction coefficient values.

Badnavirus virions contain a major capsid protein of 39 kDa. Proteolysis by proteases generates a second major polypeptide of 37 kDa. Larger virus-related polypeptides are also detected by immunoblotting, and these most probably represent various fragments of the polyprotein from which the capsid protein is released by post-translational processing. The CoYMV capsid protein is not glycosylated, and there is no evidence for the presence of any other non-protein components in the capsid. Analysis of the particle structure of RTBV using optical diffraction

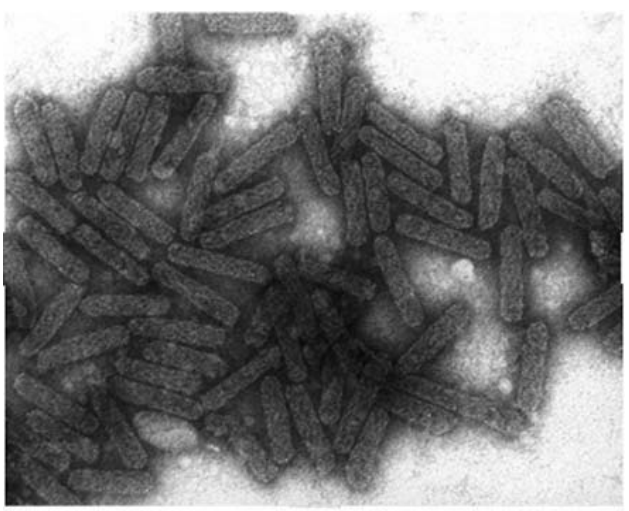

Figure 1 Particles of sugarcane bacilliform virus (ScBV) negatively stained with sodium phosphotungstate. Scale bar = 100 nm.

caulimoviruses the precapsid protein is cleaved at both ends removing its very acidic termini. This process might be coupled to virus assembly and maturation. The capsid protein is both methylated and glycosylated. The Pol protein is cleaved to yield the aspartic proteinase and reverse transcriptase/RNase H. At least some of these cleavages occur by the action of the viral proteinase. In contrast, the ORF III product is cleaved by a host cysteine proteinase. The genome arrangement and the presence of protease domains suggest that protein processing also occurs in CVMV and PVCV. It can be assumed that this is even more extensive, since the primary translation products are fewer and larger.

Cassava Vein Mosaic Virus

Alexandre de Kochko, International Laboratory for Tropical Agricultural Biotechnology, La Jolla, California, USA

History, Taxonomy and Classification

The symptoms induced on cassava plants by cassava vein mosaic virus (CsVMV) were recognized as early as 1940 but the virus itself was first described by Kitajima and Costa in 1966. Based on preliminary observations, which showed that it has isometric particles and that its genome consisted of double-stranded DNA (dsDNA), it was tentatively classified in the *Caulimovirus* genus. More recent work led to the characterization of its genomic organization and showed important features which differ from caulimoviruses as well as from badnaviruses, the two genera of plant dsDNA formerly recognized. In response to these results and additional observations made on other plant dsDNA viruses, executive committee of the International Committee on Taxonomy of Viruses (ICTV) created a new genus (not yet named) with CsVMV designated as the type species. It was also decided to create and name *Caulimoviridae,* the family which contains all the plant dsDNA viruses including the genera *Caulimovirus, Badnavirus,* and three newly created genera. One includes CsVMV, another the former caulimoviruses infecting legumes (Soybean chlorotic mottle virus, SbCMV, and peanut chlorotic streak virus, PCSV) and the third has rice tungro bacilliform virus (RTBV) as its type species.

Geographic Distribution, Host Range and Virus Propagation

CsVMV was described in Brazil, with detailed accounts of its presence in the states of São Paulo and Ceará, but this limited description is certainly a consequence of the very few studies carried out on this virus. It infects plants from the cultivated cassava species, *Manihot esculenta* Crantz, which originated from the Amazon basin. Its complete host spectrum is not known, in particular no surveys have been made on wild cassava relatives. The impact on cassava production seems to be limited. Caulimoviruses are aphid-transmitted but in the case of CsVMV the natural vector is unknown. As cassava is mainly reproduced vegetatively, the virus is propagated very easily through cuttings. Experimentally it is possible to infect cassava plants by introducing an infectious clone using microbombardment. It has also been

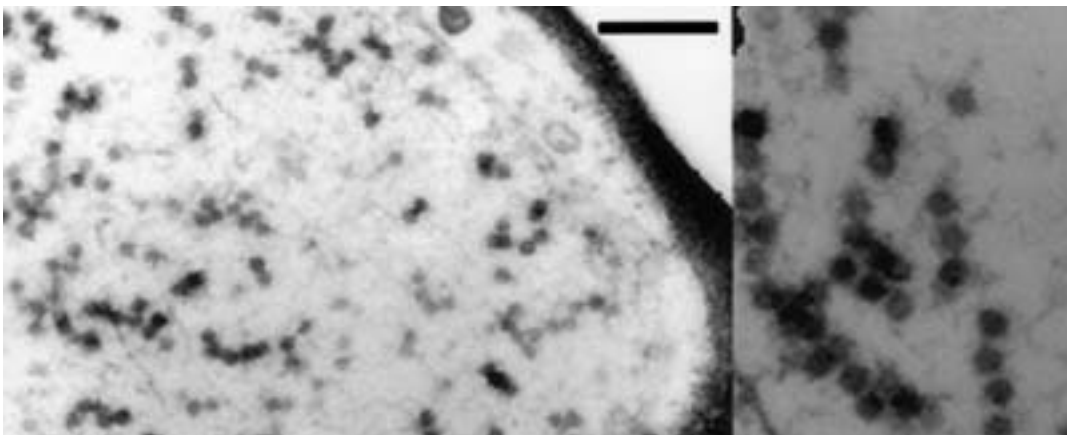

Figure 1 Electron microscopy views of CsVMV particles: (**A**) in inclusion bodies, ×40 000, bar = 250 nm; (**B**) as a cluster in the cytoplasm, ×80 000, bar = 125 nm.

shown that several dsDNA viruses are mechanically transmissible, namely cauliflower mosaic virus (CaMV) and cacao swollen shoot virus (CSSV).

The symptoms developed by the plants while in tissue culture, include discoloration of the veins, mottling, reduced leaf lamina and necrosis, starting from the tip and extending to the whole leaf. When the plants are grown under growth chamber conditions, the appearance of symptoms is very slow; only old leaves, over one month old, present symptoms similar to those observed in tissue culture except that the necrosis does not extend to the entire leaf.

Virus Structure and Genome Organization

Particles of CsVMV were observed by electron microscopy (**Fig. 1**). They appear to be isometric and about 50 nm in diameter. The particles accumulate in inclusion bodies in the cytoplasm of infected cells. The shape and the size of the virions of CsVMV are similar to those of CaMV which contain 420 subunits of a single coat protein (CP) arranged with $T = 7$ icosahedral symmetry. No studies have been made on CsVMV ultrastructure. CsVMV encodes its CP as a portion of a polyprotein which undergoes a post-translational processing. The exact size of the CP has not yet been determined.

The genome of CsVMV is a single circular molecule of a dsDNA 8159 nucleotides long. **Figure 2** depicts the organization of the genome which contains four open reading frames (ORFs), with a possible fifth one, and a large intergenic region in which is located a promoter suspected to govern the transcription of a genome length, terminally redundant RNA. No biological studies were made on CsVMV, all the following information results from predictions deduced from sequence comparison and similarities with the genomes of plant dsDNA viruses. The large ORF 1 of CsVMV contains domains that are equivalent to the CP and the movement protein (MP) of caulimoviruses. ORF 3 shares a high degree of similarity with ORF 5 of the caulimoviruses, and the second half of ORF 3 of the badnaviruses and RTBV, which encode an aspartic proteinase (PR) and a reverse transcriptase (RT) including a RNase H domain. The aspartic PR is responsible for the post-translational processing of the polyproteins resulting from the translation of ORF 4 and ORF 5 of caulimoviruses and ORF 3 of badnaviruses.

Several unique features were identified in the genome organization of CsVMV that led to the creation of a new genus with CsVMV as the type species. The low proportion of GC, 25% vs. 34–39% for caulimoviruses, the presence of a large ORF 1, and the relative order of encoded functions. All the retroelements, including plant and animal pararetroviruses, retroviruses and retrotransposons, have in their genome a continuum between the so-called *gag* (CP) and *pol* (PR+RT) genes. The genome of CsVMV in contrast, displays first the CP (*gag*) followed by the MP and an additional ORF (ORF 2) instead of having the PR-RT (*pol*) immediately downstream of the CP (**Fig. 3**). ORF 4 of CsVMV shares a low but significant level of similarity with ORF 6 of caulimoviruses. This ORF encodes a protein involved in various functions. It plays a major role in the regulation of the translation of the polycistronic RNA (it is called transactivator or TAV in that case) and it is the main component of the viral inclusion body matrix (in that case it is called inclusion body protein or IBP).

Replication

The genome of CsVMV contains all the necessary

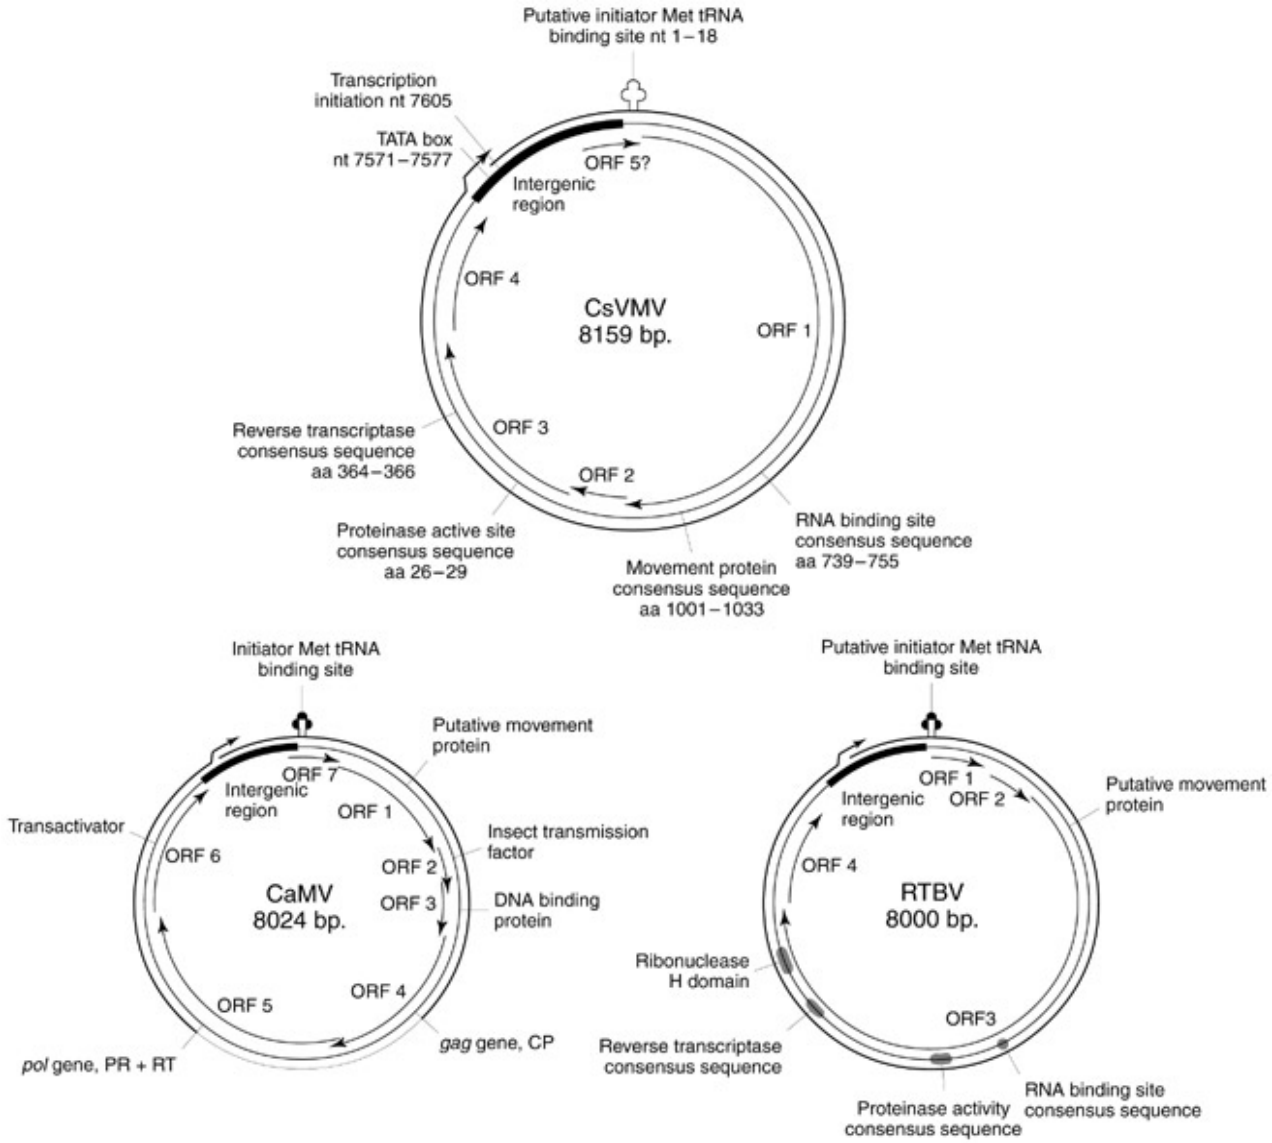

Figure 2 Genomic maps of CsVMV, CaMV and RTBV. Inner circles represent the genomic DNA on which the identified functions have been indicated. Outer circle represents the terminally redundant genome-length RNA transcript. The arrows inside the circle represent the ORFs. CsVMV has 4 ORFs (maybe 5) with a long polygenic ORF 1. CaMV, the type species of the *Caulimovirus* genus, has 7 ORFs, and RTBV, type species of a new genus of plant dsDNA viruses, has 4 ORFs; badnaviruses have three ORFs (see **Fig. 3**).

elements to make it compatible with the model of replication for the plant pararetroviruses. After infection of the host cell, the viral DNA migrates to the nucleus where the replication cycle begins with the synthesis of a terminally redundant genome-length RNA under the control of the genomic viral promoter. This synthesis is performed by a host RNA polymerase. The resulting transcript is used as a template by the viral-encoded RT when primed by a host methionine tRNA which recognizes a complementary sequence on the transcript. The RT synthesizes a minus-strand DNA and the RNase H degrades the RNA strand in the heteroduplex RNA–DNA leaving one or more specific short RNA fragments. The RT, acting now as a DNA-dependent DNA polymerase, uses these RNA fragments to prime the synthesis of the plus strand of viral DNA resulting in the circular double-stranded viral genome containing as many gaps as short RNA fragments were left. Except for the viral promoter which has been shown to be active, no experimental data have been obtained to demonstrate that CsVMV replication follows this cycle. Nevertheless, predictions deduced from sequence similarities indicate that this model should

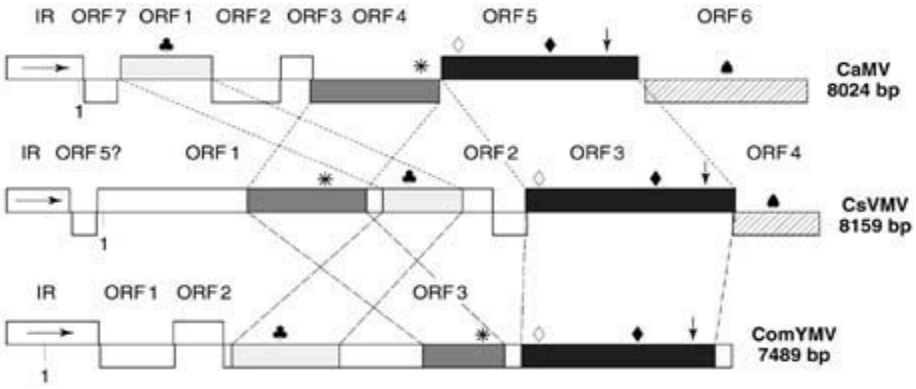

Figure 3 Comparison between genomic organization of CsVMV, CaMV, the type species of the genus *Caulimovirus*, and commelina yellow mottle virus (ComYMV) the type species of the genus *Badnavirus*. The three genomes start at the beginning of the large intergenic region for clarity purposes. ORFs or ORF segments encoding similar putative function are linked by vertical lines; the number 1 indicates the origin of DNA replication. ♣, MP active site; ✳, RNA binding site; ◇, PR active site; ◆, RT active site; ♠, TAV active center; ⸸, RNAse H consensus sequence.

be applicable to CsVMV. After assembly and accumulation in the infected cell, CaMV moves as a virion to adjacent cells through plasmodesmata where the viral MP contributes to the elaboration of tubular structures. As CsVMV encodes a predicted MP similar to the one of CaMV, it is probable that the cell to cell spread occurs by a mechanism comparable to that of CaMV.

Promoter Function and Organization

Verdaguer *et al* have shown that similarly to the 35S promoter of CaMV, the expression of CsVMV promoter is strong and constitutive. In unpublished results the same authors described that this expression requires a synergistic or combinatorial interaction between different *cis*-elements which individually confer tissue specificity and/or variation in the strength of expression. **Figure 4** represents a functional map of the CsVMV promoter. This promoter is a valuable tool for genetic engineering and a good alternative to 35S. It can be used for expressing transgenes in dicotyledonous as well as monocotyledonous plants. Its organization permits the expression of the introduced gene(s) to be modulated by removing some of the *cis*-elements.

Legume Caulimoviruses

D. V. R. Reddy, International Crops Research Institute for the Semi-Arid Tropics (ICRISAT), Patancheru, Andhra Pradesh, India

R. D. Richins, Department of Plant Pathology, University of California, Riverside, California, USA

History

The occurrence of a legume caulimovirus was first reported in 1980. The virus, subsequently identified as Peanut chlorotic streak virus (PC1SV), was found to occur naturally on peanut (groundnut, *Arachis hypogaea*) in the state of Andhra Pradesh in India. The first comprehensive report on a legume caulimovirus, Soybean chlorotic mottle (SoyCMV), was published in 1984. The virus was observed during surveys in Aichi Prefecture in 1981. To date PC1SV and SoyCMV appear to be the only caulimoviruses which were reported to occur under natural conditions on legumes.

Taxonomy and classification

DNA-containing plant viruses are included under the family *Caulimoviridae*. PC1SV and SoyCMV are in the genus Caulimovirus.

Virion Structure and Proteins

Virus particles are icosahedrical, c. 50 nm in diameter. Similar to other caulimoviruses they produce inclusions in cytoplasm which are circular or ovoid and consist of an amorphous, vacuolated, electron-dense matrix. The virus particles are embedded in the matrix.

Strains

No strains have so far been reported for SoyCMV. However a strain of PC1SV, designated as 'Chlorotic Vein-banding' strain (PC1SV-CVB) has been reported, which produces distinct symptoms on peanut. It differs from PC1SV in host range, symptoms and also in the physical map.

Geographic Distribution

SoyCMV occurs in Japan although its distribution in the various Prefectures in Japan is currently not known. PC1SV occurs in the states of Andhra Pradesh, Karnataka, Maharasthra and Tamil Nadu in India.

Symptoms and Host Range

Symptoms are here only given for the principal hosts. PC1SV in peanut causes reduced leaflets, chlorotic streaks and stunting. Symptoms produced by SoyCMV on soybean are mosaic or mottle on leaves and stunting of plants. Some soybean cultivars have been reported to produce different symptoms. A typical feature with both the viruses is the appearance of symptoms after three weeks of inoculation. The host range is given in **Table 1.**

Serological Relationships

PC1SV and SoyCMV do not react serologically with each or with a number of other caulimoviruses which include cauliflower mosaic (CaMV), figwort virus (FWV) or carnation etched ring virus (CERV). The serological tests employed were ELISA and agar gel double diffusion.

Transmission

PC1SV and SoyCMV are readily transmitted by mechanical sap inoculations. Although the majority of caulimoviruses are transmitted by aphids, attempts to transmit PC1SV or SoyCMV, both nonpersistently and persistently, by a range of aphids have so far been unsuccessful. PC1SV could not be transmitted by *Aphis craccivora* or *Myzus persicae* and SoyCMV by *Acyrthosiphon pisum, A. craccivora, Aulacorthum*

natural variants that respond in an altered manner to pathogenesis by CaMV, and these plants may be used to explain how viruses cause disease.

In addition to contributing to molecular virology, it is likely that new strategies for controlling diseases caused by caulimoviruses will emerge. Although plants have been genetically engineered to resist infection by many types of plant viruses, genetic engineering has not been used yet to create transgenic plants with resistance to caulimoviruses. As transgenic plants have already been made that express antisense or sense versions of CaMV genes, it is possible that genetic engineering for control of caulimoviruses will be an option in the near future.

Caulimoviruses – Molecular Biology

Thomas Hohn, Frederick Miescher Inst., Basel, Switzerland

Properties of the Virion and Inclusion Bodies

Caulimoviruses are icosahedral ($T = 7$), 45–50 nm in diameter and sediment between 200 and 250S. The main capsid components of the type member cauliflower mosaic virus (CaMV) are proteins with mobilities of 37 and 44 kDa on sodium dodecyl sulfate-polyacrylamide gel electrophoresis derived from open reading frame (ORF) IV. In addition, CaMV particles contain minor amounts of other polypeptides, a 15 kDa nucleic acid binding protein derived from ORF III, protease and reverse-transcriptase derived from ORF V, and host casein kinase II. In cells infected with CaMV or a number of other caulimoviruses large numbers of virus particles accumulate in typical stable inclusion bodies, the matrix of which is the virus-encoded multifunctional inclusion body protein of 62 kDa, derived from ORF VI. Inclusion bodies are visible in the light microscope and can be stained with phloxin.

Properties of the Genome

The caulimoviral genome is built from 7200–8200 bp. It exists in infected plant nuclei as supercoiled DNA bound to nucleosomes (minichromosome), in infected cytoplasm as RNA with a 180 nucleotides (nt) terminal redundancy, and in virus particles as open circular ds DNA. The open form is due to nicks at specific sites of the (+)- and (−)-strand with short 5′ overlaps (**Fig. 1**), remnants of the reverse transcription process, which are apparently removed in the infected nucleus.

The sequence of many of the caulimoviruses is known. According to sequence and ORF arrangement four groups of caulimoviruses can so far be distinguished: CaMV-like, PCSV-like, CVMV and PVCV (**Table 1** and **Fig. 2**). CaMV-like caulimoviruses contain seven ORFs in the order VII (dispensable, unknown function), I (cell-to-cell movement), II (aphid transmission), III (nucleic acid binding protein), IV (capsid protein precursor), V (protease, reverse transcriptase) and VI (multifunctional protein [inclusion body matrix protein, translation transactivator]). PCSV-like caulimoviruses differ by containing three (A, B, C), instead of two ORFs between ORFs I and III (**Fig. 2**). The ORF arrangements in

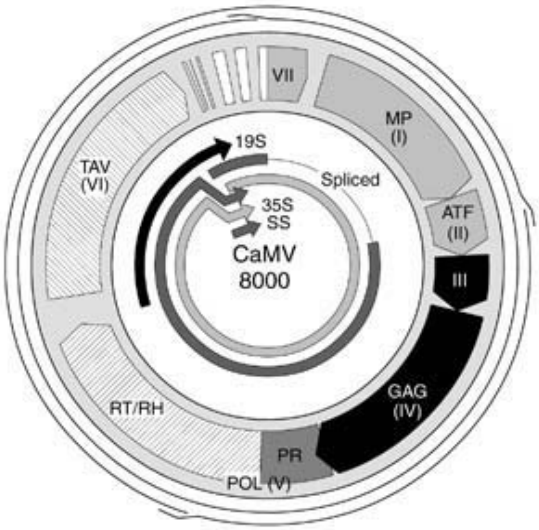

Figure 1 Map of cauliflower mosaic virus. On the outside the open circular double-stranded viral DNA with its overhangs is symbolized. The main circle shows the arrangement of open reading frames and on the inside the primary transcript and the essential spliced RNA are shown.

CVMV and PVCV are considerably different. In both cases some of the ORFs are combined to form super-ORFs (**Fig. 2**). Furthermore, in CVMV the domain corresponding to the CaMV movement protein is shifted to the middle of the genome, and, most interestingly, in PVCV an integrase motif was detected, which is absent from all other caulimoviruses and also from the related badnaviruses.

Properties of the Proteins

Movement protein

CaMV (and probably all the other caulimoviruses) move from cell to cell as particles through tubular structures spanning the cell walls between adjacent cells. In CaMV the 37 kDa movement protein, coded for by ORF I, is responsible for the formation of these tubules and also provides their main component.

Aphid transmission factor

In general, aphids transmit caulimoviruses. In the case of CaMV, ORF II codes for the 18 kDa aphid transmission factor (ATF). Some of the viral inclusion bodies in CaMV-infected cells consist mainly of ATF. ATF interacts with virus particles and with tubulin and it can be assumed that it also interacts with the cuticulum lining the aphid's stylet. ATF mutants normally infect host plants on mechanical inoculation. Viruses lacking ATF can still be transmitted by aphids if the insects have previously been in contact with wild-type ATF either by feeding on plants infected with a related virus or on nutrient solutions supplied with artificially produced ATF.

Small nucleic acid binding protein

The product of CaMV ORF III, a nucleic acid binding protein of 15 kDa, is found in the viral inclusion bodies and in small amounts also in virus particles. A processed form of 11 kDa lacking the C-terminus has lost the nucleic acid binding activity. An intact ORF III is essential for virus infectivity; however, so far, it is not known whether p15 or its processed form is an obligate component of infectious virus particles or whether it functions only transiently, e.g. in assembly.

Capsid proteins and their precursor

The product of CaMV ORF IV has a molecular weight of 56 kDa and an electrophoretic mobility of 80 kDa. It is flanked by very acidic regions, which are removed from the mature capsid proteins which have a mobility corresponding to proteins of 44 and

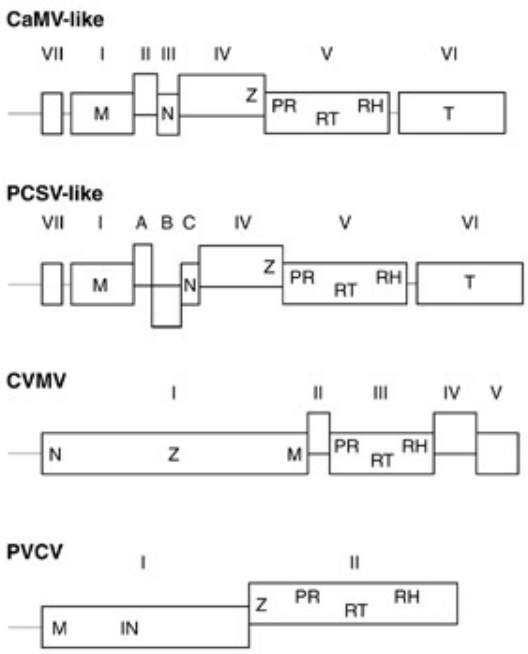

Figure 2 Open reading frame arrangement of caulimoviruses. Examples for each of the known classes are shown. For CaMV the ORFs code for dispensable unknown function (VII), movement protein (I), aphid transmission factor (II), small nucleic acid binding protein (III), capsid protein precursor (IV), Pol polyprotein (V) and inclusion body protein/translation transactivator (VI). The major known motifs indicative for protein functions are shown: M, movement protein motif; N, histone-like nucleic acid-binding motif; Z, Zn-finger; PR, protease motif; RT, reverse transcriptase motif; RH, RNase H motif; T, translation transactivator homology; IN, integrase motif.

37 kDa, although their actual molecular weight is probably smaller. The sequence of p37 is included within p44 and thus antibodies against p37 react also with p44. p44 but not p37 is phosphorylated. It is not known whether both types of proteins are required for full infection, or whether one of these types is the true functional capsid protein. It might be that p44 is the mature form of the capsid protein and p37 a degradation product or p37 might be the mature form and p44 still a precursor. Both p37 and p44 include a zinc-finger motif, which is implicated in RNA binding. Furthermore, large stretches of basic amino acids at the C-termini of p37 and p44 constitute DNA- and RNA-binding motives.

Pol-polyprotein, protease, reverse transcriptase/RNAseH

CaMV ORF V corresponds to the Pol ORF of retroviruses. It produces a polyprotein which is cleaved during virus production into a 15 kDa aspartic proteinase and a 60 kDa reverse transcriptase/RNAse H. It is not known whether the RNAse H functions as part of the 60 kDa protein or whether it is released by another cleavage reaction. One has to assume that the proteinase also functions as part of the polyprotein, i.e. when it releases itself. Caulimoviruses do not have an integrase and consequently their DNA is not integrated into the host genome. A notable exception is PVCV (**Fig. 2**) which exists in an integrated form and has integrase consensus sequences in its genome.

Inclusion body protein/translation transactivator

The 62 kDa inclusion body protein of CaMV- and PCSV-like caulimoviruses is encoded by ORF VI. It has no significant homologies to any other known viral or host gene. The inclusion body protein has been implicated in virus assembly, reverse transcription, host range determination, symptom severity, control of polycistronic translation and seclusion of virus functions. Perhaps as a consequence of the role of the ORF VI protein in translation, all CaMV proteins including foreign proteins carried by a CaMV vector can be found within the inclusion bodies. A subdomain in its center has been assigned to the translational transactivation and other domains have been found to bind RNA unspecifically. Furthermore the protein interacts with capsid protein.

Virus Stability

Both the viral inclusion bodies and the virus particles are very stable. Dissolution of the inclusion bodies to obtain virus particles requires treatment with 1 M urea over a long period. Virus particles aggregate at acidic pH and disintegrate at very high pH (0.1 M NaOH). Virus particles can also be disintegrated by boiling in sodium dodecyl sulfate/dithiothreitol or by treatment with proteinase K and phenol extraction.

Genome Replication

As in retroviruses, replication occurs by production of a terminally redundant RNA by transcription in the nucleus and its reverse transcription in the cytoplasm. Also as in retroviruses, and unlike hepadnaviruses, a tRNA primer (met-ini-tRNA) is used as the primer for (−)-strand DNA synthesis from the RNA template. The RNA template is digested by RNase H following the reverse transcriptase. However, oligo(G) stretches are resistant to this digestion and remain bound to the (−)-strand DNA where they act as primers for (+)-strand synthesis. The number of (+)-strand synthesis initiation events varies between one and three major events in different caulimoviruses and even within strains from a particular virus. Minor

initiation events also occur. The synthesis of both the strands overshoots, creating short overhangs that cannot be repaired in the cytoplasm due to lack of repair exonuclease and ligase in this compartment. Accordingly, the packaged DNA contains open circular DNA. On introduction of viral DNA into the nucleus of an infected cell, the overhangs are removed and supercoiled circular DNA is formed. This interacts with histones to form minichromosomes. Caulimovirus DNA, probably with the exception of PVCV DNA, does not integrate into the host chromosome obligatorily. The template for transcription is the supercoiled circular DNA.

Transcription

Transcription in caulimoviruses is unidirectional. All caulimoviruses produce a transcript covering the total genome plus about 180 nt, such that the RNA is terminally redundant. This RNA is called 35S RNA due to its sedimentation behavior. The terminal redundancy is caused by the polyadenylation signal located on the circular DNA 180 bp downstream of the transcription start site being ignored by the polymerase at its first passage (see below). CaMV-like caulimoviruses produce a second transcript, the 19S RNA, covering ORF VI and encoding for the inclusion body protein/translation transactivator.

The 35S promoter of CaMV, FMV and probably other caulimoviruses is very strong and quasi-constitutive, i.e. it is expressed in nearly all types of cells and at all developmental stages. This constitutivity is caused by a number of different enhancer elements, each with some specificity for certain cell types. Some of the corresponding transcription factors have been identified, e.g. ASF-1, ASF-2 and CAF recognizing a TGACG motif, a GATA motif and CA-rich region, respectively.

RNA Processing

Full-length RNA made from the circular DNA template includes a polyadenylation signal. If this is used on the first encounter, a short stop RNA of 180 nt is formed; if used on the second encounter full-length terminally redundant RNA is formed. The role of the short-stop RNA, if any, is not known.

The CaMV polyadenylation signal consists of an AAUAAA sequence, which determines the cleavage site 13 nt downstream of it. Occasionally cryptic signals are used in addition. In contrast to the animal system, single point mutations in the AAUAAA signal are partially tolerated by the plant system. Polyadenylation enhancers are located upstream of the AAUAAA signal and not downstream as in most animal cases. In CaMV and FMV these elements are tandem repeats of UAUUUGUA.

In addition to the primary CaMV 35S transcript, alternatively spliced versions of it have been detected. By removing an intron extending from close to the end of the leader to a position within ORF II, a mRNA is created in which ORF III is the first ORF and ORF IV the second. Additional splicing events were found using the same splice acceptor but using donors within ORF I. These led to ORF I–ORF II in-frame fusions, the function of which is not known. Whether the ratio of spliced to unspliced RNA is controlled, for example by nuclear export of unspliced RNA as in human immunodeficiency virus is not known.

Translation Mechanism

The 35S RNA of caulimoviruses and also its spliced derivatives serve as polycistronic mRNAs for the viral proteins. The ORFs of these viruses closely follow each other, are opened by efficiently recognized start codons and usually also contain internal start codons. In plant protoplasts and in transgenic plants most of the downstream ORFs are poorly expressed in the absence of the inclusion body protein/translation *trans*-activator encoded by ORF VI, interestingly the only ORF that is translated from a monocistronic mRNA. *Trans*-activation activity has been demonstrated for CaMV and FMV, and probably resides also in the corresponding ORFs of the other CaMV-like and PCSV-like caulimoviruses. *Trans*-activation is thought to be based on a reinitiation mechanism.

Another special feature of the caulimovirus (and also the badnavirus) 35S RNAs is their 600–700 nt-long leader, which is rather large for eukaryotic RNAs. These leaders contain several small ORFs and include a large hairpin structure. These are features that usually make an RNA a poor messenger, since initiation factors and/or 40S ribosomes initiate scanning at the cap of an RNA moving in the 3′ direction until an AUG codon is encountered and translation proper begins, whereas translation from AUGs further downstream is precluded. To overcome this problem caulimoviruses employ a shunting mechanism for translation initiation, whereby scanning is initiated at the cap as usual, but the scanning complex bypasses (shunts) most of the leader to reach the first longer ORF. This mechanism is unlike the internal initiation mechanism used by enteroviruses.

Protein Processing

Many of the caulimovirus proteins are processed, i.e. in CaMV-like (and by analogy probably the other)

caulimoviruses the precapsid protein is cleaved at both ends removing its very acidic termini. This process might be coupled to virus assembly and maturation. The capsid protein is both methylated and glycosylated. The Pol protein is cleaved to yield the aspartic proteinase and reverse transcriptase/RNase H. At least some of these cleavages occur by the action of the viral proteinase. In contrast, the ORF III product is cleaved by a host cysteine proteinase. The genome arrangement and the presence of protease domains suggest that protein processing also occurs in CVMV and PVCV. It can be assumed that this is even more extensive, since the primary translation products are fewer and larger.

Cassava Vein Mosaic Virus

Alexandre de Kochko, International Laboratory for Tropical Agricultural Biotechnology, La Jolla, California, USA

History, Taxonomy and Classification

The symptoms induced on cassava plants by cassava vein mosaic virus (CsVMV) were recognized as early as 1940 but the virus itself was first described by Kitajima and Costa in 1966. Based on preliminary observations, which showed that it has isometric particles and that its genome consisted of double-stranded DNA (dsDNA), it was tentatively classified in the *Caulimovirus* genus. More recent work led to the characterization of its genomic organization and showed important features which differ from caulimoviruses as well as from badnaviruses, the two genera of plant dsDNA formerly recognized. In response to these results and additional observations made on other plant dsDNA viruses, executive committee of the International Committee on Taxonomy of Viruses (ICTV) created a new genus (not yet named) with CsVMV designated as the type species. It was also decided to create and name *Caulimoviridae,* the family which contains all the plant dsDNA viruses including the genera *Caulimovirus, Badnavirus,* and three newly created genera. One includes CsVMV, another the former caulimoviruses infecting legumes (Soybean chlorotic mottle virus, SbCMV, and peanut chlorotic streak virus, PCSV) and the third has rice tungro bacilliform virus (RTBV) as its type species.

Geographic Distribution, Host Range and Virus Propagation

CsVMV was described in Brazil, with detailed accounts of its presence in the states of São Paulo and Ceará, but this limited description is certainly a consequence of the very few studies carried out on this virus. It infects plants from the cultivated cassava species, *Manihot esculenta* Crantz, which originated from the Amazon basin. Its complete host spectrum is not known, in particular no surveys have been made on wild cassava relatives. The impact on cassava production seems to be limited. Caulimoviruses are aphid-transmitted but in the case of CsVMV the natural vector is unknown. As cassava is mainly reproduced vegetatively, the virus is propagated very easily through cuttings. Experimentally it is possible to infect cassava plants by introducing an infectious clone using microbombardment. It has also been

Caulimoviruses: General Features

James E Schoelz and **June E Bourque**, Plant Pathology, University of Missouri, Columbia, Missouri, USA

History

Caulimoviruses are a group of plant viruses composed of double-stranded (ds) DNA encapsidated into an icosahedral virion. Caulimoviruses have been a subject of study because they cause economic losses in their respective hosts; in addition, they have made significant contributions to our knowledge of the molecular biology of plant viruses. The genome of cauliflower mosaic virus (CaMV), the type member of the genus, was the first of the plant viruses shown to contain DNA rather than RNA as genetic material. Furthermore, it was the first viral genome to be completely sequenced and cloned into bacterial plasmids in an infectious form. The caulimoviruses have also been extensively studied as a model for host–pathogen interactions and because their replication and expression strategies are unusual for plant viruses. For example, CaMV was the first plant virus to be shown to replicate by reverse transcription of an RNA intermediate into dsDNA.

In the early 1980s CaMV was thought to have some promise as a vector for foreign genes in plants. The effort to convert CaMV into a virus-based vector was scaled back when it was shown that the virus genome could tolerate only small insertions. A few small genes, such as dihydrofolate reductase and interferon, were eventually expressed in plants via a CaMV vector. However, other plant viruses, in particular tobacco mosaic virus, potato virus X and tomato bushy stunt virus, have been shown to be much more versatile as vectors for foreign genes.

Although CaMV has had only limited utility as a plant virus vector, the virus continues to have a great impact on plant biotechnology. The CaMV genome has served as a source for the most widely used promoter in plant genetic engineering. The 35S promoter of CaMV is capable of directing a high level of transcription in most types of plant tissues. This promoter was used to drive expression of the first transgene introduced into transgenic plants, and it is still the primary choice for expression of transgenes for both research and commercial applications.

Taxonomy and Classification

Members of the *Caulimovirus* genus, which has 11 definitive species (**Table 1**), have recently been assigned to the *Caulimoviridae* family. The virus genome is composed of circular, dsDNA approximately 8.0 kb in length that contains one or more single-stranded discontinuities. The viral DNA is encapsidated into isometric virions, 45–50 nm in diameter. In infected plants most virions are usually

Table 1 Definitive members of the genus *Caulimovirus*

Virus	*Transmission by aphids*	*Host families*[a]	*Distribution*
Blueberry red ringspot (BRRV)	No	*Ericaceae*	North America
Cauliflower mosaic (CaMV)	Yes	*Cruciferae* (*Solanaceae*)	Worldwide
Carnation etched ring (CERV)	Yes	*Caryophyllaceae*	Worldwide
Dahlia mosaic (DaMV)	Yes	*Compositae* (*Amaranthaceae*) (*Chenopodiaceae*) (*Solanaceae*)	Worldwide
Figwort mosaic (FMV)	Yes	*Scrophulariaceae* (*Solanaceae*)	North America
Horseradish latent (HRLV)	Yes	*Cruciferae*	Europe
Mirabilis mosaic (MMV)	Yes	*Nyctaginaceae*	North America
Peanut chlorotic streak (PClSV)	No	*Leguminosae* (*Solanaceae*)	India
Soybean chlorotic mottle (SoyCMV)	No	*Leguminosae*	Japan
Strawberry vein banding (SVBV)	Yes	*Rosaceae*	Nearly worldwide
Thistle mottle (ThMV)	ND	*Compositae*	Europe

ND, not determined.
[a] The plant family that has been found to be infected in nature by a caulimovirus is listed first. The experimental host range is indicated in parentheses.

embedded within amorphous inclusions. The most closely related virus genera are the badnaviruses, which also infect plants, and the hepadnaviruses, which infect birds and mammals. All three genera replicate by reverse transcription of an RNA intermediate and their viral genome does not integrate into host chromosomes as a part of the replication cycle. Two features can be used to distinguish the badnaviruses from the caulimoviruses. Badnaviruses form bacilliform particles rather than icosahedral particles, and the genome organization of the badnaviruses differs considerably from the caulimoviruses. Collectively, the caulimoviruses, badnaviruses, and hepadnaviruses have been called pararetroviruses to emphasize their differences in replication strategy from the true retroviruses.

Geographic Distribution

CaMV, carnation etched ring (CERV) and dahlia mosaic viruses (DaMV) are found worldwide, wherever their hosts are grown (**Table 1**). Strawberry vein banding virus (SVBV) has been reported in North and South America, Australia and Europe. The distribution of most of the other caulimoviruses is limited to a single continent, although this fact may simply reflect an incomplete search for these viruses. Figwort mosaic (FMV) and mirabilis mosaic viruses (MMV) have only been found in limited areas in the USA. In contrast, blueberry red ringspot (BRRV) has been found throughout the USA, where it causes economically significant losses in highbush blueberries. Horseradish latent (HRLV) and thistle mottle viruses (ThMV) have only been found in Europe. Peanut chlorotic streak virus (PClSV) is widely distributed in India, while soybean chlorotic mottle virus (SoyCMV) has only been recovered from a few samples in Japan. The symptoms of SoyCMV, however, are similar to the potyvirus, soybean mosaic virus, and consequently, infections caused by SoyCMV might have been mistaken for other viruses that infect soybean.

Host Range and Virus Propagation

The host range of each of the caulimoviruses is fairly narrow. In nature, caulimoviruses generally infect plants within a single family, although their experimental host range may extend to the members of one or two other families (**Table 1**). The most information about the host range of caulimoviruses has been gained from CaMV, which has been studied more extensively than other caulimoviruses. CaMV can infect a broad range of plants in the cruciferae family, but crucifers are not uniformly susceptible to infection. In fact, the degree of susceptibility of *Brassica* species to CaMV infections is regulated by the host at the level of CaMV RNA that is available for reverse transcription. In *Brassica* species such as turnip (*B. rapa* subspecies *rapifera*), CaMV 35S RNA can

accumulate to a high level. CaMV is primarily propagated in turnips because it infects this host under a broad range of environmental conditions and virions accumulate in infected leaves to higher levels than in other hosts. In contrast to turnips, *Brassica* species such as kohlrabi (*B. oleracea* subspecies *gongylodes*) remain nearly symptomless and only a very low level of viral RNA accumulates in infected cells. Interestingly, the reaction of cauliflower (*B. oleracea* subspecies *botrytis*) to CaMV infection is intermediate between that of turnip and kohlrabi, although CaMV can cause severe losses in cauliflower crops.

Strains of CaMV can also be distinguished by their ability to infect solanaceous species in the genera *Datura* and *Nicotiana*. Some CaMV strains are able to systemically infect several solanaceous species, including *N. bigelovii, N. edwardsonii* and *D. stramonium*, while other CaMV strains elicit a plant defense response that limits the infection to the inoculated leaf. By making exchanges of DNA between the two types of CaMV strains, it has been shown that solanaceous host range is conditioned by a complex interaction between the host, viral strain, and the lighting conditions under which the infected plants are grown. Three separate genes, genes II, IV and VI (**Fig. 1A**), have been shown to determine the ability of CaMV strains to infect *Nicotiana* and *Datura* species systemically. Genes II and IV may affect host specificity through an interaction with the CaMV gene VI rather than through a direct interaction with host factors. In contrast, the gene VI product likely interacts directly with host factors. The gene VI protein of some CaMV strains elicits a hypersensitive defense response (HR) in solanaceous hosts, while other variants of gene VI elicit only chlorotic primary lesions and actually facilitate systemic infection. It is not clearly understood at this time how the CaMV gene VI product mediates the host response.

Taken together, the host range studies in the cruciferae and the solanaceae indicate that at least two mechanisms may operate to limit the host range of CaMV. First the host can regulate the capacity for replication by controlling the level of transcription of viral RNA, which would effectively limit the level of reverse transcription. Second, the host can recognize and target its defense response against individual strains of CaMV to limit their spread to the first infected leaf, while other strains are able to evade the plant defense response.

Genetics

Because the genomes of caulimoviruses are composed of circular dsDNA, it has been relatively easy to clone an infectious form of the entire viral genome into bacterial plasmids using molecular techniques. Consequently, infectious plasmid clones exist for many of the caulimoviruses. In the case of CaMV, infections can be initiated with cloned DNA simply by excising the viral DNA from the vector and gently rubbing this DNA mixture on to turnip leaves that have been dusted with an abrasive. It has been possible to identify symptom and host range determinants of CaMV by exchanging viral DNA segments *in vitro* between different cloned strains. The nucleotide sequences of CaMV strains are fairly homologous, differing from each other by only about 5% on average, and most exchanges between strains will result in an infectious, hybrid virus.

Exchange of genetic material between CaMV strains can also occur quite effectively *in vivo*. Wild-type virus can be readily recovered from plants co-inoculated with viruses that contain lethal mutations in different genes. Several mechanisms have been proposed to describe recombination between CaMV strains, but the most common method is probably a copy choice mechanism in which the reverse transcriptase jumps from one viral template to another in the plant cell. CaMV strains are also adept at acquiring CaMV sequences from transgenic plants. As with recombination between wild-type CaMV strains, the CaMV sequences present in the transgene mRNA can effectively replace the analogous viral sequences and become incorporated into the viral genome during the replication process.

Evolution

All viruses that replicate by reverse transcription have one genomic feature in common. The genes encoding the structural proteins (*gag*) are always arranged upstream from the polymerase (*pol*) genes. Although the position of the *gag* gene is conserved, there is essentially no nucleotide sequence homology between capsid proteins of the caulimoviruses and the true retroviruses. In contrast to the *gag* gene, the *pol* genes of the caulimoviruses have two domains, which specify reverse transcriptase and RNase H functions, that have a significant level of homology with the *pol* genes of the retroviruses. The *pol* gene of the caulimoviruses lacks an intregrase domain, which distinguishes it from the true retroviruses. It has been suggested that the functions required for reverse transcription have been conserved amongst all retroelements, while different virus groups have acquired new genes for infection of their respective hosts. Consequently, the caulimoviruses, have a gene for

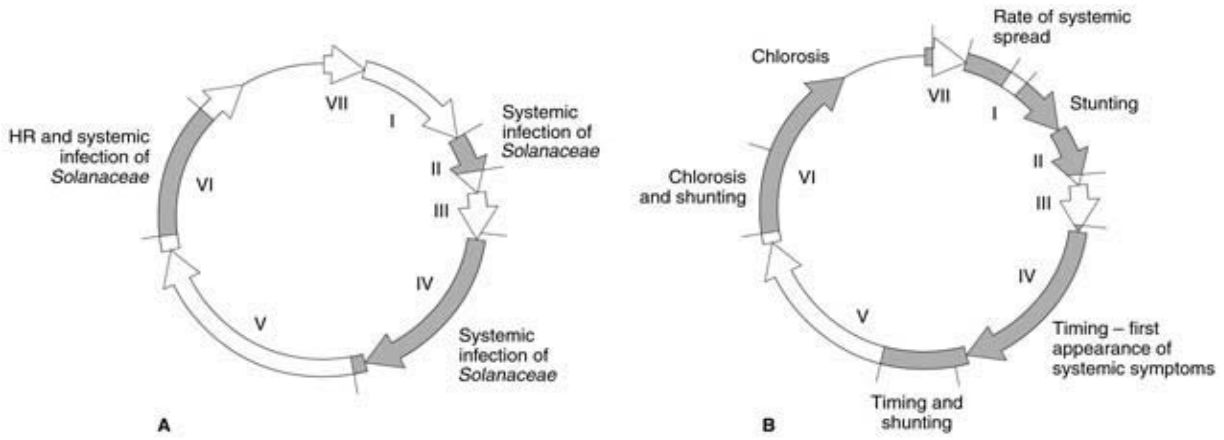

Figure 1 CaMV regions that influence solanaceous host range and pathogenicity. The positions of the genes of CaMV that comprise the circular genome are indicated by the arrows. Gene VII is nonessential and its function is unknown. Gene I encodes a protein required for cell-to-cell movement protein. Gene II encodes a protein required for aphid transmission. Gene III encodes a protein that binds nucleic acids and may be a minor component of the virions. Gene IV encodes the major capsid protein. Gene V encodes a polymerase that has reverse transcriptase, RNase H, and protease activities. Gene VI encodes a protein described as a translational transactivator that is necessary for efficient translation of the polycistronic 35S RNA. (**A**) The CaMV genes that determine the hypersensitive plant response (HR) or influence systemic infection of solanaceous species are delimited by stippling. (**B**) The CaMV regions that influence the development of specific symptoms in turnips are delimited by stippling.

cell-to-cell movement, a gene that is required for the infection of plants by plant viruses.

Caulimoviruses have evolved through the accumulation of point mutations and by recombination between strains. The mutation rate that would occur in the infection cycle in a single plant has been estimated to be $4–6 \times 10^{-4}$ changes per nucleotide. A comparison of the nucleotide sequences of nine isolates of CaMV has indicated that recombination has occurred frequently between strains in nature. A phylogenetic analysis of the sequences, which represent CaMV strains collected worldwide, also indicated that the viruses could be divided into two distinct lineages: North American and non-North American. It was concluded that the major factor that determines relatedness is the host geographic distribution.

Serologic Relationships and Variability

CaMV is serologically related to DaMV, HRLV, CERV and SVBV. Although CaMV and HRLV both infect crucifers, HRLV virions react only weakly to CaMV antiserum, evidence that HRLV is distinctly different from CaMV and not simply a CaMV strain. Interestingly, although DaMV and CaMV virions are closely related serologically, nucleic acid hybridization experiments indicate only a low level of homology. No antigenic relationships have been found between the other caulimoviruses. Virions of BRRV do not crossreact with CaMV antiserum, and MMV virions are unrelated serologically to CaMV, CERV or DaMV. SoyCMV is not serologically related to CaMV, CERV or even to PClSV, the other caulimovirus that infects legumes.

Transmission and Tissue Tropism

Most caulimoviruses are transmitted in a relatively nonspecific manner by as many as 27 species of aphids. The mode of transmission has been characterized as 'semipersistent'. The virions are acquired rapidly by the aphid, and can be transmitted immediately upon acquisition. Virions can be maintained by the aphid for as little as 5 h up to 3 days, but are not retained after the aphid molts and are thus not passed on to aphid progeny. The 18 kDa aphid transmission factor (ATF), encoded by gene II (**Fig. 1**), is required for transmission by aphids.

Although it is not known exactly how P18 mediates aphid transmission, it has been demonstrated for CaMV that P18 can bind to virions. It has been suggested that P18 may protect the virion from proteolytic enzymes in the aphid, or may function to bind the virion to the aphid stylet. Neither SoyCMV, BRRV, nor PClSV appear to be transmitted by aphids. It is not known if alternate vectors exist for these viruses. Interestingly, an analysis of the PClSV genomic sequence has shown that it does not have a gene homologous to the aphid transmission factor of CaMV.

Caulimoviruses are not transmitted by seed or

pollen, but most, with the exception of SVBV and blueberry red ringspot virus, can initiate infections after mechanical inoculation. DaMV has been shown to be transmitted by vegetative propagation of dahlia tubers, while BRRV has been transmitted through grafting and may be spread primarily through the use of infected plant material.

CaMV does exhibit some degree of tissue tropism, as virions accumulate to much higher levels in leaves than in stems and roots. An analysis of the viral nucleic acids present in root tissues indicates that roots contain relatively high levels of supercoiled viral DNA, but very low levels of viral RNA transcripts. Low transcript levels would in turn lead to a reduction in reverse transcription into viral DNA and reduced accumulation of virions. In contrast to roots, leaves contain low amounts of supercoiled DNA, high levels of viral transcripts and high levels of virions. Therefore, it has been suggested that transcription of the supercoiled DNA, a key point in the replication cycle of CaMV, is differentially regulated by leaves and roots.

Pathogenicity

Caulimoviruses induce a variety of systemic symptoms in their hosts, from ringspots to necrosis and mosaics. With the exception of CaMV, very little is known about which viral genes are responsible for symptoms or how these viruses cause disease. In the case of CaMV, several studies have focused on mapping the CaMV genes responsible for specific symptoms. It is important to note, however, that the assignment of symptom determinants reflects the differences between the two CaMV strains whose genomes are exchanged. Therefore, although symptom characters have been associated with specific regions of the CaMV genome, other CaMV regions, which might be revealed in exchanges with additional CaMV strains, could also be involved. Furthermore, the environment can have a significant impact on the development of symptoms. It has been shown that some cauliflower varieties that exhibit severe symptoms in the greenhouse may have only mild symptoms in the field, and the opposite situation has also been found. Nevertheless, the mapping studies do provide a starting point for understanding how CaMV induces symptoms in its hosts.

Several studies are in agreement that gene VI of CaMV influences the intensity of chlorotic symptoms that typify an infection in turnips (**Fig. 1B**). In addition to gene VI, chlorosis was influenced by sequences within the large intergenic region. Gene VI can also affect the degree of stunting in turnips, perhaps by regulating the expression of other viral genes. Interestingly, gene VI is one of the few plant virus genes that elicits virus-like symptoms when expressed in transgenic plants, and these symptoms largely match those associated with gene VI expressed from the viral genome. Transgenic plants that express the gene VI product exhibit chlorosis and mottling, stunting and necrosis.

Other regions of CaMV have been found to influence the timing and severity of symptoms. The severity of stunting in turnips is affected by sequences within portions of genes I and II and gene V, in addition to gene VI (**Fig. 1B**). The initial appearance of systemic symptoms, characterized as either a rapid or delayed systemic infection, was determined by sequences within genes III, IV or V. The rate of spread of the virus to other leaves, after the first appearance of systemic symptoms, was determined by sequences within genes VII and I. Further research will now be directed towards determining whether the viral gene products interact directly with the host to elicit a specific symptom or whether the viral gene may alter some aspect of viral replication that subsequently alters the symptoms in the host.

Pathology

The most prominent characteristic noted within caulimovirus-infected cells is the presence of amorphous inclusions (**Fig. 2**). The inclusion bodies are

not bound by a membrane, can range in diameter from 5–20 μm, and occur in virtually all types of plant cells. The inclusions can be visualized with a light microscope in strips of epidermal tissue after staining with phloxine B, and are a diagnostic feature of CaMV infections. Usually infected plant cells contain just one or two inclusion bodies. Close examination of these amorphous inclusion bodies using electron microscopy reveals two types which can be easily differentiated. One type contains many vacuoles and consists of an electron-dense, granular matrix that is composed primarily of the CaMV gene VI protein. A second, electron-lucent, type is made up of the CaMV 18 kDa ATF protein. In addition to the electron-lucent inclusions, the ATF protein of CaMV is capable of forming paracrystalline structures that colocalize with plant microtubules. Most virus particles are associated with either one type of amorphous inclusion or the other, but a few virions can be found free in the cytoplasm, within enlarged plasmodesmata, or in the nucleus. In one case, virions of CaMV strain CM4-184 have been localized within chloroplasts.

A second unusual characteristic of caulimovirus infections is that the plasmodesmata between infected cells can become enlarged, and virions of DaMV and CaMV have been found within these enlarged plasmodesmata. The presence of CaMV virions in the plasmodesmata has led to the suggestion that CaMV virions may move from cell to cell in the form of virions, although an alternative model postulates that CaMV moves into adjacent cells in the form of ribonucleoprotein complexes. The alteration in plasmodesmata size is dependent upon the CaMV gene I product, a cell-to-cell movement protein. In addition, the gene I product induces the formation of long tubular structures that extend away from the cell surface in studies with infected plant protoplasts. The tubular extensions are not unique to CaMV, as they have also been observed in protoplasts infected with cowpea mosaic virus and red clover mottle comovirus.

Epidemiology and Control

Caulimovirus infections of economically important hosts are initiated by viruliferous aphids or through grafting or planting of infected plant material. CaMV is most likely to cause a problem in areas where successive crops of crucifers are grown. Virus surveys of brassica crops in Britain indicated that the two viruses encountered most frequently were CaMV and the potyvirus, turnip mosaic virus. CaMV has been considered to be the most important virus disease of winter cauliflower in Britain. CaMV symptoms are most severe under low temperature conditions. In addition, high levels of sunshine inhibit virus infections. SVBV infections of strawberry are considered to be a minor problem, but the virus can cause a greater degree of loss when present in plants with other viruses, such as strawberry crinkle virus.

Diseases caused by caulimoviruses can be controlled using the same strategies that are effective for most plant viruses. Sources of resistance to CaMV in cabbages were identified as early as 1951, while resistance to CaMV in Brussels sprout has recently been found. Although no cauliflower varieties are completely resistant, the symptoms of some varieties are milder than others. In addition to resistance, cross protection, the deliberate inoculation of a mild strain to protect against more severe strains, has been demonstrated in Brussels sprout. Some effort has been directed towards creating transgenic cauliflower plants resistant to CaMV infection. Transgenic cauliflower plants that express the capsid gene and an antisense construct of gene VI have been created and are now being evaluated for their ability to resist CaMV infection. In the case of BRRV, DaMV and SVBV, it is important to start with virus-free planting material. Insecticide sprays to control the spread of the aphid vector are recommended for DaMV and SVBV, but are not considered economically feasible for CaMV.

Future Perspectives

Research on the caulimoviruses will continue to contribute to a general understanding of how viruses replicate and express their genomes, and also how plant viruses cause disease. The 35S RNA is considered to be one of the most complex eucaryotic, polycistronic messages. Although much has been learned about its expression, there are still gaps in our understanding. For example, the gene VI product is required for translation of the 35S RNA, but it is not known how it influences the host translational apparatus. The caulimoviruses will also add to our knowledge of how viruses cause disease. The host range and symptom determinants of CaMV have been identified. The challenge now will be to determine how these viral genes interact with the host. Perhaps the best approach to understanding how plant virus genes influence host range and symptomatology would be to identify their host counterparts through traditional plant breeding or through mutagenesis and then to isolate the gene(s) by map-based cloning techniques. One of the hosts of CaMV is *Arabidopsis*, a favorite plant of molecular biologists because of its ease of manipulation and small genome size. Thus, it may be possible to select *Arabidopsis* mutants or

natural variants that respond in an altered manner to pathogenesis by CaMV, and these plants may be used to explain how viruses cause disease.

In addition to contributing to molecular virology, it is likely that new strategies for controlling diseases caused by caulimoviruses will emerge. Although plants have been genetically engineered to resist infection by many types of plant viruses, genetic engineering has not been used yet to create transgenic plants with resistance to caulimoviruses. As transgenic plants have already been made that express antisense or sense versions of CaMV genes, it is possible that genetic engineering for control of caulimoviruses will be an option in the near future.

Caulimoviruses – Molecular Biology

Thomas Hohn, Frederick Miescher Inst., Basel, Switzerland

Properties of the Virion and Inclusion Bodies

Caulimoviruses are icosahedral ($T = 7$), 45–50 nm in diameter and sediment between 200 and 250S. The main capsid components of the type member cauliflower mosaic virus (CaMV) are proteins with mobilities of 37 and 44 kDa on sodium dodecyl sulfate-polyacrylamide gel electrophoresis derived from open reading frame (ORF) IV. In addition, CaMV particles contain minor amounts of other polypeptides, a 15 kDa nucleic acid binding protein derived from ORF III, protease and reverse-transcriptase derived from ORF V, and host casein kinase II. In cells infected with CaMV or a number of other caulimoviruses large numbers of virus particles accumulate in typical stable inclusion bodies, the matrix of which is the virus-encoded multifunctional inclusion body protein of 62 kDa, derived from ORF VI. Inclusion bodies are visible in the light microscope and can be stained with phloxin.

Properties of the Genome

The caulimoviral genome is built from 7200–8200 bp. It exists in infected plant nuclei as supercoiled DNA bound to nucleosomes (minichromosome), in infected cytoplasm as RNA with a 180 nucleotides (nt) terminal redundancy, and in virus particles as open circular ds DNA. The open form is due to nicks at specific sites of the (+)- and (−)-strand with short 5′ overlaps (**Fig. 1**), remnants of the reverse transcription process, which are apparently removed in the infected nucleus.

The sequence of many of the caulimoviruses is known. According to sequence and ORF arrangement four groups of caulimoviruses can so far be distinguished: CaMV-like, PCSV-like, CVMV and PVCV (**Table 1** and **Fig. 2**). CaMV-like caulimoviruses contain seven ORFs in the order VII (dispensable, unknown function), I (cell-to-cell movement), II (aphid transmission), III (nucleic acid binding protein), IV (capsid protein precursor), V (protease, reverse transcriptase) and VI (multifunctional protein [inclusion body matrix protein, translation transactivator]). PCSV-like caulimoviruses differ by containing three (A, B, C), instead of two ORFs between ORFs I and III (**Fig. 2**). The ORF arrangements in

Legume Caulimoviruses

D. V. R. Reddy, International Crops Research Institute for the Semi-Arid Tropics (ICRISAT), Patancheru, Andhra Pradesh, India

R. D. Richins, Department of Plant Pathology, University of California, Riverside, California, USA

History

The occurrence of a legume caulimovirus was first reported in 1980. The virus, subsequently identified as Peanut chlorotic streak virus (PC1SV), was found to occur naturally on peanut (groundnut, *Arachis hypogaea*) in the state of Andhra Pradesh in India. The first comprehensive report on a legume caulimovirus, Soybean chlorotic mottle (SoyCMV), was published in 1984. The virus was observed during surveys in Aichi Prefecture in 1981. To date PC1SV and SoyCMV appear to be the only caulimoviruses which were reported to occur under natural conditions on legumes.

Taxonomy and classification

DNA-containing plant viruses are included under the family *Caulimoviridae*. PC1SV and SoyCMV are in the genus Caulimovirus.

Virion Structure and Proteins

Virus particles are icosahedrical, c. 50 nm in diameter. Similar to other caulimoviruses they produce inclusions in cytoplasm which are circular or ovoid and consist of an amorphous, vacuolated, electron-dense matrix. The virus particles are embedded in the matrix.

Strains

No strains have so far been reported for SoyCMV. However a strain of PC1SV, designated as 'Chlorotic Vein-banding' strain (PC1SV-CVB) has been reported, which produces distinct symptoms on peanut. It differs from PC1SV in host range, symptoms and also in the physical map.

Geographic Distribution

SoyCMV occurs in Japan although its distribution in the various Prefectures in Japan is currently not known. PC1SV occurs in the states of Andhra Pradesh, Karnataka, Maharasthra and Tamil Nadu in India.

Symptoms and Host Range

Symptoms are here only given for the principal hosts. PC1SV in peanut causes reduced leaflets, chlorotic streaks and stunting. Symptoms produced by SoyCMV on soybean are mosaic or mottle on leaves and stunting of plants. Some soybean cultivars have been reported to produce different symptoms. A typical feature with both the viruses is the appearance of symptoms after three weeks of inoculation. The host range is given in **Table 1.**

Serological Relationships

PC1SV and SoyCMV do not react serologically with each or with a number of other caulimoviruses which include cauliflower mosaic (CaMV), figwort virus (FWV) or carnation etched ring virus (CERV). The serological tests employed were ELISA and agar gel double diffusion.

Transmission

PC1SV and SoyCMV are readily transmitted by mechanical sap inoculations. Although the majority of caulimoviruses are transmitted by aphids, attempts to transmit PC1SV or SoyCMV, both nonpersistently and persistently, by a range of aphids have so far been unsuccessful. PC1SV could not be transmitted by *Aphis craccivora* or *Myzus persicae* and SoyCMV by *Acyrthosiphon pisum, A. craccivora, Aulacorthum*

The ORFs are identified based on observed relationships with spatially homologous ORFs occurring in other caulimovirus genomes. The location of the single-stranded discontinuities (▼ and ▼) are also shown. The two major mRNA transcripts are illustrated by the dashed lines. Selected restriction endonuclease sites are also indicated.

solani or *M. persicae*. Neither of the viruses are seed transmitted.

Molecular Biology

With respect to genomic organization, gene expression and gene products, there are a variety of features which distinguish the legume caulimoviruses from other *Caulimoviridae*. First, the circular, double-stranded DNA genomes of SoyCMV and PC1SV contain 8175 and 8174 bp, respectively, making them 140–430 bp larger than the genomes of other caulimoviruses. The CVB strain of PC1SV appears also to contain about 8.2 kb of DNA, although a number of restriction site polymorphisms have been observed. SoyCMV and PC1SV appear to encode for eight major open reading frames (ORFs) compared to seven observed in CaMV, CERV and FMV (**Fig. 1**). The additional ORF occurs between ORF I (the movement protein) and ORF IV (the major capsid protein). For both SoyCMV and PC1SV, the three ORFs which occur between ORFs I and IV show little or no apparent similarity to ORFs observed in other caulimoviruses. Therefore they have been designated Ib, II and III for SoyCMV and A, B and C for PC1SV.

The location of the tRNA primer binding site (PBS), utilized during genomic replication, is also distinctive among the legume caulimoviruses. The PBS occurs 3′ to the movement protein (ORF I) in the genomes of SoyCMV and PC1SV. In contrast, the PBS occurs 5′ to the movement protein gene in the genomes of CaMV, CERV and FMV.

Transcription

Another distinguishing feature of the legume caulimoviruses is that their genomes contain only one intergenic region (IGR) which occurs between ORFs VI and VII. The IGR contains several putative regulatory domains which are also observed in the larger IGR of other caulimoviruses. The small IGR which occurs upstream of gene VI in the genomes of CaMV, CERV and FMV is not observed in the SoyCMV and PC1SV genomes. Nevertheless, two major transcripts, of 2.1 and 8.4 kb, respectively, have been observed in PC1SV-infected hosts (see **Fig. 1**). The larger transcript is likely a terminally redundant, replicative intermediate RNA. As with the other caulimoviruses, most of the polypeptides encoded by the PC1SV (and probably SoyCMV) genome are probably translated from this '35S-like' RNA. The smaller transcript hybridizes specifically to ORF VI of PC1SV, and thus appears to be an ORF VI subgenomic mRNA. A 5.7 kb minor transcript is also observed which may specify ORF V. A strong promotor within ORF III (about 200 bp 3′ to the start of ORF IV) has been

identified in the SoyCMV genome. However, transcript data are currently unavailable for SoyCMV, and consequently the role of this promotor during virus infection is yet to be established.

Gene products

Based on similarities in the deduced amino acid sequence and on mutational analyses, ORFs I, IV, V and VI of SoyCMV and PC1SV appear to specify the viral movement protein, major capsid protein, reverse transcriptase and transactivating proteins, respectively. Immunosorbent polymerase chain reaction (PCR) technique has been used to confirm the involvement of the ORF I protein in virus movement. Mutations to ORF I were shown to abolish virus movement, but not replication.

Limited amino acid sequence similarity is also observed between the PC1SV ORF I polypeptide, and the 30 kDa movement protein of tobacco mosaic virus (TMV). Interestingly, the cell-to-cell movement functions in PC1SV have been successfuly used to complement the movement of a 30 kDa-mutant of TMV.

A variety of mutation analyses have demonstrated that ORFs A and B are not essential for PC1SV replication or movement. Mutations to ORFs IV, V, VI and C are usually lethal. Similar studies have not yet been performed on SoyCMV. Nevertheless, based on the characteristically high proline content of their translation product, it seems likely that ORF C of PC1SV and ORF III of SoyCMV may encode the minor capsid protein. A low degree of similarity was observed between the putative ORF B protein of PC1SV and the ORF II protein of SoyCMV. Nevertheless, the role of these gene products, as well as the gene products of ORF 1b of SoyCMV and ORF A of PC1SV are yet to be determined.

The salient features of ORFs IV and V of SoyCMV and PC1SV are essentially the same as that for the other caulimoviruses. However, the degree of relatedness differs markedly with respect to ORF VI. The predicted amino acid sequence of the SoyCMV and PC1SV ORF VI (transactivating) products are significantly smaller than that of the other caulimovirus ORF VI proteins. The putative ORF VI gene products for SoyCMV and PC1SV are 53 and 49 kDa, respectively, compared with 56–58 kDa for CaMV, CERV and FMV ORF VI. In addition, the PC1SV gene VI protein shows little sequence to the CaMV, CERV and FMV homologues; however, a notable degree of similarity is evident between the gene VI proteins of PC1SV and SoyCMV. Phylogenetic analyses have been performed to determine the evolutionary relationships between the various plant pararetroviruses. One such analysis based on the relationships of the reverse transcriptase domains is shown in **Fig. 2**. The cladogram clearly shows that SoyCMV and PC1SV form a distinct clade with 100% of the trees containing the branch in 100 bootstrap replications.

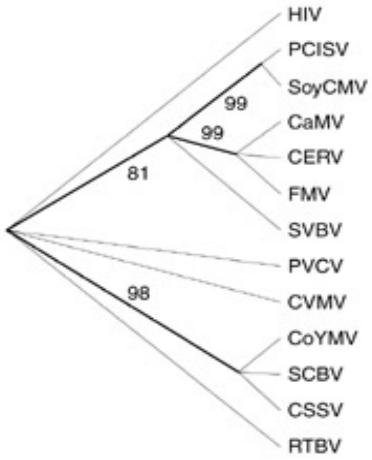

Figure 2 Cladogram depicting the phylogenetic relationships of conserved domains within the reverse transcriptase genes of members of the *Caulimoviridae* (rooted to a similar domain within the *pol* gene of human immunodeficiency virus (HIV). Parsimony was employed to generate a 70% consensus tree using the PAUP 3.1 program. Numbers above selected branches indicate the percentage of trees containing the branch for the 100 bootstrap replications.

Transactivation

The caulimoviruses have evolved a rather unique mechanism to express their genomes. Most viral gene products are translated from a single, polycistronic mRNA in caulimovirus-infected hosts in apparent violation of the 5′ proximal rule. The mechanism of this so-called translational *trans*-activation is not completely understood, but substantial evidence has been accumulated to support the involvement of the gene VI polypeptide for CaMV and FMV. For the study of transactivation by the PC1SV ORF VI protein, *Nicotiana edwardsonii* suspension cells and a 'nested' GUS reporter gene have been used. Transactivation was much stronger at 35°C than at 24°C (relative to a PC1SV 35S-GUS control). This observation may begin to provide a molecular explanation for the high temperature required by PC1SV to systemically infect many of its hosts. Support for the temperature-dependent transactivation of PC1SV came from studies which utilized FMV to complement the low temperature (25°C) systemic spread of PC1SV in doubly infected *Datura inoxia* plants. Systemic spread was not observed when PC1SV gene I mutants were co-inoculated with FMV suggesting that the FMV cell-to-cell transport

functions alone were not responsible for the complementation.

Control

PC1SV-CVB isolate was found to be economically important in some of the peanut growing areas in the state of Andhra Pradesh. Reports on the economic importance of SoyCMV are not available. No efforts have so far been made to devise any strategies for controlling PC1SV or SoyCMV.

Rice Tungro Bacilliform Virus

Roger Hull, John Innes Centre, Norwich Research Park, Colney, Norwich, UK

General Features

Rice tungro disease was first recognized in the experimental fields at the International Rice Research Institute, The Philippines in 1963 and identified as a distinct virus disease in 1965. However, previous descriptions of disorders in rice (*Oryza sativa*) would indicate that it has been present in the Philippines, and probably elsewhere in southeast Asia from at least the 1930s. Since its recognition as a virus disease, tungro has been reported in most of the rice-growing countries of south and southeast Asia (**Fig. 1**).

Tungro is unusual in that it has a multitude of local names, there being at least 40 names including 'tungro' and 'accep na pula' in The Philippines and names such as 'penyakit merah' in Malaysia and 'mentek' in Indonesia; this plurality of names reflects the importance with which farmers regarded the disease. The disease is generally endemic but has caused periodic major outbreaks in various countries in this region. Much of the increase in impact of tungro has been attributed to the 'green revolution', which resulted in large areas of rice with high fertilizer inputs and overlapping cropping of new susceptible cultivars, conditions highly suitable to rapid spread of the viruses. Overall this disease is now considered to be one of the major constraints to rice production in this region, with annual losses in excess of \$US 1.5×10^9; this does not include the costs of insecticides to control the virus vector.

It was not until 1978 that it was realized that tungro disease is caused by a complex of two viruses, rice

breeder should attempt to predict the likely durability of a resistance gene, by testing it against as many isolates of the virus as possible, at an early stage of the breeding program.

However, another problem is that the genetic base of resistance to plant viruses is rather limited, and in many crops no resistance to particular diseases is known. Screening of wild relatives and gene bank collections will undoubtedly reveal further natural resistance genes, although at a cost. The various techniques for developing resistance by introduction of transgenes offers an excellent prospect of broadening the basis of control.

Engineered Resistance

C Michael Deom, University of Georgia, Athens, Georgia, USA

Introduction

Engineered resistance (or genetically engineered resistance) to viral pathogens refers to the introduction and expression of foreign genes, termed transgenes, in plants such that expression of a transgene interferes with the virus life cycle and thereby confers resistance to the virus. Advances in plant transformation technologies for a variety of plant species have resulted in the introduction of transgenes from a variety of sources that confer resistance to viral pathogens. The transgenes are stably integrated into the plant genomes, are heritable, and resistance segregates with the transgenes. In many cases, transgenic plants have been generated that have resistance to viruses by mechanisms that do not occur naturally and could not have been introduced into the plants by traditional breeding techniques. Genetically engineered virus resistance in crop plants shows great promise in efficiently reducing losses due to virus disease and complements traditional plant breeding.

Transgenes are designed as chimeric genes under the control of a promoter and contain nonviral sequences at the 3′ end to provide transcription termination and polyadenylation signaling. With few exceptions the preferred promoter has been the 35S promoter from the plant DNA virus cauliflower mosaic virus, which is constitutively expressed and drives high levels of expression of transgenes in most plant tissues. In some cases, the transgene is placed under the control of a tissue-specific promoter to localize expression of the transgene.

Pathogen-derived Resistance

The transformation of plants to confer virus resistance was an initial focus of plant biotechnology. The most widely applied and effective strategy presently used for this purpose is pathogen-derived resistance (PDR): resistance obtained by expressing viral-derived transgenes (genes or genomic sequences) in transgenic plants (**Table 1**). This strategy has provided some degree of virus resistance in almost all hosts to which it has been applied. In all cases, the level of PDR is variable, depending on both the type of virus from which the transgene sequence is derived and on the individual transgenic plant line. In some instances, transgenic plants have been developed that are essentially immune to virus infection. Therefore, biologically screening a number of transgenic plant lines is required to identify those having the highest levels of genetically engineered virus resistance and acceptable agronomic traits. Unfortunately, the resistance mechanisms are poorly understood at the cellular and molecular levels. PDR can be divided into two broad categories, depending on whether the resistance mechanism is mediated by protein or nucleic acid. In some instances it is not clear whether the resistance is conferred by expression of the protein or the nucleic acid encoded by the transgene and in

[b] Virus sequence or portion of virus sequence introduced into transgenic plants.

some cases both mechanisms may function. The discussion below is based on interpretations and on conclusions drawn from supportive or suggestive evidence characteristic of either protein- or nucleic acid-mediated PDR. Much is yet to be determined on the specific mechanism(s) that confer PDR.

Protein-mediated resistance

Protein-mediated resistance is directed either by transgenes that express the wild-type proteins or modified transgenes that express defective or truncated proteins. With protein-mediated resistance the degree of protection is positively correlated with the level of transgene mRNA and protein accumulation. The first demonstration of PDR for virus resistance was using coat protein-mediated resistance (CPMR). Viral coat proteins (CP) are abundant structural proteins that are well studied and CP genes are easily obtained for production of transgenic plants. CPMR results from the expression of a wild-type viral CP gene in transgenic plants and the resistance conferred ranges from moderate to high. Typical of CPMR, the number of infection sites is decreased and viral systemic movement is inhibited, reduced, or delayed. Although more than one mechanism is likely to be responsible for protection conferred by CPMR, at least part of the protection is believed to result from transgenic CPs blocking uncoating of virions immediately following entry of virus into healthy cells. Upon entry into a healthy cell of a host, virions normally disassemble and initiate an infection, but in newly infected cells expressing transgenic CP the equilibrium between uncoating and coating is believed to be shifted towards coating and stabilization of incoming virus particles. CPMR, apparently free of nucleic acid-mediated resistance, has been demonstrated in tobacco with CP genes derived from alfalfa mosaic alfamovirus (ALMV), potexvirus X (PVX), and tobacco mosaic tobamovirus (TMV). CPMR is narrow, limited to closely related strains of the same type species or closely related members of the same viral genus.

A number of genes encoding nonstructural proteins have also been used for protein-derived PDR. The expression in plants of full-length viral replicase genes or truncated or mutated versions of the replicase genes conferred effective resistance to virus infection. Replicase-mediated resistance has been demonstrated in at least four virus genera: groups: alfamovirus, luteovirus, tobamovirus and potyvirus. Expression of functional, full-length replicase genes may interfere with the timing of replication and/or transcription of an infecting virus, altering the order of events that are critical during the virus' life cycle and resulting in resistance. Alternatively, constitutively expressed replicase proteins may induce defense responses that lead to resistance. On the other hand, resistance mechanisms to virus infection in transgenic plants expressing truncated or altered replicase proteins likely result from dominant-negative mutations. Genes with dominant-negative mutations encode proteins that, when overexpressed, disrupt the activity of the wild-type protein. Mutant replicases interact with host and/or viral components and block equivalent interactions with wild-type replicase proteins that are required for replication and infection. The resistance spectrum induced by altered replicase proteins is narrow and is only active against closely related strains of the virus from which the replicase was derived. The narrow resistance spectrum mirrors the specificity of viral replicase proteins, indicating that replicase-mediated resistance may be directed towards competition for viral components rather than towards cellular components that are more likely conserved between plants.

Viral movement proteins (MP) also confer resistance to virus infection in transgenic plants when

expressed as dominant-negative mutants. A number of plant viruses encode an MP that potentiates cell-to-cell and systemic movement of virus progeny. Movement proteins dilate plasmodesmata, intercellular channels through which virus progeny move, and chaperone virus progeny RNA from cell to cell. Expression of defective MPs or a wild-type MP from a virus that does not naturally move from cell to cell in the transgenic plants species confers resistance to some plant viruses. The modified MPs interfere with normal functions of wild-type MPs and block cell-to-cell and/or systemic movement of progeny virus. The expression of modified MPs in transgenic plants confers a broad spectrum of resistance to virus infection. A defective TMV MP expressed in transgenic tobacco inhibited disease development by other tobamoviruses, as well as viruses representing five additional virus genera: alfamo-, caulimo-, cucumo-, tobra- and nepovirus. The resistance was characterized by a delay in the appearance of systemic disease symptoms, which correlated with a decrease in virus accumulation in upper uninoculated leaves. Likewise, plants expressing modified potato leafroll luteovirus (PLRV) MPs conferred resistance against infection by members of the potyvirus and potexvirus groups in addition to PLRV. In one instance, the expression in tobacco of the MP of brome mosaic bromovirus (BMV), a virus that does not move in tobacco, interferes with intercellular movement of TMV. In the latter case, the expression of a wild-type MP in a nonhost plant appears to be mimicking a dominant-negative mutant. The success of both strategies implies that MPs from very different viruses have some functions that are similar and can be exploited for a broad-based resistance to virus infection.

Nucleic acid-mediated resistance (homologous-dependent resistance)

The more common mechanism conferring PDR is mediated by RNA. With RNA-mediated resistance the level of mRNA accumulation from virus-derived transgenes does not correlate with the degree of resistance, although the mechanism that confers resistance is highly sequence specific. Moreover, RNA-mediated resistance is conferred by modified transgenes that express untranslatable RNAs. Analysis of RNA-mediated resistance in transgenic plants expressing viral CP-gene sequences established an association between resistance and post-transcriptional suppression of transgene expression, indicating that the two phenomena are related. Finding that gene silencing of nonviral transgenes results from a post-transcriptional cosuppression mechanism supports this interpretation. In gene silencing, the post-transcriptional mechanism results in the cosuppression of the transgene and the homologous cellular gene. Similarly, in transgenic plants expressing viral transgenes, post-transcriptional transgene silencing suppresses expression of the transgene and accumulating viral RNA, which shares sequence homology with the transgene. Post-transcriptional cosuppression of the viral transgene and viral RNA explains why resistance does not show a positive correlation with the level of transgene mRNA. Virus resistance resulting from this type of mechanism is referred to as homology-dependent resistance. Because a high degree of sequence homology is required for homology-dependent resistance, it is not unexpected that the resistance in the systems that have been investigated are highly strain specific. When transgene sequences as small as approximately 400 nucleotides are expressed alone, homology-dependent resistance can be conferred. When fused to nonviral (nontarget) DNA sequences, transgene segments as short as approximately 100 nucleotides can confer homology-dependent resistance, although when expressed alone the small virus-derived transgene segments are ineffective in conferring resistance.

Homology-dependent resistance is thought to be mediated by small antisense RNAs that are produced by cellular encoded RNA-dependent RNA polymerases, using transgene mRNA as a template. The duplex formed between viral-transgene antisense RNAs and viral RNA and transgene mRNA could be degraded by RNAases specific for double-stranded RNA. Alternatively, the RNA duplex formed could arrest translation and affect RNA stability indirectly. Both possibilities could reduce the accumulation of transgene mRNA and viral RNA. In addition, viral RNA levels could be affected directly if the RNA duplex inhibited translation of a viral product required for replication or inhibited replication by blocking access of viral replication machinery to viral RNA.

Homology-dependent resistance has been described extensively in transgenic plants expressing replicase, coat protein and protease gene sequences from PVX, tobacco etch potyvirus (TEV), potato potyvirus Y (PVY), PLRV and tomato spotted wilt tospovirus (TSWV). Indeed, it is likely that homology-dependent resistance is the resistance mechanism functioning in a number of examples of PDR where there is no correlation between transgene mRNA levels and resistance.

Other nucleic acid-mediated resistance strategies

Expression in transgenic plants of viral antisense

RNAs to block translation and/or replication has been used with limited success. Antisense-mediated resistance developed against RNA viruses (e.g. cucumo-, potex-, poty- and tobamoviruses) has been weak to moderate and is only effective at low virus inoculum. In contrast, expression of antisense RNA to a replicase protein of a DNA virus (geminivirus) was effective, showing reduced symptoms that correlated with the level of antisense RNA. Because DNA viruses replicate in the nucleus where antisense RNA levels are more abundant, this strategy may be more effective against DNA viruses.

Several groups of viruses can acquire satellite RNAs: small RNAs (approximately 300 nucleotides) that require a helper virus for replication, but are usually not related by sequence homology to the helper virus. Satellite RNAs, which are not essential to the helper virus, can enhance or ameliorate symptoms, depending on the host. Because of their ability to suppress symptoms, satellite RNAs have been candidates for genetically engineered resistance. Inoculation of transgenic tobacco plants expressing satellite RNAs of tobacco ringspot tobravirus (TRSV) or cucumber mosaic cucumovirus (CMV) with the respective helper viruses resulted in the amplification of the transgene-derived satellite RNAs to a high level, presumably because the helper virus replicated the satellite RNAs. In each case, helper virus accumulation was greatly reduced and symptom development was largely suppressed, especially in noninoculated leaves. While this strategy appears promising, the utility of using satellite-mediated resistance is in question because only a few nucleotide changes are required to change a satellite that suppresses symptoms to one that enhances disease symptoms and subsequent yield losses.

Defective interfering nucleic acids (DIs) represent another type of nucleic acid that has been exploited for engineered resistance. DI-RNAs or DI-DNAs are deletion mutants of infectious viral genomes that are associated with RNA or DNA viruses, respectively, and generally suppress symptom development. While DIs are incapable of autonomous replication, they do retain the necessary sequences to be replicated. Presumably, because the DI is smaller than the virus genome, it competes efficiently against the infectious viral genome during replication and is subsequently amplified at the expense of the virus genome. DI-DNAs of two geminiviruses expressed in transgenic plants conferred virus resistance. The resistance was characterized by amplification of the DI-DNAs, symptom amelioration, and a significant decrease in the levels of virus in the infected plants. Similarly, expressing a DI-RNA of cymbidium ringspot tombusvirus (CyRSV) in transgenic *Nicotiana benthamiana* plants resulted in the suppression of symptoms and the plants subsequently produced seed, whereas, in the absence of the DI-RNA, CyRSV caused apical necrosis and death in control plants. Unfortunately, the occurrence of naturally occurring DIs is rare, so this strategy will not be very useful for engineering resistance to the large majority of viral diseases.

Pathogen-derived resistance has been applied to viruses having either positive or negative sense RNA genomes, and against a virus having a DNA genome. The viruses differ in their genome organization, particle morphology and mode of transmission, indicating the utility of the approach. In the few cases examined, PDR is effective against vector transmission of virus infection. Genetically engineered virus resistance conferred by CP or replicase genes (protein or RNA mediated) have been sufficiently developed for use in commercial agriculture.

Plant-derived Resistance Genes

Naturally occurring virus resistance genes

A large number of naturally occurring viral resistance genes have been identified in plants and the utilization of these genes by traditional breeding techniques has resulted in stable, and in many cases, durable resistance. While traditional breeding techniques will continue to be used in developing resistant cultivars, the generation of transgenic plants expressing naturally occurring viral resistance genes offers two additional benefits: (1) resistance genes can be introduced into the plant genome rapidly and the sequence and nature of the genetic material is known; and (2) transgenic plant technology can overcome problems where genetic incompatibility between plants of related species or genera is an insurmountable barrier to introgressing naturally occurring viral resistance genes into agronomically important plants.

Most viral resistance mechanisms studied in plants are genetically simple, being monogenic and represented by either a single dominant or a single recessive gene. Typically, monogenic resistance traits function by inhibiting replication, blocking cell-to-cell movement in inoculated tissue, inhibiting long-distance movement into noninoculated tissue or blocking vector transmission of virus from infected to uninfected plants.

The validity of expressing a plant-derived viral resistance gene in transgenic plants is illustrated by the dominant *N* gene of tobacco. Resistance mediated by the *N* gene to tobamoviruses (e.g. TMV) is characterized by a hypersensitive response (HR): the formation of necrotic lesions at the site of virus infection. The role of the *N* gene in the induction of

the HR was confirmed when transgenic tobacco expressing the *N* gene responded to TMV infection with necrotic lesions. The *N* gene was also transformed into TMV susceptible tomato. When transgenic tomato plants were inoculated with TMV, the role of the *N* gene in induction of the HR was confirmed by the production of necrotic lesions on the inoculated leaves. That the *N* gene from tobacco functions in tomato illustrates the conservation of components required for *N* gene-mediated resistance across species and the utility of using genetic engineering to move resistance genes across genetically incompatible species barriers for engineering crop resistance to viruses.

While the potential to rapidly and efficiently move viral resistance genes within and between species by genetic engineering is great, the ability to isolate naturally occurring virus resistant genes is difficult. However, techniques will be developed to overcome these difficulties with the considerable interest in isolating resistance genes to viruses and other plant pathogens.

Ribosome-inactivating proteins

Ribosome-inactivating proteins (RIPs) are present in different tissue types of a wide variety of plants. Ribosome inactivation is achieved by depurinating a specific adenine residue in a conserved region of the 28S ribosomal RNA (rRNA). The modified ribosomes are unable to bind the EF-2/GTP complex and protein synthesis is blocked at the translocation step. The most common RIPs (type I) are single-chain proteins which are highly active against eukaryotic ribosomes, but are not cytotoxic because they do not bind to and enter cells. Infrequently found are type II RIPs that are composed of two subunits. The A subunit modifies rRNA, while the B subunit is a lectin that can bind to and enter cells, making type II RIPs extremely cytotoxic. It is assumed that the proteins function in a defensive role to protect both plant and seed from pathogen attack because of the toxic nature of RIPs. Many RIPs have antiviral activities towards plant and animal viruses. The broad-spectrum antiviral activities of type I RIPs, along with their inability to bind to and enter cells, make them ideal candidates for genetically engineered virus resistance. RIPs present in pokeweed tissues (collectively designated pokeweed antiviral proteins, PAP) have antiviral activity to viruses in a number of host plants. Transgenic potato and tobacco plants expressing PAP show broad-spectrum resistance to mechanical infection by CMV, PVX and PVY. The plants are also resistant to PVY inoculation with aphids, the insect vector of the virus. A moderate to high level of resistance was observed using this strategy. A negative aspect of RIP-mediated resistance is that host cell ribosomes are susceptible to exogenous RIPs, so the selection of transgenic plants with virus resistance resulting from the expression of nontoxic levels of RIPs will likely be necessary to obtain virus resistant plants with normal phenotypes and acceptable agronomic traits.

Nonplant-nonpathogen-derived Resistance

Interferon-induced 2-5A system

Components of two mammalian antiviral systems have been exploited to generate genetically engineered virus resistance. Possibly the most promising for broad-based resistance is the interferon-induced 2-5A system. Interferon (a family of cytokines present in higher vertebrates) induces antiviral activities; one such activity is the 2-5A system, which is lacking in plants (at least members of the genus *Nicotiana*). Two enzymes are essential for a functional 2-5A system: a 2-5A synthetase, which in the presence of double-stranded RNA produces 2-5A (2′,5′-linked oligoadenylates), and 2-5A-dependent RNAase L. In the presence of 2-5A, RNAase L is activated and cleaves single-stranded RNAs. In the case of a virus-infected cell, the double-stranded replicative intermediates formed during replication activate 2-5A synthetase, resulting in RNA degradation by RNAase L. Transgenic tobacco plants expressing both human 2-5A synthetase and human RNAase L show a high level of resistance to TMV and members of the *Bromoviridae* (AlMV and CMV) and *Potyviridae* (TEV and PVY). The antiviral response is presumably due to degradation of viral RNA, although the response in plants is accompanied by the destruction of infected cells as indicated by the formation of necrotic lesions. Potential advantages of the 2-5A system over PDR are that there is no potential for the generation of more virulent viruses through recombination between mRNA from virus-derived transgenes and the infecting viruses, a concern that is believed by many to be highly unlikely, and the resistance is broad based in contrast to PDR, which is generally more specific to the virus from which the transgene originated or to closely related viruses.

Plantibodies

The immune system of mammals provides an extremely efficient defense against invading pathogens, including viruses. Antibodies, representing one component of the immune system, are generated against and bind to specific antigens (i.e. viral

proteins), ultimately leading to the destruction of the antigen. Transgenic plants have been generated that express both the heavy and light chains of monoclonal antibodies or single-chain antibodies (scFv; single-chain variable region), which contain the light and heavy chain variable regions derived from monoclonal antibodies. The strategy is that antibodies expressed in plants (plantibodies) will bind to viral products during infection and interfere with aspects of the virus life cycle, resulting in either a less virulent infection or an aborted infection. Upon infection with TMV, transgenic plants expressing a high-affinity monoclonal antibody directed against a surface epitope of TMV show a reduction in the number of infection sites on inoculated leaves. The reduction in the number of infection sites correlated with increased levels of antibody detected in the transgenic plants. The expression of monoclonal antibodies in plants requires cotranslational insertion into the endoplasmic reticulum for assembly and stability, an obvious limitation since most plant viruses have RNA genomes that replicate in the cytoplasm. Therefore, since the TMV antibodies are secreted into apoplastic spaces, they likely bind to virus during inoculation to block infection, possibly by inhibiting viral disassembly after the virions have entered cells.

Using a similar approach, transgenic plants expressing a cytoplasmic targeted scFv antibody directed to a conserved site of the artichoke mottled crinkle virus (AMCV) CP were less susceptible to infection. Those transgenic plants that did become infected showed a delay in symptom development. The scFv antibody binds to a CP eptitope involved in Ca^{2+} binding, which is required to stabilize coat protein interactions in the assembled virus icosahedron shell, and may block uncoating or assembly of the virus particle. One advantage of scFv antibodies is that they do not require assembly and can be directly expressed in the cytosol. Signal peptides attached to scFv antibodies can facilitate targeting of the proteins to organelles, such as the endoplasmic reticulum, or to be secreted into apoplastic spaces.

When expressing both whole antibodies and scFv antibodies in plants, conditions need to be defined to maximize accumulation of functional molecules to a level required to neutralize infection. Another aspect of increasing importance, as the technology develops, is the ability to target the functional antibodies to appropriate subcellular compartments. Research to date has focused on well-characterized monoclonal antibodies or single-chain antibodies derived from monoclonal antibodies directed towards viral CPs with the strategy of blocking assembly or disassembly. In the future, antibodies directed to nonstructural proteins, such as those involved in replication or movement, have the potential to increase the efficacy of the approach. The utility of expressing antibodies to nonstructural proteins has been demonstrated by the ability of antibody fragments, directed against the reverse transcriptase of the human immunodeficiency virus (HIV), to prevent HIV infection in cultured mammalian cells. In addition, expression of catalytic antibodies may provide another approach for disease resistance.

Concluding Remarks

Genetically-engineered virus resistance has significantly contributed to crop improvement. While it is too early to determine which approaches to genetically-engineered virus resistance will ultimately provide the most useful and durable resistance, a broad foundation, including PDR and non-PDR strategies, is in place and new examples of application continue to appear. Some degree of resistance has been achieved in nearly all plants in which the different strategies have been tried. While immunity to virus infection has been obtained through genetically engineered resistance in a few cases, and is obviously preferred, it is generally accepted that it is not required. Engineered resistance that sufficiently retards the accumulation of virus in infected plants, and/or results in a decrease in virus transmission, will likely be adequate in the absence of immunity. Indeed, many natural forms of virus resistance do not confer immunity.

Genetically-engineered virus resistance will improve as the mechanisms behind the resistance strategies are better understood and are manipulated to further exploit these strategies. In addition, development of new strategies (e.g. ribozymes and protease inhibitors) will add to the current repertoire. Continued advancements in technology to transform plants will increase the number of species that can be engineered for virus resistance and increase the transformation efficiency of species that are currently difficult to transform. Combining several genetic engineering strategies, as well as breeding virus-resistant transgenic cultivars with cultivars that have naturally occurring resistant genes, will lead to plants having a broad-spectrum of virus resistance.

PLANT RETROELEMENTS

Roger Hull, John Innes Centre, Norwich Research Park, Colney, Norwich, UK

Introduction

The replication of most nucleic acids is mainly either DNA to DNA (chromosomal and viral nucleic acids) or RNA to RNA (viral genomes). However, there is an increasing number of nucleic acid sequences which involve a combination of transcription of RNA from DNA and reverse transcription of DNA from RNA. These are termed retroelements and they are found in many taxonomic groups, including higher animals and plants, fungi, insects and bacteria. Retroelements comprise three major groups, viral retroelements, eucaryotic nonviral retroelements and bacterial elements. These major groups have been subdivided on structural and biological criteria (**Table 1**) but recent findings are blurring some of the boundaries between these groups.

The main features that distinguish these groups and subgroups are that viruses have properties which potentiate horizontal transmission; some may also be vertically transmitted. Nonviral retroelements are generally considered to be only vertically transmitted but there may be instances of horizontal transmission, say between plants by pathogenic fungi. Retroviruses and the nonviral retroelements integrate into the 'host's' genome, whereas pararetroviruses are episomal. The genomes of retroviruses, retrotransposons and retroposons encode an integrase activity, and those of retroviruses and retrotransposons have long terminal repeats, both features involved in integration. All, except for retrosequences, which are cDNAs converted from cellular RNAs by endogenous reverse transcriptase activity, encode for reverse transcriptase and its associated RNaseH.

In plants the retroelements currently described fall into the pararetrovirus, retrotransposon, retroposon and retrosequence groups. The reason for there being no known examples of plant retroviruses *sensu stricto* is unknown.

Plant Pararetroviruses

There are two genera of plant pararetroviruses, the Caulimovirus and the Badnavirus in the *Caulimoviridae* family. The genome organization can be considered as comprising the core replicon of polymerase (reverse transcriptase + RNaseH) and coat protein which is considered to organize the replication complex together with genes which adapt the replicon to the plant viral situation. These additional genes are best characterized in cauliflower mosaic virus (CaMV) in which the core replicon is encoded by open reading frame (ORF) IV giving the coat protein and ORF V the polymerase. The plant-adapting genes include the ORF I product which facilitates the movement of the virus from cell to cell through plasmodesmata, and the ORF II product which is

disease epidemiology, RTBV-induced disease in rice is amenable to control strategies not relevant to the other badnavirus diseases. Breeding and selection of virus- or vector-resistant varieties is a prime option in the case of rice, but is less readily accomplished in clonally propagated crop plant hosts of other badnaviruses. Control of vector populations by cultural or chemical methods is also far more relevant to RTBV than to other badnaviruses.

PLANT RESISTANCE TO VIRUSES

Contents

Natural Resistance

RSS Fraser, Society for General Microbiology, Reading, UK

Importance of Resistance in Disease Control

Plant viruses cause serious economic losses in many crops, in three main ways. Infection normally reduces yield biomass; an important example is the effect of the complex of related viruses known as barley yellow dwarf on all major cereal crops. In crops which are sold on the basis of appearance, such as ornamentals and many fruits and vegetables, blemishing and distortion as a result of virus infection can lead to complete loss of marketability, even in cases where yield biomass is only slightly reduced. Finally, costs are incurred if eradication or avoidance programs are enforced, for example in production and certification of virus-tested seed potatoes.

In contrast to the control of fungal diseases of plants, no chemical pesticides are available for routine use as direct antiviral agents. It has, therefore, been necessary to develop a number of alternative control strategies. These include control of the biotic vectors of particular plant viruses, use of virus-free seed or planting material of vegetatively propagated crops, good cultural practices to minimize transmission, and deployment of a number of different mechanisms of plant resistance. Naturally occurring resistance mechanisms, the topic of this article, have been of most use in crop protection until now, but several types of genetically engineered resistance mechanisms, using viral and nonviral genes, are now becoming available. In both types of resistance, it is important to study the mechanisms involved, to increase the effectiveness with which resistance can be used in crop protection, and to understand more fundamental questions about the molecular interactions between plants and viruses.

Types of Natural Resistance Mechanism

Plant viruses are very diverse in their structure, mode of replication and transmission, and in their pathogenic effects on their hosts. Perhaps not surprisingly,

Table 1 Resistance at different levels of plant population complexity

Plant population	*Type of resistance*	*Features and questions*
Species	Nonhost immunity	What determines the host range of a virus?
Cultivar	Cultivar resistance	As used in plant breeding. Resistance overcome by virulent isolates
Normally susceptible individual plant	Acquired or induced resistance	A number of mechanisms of varying usefulness in crop protection

plants have evolved a correspondingly diverse array of resistance mechanisms, and a number of examples are considered here. However, it will first be useful to provide a framework for this diversity, by considering resistance mechanisms in a more conceptual manner. This is approached in two ways: in relation to the stages of the virus replicative and transmission cycle in a model susceptible plant which might form potential targets for different types of resistance mechanism (**Fig. 1**), and in relation to differences in the complexity of the plant populations in which these resistance mechanisms might operate (**Table 1**).

Plant viruses initiate infection of susceptible hosts through wounds, either caused mechanically by abrasion or by plant-feeding virus vectors such as insects and nematodes. There is no evidence for virus-specific cell surface receptors such as exist for many animal viruses and bacteriophages. Once within a cell of a susceptible plant, the virus exposes its genetic material for translation of catalytic and structural viral proteins, and production of further copies of the genome, which are then assembled to form progeny virus particles. Virus multiplication requires a number of host-provided 'helper' functions. These may be nonspecific 'housekeeping' functions such as the provision of ribosomes, amino acids, nucleoside triphosphates and an energy supply, or specific to the particular virus. For example, there is evidence that the complex enzymes responsible for replicating the tobamovirus and bromovirus genomes, and expressing subgenomic viral messenger RNAs, involve not only virus-coded components, but also one or more polypeptides of host origin.

Here it is useful to introduce the concepts of *positive* and *negative* mechanisms of resistance, alternatively referred to by some authors as *active* and *passive* mechanisms. In positive mechanisms a plant is resistant because it produces an inhibitor which interferes with some stage of the virus replicative cycle, or contains a factor which recognizes some virus-coded molecule and switches on a resistance response. In negative mechanisms a plant is resistant because it lacks the specific helper functions required by the virus, or possesses them in mutated form unable to operate in the virus replicative cycle. The host-coded component of the virus replicase mentioned above would fall into this category.

From the initially infected cell, the virus spreads to establish further cycles of infection in adjoining cells. The nature of the infectious entity that moves from cell to cell differs for different types of plant virus. For tobamoviruses and potyviruses, the entity is the virus genomic RNA, in association with one or more virus-coded proteins known as movement proteins. These have a number of functions, including binding to the viral RNA and unfolding it; modifying the plasmodesmata which form cytoplasmic connections between adjoining cells, to permit the passage of larger molecules than in healthy plants; and possible interactions with the cytoskeleton, all of which can be seen as facilitating cell-to-cell movement. Viruses in other groups, such as the comoviruses, appear to move from cell to cell as assembled virions, through virus-induced tubular structures which contain virus-coded movement proteins also involved in modification of plasmodesmata. Clearly, both types of movement mechanism, with the likelihood of complex interactions between virus- and host-coded components, could be potential targets for resistance mechanisms of positive or negative types. The evidence, to be considered in detail later in this article, indicates that cell-to-cell movement is indeed the critical stage for a number of different resistance mechanisms.

Long-distance movement of infection is via the phloem. The evidence suggests that the mechanisms of passage of the virus into and out of the sieve tubes may be in part different from those involved in cell-to-cell movement. Thus for tobamoviruses, coat protein is required for long-distance transport but not for cell-to-cell movement. One of several mechanisms of resistance to bean common mosaic virus (BCMV) in *Phaseolus vulgaris* appears to operate by restricting virus movement from the initially infected leaf. At the other end, lettuce cultivars differ in the extent to which lettuce mosaic virus is seed transmitted, and this may reflect genetic differences in virus transport into the developing seed.

During the course of accumulation of progeny virus

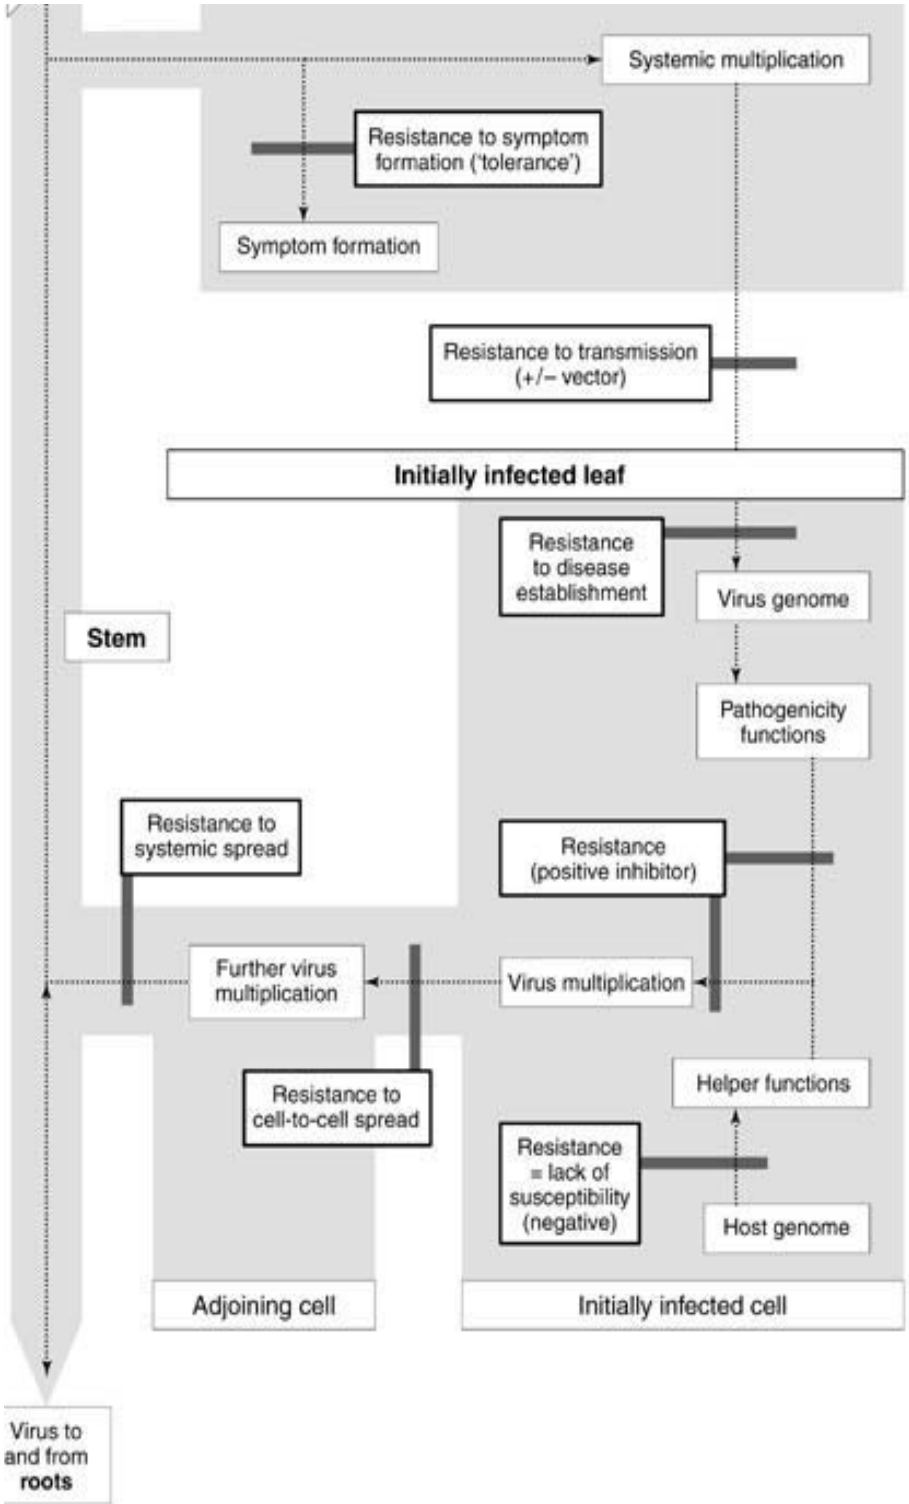

Figure 1 A model replicative cycle of a typical plant virus, showing various possible targets of resistance mechanisms. The track of the virus replicative cycle within the plant and from plant-to-plant is shown by the dotted line.

particles and colonization of a susceptible plant, the virus usually causes formation of visible symptoms such as mosaic or yellowing, as well as reduced and distorted growth. A type of resistance mechanism which appears to operate primarily against symptom formation is referred to as *tolerance*. However, the

term is rather loosely used and some plant virologists prefer to avoid it. Infectious virus can be detected in tolerant plants, but most studies have not measured virus concentration by quantitative methods to determine whether inhibition of multiplication, with a possible indirect effect on symptom severity, does or does not occur.

Progeny viruses are eventually released into the environment, by plant death and decay, mechanical contact, or into a biotic vector such as a phloem-feeding aphid. These routes eventually allow some of the progeny to establish fresh cycles of infection in further plants. There are potential targets for resistance mechanisms in the processes of transmission and establishment, which may operate directly against the virus or indirectly against the vector. An example of the former is a tobacco cultivar partly resistant to mechanical inoculation by a number of viruses because its epidermal cells have a reduced number of ectodesmata, thought to be an important initial channel of infection by wounding. A good example of the latter is the secretion of the aphid alarm pheromone (E)-β-farnesene by glandular hairs on the leaf surfaces of the wild potato species *Solanum berthaultii*, which causes aphids to avoid the plant and reduces transmission of potato virus Y and beet yellows virus.

In summary, there are clearly many and varied potential targets for resistance mechanisms in the virus replicative cycle; it is now appropriate to examine their operation in more detail, in the different types of plant population described in **Table 1**.

Nonhost Resistance

Effectively, most plant species appear to be nonhosts for most plant viruses. In the natural or cultivated environment they do not come into contact because of geographical separation or lack of suitable vectors. However, in the laboratory, experimental infections can often be established. Some viruses such as tobacco mosaic virus (TMV), cucumber mosaic virus (CMV) and tomato spotted wilt virus have been found to infect hundreds of species naturally and experimentally. In contrast, some other viruses have very limited natural host ranges, which cannot easily be extended under experimental conditions. Thus, BCMV is almost entirely restricted to *Phaseolus vulgaris*. What determines host range, and how is it much wider for some viruses than others? What are the mechanisms involved in resistance by nonhost species to different viruses, and could they be further exploited in plant breeding for virus disease control?

Two main types of mechanism have been proposed. The first centers on the interaction of virus-coded pathogenicity factors with host-coded 'helper' functions: nonhost species would simply be those lacking the necessary specific helper functions, a prime example of a negative-type resistance mechanism and perhaps difficult to exploit further in breeding for that reason. At the time of writing, the molecular biology of host components required by viruses – such as replicase subunits, or plasmodesmatal components able to interact with virus-coded movement proteins – is just beginning to be understood. This should lead to an improved ability to evaluate the importance of this model, which conceptually seems a probable one.

The available evidence suggests that cell-to-cell movement of infection is a critical stage in some cases of nonhost resistance. In so-called 'subliminal' infections, plant species previously thought to be completely immune to infection by particular viruses were shown to contain a very small number of cells in the inoculated leaf in which virus multiplication had occurred: presumably those directly infected by the inoculation. Further work with protoplasts prepared from apparent nonhost species for particular viruses showed that they too supported virus multiplication when inoculated. It will be intriguing to discover the basis for the failure of cell-to-cell spread in these situations, but absence of a host component able to interact with the virus movement proteins would seem a possibility. Information is available on too few plant–virus combinations to say whether this is a predominant mechanism in nonhost resistance. As others have pointed out, the data may be skewed, in that reports of failure of viruses to multiply in protoplasts of nonhost species would be difficult to publish. Alternative mechanisms such as lack of a suitable host-coded replicase subunit must remain as attractive possibilities.

The second type of mechanism suggests that plant species may be nonhosts of particular viruses for much less specific reasons, for example because of their content of chemicals such as tannins or phenolics generally antagonistic to viruses, or unsuitable chemical conditions such as cytoplasmic pH. The former may explain the scarcity of reports of virus infections in plant groups such as the Gymnosperms and Pteridophytes. As a possible example of the latter, TMV is known to require a cytoplasmic region with a pH of around 8 and low Ca^{2+} concentration to remove the coat protein subunits from the 5′ end of its genomic RNA, and thus permit a host ribosome to initiate expression of the virus replicase genes and the processes of virus multiplication. A plant species with lower cytoplasmic pH or generally higher Ca^{2+} concentration might not permit TMV to initiate infection.

Table 2 The gene-for-gene relationship between resistance in tomato and virulence in tomato mosaic virus (ToMV)

	ToMV strain							
Host genotype	*0*	*1*	*2*	*2^2*	*1.2*	*1.2^2*	*2.2^2(rare)*	*$1.2.2^2$(rare)*
+/+	M	M	M	M	M	M	M	M
Tm-1	R	M	R	R	M	M	R	M
Tm-2	R	R	M	R	M	R	M	M
Tm-2^2	R	R	R	M	R	M	M	M
Tm-1/Tm-2	R	R	R	R	M	R	R	M
Tm-1/Tm-2^2	R	R	R	R	R	M	R	M
Tm-1/Tm-2/Tm-2^2	R	R	R	R	R	R	R	M

R, resistant, no symptoms; M, susceptible, systemic mosaic and stunting.

Cultivar Resistance

In a crop species normally susceptible to a particular virus, some cultivars may be resistant because of possession of one or more genes for resistance to that virus. The resistance genes have either been detected by screening a wide range of germplasm of the species, including landraces, or transferred from closely related wild species.

The review articles cited in the Further Reading section list well over one hundred examples of virus resistance in crop species where the resistance has been characterized genetically, where something may be known about the mechanism of resistance, and where the response of the virus to the challenge of resistance is known. Strains of virus which are controlled by a resistance mechanism are referred to as *avirulent* against that mechanism. However, many viruses either contain strains with the ability to overcome particular resistance genes, or have evolved this ability in the face of the selection pressure stemming from resistance. These resistance-breaking isolates are referred to as *virulent*. Where a host contains several genes for resistance to a particular virus, and the virus contains one or more virulence determinants against these genes, a *gene-for-gene relationship* is said to exist between the plant and virus. An example is shown in **Table 2**. The study of virulence has given some insights into the mechanisms of resistance, and is clearly relevant to the effectiveness of resistance gene deployment in practical crop protection.

The great majority of the resistances in these review surveys involve genes at a single locus. There are a few well-attested examples of resistance mechanisms which require cooperative (as opposed to merely additive) effects of genes at two loci. Thus resistance to BCMV in *Phaseolus vulgaris* conferred by any one of the genes referred to as *bc-1, bc-2* or *bc-3* requires the presence of the *bc-u* gene as well. The vast majority of genes confer resistance against a single virus or a closely related group. A possible exception is the *I* gene in *Phaseolus vulgaris* which confers resistance against nine different viruses within the potyvirus group, presumably by recognizing some strongly conserved structural element common to all.

About half the resistance genes in the survey are classified genetically as dominant over susceptibility. About one-quarter are incompletely dominant, that is they show a clear effect of resistance allele dosage, with more effective resistance in plants homozygous for the resistance allele than in those that are heterozygous. The remainder of the resistance mechanisms appear to involve recessive alleles. This distribution from dominance to recessiveness is interesting in its diversity; it contrasts with resistance to fungal and bacterial pathogens of plants, which is much more strongly associated with dominance.

In terms of mechanism, dominant resistance is strongly associated with the hypersensitive response (HR), in which the virus initially multiplies unhindered and spreads from the primarily infected cell to a small group of several hundred. However, within a few days, virus spread ceases and the infected area forms a necrotic local lesion (**Fig. 2**). The best-known example of this type of resistance is the *N* gene for TMV resistance in tobacco. This originated in the wild species *Nicotiana glutinosa* and was transferred to the cultivated tobacco *N. tabacum* via an interspecific synthetic hybrid as early as 1925, and was characterized genetically by F. O. Holmes by 1938. This gene has been introduced into a number of commercial cultivars – cigar smokers may have noticed its presence as betrayed by the occasional lesion on the cigar outer leaf.

The *N* gene is the first (and at the time of writing the only) plant virus resistance gene to have been isolated, using a transposon-tagging technique. The isolated gene was shown to be the *N* gene by transformation into susceptible tobacco, which subse-

quently exhibited the hypersensitive response when inoculated with TMV. Further confirmation that this single gene was enough to switch on HR came from the demonstration that it could also confer HR in transformed TMV-susceptible tomato plants.

Sequence analysis of the *N* gene cDNA and genomic clones indicated that it contains five exons which could be spliced to give a protein with 1144 amino acids and a molecular mass of 131 kDa. Comparison of the deduced amino acid sequence of the *N* gene product shows close structural similarities to a number of other genes for resistance to bacterial and fungal pathogens, with common elements indicating a cytoplasmic location, nucleotide binding sites and a region of leucine-rich repeats. The main structural motifs in these resistance genes also occur in a number of other proteins whose function is more clearly understood, for example in the activity of mammalian hormones, and control of insect development. These similarities may give some clues as to how the *N* gene product specifically recognizes TMV, then signals a series of metabolic changes which include the mechanisms responsible for inhibition of virus multiplication or spread. A tobamovirus closely related to TMV, *Solanum dulcamare* yellow fleck virus, has the unique property for this group of being able to overcome *N*-gene resistance. This has been shown to be determined by a single base change in the 126 kDa viral replicase gene, which may alter the recognition or inhibition components of the resistance mechanism.

A great variety of metabolic changes occur during the formation of local lesions, and most probably represent a generalized activation of defense responses rather than specific antivirus mechanisms only. They include induction of synthesis of the pathogenesis-related proteins, which are potentially involved in resistance to fungal and bacterial pathogens, synthesis of phytoalexins with antifungal activity, increased activities of certain enzymes such as phenylalanine ammonia lyase and chalcone synthase, alterations in cell wall structure by lignification and callose deposition, stimulated production of activated oxygen species, and synthesis of various putative inhibitors of virus multiplication. Of these, cell wall modification to restrict virus movement through plasmodesmata, and multiplication inhibitors, would seem attractive suggestions for the means of expression of the ultimate antiviral activity conferred by the *N* gene, but the case for either has not yet been fully made. What is clear is that necrosis itself is not the primary antiviral mechanism, but a secondary consequence of the other metabolic changes.

Another type of localizing resistance is exemplified by the *Tm-2* and *Tm-2*^{2} genes in tomato, which confine avirulent isolates of tomato mosaic virus (ToMV) to the initially infected cells, in which, however, they multiply normally. It appears therefore that cell-to-cell movement of infection is the target of these resistances. It is entirely consistent with this that virulent isolates of ToMV, which spread unhindered, have been shown to have critical point mutations in their movement protein.

Resistance mechanisms involving alleles that show dosage dependence may be associated with mechanisms that inhibit virus multiplication and symptom development, while allowing some virus spread locally or systemically. A good example is provided by the *Tm-1* gene for ToMV resistance in tomato. This inhibits virus multiplication by 70% in heterozygous form and by 95% when homozygous. Virulent ToMV isolates overcoming the *Tm-1* gene have been shown to have a mutation in the viral replicase gene. The implication is that resistant plants contain an inhibitor of replicase activity, and that the replicase of virulent isolates does not interact with the inhibitor.

Very little appears to be known about the mechanisms of action of resistance controlled by recessive alleles; the recessiveness would certainly be consistent with the model involving lack of a required host-specified helper function.

Two further specific mechanisms of resistance deserve mention because their biochemistry is comparatively well understood. In cowpea, resistance to cowpea mosaic virus (CPMV) is conferred by a specific protease inhibitor. Comoviruses such as CPMV express their genomic information initially as two polyproteins transcribed from the two genomic RNAs. The polyproteins are then cleaved to mature products such as coat protein and replicase components by a virus-coded protease, which is the target of this resistance mechanism.

Ribosome-inactivating proteins (RIPs) occur in numerous plant species, and inhibit the translocation step of translation by removing a specific adenine base from the larger ribosomal RNA. Many RIPs, such as that from *Phytolacca americana* (pokeweed antiviral protein, PAP), have been shown to have broad-spectrum antiviral activity. PAP is normally sequestered in the cell walls in healthy plants, and thus does not inactivate their ribosomes. This led to the 'local suicide' hypothesis for the observed antiviral effects: when a virus enters a cell by wounding or insect feeding, PAP is also allowed to enter the cytosol where it inhibits protein synthesis and thus prevents expression of viral functions. However, more recent results suggest that the antiviral activity of PAP may be even more specific than a general, if highly localized, inhibition of total protein synthesis.

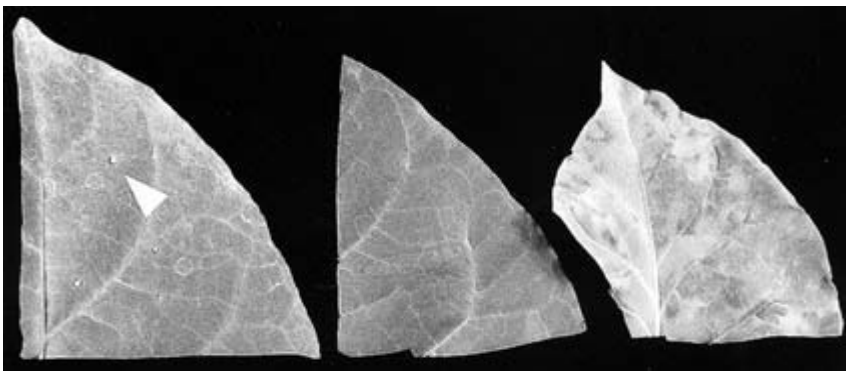

Figure 2 Reaction of tobacco to inoculation with tobacco mosaic virus (TMV). Center: healthy, uninoculated leaf. Right: systemically infected leaf of a susceptible cultivar, showing light-green/dark-green mosaic symptoms of virus infection. Left: an inoculated leaf of a resistant variety carrying the *N* gene, showing restriction of the virus to necrotic local lesions formed around each site of infection (arrowed).

Acquired or Induced Resistance

This heading covers a diverse collection of resistance or resistance-like mechanisms. Some are as yet of academic interest only, whereas a few have found application in practical crop protection.

In susceptible plants showing the common light-green/dark-green mosaic symptoms in upper leaves infected at an early stage in their development by systemic spread of virus (**Fig. 2**), the dark green areas contain little or no virus, and are partly resistant to challenge inoculation. The mechanism is not understood, but one possibility is that the plasmodesmata have remained as the primary forms characteristic of meristematic tissue, and less susceptible to modification by viruses. This may also explain the fact that meristems of virus-infected plants are usually virus-free. Dark green areas of TMV-infected leaves have been shown to have significantly altered levels of the plant hormones abscisic acid and zeatin, and their metabolites, possible indicators of a maintained juvenile state.

Local and systemic acquired resistances (LAR, SAR) are phenomena occurring in plants showing a hypersensitive resistance response to a particular virus. If plants have formed lesions as a result of a first inoculation, the lesions formed after a second inoculation on the previously inoculated leaf (LAR), or on previously uninoculated upper leaves (SAR), are smaller and often fewer in number than those formed on previously uninoculated plants. The first HR induces synthesis of numerous pathogenesis related (PR) proteins, which have potential defense functions against fungal and bacterial pathogens, and insect pests. None has so far been shown to have antiviral activity. LAR and SAR are best regarded as modulations of the primary (and highly effective) resistance response; the additional effects if any have not been exploited in crop protection.

Crossprotection occurs when a plant is systemically infected by a mild (attenuated) strain of a virus, and becomes resistant to infection or disease caused by a severe strain of the same virus. It is used in agriculture for control of a small number of viruses, especially where cultivar resistance is not available. Examples include protection of tomato cultivars lacking the *Tm-2*^{2} gene for ToMV resistance, and citrus fruits against citrus tristeza virus. The mechanism of protection is probably similar to that operating in coat protein transgenic plants, described in a separate article.

The severity of disease caused by cucumoviruses and a small number of other groups can be reduced by the presence of satellite RNAs, which depend on the virus for their multiplication. Tomato and cucurbit crops in the People's Republic of China have been extensively inoculated with such benign satellites to protect against CMV.

Use of Resistance in Plant Breeding

Conventional breeding for virus resistance has had some notable successes and some unfortunate failures. The latter are largely related to the ease and speed with which the target virus has succeeded in producing resistance-breaking isolates; more than half of the resistance genes in the review surveys referred to earlier are reported as having been overcome by virulent strains of virus. Thus in tomato, the *Tm-1* gene for ToMV resistance was overcome within 1 year of its introduction; resistance-breaking isolates quickly became widespread. In contrast, the *Tm-2*^{2} gene has proved outstandingly durable, and has been the mainstay of protection for many years. The

breeder should attempt to predict the likely durability of a resistance gene, by testing it against as many isolates of the virus as possible, at an early stage of the breeding program.

However, another problem is that the genetic base of resistance to plant viruses is rather limited, and in many crops no resistance to particular diseases is known. Screening of wild relatives and gene bank collections will undoubtedly reveal further natural resistance genes, although at a cost. The various techniques for developing resistance by introduction of transgenes offers an excellent prospect of broadening the basis of control.

Engineered Resistance

C Michael Deom, University of Georgia, Athens, Georgia, USA

Introduction

Engineered resistance (or genetically engineered resistance) to viral pathogens refers to the introduction and expression of foreign genes, termed transgenes, in plants such that expression of a transgene interferes with the virus life cycle and thereby confers resistance to the virus. Advances in plant transformation technologies for a variety of plant species have resulted in the introduction of transgenes from a variety of sources that confer resistance to viral pathogens. The transgenes are stably integrated into the plant genomes, are heritable, and resistance segregates with the transgenes. In many cases, transgenic plants have been generated that have resistance to viruses by mechanisms that do not occur naturally and could not have been introduced into the plants by traditional breeding techniques. Genetically engineered virus resistance in crop plants shows great promise in efficiently reducing losses due to virus disease and complements traditional plant breeding.

Transgenes are designed as chimeric genes under the control of a promoter and contain nonviral sequences at the 3′ end to provide transcription termination and polyadenylation signaling. With few exceptions the preferred promoter has been the 35S promoter from the plant DNA virus cauliflower mosaic virus, which is constitutively expressed and drives high levels of expression of transgenes in most plant tissues. In some cases, the transgene is placed under the control of a tissue-specific promoter to localize expression of the transgene.

Pathogen-derived Resistance

The transformation of plants to confer virus resistance was an initial focus of plant biotechnology. The most widely applied and effective strategy presently used for this purpose is pathogen-derived resistance (PDR): resistance obtained by expressing viral-derived transgenes (genes or genomic sequences) in transgenic plants (**Table 1**). This strategy has provided some degree of virus resistance in almost all hosts to which it has been applied. In all cases, the level of PDR is variable, depending on both the type of virus from which the transgene sequence is derived and on the individual transgenic plant line. In some instances, transgenic plants have been developed that are essentially immune to virus infection. Therefore, biologically screening a number of transgenic plant lines is required to identify those having the highest levels of genetically engineered virus resistance and acceptable agronomic traits. Unfortunately, the resistance mechanisms are poorly understood at the cellular and molecular levels. PDR can be divided into two broad categories, depending on whether the resistance mechanism is mediated by protein or nucleic acid. In some instances it is not clear whether the resistance is conferred by expression of the protein or the nucleic acid encoded by the transgene and in

PLANT RETROELEMENTS

Roger Hull, John Innes Centre, Norwich Research Park, Colney, Norwich, UK

Introduction

The replication of most nucleic acids is mainly either DNA to DNA (chromosomal and viral nucleic acids) or RNA to RNA (viral genomes). However, there is an increasing number of nucleic acid sequences which involve a combination of transcription of RNA from DNA and reverse transcription of DNA from RNA. These are termed retroelements and they are found in many taxonomic groups, including higher animals and plants, fungi, insects and bacteria. Retroelements comprise three major groups, viral retroelements, eucaryotic nonviral retroelements and bacterial elements. These major groups have been subdivided on structural and biological criteria (**Table 1**) but recent findings are blurring some of the boundaries between these groups.

The main features that distinguish these groups and subgroups are that viruses have properties which potentiate horizontal transmission; some may also be vertically transmitted. Nonviral retroelements are generally considered to be only vertically transmitted but there may be instances of horizontal transmission, say between plants by pathogenic fungi. Retroviruses and the nonviral retroelements integrate into the 'host's' genome, whereas pararetroviruses are episomal. The genomes of retroviruses, retrotransposons and retroposons encode an integrase activity, and those of retroviruses and retrotransposons have long terminal repeats, both features involved in integration. All, except for retrosequences, which are cDNAs converted from cellular RNAs by endogenous reverse transcriptase activity, encode for reverse transcriptase and its associated RNaseH.

In plants the retroelements currently described fall into the pararetrovirus, retrotransposon, retroposon and retrosequence groups. The reason for there being no known examples of plant retroviruses *sensu stricto* is unknown.

Plant Pararetroviruses

There are two genera of plant pararetroviruses, the Caulimovirus and the Badnavirus in the *Caulimoviridae* family. The genome organization can be considered as comprising the core replicon of polymerase (reverse transcriptase + RNaseH) and coat protein which is considered to organize the replication complex together with genes which adapt the replicon to the plant viral situation. These additional genes are best characterized in cauliflower mosaic virus (CaMV) in which the core replicon is encoded by open reading frame (ORF) IV giving the coat protein and ORF V the polymerase. The plant-adapting genes include the ORF I product which facilitates the movement of the virus from cell to cell through plasmodesmata, and the ORF II product which is

Table 1 Classes of retroelements

involved in interactions with the aphid vector. The ORF III product probably assists with particle assembly and/or stabilization, and the ORF VI product, as well as being associated with the replication complex, has a transactivating activity associated with expression of the virus genome. It is likely that the gene products of most, if not all, the other caulimoviruses and badnaviruses have activities similar to those of CaMV.

Plant Retrotransposons

The plant retrotransposons are also termed LTR (long terminal repeat) retrotransposons to contrast them with retroposons or non-LTR retrotransposons. Retrotransposon sequences are found incorporated in the chromosomal DNAs of most, if not all, higher plant species, and have recently been found in the mitochondrial DNA of *Arabidopsis thaliana*. Retrotransposons encode various proteins, including the *gag* protein which is analogous to the retroviral coat protein, an aspartate protease responsible for cleaving various proteins into functional forms, the replication proteins which are reverse transcriptase and ribonuclease H and the integrase which is involved in integration of the retrotransposon into the host chromosome. There are two major groups of plant retrotransposons, the *copia*-like and the *gypsy*-like, which are so named because they have genome organizations (see below) similar to those of *Ty1/Copia* and *Ty3/Gypsy* retrotransposons of yeast and *Drosophila*. Most of these have been recognized by polymerase chain reaction (PCR) of total DNA from plants using specific primers.

Copia-like retrotransposons

The *copia*-like retrotransposons have been the most studied and are considered to be the most widespread in plants. However, this may be a reflection of the searches being targeted with PCR primers directed towards this class of retrotransposon. They can occur in very high copy number, for instance there are about 50 000 copies of *BARE1* retrotransposon in the barley genome, and the *Bis-1* retrotransposon is estimated to make up about 5% of the wheat genome. On the other hand some are present in low copy number, e.g. *Ta1* from *A. thaliana* and *Tst1* from potato, which have

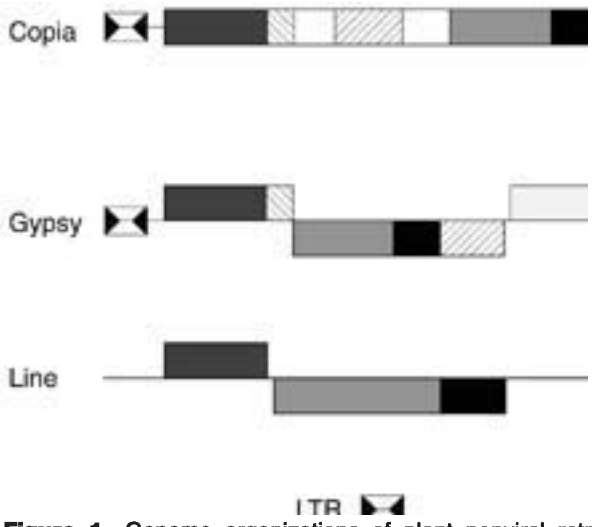

Figure 1 Genome organizations of plant nonviral retroelements. The thin line represents the DNA with the long terminal repeats (LTRs) and coding sequences shown as boxes with different infills; $(AAA)_n$ indicates the polyadenylate sequence.

one to three copies per haploid genome. Overall, *copia*-like retrotransposons appear to be in lower copy number than the *gypsy*-like elements.

The full genome of a *copia*-like retrotransposon codes for a polyprotein which is processed to give the *gag* protein, the aspartate protease, the endonuclease, the reverse transcriptase and the RNaseH (**Fig. 1**). It is thought that, as with the yeast *copia* element, the gene products downstream of the *gag* gene are expressed from a spliced mRNA, which would control the relative proportions of *gag* and *pol*.

In the plant species that have been examined most extensively, there are several to many families of *copia*-like retrotransposons which differ from each other in sequence. In rice at least 20 families (*Tos1* to *Tos20*) and in maize ten families (each with a different distinct name) have been recognized. Sequencing shows that most of these are potentially inactive as they contain point mutations, insertions or deletions which would prevent the full expression of the coding sequences essential for expression and transposition. Only a small number of *copia*-like retrotransposons (e.g. *Tnt1*, *Tto1* and *Tto2* from tobacco and *Tos10*, *Tos17* and *Tos19* from rice) have been shown to be capable of transposition. The unequivocal evidence for full transposition is limited to the detection of an insertion into a nitrate reductase gene by *Tnt1* and the increase in copy number of the other elements. However, this must be associated with the transcription of the RNA replication intermediates, which have provided useful probes for such activity. Searches for these RNA intermediates showed that they are produced under conditions of stress, such as tissue culture, bacterial and viral infections and wounding.

Gypsy-like retrotransposons

Although many fewer *gypsy*-like retrotransposons have been recognized in plants, in some species there can be many copies. For instance *del-1* makes up 0.4% of the genome of *Lilium henryi*.

The genome organization of *gypsy*-like retrotransposons (**Fig. 1**) more closely resembles that of some of the true retroviruses than does that of the *copia*-like elements. The *gag* and aspartate protease are encoded on one ORF, which can frameshift into a second ORF encoding the reverse transcriptase, RNaseH and endonuclease. However, these retrotransposons do not encode an envelope protein, which in retroviruses is on a separate ORF and is expressed from a spliced mRNA. Thus, the *gypsy*-like retrotransposon differs from the *copia*-like element by encoding the proteins in several ORFs and in the gene position of the endonuclease in relation to the reverse transcriptase and RNAse H.

Replication of retrotransposons

The replication mechanism of both groups of plant retrotransposons is considered essentially the same as that of retroviruses. A more-than-genome length RNA is transcribed from the integrated element using the promoter and termination sequences in the LTR and catalyzed by the host DNA-dependent RNA polymerase II. This acts as both the mRNA for expression of the gene products (sometimes involving splicing) and the template for reverse transcription. The formation of (−)-strand DNA is primed by the 3′ end of a tRNA whose complementary sequence is located in the transcript just downstream of the 5′ LTR. Until recently it was thought that all plant retroelements required $tRNA^{met\ init}$ for this priming but recently some other tRNA requirements have been recognized. Template strand switching, priming of (+)-strand DNA synthesis, formation of LTRs and integration of the newly synthesized retroelement are considered to be essentially as in retroviruses.

Plant Retroposons

Until relatively recently it was considered that LINEs (long interspersed nuclear elements) were exclusive to animals; however, there have been an increasing number of reports of these elements being found in plants, both in the nuclear and in the mitochondrial genomes. As with *gypsy*-like elements, this lack of their recognition is probably a reflection of targeted PCR-based searches.

The genomes of these retroposons lack LTRs but

have a 3′-terminal polyadenylate sequence. They contain two ORFs, one encoding the analogue of the *gag* gene and the other the polymerase (reverse transcriptase, RNaseH) gene (**Fig. 1**). Their replication mechanism is not yet understood. As with retrotransposons, plant species in which they have been found contain several families of LINEs, e.g. *Tal1-1* to *Tal1-17* in *A. thaliana*. Also, like retrotransposons, most of these would appear to be inactive. There is little information on activation and transposition by these elements. Fluorescent *in situ* hybridization showed that the BNR1 family of LINEs was present on all sugarbeet chromosomes but was largely excluded from the chromosomal regions harboring the 18S–5.8S–25S ribosomal RNA genes.

Evolutionary Significance of Nonviral Retroelements

There are two major aspects to the evolutionary significance of retroelements, the evolution of the elements themselves and the impact that the presence and retrotransposition of the elements has on the host plant. It has been suggested that the different types of element could occupy different 'niches' within the cell and have specific adaptation to the 'niche'. It would also appear that the relatively low proportion of active elements indicates that they are not particularly well adapted to survival in their host environment, although it may be that the inactive elements have some, as yet undetermined, positive function.

Retroelements often make up a significant proportion of the plant's genome. Although the majority of them are considered to be inactive they must represent a considerable accumulation of retrotransposition events over a long period. Various questions arise, and are currently under discussion, on the impact that these have on plant evolution. These include:

- Where did these elements come from? Do they have anything to do with retroviruses? As noted above, no true retroviruses have been found in plants. However, it is frequently overlooked that plant viruses do not require an analogue for the retroviral *env* gene that is essential for the targeting and entry of animal host cells. Plant viruses are introduced into the cytoplasm of their hosts by mechanical damage caused by their vector (often an insect feeding) and thus do not have to recognize and cross a plasmamembrane. They usually need a gene product to facilitate movement from cell to cell via cytoplasmic connections (plasmodesmata). Thus, one could envisage a plant retrovirus with the *gag* analogue, replicase, integrase and gene(s) adapting them to plants.
- Retrotransposons are widespread, if not ubiquitous, in higher plants, raising the question of whether retrotransposons move between plants. Most transmission of retrotransposons is vertical, although there is some evidence for possible horizontal transmission in association with RNA viral and fungal infections.
- What is the significance of retrotransposons to plant evolution? It is obvious that transposition into important plant genes would be detrimental to the host and most retrotransposons are found outside host coding sequences. Recent analyses have shown that, at least in some plant species, e.g. maize, retrotransposons and retroposons are grouped together, leading to the concept of 'retrotransposon landing pads'. The fact that most are 'dead', with only a small proportion being active, has led to the suggestion that they have been involved in the creation of variation in plants which is the basis for evolution. This is further supported by the recognition that activation is often in response to stress.

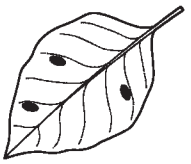
PLANT VIRUS DISEASE – ECONOMIC ASPECTS



OW Barnett and **Charles E Main**, Department of Plant Pathology, North Carolina State University, Raleigh, North Carolina, USA

Introduction

Everyone has seen some of the effects of viruses on plants, perhaps without knowing it. If you are interested in art, you probably have seen the still-life paintings from the seventeenth century Dutch school, which depict tulip flowers with beautiful stripes of color induced by tulip breaking virus. Perhaps the color variegations of certain ornamental plants have imparted their beauty to you. For example, in the woody ornamentals, velvetleaf and flowering maple (*Abutilon* spp.), which have variegated leaf colorations, the beauty of the plants is enhanced by the viral infection, increasing their economic value (**Fig. 1**).

The term 'economic aspects' can be broadly interpreted to mean not only monetary returns from crops but also the esthetic value of plants and the value of plants as members of the biosphere. Anything that affects our world will eventually have an economic effect.

There are no accurate estimates of the economic impact of viral diseases on a global basis. Among plant microbial pathogens, reduced crop production resulting from viral infections is thought to be second only to that caused by fungi. Crop production reduced from its full potential as a result of certain viral diseases varies among countries, regions and even within a local area. Although reduced production on one farm can reduce income for that farmer, a farmer in another location who has a good crop may have a higher income because increased crop prices result from the lower supply (**Fig. 2**).

A single viral disease can affect an entire country's economy. For instance, in Ghana the cacao industry provided an extremely important export commodity until cacao swollen shoot viral infections caused a decline in cocoa production by over 65% from 1936 to 1956 in the eastern region of the country. Plant viruses infect many species of Angiosperms but only a few species of Gymnosperms, Pteridophytes and Algae. In contrast to viral infections of animals, once a plant is infected with a virus it usually remains infected for life. In most plant/virus combinations, the virus invades all parts of the plant, although shoot and root meristem regions may not be invaded by some viruses. In most plant/virus combinations, viruses are not transmitted through true seed to the next generation. To understand the economic aspects of plant viral diseases, the range of effects (symptoms) of viruses on growth and development of plants need to be summarized.

Symptoms Caused by Viral Infection

Viral infections are usually obvious when a disease condition occurs, but infections can also be latent (inapparent). The diseased condition of the plant may be expressed in many ways. Reduced growth or stunting is probably the most universal symptom of a virus-infected plant. Even latent infections may result in reduced growth. Changes in color are the most obvious symptoms of viral infection for most plant/virus combinations. Decreases in green pigments of leaves lead to the development of light green and yellow areas and result in patterns of color such as mosaic, mottling, ringspots, streaking, striping or line patterns. Necrosis or death of tissue is sometimes classified as a color deviation; for instance, necrotic streaks on plant stems are common symptoms of some viral infections. Color deviations are most obvious in leaves (e.g. tobacco infected with tobacco mosaic virus), but also occur in stems (e.g. young apple twigs infected with apple mosaic virus), flowers (e.g. tulip color breaking caused by tulip breaking virus), seed pods (e.g. edible pods of French bean infected with bean pod mottle virus), fruits (e.g. tomatoes with rings and line patterns caused by tomato spotted wilt virus) and seeds (soybean seeds mottled due to infection with soybean mosaic virus).

Some viral infections interfere with water relationships, which results in wilting or desiccation leading to tissue necrosis. Tabasco pepper infected with tobacco etch virus is a classic example of a viral infection that leads to wilting. Cucumber mosaic virus infection can cause wilting of cucumber plants in certain environmental conditions.

Plant morphology can be changed by viral infection. Abnormal leaf morphology commonly occurs with viral infections that cause mosaic or mottling. The leaf lamina may be crinkled, curled, blistered, narrowed or have altered margins. Abnormal growths called enations may develop from the lamina.

Figure 1 Examples of the effects of virus infection in plants. (**A**) Tulip flower with color variegation caused by tulip breaking virus; (**B**) *Abutilon* sp. with mosaic caused by Abutilon mosaic virus.

Stems may be distorted or stem internodes shorter. Whole plants may have uncharacteristic growth patterns, such as bushy growth or a more open pattern of branching because fewer stems are produced.

Plant viral symptoms are usually not characteristic enough for identification of the virus because different viruses in the same plant can cause similar symptoms and different strains of the same virus may cause very different symptoms. Symptoms caused by viral infection may also differ with environmental conditions, plant variety and time infected. In fact, symptoms are not static and the expression of symptoms at different times after infection (symptom syndrome) must be considered when the effects of viruses on plants are studied. When viruses induce visible symptoms in

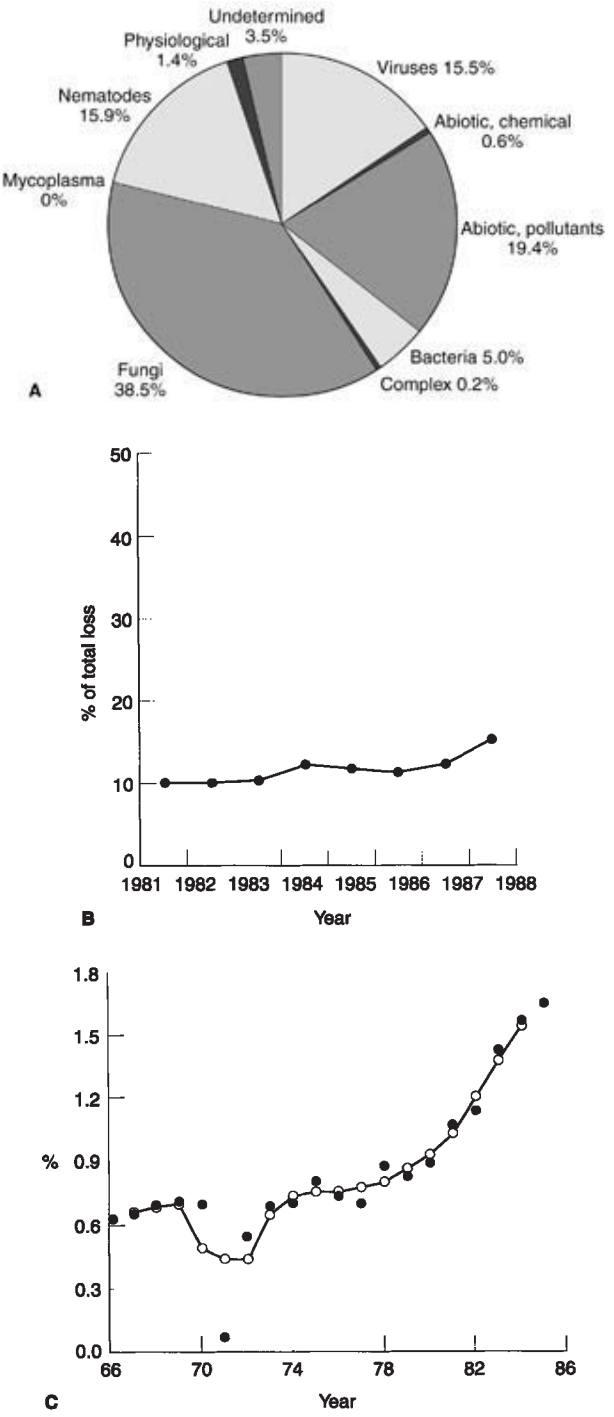


Figure 2 Relative crop losses in North Carolina, USA, due to biotic and abiotic causes and variation in crop losses due to viruses over time. (**A**) Losses from all causes in 1988 by pathogen category in 189 crop and ornamental species. Vegetables suffered a 25% reduction in yield, fruits and nuts 23%, and field crops 15% on a total crop value of $3.3 billion. (**B**) Reductions in crop value caused by viruses ranged from 9 to 15% between 1981 and 1988. Viruses reduced the value of all crops in 1988 by an average of 3.6%, a figure that is 16% of all losses. (**C**) Tobacco mosaic virus reduced the value of tobacco from 0.4% to 1.8% during 1966 to 1986; ○, moving average, ●, original values. Main CE and Gurtz SK (1989) *1988 Estimates of Crop Losses in North Carolina Due to Plant Diseases and Nematodes.* Department of Plant Pathology, Special Publication No. 8, NC State University, NC, 209pp.

plants, the initial sites of infection lead to local symptoms in 3–5 days. Upon reaching the vascular tissue, the virus is usually translocated and causes systemic symptoms. Systemic symptoms that develop first are often very severe. This acute phase is followed by a chronic phase in which symptoms are less severe or are absent even though the tissues remain infected. In some perennial plants, progressive deterioration leads to a condition called a decline. In general, viral infections cause premature senescence of plants.

Damage from Viral Infections

Viral infections of plants usually lead to symptoms of the plant disease. Symptoms result from biochemical and metabolic changes induced in the host which cause various categories of direct damage. Indirect damage from viral diseases results from procedures undertaken to maintain healthy plants. Direct damage can be categorized (Lute Bos, Research Institute for Plant Protection, Wageningen, The Netherlands) as reductions in growth, vigor, or quality and market value.

Reductions in growth

Reductions in growth due to viral infections are manifested in many ways, including crop failure, yield reductions, internode or stem length changes, reduced rooting and root growth, reduced flower and seed production and reduced seed weight (**Table 1**).

Crop failures, although not the most frequent effect, can occur with viral diseases. Sugarbeet production in the western USA was sporadic until 1940 when varieties resistant to curly top virus were introduced. In 1925, one-third of the sugarbeet crop was destroyed by the curly top disease in the Sacramento Valley of California and all of the late plantings were destroyed in the San Joaquin Valley and southern part of the Salinas Valley. When severe infections (100%) of sugarcane with Fiji disease virus occurred in Australia, growth of the canes was reduced to only 5–10% of a healthy crop, and complete fields were destroyed by growers prior to harvest because their maintenance and harvest were not economical. In The Netherlands, fields of the lily cultivar Enchantment can be 100% infected with tulip breaking virus plus lily symptomless virus. This double infection leads to leaf and stem necrosis and eventual death of the plants.

Usually even 100% viral infection does not result in total loss of the crop. For example, the complete stock of many potato varieties were once infected with one or more viruses. The production limits that viruses imposed on the genetic potential of the cultivar could not be determined until parts of the crop could be freed of virus. Potato virus M (potato paracrinkle virus) infected the total stock of King Edward potato producing only mild symptoms, but, when virus-free potatoes became available, the virus was shown to reduce the yield of tubers by around 10%. The infected plants also produced tubers of less uniform size. Potato virus X (PVX) was known as the healthy potato virus because North American potato stocks were so generally infected, with few or no symptoms. The healthiest potatoes contained only this virus. PVX was found to reduce potato yields by 9–22%, depending on viral strain and potato variety.

Potato crops have been grown in many countries for many years and cover large acreages. Viral damage which most agriculturists would consider insignificant is thus overall very extensive. The potato crop in the USA in 1989 was 370.5 million hundred weight (18.9 million tonnes) valued at $2.5 billion. A 10% reduction in yield is 41.2 million hundred weight (2.1 million tonne), or $278 million in reduced sales for 1 year.

Years ago, Holmes recognized that small yield reductions of crops having a high dollar value and grown worldwide are probably the most important economically. The mosaic disease of tobacco caused by tobacco mosaic virus (TMV) is an example of a virus that causes readily visible symptoms. Growers may not notice symptoms on plants widely scattered in a field of healthy plants. In North Carolina and South Carolina USA flue-cured tobacco, this disease causes the second or third highest losses year after year because the gene for hypersensitive resistance has not been incorporated into a flue-cured cultivar having the same high quality and yield as cultivars without this gene. For instance, when 15, 30, 60 and 100% of flue-cured tobacco plants are infected with TMV, yield is reduced by 7, 14, 21 and 30%, respectively. In 1988, TMV caused a value loss of $12.5 million with an average of 1.3% infection for North Carolina. Ironically, tobacco mosaic virus was the first plant virus described and is probably the most studied of all plant viruses. Viruses of forage legumes reduce biomass of forage from very little up to 55%. Forages are thought of as low-value crops, but they cover large areas of land so that, from a global perspective, the reduction is large.

Other viruses cause dramatic epidemics as they spread into a crop. In Ghana, cacao swollen shoot virus infected native vegetation, but soon after cacao production began the virus spread into new plantings and caused severe economic losses. Cadang-cadang is a devastating lethal disease of coconut palms, which was epidemic in the Philippines in the 1930s. Over 30 million coconut trees are estimated to have been killed

by this viroid disease since it was first recognized. The loss in production for each planting site with an infected tree has been valued at US$80–100, based on average yield and copra prices. The economic impact becomes even more vivid when it is realized that 96% of the world copra production occurs on small land holdings where coconut is both a subsistence and a cash crop. A similar disease, 'tenangaja', occurs on Guam.

Reductions in growth can be related to reduction in vigor or quality. In ornamental production, tobacco ringspot virus in *Jasminum*, a woody ornamental, causes fewer cuttings to root than from uninfected plants. Cuttings that do root are of poorer quality, produce 50% less growth, and have a higher mortality rate. Dasheen mosaic virus-infected *Dieffenbachia* plants produce only 39% as many cuttings per plant as do virus-free plants. The average weight of the cuttings was not reduced by virus infection, but only plants produced from virus-free plants were marketable. Virus-free narcissi not only produce twice as many flowers but also larger ones.

Reductions in vigor

This can be manifested in many ways. Seedlings are usually larger and better able to escape disease when derived from larger seeds. Virus-infected white clover produces fewer and smaller seeds, which produce smaller, slower growing seedlings. Infection of perennial crops may lead to reduced cold-hardiness or drought tolerance. Wheat or oat plants infected with barley yellow dwarf virus do not survive encasement in ice as well as noninfected plants. Red and white clover plants infected with clover yellow mosaic virus are less winter-hardy and more susceptible to drought.

Many perennial or vegetatively propagated plants develop conditions given various names such as 'degeneration', 'running out' and 'senility'. Many of these situations are related to the increasing prevalence of one or more viruses in the crop or stock plants. For example, from 1770 into the 1800s, potato cultivars introduced into Europe from true seed gradually became less productive and produced less vigorous growth. Eventually, this condition was found to result from mild infection of potatoes with a number of viruses.

White clover is another perennial that can be severely affected by viral infection. Individual plants infected simultaneously with as many as four viruses will not survive competition in the field. Grasses usually become predominant in a sward because the infected clover is slower growing and shaded by more vigorous uninfected clover and grasses. Infected clover is also more susceptible to root rot, and fewer and less efficient nitrogen-fixing nodules are produced. White clover–grass pastures should last 10–20 years, but, in the southeastern USA, the white clover component of pastures is often insignificant after 3–6 years. Although other factors are important, high viral incidence often precedes clover disappearance.

Early leaf fall occurs on rose bushes infected with *Prunus* necrotic ringspot virus. Bushes lack vigor, are more sensitive to winter kill, and reestablish with difficulty after transplantation.

In general, viral infection increases susceptibility of plants to infection by fungi. For instance, sugarbeet plants infected by beet mild yellowing virus are more susceptible to infection by *Alternaria*. Corn leaves infected with maize dwarf mosaic virus produce more lesions and earlier sporulation of *Helminthosporium maydis*. Wheat and barley infected with barley yellow dwarf virus are more susceptible to *Cladosporium* and *Verticillum* species.

In contrast, plants in which viral infection causes necrosis are protected from certain fungal infections. Cucumber plants artificially inoculated with tobacco mosaic virus are resistant to anthracnose, and similarly inoculated tobacco is resistant to several fungi.

Virus-infected plants generally tolerate air pollution better than uninfected plants. For example, tobacco infected with tobacco mosaic virus had 6% less leaf damage due to ozone. Virus-infected plants may be more attractive to aphids, aphid multiplication may be enhanced, and maturation of flying aphids may be more rapid, but sometimes the longevity of aphids is less than on healthy plants.

These examples are effects of viruses on plants in relation to additional abiotic and biotic stress. In general, virus-infected plants are damaged more by other stress factors but in some cases viral infection actually allows the plant to tolerate additional stress. Thus virus-infected plants may be more or less vigorous depending on other environmental and biotic factors.

Reduction of quality and market value

Quality and market value are reduced when plants are infected with viruses. Yellow summer squash from plants infected with several viruses have green markings on the fruit. Even a low percentage of green fruit means rejection of the truckload of squash at a processing plant. Snap beans for fresh market will also be rejected if they are mottled as a result of bean pod mottle virus infection, which causes pod symptoms. Sweetpotatoes infected with sweetpotato feathery mottle virus may be harvested with apparently high-quality tubers; but after storage many tubers will

have internal cork which severely reduces market quality. Tomato fruits from plants with late infections by tobacco mosaic virus develop internal necrosis, which reduces marketability.

Tulip flowers with color breaking were once highly valued. Now growers realize that flower breaking results from viral infections that lead to degeneration of bulb stocks. This often cited example of a 'beneficial viral infection' does not impress modern bulb growers. Grades of flower bulbs and quality of flowers are deleteriously affected by viral infection; color deviations intensify and the size of plants and flowers and yield of bulbs are reduced.

In roses, the onset of flowering is delayed, flower size decreases, and the percentage of deformed flowers is greater from virus-infected than from healthy bushes. Pelargoniums with ringspot symptoms, which can be caused by several viruses, exhibit delayed flowering, greater flower abortion, decreased flower and floret numbers, and reduced flower stem length. Orchids infected with one of several viruses may develop necrotic streaks on the flowers about a week after opening. Acceptable flowers are sometimes shipped to wholesale houses prior to symptom appearance. Foliage ornamentals may be deformed by viral infection; for example, *Dieffenbachia* infected with dasheen mosaic virus.

Quality factors such as these are of economic importance because they affect the growers' reputation. Commercial producers must establish a good relationship with their clientele. Viral diseases can adversely affect these relationships; quality may be acceptable when shipped, but upon or shortly after receipt the quality deteriorates. Producer/client relationships then suffer.

An unusual situation occurs with rhubarb. Virus-free rhubarb requires more chilling hours (20–50%) than virus-infected rhubarb. The virus-free rhubarb can not be forced as early in the season as the virus-infected rhubarb and was thus of lower commercial value. Some quality factors caused by viruses may thus be beneficial!

Indirect Effects of Viral Diseases: The Cost of Maintaining Plant Health

Bawden, in a discussion of the degenerative disease of potatoes in the late 1700s, mentioned that potato viruses prevalent elsewhere were rare in the UK. In 1963 he wrote: 'This does not mean that they (potato viruses) are unimportant; they are rare only because they are controlled, at a cost to the English potato growers of about £10,000,000 a year.' Potato viruses are controlled by systems for production and certification of virus-tested seed potatoes. The virus-tested planting material allows commercial growers to produce high-quality potatoes reliably. Although planting material may be more expensive, high-quality potatoes can be produced, perhaps sold at a higher price and with lower production costs because less land is required. Even though control is expensive, return must be greater than the cost or farmers would not have adopted the practice. Other economic aspects relate to programs that produce the virus-tested planting stock. Research scientists must monitor the crop for new viral diseases, mother potato stocks must be maintained free of virus and tested regularly, and stock increases require that inspectors monitor the process. Some growers in areas where virus spread is low will produce high-value seed potato crops. Thus, control of viral diseases means more jobs, another industry and more governmental agencies. A simple balance sheet really tells only a portion of the story about viral disease control.

When individual growers cannot solve a disease problem, governments may assist. Control of swollen shoot of cacao in Ghana included several approaches, but the major procedure was eradication of infected plants. The disease was recognized in 1936, the eradication program began in 1946 and by 1989 had removed over 188.7 million infected trees. Farmers resisted eradication of infected trees, especially those without symptoms surrounding infected trees, even though compensation was paid for trees cut down and grants were made for replanting. Political concerns sometimes override control programs for this viral disease; war, farmer opposition, political intervention, lack of trained manpower and financial resources all affected the eradication program. It is interesting that when compulsory eradication was abandoned, eradication continued on a voluntary or consent basis, but when officials announced that the compensation program might resume, farmers discontinued voluntary eradication and less effective control resulted. Despite the control efforts, this disease is still prevalent, especially in the eastern growing region.

Zadoks contends that 'most researchers have little understanding of farmers' needs' as the farmer 'has more – and often more important – concerns than crop protection.' However, successful modern agriculturists must make crop protection in general, and viral disease control in particular, an important management concern. Profit margins are so low that growers cannot afford to make many mistakes.

Assessment of Damage

Observations by trained agriculturists reveal that viruses occur commonly on many plants. Clinic

records confirm that viruses occur consistently in various crops (**Table 2**). Assessment of damage caused by a virus requires more than knowing that a plant is infected, but this is an important first step. Diagnosis (detection and identification) often requires application of serological, nucleic acid hybridization or biological assays. Mixed infections with two or more viruses commonly occur, and these plants may have symptoms similar to those of a single infection. Effects may be additive, or a synergistic reaction may occur.

Experimental measurement of damage should be carried out in several environments, with plants inoculated at different ages, in different cultivars, with different viral strains and at various plant densities. Ideally these measurements should be made in the field, but viral spread into uninfected control plants may make this impossible. Greenhouse or growth chamber experiments allow use of more defined conditions but do not mimic field conditions.

Next, viral incidence in the crop must be determined. Surveys for viral incidence may be intensive (accurate knowledge of viral incidence but of only a small area) or extensive (less accurate viral incidence but over larger areas). Field surveys may be needed several times during crop growth to determine the duration of infection or increase in incidence. Knowing how much damage an infected plant incurs and how many plants are infected allows calculation of yield reductions and even modeling of the disease for forecasting of what will happen.

The best example of predicting viral spread, viral incidence and potential loss due to viral infection and developing spray warning schedules for control of spread by vectors is for yellows disease of sugarbeet in the UK caused by a complex of aphid-borne viruses. Yield reductions can be large and are related to the length of time sugar beet plants are infected (3–5% potential sugar yield reduction per week infected). Predictions of viral incidence for the coming growing season can be made on the basis of vector numbers and winter severity. Spray warnings are usually based on aphid numbers and viral incidence.

Concluding Remarks

Viruses are very important economically because of the diseases that they cause; they are also important tools for scientific study leading to better understanding of protein structure, antibody/antigen reactions and plant functions at the molecular level. Plant viruses have also invoked curiosity, as well as inspired poetry and art. They have been present throughout recorded history and have been a part of natural ecosystems for much longer. They are a normal part of our environment and become disruptive forces in situations where humans have managed crops for human gain.

The use of resistant varieties, if available, is the most reliable means of control. However, many strains of each virus occur and resistance is often strain specific. Biotechnology offers the means of engineering plants with novel types of viral resistance, which may be useful against a range of viruses. Transgenic plants with genes coding for the viral replicase, antisense RNA and satellite RNA may allow control of some viruses. Biotechnology has stimulated development of sensitive methods for identification and detection of viruses with such tools as monoclonal antibodies and DNA probes. Virology is an exciting and dynamic science, which promises better control methods for viral diseases.

POLIOVIRUSES (*PICORNAVIRIDAE*)

Contents

General Features

Philip D. Minor, National Institute for Biological Standards and Control, South Mimms, Potters Bar, Hertfordshire, UK

History

A funerary stele of a Middle Kingdom Egyptian scribe from about 1500 BC bears a carving of an individual with the withered leg and foot drop deformity characteristic of paralytic poliomyelitis. If the diagnosis is correct, this is the earliest record of a virus disease. Poliomyelitis, which is caused by poliovirus, became a well-recognized disease in Europe and North America in the first decade of the twentieth century as a result of serious epidemics which replaced the endemic pattern of disease that had occurred previously.

Poliomyelitis was transmitted to monkeys by the inoculation of extracts of spinal cord obtained from fatal human cases by Landsteiner and Popper in 1909. Enders and coworkers demonstrated that the virus could be grown in tissue culture in cells of nonneural origin in 1949, and this encouraged the development of formalin-inactivated vaccines by Salk in the mid-1950s. The difficulties of producing sufficient safe and potent vaccine led to the use of the live attenuated vaccines developed by Sabin in the late 1950s and the early 1960s. The World Health Organization has declared its intention of eliminating the disease from the world by the year 2000 and has made substantial progress towards this goal. The first complete sequence of poliovirus genomic RNA was published by Wimmer and coworkers in 1981, and the first atomic structure in 1985 by Hogle.

Taxonomy and Classification

Poliovirus is a member of the family *Picornaviridae* genus *Enterovirus*. Shown by electron microscopy to be icosahedral viruses about 28 nm in diameter, particles lack a lipid membrane. Current classification of the *Picornaviridae* divides them into six genera: *Enterovirus* of which poliovirus is the type member; *Rhinovirus* which is the causative agent of the common cold; *Hepatovirus* which causes hepatitis A; *Cardiovirus* of mice; and *Aphthovirus* or foot-and-mouth disease viruses. A sixth genus (*Parechovirus*) composed of echoviruses 22 and 23 has been recently added as the genomic sequences of these viruses are strikingly different from that of the enteroviruses with which they were previously grouped.

Classically the picornaviruses have been assigned to genera largely on the basis of buoyant density and sensitivity to acid pH, although increasingly sequence comparisons have been used. Polioviruses exist in three distinct serotypes designated type 1, type 2 and type 3. Strains may be distinguished by comparison of the sequence of small regions of the genomic RNA and are identified by serotype, name, country of isolation and year of isolation, e.g. P3/Leon/USA/1937.

Geographic and Seasonal Distribution

Polioviruses are found worldwide, although less commonly in areas where hygiene is good, and inactivated rather than live attenuated vaccines are used. Isolates are thus rare in countries such as Sweden, but common in developing countries or in

History

A funerary stele of a Middle Kingdom Egyptian scribe from about 1500 BC bears a carving of an individual with the withered leg and foot drop deformity characteristic of paralytic poliomyelitis. If the diagnosis is correct, this is the earliest record of a virus disease. Poliomyelitis, which is caused by poliovirus, became a well-recognized disease in Europe and North America in the first decade of the twentieth century as a result of serious epidemics which replaced the endemic pattern of disease that had occurred previously.

Poliomyelitis was transmitted to monkeys by the inoculation of extracts of spinal cord obtained from fatal human cases by Landsteiner and Popper in 1909. Enders and coworkers demonstrated that the virus could be grown in tissue culture in cells of nonneural origin in 1949, and this encouraged the development of formalin-inactivated vaccines by Salk in the mid-1950s. The difficulties of producing sufficient safe and potent vaccine led to the use of the live attenuated vaccines developed by Sabin in the late 1950s and the early 1960s. The World Health Organization has declared its intention of eliminating the disease from the world by the year 2000 and has made substantial progress towards this goal. The first complete sequence of poliovirus genomic RNA was published by Wimmer and coworkers in 1981, and the first atomic structure in 1985 by Hogle.

Taxonomy and Classification

Poliovirus is a member of the family *Picornaviridae* genus *Enterovirus*. Shown by electron microscopy to be icosahedral viruses about 28 nm in diameter, particles lack a lipid membrane. Current classification of the *Picornaviridae* divides them into six genera: *Enterovirus* of which poliovirus is the type member; *Rhinovirus* which is the causative agent of the common cold; *Hepatovirus* which causes hepatitis A; *Cardiovirus* of mice; and *Aphthovirus* or foot-and-mouth disease viruses. A sixth genus (*Parechovirus*) composed of echoviruses 22 and 23 has been recently added as the genomic sequences of these viruses are strikingly different from that of the enteroviruses with which they were previously grouped.

Classically the picornaviruses have been assigned to genera largely on the basis of buoyant density and sensitivity to acid pH, although increasingly sequence comparisons have been used. Polioviruses exist in three distinct serotypes designated type 1, type 2 and type 3. Strains may be distinguished by comparison of the sequence of small regions of the genomic RNA and are identified by serotype, name, country of isolation and year of isolation, e.g. P3/Leon/USA/1937.

Geographic and Seasonal Distribution

Polioviruses are found worldwide, although less commonly in areas where hygiene is good, and inactivated rather than live attenuated vaccines are used. Isolates are thus rare in countries such as Sweden, but common in developing countries or in

countries where live vaccines are used extensively. Strains may be indigenous to the country of origin, imported from other areas or derived from live attenuated vaccines. It has been found that the sequence similarities between indigenous strains are surprisingly well conserved over time, and that specific genotypes (defined as those differing by less than 15% at the nucleotide level) are confined to particular geographic areas, thus making it possible to identify the probable source of epidemics. This has great value in vaccination and eradication programs, as it provides a clear measure of indigenous viral transmission and its interruption by vaccination. Viral prevalence is favored by warm wet conditions and is thus high in temperate climates in summer and autumn. In tropical climates the virus is believed to be endemic.

Host Range and Virus Propagation

Poliovirus grows naturally only in humans and chimpanzees, which may both be infected by the oral route. Old World monkeys may be infected parenterally and less readily by mouth. Certain strains of virus, notably of serotype 2, can cause a paralytic disease very similar to poliomyelitis following parenteral inoculation of mice although murine cells *in vitro* are not susceptible to infection. Host restriction has been shown to be attributable to a specific receptor. Transgenic mice carrying the gene for the human receptor have been prepared, and shown to be susceptible to infection with all three serotypes, although not readily by the oral route.

Virus can be propagated in cells of human or primate origin, such as primary monkey kidney cells, human diploid cells such as MRC5 or WI38, continuous cell lines of human origin such as HeLa or Hep2c, or continuous cell lines of simian origin such as Vero. Mouse cells stably transfected with the gene for the human receptor for poliovirus are also able to support virus infection.

Genetics

Polioviruses of all three serotypes rapidly mutate on replication in the human gut, accumulating point changes during an epidemic at an estimated rate of about 10 per genome per month. Point mutations are readily selected *in vitro*. Deletions and insertions may be less common because of the strategy of translation of the viral proteins, which involves a single large open reading frame encoding a polyprotein which is then subjected to proteolytic processing. Mutations must, therefore, conserve the reading frame to give viable virus. Recombination between viruses of different serotypes is extremely common in recipients of the live vaccines and recombination *in vitro* is well documented. It is therefore likely to occur in the wild, both between and within serotypes, although this may be difficult to prove in practice. The relative stability of the sequences associated with isolates from a given geographical region is surprising in view of the high potential variability of the genome.

Serologic Relationships and Variability

Polioviruses of different serotypes are antigenically distinct and immunity to one serotype is believed not to confer significant immunity to the other two. There is evidence for antibodies able to neutralize both type 1 and type 2, however, and partial denaturation of the virus exposes antigenic sites which are crossreactive between viruses of different serotypes and other enteroviruses. Point mutations in known antigenic sites are common during infections, but the viruses can still be neutralized by polyclonal type-specific sera. Significant antigenic drift is therefore not observed, as illustrated by the fact that the vaccine strains of virus in use since 1955 have remained able to induce protective immunity against wild strains. The continuing efficacy of vaccines is also evidence that no serotype 4 poliovirus exists. It is possible that the pathology associated with poliovirus is linked to its use of a particular cellular receptor site which is determined by its structural proteins. A virus whose structural proteins have drifted to such an extent that the virus is no longer antigenically recognizable as one of the three serotypes may therefore have concomitantly changed receptor site and pathology.

Epidemiology

Young children form a reservoir of infection and high frequencies of transmission are associated with poor living conditions and low socioeconomic status. Improvements in hygiene result in less exposure in extreme infancy, when the child is protected from disease in infants by maternally acquired antibody and exposure at slightly greater ages, leading to disease, hence infantile paralysis as a term for poliomyelitis.

Transmission and Tissue Tropism

Polioviruses are generally transmitted by the fecal–oral route, although transmission from the nasopharynx also occurs. A transient viremia may follow infection but the major site of virus growth is the gut, where replication may be expected to persist for about 5 weeks in half of infected individuals. The restriction of replication to the intestine, the central

nervous system (CNS) and lymphoid tissues, such as Peyer's patches and the tonsils, cannot be explained by the exclusive expression of the cellular receptor in those tissues as it is also found in such tissues as kidneys, which are thought not to be susceptible. Virus can be excreted in stool at a level of 10^5 infectious units g^{-1}.

Pathogenicity

Most poliovirus infections are asymptomatic, with generally no more than 1 in 100 resulting in disease. Infections with type 1 polioviruses are more likely to lead to disease than those with type 3, whereas infections with type 2 are the least likely to have clinical effects. The circulation of the three serotypes occurs at a similar rate, as shown by the similar age of seroconversion to each type, and it is believed that the differences in morbidity rates reflect general differences of pathogenicity between the serotypes. Within a type, however, strains may also differ widely in pathogenicity. Although the molecular basis for the lack of pathogenesis of the live Sabin vaccine strains is at least partially understood for each of the three strains, the variation in the virulence of the wild strains has not been systematically examined and could have a number of different molecular explanations.

Clinical Features of Infection

Infection with poliovirus may initially be associated with slight gastrointestinal symptoms. This may be followed by fever, sore throat or influenza-like illness, from which the patient recovers within a few days. This pattern has been termed abortive poliomyelitis. Nonparalytic poliomyelitis may occur in 1–2% of infections, and is associated with the symptoms of abortive poliomyelitis, followed by invasion of the CNS leading to aseptic meningitis, often accompanied by back pain and muscle spasm. The illness lasts 2–10 days and recovery is usually complete. Paralytic poliomyelitis occurs in 0.1–2% of infections approximately 7–30 days after infection and usually begins with the symptoms of abortive poliomyelitis, progressing to flaccid paralysis resulting from lower motor neuron damage. Paralysis is defined as spinal or bulbar if it affects the brainstem. Encephalitis also occurs. Paralyzed patients recover wholly or to a significant degree in 10% of cases, up to 10% of cases are likely to be fatal, and in 80% of patients there is significant residual paralysis.

Pathology and Histopathology

Poliovirus naturally infects via the oral route and multiplies either in the mucosa of the intestinal tract as proposed by Sabin, or in lymphatic tissues including tonsils, lymph nodes of the neck and Peyer's patches of the small intestine as proposed by Bodian. Infection of the tonsils may occur after replication is established in the gut following a brief viremic phase, or in the initial infection by mouth. Low levels of circulating antibody, including passively administered antibody are able to prevent paralytic poliomyelitis suggesting that CNS infection requires a viremic phase. However, the clinical development of some cases suggests that infection of the CNS may occur directly from nerves associated with the intestine. Virus growth in nerve cells is restricted to motor neurons, usually the anterior horn cells of the spinal cord although in severe cases intermediate gray ganglia and posterior horn and dorsal root ganglia may be affected. Damage appears to be by replication in the neurons themselves rather than in supportive tissues, as shown by the histological location of viral genomes and antigens. In the brain, affected areas may include the reticular formation, the vestibular nuclei, the cerebellar vermis and the deep cerebellar nuclei. Polioviruses may also infect the myocardium.

Immune Response

The virus may be partially denatured by relatively mild treatments, such as heating at 56°C for 10 min or UV irradiation, changing in antigenic properties as a result from the N (or D) form found in the infectious virus to an H (or C) form. This change is also associated with the early stages of virus uncoating and is sufficiently drastic to be readily demonstrated with polyclonal sera. Individuals in the acute phase of poliomyelitis mount a humoral immune response predominantly directed against H (or C) antigen, whereas those in the convalescent phase have antibodies to the N (or D) form. Immune serum with antibodies specific for the N form is protective. Moreover, individuals suffering from primary immune deficiencies associated with defects in the humoral but not cellular arms of the immune response are particularly susceptible to infection and disease caused by enteroviruses in general and poliovirus in particular. The predominant protective immune response is thus believed to be humoral. The significance of cellular immunity to protection is not clear. However, infection or immunization with type 2 poliovirus is believed to be able to prime for a secondary response to type 1 and type 3 and this may be due to crossreactive T helper cells. Although an immune response may be detected in sera by 1–2 weeks postinfection, virus excretion persists for much longer periods. There is evidence for a mucosal

immune response and the production of immunoglobulin (Ig)A antibodies. Infection with the live attenuated vaccines produces immunity to reinfection in the gut, which although real may be of short duration.

Prevention and Control of Poliomyelitis

Whereas passive immunoglobulin confers short-lived protection from disease, strategies for the prevention and control of poliomyelitis depend on the use of vaccines either based on the formalin-killed preparations developed by Salk or the live attenuated strains developed by Sabin. No antiviral chemotherapy is available.

Vaccine viruses are grown in susceptible cells, usually primary monkey kidney cells or human diploid cells. Modern Salk-type vaccines are of far greater potency and quality than those manufactured in the 1950s and are currently prepared by concentrating, purifying and filtering the harvest to remove aggregates, then treating with 3 mM formaldehyde at 37°C for 2 weeks, before a second filtration step. The prolonged and slow inactivation method conserves the antigenic properties of the virus and the filtration steps remove aggregates which may protect virus from the formalin and therefore contain live virus particles. Such infectious aggregates are believed to have been the cause of the 'Cutter incident' of the mid-1950s in which recipients of inactivated vaccine became paralyzed. It is widely believed that immunization with inactivated vaccine has little effect on the infection of the human gut by other viruses. However, circulation of wild-type viruses in several European countries appears to have been prevented by its use.

The Sabin vaccine strains were produced by passage of poliovirus isolates under a variety of regimens. The type 1 strain is designated LSc_1 the type 2 strain P2712 and the type 3 strain Leon $12a_1b$. The passage histories leading to attenuation, including *in vivo* passage in primates and *in vitro* passage under different conditions are very different for each serotype. Attenuated strains were selected on the basis of their clinical and histopathological properties when inoculated into primates by different routes, and by their growth properties and stability in the laboratory. The molecular basis of the attenuation of the three strains has been examined, and there are striking similarities between them, including the presence of comparable mutations in the 5′ noncoding portion of the genome before the single open reading frame which probably act by reducing the efficiency of initiation of translation. The viruses are usually given as a trivalent mixture, and extensive changes occur in recipients, including loss or suppression of attenuating mutations, simple or complex intertypic recombination events in the region of the genome encoding the nonstructural proteins, point mutations in known antigenic sites and other changes of unknown significance. The estimated incidence of paralytic poliomyelitis due to reversion of the vaccine strain is 1 per 530 000 primary vaccinees, and 1 per 2 million of all vaccinees.

Live vaccines eliminated poliomyelitis attributable to wild-type poliovirus from developed countries when they were administered to infants at specified ages during the first year of life. This strategy was ineffective in developing countries, probably because many children were infected before the first vaccination and coverage was probably low. A strategy of national immunization days has therefore been developed in which the aim is to vaccinate all children up to a certain age in a single day; thus all susceptible intestinal tracts are colonized with vaccine virus and transmission of wild virus is broken. This approach has eradicated wild-type polio in the Americas, which have not had a case since 1992, and nearly eliminated it in the Far East, including China. Major efforts to eradicate polio in Africa are underway.

Future Perspectives

The World Health Organization has declared its intention of eradicating poliomyelitis by the year 2000, and substantial progress has been made to this end, using the existing live vaccines. Although a number of potential difficulties may be envisaged, including the question of when it is safe to stop vaccinating as the wild-type virus is replaced by viruses derived from the live vaccine strains, it is likely that the goal will be achieved at or near that date. Poliomyelitis will thus have been a significant human disease for exactly 100 years.

Introduction

Picornaviridae is the name of a large family of small (Lat. *pico*) RNA (rna) viruses that has been subdivided into six genera: *Enterovirus*, *Rhinovirus*, *Hepatovirus*, *Parechovirus*, *Cardiovirus* and *Aphthovirus*. The first four of these genera include numerous human pathogenic agents of which poliovirus (PV) is the best known and the most feared. Poliovirus belongs to the genus *Enterovirus* which is a large group of pathogens that replicate predominantly in the gastroenteric tract, spreading occasionally from there to other tissues in the human body. Poliovirus rarely (1–2% of normal infections) invades the central nervous system (CNS). However, once in the CNS, poliovirus displays a remarkable preference for replicating in motor neurons of the gray matter of the spinal cord, causing paralysis and even death. This dreaded disease has been called poliomyelitis from the Greek words: πολιὸζ (polios, gray) and μυελὸζ (myelos; the gray matter of the spinal chord). The term poliovirus is an abbreviation of 'poliomyelitis virus'.

Poliovirus is a nonenveloped icosahedral particle, 28 nm in diameter, that consists of 60 copies each of the structural proteins VP1 and VP3, 58–59 copies of VP2 and VP4, and one or two copies of VP0 (the uncleaved precursor of VP4 and VP2) (see **Table 1**). This viral capsid is remarkably stable to organic solvents, detergents and acidic conditions. It encloses a positive-sense (mRNA sense) genome of single-stranded RNA of approximately 7500 nucleotides that is polyadenylylated at its 3′ end and linked at its 5′ end to a small viral polypeptide, VPg.

There are three serotypes of poliovirus (PV1, PV2 and PV3), classified according to the ability of immune sera or monoclonal antibodies to neutralize viral infectivity. That is, immune sera against poliovirus type 1 will neutralize (inactivate) infectivity only of poliovirus type 1, but not of type 2 or type 3. Each serotype has been further subdivided into different strains that can be identified via neutralization by strain-specific antiserum or by determining nucleotide and amino acid sequences. Poliovirus type 1, strain Mahoney [PV1(M)] was the first picornavirus genome whose sequence was determined in its entirety. Representative strains of the three serotypes have subsequently been sequenced and found to be highly homologous in both nucleotide and amino acid sequence. Moreover, microsequence analysis of all viral polypeptides has led to the establishment of a complete genetic map.

Numerous studies on the molecular biology of poliovirus, together with the elucidation of the primary structure and gene organization, and the development of means for genetic manipulation of its RNA genome (infectious cDNA) have led to the recognition of many biological processes that are representative of all picornaviruses and, indeed, of numerous plus strand RNA viruses belonging to entirely different families. First, the positive-stranded RNA genome is of messenger-sense polarity and is thus immediately infectious upon entry into the cell. Second, polioviruses have evolved a cap-independent translational mechanism which, coupled to their ability to inactivate cap-dependent translation of host cellular mRNAs, selectively promotes translation of their own genome. Third, while maintaining a monocistronic genome, they encode multiple polypeptides that are liberated by proteolysis from a single translation product, the polyprotein. Limited proteolytic processing yields precursor molecules that may serve a function distinct from those of their cleavage products. Here, unique properties of poliovirus structure and proliferation will be discussed in relation to viral and host cell metabolism.

Capsid Structure and Antigenicity

The poliovirus capsid has icosahedral symmetry and consists of 60 identical asymmetric protomers (**Fig. 1a**). Each protomer is composed of a single copy of each of the three nonidentical capsid proteins VP1, VP2 and VP3 (**Fig. 1b**). Five protomers are located in a pentameric arrangement around the fivefold symmetry axis. Twelve pentamers build up the complete virus capsid. At the interface between the pentamers, twofold and threefold symmetry axes are located (**Fig. 1a**). The smallest capsid protein, VP4, is located on the inner surface of the virion and is relatively disordered. The crystal structure of PV1 (Mahoney) revealed remarkable similarity to that of human rhinoviruses and spherical RNA plant viruses.

Although VP1, VP2 and VP3 differ in size and amino acid sequence, they have similar tertiary structures. Each capsid protein presents a common structural motif, an eight-stranded antiparallel β-barrel core (**Fig. 2A**). The loop extensions protrude from the surface of the virion where they may become well exposed, serving as the major antigenic sites of the virus.

The folding of the β strands gives the barrel the shape of a triangular wedge where the thin end of the

VP1 wedge is directed toward the fivefold axis, and the equivalent ends of VP2 and VP3 alternate around the threefold axis. The N-terminal extensions of the capsid proteins (including VP4) form an intertwined network of connections in the interior of the capsid shell which contributes largely to its stability. Of significance is the interaction of the N-termini of five subunits of VP3 around the fivefold axis to form a five-stranded twisted tube, described as a 'β cylinder' which in turn interacts with five two-stranded β-sheets formed by the N-termini of VP4. Proteolytic processing of the P1 capsid precursor is *a priori* in this assembly pathway because the N-termini of VP3 and VP1 must be freed before pentamer formation. Additional factors may favor stability of capsids in the assembly process. One notable example is a myristic acid moiety, covalently attached to the N-terminal Gly of VP4. Myristate forms an integral part of the interior protein shell of the virion. Myristate groups are thought to stabilize the association of N-termini of VP4 with the β cylinder at the fivefold axis by interacting with amino acid sidechains of VP4 and VP3.

The exterior of the virion is marked by the already mentioned protrusions, by 'broad plateaus' and 'deep crevices'. One notable surface feature is a depression or 'canyon' formed at the junction of VP1 and VP3, encircling the fivefold axis. The 'canyon' is the receptor binding site on the virion for human rhinovirus 14 (HRV14) and for polioviruses (see next section). A number of drugs known as 'WIN compounds' have been reported to inhibit attachment of HRV to the cellular receptor or uncoating, the effect depending on the type of rhinovirus. These compounds insert into a hydrophobic pocket which lies just beneath the floor of the canyon. Drug binding induces a conformational change in this pocket that inhibits virus binding to the cellular receptor. Interestingly, in PV1 (Mahoney), the hydrophobic pocket appears to be occupied by a sphingosine-like molecule. Whether this lipid is a cofactor in assembly or disassembly remains to be seen.

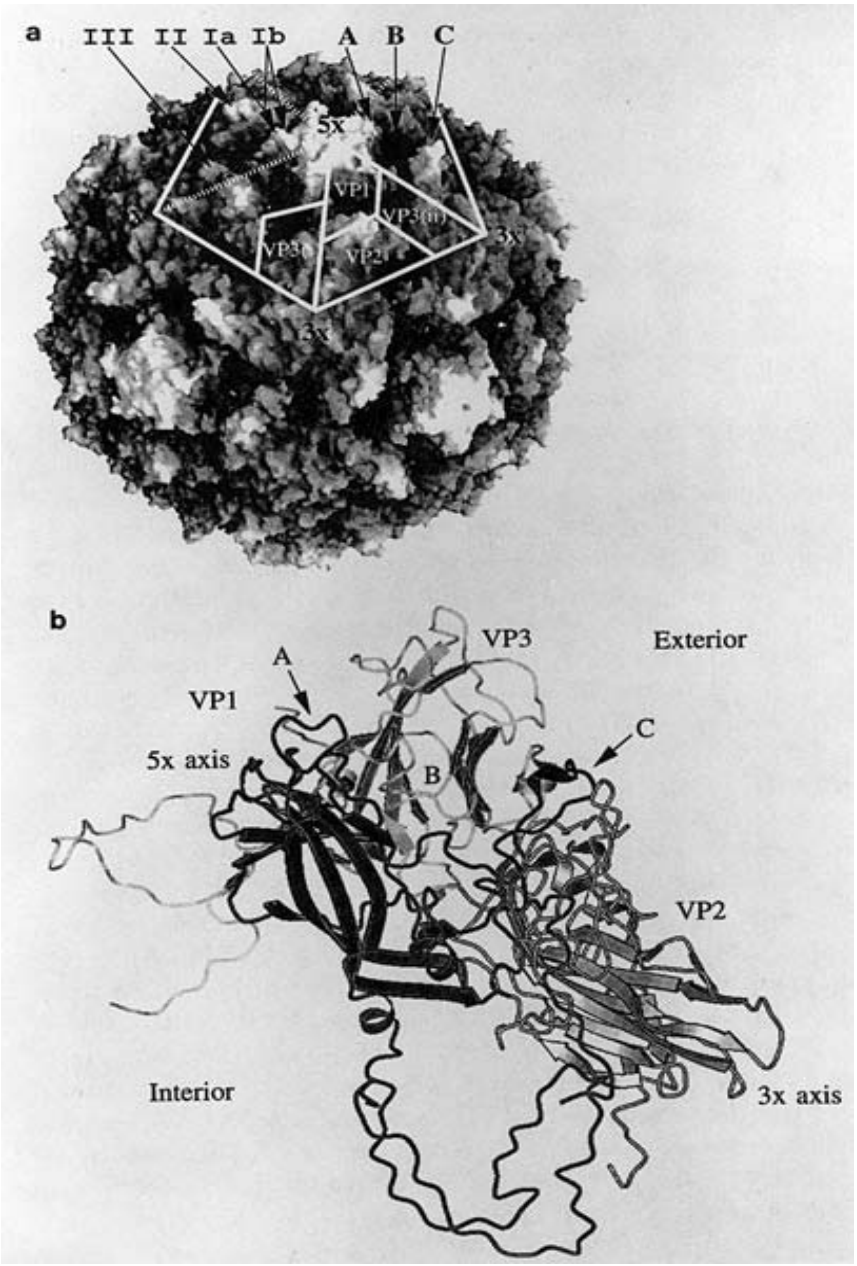

Figure 1 Structure of the poliovirion and its protomer. A complete capsid structure of PV1(M) illustrated as a water-accessible molecular surface. One of the 12 pentameric subunits of the capsid and its five constituent triangular pseudoprotomeric subunits are illustrated. The 5× and 3× labels indicate the locations of the fivefold and the threefold axes of this pentamer. The twofold axes occur at the intersection of the three adjacent pentamers. The central pseudoprotomer illustrates the subunit geometry of VP1, VP2 and VP3 (ii). The biologically relevant protomer (to viral assembly) is pear-shaped and consists of VP1, VP2, and VP3 (i). The internal VP4 protein is not visible from the surface. The canyon's north wall (A), south wall (C), and bottom (B) are indicated. The major antigenic sites to which neutralizing antibodies bind, are labeled Ia, Ib, II, III on an adjacent pseudoprotomer.

Neutralization antigenic sites (N-Ags) on the surface of the virion have been identified with neutralizing monoclonal antibodies that selected neutralization 'escape mutants' among the virus population. These escape mutants are resistant to neutralization; sequence analyses of the capsid proteins identified the site responsible for escape. The escape mutations, by definition, are located at sites to which the neutralizing monoclonal antibody would bind in the case of wild-type virus. Such mutations are found in surface

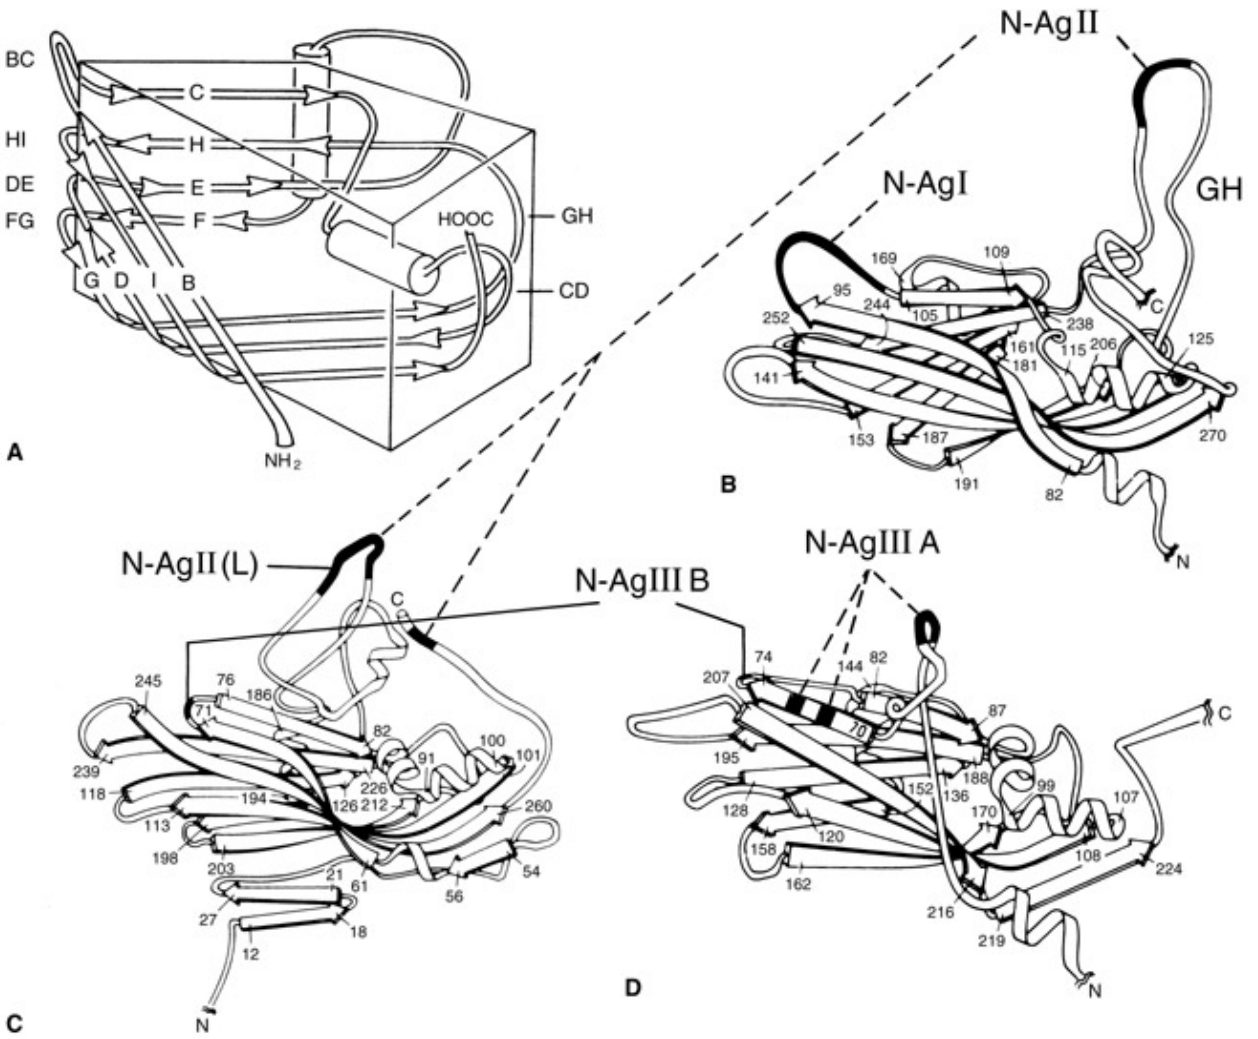

Figure 2 Schematic representation of the poliovirus capsid proteins. A common structural motif, an eight-stranded antiparallel β-barrel core, is shared among each capsid protein (**A**). Ribbon diagrams show (**B**) VP1, (**C**) VP2 and (**D**) VP3. Four neutralization antigenic sites (N-Ags) mapped to surface loop extensions are colored black. N-AgI is a continuous sequence of amino acids mapping to positions 95–105 of VP1. N-AgII is discontinuous, being composed of amino acids 221–226 of VP1 and of amino acids 164–172 and 270 of VP2. N-AgIII is composed of two independent sites, IIIA and IIIB. N-AgIIIA consists of amino acids 58–60 and 71–73 of VP3, whereas N-AgIIIB consists of amino acid 72 of VP2 and 76–79 of VP3. Note that N-AgI and N-AgII may also be subdivided, but the divisions are less distinct than those in N-AgIII.

loop structures or adjacent β strands on the exterior of the virion. Four neutralizing antigenic sites (N-Ags I, II, IIIA and IIIB) are known to map to the capsid proteins, VP1, VP2 and VP3 (**Fig. 2B, C, D**). The B–C loop of VP1 is a continuous sequence of amino acids (95–105) which maps to N-AgIA. Remarkably, this sequence can also carry determinants for poliovirus host range. A hybrid virus containing a six amino acid replacement in the N-AgIA site of PV1 (Mahoney) with that of PV2 (Lansing) can confer neurovirulence in mice. More strikingly, this sequence of ten amino acids can be replaced by heterologous amino acids; in many cases, such manipulation does not lead to loss of viral proliferation. If the heterologous sequence is that of a neutralizing antigenic determinant of another virus, a poliovirus variant has been created that can induce immune sera to foreign infectious agents. Unfortunately, this strategy has not yet led to novel vaccines, as was originally anticipated.

Recent genetic and biochemical analyses have led to the conclusion that, unexpectedly, some neutralization antigenic sites of poliovirus participate in the binding of the cognate poliovirus receptor.

The Cellular Receptor CD155 of Poliovirus

The poliovirus infectious cycle is initiated by attach-

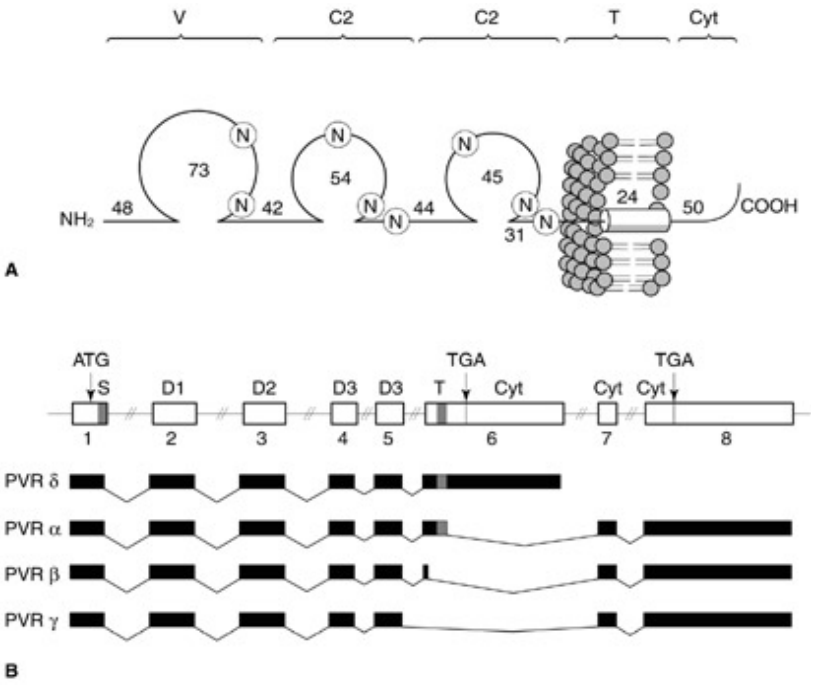

Figure 3 Structure of CD155/hPVRα and genetic organization of *CD155* isoforms α–δ. **(A)** The overall domain arrangement is indicated on top. The length of individual domains subdivided by the cysteine disulfide bonds characteristic for the immunoglobulin-like domains is indicated by numbers. Potential extracellular glycosylation sites are represented by circled 'N' symbols. **(B)**. Eight exons specifying the three extracellular domains (D1–D3), the signal peptide (S), the transmembrane region (T), and the cytoplasmic tail (Cyt) are displayed. ATG and TGA triplets determine the open reading frame for CD155 proteins. The composition according to the structure of their mRNA splice variants is indicated for each *CD155* isoform (PVRα–δ).

ment and internalization of the virus via a cellular receptor, followed by uncoating of the virus and release of the viral genome into the cytoplasm. Little is known regarding the mechanism of internalization, but the cloning and identification of the cellular receptor for poliovirus have greatly advanced knowledge of the first step of virus infection: attachment to the host cell. The cellular receptor for poliovirus (referred to as PVR and, more recently, as CD155) is a new member of the immunoglobulin (Ig) super gene family with three distinct Ig-like domains, arranged in the order, V-C2-C2, transmembrane and C-terminal cytoplasmic tail (**Fig. 3A**). The gene for CD155 has been extensively characterized; it is expressed in human tissues as four isoforms of which two are membrane-associated (and serve as poliovirus receptor), whereas the two other isoforms are secreted from cells (**Fig. 3B**). Monkeys express a homologue to CD155 that can serve as poliovirus receptor; hence, monkeys are susceptible to poliovirus infections. Mice also express a CD155 homologue. However, this protein does not bind poliovirus for which reason mice are resistant to poliovirus infection (except for some mouse-adapted virus strains that, upon injection, can kill a mouse).

All three serotypes of poliovirus compete for the same receptor; CD155, however, is not used by any other picornaviruses. Most recently, it has been reported that homologues to the human protein CD155 (*p*oliovirus *r*eceptor-*r*elated proteins PRR1 and PRR2) can serve as receptors for certain herpes viruses. The sequences of poliovirus receptor cDNAs predict protein(s) of ca. 46 kDa. However, the real splice isomers of CD155 are proteins of $\geq$80 kDa, an increase due to *N*-glycosylation of eight potential sites on the extracellular portion of the polypeptide chain. Serial deletion of the Ig-like domains of the receptor molecule has demonstrated that the V-domain is both necessary and sufficient for virus binding and infection, although the presence of the C2-domains augment this interaction. Hybrid receptor molecules have been constructed whereby the CD155 V-domain was fused to a truncated ICAM-1 molecule (the receptor for the major human rhinovirus group) or to the CD4 molecule (the receptor for the human immunodeficiency virus, type 1). These hybrid molecules are functional poliovirus receptors, confirming the V-domain as the major virus binding site. Detailed analyses of the poliovirus/CD155 interaction has identified regions in the V-domain that are likely contact points between the binding partners.

Tissue tropism, a term defining susceptibility of

specific tissues to infection with a virus, has been generally attributed to the presence or absence of receptor(s). Polioviruses display a restricted tissue tropism. They infect predominantly cells in the nasopharynx, Peyer's patches of the gut and the motor neurons in the CNS. Northern blot analyses, however, have suggested that the expression of receptor-related mRNA in human tissues is more widespread than was expected from tissues supporting poliovirus infection. Currently, this conundrum has not been solved.

As mentioned, mice are resistant to poliovirus infection (with the exception of specific mouse-adapted viral strains). Mice transgenic with the CD155 gene (CD155 *tg* mice) have been generated and they have been found to be susceptible to all three serotypes of poliovirus. However, for unknown reasons the CD155 *tg* mice cannot be infected via the oral route with poliovirus. Intramuscular, intravenous or intraspinal injections of poliovirus in the CD155 *tg* mice lead to a syndrome that is indistinguishable from human poliomyelitis (flaccid paralysis or death). Thus, although not a precise animal model for poliomyelitis, CD155 *tg* mice have served as highly valuable agents to study poliovirus pathogenesis.

The role of CD155 in docking the virus to the cell surface is undisputed. However, details of the steps subsequent to docking – uptake and uncoating – are largely obscure. Nevertheless, the interaction between cell-associated receptor and virus has a profound effect on the structure of the virion, a phenomenon that can be reproduced with purified CD155 and purified virus. Physical characteristics associated with the structural rearrangements of the virion are: altered sedimentation rate (160S to 135S), change in antigenic properties, loss of viral capsid protein VP4, and extrusion of the N-terminus of VP1. The irreversible process leads to the so-called 'A-particle'. The 'A-particle' is significantly more hydrophobic than the parental derivative and, as a result, it is able to attach to membranes. The affinity to lipids which is absent from virions, has been attributed to the N-terminal 30 amino acid residues of VP1 which may form an amphipathic helix. Currently, it is believed that endocytosis is the first step of uptake. It is possible that the hydrophobic N-termini of the VP1 molecules may make contact with the endosomal membrane, thereby building a pore through which the RNA is extruded into the cytoplasm.

Based on these considerations, it can be concluded that CD155 plays a dual role in the early steps of poliovirus infection: binding the virus to the cell surface, and 'unlocking' the integrity of the virus to allow ultimately escape of the viral genome into the cell cytoplasm. This CD155-mediated destabilization of the virus makes sense: poliovirus is extraordinarily stable to acid pH and proteases, as would be necessary for an enteric virus passing through the stomach (pH 2) on route to the intestines. Uptake into an endosomal compartment whose pH does not go below 5, would not change the virus structure and, consequently, would not lead to infection. Indeed, Fc-receptor-mediated uptake of poliovirus is nonproductive.

The Poliovirus Genome

The 'brain' of poliovirus is its genome, a single copy of single-stranded RNA, approximately 7500 nucleotides (nt) in length (**Fig. 4**). Generally, storing genetic information in RNA rather than in DNA is a poor choice since RNA is chemically less stable than DNA, even at physiological pH. Second, on entry into the cell, RNA genomes face numerous cytoplasmic and nuclear enzymes that may degrade, splice, or modify them. Third, RNA viruses cannot use cellular proofreading and editing functions to eliminate errors occurring spontaneously during genome replication at the astoundingly high rate of ca. 10^{-4} per nucleotide incorporated. RNA viruses must, therefore, live with high mutation rates. All RNA viruses, poliovirus included, have responded to these predicaments by minimizing the size of their genomes. Thus, most RNA virus genomes are $\leq$15 000 nt in length. The small genome size and the high spontaneous mutation rate has the advantage of rapid replication and swift adaptation to a new environment, respectively (for example, resistance to a drug). It has the disadvantage that these viruses must exist under conditions of extreme genetic austerity (limited coding capacity for proteins).

The heteropolymeric region of the PV1, PV2 and PV3 genomes is 7440 nt, 7439 nt and 7434 nt long, respectively. All serotypes carry at the 3′ end polyadenylic acid on the average 60 nt long. The 5′ end is covalently linked to the small, virus-encoded protein VPg. VPg is only 22 amino acids long; its third amino acid is tyrosine whose O^4 hydroxyl group is esterified to the 5′ terminal phosphate of the genome [O^4-(5′-uridylyl)tyrosine bond) such that the general structure of the 5′ end is VPg-pUU... This terminus is invariant among all picornavirus genomes.

The first 88 nucleotides of the genome form a cloverleaf structure that is an essential *cis*-acting signal for genome replication. It is followed by the *i*nternal *r*ibosomal *e*ntry *s*ite (IRES) of roughly 400 nt, a complex structure regulating translation. The IRES is separated from the long open reading frame (ORF) of the polyprotein by a spacer of 154 nt. Poliovirus

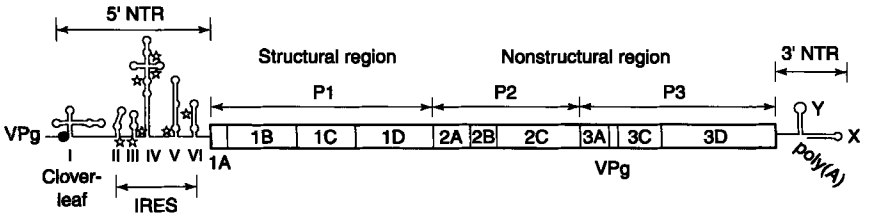

Figure 4 Genomic structure of poliovirus. The single-stranded RNA of poliovirus is shown with the genome-linked protein VPg (3B) at the 5′ end of the nontranslated region (5′ NTR, single line) and the 3′ NTR (single line) with the poly(A) tail. The boxed region shows the ORF and vertical lines within the box indicate proteinase cleavage sites within the polyprotein. The locations of the structural (P1) and nonstructural (P2, P3) region is shown on top. RNA structural domains within the 5′ nontranslated region are shown by Roman numerals; cloverleaf (I), IRES (II–VI). Stars indicate the positions of noninitiating AUG triplets. The stem–loop structures within the 3′ NTR are labeled with the letters X and Y.

encodes only one polypeptide, the polyprotein. The ORF is followed by the 3′ nontranslated region (3′NTR) that consists of 65 heteropolymeric nucleotides forming a complex double stem–loop structure, and, finally, the poly(A) tail (**Fig. 4**). Details of the function of the different sections of the viral genome are presented below.

Translation

Following uncoating of the virus in the cytoplasm, the plus-stranded RNA serves as mRNA to translate its single ORF. However, the elucidation of the genome structure of poliovirus led to the surprising discovery that poliovirus mRNA lacks some essential *cis*-acting signals common to all eukaryotic cellular mRNAs.

All eukaryotic mRNAs carry at their 5′ end a 'cap' which consists of a methylated guanosine nucleotide (m^7GpppNp...). Initiation of translation depends on recognition of the cap by, and binding of, a specific initiation factor (eIF-4) that subsequently recruits the 40S ribosomal subunit. The 40S ribosomal subunit, once associated with the mRNA, is then thought to 'scan' along the 5′ nontranslated region (5′NTR) of the mRNA until the first AUG triplet in a 'favorable context' is encountered where it pauses to assemble to a mature initiation complex. Poliovirus mRNA, however, displays a number of unique features that differ from the paradigm of the eukaryotic mRNA. In place of the cap structure, the 5′ end of poliovirus genomic RNA is covalently bound to VPg that, in fact, is removed by an unknown cellular enzyme from those viral RNA molecules destined to engage in protein synthesis. Thus, poliovirus mRNAs found in polysomes have a pUp.... 5′ terminus (note that poliovirus genomic RNA and mRNA are identical except for the presence or absence of VPg, respectively).

In addition to its unconventional pUp... terminus, poliovirus genomic RNA (= mRNA) also contains an unusually long 5′NTR of 743 nt whereas the 5′NTRs of its eukaryotic counterparts are on the average only 50–100 nt in length. In view of the fact that viral genomes tend to be small for reasons discussed above, such a long segment of noncoding viral RNA is highly unusual. Moreover, the poliovirus 5′NTR contains secondary structures that are thought to be sufficiently stable to obstruct ribosome scanning toward the initiation codon (**Fig. 4**). Finally, eight AUG codons are scattered throughout the 5′NTR preceding the initiating AUG at nucleotide 743. At least one of these AUGs is in a correct nucleotide context for efficient translation by the criterion of Kozak yet it appears to be silent.

Given these observations, it appeared likely that polioviruses (and, by analogy, all picornaviruses) use a method for initiation of protein synthesis that is radically different from that of cap-dependent eukaryotic mRNAs. Since polioviruses translate their RNA under conditions where cap-dependent translation is inactivated (see later), it was speculated that translational initiation is independent of the viral 5′ end altogether. Evidence in support of this hypothesis was obtained by constructing dicistronic mRNAs in which the first and second cistron were separated by a segment of the 5′NTR of poliovirus or EMCV (cellular 5′NTR-CISTRON 1-picornavirus 5′NTR-CISTRON 2). It was found that translation of the second cistron occurred independently of the first cistron, an observation suggesting that ribosomes could bind to a region of the viral 5′NTR placed downstream of the first cistron, and direct translation of the second cistron.

The genetic element in the 5′NTR of picornaviruses that was discovered to be necessary and sufficient to direct internal ribosomal binding was termed 'IRES', an acronym for *i*nternal *r*ibosomal *e*ntry *s*ite. All picornaviruses contain IRES elements in their respective 5′NTRs. Indeed, even the genome of hepatitis C virus, a flavivirus, contains an IRES

element. Although the function of IRES element as an internal ribosomal entry site *in vivo* was convincingly shown by expression of suitable dicistronic mRNAs in COS-I cells, final proof for 5′-independent initiation of translation was provided by an analysis of a dicistronic poliovirus containing two distinct IRES elements, one of poliovirus, the other of encephalomyocarditis virus (EMCV), a picornavirus belonging to the genus *Cardiovirus* (**Fig. 5**). Remarkably, IRES elements from different picornaviruses, or that of HCV, may not show any apparent homology in sequence and structure (**Fig. 5**). Yet, these elements function in a similar manner, a phenomenon which is demonstrated best by the fact that the cognate IRES of poliovirus can be replaced with that of EMCV, thereby generating a virus that replicates with near wt kinetics. Thus, the term IRES refers to function, not to specific structural features.

Indeed, small deletions and point mutations have profound effects on the efficiency of translation indicating that the structural integrity of the IRES element is of paramount importance. The identification of a large region of nucleotides defining the IRES elements argues for the occurrence of long-range tertiary interactions between *cis*-acting nucleotide elements and *trans*-acting factors.

The mechanism by which IRES elements function is still obscure. The minimal length for efficient function is roughly 400 nt, and some of the domains of the overall IRES structure are more sensitive to mutation than others. *Cis*-acting sequence elements have been identified that are required for IRES function. For example, all picornavirus IRESes contain an essential Y_n-X_m-AUG motif where Y is pyrimidine, n = 6–8, X is any nucleotide and m = 18–20 nucleotides). This Y_n-X_m-AUG motif may play an important role in ribosome entry. In the poliovirus IRES the Y_n-X_m-AUG motif is separated from the downstream-initiating AUG by a spacer sequence of 154 nucleotides, whereas in the EMCV IRES, the AUG of the Y_n-X_m-AUG motif is the codon from which polyprotein synthesis is initiated (see **Fig. 5**).

Depending on the origin of the element, specific sets of canonical cellular initiation factors for protein synthesis are required for IRES function. Surprisingly, cellular proteins not known to be involved in cellular protein synthesis are required as *trans*-acting factors for IRES function. The number of these cellular factors seems to be rising and their role in IRES translation has been deduced only by biochemical approaches. Genetic evidence for absolute requirement of these cellular proteins is as yet lacking. For polio- and rhinoviruses, the list of cellular factors includes: *PTB* (p57, polypyrimidine track binding protein); *PCBP1, 2* (p38, polycytidine binding protein 1 and 2); *unr* (p96; *u*pstream of *N-r*as) that is complexed to *unrip* (p38; *unr*-interacting protein), and *La* (p52, *La* auto antigen).

Little is known about tissue-specific expression of cistrons under the translational control of IRES elements. However, it has been known for some time that the IRES elements of entero- and rhinoviruses do not function well in cell-free lysates of rabbit reticulocytes (RRL). This property has contributed to the discovery of IRES elements. Presumably, RRL lacks (or is in short supply of) cellular factors for efficient function, and *unr* and *unrip* have been suggested to be responsible for this *in vitro* 'tropism' effect.

Two other cases are noteworthy. First, the attenuated vaccine strains of poliovirus (the Sabin strains) have been shown to carry point mutations in the IRES that contribute to a decrease of these strains to proliferate in cells of neuronal origin. Specifically, each vaccine strain harbors a single attenuating point mutation in domain V of the poliovirus IRES. Whereas there is no doubt about the significance of these mutations it is important to realize that the genomes of the vaccine strains contain many more mutations important for the attenuation phenotype. Second, a virus hybrid in which the cognate IRES element has been replaced by that of human rhinovirus type 2 (HRV2), has been found to be highly attenuated in *CD155 tg* mice and in *Cynomolgus* monkeys. On the other hand, the hybrid virus, called PV1(RIPO), replicates in human transformed cell lines, such as HeLa cells, with *wt* kinetics. The locus for this host range effect has been mapped to domains V and VI of the poliovirus IRES.

Proteolytic Processing of the Poliovirus Polyprotein

The poliovirus genome is monocistronic encoding a single polyprotein of 247 kDa. The polyprotein is highly unstable and will undergo multiple steps of proteolytic cleavages to yield functional structural and nonstructural proteins (**Fig. 6**). This strategy of gene expression is characteristic for most positive-strand RNA viruses and for all retroviruses. It allows maximal exploitation of genetic information under conditions of genetic austerity.

The poliovirus structural proteins encoded in the N-terminal half of the genome are four nonidentical polypeptides encoded in the order VP4-VP2-VP3-VP1. They are products of proteolytic processing of the capsid precursor P1. VP4 and its precursors VP0 and P1 are myristoylated at the N-terminus. Apart from VPg uridylylation (see below), myristoylation is the only other known modification of a polioviral

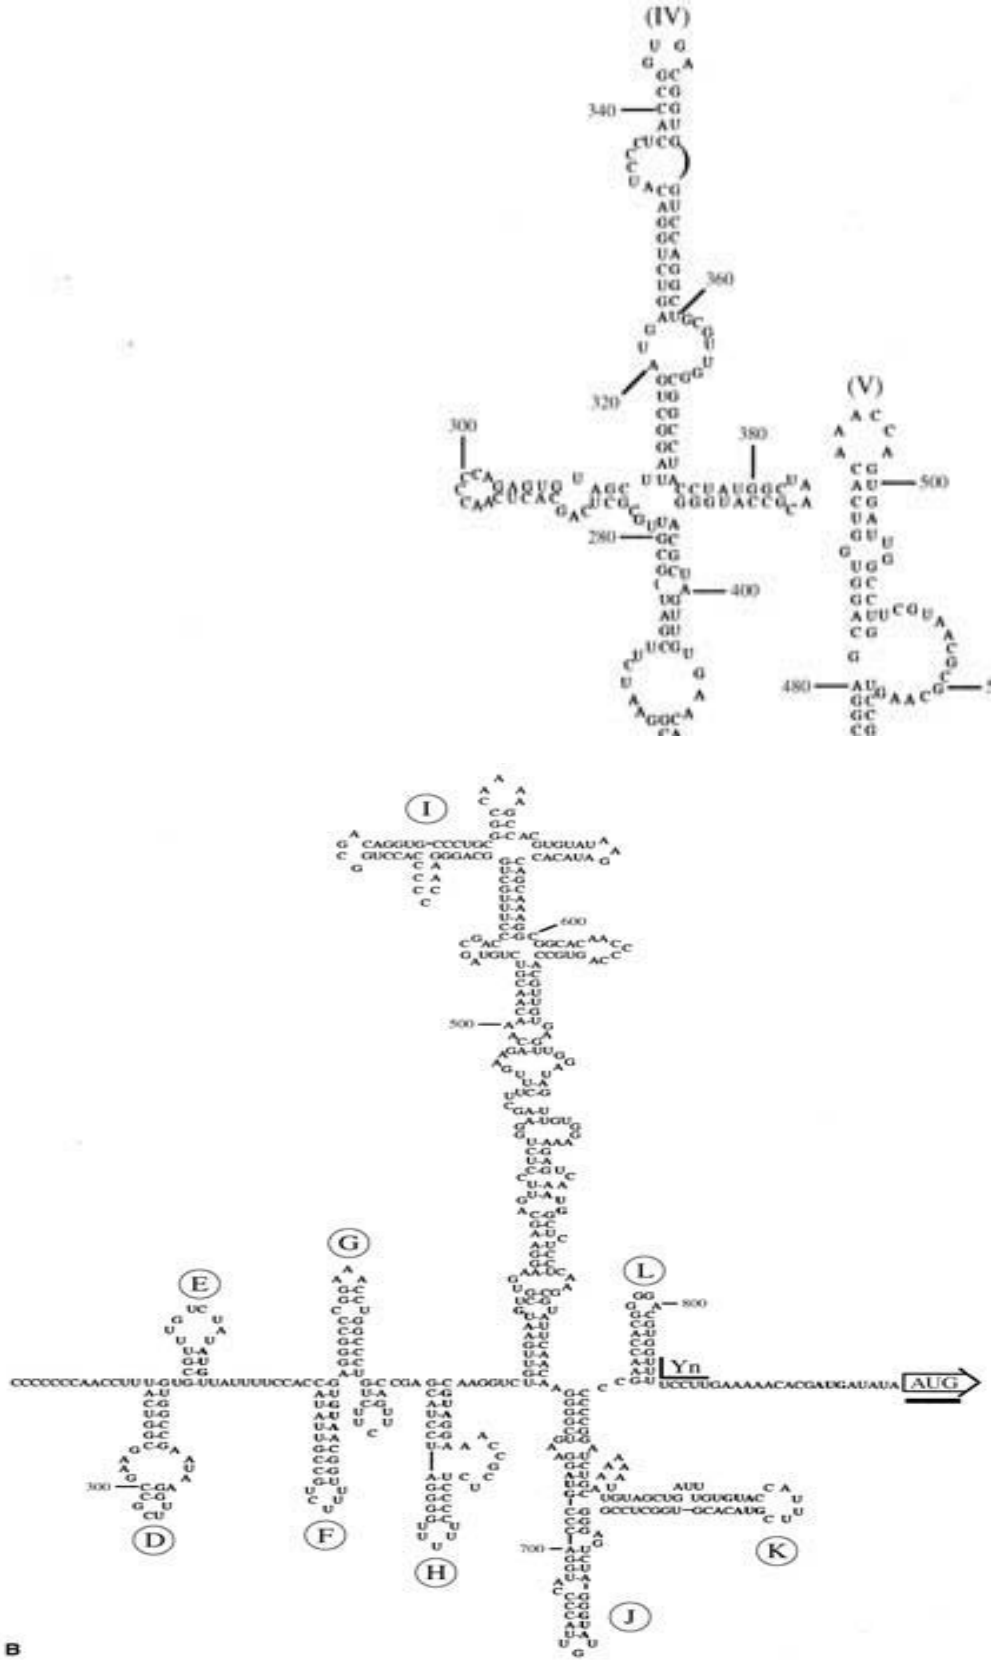

Figure 5 Comparison of the secondary structures of (**A**) poliovirus type 1 IRES element and (**B**) EMCV type 2 IRES element. Stem–loop structures are labeled with Roman numerals and letters. Yn and AUG of the YnXmAUG motif are indicated by thin and thick bars, respectively. The position of the start codons are indicated by arrows. The mutation at nt 480 (A to G) in PV1 IRES confers attenuation in the Sabin strains of PV1.

Figure 6 Processing scheme and cleavage sites of the poliovirus polyprotein. (**A**) Proteolytic cleavages of the polyprotein. Triangles indicate cleavage by $3C^{pro}$ and/or $3CD^{pro}$. Solid triangles represent efficient cleavage sites, whereas open triangles represent slowly cleaved sites resulting in stable precursor proteins. The $2A^{pro}$-mediated cleavages are depicted with circles. Only the cleavage between P1 and P2–P3 (solid circle) is essential, whereas the cleavage of $3CD^{pro}$ in 3C′ and 3D′ is dispensable (open circle). The maturation cleavage is indicated by the open diamond. Numbers in brackets indicate the molecular weight in kDa. The amino acid residues at sites cleaved (**B**) by $3C^{pro}$ and/or $3CD^{pro}$, (**C**) by $2A^{pro}$ and (**D**) by an unknown mechanism (maturation cleavage) are shown by single-letter code. The positions of the amino acid residues are designated P1, P2, P3... at the newly generated C-termini, or P1′, P2′, P3′... at the newly generated N-termini.

polypeptide. The downstream P2 and P3 precursors encode the nonstructural proteins of which all are involved in genome replication and/or processing. As endproducts of processing, the P2 region yields polypeptides $2A^{pro}$ (a proteinase), 2B, and $2C^{ATPase}$, whereas the P3 region yields polypeptides 3A, $3B^{VPg}$, $3C^{pro}$ (a proteinase) and $3D^{pol}$, the RNA polymerase (**Fig. 6**). However, intermediates in the processing pathway fulfill important functions on their own, such as 2BC, 3AB, and $3CD^{pro}$.

Proteolysis of the polyprotein can be divided into three steps. The first step is to cleave the P1 capsid protein precursor from the nascent polyprotein. This primary cleavage event is catalyzed by the viral proteinase $2A^{pro}$. The second step is to process P1 into the structural proteins and to process the P2-P3 precursor into the nonstructural proteins. These reactions are catalyzed by $3C^{pro}$ and its precursor $3CD^{pro}$. The third step is the processing of VP0 into VP4 and VP2 ('maturation cleavage') which takes place at the time of encapsidation of the viral RNA. The catalyst for this event has not been identified, but it is unlikely to involve any of the aforementioned viral proteinases.

Proteolysis of the polioviral polypeptide occurs in a temporally controlled fashion. Moreover, precursor polypeptides liberated first may execute specific functions early in the viral life cycle, but are subsequently cleaved to mature proteins that have separate functions. Polypeptide $3CD^{pro}$, an RNA binding protein and important proteinase, is an example of this dual function that extends the genetic

content of the virus (see later). $3CD^{pro}$ that itself has no RNA polymerase activity, is slowly cleaved to $3C^{pro}$ and the all-important RNA polymerase $3D^{pol}$.

Substrate recognition by the poliovirus proteinases is highly restricted to viral proteins and only a few heterologous polypeptides of the cell are cleaved (see later). Proteinase $2A^{pro}$ cleaves at only two of the 10 Tyr-Gly dipeptides in the polyprotein. The first site is at the junction of VP1 and 2A and is cleaved in *cis*, whereas the second site (within the RNA polymerase, $3D^{pol}$) is cleaved in *trans* yielding products 3C′ and 3D′. This latter cleavage may be adventitious, since these cleavage products are not necessary for viral replication or proliferation. Alignment of $2A^{pro}$ cleavage sites (**Fig. 6**) shows the prevalence of a Thr residue in the P_2 position and a Leu in the P_4 position (the newly generated C terminus of a peptide bond is designated P_1, followed by the P_2, P_3, etc. residues; the newly generated N-terminus is designed P_1, followed by P_2', P_3' etc. residues). Site-directed mutagenesis of cleavage site residues suggests that the requirements for recognition of a cleavage site by 2A in *trans* are more stringent than for recognition in *cis*.

Cleavage by $3C^{pro}$ or $3CD^{pro}$ in the poliovirus polyprotein occurs exclusively at Gln-Gly dipeptides (a single exception occurs in a mouse-adapted W2 strain), but residues at positions flanking the scissile bond are mostly heterogeneous (**Fig. 6b**). Exceptions are found in the P_4 position where an Ala or other small aliphatic amino acids prevail, and to a lesser extent the P_2' position of efficiently cleaved sites, where Pro residues prevail. Only nine of 13 Gln-Gly dipeptides in the polyprotein are cleaved, an observation indicating that there must be additional determinants of cleavage site recognition. In principle, the sequence of the cleavage site determines the kinetics of cleavage. This, in turn, determines the half-life of precursor polypeptides which is very important if the precursors are to be used for special functions (see below).

Oligopeptide substrates that mimic dipeptide $3C^{pro}$ or $3CD^{pro}$ cleavage sites are cleaved *in vitro* with an efficiency that parallels the efficiency of cleavage *in vivo*. Peptides corresponding to the 2B/2C site were cleaved rapidly, whereas those corresponding to the 3A/3B and 3C/3D sites were hydrolyzed slowly or not at all. The contribution of residues flanking the scissile bond to recognition by $3C^{pro}$ or $3CD^{pro}$ has been assessed by site-directed mutagenesis of polyprotein substrates and by varying the length and composition of peptide substrates. There is a minimum substrate requirement of six or seven residues for peptide substrates to ensure cleavage; although the efficiency of cleavage increases as substrate length increases further. Experimental evidence obtained both *in vitro* and *in vivo* indicates that the P4 position regulates the efficiency of cleavage. Thus, a peptide mimicking the 3CD site was cleaved at least 100 times more efficiently following substitution of the wild-type Thr residue by Ala. The inefficient cleavage at specific sites leading to accumulation of stable precursors *in vivo* is significant, since some precursor polypeptides such as $3CD^{pro}$ have been shown to have roles (proteinase and RNA binding protein) that are distinct from those played by their constituent moieties (i.e. RNA polymerase $3D^{pol}$) after proteolytic scission. In addition to specificity at the primary amino acid level, additional determinants are dictated at the structural level. Experimental evidence supports that the entire P1 precursor is required for cleavage at Gln-Gly pairs within the structural precursor P1. Furthermore, the proper folding of the P1 (barrel structure) is required for efficient cleavage at Gln-Gly pairs. Therefore, it is likely that primary substrate recognition by $3C^{pro}$ leads to the specificity for the Gln-Gly pair whereas differences in residues flanking this dipeptide in concert with structural determinants mediate efficiency of cleavage.

Both $2A^{pro}$ and $3C^{pro}$ have been classified as cysteine proteinases since they are inhibited by iodoacetamide and *N*-ethylmaleimide, two agents blocking proteases with an active-site thiol group. On the other hand, sequence alignment and tertiary structure modeling have suggested that the picornavirus proteinases are structurally related to the cellular trypsin-like serine proteinases. On this basis, an evolutionary relationship has been proposed whereby the nucleophilic Ser residue in the catalytic triad of the cellular enzyme is replaced by a Cys residue in the equivalent viral proteinase. Site-directed mutagenesis has confirmed the proposed constituents of the catalytic triad of the poliovirus proteinases as His20, Asp38 and Cys109 for $2A^{pro}$ and His40, Glu71 and Cys147 for $3C^{pro}$. The predictions have been confirmed by the solution of the crystal structure of several picornavirus $3C^{pro}$ proteinases.

The third and final proteolytic processing step in the poliovirus replicative cycle is the cleavage of VP0 into VP4 and VP2 at an Asn-Ser site. It occurs during the final stages of virion assembly, probably after RNA encapsidation. It is not yet known what catalyzes this cleavage event, although the participation of $2A^{pro}$ or $3C^{pro}$ is unlikely since the cleavage site specificity is different from those recognized by either proteinase. It has been suggested that cleavage of VP0 may occur autocatalytically.

Finally, it has been possible to construct a dicistronic poliovirus in which the ORF of the polyprotein has been genetically disrupted at the P1*P2 junction by 602 nucleotides containing the

EMCV IRES element. This poliovirus whose genotype is (*PV*)5′NTR-P1-(*EMCV*)IRES-(*PV*)P2-P3-3′NTR grows well in HeLa cells albeit with a small plaque phenotype. Clearly, the primary cleavage is no longer required in this viral construct as the capsid precursor P1 has been genetically separated from the rest of the viral polyprotein by engineering a termination codon into the C-terminal region immediately after the C-terminal Gln residues of P1. The EMCV IRES, in turn, allows initiation at the beginning of the $2A^{pro}$ coding sequences by the use of an engineered AUG codon. This dicistronic virus is interesting for several reasons. First, as mentioned before, it provided the first conclusive evidence that IRES elements function *in vivo* as predicted from biochemical studies. Second, it represented a truly dicistronic plus strand RNA virus for which there is no other example (since mammalian mRNAs are for the most part, monocistronic, the dicistronic mRNA is a biological oddity). Third, the general gene organization of the dicistronic virus is reminiscent of that of the comoviruses. These plant viruses are closely related to the picornaviruses except that there P1 coding sequence is encoded by a separate gene segment (dipartite virus). Fourth, the viability of the dicistronic poliovirus described above has encouraged experiments in which the polyprotein was interrupted with the EMCV IRES at every site of proteolytic processing of the poliovirus polyprotein (IRES scanning). Interestingly, only two IRES insertions are tolerated by the virus: that between P1*P2 and that between P1-2A*2B-2C-P3. This result has been interpreted to mean that precursors (e.g. 2BC) are absolutely required for viral proliferation. However, in some cases, the IRES insertion led to totally aberrant proteolytic processing products, a result indicating that proper folding of the polyprotein did not occur.

RNA Replication

The replication of the poliovirus RNA genome is exceedingly complex. Any model describing the mechanism of replication must accommodate the following facts.

1. The viral genome has two different termini (see **Fig. 4**) that may suggest different mechanisms for initiation of transcription.
2. The viral RNA polymerase $3D^{pol}$ is primer dependent.
3. The genome and even minus-stranded viral RNA (the template for genomic RNA synthesis) are VPg linked (see above).
4. Genome replication occurs in a membranous environment.

Numerous biochemical and genetic studies have shown that all nonstructural proteins are involved in poliovirus genome replication. Whether cellular polypeptides ('host factors') also play an essential role in this process has not yet been proven but there is a candidate protein that may qualify for such a task (see below).

The functions of the P2-encoded polypeptides $2A^{pro}$, 2BC, 2B, and $2C^{ATPase}$ are the least understood in poliovirus replication. Genetic evidence suggested that these proteins are essential for RNA replication. Their precise function on RNA replication is yet unknown. 2BC on its own has been shown to induce membrane rearrangements in the host cell that resemble those observed in poliovirus infected cells. $2C^{ATPase}$ contains a motif (motif 'C') that is conserved among superfamily III helicases. Whereas no helicase activity has been associated with $2C^{ATPase}$, an ATPase activity and specific and unspecific RNA binding abilities have been reported. The ATPase activity of $2C^{ATPase}$ has been identified as a function that is inhibited by low concentrations of guanidine hydrochloride (Gua-HCl; $\leq$2 mM). These low concentrations of Gua-HCl were known for decades to inhibit picornavirus RNA replication. By growing poliovirus in the presence of inhibiting levels of Gua-HCl, it was possible to select viral variants that displayed guanidine resistance (g^r) or dependence (g^d). Characterization of resistant mutants identified a single mutation, Asn179-Gly, in $2C^{ATPase}$ as sufficient to render a guanidine-sensitive (g^s) virus g^r. $2C^{ATPase}$ is an example for the multifunctionality of many polioviral proteins as a consequence of genetic austerity: $2C^{ATPase}$ contains the determinants for vesicle induction (see below), is involved in initiation and elongation of RNA synthesis, and functions during RNA encapsidation and virus uncoating.

Biochemical and genetic studies of the P3 polypeptides in genome replication have yielded more information than those of P2 protein. 3AB is a nonspecific RNA binding protein that interacts specifically with both $3CD^{pro}$ and $3D^{pol}$. 3AB stimulates the polymerase activity of $3D^{pol}$ *in vitro* and may thus be a cofactor during RNA synthesis. VPg (=3B) is the primer for the RNA polymerase (see below). $3C^{pro}$ is a proteinase whose function in RNA replication may only be expressed as $3CD^{pro}$. The latter is an RNA binding protein in conjunction with 3AB (or a 'host factor', see below) and the most active proteinase encoded by the virus. $3D^{pol}$ is an RNA polymerase, that is dependent on a primer and an

RNA template. In the process of RNA elongation, $3D^{pol}$ has unwinding activity.

A hallmark of all RNA molecules synthesized by the virus is that they are covalently attached to the genome-linked protein, VPg (3B) at their 5′ end, an observation suggesting that VPg may be a primer for initiation of both plus-strand and minus-strand RNA synthesis. Biochemical studies using membrane-associated replication complexes isolated from infected cells, and genetic data have led strong support for this model. Moreover, genetic data implicated the RNA polymerase $3D^{pol}$ in the first step of initiation: the synthesis of uridylylated VPg. This biochemical reaction has been reproduced recently in a reconstituted system using purified components. Uridylylation of VPg to VPg-pU, and elongation of this nucleotidylyl-peptide to VPg-poly(U) required synthetic VPg, bacterially expressed $3D^{pol}$, poly(A), UTP, and Mn^{2+} or Mg^{2+} cations. It has been proposed that this reaction occurs at the 3′-terminal poly(A) of poliovirus, leading to the synthesis of minus strands whose 5′ termini are indeed poly(U). The 3′ end of poliovirus [the stem–loop structures together with the poly(A)] has, therefore, been termed *oriR*, the origin of synthesis of minus-strand RNA.

What is the nature of the origin of synthesis of plus strand RNA which we will call *oriL*? Clearly, it was anticipated that the 3′ end of minus strands would constitute the *oriL*. It came as a big surprise when it was discovered that the 5′ end of plus strands, the 'cloverleaf', is an essential component of the *oriL*.

The 5′NTR of poliovirus stands out due to linkage to VPg and the complex structures of cloverleaf and IRES. Genetic evidence, supported by biochemical data, has revealed that the integrity of the cloverleaf of the plus strand plays a crucial role in plus-strand RNA synthesis. Computer-aided folding, phylogenetic studies, and biochemical probing has led to a model of the cloverleaf consisting of four domains Ia–d. The integrity of these domains is important for plus-strand RNA synthesis to occur.

Studies of the role of the cloverleaf were greatly advanced when a suppresser mutation to a linker insertion at nucleotide 68 in domain d of the cloverleaf was found to map to the coding region of $3C^{pro}$. This led to the important discovery that proteinase $3CD^{pro}$, in conjunction with a second protein, has the ability to form an RNP with the cloverleaf, a process that has been proven to be essential in poliovirus RNA synthesis.

Purified poliovirus $3CD^{pro}$ or $3C^{pro}$ do not, or only weakly, bind to RNA. However, in conjunction with an RNA binding protein, $3CD^{pro}$ will bind strongly to the cloverleaf. Currently, there are two candidate polypeptides that can augment the $3CD^{pro}$ RNA binding activity: viral protein 3AB and cellular protein PCBP2, the latter being a protein that also binds specifically to a segment within the IRES. Biochemical and genetic evidence carried out at the level of RNA and $3CD^{pro}$ support the role of either protein. Genetic analyses of 3AB revealed that this protein is crucial in the formation of the cloverleaf RNP involved in plus-strand RNA synthesis.

Semiconservative nucleic acid synthesis requires base pairing of the nascent strand to the template. Therefore, synthesis of minus-strand RNA leads to the formation of double-stranded (ds) RNA (**Fig. 7**). It has not yet been determined whether dsRNA is unwound immediately following its synthesis resulting in a predominantly single-stranded (ss) RNA of negative polarity, or whether dsRNA is stable until the next round of replication. Available evidence argues for the latter scenario. First, dsRNA (replicative form, RF) has been isolated from infected cells, and its role as an intermediate in RNA replication has been shown in kinetic experiments. Second, free minus-stranded RNA has not been detected in infected cells. Thus, only RF and RI contain minus strands in infected cells. Third, $3D^{pol}$ has unwinding activity during elongation indicating that the RNA replication mechanism encounters dsRNA. In contrast, helicase activity, that would unwind dsRNA in a polymerase-independent fashion, has not been found to be associated with any of the viral and cellular proteins involved in polioviral RNA replication.

There are two possible mechanisms for the initiation of plus-strand RNA synthesis. First, a preformed VPg-pU primer may be translocated from the 3′ end of the plus strand to the 3′ end of the minus strand. Second, uridylylation of VPg may occur with the 3′ end of minus strand as template. Initiation of plus strand RNA synthesis is expected to commence on the single-stranded 3′ termini of minus strands. It is possible that the left end of the RF (**Fig. 7**) serves as *oriL* whose heteroduplex structure, after recognition by the viral replication machinery, is destabilized by viral and cellular proteins. This would allow formation of the plus-sense cloverleaf RNP which, in turn, would liberate a free 3′ end of minus strands for initiation of plus-strand synthesis. This scenario is persuasively similar to the events leading to initiation of DNA synthesis in the replication of DNA viruses with protein-linked genomes, such as adenovirus. For example in the replication of adenovirus one viral (DNA binding protein) and three cellular polypeptides (two transcription factors and one topoisomerase) stimulate protein-primed DNA synthesis on a heteroduplex template. By analogy, the *oriL* of poliovirus RF could be destabilized by several viral

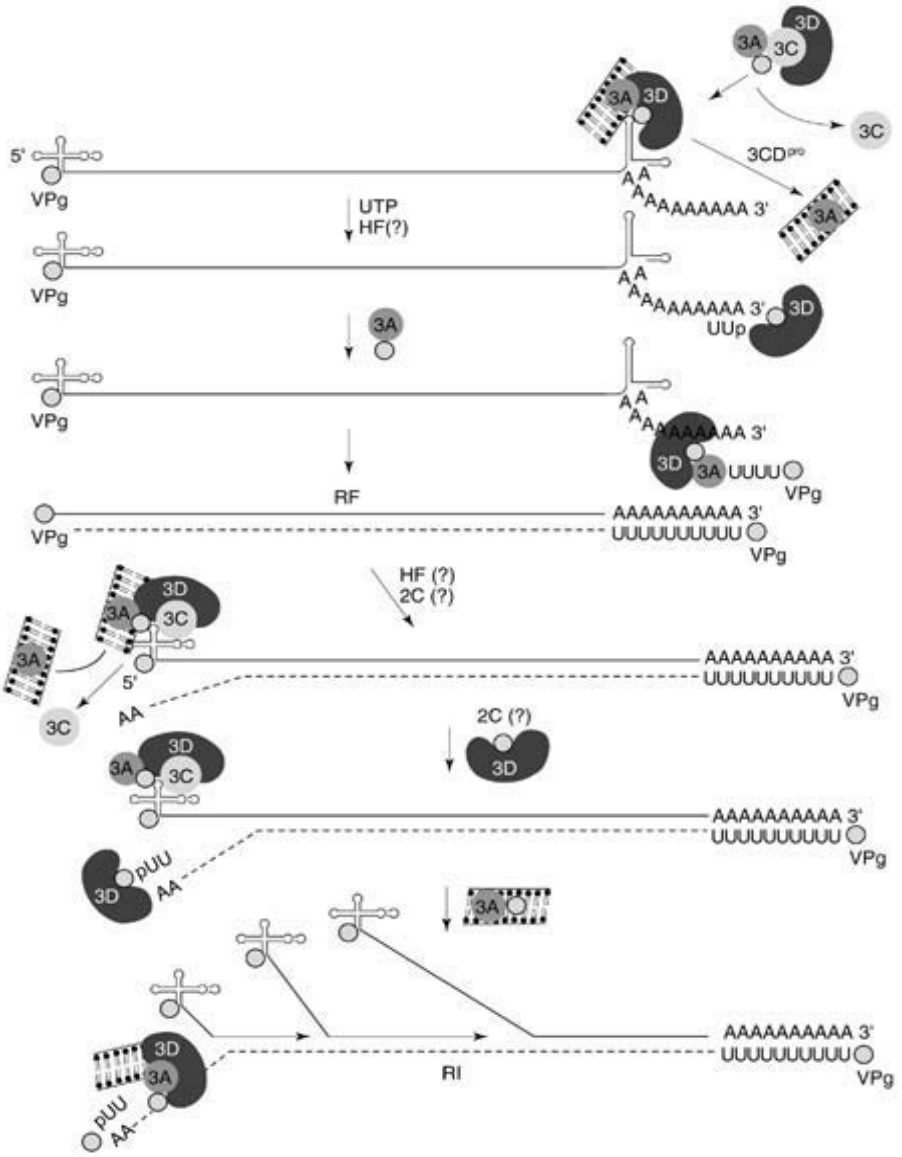

Figure 7 Models of poliovirus minus and plus-strand RNA synthesis. Plus-strand is shown with solid line, minus-strand with dashed line. The viral proteins involved in RNA synthesis and the details of the process are described in the text. The association of 3A and 3AB with membranes is indicated. RF, replicative form; RI, replicative intermediate; HF, putative host factor.

and cellular proteins, presumably those proteins that bind subsequently to the 5′ cloverleaf of plus-strand RNA or to the complementary 3′ cloverleaf of the minus-strand RNA. This hypothesis also provides an explanation for the bizarre requirement of the 3AB/3CD^{pro}/cloverleaf RNP at the 5′ end of plus-strand RNA for initiation of positive-stranded RNA. Apart from preventing annealing of the strands, the RNP may also aid in the recruitment of VPg and 3D^{pol} for uridylylation to occur at the 3′ end of minus strands, and for an influx of 3AB for stimulation of the elongation reaction. This speculation is based on the observation that many of the viral nonstructural proteins display homo- and heterobinding affinities to each other.

If the RF is the template for plus-strand synthesis, strand elongation and multiple rounds of initiation on the same minus-strand template will lead to the multistranded RI. What factors are responsible for the separation of the two RNA strands of the RF at the replication fork? As mentioned before, 3D^{pol} has RNA duplex unwinding activity while in the process of strand elongation. Thus, a requirement for a helicase in the replication fork, originally assigned

to $2C^{ATPase}$, may not exist. It should be noted that no helicase activity is used at any stage of protein-primed DNA synthesis on dsDNA templates by the polymerases of the DNA viruses. If this scenario is correct, it follows that the structure involved in the synthesis of plus strands may consist of a double-stranded backbone from which newly synthesized RNA strands emerge (**Fig. 7**). Such structure has been called 'replicative intermediate' (RI).

Considering the available information, the model of poliovirus genome replication that emerges is described in **Fig. 7**. The *oriR* is recognized by the membrane bound complex of $3AB/3D^{pol}$, and/or by $3AB/3CD^{pro}$, that leads to cleavage of 3AB and template-dependent uridylylation of VPg (3B). The template at the *oriR* is poly(A). Chain elongation leads to the synthesis of VPg-poly(U) and, subsequently, to the formation of RF. It is possible that this mechanism of initiation can only occur on single-stranded plus strands; hence, there would be no reinitiation on a template strand, and no formation of 'negative' RI molecules. The double-stranded *oriL* of the RF then is being recognized by viral proteins such as 3AB, $3CD^{pro}$, and perhaps $2C^{ATPase}$ and cellular proteins, leading to the formation of the plus-strand cloverleaf RNP. Processing of 3AB and release of the $VPg/3D^{pol}$ complex from the membranes is followed by uridylylation of VPg and synthesis of plus strands (VPg-pUUAAAACAG...). Reinitiation at the *oriL* may not only be possible but also efficient, hence the formation of RI molecules and excess synthesis of plus strands over minus strands during genome replication.

Morphogenesis

Morphogenesis of viral particles from isolated components has not been achieved to date. Morphogenesis involves proteolytic cleavage of P1 to yield the protomer (VP0, VP3, VP1), a complex that does not dissociate but forms pentamers $(VP0, VP3, VP1)_5$ that may aggregate to form empty capsids ('procapsids') $[VP0, VP3, VP1)_5]_{12}$. Crystallographic studies indicate that the processing of P1 leads to extensive 'migration' of newly formed polypeptide termini that, as noted earlier, result in stable interactions within protomers and pentamers. Whether empty capsids are biologically significant or merely an experimental artifact is uncertain. In contrast, pentamers have been shown to be associated with RNA *in vivo* and to possess RNA binding activities *in vitro*. Thus, morphogenesis may be triggered by binding of pentamers to progeny RNA. This first step in virus morphogenesis may be relatively uncoordinated, since no encapsidation signal has been identified so far. Binding of pentamers to the RNA may be followed by condensation of the RNA and capsid assembly. These events may require functions of $2C^{ATPase}$ and membranes. The ultimate particle is the provirion that contains uncleaved VP0. The existence of the provirion has been supported by biochemical and genetic analyses. The subsequent cleavage of VP0 into VP2 and VP4 marks the final step in virus maturation and renders the particle infectious.

Cellular Responses to Poliovirus Infection

Poliovirus replication takes place in the cytoplasm of the host cell and can occur in enucleated cells. It has been shown that concomitant with poliovirus infection is a rapid shut-off of host cell protein synthesis. This event is accompanied by the proteolytic cleavage of a polypeptide of 220 kDa, termed eIF-4G (formerly p220). This protein is part of the cap-binding complex eIF-4 (consisting, in addition to eIF-4G, of the cap binding protein and the initiation factor eIF-4A) that recognizes the capped 5′ end of eukaryotic mRNAs in initiation of translation. A poliovirus mutant was reported with a single amino acid insertion in $2A^{pro}$ (nucleotide 3690) that was deficient in inhibition of host cell protein synthesis. Moreover, cleavage of eIF-4G did not occur in cells infected with this mutant. Indeed, $2A^{pro}$ synthesized *in vitro* can induce cleavage of eIF-4G *in vitro*. Although purified $2A^{pro}$ can cleave eIF-4G directly, the slow kinetics of processing suggests that cellular factors are involved in this reaction. EIF-4G is a component of the cap-recognition factor eIF-4. It follows, that degradation of the eIF-4G leads to a decline of cap-dependent translation. Indeed, poliovirus uses its $2A^{pro}$ proteinase to induce the total shut-off of cellular protein synthesis while using its IRES to proceed with cap-independent translation.

More recently, genetic and biochemical evidence have implicated $3C^{pro}$ in the inhibition of the polymerase III transcription system, specifically, in the cleavage of a TFIIIC-containing complex. Whether $3C^{pro}$ directly or indirectly cleaves TFIIIC, or a component of this complex is unclear.

Electron microscopical studies of poliovirus-infected cells has revealed the emergence of an enormous body of virus-induced vesicles (viroplasm) that occupies almost the entire cytoplasmic space of the infected cell. Vesiculation of the cytoplasm coincides with RNA replication and with the occurrence of cytopathic effect (CPE) of the infected cells. On an ultrastructural level, the vesicles have been shown to bud from the endoplasmatic reticulum (ER), but other organelles like Golgi apparatus and

lysosomes may also contribute to vesicle formation which results in the disappearance of the morphological features of ER and Golgi. The expression of protein 2BC in yeast and mammalian cells in the absence of other viral proteins leads to the induction of vesicles indistinguishable from those observed in poliovirus-infected cells. The determinants of vesicle induction are located in the 2C moiety of 2BC, whereas the 2B moiety contains determinants that control the morphology of the vesicles. Protein trafficking along the secretory pathway is severely inhibited in the host cell. Inhibition is mediated by the viral proteins 2B, 2BC and 3A. Interestingly, the fungal metabolite brefeldin A (BFA) that also interferes with the secretory pathway, inhibits poliovirus replication. This observation suggests that certain steps of the secretory pathway are required for virus replication whereas other steps are disadvantageous and blocked by the viral gene products.

Virus-induced vesicles have been isolated and their morphology and biochemical activities have been studied. The isolated membranous fractions ('crude replication complex'; CRC) contain single-stranded, RI and RF RNA as well as structural and nonstructural proteins. In the presence of nucleoside-triphosphates, VPg is uridylylated, RF is chased into RI and plus-stranded RNA molecules are released. Detergent treatment of CRC prevents the release of ssRNA and abolishes uridylylation of VPg. This latter observation contrasts with the aforementioned ability of $3D^{pol}$ to uridylylate VPg in the absence of membranes in a reconstituted system.

Electron microscopy combined with immunocytochemistry, shed light on the structural organization of the RC. The RCs appear to be surrounded by virus-induced vesicles with a diameter of 100–500 nm, giving the complex the shape of a rosette with the RC in its center. The RC itself harbors numerous smaller vesicles. Both types of vesicle carry the proteins 2B, 2BC and $2C^{ATPase}$ on their surface. It has been proposed that these proteins mediate the structural organization of the RC. 3AB, the precursor of VPg, is also associated with the membranes by virtue of a hydrophobic domain in the 3A moiety. Binding of 3AB to $3D^{pol}$ and $3CD^{pro}$ recruits these proteins to the membranous RC, since $3D^{pol}$ and $3CD^{pro}$ do not associate with membranes by themselves. In addition, capsid precursors, antigenically related to protomers and pentamers are located on the surface of the virus-induced vesicles and within the RC, where they associate with RNA. It was therefore concluded that the RC is not only the site of RNA replication but also the site of early events in RNA encapsidation.

All *in vivo* RNA replicating systems known today function in close association with cellular membranes. However, the role of membranes in RNA replication is not clear. One can imagine membranes to act as a scaffolding for the replication complex, analogous to the role of the nuclear matrix in DNA replication and transcription. Membranes may also act to concentrate the viral proteins at the site of replication. Alternatively, since the viral RNA polymerase ($3D^{pol}$) is promiscuous in the choice of template, membranes may serve to separate the vRNA from contaminating cellular RNAs during replication. In addition, the virus-induced vesicles may also protect the viral replication machinery from a hostile cellular environment.

The Replication of Poliovirus: An Overview

Poliovirus is an extremely efficient parasite. Immediately upon entry and uncoating of the virion, its messenger-sense RNA is translated. Protein synthesis peaks between 2.5 and 3.5 h post infection (pi). In the same period, virus-induced vesicles start to appear. Maximal RNA synthesis is delayed by 1 h compared to protein synthesis. The onset of infectious virus correlates well with RNA replication. One infectious cycle takes only 6–7 h and, under optimal conditions in suitable host cells (e.g. HeLa cells, a human tumor cell line), up to 10^5 new virus particles may be synthesized per cell.

The replicative cycle of poliovirus is shown schematically in **Fig. 8**, and can be summarized as follows.

1. Poliovirus attaches to and is destabilized by the cellular receptor CD155.
2. Uptake and uncoating occurs presumably via the endocytotic pathway.
3. Genomic RNA is immediately translated into one polyprotein that is proteolytically cleaved by three virus-encoded proteinases ($2A^{pro}$, $3C^{pro}$ and $3CD^{pro}$) to yield functional proteins. The initiation of translation is controlled by the IRES element. Processing, in turn, is controlled by specific amino acid sequences surrounding the scissile bonds.
4. The production of protein 2BC leads to the proliferation of membranous vesicles that are involved in the membrane-associated RNA replication. Host cell protein synthesis is shut off by the action of the proteinase $2A^{pro}$ that induces the cleavage of eIF-4G.
5. RNA replication follows the common pathway of plus strand–minus strand–plus strand synthesis.

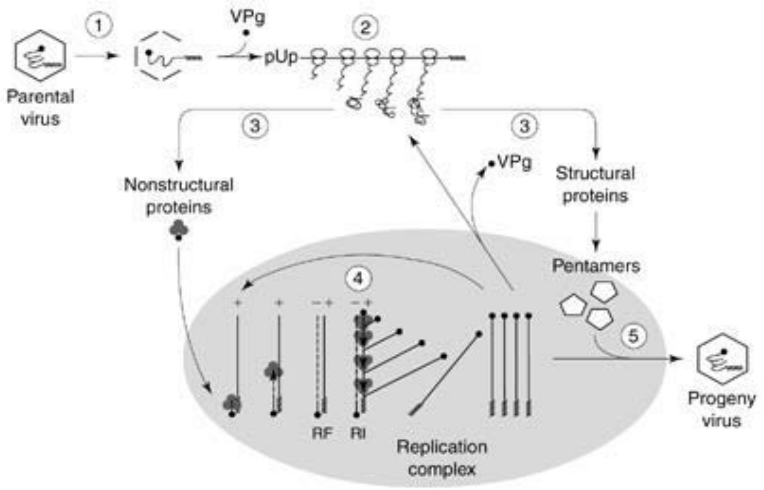

Figure 8 The replicative cycle of poliovirus. The replicative cycle of poliovirus is located in the cytoplasm of the host cell. The major steps are (1) virus binding to the receptor and uncoating, (2) translation, (3) processing of the polyprotein into functional proteins, (4) RNA replication, (5) encapsidation and virus morphogenesis. Newly synthesized plus-stranded RNA molecules may have three destinies: translation, template for RNA transcription, or encapsidation. RNA replication and early events in encapsidation are confined in a structure called replication complex.

Initiation of RNA synthesis by $3D^{pol}$ is protein (VPg)-primed.

6. Newly synthesized plus-strand RNA can enter the RNA synthesis cycle, or it can become mRNA (whereupon its 5′ terminal VPg is cleaved off), or it can be encapsidated once enough capsid proteins have been synthesized.
7. Virus assembly is poorly understood. Progeny RNA may be encapsidated by 12 pentamers. The mechanism of the maturation cleavage is obscure.

Molecular Genetics

The genetics of poliovirus is dominated by an average mutation rate of 6.3×10^{-4} per nucleotide incorporated. This high rate of mutation, a phenomenon common to all RNA viruses, results from the fact that, during evolution, RNA viruses have made the choice not to develop proof reading and editing functions (DNA and RNA polymerases operate with a similar error frequency of roughly 10^{-4}). Consequently, virions of an RNA virus isolate constitute a vast population of different genotypes replicating at the threshold of error catastrophe – the hallmark of a quasi-species. For quasi-species, a *wild-type* isolate is defined as (1) a population of viruses not having a single sequence, and (2) a population of viruses having a consensus sequence.

The high error rate in genome replication may be the main reason for the small size of the genome. An advantage of small ($<10^4$ bases) over large genome size is that more progeny RNAs can be generated from input RNA per unit time and thus more replicas are likely to survive in a hostile environment. This, combined with rampant genetic variation (mutation and recombination) allows for the rapid genetic adaptation to a new environment (host cell adaptation, drug resistance, etc). A harsh consequence of the small genome size, however, is that poliovirus must live under conditions of severe genetic austerity. That is, the virus encodes just enough proteins to survive. No viral gene products, and hardly any viral genome sequence, can be deleted without lethal consequence to the virus.

The extent of genome compression due to the high error frequency in replication has led to the elimination of sequence motifs that could effect temporal expression of poliovirus genes. This, in turn has led to the evolution of the viral polyprotein, the only translation product of the viral genome-length mRNA. This polyprotein, however, is not very stable as functional polypeptides are generated rapidly by proteolytic processing of the polyprotein, catalyzed in *cis* and *trans* by virus-encoded proteinases. As mentioned before, some precursor polypeptides in the processing cascade have functions distinct from that of their endproducts, and several processing products may have multiple distinct functions (e.g. 3AB, $3C^{pro}$, $3CD^{pro}$ and $3D^{pol}$). This strategy has provided the means to expand the number of tools available for virus replication. It also serves to explain why experiments of genetic complementation, although well documented for some viral mutants

but not for others, have not allowed genetic complementation groups to be deduced.

Genetic variation of the poliovirus genome, through misincorporation of nucleotides, is augmented by genetic recombination occurring with astounding high frequencies ranging from 10^{-2} (intratypic) to 10^{-5} (between different serotypes). Homologous recombination takes place by a mechanism of copy choice during minus-strand synthesis, and it occurs between heterologous genomes as well as, preferentially, between sibling genomes. Using the HeLa cell-free system of *de novo* poliovirus growth *in vitro*, genetic recombination has been achieved also *in vitro* by simultaneously growing genetically different poliovirus strains (starting with isolated viral RNAs) in extracts of uninfected HeLa cells.

Considering the genetic 'plasticity' of the poliovirus genome, the restriction of poliovirus to only three serotypes is surprising. A hypothesis has been developed that suggests that the serotype restriction is related to the specific manner in which poliovirus capsid interacts with the cognate cellular receptor.

The study of the genetics of poliovirus was revolutionized by the generation of infectious poliovirus cDNA. The viral RNA genome that was converted into double-stranded DNA was suddenly available for genetic manipulations hitherto unheard of. Due to the cellular transcription machinery, transfection of suitable cells with the virus-specific double-stranded DNA then yielded poliovirus at low frequency. The efficiency of this process was greatly enhanced when it was shown that the virus-specific cDNA could be transcribed with phage T7 RNA polymerase to yield unlimited amounts of viral RNA that was nearly as infectious as RNA isolated from virions.

Cell-free, *De Novo* Synthesis of Poliovirus

Viruses, lacking the genetic information as well as the tools to provide most of the essential components to replicate, are obligatory intracellular parasites. The complexity of viral proliferation – macromolecular synthesis of polypeptides and genomic nucleic acid, and encapsidation – has led to the text book wisdom that viruses are obligatory intracellular parasites unable to proliferate outside living cells.

However, poliovirus RNA (either obtained from virions or by transcription from plasmid DNA), when incubated in an extract of uninfected HeLa cells void of nuclei, mitochondria and cellular mRNA, will direct translation, genome replication, and genome encapsidation such that infectious particles are formed that are indistinguishable from poliovirus isolated from tissue cultures. Thus, poliovirus is the first virus that has been synthesized *de novo* in a cell-free extract of mammalian cells.

This experiment that has been repeated in several laboratories, has nullified the notion that viruses can proliferate exclusively in living cells. Moreover, the novel approach can be used to study individual steps of viral replication in the absence of cell membrane barriers. Since *de novo* RNA synthesis was found to be a prerequisite for production of infectious particles in the cell-free extract, this system has provided a unique tool for the study of RNA replication, recombination and morphogenesis *in vitro*. Indeed, two reports have recently described experiments of genetic recombination of poliovirus in the cell-free environment.

Concluding Remarks

Poliovirus is a virus with a brilliant past and a fascinating presence, but with no future. Poliovirus, the etiologic agent of poliomyelitis, was one of the most feared and, therefore, is one of the most thoroughly studied infectious agents today. Ninety years of investigations of poliovirus biology and pathology have unraveled numerous secrets in virology and cell biology. These efforts produced two superb vaccines that, as a triumph of medical research, will ultimately lead to a global eradication of poliovirus.

The nature of the causative agent of poliomyelitis was identified 90 years ago by Karl Landsteiner and Erwin Popper. On 18 December 1908, they reported to the k.k. Society of Physicians in Vienna the successful transfer of poliomyelitis from a deceased victim to *Cynocephalus hamadryas* monkeys. Since the human specimen from the spinal cord was free of bacteria, Landsteiner and Popper concluded correctly that 'a so-called "invisibles" e.g. a virus belonging to the class of Protozoa, must have caused the disease'.

Chemical and molecular studies have shown that poliovirus is a remarkably simple biological entity: an aggregate consisting of only five different species of macromolecules (four proteins and one single-stranded RNA) that form an icosahedral particle of 241 macromolecules altogether. This 'chemical' can be crystallized, just as has been done with tobacco mosaic virus before, and the empirical formula of its organic matter can be calculated ($C_{332\,662}$; $H_{492\,388}$; $N_{98\,245}$; $O_{131\,196}$; P_{7500}; S_{2340}). Spectacularly, the information stored in the genomic RNA is sufficient for replication and *de novo* poliovirus synthesis, provided an extract of mammalian cells. The 'chemical' poliovirus will now reveal properties of a living entity: the ability to proliferate. These studies have

demonstrated that the life cycle of a virus can be studied outside living cells, a new strategy in virus research as yet unique to poliovirus.

In nature, poliovirus will only replicate if it collides with a suitable host cell that provides the means of entry and the environment for virus-specific synthesis. Infection of host cells reveals the second face of the particle: that of a pathogen leading to the destruction of the host cell, if not incapacitation or death of the host organism.

During the last 40 years, many aspects of the genetics and molecular biology of poliovirus have been extensively studied. A model of replication has emerged, as yet incomplete, that describes the most important steps in proliferation. Hallmarks are the mode of initiation of protein synthesis by an IRES element, the processing of the single polyprotein in a variety of functional proteins, the initiation of RNA synthesis by protein priming, and the replication of RNA in the absence of a DNA intermediate.

Viral pathogenicity is governed by tissue tropism which, in turn, is determined by the distribution of the viral receptor and cell-internal conditions for replication. The poliovirus receptor (CD155), an immunoglobulin-like molecule of unknown non-pathological function, has been identified, but its distribution in human cells does not seem to match the targets of poliovirus infection. Poliovirus normally growths in the gastrointestinal tract. Serious pathogenic properties become apparent only when the virus, by a 1% chance, invades the CNS. There, the virus has a unique and as yet unexplained preference to attacking and destroying motor neurons, the reason for the flaccid paralysis characteristic of poliomyelitis. The spread of the virus from the gastrointestinal tract to the CNS can occur either by passage through the blood–brain barrier or by retrograde axonal transport. The IRES element of poliovirus functions well in cells of the CNS; this is not true for IRES elements of some of the other picornaviruses. Thus, exchanges of IRES elements can lead to highly attenuated poliovirus strains.

Following the success in the global eradication of human smallpox virus, the 42nd World Health Assembly of the World Health Organization adopted an action plan (WHA42.22) to eradicate poliovirus by the year 2000. Progress is impressive as at the time of the writing of this review, *wt* polioviruses have vanished from most parts of the world. Eventually, poliovirus will be history. Although poliovirus might be gone, the lessons it told us in molecular biology and viral pathogenesis will survive and help to unravel the secrets of the remaining viral pathogens belonging to the *Picornaviridae* and other plus-strand RNA virus families.

POLYDNAVIRUSES (*POLYDNAVIRIDAE*)

Don Stoltz, Department of Microbiology and Immunology, Dalhousie University, Halifax, Nova Scotia, Canada

Taxonomy and Classification

The polydnaviruses are defined primarily on the basis of genome structure. The polydnavirus genome is segmented, consisting of a population of double-stranded, circular DNA molecules of variable molecular mass (the name 'polydnavirus' is derived from: *poly*disperse *DNA virus*); it should be noted that no other dsDNA virus is known to have a segmented genome. Two distinct genera of polydnaviruses are recognized: the bracoviruses, found only in the parasitoid (wasp) family *Braconidae,* and the ichnoviruses, found only in the family *Ichneumonidae.* In addition to having distinct host ranges, the braco- and ichnoviruses are quite different in terms of at least one other important parameter: morphology.

Virion Structure and Morphogenesis

Bracovirus particles consist of cylindrical nucleocapsids of uniform diameter (40 nm) but variable length (30–150 nm); these are surrounded either individually or in groups by a single unit membrane (**Fig. 1**). Ichnovirus particles possess considerably larger nucleocapsids (approximately 85 × 330 nm) which are typically uniform in size, having the form of a prolate ellipsoid; ichnovirus nucleocapsids are commonly, but not always, uniform in length. Typically, nucleocapsids are individually surrounded by *two* unit membranes (**Fig. 2**).

Morphogenesis occurs only in the wasp ovary, specifically in a region referred to as the calyx, which lies between the ovarioles and the oviducts; it begins during the late pupal stages of parasitoid development, with the *de novo* appearance within the nucleus of membranes destined to form the envelope and the inner membrane, respectively, of braco- and ichnoviruses. In both braconid and ichneumonid parasitoids, mature virions enter the lumen of the oviduct, where in large numbers they comprise what is generally referred to as calyx fluid, which, like typical virus suspensions at high concentration, is opalescent. Exit of mature bracovirus particles appears to involve sloughing and lysis of calyx epithelial cells; ichnovirus particles, on the other hand, bud through the plasma membrane, thereby acquiring a second envelope. It is known that the ichnoviruses bud through the nuclear envelope, but how they traverse the cytoplasm prior to budding through the plasma membrane has not as yet been determined.

The Polydnavirus Genome

The polydnavirus genome, as extracted from purified virions, consists of double-stranded circular DNA molecules of variable molecular mass. A single female wasp ovary will often contain virus sufficient for most

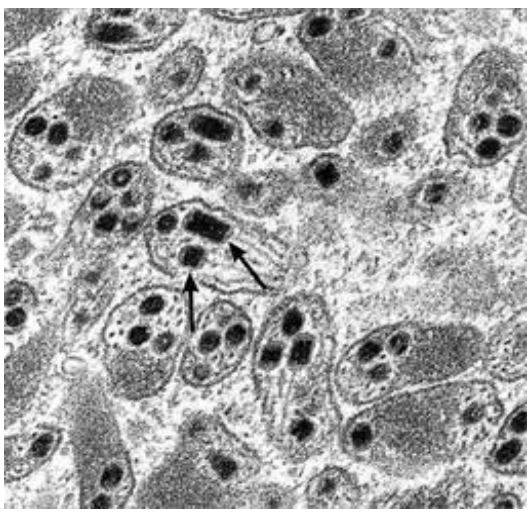

Figure 1 Bracovirus from *Cotesia paleacritae*; note that each viral envelope encloses several nucleocapsids. Nucleocapsids are indicated by arrows.

Figure 2 Ichnovirus from *Hyposoter exiguae*; note that each nucleocapsid is surrounded by two unit membranes. Nucleocapsids are indicated by arrows.

of the virus genome to be visualized following agarose gel electrophoresis and ethidium bromide staining. Ichnovirus genomes (which have been most fully characterized) appear to consist of 20–40 different molecules (genome segments), with an aggregate molecular mass of 300 kbp or more. Genetic complexity may be less than this might suggest, however, since a number of genes have been observed to be present on more than one genome segment; indeed, in some cases, smaller genome segments are repeated in their entirety within one or more larger ones. There thus exist families of both genes and genome segments. Smaller repetitive motifs have also been described. Bracovirus genomes have not as yet been investigated to the same extent; however, preliminary observations would suggest that some bracovirus genome segments are larger than those typically associated with the ichnoviruses. No convincing rationale for the segmentation of polydnavirus genomes has not as yet been proposed.

Almost nothing is known concerning how polydnavirus genomes are packaged. However, it is reasonable to suspect that the relatively large ichnovirus particle would contain a complete genome (i.e. all genome segments packaged within each nucleocapsid); on the other hand, the variable length of bracovirus nucleocapsids likely reflects packaging of DNA molecules of different sizes (i.e. one genome segment/nucleocapsid).

It is now clear that there exist within the parasitoid genome stretches of DNA which are homologous to, and colinear with, each encapsidated viral DNA molecule. Common sequences, then, are represented in both linear (chromosomal) and circular (viral) form.

Life Cycle

It is now evident that *all* individuals of *all* affected species carry polydnavirus. In keeping with this observation, it now seems clear that polydnavirus genomes are chromosomally transmitted in both egg and sperm cells in accordance with simple mendelian rules; transmission then, occurs with 100% efficiency. Recent work suggests that viral DNA replication is preceded by a series of excision events, which serve to release proviral sequences from the wasp genome; a site-specific recombinase (Hin-like) may be involved. After being excised, viral genome segments are amplified, possibly by a rolling circle mechanism (not proven yet), prior to encapsidation into virions. Preliminary evidence suggests that DNA replication may be triggered by the molting hormone, ecdysone.

Electron microscopy has established that virus particles are exported, initially into the lumen of the oviduct; during oviposition, both parasitoid eggs and polydnavirus particles are injected into the larvae of insects destined to serve as hosts for the next generation of parasitoids. Considerable experimentation has shown that in the absence of polydnavirus, parasitoid eggs/larvae are typically destroyed by an immune response. Polydnaviruses are in fact responsible for a variety of physiological changes which are induced in the parasitized host; in addition to immunosuppression, these include growth inhibition, hormonal perturbation, the inhibition of phenoloxidase activity, and so on. Many of the observed physiological changes are assumed to be relevant to successful parasitism; this raises the very important question of how polydnaviruses mediate these myriad activities.

Following oviposition, polydnavirus particles gain entry to a variety of host tissues. Nucleocapsids reach the nuclei and become uncoated either at nuclear pores (bracoviruses) or within the nucleus itself (ichnoviruses); following this, viral DNA apparently persists within host cells throughout the natural course of parasitism (parasitoid larvae usually complete development within one to two weeks.) Virus-specific transcription occurs in parasitized host animals, and would appear to be required for successful parasitism; again, note that transcription occurs here in the absence of viral morphogenesis. Viral gene products are assumed to be responsible for some or all of the observed changes associated with parasitism.

The polydnavirus life cycle, then, may be envisioned as consisting of two 'arms'. One of these, responsible for virus transmission and replication, is mediated by linear, chromosomal DNA. The second arm, mediated by circular, encapsidated DNA molecules, is responsible for a genetic colonization of the parasitized host, ultimately ensuring successful parasitism, and indeed a candidate immunosuppressive gene product has now been identified. Other virus-specific gene products have been identified, but not as yet associated with a specific biological function.

Origin

The polydnavirus phenomenon compels us to ponder the meaning of the word 'virus', since these agents could just as well be referred to as nuclear secretions. Whether or not they are viruses depends, in the first instance, on how one defines a virus. Certainly, the polydnaviruses must at the very least be described as unconventional, in the sense that there is no such thing as an uninfected host in which a productive infection can be initiated: as noted previously, all polydnavirus-carrying wasps are already infected! In

essence, each polydnavirus genome is part of a cognate wasp genome. The important question, then, is: did polydnaviruses arise from wasp genomes, or did the genes of a formerly 'classical' virus somehow become associated with certain ancestral wasp genomes.

Definitive answers to these questions are at this point in time unavailable, perhaps in part because very little sequence information is available for any polydnavirus genome. Thus, for example, we are presently unable to determine whether homologies with other viral genes exist. Although the evidence for a viral origin for the polydnaviruses is only indirect, it is nonetheless compelling: wasp ovaries appear to be unusually permissive to the apparently noncytocidal replication of a wide variety of viruses (a recent compilation included at least one member of each of the following: baculoviruses, poxviruses and rhabdoviruses, to which we may now add reoviruses and ascoviruses) and a number as of yet unclassified agents. Such observations strongly suggest that opportunities have existed (and maybe still do) for the establishment of symbioses between viruses and parasitic wasps; it may reasonably be argued that two such symbioses gave rise to the braco- and ichnoviruses.

Significance

Polydnaviruses have obvious significance in the sphere of ecology. These viruses are carried by hundreds, perhaps thousands, of species of parasitic Hymenoptera, many of which parasitize more than one species of insect (indeed, it may be argued that this is the largest group of viruses known to exist). Many host species are important pests, populations of which are often maintained at acceptably low densities as a consequence of parasitism by wasp species which carry polydnaviruses. It may be assumed that some of the virus-specific gene products expressed in parasitized host insects, particularly those having immunosuppressive properties, will ultimately have potential in the biopesticide industry.

What is perhaps most significant about polydnaviruses, however, is the degree to which these viruses may modify our concept of the range of possible virus/host interaction. Arising, one assumes, from originally 'typical' viruses (i.e. those capable of initiating a fully productive infection), the polydnaviruses would appear to have achieved considerable success in terms of the degree to which their life cycles have become integrated with those of their hosts (and see above). Since all individuals belonging to any given affected species carry virus, the acquisition of a polydnavirus genome must presumably have preceded speciation. Perhaps in keeping with this observation, no other viruses have been shown to be required for the survival of the organisms which carry them. An investigation into the coevolution of parasitoids and polydnaviruses – insofar as this is possible – will surely provide interesting reading for years to come!

POLYOMAVIRUSES – MURINE (*PAPOVAVIRIDAE*)

Contents

General Features

James M Pipas, Department of Biological Sciences, University of Pittsburgh, Pittsburgh, USA

History

Polyomavirus was discovered by Ludwig Gross in 1953 by virtue of its ability to induce tumors in inoculated newborn mice. While studying murine leukemia virus (MLV), a retrovirus that induced chronic leukemia when injected into newborn mice, Gross observed that some animals inoculated with MLV preparations developed adenocarcinomas of the parotid gland. Extracts of the tumor contained an activity, termed parotid virus, that passed the tumor to newly inoculated animals. A variety of physical techniques demonstrated that parotid virus was a different virus from MLV. Later it was shown that the virus could induce the formation of a variety of tumor types in newborn animals, and hence was given the name polyomavirus.

In 1957 Stewart, Eddy and colleagues reported that polyomavirus could be propagated in cultures of mouse embryo cells. Thus, for the first time the viral productive cycle could be analyzed in cell culture. This was followed by the development of a viral plaque assay. With these tools in hand, an exploration of the genetics of polyomavirus could begin.

Classification

Murine polyomavirus is a member of the *Paporaviridae* family which consists of two genera, *Papillomavirus* and *Polyomavirus*. The prototype members of the *Polyomavirus* genus are simian virus 40 (SV40) and murine polyomavirus itself. Also included in this genus are the human viruses BKV and JCV, SA12 (baboon), LPV (African green monkey), bovine polyomavirus (bovine), Budgerigar fledgling disease virus (BFDV), HaPV (hamsters) and KV (mice). While representatives of the family are found in species ranging from birds to humans, each virus shows a restricted host range.

Properties of the Virion

Members of the polomavirus group are characterized by icosahedral virions, approximately 45 nm in diameter, containing the viral-encoded capsid proteins VP1, VP2 and VP3. Each virion contains a single molecule of circular duplex DNA of about 5 kb, along with the cellular histones H2A, H2B, H3 and H4. Mature virions do not contain histone H1.

Genome Organization and Properties of Proteins

The circular double-stranded genome of polyomavirus consists of 5297 bp. By convention the nucleotide at the center of an imperfect palindrome that forms part of the origin of DNA replication is designated as '1' and numbering proceeds through the early coding sequences around the circle. Sometimes positions on the genome are indicated by map units (MU). This older system divides the genome into 100 MU using the single *Eco*RI site (n1562) as 0 and proceeding through the remainder of the early region and then the late region and regulatory region to 100.

Regulatory region

The viral regulatory region consists of approximately 400 bp lying between the early and late coding regions (n5086–156) and contains the *ori,* the promoters for early and late region transcription and the transcriptional enhancers. Early region transcription initiates at position 156, with the initiation codon for all three T antigens lying at position 175. The major initiation site for the late region mRNAs is at position 5086. The *ori* and all of the known *cis*-acting sequences required for early and late transcription lie between these points. This region contains multiple binding sites for the large T antigen which is thought to recognize the consensus pentanucleotide G(A/G)GGC. There are three strong T antigen-binding sites located upstream of the start of early region transcription. These are termed sites A (n27–76), B (n86–116) and C (n121–164). Each of these contain multiple copies of the recognition pentanucleotide in various orientations and spatial arrangements. None of these sites

appear to play a major role in viral DNA replication and are perhaps involved in transcriptional control. The TATA box associated with the early region promoter lies between sites B and C.

Viral DNA replication requires a stretch of nucleotides termed the core *ori* (n45–5274) linked in *cis* to either enhancer element α or β. A stretch of DNA very rich in AT residues lies just to the late side of the core *ori*. This is followed by the β and then the α elements. The specific roles of each of these sequence motifs in viral DNA replication and transcription will be discussed in an accompanying entry.

Early region

The viral early region encodes four proteins: the tiny, small, middle and large T antigens (TT, ST, MT and LT). The mature mRNAs encoding each of these proteins are produced by differential splicing of a single primary transcript which starts at nucleotide 156. The polyadenylation signal for these mRNAs lies at position n2930. All three proteins initiate at the methionine codon at position 175, and thus share a common N-terminus. The mRNA for ST is generated by splicing a donor site at n748 to an acceptor site at n797, thus eliminating an intron of 49 nucleotides. Translation of this mRNA initiates at the ATG at n175 and terminates at n807. The mRNA encoding MT is generated by utilizing the same donor site (n748) but using an acceptor at n811. This results in loss of the termination codon used for ST and opens a new open reading frame (ORF), which terminates at position n1499. Thus, MT shares N-terminal residues with ST, but each have unique C-termini. The LT mRNA is generated by utilization of a splice donor site at n411 and an acceptor site at n797. This generates an ORF that shares the first 82 codons with MT and ST, but possessing a unique C-terminus.

The LT protein plays a central role in regulating productive infection. This 795 amino acid protein is the only viral product required for viral DNA replication. One way in which LT acts is to bind specific sequences located within *ori*. The consensus sequence for LT recognition is the pentanucleotide G(A/G)GGC, which occurs multiple times within *ori* and the viral regulatory region. LT carries an ATPase/DNA helicase function which acts to melt and unwind *ori* to allow initiation of DNA replication. LT also autoregulates early region transcription, at least partially by binding to sequences located to the early side of *ori*. In addition, LT transactivates the polyomavirus late promoter, as well as a number of heterologous promoters of both viral and cellular origin. LT also carries the ability to complex the cellular retinoblastoma (Rb) protein as discussed below, and probably additional activities involved in transformation.

MT is a 432 amino acid protein that plays a role in viral assembly by regulating the phosphorylation of the major capsid protein VP1. In addition, MT is an oncogene which is sufficient to transform a number of established cell lines, and cooperates with LT to transform primary cells. Many of the actions of MT are mediated by its direct interaction with proteins involved in signal transduction (see above).

The role of the 195 amino acid ST in productive infection is unclear. Under many conditions tested, polyomavirus mutants that do not produce ST are viable and can fully transform cells. Under other conditions, such as infection of quiescent cells, ST seems to increase the efficiency of transformation. ST of both polyomavirus and SV40 are found in complex with two cellular proteins, the α and β subunits of phosphatase pp2A. ST seems to displace the γ subunit and serves to inhibit phosphatase activity. The SV40 ST transactivates the adenovirus E2 promoter in some cell types. Whether the polyomavirus ST carries a similar transactivation activity has not been reported.

Late region

As discussed above, the three viral capsid proteins are expressed by the late transcription unit. The major capsid protein is the 385 amino acid VP1. In infected cells VP1 occurs as multiple species that differ in their states of phosphorylation. Some species appear to play a role in virus adsorption and at least one is involved in virus assembly. MT seems to play a role in inducing this species. VP2 and VP3 are proteins of 319 and 204 amino acids respectively.

Additional ORFs

In addition to the major proteins discussed above, the polyomavirus genome contains several additional ORFs that could potentially encode proteins, although in most cases whether these proteins are actually made or not has not been studied. SV40 is known to express a protein termed agnoprotein from the late mRNA leader sequence. Agnoprotein is a basic protein of 61 amino acids that seems to play a role in transport of the capsid proteins to the nucleus and possibly viral assembly. Other members of the polyomavirus group, including murine polyomavirus, possess a similar ORF that would encode proteins highly related to the SV40 agnoprotein. However, the observation of an agnoprotein from these other viruses has not been reported.

Productive Infection

The viral productive cycles have been most well characterized for SV40 and polyomavirus because of well-developed cell culture systems for propagating these viruses.

Polyomavirus was first propagated in primary mouse embryo fibroblast cell cultures. Established cell lines that supported productive infection and plaque formation were discovered later. The most commonly used is NIH3T3. Polyomavirus forms plaques on monolayer cultures of these cells visible by staining with neutral red after 8 days of incubation. Infection of these cells results in a yield of approximately 300 infectious particles, or plaque forming units (PFU), per infected cell. The ratio of physical:infectious particles is about 100:1 for polyomavirus.

The polyomavirus infectious cycle can be divided into steps typical for animal virus productive infections. First, polyomavirus virions attach to a specific receptor on the cell surface. The receptor probably contains neuraminic acid, as treatment of permissive cells with neuraminidase renders them resistant to polyomavirus infection. The mechanisms involved in penetration and uncoating are not well understood, but the result is that by approximately 4–6 h postinfection, free viral DNA is present in the nucleus of the infected cell. Soon afterwards mRNAs representing about half of the viral coding sequences (see below) are detectable, followed by synthesis of four virus-encoded proteins: LT, MT, ST TT. These are collectively referred to as the early proteins, and they are encoded by the early region genes. Early region genes are those that are expressed prior to the onset of viral DNA replication.

By about 24 h postinfection, the early proteins have reached their maximum levels and viral DNA replication begins. Replication initiates within a 65 bp segment termed the *ori* and proceeds bidirectionally around the circular genome. Viral DNA replication requires a single viral-encoded protein, LT. Much progress has been made in investigations concerning the role of the polyomavirus and SV40 LT in initiating viral DNA replication. These results are reviewed elsewhere.

Shortly after the onset of viral DNA replication, transcription of the remainder of the viral genome, termed the late region, begins. This results in the synthesis of the three viral capsid proteins, VP1, VP2 and VP3. Late region mRNA generation is very complicated, with multiple 5′ ends and numerous alternate splicing events occurring. All of the 5′ ends of late mRNAs lie between n5075 and 5170 on the viral genome. Both the early and late mRNA polyadenylation sites lie about 180° around the circular genome from the *ori*. Viral assembly begins shortly after the onset of late region protein synthesis. While all of the steps in assembly have not yet been elucidated it is known that purified VP1 expressed in *Escherichia coli* will self-assemble into pentamers. However, the complete assembly of infectious particles apparently requires the action of MT, which plays a role in post-translational modification of VP1.

As the infected cells die they exhibit a characteristic cytopathic effect. There does not seem to be any specific mechanism for viral release. Rather, progeny virions seem to be released as the cell dies, with much of the viral material remaining attached to the cellular debris.

What has just been outlined is a typical cycle following polyomavirus infection of a permissive cell. In fact, the outcome of infection depends upon the type of cell infected. Infection of cell types that are semipermissive for polyomavirus can result in a persistent infection. This is perhaps more representative of the natural course of infection with this agent. Other cell types are nonpermissive, either because they lack a viral receptor and infection is blocked at the stage of attachment, or because they lack the proper machinery for allowing viral DNA replication. These latter cell types are of interest because they allow virus penetration and expression of the early viral proteins. However, as replication is blocked these infected cells do not die, and a subset of them are transformed to neoplastic cells.

Viral Transformation

When nonpermissive cells, such as those of rat or hamster origin, are infected with polyomavirus, the early stages of infection proceed normally, resulting in the synthesis of ST, MT and LT; however, viral DNA does not replicate and the late region genes are not expressed. Rather, cellular DNA synthesis is stimulated and the infected cells are driven through at least one to several rounds of division. During this period, actin cables are disassembled and the cells acquire a phenotype associated with transformed cells. After a couple of days, most of the cells in the culture resume a normal appearance and viral nucleic acid and proteins can no longer be detected. This phenomenon is termed abortive transformation.

During such infections a small percentage of the infected cells permanently acquire the transformed phenotype, including the ability to: (1) form foci on a monolayer of normal cells; (2) proliferate in low serum concentrations; (3) grow independent of anchorage to a solid substrate; and (4) form tumors in test animals. Such cells continuously express the

viral T antigens and contain viral DNA covalently integrated into the cellular chromosome. A number of genetic and biochemical experiments have led to the conclusion that the ST, MT and LT are responsible for initiating and maintaining the transformed phenotype. The TT has only been recently discovered and its role in transformation is unclear.

The rate-limiting step in neoplastic transformation appears to be the integration of viral DNA into the cellular chromosome. Polyomavirus has not evolved any specific mechanism for integration. In fact, integration is not a normal part of infection and appears to occur by cell-mediated nonhomologous recombination. Insertion occurs at random locations with respect to both the viral and cellular chromosomes. This appears to explain the phenomenon of abortive transformation. During the viral infection of nonpermissive cells, nearly all the cells are initially infected and thus express the viral T antigens. As a result the cells temporarily acquire the transformed phenotype. However, in most cells, as proliferation proceeds the viral genome is diluted out and thus nearly all progeny cells lose expression of the T antigens and revert to a normal appearance. In a minority of the infected cells, the viral DNA integrates in such a manner as to allow continuous expression of the T antigens. Since the viral genome, and thus T antigen expression, is passed on to all progeny cells, this leads to a stably transformed phenotype.

Much effort has been directed towards understanding the role that each of the viral tumor antigens plays in transformation and the molecular mechanisms by which they achieve their effects. ST increases the efficiency of transformation in certain cell types or when quiescent cells are infected. LT is sufficient to immortalize primary lines. While lines expressing LT exhibit a reduced requirement for serum, they do not form foci, grow independent of anchorage, or form tumors in animals. MT is the only viral gene product required to transform a number of established cell lines; however, both LT and MT are required to induce the fully transformed phenotype in primary cells. Established cell lines transformed by MT alone form foci, grow independent of anchorage and are tumorigenic. They do not show a reduced serum requirement.

Each of the viral T antigens are thought to act by targeting key cellular proteins that normally play a role in the regulation of proliferation. ST complexes with the cellular phosphatase pp2A and alters its activity. LT complexes the Rb protein and probably other targets. MT complexes with at least three nonreceptor tyrosine kinases, c-*src*, c-*fyn* and c-*yes*, phosphoinositide kinase, 14-3-3 proteins and phospholipase C-γ, all of which are components of cellular signal transduction pathways. Details concerning polyomavirus-induced tumorigenicity can be found in the accompanying article.

Genetics

The genetic analysis of polyomavirus began with the isolation of mutants that were temperature-sensitive for the ability to form plaques on a monolayer of permissive cells. In these experiments the permissive temperature was usually 32–35°C, while 39–40.5°C was nonpermissive.

These mutants fell into distinct phenotypic classes which corresponded to genetic complementation groups. Simultaneous studies with SV40 led to the identification of similar classes. The *ts-a* mutants fail to accumulate progeny viral DNA at the nonpermissive temperature. All of the *ts-a* mutants carry base-pair substitutions in sequences encoding the viral LT. All temperature-sensitive mutants mapping in the T antigen gene fall into a single complementation group and are defective for viral DNA replication at the nonpermissive temperature. The *ts-a* mutants also lose the ability to transform nonpermissive cells at the nonpermissive temperature. However, there is a class of mutants mapping to the T antigen gene that are temperature-sensitive for viral DNA replication while retaining the ability to transform at all temperatures.

The remaining classes of temperature-sensitive mutants carry lesions that affect the structure of the viral capsid proteins. One class, exemplified by *ts-10*, fail to accumulate the major viral capsid VP1 and to assemble mature virions. Another class, exemplified by *ts-3*, maps to the VP2/VP3 coding sequences, and seem to exhibit a defect in the uncoating step of infection.

Another class of polyomavirus mutants exhibit a host-range phenotype, in that they undergo a complete productive infection on murine cells transformed by polyomavirus, but are defective on normal murine cells. The lesions in these mutants map to sequences encoding both the LT and MT, but it is their effect on MT function that is thought to result in the defect. These mutants, exemplified by *NG18*, are also defective for viral transformation.

In recent years, a large collection of polyomavirus mutants have been generated by *in vitro* mutagenesis. Most of these mutations have been targeted to the regulatory region of the virus in order to better define *cis*-acting sequences important for the regulation of DNA replication and transcription, or to the viral early protein genes. Site-directed mutagenesis of the T antigen genes has also been used to establish structure–function relations in these proteins.

Relation to Other Members of the Polyomavirus Group

To date the complete nucleotide sequence of 12 members of the polyomavirus group have been completed and the partial sequences of two others are available. These studies demonstrate that all members of this group have essentially the same genome organization and use very similar strategies for controlling genome replication and expression.

There are important differences between various members of the polyomavirus group. First of all, murine polyomavirus and hamster polyomavirus both encode three early viral tumor antigens (LT, MT, ST), whereas other members of the group, such as SV40, encode only an LT and ST. SV40 LT possesses a C-terminal domain, termed the host-range domain, that appears to play a role in virus assembly. Viruses that encode an MT lack a host-range domain on the LT.

A second difference is that murine polyomavirus expresses each of the major capsid proteins, VP1, VP2 and VP3, off separate mRNAs. On the other hand, SV40 expresses only two late mRNAs. One encodes VP1, while the other encodes VP2 and VP3. Differential synthesis of VP2 and VP3 is controlled by the efficiency of translational initiation.

Summary

Murine polyomavirus has proved to be an excellent model for studying mechanisms of genome replication and expression in higher eukaryotes. While members of this group are not important pathogens, they have served as models for viral infection and spread in a natural population. But most of the effort has been put into learning how these small DNA viruses propagate. In addition, these viruses have served as invaluable models for discerning the mechanisms involved in neoplastic transformation.

Properties of the Virion

The polyoma virion is spherical in shape, with icosahedral symmetry and a diameter of about 45 nm. It contains 360 copies of a major protein, VP1, and 30–60 copies of minor proteins, VP2 and VP3, encoded by the viral DNA. The VP1 proteins are assembled as 72 pentamers. Twelve of the pentamers are surrounded by five others, whereas 60 are surrounded by six others. The pentamers are roughly cylindrical, with a tapering cavity. Each pentamer has one copy of VP2 or VP3 associated with it in the region of the cavity.

Properties of the Genome

The polyoma genome is a covalently closed circle of double-stranded (ds) DNA about 5300 bp in size. The DNA in the virion is supercoiled. The viral DNA is associated with four cellular histones, H2A, H2B, H3 and H4, organized into nucleosomes and packaged as a 'minichromosome'.

The genome is divided into early and late regions. The early region, which is expressed before the onset of viral DNA replication, encodes three proteins called T antigens. The T antigens are designated as small (ST), middle (MT) and large (LT). The late region, which is expressed after viral DNA replication begins, encodes the virion proteins, VP1, VP2 and VP3. There is a single origin of DNA replication. The origin 'core' comprises about 66 bp. The early and late coding regions are located on either side of the origin of replication. There is a noncoding region of about 150 bp on the early side of the replication origin which contains early promoter sequences. A noncoding region of about 250 bp on the late side of the replication origin contains enhancer sequences, which are binding sites for cellular transcription factors, notably PEA-1/AP-1 and PEA-3/ets. A diagram of the coding regions of the polyoma genome is shown in **Fig. 1.**

Properties of the Viral Proteins

Polyoma LT consists of 782 amino acids. It contains two independent nuclear location signals, spanning amino acids 189–195 and 280–286, respectively. The protein is located in the nucleus, where it functions in viral DNA replication, binding to the origin of

The genome is divided into early and late regions. The early region, which is expressed before the onset of viral DNA replication, encodes three proteins called T antigens. The T antigens are designated as small (ST), middle (MT) and large (LT). The late region, which is expressed after viral DNA replication begins, encodes the virion proteins, VP1, VP2 and VP3. There is a single origin of DNA replication. The origin 'core' comprises about 66 bp. The early and late coding regions are located on either side of the origin of replication. There is a noncoding region of about 150 bp on the early side of the replication origin which contains early promoter sequences. A noncoding region of about 250 bp on the late side of the replication origin contains enhancer sequences, which are binding sites for cellular transcription factors, notably PEA-1/AP-1 and PEA-3/ets. A diagram of the coding regions of the polyoma genome is shown in **Fig. 1.**

Properties of the Viral Proteins

Polyoma LT consists of 782 amino acids. It contains two independent nuclear location signals, spanning amino acids 189–195 and 280–286, respectively. The protein is located in the nucleus, where it functions in viral DNA replication, binding to the origin of

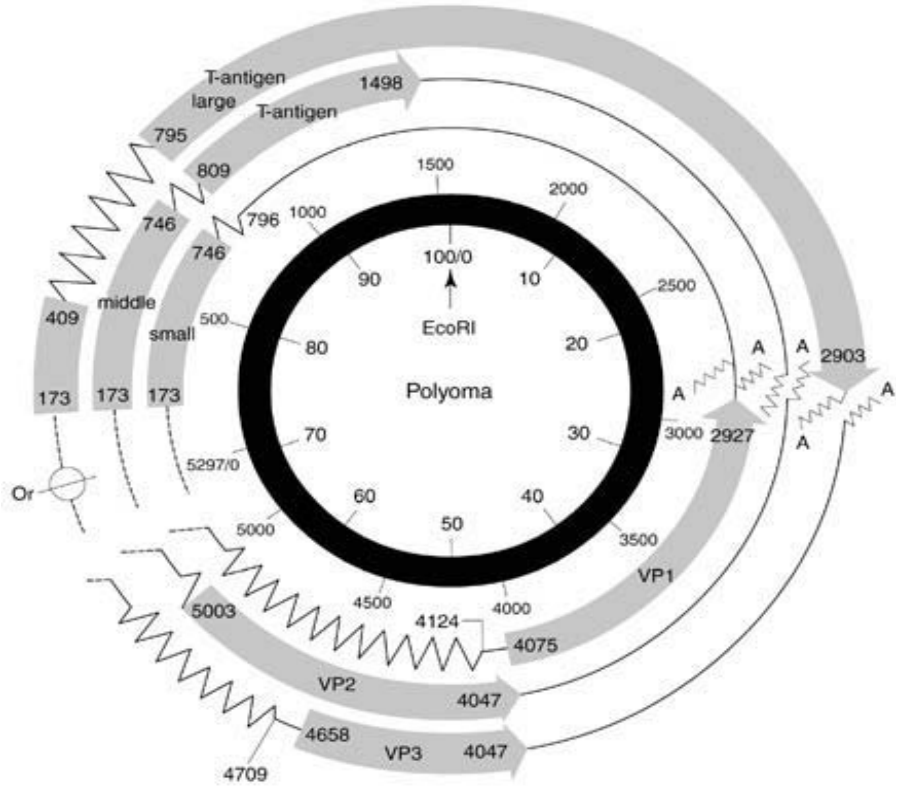

Figure 1 Coding regions of the polyoma genome. The coding regions for the early viral proteins (T antigens) and the late viral proteins (VP1, VP2 and VP3) are shown. (Adapted from Eckhart W (1990) In: Fields BN and Knipe DM, *Fields Virology*, 2nd edn. New York, Raven Press.)

replication and unwinding DNA in the region of the origin. Several biochemical activities are associated with LT, including ATPase and helicase activities. The protein helps to 'immortalize' primary rodent cells in culture, and cooperates with certain activated oncogenes to produce neoplastic cell transformation. Polyoma LT forms a complex with the retinoblastoma susceptibility protein, Rb, blocking the function of Rb in cell cycle progression. Mutants of polyoma LT that fail to bind Rb grow poorly in cells expressing functional Rb, suggesting that viral replication is coupled to induction of progression through the cell cycle. Unlike the simian virus 40 (SV40) LT, polyoma LT does not form a complex with the tumor suppressor protein, p53. However, polyoma LT can overcome p53-induced growth arrest through interaction with Rb.

The amino-terminal region common to all three T antigens contains a sequence similar to the domains of DnaJ proteins that activate molecular chaperones of the DnaK family. LT binds a cellular DnaK, heat shock protein 70. Mutation of the LT J domain abolishes the ability of LT to block the function of Rb, suggesting a role for J domains in regulation of Rb family members.

Polyoma MT contains 421 amino acids. MT is associated with the plasma membrane of the cell through a sequence of 22 uncharged and hydrophobic amino acids, bordered by positively charged amino acids, near the C terminus, which comprise a transmembrane domain. When expressed in established mouse or rat cell lines, MT induces neoplastic cell transformation. The transformed cells form tumors in animals.

The MT protein forms complexes with a variety of growth regulatory proteins in the cell. MT binds and activates three members of the src family of protein tyrosine kinases, $pp60^{c\text{-}src}$, $pp62^{c\text{-}yes}$, and $pp59^{c\text{-}fyn}$. Activation of protein tyrosine kinase activity occurs through decreased phosphorylation of a regulatory tyrosine in the C-terminal region of the $pp60^{c\text{-}src}$ associated with MT.

Activated $pp60^{c\text{-}src}$ phosphorylates tyrosines in MT itself, which serve as binding sites for proteins containing Src homology 2 (SH2) domains or phosphotyrosine-binding (PTB) domains. The SH2

domain of the 85 kDa regulatory subunit of phosphatidylinositol 3′ kinase (PI3K) binds phosphorylated tyrosine 315 of MT. The SH2 domain of phospholipase C-gamma 1 (PLC-γ1) binds phosphorylated tyrosine 322 of MT. As a consequence of binding the enzymatic activities of PI3K and PLC-γ1 are stimulated. Binding of PI3K by MT leads to enhanced glucose transport and activation of pp70 S6 kinase.

The PTB domain of the adaptor protein, Shc, binds phosphorylated tyrosine250 of MT. Shc itself then becomes phosphorylated on tyrosine, providing a binding site for the SH2 domain of the adaptor molecule, Grb2, which in turn brings the guanine nucleotide exchange factor, mSos into the complex. The presence of mSos in a membrane site activates p21*ras* and MAP kinase pathways, however PI3K association with MT is also required for maximum activation. One of the consequences of p21*ras* and MAP kinase activation is an increase in the transcriptional activating activity of the transcription factor, AP-1. The increase is caused by increased phosphorylation of regulatory serine residues in the N-terminal transactivating domain of c-Jun, which is a component of AP-1.

Mutation of tyrosine250, 315 or 322 decreases or abolishes the transforming activity of MT, assayed by anchorage-independent growth of transformed cells. There are variable and less pronounced effects on the frequency, time of appearance and spectrum of tumors induced in animals by the mutant viruses. Mutation of both tyrosine250 and 315 has more severe effects than mutation of either alone. Mutation of either tyrosine250 or tyrosine315 causes increased sensitivity to apoptosis induced by serum starvation, suggesting that imbalanced signal transduction driven by MT may potentiate apoptosis.

The N-terminal region of MT (amino acids 1–185) binds the regulatory and catalytic subunits (A and C) of protein phosphatase 2A (PP2A). Binding of PP2A appears to be required for subsequent binding of $pp60^{c\text{-}src}$ by MT, as mutations in MT that disrupt PP2A binding also abolish binding of $pp60^{c\text{-}src}$, and equimolar amounts of PP2A are present in the MT–$pp60^{c\text{-}src}$ complex. Amino acids 185–210 of MT are additionally required for the interaction with $pp60^{c\text{-}src}$. The phosphatase activity of PP2A may be required to facilitate the interaction of MT with $pp60^{c\text{-}src}$. The majority of MT in the cell is associated with PP2A, whereas only a small fraction (5–10%) of MT is associated with $pp60^{c\text{-}src}$.

MT also associates with 14.3.3 proteins, which have been implicated in signaling and cell cycle regulation. Serine257, which is the major site of serine phosphorylation in MT, is required for association with 14.3.3 proteins. Mutation of serine257 does not affect transformation or tumor formation by MT.

Table 1 Cellular proteins complexed with MT

Protein	*MT binding site/region*
PP2A	AA 1–185
$pp60^{c\text{-}src}$	AA 1–210
Shc	Tyrosine 250
PI3K	Tyrosine 315
PLC-γ1	Tyrosine 322
14.3.3	Serine 257

Table 1 summarizes the cellular proteins found in complexes with MT.

ST contains 195 amino acids. It is partitioned between the nucleus and cytoplasm. The protein is not absolutely required for viral replication, but facilitates the accumulation of viral DNA under certain conditions. Virus mutants lacking ST replicate poorly and fail to form tumors in newborn mice. Like MT, ST forms a complex with PP2A.

The major virion protein, VP1, contains 384 amino acids. It is responsible for the binding of polyoma virions to cellular receptors. Mutations in VP1 affect the plaque morphology, virion stability, hemagglutination properties and pathogenicity of polyoma strains. The minor virion proteins, VP2 and VP3, contain 319 and 204 amino acids, respectively. VP1 binds DNA, whereas VP2 and VP3 do not. The first five amino acids of VP1 are essential for DNA binding. Nuclear location signals are found in the N-terminal region of VP1, amino acids 1–11, and in the C-terminal region of VP2 and VP3, amino acids 307–318. Although the coding regions of the nuclear location signals of VP1 and VP2/3 overlap, as described below, the amino acid sequences are different because the proteins are translated in different reading frames.

Physical Properties

Polyoma infectivity survives months at 4°C and weeks at 37°C. Infectivity is inactivated at 70°C, but is not inactivated by heating to 60°C for 30 min. The virus is resistant to ether, 2% (v/v) phenol and 50% (v/v) ethanol. Virus preparations contain several kinds of particles: infectious viruses, containing intact viral DNA, noninfectious viruses, containing deleted or rearranged viral DNA molecules, empty particles, lacking DNA, and pseudovirions, containing cellular DNA. The density of DNA-containing viral particles is 1.34 g ml^{-1}. The virus agglutinates erythrocytes of a number of species. The ratio of physical particles to infectious units under conditions of standard plaque assays is 100:1–1000:1.

Replication: Strategy of Replication of Nucleic Acid

Polyoma produces a lytic infection in mouse cells, characterized by viral replication, production of infectious progeny and lysis of the infected cell. In hamster or rat cells, the infection is generally abortive; the virus replicates poorly and many infected cells survive. In lytically infected cells, viral DNA replication begins 12–18 h after infection and continues for about 24–48 h until the cell dies.

Polyoma DNA replication requires the origin core and an element from the enhancer region. Replication begins at the origin core and proceeds bidirectionally, terminating about 180° away on the circular viral DNA. An initiation complex containing LT binds to repeated pentanucleotide sequences in the origin core of a circular covalently closed viral DNA molecule and unwinds a region of dsDNA. This creates a replication 'bubble' of diverging replication forks. Nascent chains are initiated by DNA primase–DNA polymerase α. The nascent chains begin with an RNA primer, six to nine ribonucleotides long, which is extended as DNA. At the replication fork, one strand is synthesized continuously in the direction of fork movement, while the other strand is synthesized discontinuously in segments about 135 nucleotides long in the opposite direction. As replication proceeds, the torsional strain created by the unwinding of the parental strands of DNA is released by a topoisomerase activity. Bidirectional replication proceeds until the replication forks meet, at which point the daughter molecules separate.

Binding of cellular transcription factors to the enhancer region is necessary for efficient viral DNA replication. Binding is required on the molecule being replicated (i.e. in *cis* configuration), suggesting that the transcription factors may interact with LT, or with components of the replication complex. The transcription factor AP-1, which binds in the enhancer region, enhances DNA unwinding by LT *in vitro*.

Polyoma LT can be divided into N-terminal and C-terminal domains with independent functions in cellular and viral DNA replication. The N-terminal region, amino acids, 1–260, is sufficient to induce cellular DNA synthesis, but fails to replicate viral DNA, whereas the C-terminal region, amino acids 264–782, is sufficient to replicate viral DNA in actively growing cells, but fails to induce cellular DNA synthesis in serum-starved cells.

Characterization of Transcription

The early and late regions of the polyoma genome are transcribed from opposite strands of the DNA. Transcription begins at sites on either side of the origin of replication and proceeds in opposite directions. Transcription is carried out by the cellular RNA polymerase II. Transcription of early mRNA does not require viral proteins. The early promoter resembles other eucaryotic promoters in having a TATA box about 30 bp upstream of the early mRNA initiation site. The major 5′ termini of polyoma early mRNAs are located about 20 bp upstream of the initiation codon for the early proteins. Three kinds of early mRNAs are produced by alternative splicing. Each of the mRNAs encodes one of the T antigens.

Transcription of early mRNA is regulated by sequences in the enhancer region, and by LT. Mutations in binding sites for cellular transcription factors in the enhancer region reduce transcription of early mRNA.

Late transcription occurs primarily after the onset of viral DNA synthesis. Polyoma late mRNAs are heterogeneous in size. The nuclei of infected cells contain large transcripts that are tandem repeats of the entire viral genome. These transcripts are processed by splicing to produce mature polyadenylated mRNAs with unique coding regions attached to a common untranslated leader sequence. The 5′ termini of the late mRNAs are heterogeneous. The leader sequence is tandemly repeated, presumably because of successive leader to leader splicing which occurs during the processing of the large primary transcripts. Alternative splicing produces individual mRNAs encoding each of the virion proteins.

During the late phase of infection the amount of early RNA detectable by hybridization decreases. This effect is caused by the presence of antisense transcripts present in the late RNA (the early region is transcribed in opposite orientation in the late RNA). The antisense transcripts hybridize with early RNA in the nucleus. The double-stranded molecules are susceptible to modification by dsRNA-specific adenosine deaminase, which modifies adenosine to inosine, rendering the early RNA undetectable by hybridization. The modified RNAs accumulate in the nucleus, and thus are inert for protein synthesis. This process suggests a mechanism by which naturally occurring antisense transcripts downregulate early gene expression during the late phase of infection.

Characterization of Translation

The coding regions of the T antigens overlap, producing proteins with common N-terminal regions and unique C-terminal regions, determined by alternative splicing of the early mRNAs and translation in different reading frames. The three T antigens share

79 amino acids at their N-termini. ST and MT share an additional 112 amino acids which are not present in LT. The unique C-terminal regions of ST, MT and LT are four, 230 and 703 amino acids, respectively. The T antigens are synthesized in the cytoplasm. After synthesis they are partitioned to different cellular compartments: LT to the nucleus, MT to the plasma membrane and ST to the nucleus and cytoplasm.

The virion proteins, VP1, VP2 and VP3, are synthesized in the cytoplasm, but are transported to the nucleus, where assembly of infectious virions occurs. The coding regions of VP2 and VP3 overlap. The proteins have different N-terminal initiation codons, determined by alternative splicing of the late mRNAs, and a common C-terminal termination codon, so that the sequence of VP3 is entirely contained in VP2. The C-terminal coding region of VP2/3 overlaps the N-terminal coding region of VP1 for 29 nucleotides, but the amino acid sequences of the proteins are different because they are translated in different reading frames.

Post-translational Processing

Polyoma LT is phosphorylated on serine and threonine residues. Threonine278, which is phosphorylated by S- and G2-specific cyclin/cyclin-dependent kinase (cdk) complexes, is required for viral DNA replication. Mutation of threonine278 to alanine results in defects in origin binding and unwinding by LT. The phosphorylation of threonine278 by cyclin/cdk complexes suggests a reason why polyoma replication requires actively growing cells. Serines267, 271 and 274, which are also sites of phosphorylation, are not required for replication of viral DNA by the C-terminal domain of LT, but may regulate the relationship of the N- and C-terminal domains.

The MT protein is phosphorylated on serine 257, and on tyrosines250, 315 and 322, as described above. Serine257 phosphorylation regulates binding of 14.3.3 proteins by MT, whereas tyrosine phosphorylation provides binding sites for Shc, PI3K and PLC-γ1.

The virion proteins of polyoma are also modified by phosphorylation. About 15% of the VP1 molecules in virions are phosphorylated. VP2 and VP3 are phosphorylated to a lesser extent. The major phosphorylated amino acid of VP1 is threonine; serine is a minor component. The major sites of threonine phosphorylation are threonine63 and threonine156. VP1 is phosphorylated *in vitro* on serine66 by casein kinase II. Serine66 also appears to be a site of *in vivo* phosphorylation. Phosphorylation of VP1 takes place in the cytoplasm of the cell, possibly during translation. Phosphorylation of VP1 plays a role in virus assembly, because mutation of threonine156 to alanine causes defects in assembly. VP1 is also modified by acetylation, methylation, tyrosine sulfuration and proline hydroxylation. The role of these modifications is unknown.

The N-terminal glycine residue of VP2 is acylated with myristic acid. This modification takes place cotranslationally. Mutation of the glycine residue, preventing myristoylation, results in decreased infectivity.

Assembly Site, Uptake, Release and Cytopathology

Polyoma virions are assembled in the nucleus of the infected cell. VP2 binds to VP1, and VP2 can transport VP1 lacking nuclear location signals into the nucleus, suggesting that complexes of VP1 and VP2 may form in the cytoplasm before moving to the nucleus. Binding of calcium by VP1 is required for efficient virus assembly.

Infectious virus particles adsorb to susceptible cells through the interaction of VP1 with cellular receptors. Infection can be blocked by treatment of cells with sialidase, suggesting that *N*-acetylneuraminic acid (sialic acid) on the cell surface is required for polyoma infectivity. Polyoma attaches to the surface of susceptible cells by stereospecific recognition of oligosaccharides terminating in (α 2,3)-linked sialic acid. The structure of VP1 complexed with 3′-sialyl lactose shows van der Waals' contacts between the side chain of valine296 of VP1 and the sialic acid ring. Alanine at position 296 reduces the contacts and decreases the affinity of VP1 for the receptor fragment. Viruses with alanine at position 296 are more virulent than viruses with valine, suggesting that decreased binding of polyoma to its receptors promotes spread of the virus and increases pathogenicity. After adsorption, the virus is internalized and transported to the nucleus where replication occurs. Progeny virus particles are passively released when the infected cell dies. Each infected cell produces 10 000–100 000 virions (100–1000 PFU).

POMOVIRUSES

L. Torrance, Scottish Crop Research Institute, Invergowrie, Dundee, UK

History

Fungus-transmitted, tubular rod-shaped viruses were classified as furoviruses in 1987 based on the properties of particle shape, transmission by zoosporic Plasmodiophorid 'fungi' and the possession of a divided genome. However, as more nucleotide sequences became available, it was apparent that the *Furovirus* genus contained species with different genome organizations and sequence relatedness. The classification was revised in 1998 and three new genera (*Pomo-*, *Peclu-* and *Benyvirus*) were established in addition to the genus *Furovirus* with no assignment to families.

Taxonomy and Classification

Pomovirus is a siglum derived from *po*tato *mo*p-top virus (PMTV), the type species. There are four member species in the genus *Pomovirus:* PMTV, beet soil-borne virus (BSBV), beet virus Q (BVQ) and broad bean necrosis virus (BBNV). Pomoviruses have genomes comprising three species of linear positive-sense single-stranded RNA of c. 5.8–6.5 kb, 2.9–3.5 kb and 2.5–3 kb, respectively. The RNA is not polyadenylated, and the genome encodes a triple block of proteins thought to be involved in virus movement.

Physical Properties of Particles

Pomovirus particles have helical symmetry, and are 18–20 nm in diameter comprising multiple copies of the major coat protein (c. 19–20 kDa). The stop codon of the coat protein gene can be suppressed to produce a larger readthrough protein. The readthrough domain of PMTV is expressed as a fusion with the coat protein and remains attached to one extremity of some virus particles. Virus particles are fragile and preparations contain large numbers of short fragments; the protein helix is sometimes uncoiled at one end in particles of PMTV. The particle size distribution is reported to be 100–150 nm and 250–310 nm. Measurements of PMTV particles gave predominant lengths of 125 nm, 137 nm and 283 nm. Virus particles sediment as three components and sedimentation coefficients ($s_{20,w}$) of PMTV are reported to be 126, 171 and 236S.

Genome Properties

The complete sequence has been determined for the genomes of BSBV (**Fig. 1**) and BVQ, and for RNA 2 and 3 of PMTV. Partial sequence information is available for PMTV RNA 1 and the three RNA species of BBNV.

RNA 1 contains a single large open reading frame (ORF) that is interrupted by a UAA codon followed in phase by an additional coding region. The ORF encodes putative proteins of c. 145–149 kDa and c. 204–207 kDa (readthrough protein). The smaller protein contains methyltransferase and helicase motifs, and the readthrough protein also contains a RNA-dependent RNA polymerase (RdRp) motif suggesting that these proteins are involved in virus replication.

RNA 2 (RNA 3 of PMTV) encodes the coat protein gene which is terminated by a UAG stop codon and followed in phase by an additional coding region of variable size. Suppression of the UAG stop codon produces a readthrough protein of 54–104 kDa. The molecular mass of the readthrough protein of a glasshouse-maintained isolate of PMTV (PMTV-T) is 67 kDa, but is c. 82 kDa in several field isolates. The shorter size of PMTV-T is caused by internal sequence deletion in the 3′ half of the gene.

RNA 3 (RNA 2 of PMTV) contains three or four ORFs. The first three ORFs partially overlap and

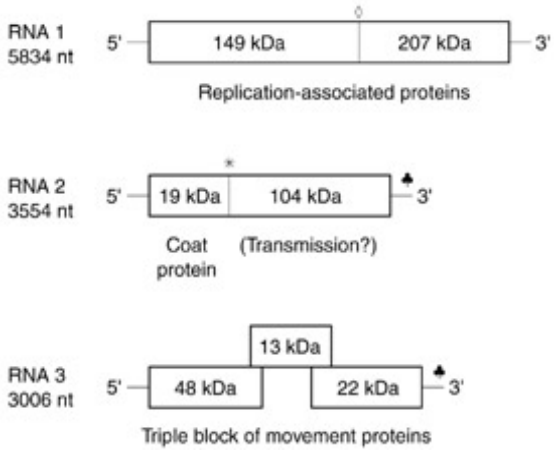

Figure 1 Diagram of BSBV genome organization showing the molecular mass of predicted protein products and their putative functions. * represents an UAG stop codon; ◇ represents a UAA stop codon; ♣ represents a tRNA-like structure.

share some characteristics with the triple gene block (TGB) found in the genomes of other rod-shaped viruses such as barley stripe mosaic hordeivirus and beet necrotic yellow vein benyvirus (BNYVV). By analogy they are thought to encode proteins that are involved in virus movement. The pomovirus-encoded proteins share the greatest sequence identity with each other in the second TGB protein (68–75%), and share 53–58% and 35–41% identity in the first and third TGB proteins, respectively. Also, the dNTP binding site motif in the first TGB protein is conserved. Pomovirus TGBs share some sequence identity with the respective TGB proteins of furo-, peclu-, beny- and hordeiviruses, but fewer identical amino acids when compared with those of other TGB containing viruses. PMTV (RNA 2) and BBNV (RNA 3) contain a fourth ORF which in PMTV encodes a putative 8 kDa cysteine-rich protein and in BBNV a putative 6 kDa protein. The RNA 3 of BVQ is shorter than the equivalent RNA in the other pomoviruses mainly because of the shorter lengths of its 5′ and 3′ untranslated regions. The three prime ends of the BSBV and BVQ RNAs and of PMTV RNA 2 can be folded into tRNA-like structures which contain an anticodon for valine.

Serological Relationships

The viruses are serologically distinct. PMTV particles contain an immunodominant epitope at the extreme N-terminus of the coat protein which is exposed along the entire length of the particles and reacts with monoclonal antibody SCR 69 (**Fig. 2**). The coat proteins of PMTV, BSBV and BVQ contain a conserved sequence of amino acids (SALNVAHQL) which are not exposed in the assembled particles but which react with a monoclonal antibody SCR 70 (raised to PMTV) in western immunoblotting tests. Distant serological relationships have been reported between BSBV and BVQ, and between soil-borne wheat mosaic furovirus and tobamoviruses with PMTV or BBNV.

Host Range and Geographical Distribution

The host range of pomoviruses is narrow, and restricted to dicotyledonous plants principally in the families Aizoaceae, Solanaceae, Chenopodiaceae and Leguminosae (only BBNV). The principal hosts of PMTV, BSBV and BBNV are potato, sugar beet and broad bean, respectively. PMTV occurs in Europe, South and North America and Asia in regions that have a cool, wet potato growing season. BSBV is widespread in sugar beet growing areas in Europe and North America. BVQ has been reported to occur only in sugar beet crops in Europe and BBNV has been reported only from Japan.

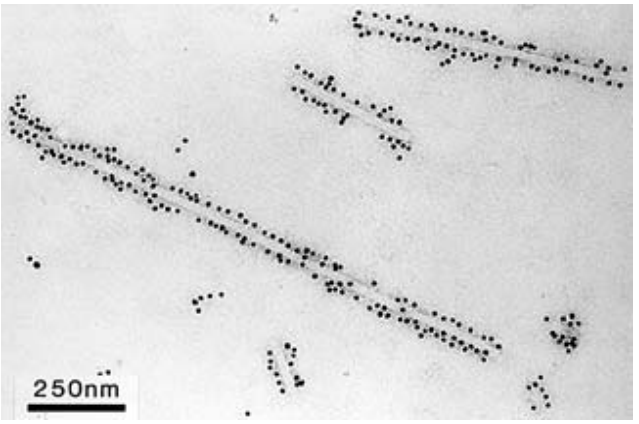

Figure 2 Electron micrograph of PMTV particles labelled with monoclonal antibody SCR 69/gold conjugate.

Cytopathology

Virus-induced inclusions are seen in thin sections of virus-infected plants. Sheaves of PMTV particles have been found in thin sections of all cell types including vascular tissues. In addition, microtubules have been seen in the cytoplasm, apoplast and vacuole of most cell types, sometimes associated with membranes of the endoplasmic reticulum and tonoplast. Enlarged endoplasmic reticulum and distorted membranes are seen in thin sections of plants infected with BSBV and BVQ.

Transmission

Pomovirus vectors are zoosporic protozoans in the family *Plasmodiophoridae*. They are obligate parasites with a complex life cycle, producing resting spores that survive in soil for long periods and biflagellate zoospores that swim in soil water and infect plant roots. The viruses are acquired during infection of root cells by the vector, and virus particles are thought to be carried within the zoospores and resting spores. Soil remains infective after air-drying. PMTV is transmitted by the potato powdery scab pathogen *Spongospora subterranea* f. sp. *subterranea*. *Polymyxa betae* is thought to be the vector of BSBV and BVQ. The viruses can also be transmitted by mechanical inoculation.

By analogy with BNYVV, the readthrough domain of the coat protein may play a role in vector transmission of virus. A correlation has been found between the deletion of amino acids in the C-terminal

portion of the readthrough domain and lack of transmission of PMTV by *S. subterranea*.

Ecology and Control

BBNV causes spots, streaks and veinal necrosis on the leaves of broad bean and pea and severely affected plants are stunted and defoliated. BSBV is widespread in sugar beets, it has been found in mixed infections with BNYVV, but no distinct symptoms have been attributed to infection by BSBV alone.

PMTV induces internal brown lines (spraing) and raised surface lines on potato tubers of sensitive cultivars infected directly from infested soil (**Fig. 3**). The spraing symptoms can be confused with those induced by the nematode-transmitted tobacco rattle tobravirus. Potato plants grown from infected tubers display yellow chevrons or markings on leaves or the mop-top dwarfing symptom caused by shortened internodes. PMTV decreases the quality of tubers produced for processing and consumption, and decreases the yield of tubers produced from plants of sensitive cultivars. Not every stem on an infected plant displays symptoms, and PMTV is erratically distributed in plants. The virus infects only a small proportion of plants grown from infected tubers, and it can be eliminated from stocks of cultivars that display obvious symptoms by removing infected plants. However, this method of control is limited to sensitive cultivars, and it carries the risk of establishment of PMTV at new sites. Haulm and tuber symptoms vary greatly with potato cultivar and environmental conditions especially temperature.

Resting spores of viruliferous vectors can be spread to new sites on contaminated farm vehicles or equipment, by planting contaminated tubers, by wind-blown surface soil or contaminated drainage water. Once the soil is infested by the viruliferous vector it is very difficult to control virus incidence. The Plasmodiophorid resting spores are resistant to chemical and environmental stresses and can remain viable in soil for many years, constituting an important reservoir of infection. The viruses are transmitted by the motile zoospores that swim in soil water, and their spread is favored by wet conditions. Soil fumigants such as methyl bromide are effective in controlling the Plasmodiophorids but it is environmentally damaging and its use is being restricted. Other chemical methods can provide partial control, e.g. decreasing soil pH to 5.0, by the application of sulphur, inhibits the spread of *S. subterranea* zoospores but the resting spores are not affected. At present there are no effective and environmentally safe chemical control methods. The best prospect for control of these soil-borne viruses is the development of virus-resistant cultivars. There are no sources of natural resistance in potato to PMTV but plants transformed with the PMTV coat protein gene have shown high levels of resistance to virus infection by manual or fungal inoculation. This form of resistance may provide effective control if incorporated into potatoes.

POTEXVIRUSES

Mounir G AbouHaidar and **Duncan Gellatly**, University of Toronto, Toronto, Ontario, Canada

General Features

Potexviruses consist of a genus (no family) of about 30 definite and possible member viruses, with the prototype member being potato virus X (PVX). The potexviruses share common properties with the carlavirus genus of plant viruses. The two genera are now being considered for merger into a single family. All potexviruses are morphologically similar, flexuous, filamentous viruses with virions ranging in size from 470 to 580 nm in length and about 14 nm in width. The central canal of the particle is about 3 nm in diameter. Infectious potexvirus particles typically consist of 1000–1500 subunits of a single species of capsid protein (CP) wrapped around one single-stranded, messenger-sense genomic RNA (gRNA) that ranges in size from 5845 to 7057 nucleotides (nt) (**Table 1**). These viruses have a broad geographic range reflecting the distribution of their hosts. Although any one potexvirus member has a limited number of hosts, many dicotyledonous and monocotyledonous plant species are susceptible to infection when the group is considered together. Unlike many other plant viruses that are transmitted by insect vectors, potexviruses are apparently spread via a mechanical mode of transmission. Seed transmission has been reported in a few cases, but it is not confirmed. Systemically infected plants usually display chlorotic mosaic or mottle symptoms. Yield losses due to potexvirus infection of crops can be as high as 30%.

Virion Structure and Assembly

Potexvirus particles are highly hydrated particles that have molecular weights ranging in the order of 35×10^6 kDa and sediment from 100 to 130 S. The single species of CP, which ranges in size from 21 to 29 kDa, coats the genomic RNA in a helical fashion giving rise to a flexible rod. Optical and x-ray diffraction studies of virus particles have shown that there are $8\frac{3}{4}$ subunits per turn of the helix, which repeats one every four turns and exhibits a pitch of 3.3–3.6 nm, depending on the degree of hydration of the particle. The RNA is localized to a position about 3.5 nm radius (in contrast to tobacco mosaic virus (TMV)-RNA which is located at about 4 nm radius). The tendency for viral RNA to be encapsidated at a low radius may afford the RNA better protection and allow for bending (flexibility) of the particle. There are approximately five nucleotides of the RNA which interact with the protein subunit. A considerable degree of variability (40–65%) in the amino acid sequences of the CPs of potexviruses, much of which is localized to the amino terminus (located on the outside of the virus particle), results in low serological cross-reactivity between different potexvirus members. The gRNA comprises 6.5–7.5% of the viral mass and ranges from 5845 to 7057 nt in size.

Self-assembly of purified CP monomers and gRNA to produce reconstituted virion particles resistant to ribonuclease A can occur *in vitro* in low ionic-strength buffers (e.g. pH 8.0). The assembly process

occurs in two stages: initiation and elongation. The initiation step is rapid (less than 20 s) and independent of temperature. Initiation occurs at a specific sequence (packaging signal, 38 to 47 nt in size) at the 5′ end of the gRNA. In papaya mosaic virus (PMV), this sequence contains several repeats (of the type GCAAA) which are postulated to interact with $8\frac{3}{4}$ protein subunits of the 14S double disk (or helix) to specifically initiate assembly. Particles approximately 50 nm in length are formed. Synthetic poly(A) and poly(C) can also be specifically recognized and packaged at pH 8.0 by PMV protein. The elongation phase is a slower, temperature-driven process in which small polymers of CP are added, with growth toward the 3′ end. Elongation, unlike the initiation process, seems to be non-specific. Any RNA can be packaged by PMV protein provided that the initiation sequence (packaging signal) is present at the 5′ end. At lower pH values, the specificity of PMV protein for its RNA is lost. Any viral and non-viral RNAs may be packaged by the PMV CP but no complete particles are formed because initiation simultaneously starts at several sites of the RNA, resulting in multi-initiated 'kinky' particles. In the absence of RNA, CP monomers will assemble to form helical or stacked disk structures at low pH. Assembly of potexviruses is unlike that of tobamoviruses because it is unidirectional (starts at the 5′ end of RNA) and no site of internal initiation is present.

Genome Organization

The monopartite genome of potexviruses consists of a messenger-sense, single-stranded RNA that is 5′ capped (m^7GpppG) and 3′ polyadenylated. An A-C-rich 5′ noncoding region, from 80 to 107 nt in length, occurs upstream of five open reading frames (ORFs) which are well conserved in sequence and position among different potexviruses. The largest ORF, ORF 1, codes for a protein that has two motifs of amino acid sequences that are present in the conserved domains of NTP-binding helicases and RNA-dependent RNA polymerases. Mutation of PVX ORF 1 in one of the conserved glycine-lysine-serine (GKS) sequence, a motif that is present among the replicating enzymes of many RNA viruses, eliminates PVX replication. The product of ORF 1 thus appears to represent a component of a replicase complex that directs, together with host proteins, and possibly other viral proteins, the synthesis of viral RNA

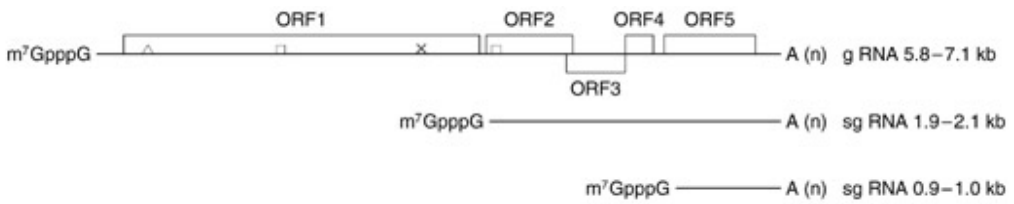

Figure 1 Organization of a potexvirus genome (gRNA). The diagram represents genomic organization of PVX, the type member of potexviruses. Five open reading frames (ORF) encoding the viral proteins with the following molecular weights: 166 kDa (ORF 1/putative RNA polymerase), 25 kDa (ORF 2), 12 kDa (ORF 3), 8 kDa (ORF 4) (ORF 2–4/triple gene block involved in viral transport) and 25 kDa (ORF 5/capsid protein). The sizes of the viral proteins vary among the other potexviruses of which the genomes have been sequenced. The sizes are: 147–191 kDa, 24–26 kDa, 11–14 kDa, 6–11 kDa and 21–26 kDa for ORF 1 to ORF 5, respectively. The two most abundant subgenomic RNAs (sgRNA) are also depicted. m^7GpppG represents the cap structure. $A_{(n)}$ represents the poly(A) tail. Triangle depicts the methyltransferase motif. Squares represent the NTPase/helicase motif (GSK). × depicts the GDD polymerase motif.

(Fig. 1). ORFs 2, 3 and 4 slightly overlap, and are commonly referred to as the 'triple gene block'. Products of the triple gene block function in cell-to-cell movement, being required for infectivity in a host plant but not in protoplasts. The amino acid sequences of ORF 2 from various potexviruses indicate an ATPase–helicase function, and the ORF 2 product of PVX has been shown to bind nucleic acids *in vitro*. Hydrophobic sequences in the products of ORFs 3 and 4 suggest an association with host cell membranes. Immunological localization has demonstrated the product of PVX ORF 4 to be associated with the cell wall. There are some apparent exceptions to the organization of ORFs 2–4. The genome of lily virus X (LVX) lacks the initiation codon for ORF 4, strawberry mild yellow edge-associated potexvirus (SMYEAV) lacks one for ORF 2. However, the rest of the coding sequences of these ORFs are present and are similar to other potexviruses. The exact role(s) of these ORFs in the potexvirus life cycle is not fully determined at present. ORF 5 codes for the CP. In two potexviruses, clover yellow mosaic (CYMV) and foxtail mosaic virus (FoMV), ORF 5 is contained within a larger ORF that appears to encode a 'read-through' protein. Various potexviruses also contain other small putative ORFs that are embedded in, and often out of frame from, the five major ORFs. Other putative ORFs found on the negative (complement) strand have also been described. The *in vivo* significance of such ORFs remains speculative. The 3′ noncoding region ranges from 43 to 138 nt in length and precedes a poly(A) tail that varies in length. A U-rich 8-nt sequence within the 3′ noncoding region of PVX is required for virus replication by binding two host proteins (28 and 32 kDa in tobacco) of unknown function. A consensus polyadenylation sequence (5′-AAUAAA-3′) occurs at different distances from the 3′ end of the gRNA.

During potexvirus replication, capped and poly(A)-tailed subgenomic RNAs (sgRNAs) are produced. The two most abundant sgRNAs are 1.9–2.1 kilobase (kb) and 0.9–1.0 kb in size. These have 5′ ends which correspond to internal regions of the gRNA, and are coterminal with the gRNA at their 3′ ends. The formation of sgRNAs was previously thought to alleviate the problem of translation of polycistronic mRNAs by eukaryotic ribosomes, which follow the Kozak scanning model. However, recent work has demonstrated that the PVX CP gene can be expressed in transgenic plants from an internal ribosome binding site. Consequently, the formation of sgRNAs in this group of viruses (and probably in other viruses) is merely for amplification (and not for initiation of translation) purposes. A 1.2-kb sgRNA in CYMV has been isolated, consisting of 757 and 415 nt segments from the 5′ and 3′ ends, respectively, joined so that the N-terminus of ORF 1 and C-terminus of ORF 5 are fused in frame. This sgRNA is clearly defective and requires the full-length genome as a helper for replication. Furthermore, this CYMV 1.2-kb sgRNA appears to be the only defective-interfering (DI)-like RNA seen among potexviruses.

Replication

The essential potexvirus replication strategy is believed to involve an RNA intermediate, in which the messenger-sense gRNA is initially copied to produce a full-length antisense complement. This antisense complement is then used as a template for the synthesis of full-length messenger-sense gRNA. Detection of double-stranded gRNA in infected tissue supports this model. The full-length antisense complement also serves as a template for the synthesis of sgRNAs. These sgRNAs are 3′ coterminal with the gRNA, and function as mRNAs for viral products coded for in the 3′-half of the gRNA. It is believed the sgRNAs are produced from the full-length antisense

complement via internal initiation. Membrane-containing extracts isolated from PVX-infected tobacco plants have been shown to support synthesis of all viral RNA types, both single and double stranded. Several conserved sequence motifs, identified at the 5′ and 3′ ends of the gRNA as well as regions immediately 5′ to the initiation sites of sgRNAs synthesis, may act as promoter elements for a replicase complex. The putative promoter sequence at the 5′ end of all potexvirus gRNAs is 5′-GAAAACAAAAC-3′ and at the 3′ end is 5′-ACUUAA-3′. PVX mutants in the 5′ noncoding region have demonstrated that sequence elements in this region also play a crucial role in the synthesis of both gRNA and sgRNA. The presence of a conserved octanucleotide sequence, and the spacing between this sequence and the 5′ start site of sgRNA synthesis initiation, has been shown to be essential for accumulation of the two major sgRNAs in PVX replication. The RNA-dependent RNA polymerase (RdRp) of PVX (ORF 1) contains a glycine-lysine-serine (GKS), a glycine-aspartate-aspartate (GDD) and a methyltransferase (for capping) motif which are also found in many RdRps of RNA viruses. The GKS motif is thought to be required for the binding of nucleoside triphosphates. Mutation of GKS to GNS or GES rendered that virus unable to replicate in plants or protoplasts. Substitution of glycine to alanine had only a minor effect on the replication of PVX. However, mutation of any of the three amino acids GDD rendered the viral genome noninfectious.

The function of the triple gene block products appears to be that of cell-to-cell movement, as mutations in ORFs 2, 3 or 4 prevent the development of systemic infection in plants but not of viral replication in protoplasts. Systemic spread of a transport-defective PVX ORF 2 mutant was restored by transformation of host cells with transport proteins from either a tobamovirus, dianthovirus, or bromovirus. Mutations to the conserved elements of ORF 2 (ATPase-helicase domain) and ORF 3 (hydrophobic domain) also inhibited viral spread in intact hosts. In PVX, the ORF 2 product has been localized to complex lamellar structures and inclusion bodies in the cytoplasm and possibly the nucleus, whereas in bamboo mosaic potexvirus, the ORF 2 product is found in electron-dense crystalline bodies in both the cytoplasm and nucleus. From studying size-exclusion limits of plasmodesmata, the 25-kDa protein (ORF 2) of PVX was shown to be required for full plasmodesmatal modification. A nucleotide triphosphate/helicase consensus sequence (GSGKS/T), similar to that found in ORF 1, has also been found in the ORF 2 of some potexviruses. The ORF 4 product of PVX has been localized to the cell wall. An intact product of ORF 5, the CP, is essential for systemic infection with PVX as well as for replication of PVX gRNA and packaging of this RNA to form complete virus particles.

The messenger-sense gRNA of potexviruses can be translated directly after uncoating in the plant cell. *In vitro* translation of gRNAs isolated from virions typically generates products that correspond to the putative replicase protein encoded by ORF 1 at the 5′ end of the gRNA. Only small and variable amounts of CP, encoded by ORF 5 at the 3′ end, are produced. Production of any CP is likely a result of internal initiation of translation. Efficient *in vitro* synthesis of CP can be achieved by using the smaller (0.9–1.0 kb) of the two major sgRNAs as template. *In vitro* translation of the larger (1.9–2.1 kb) major sgRNA yields product corresponding to ORF 2. The mechanism of expression of the products of ORFs 3 and 4 is less clear, apparently involving internal initiation or the presence of less abundant sgRNAs.

The 5′ cap structure, present on all potexvirus gRNAs and sgRNAs, is essential for infectivity. For instance, infectious *in vitro* RNA transcripts of white clover mosaic potexvirus (WCMV) are only 4% as infectious as capped viral gRNA. Similarly, the length of the 3′ poly(A) tail is critical; shortening the tail length from 71 to 24 nt of *in vitro* RNA transcripts of papaya mosaic virus reduced infectivity from 43% to 16% of native viral gRNA. Mutations to the polyadenylation signal of WCMV reduced both transcript infectivity and the average length of the poly(A) tail in progeny virus.

Fusion of a 27-kDa reporter gene (*Aequorea victoria* green fluorescent protein) to the amino terminus of PVX ORF 5 (CP) resulted in assembly of intact virions that were over twice the diameter of wild-type PVX virions. However, free CP was also required. Efficient functioning of the reporter-gene product was observable, and the assembled virus was capable of both local and systemic movement. The further potential of the use of potexviruses as vectors for the production of high levels of foreign proteins in plants remains to be seen.

Pathology

Symptoms on systemically infected hosts range from undetectable to moderate, depending on the individual potexvirus. Generally, systemic symptoms include chlorotic mottle or mosaic patterns, with stunting also being common. Potexviruses are capable of infecting most host tissues. Both primary and systemic cytopathology can occur in a single host. *Gomphrena globosa* is the most common local lesion host among members of the potexvirus group.

Inclusion bodies, composed of potexvirus particles

packed in parallel arrays, often form in the cytoplasm and sometimes in the nucleus of infected cells. These aggregates often vary in size and have irregular shapes, but can form spindle-shaped structures in some potexviruses. Another type of inclusion, laminated inclusion components (LIC), are thin proteinaceous sheets associated with bead-like structures. LICs display no viral antigens. A third type, the amorphous inclusions, occur in the cytoplasm and vacuoles. Amorphous inclusions contain viral antigens.

Co-infecting a single host with a potexvirus and another virus (e.g. a potyvirus) can have a synergistic effect on symptoms. For instance, mixed infections with PVX and potato virus Y (PVY) produces a dramatic increase in the severity of PVX symptoms, pathogenicity and accumulation, compared to that observed by infection with PVX alone. Other potyviruses such as tobacco vein mottling virus (TVMV), tobacco etch virus (TEV) and pepper mottle virus are also capable of the synergistic effect on PVX replication and symptom severity. The replication of the entire potyviral genome is not increased nor required for PVX/potyviral synergism. The synergistic response is mediated by expression of the 5′-proximal third of the genomic potyviral RNA (i.e. protease-1, helper component protease (HC-Pro) and protein-3 gene). The exact molecular basis for PVX/PVY synergism is not presently well understood.

Host Resistance

The product of the N gene in tobacco confers resistance to PVX. Similarly, three genes in potato have been identified which are associated with potexvirus resistance: Nx and Nb are involved in hypersensitivity, and Rx with immunity. Rx1 has been mapped to the distal end of potato chromosome XII. PVX is recognized to comprise five subgroups (i.e. I, II, III, IV and HB) based on the ability to infect hosts of different resistance genotypes. For instance, group III is the largest PVX subgroup, which systemically infects Nb hosts. Within a group, sequence conservation and host susceptibility are difficult to correlate. In PVX, the CP has been shown to be a strain-specific elicitor of Rx-mediated resistance in potato. Amino acids 121 and 127 may interact with cellular components involved in spread of the virus and with products of Rx resistance gene. The PVX CP also harbors at least two types of virulence determinants, X and B, which differ by only 14 amino acids. Type X CPs are avirulent on potato cultivars carrying the Nx resistance gene, whereas type B CPs are capable of overcoming Nx resistance. Resistance 'breaking' strains of PVX have emerged by minor sequence changes in both the CP and other regions of the viral genome. Expression of the PVX CP or mutant movement proteins in transgenic plants can result in a delay in the onset of symptoms upon subsequent challenge with PVX virus or gRNA. It has been shown recently that a replicating viral RNA (i.e. PVX) is a potent trigger of 'gene silencing', a phenomenon characterized by a genetic control mechanism implicated in virus resistance. Gene silencing is associated with the induced natural defense response of plants against viruses. The signal may move ahead of the inducing virus and result in delaying the spread of the infectious front. The exact molecular mechanisms involved in this phenomenon are currently not well understood.

This work is dedicated to the memory of Duncan Gellatly (1969–1998).

POTYVIRUSES (*POTYVIRIDAE*)

Juan José López-Moya and **Juan Antonio García**, Centro Nacional de Biotecnologia, CSIC, Campus UAM, Cantoblanco, Madrid, Spain

History, Taxonomy and Classification

The *Potyvirus* genus (type species potato virus Y) of the *Potyviridae* family currently contains the largest group of plant viruses – up to 30% of the total number of plant viruses. The family *Potyviridae* includes five other genera: *Rymovirus, Macluravirus, Ipomovirus, Bymovirus* and *Tritimovirus*. Historically, several viruses later classified in the family *Potyviridae* were known for a long time; some were reported as early as the beginning of the twentieth century, some during the 1930s and the number has increased further from the 1960s to the present day. Viruses of the *Potyviridae* family are among the most damaging plant viruses and a considerable literature has been devoted to them. Since the mid-1980s, complete genome sequences of potyviruses have become available, and genetic studies were made possible by the production of full-length directly infectious cDNA clones, or from infectious transcripts. This technique has also become available for a bymovirus.

The taxonomic standards currently in use for classification into the family *Potyviridae* include properties of the virus particles (long flexuous, as shown in **Fig. 1A**), their genome structure (positive sense single-stranded (ss) RNA, with a 5′ terminal protein and a 3′ poly(A) tail), their expression strategy (polyprotein containing several gene products, separable by proteolysis) and their cytopathological manifestations (particularly the formation of pinwheel- or scroll-shaped cylindrical cytoplasmic inclusions in infected plant cells, as shown in **Fig. 1B**).

Potyviruses can be differentiated from other genera in the family because they are aphid-transmissible and possess a monopartite genome. Bymoviruses are transmitted by fungi and have a genome composed of two molecules of ssRNA which are encapsidated separately. Rymoviruses and Tritimoviruses have monopartite genomes, and their natural vectors are eriophyd mites. Ipomoviruses and Macluraviruses also have monopartite genomes, and they are whitefly and aphid transmitted, respectively.

Although an extensive review of taxonomic issues exceeds the purpose of this entry, recent molecular information has essentially confirmed the classification shown in **Table 1**. Relationships between members of the family should be further examined when more complete sequences become available.

Geographic Distribution, Host Range, Epidemiology and Propagation

Members of the *Potyviridae* family are distributed throughout the world. Some of them have restricted natural and experimental host ranges; others may infect a considerable number of plant species distributed in many families. In general, there are members that are able to infect the most economically important crops, including grain, legumes, forage, vegetables, fruits and ornamentals.

Severity of outbreaks is commonly related to the abundance of initial foci of infection, vector populations and other factors. Vector organisms are mainly involved in the propagation of viruses within a localized region, although they might also have a role in initiation of epidemics at long distance. Human intervention is responsible in many cases for the spread of diseases in larger areas, and the introduction of new diseases. Seed transmission is also important in some potyviruses, and weeds can act as reservoirs of viruses. A typical example of well-documented spread of a potyvirus over a territory and over time is the progressive emergence of plum pox virus (PPV) in European countries during the twentieth century, and its recent spread to other continents.

Properties of Virions

Virion particles of potyviruses are long and flexuous (**Fig. 1A**), 680–900 nm long and 11–15 nm wide. They comprise protein (95%) and RNA (5%). Viruses belonging to other genera in the family possess particles with similar properties. Ipomovirus particles are around 900 nm long, while macluravirus ones are shorter (around 650 nm). The two bymovirus particles are about 250–300 and 500–600 nm in length.

Around 2000 subunits of a single protein (CP) compose the capsid of potyviruses. The molecular weight of each subunit ranges between 30 and 47 kDa, and they are disposed helicoidally around the nucleic acid. Variations in CP size are due mainly to

Table 1 Classification of members of the family *Potyviridae* into genera, with indication of the number of members, transmission vectors and number of genomic RNAs

	Members[a]			
Genus	*Definite*	*Possible*	*Transmission*	*Genome*
Potyvirus	75	93	Aphids	Monopartite
Bymovirus	5	—	Fungi	Bipartite
Rymovirus	3	2	Mites	Monopartite
Tritimovirus	2	—	Mites	Monopartite
Ipomovirus	1	1	Whiteflies	Monopartite
Macluravirus[a]	2	—	Aphids	Monopartite

[a] Number of members according to the International Committee on Taxonomy of Viruses.

differences in the length of the variable N-terminal region, while the internal core (of about 220 amino acids) is more conserved, as expected for its involvement in particle architecture. Although the structure of the potyvirus virions has not yet been determined, Shukla and others have established some structural characteristics (**Fig. 2**). It is known that both N- and C-termini of CP are surface exposed on the particle, the N-terminus being the immunodominant region. In addition, superficially located residues in this region play a role during aphid transmission and are involved in other important functions such as long distance movement in the host plant. A nonspecific nucleic acid binding-domain has been characterized recently in the CP of barley yellow mosaic bymovirus (BaYMV).

Serologic Relationships

Relationships among members of the *Potyviridae* family, based on serology, have been problematic because of their extreme complexity. Virus particles are strongly immunogenic as a general rule, but for many years antisera had limited application in taxonomy. Nonstructural proteins had even more restricted use in serological identification.

The unexpected serological crossreactivities between viruses, and inconsistent relationships derived from virion-based serology, may be due to the fact that group-specific epitopes are mainly located in the conserved internal core region of CP, while the virus-specific ones map in the variable N-terminus, a region that is surface-exposed and prone to undergo degradation. Once the origin of the problem has been identified, solutions have been proposed to obtain virus-specific antibodies by targeting towards the N-terminal epitopes. In addition, the highly conserved CP core may be used to generate *Potyviridae*-specific antibody probes, useful in detecting numerous viruses.

López-Abella, CIB, CSIC.)

Properties of the Genome

The nucleic acid of potyviruses is an ssRNA molecule of 9.4–10.3 kb, messenger (positive) sense, with a 5′ terminal protein (VPg), and polyadenylated at its 3′ end. It comprises a single open reading frame (ORF) coding for a long polyprotein (340–370 kDa) that

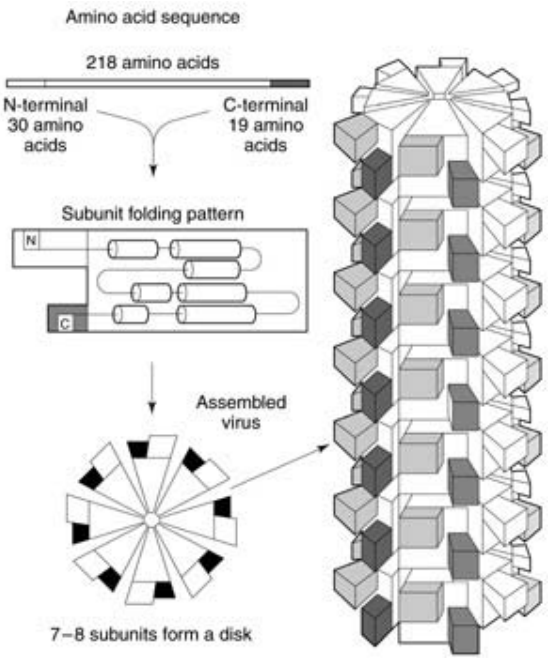

Figure 2 Structural model of potyvirus particles. The predicted folding of individual CP subunits is shown. CP cores unite together to build the virion, leaving both N- and C-termini superficially exposed. (Reproduced with permission from Shukla DD and Ward CW (1989) *Adv. Virus Res.* 36: 273.)

generates mature products (**Fig. 3**) after initiating an autoproteolysis processing cascade. Genomes of rymo- and ipomoviruses are similar in size and organization. In contrast, bymoviruses have their genome divided into two RNAs: the long RNA1 is analogous to the 3′ three-quarters portion of potyvirus genome, and the short RNA2 includes sequences corresponding to others in the 5′ portion of potyviruses, not having in the rest of the molecule clearly matching counterparts in the potyvirus genome. The majority of molecular data available have been obtained with potyviruses. Unless otherwise noted, the following sections describe characteristics of potyviruses.

Three potyvirus-encoded proteinases are involved in the proteolytic cleavage of gene products. The processing events have been studied in depth *in vitro*, and the present figure includes probable cotranslational and autocatalytic cleavages, followed by *trans* cleavages. Processing is dependent on the sequences surrounding each particular cleavage site. A review of this process can be found in the article by Riechmann and coworkers cited in the further reading section.

A typical potyvirus genome starts at the 5′ end with a noncoding region (NCR), usually less than 200 bp long. Studies performed with PPV showed that most of this region is dispensable for infectivity, although it contributes to viral competitiveness and pathogenesis. Although there is some controversy about the existence of internal ribosome entry sites in the 5′ NCR of potyviruses, recent results seem to indicate that translation takes place by a cap-independent leaky scanning mechanism. The 5′ NCR of poty-

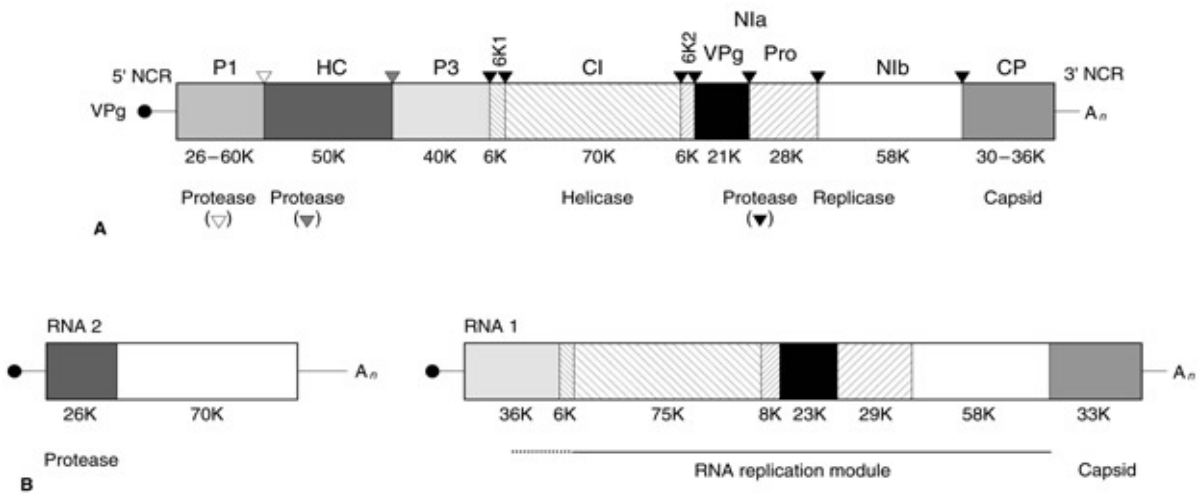

Figure 3 Genomic maps of (**A**) potyviruses and (**B**) bymoviruses. The ssRNA genomes are shown with boxes representing ORFs flanked by NTRs as lines. VPgs are represented by solid circles at each 5′ end, and poly(A) tails are located at each 3′ end. Names of gene products are indicated, as well as some of their known functions and their approximate size K (kDa). The three protease-specific cleavage sites (rendering functional proteins or regulating their activity) are also indicated by triangles above the potyvirus polyprotein. Genomic structures of rymo-, ipomo-, tritimo- and macluraviruses are similar to that of potyviruses.

viruses has been used as an enhancer of translation in transgenic plants.

Another NCR of about 200 bp is located at the 3′ end of the genome, before a variable-length poly(A) tail. Putative RNA structures in this region confer pathogenic properties, as shown in tobacco vein mottling virus (TVMV). In addition, work performed with tobacco etch virus (TEV) has demonstrated the existence of a *cis*-acting element necessary for infectivity near the 3′ end of the genomic RNA, including sequences contained in the last cistron of the ORF.

Properties and Functions of Gene Products

The polyprotein coded in the genome of a potyvirus comprises the following gene products. The first N-terminal protein, named P1, is a protease (similar to chymotrypsin-like serine proteinases) responsible for cleavage at its C-terminus. This region accounts for the largest sequence differences among potyviruses, being extremely variable in size (26–60 kDa) and sequence. Its functions have not yet been established. In TEV, it acts in *trans* as an accessory factor for genome amplification, and experiments suggest that it must be separated from the next gene product to restore debilitated infectivity caused by inactivation of its proteolytic activity. It also has RNA-binding activity.

After P1, the next gene product is the helper component, HC (about 50 kDa), a protein implicated in aphid transmission. Its N-terminal region, which includes a cysteine-rich portion with a putative zinc-finger-type structure, seems to be essential for transmission but is also needed for efficient RNA replication. The carboxy half of the protein is a papain-like cysteine protease, which serves to cleave at its own C-terminus. It has been reported that, like P1, HC is able to interact with RNA *in vitro*. Other functions have been assigned to this protein, such as a factor for long-distance transport and genome amplification. HC also forms amorphous-type inclusions in the cytoplasm of several potyviruses.

All other gene products are excised from the polyprotein by the action of the NIa protease (see below). The third gene product in the ORF is known as P3 (about 40 kDa), and there is little information regarding its role during infection. Immunocytological studies have found P3 associated with cylindrical inclusions in TVMV, and nuclear inclusions in TEV. A small protein $6K_1$ is located next. However in potyviruses such as TEV cleavage between P3 and $6K_1$ has not been observed *in vitro*, and in PPV excision seems not to be required for virus viability. Immunological data suggest that both P3 and $P3{+}6K_1$ products are present in infected cells. The region contains hydrophobic domains which might result in association to membranes. It has been hypothesized that the functional product of this genome region is $P3{+}6K_1$, whose activity would be modulated by cleaving off the $6K_1$ fragment.

The next protein, CI, is the largest potyvirus gene product in size (around 70 kDa). It forms very distinctive cylindrical inclusions in the cytoplasm of infected cells, with a high taxonomic value because they are unique to members of the *Potyviridae* family (**Fig. 1B**). CI includes domains peculiar to RNA helicases, and this activity has been proved experimentally. Two domains have been shown to bind RNA. Functionally, CI is believed to act during unwinding of RNA chains in replication. In addition, it has been found associated to the plasma membrane and plasmodesmata in early stages of infection and it is required for cell-to-cell spread.

A second small peptide, $6K_2$, is involved in virus replication, and its role seems to be related to its membrane-anchoring properties, maintaining the replication complex in place. Separation of $6K_2$ from NIa by autoproteolysis regulates localization of the latter in the nucleus.

The next protein, NIa, of about 49 kDa, may undergo a further cleavage in an internal suboptimal processing site, giving origin to NIaVPg (21 kDa) and NIaPro (27 kDa). VPg is found covalently attached to the 5′ end of genomic RNAs, and it may act as a protein primer during initiation of replication. However, parental VPg is not needed for infectivity (RNA synthesized *in vitro* without VPg is infectious). Recently, a role for VPg during long-distance movement has been identified. In addition to forming VPg, NIa is the protease responsible for the majority of proteolytic events leading to the appearance of final gene products, acting in *cis* and *trans* at processing sites mainly defined by characteristic heptapeptides. Although NIa is structurally related to serine proteases, it has a cysteine at the active site. Moreover, the protease domain of NIa resembles P1 and HC in having nonspecific RNA-binding activity. The complete NIa forms inclusion bodies in the nucleus, where it is translocated by a bipartite signal sequence.

NIb (58 kDa), the second component of nuclear inclusions, is located next. It is the RNA-dependent RNA polymerase (RdRp). NIb contains domains distinctive of polymerases, including a highly conserved GDD motif. Recruitment for the replication complex is postulated to occur via its interaction with NIa. As well as NIa, it is directed to the nucleus by signals in its sequence.

The last product in the ORF is CP. Many roles have been assigned to this protein. First, it forms the virus

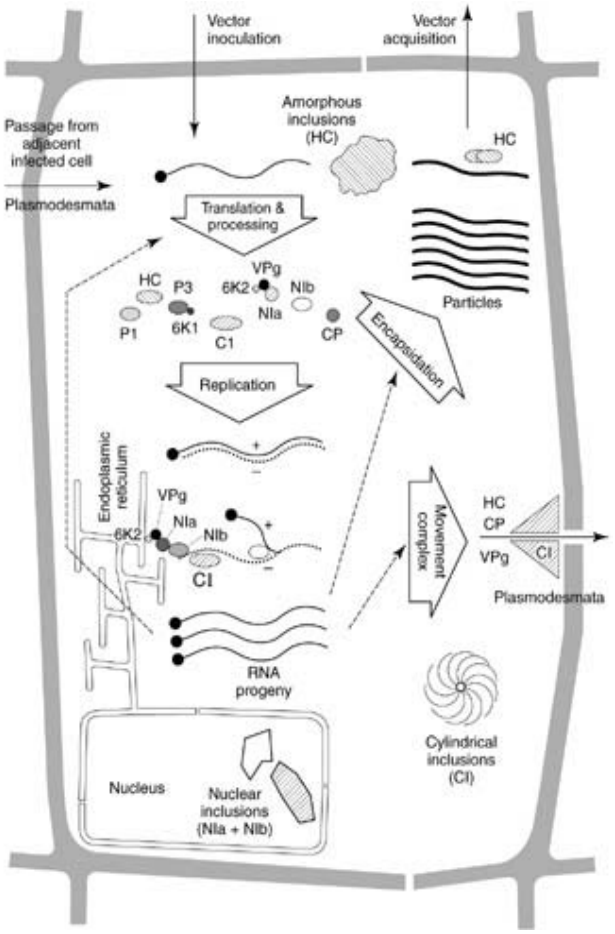

Figure 4 Different events during potyvirus infection of a plant cell. The eventual accumulation of viral proteins as inclusions in different compartments is also indicated.

particles, acting as protection for the genomic RNA. It is implicated in aphid transmission by interaction with HC (see Transmission). CP also participates in cell-to-cell and long-distance movement.

Gene products of viruses belonging to other genera in the family are believed to have equivalent functions. In the case of bymovirus RNA2, the large gene product has no sequence similarity with any potyvirus protein, and it has been postulated to play a role in fungus transmission.

Replication

Potyviruses replicate in the cytoplasm of infected cells. A scheme, based on works done by many researchers, is given in **Fig. 4**. After entering into a cell and undergoing desencapsidation, the genomic RNA must first be translated to give origin to the replication complex, which is composed of several viral products and probably host factors. The replication complex uses the genomic RNA (+ sense) as a template to generate a complementary chain (− sense), which serves as a template for the synthesis of numerous genomic RNAs. Translation of these genomic molecules results in accumulation of viral proteins, including the structural CP which encapsidates RNA to generate viral progeny particles. Movement to adjacent cells in the plant occurs via passage of the RNA through the plasmodesmata, in a form not totally identified, with the involvement of many products such as HC, CI, VPg and CP, and in the newly infected cell the replication cycle is repeated. Proteins involved could vary depending on cell type. Movement has been thoroughly studied by J. C. Carrington.

As a result of the potyvirus expression strategy using a polyprotein, the generation of many copies of CP needed to encapsidate progeny genomes implies the production of equimolar amounts of all other gene products. Some of them accumulate in inclusion bodies in different cellular compartments, while others might be secreted, degraded or remain in a nonnoticeable pattern. It is interesting that, whereas in all potyviral infections cylindrical inclusions (made by CI) are formed in the cytoplasm of infected cells, amorphous or nuclear inclusions (made by HC or NIa and NIb, respectively) are formed by some, but not all, potyviruses.

Potyvirus RNA replication takes place in membranous structures, probably derived from endoplasmic reticulum. NIb forms the core of the viral RNA replicase. NIb protein from TVMV shows *in vitro* RdRp activity, as recently proved. All NIb functions essential for RNA amplification may be provided *in trans*, as free protein supplied in transgenic plants complement TEV deletion mutants. Other proteins probably involved in viral RNA replication are the RNA helicase CI, the putative replication primer VPg, and the membrane anchoring factor $6K_2$. On the other hand, NIa interacts with NIb and RNA, serving perhaps to recruit products during the process. Other factors such as P3 might be involved as found by mutagenesis studies. P1 is also believed to play a role in replication, although it is the only nonessential potyvirus protein. Host factors also might be involved. In this regard, turnip mosaic virus (TuMV) VPg is able to interact with the translational eukaryotic initiation factor (iso) 4E, which may be involved in virus replication or/and translation.

A novel approach for the study of potyvirus replication and its effects on host cells has been developed by Maule. Using pea seed-borne mosaic virus (PSbMV) synchronous infection of cotyledon tissue and *in situ* hybridization, early events during infection have been studied. An infectious front can be identified, which involves active synthesis of minus-strain

RNA and subsequent later accumulation of genomic forms. Along with the presence of the viral RNAs in newly infected cells, a shutoff mechanism of translation of many host proteins was observed, as well as upregulation of other products (interestingly heat shock-related proteins or ubiquitin). These findings have been extended to other viruses and tissues, suggesting common molecular processes which might be significant in pathogenesis.

Evolution

Members of the family *Potyviridae* were considered within the Picorna-like supergroup of viruses, due to a fairly conserved set of proteins with replication-related functions present in analogous placement in the genome.

Genera in the family show a close relationship, indicated by gene product order in the polyprotein, strategy of expression and protein homologies. Each genus within the family seemed to be adapted to specific vector organisms. Cassette evolution has been proposed as the means used by viruses to incorporate new functions in their genomes, and this must have been the case for members of the family *Potyviridae*.

One intriguing issue is the shocking number of aphid-transmitted potyviruses. A combination of a very efficient transmission system and adaptation to new hosts must have contributed to this large expansion. In particular, vector transmission acting as bottlenecks might lead to broad speciation in the highly variable quasispecies structure of RNA genomes. Indications of recombination events, partial duplications, point mutations which confer different host responses, as well as other facts, might help to explain the extraordinary variability observed among potyviruses.

Transmission

As mentioned above, viruses in the *Potyviridae* family have different vector organisms. Bymoviruses are believed to be present and travel in the zoospores of their fungus vector. Rymoviruses and tritimoviruses are transmitted by eriophyd mites through a little known mechanism. Similarly, relationships between ipomoviruses and their whitefly vectors have not been clearly established. In contrast, the process of aphid transmission of potyviruses has been intensely studied in several aspects, specially in Pirone's laboratory. Transmission occurs in a nonpersistent manner, with the involvement of two viral proteins, CP and HC. There are nontransmissible variants of potyviruses exhibiting defects in either of these proteins, and by mutagenesis analysis alterations responsible for these phenotypic effects have been identified in TVMV and other potyviruses. The integrity of a highly conserved DAG motif near the N-terminus of CP has proved to be essential for transmission. In HC, mutations in several domains, mainly located in its N-terminal portion, result in failure of transmission.

The hypothesis currently suggested for the mechanism of aphid transmission involves a function for HC serving as a bridge to retain virus particles to internal structures in the aphid stylets. Using radioactively-labeled virions, it has been found that they are retained mainly in the distal part of the stylets. An *in vitro* interaction between HC and CP has been shown recently to correlate with transmissibility of CP variants of TVMV, and the domain of CP involved in the interaction includes the DAG motif. Recent results show that a PTK domain identified in the HC of zuchini yellow mosaic virus (ZYMV) is likely to be related to this binding to CP. Presumably other motifs in the HC might be involved in the interaction with the vector. In addition, specificity for each virus–vector combination is probably determined by compatibility between HC and the aphid.

Pathogenicity

The information about how potyviruses cause diseases in their host plants is limited. Recent research has begun to identify sequences and products in the genome of potyviruses that are directly implicated in the production of symptoms. As mentioned above, symptom alteration determinants have been identified in the 3′ NCR of TVMV, and sequences in the 5′ NCR of PPV, not essential for infectivity, contribute to pathogenesis. Chimeras between variants of viruses differing in their pathogenic responses have been generated, and thus used to identify the differences accounting for their phenotypic behavior. Single products are not always responsible for the effects. For instance, two separate domains have been identified in TEV implicated in the specific wilting response of Tabasco pepper.

VPg seems to be an important determinant of pathogenicity in potyviruses. Thus, sequence variations in the VPg are involved in resistance-breaking of TVMV and TEV in tobacco, and VPg determines pathotype-specificity of PSbMV in pea.

Sequences of the P1/HC region are involved in a synergistic effect in the case of mixed infections with other viruses. It has been proposed that HC is a broad-range pathogenicity enhancer that seems to transactivate viral replication by interfering with a plant defense response.

For bymoviruses, determinants for pathogenicity

and symptomatology have been found in the RNA1 of barley mild mosaic virus (BaMMV).

Control

Strategies considered for potyvirus control are diverse, from culture practices to the use of genetic resistance. Insecticide treatment of vectors has limited use because of the transmission type. The knowledge currently available about potyvirus replication, movement and transmission will eventually allow design strategies directed at interfering with these key roles during the virus life cycle.

Presently, a considerable effort (with not always equally gratifying results) has been placed in the exploitation of pathogen-derived resistance. Transgenic plants have been generated incorporating viral sequences. Since the early reports of CP-mediated resistance to plant viruses, this approach has been tried with several potyviruses. Results show that expression of one potyvirus CP in transgenic plants might confer resistance to other unrelated potyviruses. Nonstructural genes of viruses have been tested as sources of resistance, with promising results. Replicase sequences, for instance, create several resistant phenotypes, considered to be RNA-mediated. Elucidation of the mechanisms involved in resistance has been initiated after works done by Dougherty with potyvirus-derived transgenic lines, which pointed out the relationship of resistance and the cellular phenomenon known as cosuppression or gene silencing.

Future Perspectives

Analysis of potyvirus molecular biology using full-length cDNA clones has been extraordinarily successful in many respects, and it is likely to continue to provide interesting data. In particular, new control strategies might be developed after much better understanding of the potyvirus life cycle is achieved. Virus–host relationships involved in virus multiplication and pathogenesis, as well as in virus resistance, must be further characterized. Transgenic plants will provide information at this level, and even extend beyond, to be used as tools in plant molecular biology studies.

In addition, biotechnological uses of potyviruses has begun. The junction of P1–HC has been manipulated as a potential insertion site for foreign genes, allowing applications of potyviruses as expression vectors in plants, and it is likely that this or similar strategies will be further exploited.

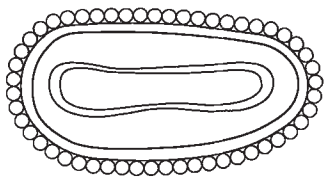
POXVIRUSES (*POXVIRIDAE*)



Contents

Capripoxviruses

R Paul Kitching, World Reference Laboratory for Foot and Mouth Disease, Pirbright Laboratory, BBSRC Institute for Animal Health, Pirbright, UK

History

Sheeppox and goatpox are malignant pox diseases of sheep and goats easily recognizable by their characteristic clinical signs, and described in the earliest texts on animal diseases. Lumpy skin disease (Neethling) of cattle (LSD), however, was first described in 1929 in Northern Rhodesia (Zambia), having apparently been absent from domestic cattle until that time. From Zambia LSD spread south to Botswana and Zimbabwe and by 1944 the disease appeared in South Africa, where it caused a major epizootic, affecting over 6 million cattle. In 1957 LSD was first diagnosed in Kenya, and was thought at the time to be associated with the introduction of a flock of sheep affected with sheeppox on to the farm. Since then LSD has been present in most of the countries of sub-Saharan Africa, often associated with large epizootics followed by periods in which the disease is only rarely reported. In 1988 LSD caused a major outbreak in Egypt and in 1989 spread from Egypt to a village in Israel. This was the first time that a diagnosis of LSD outside of Africa had been supported by laboratory confirmation.

Taxonomy and Classification

The viruses that cause sheeppox, goatpox and LSD are all members of the genus *Capripoxvirus,* in the *Chordopoxvirinae* subfamily of the *Poxviridae* family, and have morphological, physical and chemical properties similar to vaccinia virus. Originally the viruses were classified according to the species from which they were isolated, but comparisons of their genomes indicate that the distinction between them is not so clear, and that recombination events occur naturally between isolates from different species. This is reflected in the ability of some strains to cause disease in both sheep and goats and in experimental results which show that all the sheep isolates examined could infect goats, and that goat isolates could infect sheep. The epidemiological relationship between sheeppox and goatpox isolates and cattle isolates is less clear, apparent in differences in the geographical distribution of sheeppox and goatpox and LSD (see later). However, some isolates recovered from sheep and goats in Kenya have genome characteristics very similar to cattle isolates. It has been proposed that confusion can be reduced by referring to the malignant pox diseases of sheep, goats and cattle, including Indian goat dermatitis and Kenyan sheep and goatpox, as capripox. It is envisaged that when sufficient isolates have been examined biochemically, no clear distinction will be possible between sheep, goat and cattle isolates, but a spectrum will emerge in which some strains have clear host preferences while others will be less defined and will naturally infect the host with which they come into contact.

Geographical and Seasonal Distribution

Capripox of sheep and goats is enzootic in Africa north of the equator, the Middle East and Turkey, Iran, Afghanistan, Pakistan, India, Nepal and parts of the People's Republic of China, and in 1986, Bangladesh. Sheeppox was eradicated from Britain in 1866, and from France, Spain and Portugal in 1967, 1968 and 1969 respectively. Sporadic outbreaks still occur in Europe, for instance in Italy in 1983 and Greece and Bulgaria both in 1995 and 1996, and Greece in 1997 and 1998.

LSD is enzootic in the sub-Saharan countries of Africa and is possibly still present in Egypt. The single outbreak in Israel was eradicated by slaughter of affected and in-contact cattle.

There is no clear seasonality to outbreaks of capripox in sheep and goats. In enzootic areas lambs and kids are protected against infection with capripoxvirus for a variable time dependent on the immunity of the mother. However, the spread of LSD is related to the density of biting flies and consequently major enzootics have been associated with humid weather when fly activity is greatest.

Host Range and Virus Propagation

Amongst domestic species, capripoxvirus is restricted to cattle, sheep and goats. Experimentally it is possible to infect cattle, sheep or goats with isolates derived

from any of these three species, although clinically the reaction following inoculation may be indiscernible. Viral genome analysis using restriction endonucleases has identified fragment size characteristics by which it is possible to classify strains into cattle, sheep or goat isolates. However, the identification of strains that have intermediate characteristics between typical sheep and goat isolates does suggest the movement of strains between these species. Analysis of some Kenyan isolates derived from sheep and goats shows very close homology with cattle LSD isolates.

The involvement of the African buffalo (*Syncerus caffer*) in the maintenance of LSD has not been clearly established. Some surveys have shown the presence of capripoxvirus antibody in buffalo, while others have failed to show its presence. Buffalo clinically affected with LSD have not been described. Experimental infection of giraffe (*Giraffe calemopardelis*), impala (*Aepyceros melampus*) and gazelle (*Gazella thomsonii*) has resulted in the development of clinical disease.

Bos indicus cattle are generally less susceptible to LSD and develop milder clinical disease than *B. taurus*, of which the fine-skin Channel Island breeds are particularly susceptible. Similarly, breeds of sheep and goats indigenous to capripoxvirus enzootic areas appear less susceptible to severe clinical capripox than do imported European or Australian breeds.

Capripoxvirus will grow on the majority of primary and secondary cells and cell lines of ruminant origin. Primary lamb testes cells are considered the most sensitive system for isolation and growth of capripoxvirus. The virus produces a characteristic cytopathic effect (cpe) on these cells which can take up to 14 days for field isolates, but can be as short as 3 days for well-adapted strains.

Isolates of capripoxvirus derived from cattle have been adapted to grow on the chorioallantoic membrane of embryonated hens' eggs, although attempts to grow isolates from sheep and goats in eggs have been unsuccessful. Vaccine strains of capripoxvirus have been adapted to grow on Vero cells. Capripoxvirus will not grow in any laboratory animals.

Genetics

Less is known concerning the specific genetics of capripoxvirus than is known about the orthopoxvirus genome. Studies on field isolates taken from cattle suggest that the virus is very stable, as *Hind* III restriction endonuclease digest patterns of isolates from the 1959 Kenya outbreak of LSD are identical to those obtained from 1986 LSD isolates. However, recombination has been shown to occur between cattle and goat isolates and this could be the natural method by which the virus evolves. By analogy with the orthopoxviruses, it is also likely that sequences are deleted or repeated within the genome in the normal replicative cycle.

Comparisons between the genomes of the different poxvirus genera show a relatively low level of nucleotide sequence homology. In common with other poxviruses, capripoxviruses contain a gene coding for thymidine kinase. Genes which code for attachment, fusion, interferon γ receptor and chemokine receptor proteins have also been identified, and sequenced, and shown to be highly conserved between isolates. Within the capripoxvirus genus, nucleotide divergence values suggest that the typical sheep and cattle isolates are more closely related to each other than to goat isolates. There is, however, less divergence between capripoxvirus genomes than seen in orthopoxvirus genomes, particularly in the near-terminal regions, which in the orthopoxvirus is considered to account for the considerably larger host range of this genus.

The usual technique for developing capripox vaccines has been to serially passage virulent isolates in tissue culture. This has been shown to reduce the virulence of the strain, although the mechanism by which it occurs is not known.

Evolution

The capripoxviruses have evolved into specific cattle, sheep and goat lines, but, as has been described above, intermediate strains exist, particularly those with cattle and goat genome characteristics. In Kenya there is evidence of movement of strains between all three species, but the absence of sheeppox or goatpox in LSD enzootic areas in Southern Africa, and the absence of LSD outside of Africa, would suggest that host-specific strains are being maintained and presumably are continuing to evolve.

Serologic Relationships and Variability

Polyclonal sera fail to distinguish in the virus neutralization test between any of the isolates of capripoxvirus so far examined. Sheep, goats or cattle that have been infected with any of the isolates are totally resistant to challenge with any of the other isolates. On this basis it has been possible to use the same vaccine strain to protect all three species. No monoclonal antibodies are yet available against capripoxvirus, but it can be expected that differences will emerge between strains using these reagents.

Capripoxviruses share a precipitating antigen with parapoxviruses, but no crossimmunity has been

shown between these two genera, or between capripoxvirus and any other pox virus genera.

Epidemiology

In sheeppox and goatpox enzootic areas the distribution of disease is frequently a reflection of the traditional form of husbandry. For instance, in the Yemen Arab Republic, the sheep and goat flocks kept on the grassland of the central plateau and better irrigated regions of the coastal plain move about in search of food, frequently mixing with flocks from neighboring villages at water holes, and in this situation disease is restricted to the young stock. Animals over 1 year of age have a solid immunity. The animals belonging to villages in the more mountainous regions and the arid areas of the coastal plain are isolated by terrain or semidesert from mixing with animals from other villages. It is not known what is the critical number of animals required to maintain capripoxvirus within a single population but it is over a thousand adult animals, which is the approximate village sheep and goat populations. In these villages disease is usually only seen following the introduction of new animals, typically from market, and generally affects animals of all age groups. The disease spreads through the village, usually within 3–6 months, and then disappears in the absence of more susceptible animals. Occasionally, even within areas of high sheep and goat density, it is possible to encounter animals that have been kept totally isolated in the confines of a domestic residence, and these may remain susceptible to infection until adult.

In Sudan, large numbers of sheep and goats are trekked from the west to the large collecting yards and markets of Omdurman, outside Khartoum. Here also it is possible to see capripox infection in adult animals. Many of the flocks originate in villages which, like in the Yemen, are isolated from their neighbors. Capripoxvirus does not persist in these villages, and as a result the animals acquire no resistance, and are fully susceptible when they first encounter disease on the long journey across Sudan. Animals being exported from countries that are free of capripoxvirus may suffer a similar fate when they arrive in a capripoxvirus enzootic area, as often seen in Australian or New Zealand sheep imported into the Middle East.

In a study of 49 outbreaks of capripox in the Yemen, only eight were reported to affect both sheep and goats, the remaining 41 causing clinical disease in either sheep or goats. It is possible that both sheep and goats could have been involved in more than the eight outbreaks, but that the disease was inapparent in one species; whether, therefore, the species in which the disease was inapparent could transmit virus and become a vector for disease has not been determined. In Kenya, capripox is frequently encountered in both sheep and goats within the same flock, and there is the possibility that the same strain of capripoxvirus could also cause LSD in cattle.

The epidemiology of sheeppox, goatpox and LSD is similar; the severity of outbreaks depends on the size of the susceptible population, the virulence of the strain of capripoxvirus, the breed affected (indigenous animals tending to be less susceptible to clinical disease than imported), and, with LSD, the presence of suitable insect vectors. Morbidity rates vary from 2 to 80%, and mortality rates may exceed 90%, particularly if the infection is in association with other disease or bad management.

Transmission and Tissue Tropism

Under natural conditions capripoxvirus is not transmitted very readily between animals, although there are circumstances when transmission appears very rapid; for example, in association with factors that damage the mucosae, such as peste des petits ruminants infection or feeding on abrasive forage. Animals are most infectious soon after the appearance of papules and during the 10 day period before the development of significant levels of protective antibody. High titres of virus are present in the papules, and those papules on the mucous membranes quickly ulcerate and release virus in nasal, oral and lachrymal secretions, and into milk, urine and semen. Viremia may last up to 10 days, or in fatal cases until death. Those animals that die of acute infection before the development of clinical signs and those that develop only very mild signs or single lesions rarely transmit infection, while those that develop generalized lesions produce considerable virus and are highly infectious. Aerosol infection over a few meters only, as with other poxvirus infections, is probably the usual form of transmission. Contact transmission of LSD virus under experimental conditions in the absence of insect vectors has only rarely been reported. Biting flies are significant in the mechanical transmission of LSD, and *Stomoxys calcitrans* and *Biomyia fasciata* have been implicated. There are probably a number of insects capable of mechanically transmitting LSD virus, but insects such as mosquitoes, which preferentially feed on hyperaemic sites such as papules and if interrupted inoculate a new host intravenously, are considered the most likely to be involved in outbreaks characterized by large numbers of affected animals with generalized infections. Experimentally, *S. calci-*

trans has also been shown to be capable of transmitting sheeppox and goatpox.

During the recovery phase following infection, the papules on the skin become scabs. It is relatively easy to demonstrate virions in the scab, but difficult to isolate virus on tissue culture, probably because of the complexing of antibody and virus within the scab. Capripoxvirus is reported to remain viable in wool for 2 months and in contaminated premises for 6 months, and is reported to remain infectious in skin lesions of cattle for 4 months. The true epidemiological significance of the virus within the scab, and ultimately the environment, is not clear. It has been suggested that the protein material that envelops the virus within the type A intracytoplasmic inclusion bodies of infected cells protects the virus in the environment.

There is no evidence for the existence of animals persistently infected with capripoxvirus. Transplacental transmission of capripoxvirus may be possible in association with simultaneous pestivirus infection, as may occur with pestivirus-contaminated capripox vaccine.

Capripoxvirus can be isolated from the leukocytes during viremia, and has been isolated from lesions in the liver, urinary tract, testes, digestive tract and lungs; however, the cells of the skin and skin glands and the internal and external mucous membranes appear to be the major sites of virus replication.

Pathogenicity

There is considerable variation in the pathogenicity of strains of capripoxvirus. Nothing is known concerning the genes responsible in the capripoxvirus genome for virulence or host restriction.

Clinical Features of Infection

The incubation period of capripox infection, from contact with virus to the onset of pyrexia, is approximately 12 days, although it frequently appears longer as transmission is often not immediate between infected and susceptible animals. Following experimental inoculation of virus the incubation period is approximately 7 days, and this is similar to that shown experimentally using biting flies to transmit virus.

The clinical signs of malignant disease are similar in sheep, goats and cattle. Twenty-four hours after the development of pyrexia of between 40 and 41°C, macules (2–3 cm diameter areas of congested skin) can be seen on the white skin of sheep and goats, particularly under the tail. Macules are not seen on the thicker skin of cattle, and are frequently missed on

Figure 1 Sheep pox showing rhinitis and conjunctivitis.

skin of pigmented sheep and goats. After a further 24 h the macules swell to become hard papules of between 0.5 and 2 cm diameter, although they may be larger in cattle. In the generalized form of capripox, papules cover the body, being concentrated particularly on the head and neck, axilla, groin and perineum, and external mucous membranes of the eyes, prepuce, vulva, anus and nose. In cattle these papules may exude serum, and there may be considerable edema of the brisket, ventral abdomen and limbs. The papules on the mucous membranes quickly ulcerate, and the secretions of rhinitis and conjunctivitis become mucopurulent (**Fig. 1**). Keratitis may be associated with the conjunctivitis.

All the superficial lymph nodes, particularly the prescapular, are enlarged. Breathing may become labored as the enlarged retropharyngeal lymph nodes put pressure on the trachea. Mastitis may result from secondary infection of the lesions on the udder.

The papules do not become vesicles and then pustules, typical of orthopoxvirus infections. Instead they become necrotic, and if the animal survives the acute stage of the disease, change to scabs over a 5–10

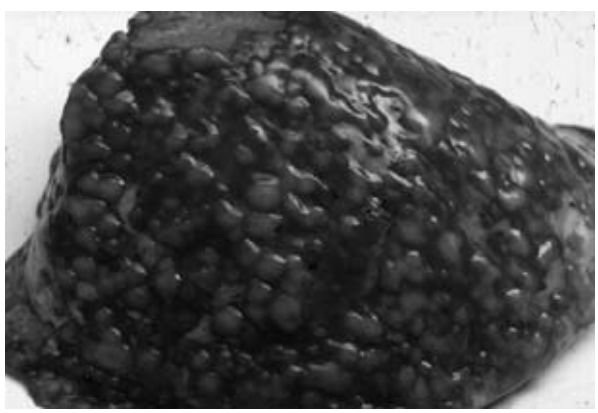


Figure 2 Sheep pox showing severe lung lesions.

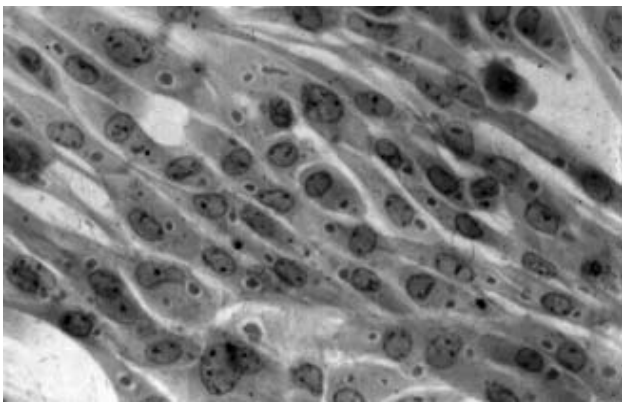

Figure 3 Capripoxvirus growing in lamb testis cells showing many intracytoplasmic inclusion bodies. ×400.

day period from the first appearance of papules. The scabs can persist for up to a month in sheep and goats, whereas in cattle the necrotic papules which penetrate the thickness of the skin may remain as 'sitfasts' for up to a year.

Severe disease is accompanied by significant loss of condition, agalactia, possibly secondary abortion and pneumonia. Eating, drinking and walking may become painful, and death from dehydration is not uncommon. Secondary myiasis is also a major problem in tropical areas.

Pathology and Histopathology

The lesions of capripox are not restricted to the skin, but also may affect any of the internal organs, in particular the gastrointestinal tract from the mouth and tongue to the anus, and the respiratory tract. In generalized infections papules are prominent in the abomasal mucosa, trachea and lungs. Those in the lungs are approximately 2 cm in diameter, and papules may coalesce to form areas of gray consolidation (**Fig. 2**).

In affected skin there is an initial epithelial hyperplasia followed by coagulation necrosis as thrombi develop in the blood vessels supplying the papules. Histiocytes accumulate in the areas of the papules, and the chromatin of the nuclei of infected cells marginates. The cells appear stellate as their boundaries become poorly defined, and many undergo hydropic degeneration with the formation of microvesicles. Intracytoplasmic inclusion bodies are present in infected cells of the dermis and also in the columnar epithelial cells of the trachea where frequently gross lesions may not be apparent. These are initially type B inclusions at the sites of virus replication (**Fig. 3**), but later in infection they are replaced by type A inclusions (see earlier). The maximum titer of virus is obtained from papules approximately 6 days after their first appearance.

Immune Response

Capripoxvirus, like orthopoxvirus, is released from an infected cell within an envelope derived from modified cellular membrane. The enveloped form of the virus is more infectious than the nonenveloped form, which can be obtained experimentally by freeze–thawing infected tissue culture. By analogy with orthopoxvirus, antigens on the envelope and on the tubular elements of the virion surface may stimulate protective antibodies. Animals immune to nonenveloped virus are still fully susceptible to the enveloped form. Passively transferred antibody, either colostral or experimentally inoculated, will protect susceptible animals against generalized infection; however, in the vaccinated or recovered animal there is no direct correlation between serum levels of neutralizing antibody and immunity to clinical disease. Antibody may limit the spread of capripoxvirus within the body, but it is the cell-mediated immune response which eliminates infection. In sheep, major histocompatibility complex (MHC)-restricted cytotoxic T lymphocytes are required in the protective immune response to orthopoxvirus infection, and therefore probably also capripoxvirus infection.

Immune animals challenged with capripoxvirus by intradermal inoculation develop a delayed-type hypersensitivity reaction at the challenge site. This may not be apparent in animals with high levels of circulating antibody. It has been suggested that the very severe local response shown by some cattle at the site of vaccination against LSD may be a hypersensitivity reaction due to previous contact with the antigens of parapoxvirus.

There is total crossimmunity between all strains of capripoxvirus, whether derived from cattle, sheep or goats.

Prevention and Control

In temperate climates capripox can be effectively controlled by slaughter of affected animals, and movement control of all susceptible animals within a 10 km radius for 6 months. In tropical climates, particularly in humid conditions when insect activity is high, movement restrictions are not sufficient and vaccination of all susceptible animals should be considered. In outbreaks of LSD it is not considered necessary to vaccinate sheep and goats, although theoretically cattle strains of virus could infect them. Similarly, in outbreaks of capripox in sheep and goats, cattle are not normally vaccinated.

Countries in which capripoxvirus is absent can maintain freedom by preventing the importation of animals from infected areas. There is always a possibility that skins from infected animals could introduce infection into a new area, although there have been no proven examples of this. The insect transmission of capripoxvirus into Israel from Egypt over a distance of between 70 and 300 km would indicate that it is impossible for countries neighboring enzootic areas totally to secure their borders.

In enzootic areas annual vaccination of susceptible animals with a live vaccine will control the disease. Calves, kids and lambs up to 6 months of age may be protected by maternal antibody, but this would only occur if the mother had recently been severely affected with capripox. Although maternal antibody will inactivate the vaccine, it is advisable to vaccinate all stock over 10 days of age. No successful dead vaccines have been developed for immunization against capripoxvirus infection, other than those that give only very short-term immunity.

Future Perspectives

Capripox of sheep and goats is present in most of Africa and Asia, whereas LSD is restricted to Africa. There is no good explanation as to why LSD has not spread into the Middle East and India, carried by the considerable trade in live cattle. Unless there is a reservoir host in Africa which is required for the maintenance of the cattle-adapted capripoxvirus, it can be anticipated that LSD will spread out of Africa, with major economic consequences.

While considerable attention has been given to vaccinia virus as a vector of other viral genes for development as a recombinant vaccine, little attention has been given to capripoxvirus as a potential vector vaccine. Although its use would be restricted to the not inconsiderable capripoxvirus enzootic area, it would have the advantage of not being infectious to humans, and being a useful vaccine in its own right.

Leporipoxviruses and Suipoxviruses

Grant McFadden, The John P. Robarts Research Institute, University of Western Ontario, London, Ontario, Canada

History

Poxviruses of leporids and swine cause a broad range of symptoms varying from mild lesions of the skin right up to lethal systemic diseases (**Table 1**). The agent of myxomatosis, a virulent disease of domestic rabbits described originally by G. Sanarelli in 1896, was in fact the first viral pathogen discovered for a laboratory animal. The close similarity of myxoma virus (MYX) with other members of the poxvirus family, such as variola and fowlpox, was first recognized by Aragão in 1927. MYX is notable because, although it causes rather benign lesions in the native *Sylvilagus* rabbit (the brush rabbit in North America and the tropical forest rabbit in South America), when introduced to the European (*Oryctolagus*) rabbit it causes an invasive disease syndrome with up to 100% mortality. MYX was the first viral agent ever introduced into the wild for the purpose of eradicating a vertebrate pest, namely the feral European rabbit population in Australia in 1950 and, two years later, in Europe. The resulting genetic selection of virus isolates with lesser pathogenicity and upsurgence of rabbits with greater resistance to the viral disease was studied intensively by Frank Fenner and his colleagues as a model system to investigate the ecological consequences of virus/host evolution in an outbred population.

Also of interest to the history of animal virology is the fact that the first DNA virus associated with

[d]MRV has been propagated only by serial inoculation of lab. rabbits and in cultured cells.

transmissible tumors was Shope fibroma virus (SFV), described in 1932 by Richard Shope as an infectious agent of fibroma-like hyperplasia in cottontail rabbits (*Sylvilagus floridanus*) in eastern USA. It is likely that the agent of 'hare sarcoma', described first in Germany in 1909, was also a poxvirus, now called hare fibroma virus (HFV). HFV remains the only leporipoxvirus to have arisen outside the Americas but its biology closely resembles that of SFV.

Very little is known about the remaining leporipoxviruses. Subcutaneous fibromatosis in gray squirrels of eastern USA and western gray squirrels in California, caused by poxviruses now collectively called squirrel fibroma virus (SqFV), have been observed since 1936, but their rigorous classification within the MYX–SFV family was not made until 1951 by L. Kilham. Similarly, HFV, described first in 1959 in the European hare (*Lepus europaeus*), was also shown to be a closely related poxvirus in 1961. In 1983, an outbreak of a disease resembling myxomatosis in laboratory rabbits in San Diego was caused by a novel leporipoxvirus later shown to be a genetic recombinant between SFV and a still-undefined strain of MYX. This virus, called malignant rabbit fibroma virus (MRV), has never been observed in wild rabbit populations but is of interest as an experimental model for poxvirus-induced immunosuppression and tumorigenesis. In most respects, MRV can be considered to be a substrain of MYX.

Based on landmark experiments with pneumococcus in the 1920s, the very first example of what was believed to be genetic interaction between viruses was reported in 1936 with the discovery that heat-inactivated myxoma could be reactivated with live SFV ('Berry-Dedrick' transformation), but later work showed this to be a genome rescue phenomenon rather than true recombination.

The only known member of the *Suipoxvirus* genus, swinepox virus (SPV), has been observed sporadically in pig populations throughout the world, but is not considered a serious pathogen because infected animals usually have only moderate symptoms and recover completely.

Taxonomy and Classification

The *Leporipoxvirus* and *Suipoxvirus* genera are in the subfamily *Chordopoxvirinae* of the family *Poxviridae*. The name lepori- comes from Latin *lepus* or *leporis* ('hare') and sui- from Latin *sus* ('swine'), to denote the relatively restricted host range of these viruses. All the viruses in the genus *Leporipoxvirus* can be shown to be closely related to each other by serology, immunodiffusion and fluorescent antibody tests although antigenic differences can be detected in strains of MYX. SPV (genus *Suipoxvirus*) is antigenically unique and is not known to have any closely related members. In terms of broad features, all are typical poxviruses, with characteristic brick-shaped virions containing a double-stranded (ds) DNA genome with covalently closed hairpin termini and terminal inverted repeat (TIR) sequences. Like other poxviruses, viral macromolecular synthesis takes place exclusively in the cytoplasm of infected cells.

Properties of the Virion

Like all members of the poxvirus family, the virions have a characteristic brick-shaped morphology with dimensions of approximately 250–300 nm × 250 nm × 200 nm. The leporipoxviruses are uniquely sensitive to ether and chloroform but otherwise the virions are very stable at ambient temperatures and in skin lesions. In all other respects, such as chemical composition and physical properties, the virus particles are very similar to those of vaccinia.

Properties of the Viral DNA and Protein

Detailed information about the viral DNA is available only for SFV, MYX and SPV. The leporipoxviruses have dsDNA genomes of 160–163 kb, with hairpin termini and TIR sequences of 10–13 kb. SPV DNA is somewhat larger (175 kb) and the TIR is only 4–5 kb but otherwise the genome has similar characteristics. It is believed that each virus encodes in excess of 200 genes. Restriction cleavage maps have been deduced for these viral genomes and generally the profiles are unique for each genus member but relatively well conserved amongst substrains and variants. Viral DNAs of leporipoxviruses crosshybridize at moderate stringencies only with other members of the genus, and SPV DNA is unique and is not known to crosshybridize with any other poxvirus DNA. The MRV DNA genome is 95% identical to MYX, except that it encodes five genes derived from SFV plus three SFV/MYX fusion genes.

The GC content of the leporipoxviruses (40% for SFV) is higher than that of the orthopoxviruses (35% for vaccinia) but there is evidence that many of the viral genes important for replication, gene expression and viral assembly are conserved between the genera. These essential genes for viral replication are clustered near the central regions of the viral genome. In contrast, viral genes mapping near the termini show considerable variability, and are believed to encode many of the specific determinants of pathogenesis that dictate host range and disease characteristics.

The protein complexities of these viruses as determined by one-dimensional gel electrophoresis

are comparable to that of vaccinia virus, although the profiles are unique for each member. In the cases where specific genes involved in viral propagation have been sequenced, such as thymidine kinase and topoisomerase, the proteins have been shown to be highly homologous to their counterparts from other poxviruses. Leporipoxviral proteins involved in virulence and pathogenesis, such as growth factors and serine proteinase inhibitors, tend to diverge more extensively from homologues in other poxviruses.

DNA Replication, Transcription and Translation

All of the major features of macromolecular synthesis by these viruses are very analogous to those deduced for the prototype poxvirus, vaccinia. DNA synthesis is restricted to cytoplasmic sites, although replication tends to be initiated somewhat more slowly than for vaccinia. The virus-encoded transcriptional apparatus is well conserved between the poxvirus genera, and many of the important regulatory signals that are utilized by vaccinia, such as promoters and transcription termination sequences, are also utilized with comparable efficiency in the leporipoxviruses. Thus, viral genes from one genus can be introduced to another by recombination or by DNA transfection technologies to generate chimeric virus constructs that maintain the correct regulation of the new genetic information. As in the case of vaccinia, transcriptional units can be of different kinetic classes (early/intermediate/late) and there is no splicing of viral mRNA.

The leporipoxviruses replicate in cytoplasmic factories that appear by microscopic analysis as eosinophilic B-type inclusion bodies. These factories, also called virosomes, can also be visualized by Feulgen, Giemsa or fluorescent antibody staining. SPV produces nuclear inclusions and vacuolations in addition to cytoplasmic bodies but these nuclear alterations are not believed to be sites of viral replication.

Molecular Mechanisms of Pathogenesis

Since these viruses are of only minor veterinary importance, recent research has focused on the elucidation of the determinants for viral virulence, particularly with respect to the cellular hyperplasia associated with viral replication in affected tissue and the mechanism(s) underlying the immune dysfunction caused by MYX in *Oryctolagus* rabbits. To date, at least two classes of leporipoxvirus gene products have been directly implicated in viral pathogenesis.

1. 'Virokines' are secreted virus-encoded proteins that are targeted to host-specific pathways outside the infected cell. For example, SFV and MYX encode growth factors related to epidermal growth factor and transforming growth factor alpha that participate in stimulating fibroblastic proliferation at primary and secondary tumors.
2. 'Viroceptors' are viral proteins that mimic cellular receptors and function by sequestering important host cytokines that normally participate in the antiviral immune response. Leporipoxviral-encoded receptor-like molecules have been discovered for tumor necrosis factor (TNF) and interferon γ (IFN-γ), and may exist for other antiviral lymphokines as well. Swinepox virus encodes a novel homologue of cellular chemokine receptors, and the leporipoxviruses express secreted chemokine binding proteins that are important for virus pathogenesis.

Interference with antigen presentation by MYX is believed to play a role in circumventing T-cell recognition during early stages of virus infection. One MYX gene product responsible for evading immune clearance, designated Serp1, is an extracellular inhibitor of cellular serine proteinases but its precise target remains to be identified.

Geographic and Seasonal Distribution

All three major species of *Sylvilagus* rabbits in the Americas have endemic fibroma-like poxviruses, and myxomatosis is now established in wild *Oryctolagus* rabbit populations of South America, Europe and Australia. SqFV and HFV have been reported to date only in North America and Europe, respectively. The leporipoxviruses in the wild undergo seasonal fluctuations that correlate well with increased populations of arthropod vectors in summer and autumn, most prominently mosquitoes. An exception to this is found in Britain, where the major vector of MYX is the flea, which is not as seasonally variable.

In the case of SPV, outbreaks are not tied to seasonal cycles but are generally associated with the degree of hog lice infestation.

Host Range and Virus Propagation

These viruses demonstrate a very restricted host range in terms of ability to cause disease, although viral replication can also occur in cultured cells from some nonsusceptible hosts as well. In some cases viral replication in tissue culture monolayers or chicken chorioallantoic membranes produces 'foci' in which infected cells manifest minimal cytopathic effects, thus permitting macroscopic cell aggregations to

develop. The extent of cytopathology is markedly influenced by both the cell type and the virus strain and in some instances the infected cells may detach from the monolayer to produce visible plaques. When viral replication is relatively slow and the toxicity to the target cell sufficiently moderate, a chronically infected carrier culture can be established in which progeny virus production persists for extended passages. Although poxviruses cannot permanently transform primary cells into an immortalized state, cells persistently infected with the fibroma-inducing leporipoxviruses assume many of the phenotypic characteristics associated with the transformed phenotype, such as novel morphology, growth in reduced serum and ability to form colonies in soft agar. It is likely that some of these phenotypic characteristics are facilitated by secreted poxviral proteins which mimic cellular mitogens, such as epidermal growth factor, and trigger neighboring cells into excessive proliferation.

In the cases of the benign leporipoxviruses and SPV, replication is restricted to dermal and subcutaneous sites, with occasional involvement of draining lymph nodes. However, MYX and MRV are unique in that they also replicate efficiently in lymphoid cells, such as macrophages, B cells and T cells. MYX, like HIV-1, replicates in either resting or stimulated T cells, and can be readily isolated from splenocyte cultures. The molecular basis for the uniquely permissive nature of MYX replication in lymphocytes is unknown, but is unquestionably an important factor in the extreme virulence of myxomatosis. Several MYX genes have been identified (M-T2, M-T5 and M11L) which function as host range determinants in infected lymphocytes by blocking the apoptosis response to infection.

Evolution and Genetic Variability

The deliberate release of MYX into rabbit populations of Australia, France and Britain in the early 1950s provided a unique opportunity to study the natural selection pressures exerted on a particularly virulent virus/host interaction. There is an extensive literature on the ecological consequences of this eradication program and the rapid evolution of myxomatosis in the wild is well documented. Although the original South American MYX virus strain that was introduced left very few survivors in selected populations, within a few years attenuated viral strains with reduced virulence took over and more resistant rabbits became predominant.

In terms of the categories of viral virulence, some strains of MYX are classified as highly virulent (e.g. Moses and Lausanne), and attenuated variants exist down to relatively nonpathogenic (e.g. neuromyxoma and the Nottingham strains). Little is known about the extent of genetic variation in other leporipoxviruses, although different isolates of SFV show marked variations in tumorigenicity. Generally, leporids which recover from infection with one member either become resistant or undergo partial protection from infection by another member.

SPV shares some antigenic crossreactivity with vaccinia, but neutralizing antibody does not confer crossprotection for secondary infections by members of different genera.

Transmission and Tissue Tropism

The principal mode of transmission is by biting arthropod vectors, and the major inoculation route is dermal. Since these viruses do not replicate in the vector, the transmission is purely mechanical and hence virus spread can be readily accomplished by alternative routes as well. Thus, mosquitoes, fleas, blackflies, ticks, lice, mites, and even thistles and the claws of predatory birds, have all been implicated in leporipoxvirus transmission. The efficiency of transmission by arthropods is quite variable, and is related to viral titers in skin lesions as well as the size of the vector populations. There are no known respiratory or oral routes of infection with members of either genus, but in some infections, such as MYX in domestic rabbits, the disease can be transmitted by direct contact with ocular discharges or open cutaneous lesions.

The sui- and leporipoxviruses in their native hosts are specific for the epidermis or subdermis and usually do not progress to secondary sites, although draining lymph nodes can be affected. However, in the case of MYX infection of the domestic rabbit the virus can propagate efficiently in lymphocytes and migrates via infected leukocytes through lymphatic channels to establish secondary sites of infection.

Pathogenicity

The leporipoxviruses are restricted to rabbits, squirrels and hares and swinepox is found only in domestic pigs. For SFV infection of *Sylvilagus* rabbits, tumors can last for many months before regressing, whereas in *Oryctolagus* rabbits recovery is usually complete within a few weeks. Only MYX manifests dramatic alterations in pathogenicity when the European rabbit is infected. For all of these viruses the immune status of the host rabbit plays a critical role; for example, in adult rabbits SFV rarely causes disease symptoms except for the primary fibroblastic lesion but in newborn or immunocompromised animals the infec-

tion can lead to invasive tumors and much higher titers of infectious virus in infected tissues. Agents such as cortisone, x-rays or immunosuppressants can dramatically increase SFV tumor development, and chemical promoters like 3,4-benzopyrene or methylcholanthrene can predispose progression to invasive fibromatosis or even metastatic fibrosarcoma.

The ability to evade the host immune response, replicate in lymphocytes and spread efficiently to secondary sites is a unique property of MYX in *Oryctolagus* rabbits. The myxomatosis syndrome can be associated with multiple external signs (e.g. South American MYX) or may have relatively fewer gross symptoms (e.g. California MYX) and mortalities can range up to 100%. Supervening Gram-negative bacterial infections in the respiratory tract and conjunctiva are often observed concomitantly with MYX, particularly by the adventitious pathogens *Pasteurella multocida* and *Bordetella bronchoseptica,* and contribute to the lethality of the disease.

SPV is only mildly pathogenic in pigs although it can cause a minor level of mortality, usually associated with milk feeding reduction in younger animals.

Clinical Features of Infection

The cutaneous tumors induced by the different leporipoxviruses in their natural hosts are clinically very similar to each other. The fibromas are rarely associated with any other symptoms, such as fever or appetite loss, and invariably regress as long as the animal is not otherwise immunocompromised. In the case of MYX in *Oryctolagus* rabbits, however, the symptoms rapidly become severe as the tumors fail to regress and the concomitant immunosuppression contributes to the lethal myxomatosis syndrome. The clinical features of myxomatosis are influenced by the genetic background of both the virus strain and the rabbit host. In the preacute form of the disease caused by California MYX the rabbits succumb in less than a week, and often have only minor external symptoms, such as inflammation and edema of the eyelids. Skin hemorrhages can be observed in some cases and convulsions often precede death. In the acute form caused by South American strains of MYX, the rabbits survive 1–2 weeks and develop more distinctive symptoms. The primary tumor can be either flat and diffuse or protuberant, and secondary site tumors around the nose, eyes and ears become prominent by 6–7 days, at which time purulent exudates from the nose and eyes frequently develop. The cutaneous tumors often become necrotic and a generalized immune dysfunction exacerbates the progressive secondary bacterial infestation of the respiratory tract. In the case of the more attenuated MYX isolates, such as neuromyxoma, the disease course is less severe and may be associated with little or no mortality.

The disease course of SPV in pigs is rather different, and resembles vaccinia in humans. Inoculation results in localized dermal papules, which progress on to vesicles and pustules, after which the lesions crust and scab over. The only clinical symptom is occasional minor fever and the animals recover completely within three weeks.

Pathology and Histopathology

The primary tumors caused by leporipoxviruses in *Sylvilagus* rabbits, squirrels and hares all closely resemble proliferant fibromas. Following inoculation, an acute inflammatory reaction occurs with infiltration of polymorphonuclear and mononuclear cells and proliferation of fibroblast-like cells of uncertain origin. The 'tumor' consists of pleomorphic cells imbedded in a matrix of intercellular fibrils of collagen. Unlike the transformed cells induced by other DNA tumor viruses, cells from poxviral tumors are not immortalized and cannot be propagated independently. Instead they appear to require secreted virus-encoded proteins in order to sustain the hyperproliferative state. Inclusion bodies characteristic of poxviral replication can be observed in the cytoplasms of epithelial and some fibroma cells. As the tumor develops, mononuclear leukocyte cuffing of adjacent vessels is observed and at the base of the tumor there is accumulation of lymphocytes, plasma cells, macrophages and neutrophils. The ratio between influx of inflammatory cells and fibroblast proliferation is variable but generally there is little or no necrosis. The speed with which immune cells clear the viral infection and reverse the hyperproliferation can range from 1–2 weeks up to 6 months, depending on both the virus and the host.

The principal difference between the benign fibroma syndrome described above and the devastating disease caused by MYX in *Oryctolagus* rabbits is that the latter viruses efficiently propagate in host lymphocytes and are able to circumvent the cell-mediated immune response to the viral infection. The subcutaneous tumors consist of proliferating undifferentiated mesenchymal cells which become large and stellate with prominent nuclei ('myxoma' cells). In surrounding tissue there can be extensive proliferation of endothelial cells of the local capillaries and venules, often to the point where complete occlusion leads to extensive necrosis of the infected site. The overlying epithelial cells can show hyperplasia or degeneration, depending on the virus strain, and

poxviral inclusion bodies are frequently observed in the prickle-cell layer. In some MYX strains primary and secondary skin tumors can undergo extensive hemorrhage and internal lesions may be found in the stomach, intestines and heart. The virus readily migrates to secondary sites within infected immune cells and concomitant cellular proliferation can be detected in the reticulum cells of lymph nodes and spleen, as well as the conjunctival and pulmonary alveolar epithelium. The nasal mucosa and conjunctiva overlying secondary tumors undergo squamous metaplasia such that the epithelia become nonciliated and nonkeratizing. Disruption of the ciliary architecture may be one of the factors which facilitate the extensive Gram-negative bacterial infections of the eyes, nose and respiratory tract. Varying degrees of inflammatory cell infiltration by polymorphonuclear heterophils occur soon after infection but there is only a limited effective cellular immune response. The lymph nodes and spleen show evidence of aberrant T-cell activation and hyperplasia and infectious virus can be isolated from all lymphoid organs except the thymus. Death is believed to be caused by a combination of tissue damage from the increasing tumor burden, generalized immunosuppression and debilitating bacterial colonization of the respiratory tract.

Little is known about SPV pathogenesis but gross features closely resemble those of the noninvasive orthopoxviruses in their native hosts.

Immune Response

The benign fibromas caused by SFV/SqFV/HFV regress, albeit slowly, due to a combined cellular and humoral immune response. These viruses are excellent antigens and neutralizing antibody produced during recovery will also crossreact with other members of the genus. All of the leporipoxviruses are strongly cell-associated and cell-mediated immunity is probably the single most important mechanism of viral clearance. Other immune mechanisms are also activated, including interferon production, antibody-mediated cell lysis, sensitized macrophages and natural killer (NK) cells. Neutralizing antibody can last for many months after viral clearance and immunity is usually crossprotective to the other leporipoxviruses.

In the case of MYX in *Oryctolagus* rabbits the picture is very different. Although circulating antibody can be detected against virions, as determined by neutralization or agglutination, and against soluble antigens, as determined by complement fixation and precipitin tests, the antibody provides little protection against the disease progression. Instead, cellular immunity is severely compromised, and by day 6–7 lymphocytes (especially splenocytes) are demonstrably dysfunctional in their response to mitogens and lose the ability to secrete critical cytokines such as interleukin-2. Unlike the case of SFV, there is a notable absence of virus-specific T-cells in either the spleen or draining lymph nodes. Immune dysfunction is common in viruses that replicate in lymphocytes, but the precise levels at which MYX intervenes in cellular immunity remain to be clarified. There is some evidence that these viruses interfere with the function of cell surface MHC class I molecules, which could prevent proper viral antigen presentation and hence interfere with immune recognition of infected cells. Also, several virus-specific gene products have been shown to be secreted homologues of the cellular receptors for TNF and IFN-γ that are believed to bind and sequester these extracellular ligands in the vicinity of virus-infected cells and thus short-circuit immune pathways dependent on TNF and IFN-γ.

SPV-infected pigs generally recover from the infection and become immune to secondary challenge. There are few data on the nature of this immunity, but it bears close resemblance to that of vaccinia immunization in humans.

Prevention and Control

Since these viruses are spread principally by biting arthropods, vector control is the single most effective method of disease prevention. The viruses are susceptible to standard anti-poxvirus chemical agents, such as phosphonoacetic acid, arabinosyl cytosine and rifampicin, but these are of limited utility in infected animals. Immunization against myxomatosis can be accomplished with live SFV or attenuated strains of MYX.

Future Perspectives

Now that DNA sequencing studies have been initiated for many different poxviruses, it is likely that more viral genes which determine the clinical characteristics of their diseases will be discovered. Studies on viral gene products which stimulate fibroblastic and endothelial cells to proliferate will likely provide information on how mitogenesis is regulated by surface receptors on these target cells. The ability of MYX to replicate in lymphocytes offers an important system in which to elucidate the mechanisms of cellular tropism by which these viruses suppress the innate apoptosis response to virus infection. Furthermore, the analysis of virus-induced immunosuppression should shed light on the various immune strategies used by the host to combat viral infections

in general. Finally, the restricted host ranges of the lepori- and suipoxviruses suggests the potential for the genetic manipulation of these viruses such that heterologous foreign antigen genes can be expressed for the purpose of developing novel vaccines against important pathogens of domestic leporids and swine.

Introduction

Prions are novel transmissible pathogens causing a group of invariably fatal neurodegenerative diseases that present as genetic, infectious or sporadic disorders, all of which involve modification of the prion protein (PrP). This unprecedented spectrum of disease presentations demanded a new mechanism; prions provide a conceptual framework within which this remarkably diverse spectrum can be accommodated.

Prion diseases of humans are referred to as Creutzfeldt–Jakob disease (CJD), Gerstmann–Sträussler–Scheinker disease (GSS), fatal familial insomnia (FFI), fatal sporadic insomnia (FSI) and kuru (**Table 1**). In animals the prion diseases are called scrapie of sheep and goats, bovine spongiform encephalopathy (BSE), chronic wasting disease (CWD) of mule deer and elk, feline spongiform encephalopathy (FSE) and transmissible mink encephalopathy (TME).

Because prions and the mechanism of disease pathogenesis are without precedent, classification of the prion diseases has been quite varied. For many years, the human prion diseases were classified as neurodegenerative disorders of unknown etiology based upon pathologic changes being confined to the central nervous system (CNS). With the transmission of kuru and CJD to apes, investigators began to view these diseases as CNS infectious illnesses caused by slow viruses. Even though the familial nature of a subset of CJD cases was well described, the significance of this observation became more obscure with the transmission of CJD to animals. Eventually, the meaning of heritable CJD became clear with the discovery of mutations in the PrP gene of these patients.

in general. Finally, the restricted host ranges of the lepori- and suipoxviruses suggests the potential for the genetic manipulation of these viruses such that heterologous foreign antigen genes can be expressed for the purpose of developing novel vaccines against important pathogens of domestic leporids and swine.

Introduction

Prions are novel transmissible pathogens causing a group of invariably fatal neurodegenerative diseases that present as genetic, infectious or sporadic disorders, all of which involve modification of the prion protein (PrP). This unprecedented spectrum of disease presentations demanded a new mechanism; prions provide a conceptual framework within which this remarkably diverse spectrum can be accommodated.

Prion diseases of humans are referred to as Creutzfeldt–Jakob disease (CJD), Gerstmann–Sträussler–Scheinker disease (GSS), fatal familial insomnia (FFI), fatal sporadic insomnia (FSI) and kuru (**Table 1**). In animals the prion diseases are called scrapie of sheep and goats, bovine spongiform encephalopathy (BSE), chronic wasting disease (CWD) of mule deer and elk, feline spongiform encephalopathy (FSE) and transmissible mink encephalopathy (TME).

Because prions and the mechanism of disease pathogenesis are without precedent, classification of the prion diseases has been quite varied. For many years, the human prion diseases were classified as neurodegenerative disorders of unknown etiology based upon pathologic changes being confined to the central nervous system (CNS). With the transmission of kuru and CJD to apes, investigators began to view these diseases as CNS infectious illnesses caused by slow viruses. Even though the familial nature of a subset of CJD cases was well described, the significance of this observation became more obscure with the transmission of CJD to animals. Eventually, the meaning of heritable CJD became clear with the discovery of mutations in the PrP gene of these patients.

Table 1 The prion diseases

Disease	*Host*	*Mechanism of pathogenesis*
A. Kuru	Fore people	Infection through ritualistic cannibalism
iCJD	Humans	Infection from prion-contaminated hGH, dura mater grafts, etc.
vCJD	Humans	Infection from bovine prions?
fCJD	Humans	Germline mutations in PrP gene
GSS	Humans	Germline mutations in PrP gene
FFI	Humans	Germline mutation in PrP gene (D178N, M129)
sCJD	Humans	Somatic mutation or spontaneous conversion of PrP^{C} into PrP^{Sc}?
FSI	Humans	Somatic mutation or spontaneous conversion of PrP^{C} into PrP^{Sc}?
B. Scrapie	Sheep	Infection in genetically susceptible sheep
BSE	Cattle	Infection with prion-contaminated MBM
TME	Mink	Infection with prions from sheep or cattle
CWD	Mule deer, elk	Unknown
FSE	Cats	Infection with prion-contaminated beef
Exotic ungulate encephalopathy	Greater kudu, nyala, oryx	Infection with prion-contaminated MBM

BSE, bovine spongiform encephalopathy; CJD, Creutzfeldt–Jakob disease; sCJD, sporadic CJD; fCJD, familial CJD; iCJD, iatrogenic CJD; vCJD, (new) variant CJD; CWD, chronic wasting disease; FFI, fatal familial insomnia; FSE, feline spongiform encephalopathy; FSI, fatal sporadic insomnia; GSS, Gerstmann–Sträussler–Scheinker disease; hGH, human growth hormone; MBM, meat and bone meal; TME, transmissible mink encephalopathy.

The Prion Concept

Prions are unprecedented infectious pathogens that are devoid of nucleic acid and seem to be composed exclusively of a modified isoform of PrP designated PrP^{Sc}. The normal, cellular PrP, denoted PrP^{C}, is converted into PrP^{Sc} through a process whereby a portion of its α-helical and coil structure is refolded into a β sheet. This structural transition is accompanied by profound changes in the physicochemical properties of the PrP. The amino acid sequence of PrP^{Sc} corresponds to that encoded by the PrP gene of the mammalian host in which it last replicated. In contrast to pathogens with a nucleic acid genome that encode strain-specific properties in genes, prions encipher these properties in the tertiary structure of PrP^{Sc}. Transgenetic studies argue that PrP^{Sc} acts as a template upon which PrP^{C} is refolded into a nascent PrP^{Sc} molecule through a process facilitated by another protein.

Perhaps the best current working definition of a prion is a proteinaceous infectious particle that lacks nucleic acid. Because prions appear to be composed entirely of a protein that adopts an abnormal conformation, it is not unreasonable to think of prions as infectious proteins. Although PrP^{Sc} is the only *known* component of the infectious prion particles, these unique pathogens share several phenotypic traits with other infectious entities such as viruses.

In a broader view, prions are elements that impart and propagate variability through multiple conformers of a normal cellular protein. The species of a particular prion is encoded by the sequence of the chromosomal PrP gene of the mammal in which it last replicated. In contrast to pathogens with a nucleic acid genome that encode strain-specific properties in genes, prions seem to encipher these properties in the tertiary structure of PrP^{Sc}.

The discovery that mutations of the PrP gene caused dominantly inherited prion diseases in humans linked the genetic and infectious forms of prion diseases and presented another hurdle for investigators who continued to argue that prion diseases are caused by viruses. More than 20 mutations of the PrP gene are now known to cause the inherited human prion diseases and significant genetic linkage has been established for five of these mutations. The prion concept readily explains how a disease can manifest as a heritable as well as an infectious illness. Moreover, the hallmark common to all of the prion diseases, whether sporadic, dominantly inherited or acquired by infection, is that they involve the aberrant metabolism of the prion protein.

Prion Protein Isoforms

PrP^{C} and PrP^{Sc} have the same covalent structure and each consists of 209 amino acids in Syrian hamsters (**Fig. 1**). The N-terminal sequencing, the deduced

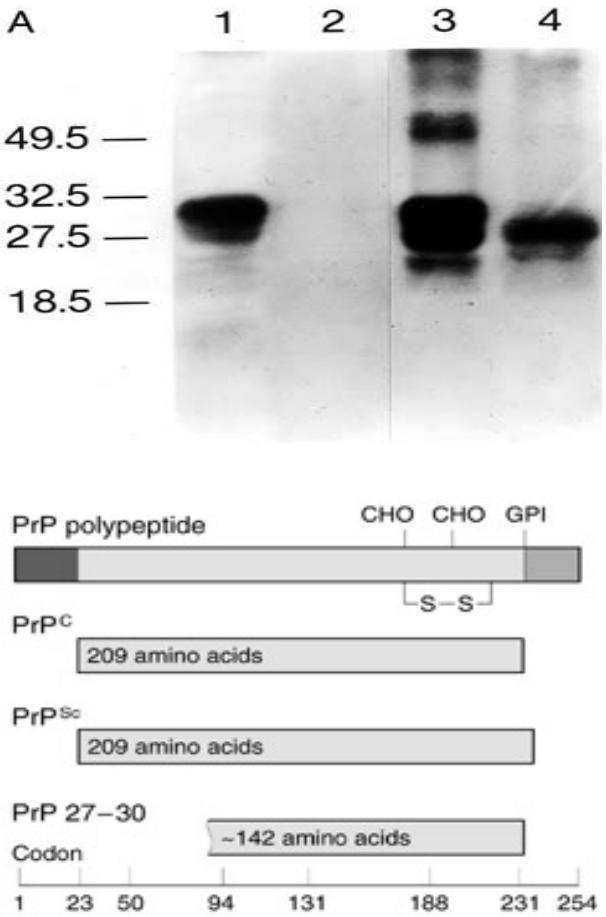

Figure 1 Prion protein isoforms. (**A**) Western immunoblot of brain homogenates from uninfected (lanes 1 and 2) and prion-infected (lanes 3 and 4) Syrian hamsters. Samples in lanes 2 and 4 were digested with 50 μg ml^{-1} of proteinase K for 30 min at 37°C. PrP^C in lanes 2 and 4 was completely hydrolyzed under these conditions, whereas approximately 67 amino acids were digested from the N-terminus of PrP^{Sc} to generate PrP 27–30. After polyacrylamide gel electrophoresis (PAGE) and electrotransfer, the blot was developed with anti-PrP R073 polyclonal rabbit antiserum. Molecular size markers are in kilodaltons (kDa). (**B**) Bar diagram of SHaPrP which consists of 254 amino acids. After processing of the N- and C-termini, both PrP^C and PrP^{Sc} consist of 209 residues. After limited proteolysis, the N-terminus of PrP^{Sc} is truncated to form PrP 27–30 which is composed of approximately 142 amino acids. (Reprinted with permission from *Molecular Neurology*, pp 175–204. Copyright 1998 Scientific American, Inc.)

amino acid sequences from PrP cDNA and immunoblotting studies argue that PrP 27–30 is a truncated protein of about 142 residues that is derived from PrP^{Sc} by limited proteolysis of the N-terminus.

In general, ~10^5 PrP^{Sc} molecules correspond to one ID_{50} unit of prions, using the most sensitive bioassay. PrP^{Sc} is probably best defined as the abnormal isoform of the prion protein that stimulates conversion of PrP^C into nascent PrP^{Sc}, accumulates and causes disease. Although resistance to limited proteolysis has proved to be a convenient tool for detecting PrP^{Sc}, not all PrP^{Sc} molecules possess protease resistance.

The prion diseases are caused by the accumulation of PrP^{Sc}. In accord with the autosomal dominant inheritance of familial prion diseases caused by mutations of the PrP gene, PrP^{Sc} represents a gain of dysfunction.

Human Prion Diseases

Most humans afflicted with prion disease present with rapidly progressive dementia, but some manifest cerebellar ataxia. Although the brains of patients appear grossly normal upon postmortem examination, they usually show spongiform degeneration and astrocytic gliosis under the light microscope (**Fig. 2**). In all cases of GSS and variant (v) CJD, PrP amyloid plaques are found. Before PrP immunostaining was available, histochemical staining was used to examine brains from kuru patients where ~70% of cases were thought to have amyloid plaques. The presence or absence of PrP amyloid plaques in sporadic and inherited CJD is quite variable.

Human prion disease should be considered in any patient who develops a progressive subacute or chronic decline in cognitive or motor function. Typically, adults between 40 and 80 years of age are affected. The young age of more than 30 people who have died of vCJD in Britain and France has raised the possibility that these individuals were infected with bovine prions that contaminated beef products. Over 100 young adults have also been diagnosed with iatrogenic CJD between 4 and 30 years after receiving human growth hormone (hGH) or gonadotropin derived from cadaveric pituitaries. The longest incubation periods (20–30 years) are similar to those associated with more recent cases of kuru.

Sporadic CJD

Sporadic forms of prion disease comprise most cases of CJD and possibly a few cases of GSS (**Table 1A**). In these patients, mutations of the PrP gene are not found. How prions causing disease arise in patients with sporadic forms is unknown; hypotheses include horizontal transmission of prions from humans or animals, somatic mutation of the PrP gene, and spontaneous conversion of PrP^C into PrP^{Sc}. Since numerous attempts to establish an infectious link between sporadic CJD and a pre-existing prion disease in animals or humans have been unrewarding,

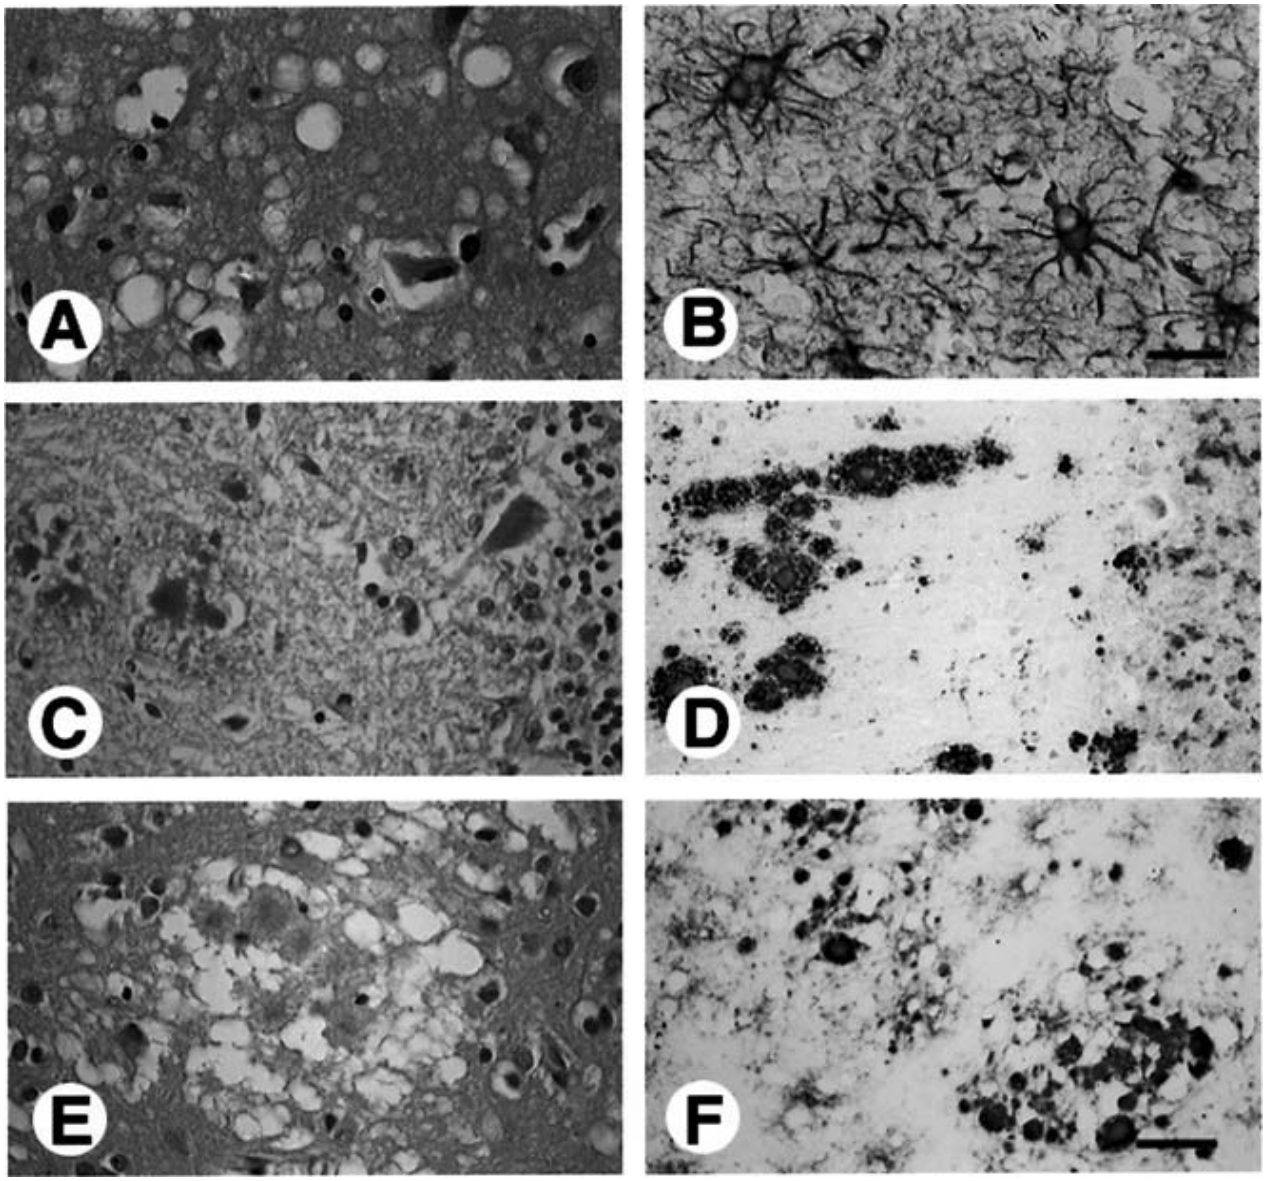

Figure 2 Neuropathology of human prion diseases. Sporadic CJD is characterized by vacuolation of the neuropil of the gray matter, by exuberant reactive astrocytic gliosis, the intensity of which is proportional to the degree of nerve cell loss, and, rarely, by PrP amyloid plaque formation (not shown). The neuropathology of familial CJD is similar. GSS(P102L), as well as other inherited forms of GSS (not shown), is characterized by numerous deposits of PrP amyloid throughout the CNS. New variant CJD (vCJD) has clinical and epidemiological features that suggest it was acquired by infection with prions. The neuropathological features of vCJD are unique among CJD cases because of the abundance of PrP amyloid plaques that are often surrounded by a halo of intense vacuolation. (**A**) Sporadic CJD, cerebral cortex stained with hematoxylin and eosin showing widespread spongiform degeneration. (**B**) Sporadic CJD, cerebral cortex immunostained with anti-GFAP antibodies demonstrating the widespread reactive gliosis. (**C**) GSS, cerebellum with most of the GSS-plaques in the molecular layer (left 80% of micrograph) and many but not all are periodic acid Schiff (PAS) reaction positive. Granule cells and a single Purkinje cell are seen in the right 20% of the panel. (**D**) GSS, cerebellum at the same location as panel C with PrP immunohistochemistry after the hydrolytic autoclaving reveals more PrP plaques than seen with the PAS reaction. (**E**) Variant CJD, cerebral cortex stained with hematoxylin and eosin shows that the plaque deposits are uniquely located within vacuoles. With this histology, these amyloid deposits have been referred to as 'florid plaques'. (**F**) Variant CJD, cerebral cortex stained with PrP immunohistochemistry after hydrolytic autoclaving reveals numerous PrP plaques often occurring in clusters as well as minute PrP deposits surrounding many cortical neurons and their proximal processes. Bar in B = 50 μm and applies also to panels A, C, and D. Bar in F = 100 μm and applies also to panel D. **(For color references see Color Plate 27.)**

it seems unlikely that transmission features in the pathogenesis of sporadic prion disease.

Inherited prion diseases

To date, 20 different mutations in the human PrP gene resulting in nonconservative substitutions have been found that segregate with the inherited prion diseases (**Fig. 3**). Familial (f) CJD cases suggested that genetic factors might influence pathogenesis, but this was difficult to reconcile with the transmissibility of fCJD and GSS. The discovery of genetic linkage between the PrP gene and scrapie incubation times in mice raised the possibility that mutation might feature in the hereditary human prion diseases. The P102L mutation was the first PrP mutation to be genetically linked to CNS dysfunction in GSS (**Fig. 3**) and has since been found in many GSS families throughout the world. Indeed, a mutation in the protein coding region of the PrP gene has been found in all reported kindred with familial human prion disease; besides the P102L mutation, genetic linkage has been established for four other mutations.

Tg mouse studies confirmed that mutations of the PrP gene can cause neurodegeneration. The P102L mutation of GSS was introduced into the MoPrP transgene, and five lines of Tg(MoPrP-P101L) mice expressing high levels of mutant PrP developed spontaneous CNS degeneration consisting of widespread vacuolation of the neuropil, astrocytic gliosis and numerous PrP amyloid plaques similar to those seen in the brains of humans who die from GSS(P102L). Brain extracts prepared from spontaneously ill Tg(MoPrP-P101L) mice transmitted CNS degeneration to Tg196 mice but contained no protease-resistant PrP. The Tg196 mice do not develop spontaneous disease, but express low levels of the mutant transgene MoPrP-P101L and are deficient for mouse PrP ($Prnp^{0/0}$). These studies, combined with the transmission of prions from patients who died of GSS to apes and monkeys or to Tg(MHu2M-P101L) mice, demonstrate that prions are generated *de novo* by mutations in PrP. Additionally, brain extracts from patients with some other inherited prion diseases, fCJD(E200K) or FFI, transmit disease to Tg(MHu2M) mice.

Infectious prion diseases

The infectious prion diseases include kuru of the Fore people in New Guinea, where prions were transmitted by ritualistic cannibalism. With the cessation of cannibalism at the urging of missionaries, kuru began to decline long before it was known to be transmissible. Sources of prions causing infectious CJD on several different continents include improperly sterilized depth electrodes, transplanted corneas, hGH and gonadotropin derived from cadaveric pituitaries, and dura mater grafts. As noted above, many young adults have developed CJD after treatment with cadaveric hGH. Dura mater grafts implanted during neurosurgical procedures seem to have caused more than 60 cases of CJD; these incubation periods range from 1 to more than 14 years.

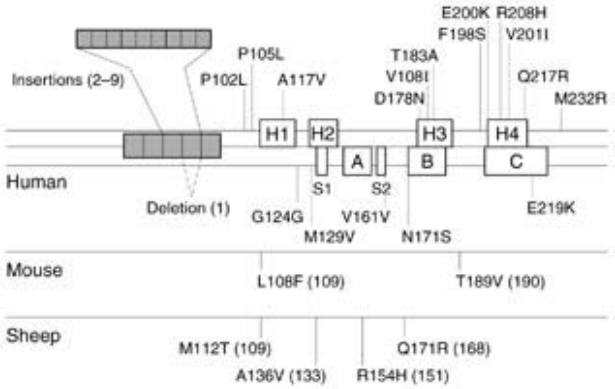

Figure 3 Mutations and polymorphisms of the prion protein gene. Mutations causing inherited human prion disease and polymorphisms in human, mouse and sheep. Above the line of the human sequence are mutations that cause prion disease. Below the lines are polymorphisms, some but not all of which are known to influence the onset as well as the phenotype of disease. Data were compiled by Paul Bamborough and Fred E Cohen. (Reprinted with permission from *Science* 278: 245–251. Copyright 1997 American Association for the Advancement of Science.)

Studies of the prion diseases have taken on new significance with the recent reports of ~30 cases of an atypical vCJD in teenagers and young adults. To date, all of these cases have been reported in Great Britain, with the exception of one case from France. It now seems possible that bovine prions passed to humans through the consumption of tainted beef products. How many cases of vCJD caused by bovine prions will occur in the years ahead is unknown. Until more time passes, we shall be unable to assess the magnitude of this problem. These tragic cases have generated a continuing discourse concerning mad cows, prions and the safety of human and animal food supplies throughout the world. Untangling politics and economics from the science of prions seems to have been difficult in disputes between Great Britain and other European countries over the safety of beef and lamb products.

Strains of Prions

The existence of prion strains raises the question of how heritable biological information can be enci-

Table 2 Distinct prion strains generated in humans with inherited prion diseases and transmitted to transgenic mice

Inoculum	*Host species*	*Host PrP genotype*	*Incubation time (days ± SEM) (n/n_o)*	*PrP^{Sc} (kDa)*
None	Human	FFI(D178N, M129)		19
FFI	Mouse	Tg(MHu2M)	206 ± 7 (7/7)	19
FFI → Tg(MHu2M)	Mouse	Tg(MHu2M)	136 ± 1 (6/6)	19
None	Human	fCJD(E200K)		21
fCJD	Mouse	Tg(MHu2M)	170 ± 2 (10/10)	21
fCJD → Tg(MHu2M)	Mouse	Tg(MHu2M)	167 ± 3 (15/15)	21

phered in any molecule other than nucleic acid. Strains or varieties of prions have been defined by incubation times and the distribution of neuronal vacuolation. Subsequently, the patterns of PrP^{Sc} deposition were found to correlate with vacuolation profiles and these patterns were also used to characterize strains of prions.

The typing of prion strains in C57BI, VM and F1(C57BI × VM) inbred mice began with isolates from sheep with scrapie. The prototypic strains, called Me7 and 22A, gave incubation times of ~150 and ~400 days in C57BI mice, respectively. The PrPs of C57BI and I/Ln (and later VM) mice differ at two residues and control incubation times (**Fig. 3**).

Until recently, support for the hypothesis that the tertiary structure of PrP^{Sc} enciphers strain-specific information was minimal, except for the DY strain isolated from mink with transmissible encephalopathy. PrP^{Sc} in DY prions showed diminished resistance to proteinase K digestion as well as an anomalous site of cleavage. The DY strain presented a puzzling anomaly as other prion strains exhibiting similar incubation times did not show this altered susceptibility to proteinase K digestion of PrP^{Sc}. Also notable was the generation of new strains during passage of prions through animals with different PrP genes.

PrP^{Sc} conformation enciphers variation in prions

Persuasive evidence that strain-specific information is enciphered in the tertiary structure of PrP^{Sc} comes from transmission of two different inherited human prion diseases to mice expressing a chimeric MHu2M PrP transgene. In FFI, the protease-resistant fragment of PrP^{Sc} after deglycosylation has an M_r of 19 kDa, whereas in fCJD(E200K) and most sporadic prion diseases it is 21 kDa. This difference in molecular size was shown to be due to different sites of proteolytic cleavage at the NH_2-termini of the two human PrP^{Sc} molecules, reflecting different tertiary structures. These distinct conformations were not unexpected because the amino acid sequences of the PrPs differ.

Extracts from the brains of FFI patients transmitted disease into mice expressing a chimeric MHu2M PrP gene about 200 days after inoculation and induced formation of the 19 kDa PrP^{Sc}, whereas fCJD(E200K) and sporadic (s) CJD produced the 21 kDa PrP^{Sc} in mice expressing the same transgene. On second passage, Tg(MHu2M) mice inoculated with FFI prions showed an incubation time of ~130 days and a 19 kDa PrP^{Sc}, while those inoculated with fCJD(E200K) prions exhibited an incubation time of ~170 days and a 21 kDa PrP^{Sc} (**Table 2**). The experimental data demonstrate that MHu2MPrP^{Sc} can exist in two different conformations based on the sizes of the protease-resistant fragments, yet the amino acid sequence of MHu2MPrP^{Sc} is invariant.

The results of our studies argue that PrP^{Sc} acts as a template for the conversion of PrP^{C} into nascent PrP^{Sc}. Imparting the size of the protease-resistant fragment of PrP^{Sc} through conformational templating provides a mechanism for both the generation and propagation of prion strains.

Interestingly, the protease-resistant fragment of PrP^{Sc} after deglycosylation with an M_r of 19 kDa has been found in a patient who died after developing a clinical disease similar to FFI. Since both PrP alleles encoded the wt sequence and a Met at position 129, we labeled this case fatal sporadic insomnia (FSI). At autopsy, the spongiform degeneration, reactive astrogliosis, and PrP^{Sc} deposition were confined to the thalamus. These findings argue that the clinicopathologic phenotype is determined by the conformation of PrP^{Sc}, in accord with the results of the transmission of human prions from patients with FFI to Tg mice.

Interplay between the species and strains of prions

Studies on the role of the primary and tertiary structures of PrP in the transmission of disease have given new insights into the pathogenesis of the prion diseases. The amino acid sequence of PrP encodes the species of the prion, and the prion derives its PrP^{Sc}

sequence from the last mammal in which it was passaged. While the primary structure of PrP is likely to be the most important, or even sole, determinant of the tertiary structure of PrP^C, existing PrP^{Sc} seems to function as a template in determining the tertiary structure of nascent PrP^{Sc} molecules as they are formed from PrP^C. In turn, prion diversity appears to be enciphered in the conformation of PrP^{Sc}, and prion strains may represent different conformers of PrP^{Sc}.

Evidence for different conformations of PrP^{Sc} in eight prion strains

Using a highly sensitive conformation-dependent immunoassay for measurement of PrP^{Sc} in tissue homogenates, eight different prion strains passaged in Syrian hamsters were examined. Brains from Syrian hamsters were collected when the animals displayed signs of neurologic dysfunction; the incubation times for the prion strains varied from 70 to 320 days. Most of the PrP in the brains of Syrian hamsters with signs of neurologic disease was PrP^{Sc} as defined by the β-sheet conformation. The level of PrP^{Sc} in the brains of these clinically ill animals exceeded that of PrP^C by 3- to 10-fold. The highest levels of PrP^{Sc} were found in the brains of Syrian hamsters infected with the Me7-H strain; in contrast, the lowest levels were found in the brains of Syrian hamsters inoculated with the SHa(Me7) strain. Interestingly, the Me7-H and SHa(Me7) strains were both derived from Me7 passaged in mice, but they accumulated PrP^{Sc} to quite different levels.

Using this conformation-dependent immunoassay, each strain was found to initiate formation of PrP^{Sc} molecules with a distinct conformation. When the incubation times of the eight strains were plotted as a function of the concentration of either PrP^{Sc} or PrP 27–30, no relationship could be discerned.

To assess the fraction of PrP^{Sc} that is sensitive to proteolysis during limited digestion with proteinase K, we subtracted the protease resistant PrP 27–30 fraction from the total PrP^{Sc} for each of the eight prion strains. It was asked whether the proteinase K-sensitive fraction of PrP^{Sc} ($[PrP^{Sc}] - [PrP\ 27–30]$) might reflect those PrP^{Sc} molecules that are most readily cleared by cellular proteases. The clearance of PrP^{Sc} is of considerable interest with respect to control of the length of the incubation time and other phenotypic features of prion strains. When the $[PrP^{Sc}] - [PrP\ 27–30]$ fraction was plotted as a function of the incubation time, a linear relationship was found with an excellent correlation coefficient ($r = 0.94$) (**Fig. 4**).

The above results demonstrate that eight different strains possess at least eight different conformations. Additional data argue that each strain is composed of a spectrum of conformations as revealed by limited protease digestion and GdnHCl denaturation studies. These findings contrast with the until recently held notion that the primary structure of a protein determines a single tertiary structure.

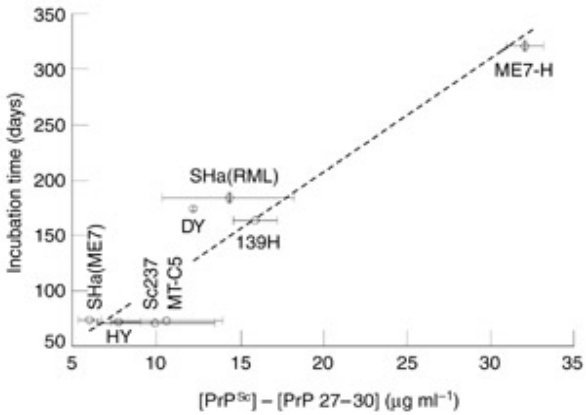

Figure 4 Eight prion strains distinguished by the conformation-dependent immunoassay. Brain homogenates of Syrian hamsters (LVG/LAK) inoculated with different scrapie strains were either undigested or digested with 50 μg ml^{-1} of proteinase K for 2 h at 37°C prior to the conformation-dependent immunoassay. The immunoassay was used to measure the concentration of PrP^{Sc} and PrP 27–30 for each strain. Incubation time plotted as a function of the concentration of the proteinase K-sensitive fraction of PrP^{Sc} ($[PrP^{Sc}] - [PrP\ 27–30]$). (Reprinted with permission from *Nature Medicine*, in press. Copyright 1998 Nature America, Inc.)

How many formations can PrP^{Sc} adopt? The conformation-dependent immunoassay described here provides a rapid tool capable of discriminating the secondary and tertiary structures of a substantial number of PrP^{Sc} molecules.

As noted above for studies of strains passaged from humans with fCJD(E200K) and FFI, PrP^{Sc} must act as a template in the replication of nascent PrP^{Sc} molecules. Also as discussed above, it seems likely that the binding of PrP^C or a metastable intermediate PrP* to protein X is the initial step in PrP^{Sc} formation and that this is the rate-limiting step in prion replication. PrP^{Sc} interacts with PrP^C but not protein X in the PrP^C–protein X complex. When PrP^C or PrP* is converted into a nascent PrP^{Sc} molecule, protein X is released.

It also follows from these observations that the different incubation times of various prion strains should arise predominantly from distinct rates of PrP^{Sc} clearance rather than from different rates of PrP^{Sc} formation. Thus, prion strains that are readily cleared should have prolonged incubation times,

while those that are poorly cleared should display abbreviated incubation periods. This hypothesis was investigated by relying upon the difference in brain PrP^{Sc} concentrations before and after proteinase K treatment as a surrogate for *in vivo* clearance of each prion strain. When clearance, as approximated by $[PrP^{Sc}] - [PrP\ 27–30]$, was plotted as a function of the incubation time for eight strains, a linear relationship was found (**Fig. 4**). It is important to recognize that proteinase K sensitivity is an imperfect model for *in vivo* clearance and that only one strain with a long incubation time exceeding 300 days has been studied.

It has been suggested that Asn-linked carbohydrates (CHOs) specify prion strains, but this proposal is difficult to reconcile with the addition of high mannose oligosaccharides to Asn-linked consensus sites on PrP in the endoplasmic reticulum and subsequent remodeling of the sugar chains in the Golgi. Modification of the complex CHOs attached to PrP^{C} is clearly completed prior to the PrP^{C} trafficking to the cell surface, which indicates that the Asn-linked CHOs of PrP^{Sc} do not instruct the addition of such complex-type sugars to PrP^{C}.

Mutagenesis of the complex-type sugar attachment sites seemed to increase PrP^{Sc} formation in cultured cells, but resulted in prolonged incubation times in Tg mice and differences in the patterns of PrP^{C} distribution and PrP^{Sc} deposition in mice expressing mutant PrPs. These studies suggest that Asn-linked glycosylation might alter the stability of PrP, and in particular PrP^{Sc}, which results in various patterns of PrP^{Sc} deposition. Thus, different clearance rates of PrP^{Sc} may be important in determining not only strain-specific neuropathology but also the length of the incubation time.

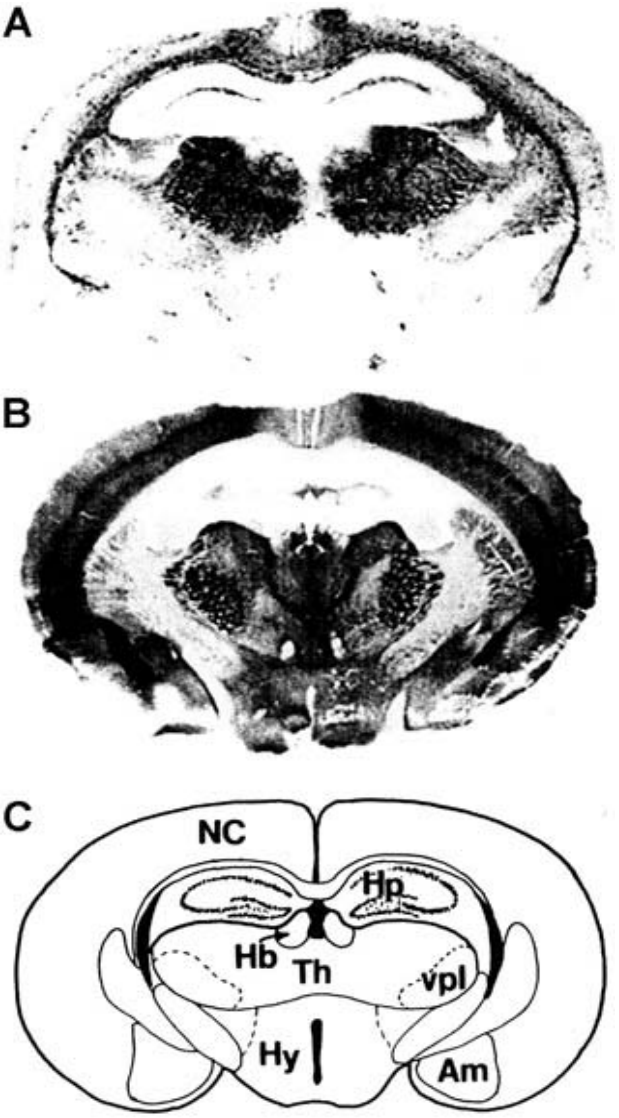

Figure 5 Regional distribution of PrP^{Sc} deposition in $Tg(MHu2M)Prnp^{0/0}$ mice inoculated with prions from humans who died of inherited prion diseases. Histoblot of PrP^{Sc} deposition in a coronal section of a $Tg(MHu2M)Prnp^{0/0}$ mouse through the hippocampus and thalamus. (**A**) The Tg mouse was inoculated with brain extract prepared from a patient who died of FFI. (**B**) The Tg mouse was inoculated with extract from a patient with fCJD(E200K). Cryostat sections were mounted on nitrocellulose and treated with proteinase K to eliminate PrP^{C}. To enhance the antigenicity of PrP^{Sc}, the histoblots were exposed to 3-guanidinium isothiocyanate before immunostaining using α-PrP 3F4 mAb. (**C**) Labeled diagram of a coronal section of the hippocampus/thalamus region. Mechanism of selective neuronal targeting?

In addition to incubation times, neuropathologic profiles of spongiform change have been used to characterize prion strains. However, recent studies with PrP transgenes argue that such profiles are not an intrinsic feature of strains. The mechanism by which prion strains modify the pattern of spongiform degeneration was perplexing, as earlier investigations had shown that PrP^{Sc} deposition precedes neuronal vacuolation and reactive gliosis. When FFI prions were inoculated into Tg(MHu2M) mice, PrP^{Sc} was confined largely to the thalamus (**Fig. 5A**), as is the case for FFI in humans. In contrast, fCJD(E200K) prions inoculated into Tg(MHu2M) mice produced widespread deposition of PrP^{Sc} throughout the cortical mantel and many of the deep structures of the CNS (**Fig. 5B**), as is seen in fCJD(E200K) of humans. To examine whether the diverse patterns of PrP^{Sc} deposition are influenced by Asn-linked glycosylation of PrP^{C}, we constructed Tg mice expressing PrPs mutated at one or both of the Asn-linked

glycosylation consensus sites. These mutations resulted in aberrant neuroanatomic topologies of PrP^C within the CNS, whereas pathologic point mutations adjacent to the consensus sites did not alter the distribution of PrP^C. Tg mice with mutation of the second PrP glycosylation site exhibited prion incubation times of >500 days and unusual patterns of PrP^{Sc} deposition. As noted above, glycosylation can modify the conformation of PrP and affect either the turnover of PrP^C or the clearance of PrP^{Sc}. Regional differences in the rate of deposition or clearance would result in specific patterns of PrP^{Sc} accumulation.

Prion Diseases of Animals

The prion diseases of animals include scrapie of sheep and goats, bovine spongiform encephalopathy, transmissible mink encephalopathy, chronic wasting disease of mule deer and elk, feline spongiform encephalopathy and exotic ungulate encephalopathy (**Table 1B**).

Sheep and cattle PrP gene polymorphisms

Parry argued that host genes were responsible for the development of scrapie in sheep. He was convinced that natural scrapie is a genetic disease that could be eradicated by proper breeding protocols. He considered its transmission by inoculation of importance primarily for laboratory studies and communicable infection of little consequence in nature. Other investigators viewed natural scrapie as an infectious disease and argued that host genetics only modulates susceptibility to an endemic infectious agent.

In sheep, polymorphisms at codons 136, 154 and 171 of the PrP gene that produce amino acid substitutions have been studied with respect to the occurrence of scrapie (**Fig. 3**). Studies of natural scrapie in the USA have shown that ~85% of the afflicted sheep are of the Suffolk breed. Only those Suffolk sheep homozygous for Gln (Q) at codon 171 developed scrapie, although healthy controls with QQ, QR and RR genotypes were also found. These results argue that susceptibility in Suffolk sheep is governed by the PrP codon 171 polymorphism. In Cheviot sheep, the PrP codon 171 polymorphism has a profound influence on susceptibility to scrapie, as in the Suffolk breed, and codon 136 seems to play a less pronounced role.

In contrast to sheep, different breeds of cattle have no specific PrP polymorphisms. The only polymorphism recorded in cattle is a variation in the number of octarepeats: most cattle, like humans, have five octarepeats but some have six; however, the presence of six octarepeats does not seem to be overrepresented in BSE.

Bovine spongiform encephalopathy

Prion strains and the species barrier are of paramount importance in understanding the BSE epidemic in Britain, in which it is estimated that almost one million cattle were infected with prions. The mean incubation time for BSE is about 5 years. Therefore, most cattle did not manifest disease because they were slaughtered between 2 and 3 years of age. Nevertheless, more than 170 000 cattle, primarily dairy cows, have died of BSE over the past decade. BSE is a massive common source epidemic caused by meat and bone meal (MBM) fed primarily to dairy cows. The MBM was prepared from the offal of sheep, cattle, pigs and chickens as a high-protein nutritional supplement. In the late 1970s, the hydrocarbon-solvent extraction method used in the rendering of offal began to be abandoned, resulting in MBM with a much higher fat content. It is now thought that this change in the rendering process allowed scrapie prions from sheep to survive rendering and to be passed into cattle. Alternatively, bovine prions were present at low levels prior to modification of the rendering process and, with the processing change, survived in sufficient numbers to initiate the BSE epidemic when inoculated back into cattle orally through MBM. Against the latter hypothesis is the widespread geographical distribution throughout England of the initial 17 cases of BSE, which occurred almost simultaneously. Furthermore, there is no evidence of a pre-existing prion disease of cattle, either in Great Britain or elsewhere.

Origin of BSE prions?

The origin of the bovine prions causing BSE cannot be determined by examining the amino acid sequence of PrP^{Sc} in cattle with BSE, as the PrP^{Sc} in these animals has the bovine sequence, whether the initial prions in MBM came from cattle or sheep. The bovine PrP sequence differs from that of sheep at seven or eight positions. In contrast to the many PrP polymorphisms found in sheep, only one PrP polymorphism has been found in cattle. Though most bovine PrP alleles encode five octarepeats, some encode six. PrP alleles encoding six octarepeats do not seem to be overrepresented in BSE, as noted above (**Fig. 3**).

Brain extracts from BSE cattle cause disease in cattle, sheep, mice, pigs and mink after intracerebral inoculation, but prions in brain extracts from sheep with scrapie fed to cattle produced illness substantially different from BSE. However, no exhaustive effort has been made to test different strains of sheep prions or to examine the disease following bovine to bovine passage. The annual incidence of sheep with scrapie in Great Britain over the past two decades has

remained relatively low. In July 1988, the practice of feeding MBM to sheep and cattle was banned. Recent statistical analysis argues that the epidemic is now disappearing as a result of this ruminant feed ban, reminiscent of the disappearance of kuru in the Fore people of New Guinea.

Monitoring cattle for BSE prions

Although many plans have been offered for the culling of older cattle in order to minimize the spread of BSE, it seems more important to monitor the frequency of prion disease in cattle as they are slaughtered for human consumption. No reliable, specific test for prion disease in live animals is available, but immunoassays for PrP^{Sc} in the brainstems of cattle might provide a reasonable approach to establishing the incidence of subclinical BSE in cattle entering the human food chain. Determining how early in the incubation period PrP^{Sc} can be detected by immunological methods is now possible because a reliable bioassay has been created by expressing the BoPrP gene in Tg mice. Prior to development of $Tg(BoPrP)Prnp^{0/0}$ mice, non-Tg mice inoculated intracerebrally with BSE brain extracts required more than 300 days to develop disease. Depending on the titer of the inoculum, the structures of PrP^{C} and PrP^{Sc} and the structure of protein X, the number of inoculated animals developing disease can vary over a wide range. Some investigators have stated that transmission of BSE to mice is quite variable, with incubation periods exceeding 1 year, while others report low prion titers in BSE brain homogenates compared to rodent brain scrapie.

Have bovine prions been transmitted to humans?

In 1994, the first cases of CJD in teenagers and young adults that were eventually labelled new variant (v) CJD occurred in Great Britain. In addition to the young age of these cases, the brains of these patients showed numerous PrP amyloid plaques surrounded by a halo of intense spongiform degeneration. These unusual neuropathologic changes have not been seen in CJD cases in the USA, Australia or Japan. Both macaque monkeys and marmosets developed neurologic disease several years after inoculation with bovine prions, but only the macaques exhibited numerous PrP plaques similar to those found in vCJD.

The restricted geographical occurrence and chronology of vCJD have raised the possibility that BSE prions have been transmitted to humans. That only ~30 vCJD cases have been recorded and the incidence has remained relatively constant make establishing the origin of vCJD difficult. No set of dietary habits distinguishes vCJD patients from apparently healthy people. Moreover, there is no explanation for the predilection of vCJD for teenagers and young adults. Why have older individuals not developed vCJD-based neuropathologic criteria? It is noteworthy that epidemiological studies over the past three decades have failed to find evidence for transmission of sheep prions to humans. Attempts to predict the future number of cases of vCJD, assuming exposure to bovine prions prior to the offal ban, have been uninformative because so few cases of vCJD have occurred. Are we at the beginning of a human prion disease epidemic in Britain like those seen for BSE and kuru, or will the number of vCJD cases remain small, as seen with iatrogenic (i) CJD caused by cadaveric hGH?

Strain of BSE prions

Was a particular conformation of bovine PrP^{Sc} selected for heat resistance during the rendering process, and then reselected multiple times as cattle infected by ingesting prion-contaminated MBM were slaughtered and their offal rendered into more MBM? Recent studies of PrP^{Sc} from brains of patients who died of vCJD show a pattern of PrP glycoforms different from those found for sCJD or iCJD. But the utility of measuring PrP glycoforms is questionable in trying to relate BSE to vCJD because PrP^{Sc} is formed after the protein is glycosylated and enzymatic deglycosylation of PrP^{Sc} requires denaturation. Alternatively, it may be possible to establish a relationship between the conformations of PrP^{Sc} from cattle with BSE and those from humans with vCJD by using Tg mice, as was done for strains generated in the brains of patients with FFI or fCJD. A relationship between vCJD and BSE has been suggested, based on the finding of similar incubation times in non-Tg RIII mice of ~310 days after inoculation with human or bovine prions.

Summation

Although prions were originally defined in the context of an infectious mammalian pathogen, it is now becoming widely accepted that prions are elements that impart and propagate variability through multiple conformers of a normal cellular protein. Such a mechanism must surely not be restricted to a single class of transmissible pathogens. Indeed, proteins that act like prions have recently been reported in fungi. It is likely that the original definition will need to be extended to encompass other situations where a similar mechanism of information transfer occurs.

The study of prions has taken several unexpected directions over the past three decades; a novel and

fascinating story of prion biology is emerging. Investigations of prions have elucidated a previously unknown mechanism of disease in humans and animals. While learning the details of the structures of PrPs and deciphering the mechanism of PrP^{C} transformation into PrP^{Sc} will be important, the fundamental principles of prion biology have become reasonably clear. Though some investigators prefer to view the composition of the infectious prion particle as unresolved, such a perspective denies an enlarging body of data, none of which refutes the prion concept. Moreover, the discovery of prion-like phenomena mediated by proteins unrelated to PrP in yeast and other fungi serves not only to strengthen the prion concept but also to widen it.

The discovery that prion diseases in humans are uniquely both genetic and infectious greatly strengthened and extended the prion concept. To date, 20 different mutations in the human PrP gene, all resulting in nonconservative substitutions, have been found either to be linked genetically to or to segregate with the inherited prion diseases (**Fig. 3**). Yet the transmissible prion particle is composed largely, if not exclusively, of an abnormal isoform of the prion protein designated PrP^{Sc}.

The wealth of data establishing the essential role of PrP in the transmission of prions and the pathogenesis of prion diseases has provoked consideration of how many biological processes are controlled by changes in protein conformation. The extreme radiation-resistance of the scrapie infectivity suggested that the pathogen causing this disease and related illnesses would be different from viruses, viroids and bacteria. Indeed, an unprecedented mechanism of disease has been revealed where an aberrant conformational change in a protein is propagated. The future of this emerging area of biology should prove even more interesting and productive as many new discoveries emerge.

Kuru

Carlo Masullo, Institute of Neurology, Catholic University School of Medicine, Rome, Italy

History

Kuru was the first naturally occurring subacute spongiform encephalopathy of humans shown to be caused by an unconventional transmissible agent. Kuru means shivering or trembling in the Fore language. It was first described by Gajdusek and Zigas in 1957 in the Fore cultural and linguistic group of isolated regions of Papua New Guinea. It was found to affect all ages, being common in male and female children and in adult females, but rare in adult males. Kuru is characterized by cerebellar ataxia and a shivering-like tremor that produces complete motor incoordination. The disease is inevitably fatal and death usually occurs in less than 1 year.

Classification

Kuru belongs to the group of subacute spongiform encephalopathies or prion diseases of humans which also include Creutzfeldt–Jakob disease (CJD), Gerstmann–Straussler syndrome (GSS) and fatal familial insomnia (FFI); related animal diseases are scrapie of sheep and goats, chronic wasting disease (CWD) of mule and deer, transmissible mink encephalopathy (TME) and bovine spongiform encephalopathy (BSE).

Geographic and Seasonal Distribution

Kuru has been found in the Eastern Highlands

fascinating story of prion biology is emerging. Investigations of prions have elucidated a previously unknown mechanism of disease in humans and animals. While learning the details of the structures of PrPs and deciphering the mechanism of PrP^{C} transformation into PrP^{Sc} will be important, the fundamental principles of prion biology have become reasonably clear. Though some investigators prefer to view the composition of the infectious prion particle as unresolved, such a perspective denies an enlarging body of data, none of which refutes the prion concept. Moreover, the discovery of prion-like phenomena mediated by proteins unrelated to PrP in yeast and other fungi serves not only to strengthen the prion concept but also to widen it.

The discovery that prion diseases in humans are uniquely both genetic and infectious greatly strengthened and extended the prion concept. To date, 20 different mutations in the human PrP gene, all resulting in nonconservative substitutions, have been found either to be linked genetically to or to segregate with the inherited prion diseases (**Fig. 3**). Yet the transmissible prion particle is composed largely, if not exclusively, of an abnormal isoform of the prion protein designated PrP^{Sc}.

The wealth of data establishing the essential role of PrP in the transmission of prions and the pathogenesis of prion diseases has provoked consideration of how many biological processes are controlled by changes in protein conformation. The extreme radiation-resistance of the scrapie infectivity suggested that the pathogen causing this disease and related illnesses would be different from viruses, viroids and bacteria. Indeed, an unprecedented mechanism of disease has been revealed where an aberrant conformational change in a protein is propagated. The future of this emerging area of biology should prove even more interesting and productive as many new discoveries emerge.

Kuru

Carlo Masullo, Institute of Neurology, Catholic University School of Medicine, Rome, Italy

History

Kuru was the first naturally occurring subacute spongiform encephalopathy of humans shown to be caused by an unconventional transmissible agent. Kuru means shivering or trembling in the Fore language. It was first described by Gajdusek and Zigas in 1957 in the Fore cultural and linguistic group of isolated regions of Papua New Guinea. It was found to affect all ages, being common in male and female children and in adult females, but rare in adult males. Kuru is characterized by cerebellar ataxia and a shivering-like tremor that produces complete motor incoordination. The disease is inevitably fatal and death usually occurs in less than 1 year.

Classification

Kuru belongs to the group of subacute spongiform encephalopathies or prion diseases of humans which also include Creutzfeldt–Jakob disease (CJD), Gerstmann–Straussler syndrome (GSS) and fatal familial insomnia (FFI); related animal diseases are scrapie of sheep and goats, chronic wasting disease (CWD) of mule and deer, transmissible mink encephalopathy (TME) and bovine spongiform encephalopathy (BSE).

Geographic and Seasonal Distribution

Kuru has been found in the Eastern Highlands

Province of Papua New Guinea, which has a population of about 35 000 people living in 160 villages. These villages are located from 1000 to 2500 meters above sea level. No cases of Kuru have been found outside this geographical region. No evidence has emerged from the clinico-epidemiological studies on different seasonal trends of the disease.

Host Range and Virus Propagation

Kuru is naturally occurring only in humans and its clinical course is inevitably fatal.

Experimental transmission of Kuru has been obtained in nonhuman primates and in some small rodents, such as minks and ferrets, through intracerebral inoculation of brain material of patients who died from Kuru. Fourteen strains of Kuru have been isolated and 11 of these human strains have been inoculated into small laboratory rodents, i.e. hamsters, mice and guinea pigs. Only three of these 11 strains produced clinical disease and neuropathological lesions in an occasional mouse on primary passage, and none of these have been successfully serially transmitted from mouse to mouse. Hamsters and guinea pigs failed to develop clinical disease or evidence of brain pathology during several years of follow-up after the experimental inoculation.

A similar pattern of strain adaptation occurred in attempting the transmission of strains of Kuru adapted into nonhuman primates to small rodents. In fact, several strains of chimpanzee, capuchin, spider, rhesus and squirrel monkey-adapted Kuru virus failed to transmit the disease or induce subclinical neuropathological lesions in small rodents for their entire lifespan. On the contrary, two primate-adapted strains of Kuru have caused disease in one of several minks and one of several ferrets, respectively. Serial passage of the Kuru virus in mink has not been successful, while primary passage into ferrets required an incubation of 31 months; serial passage of this same strain in ferrets has been associated with incubation periods of 59 and 70.5 months, respectively, in the two animals which developed the disease on the first ferret-to-ferret passage, and 9 months in the one ferret which developed the disease on the second ferret-to-ferret passage. This variable behavior of a given strain of Kuru has been observed with the passage of the virus between species and, to a lesser degree, within the same species of experimental host. The time sequence of disease progression also mimics that in humans, ranging from several months to over a year until death. A single strain of Kuru virus may cause severe neuronal spongiosis in different brain areas such as the cerebral cortex in chimpanzees without any major neuropathological involvement of the brainstem or spinal cord. On the contrary, this same virus strain may produce extensive brainstem and spinal cord lesions in the squirrel monkey.

Kuru is a naturally occurring disease and its mode of dissemination and maintenance is not completely clarified. A possible explanation is the contamination of close kinsmen by opening of the skull of dead victims in a rite of cannibalism, during which all girls, women and children of the Kuru victim's family were certainly exposed to the virus. The disease is gradually disappearing with the cessation of ritualistic cannibalism.

There are several hundred Kuru orphans born since 1957 to mothers dying of Kuru and none has yet developed the disease. Thus, the many children with Kuru seen in the 1950s were not infected prenatally, perinatally or neonatally by their mothers. Kuru has progressively disappeared, first among children and thereafter among adolescents.

Genetics

Experimental studies have shown that there are several strains of the Kuru agent. In fact, at least 14 strains of Kuru have been isolated by direct inoculation of human brain into nonhuman primates.

Recent studies on the search for possible mutations of the PRNP gene found no mutations occurred in some Kuru cases. The polymorphism at the codon 129 of the PRNP (prion protein) gene has been determined in a group of 38 Kuru patients and the genotypes were M/V in 50%, M/M in 30% and V/V in 20% of the cases; in a control group of the same ethnic background, the genotypes were M/V in 48%, M/M in 30% and V/V in 22%. Therefore, no differences between Kuru patients and their controls have been found, irrespective of the codon 129 genotype.

Evolution

The origin of Kuru is not clear; it is possible that it resulted from a sporadic case of CJD, which, in that particular environment of New Guinea, produced a unique epidemic. Serial passages of brain in successive cannibalistic rituals might have changed the clinical picture of the disease. A spontaneous case of CJD in a 26-year-old native Chimbu New Guinean from the Central Highlands has been reported – the clinical diagnosis was proved only by the neuropathological study of a brain biopsy specimen; this case might represent the basis for spread of the agent, with modifications of the virulence related to serial passages through cannibalistic procedures.

Serologic Relationships and Variability

Transmission studies in experimental animals have shown that several strains of the Kuru agent do exist. Owing to the still unknown nature of the agent causing the disease and the lack of any immune-mediated response in the course of Kuru, no antigenic variations are known.

Epidemiology

The natural incubation period of Kuru can be as long as 25–30 years and it is at times identical in two or more individuals infected at the same time, even over this span of years; the natural incubation period does not seem to be determined by age at exposure.

In the Fore group, Kuru had a yearly incidence rate and prevalence ratio of 1% of the population. As mentioned earlier, there was a marked excess of deaths of adult females over males with a male:female ratio of 1:3 for the whole South Fore group. More than 2500 patients died of Kuru in the 17 year period of surveillance by year since its discovery in 1957 through 1975.

In the last 20 years, there has been a constant and progressive decline of the incidence of Kuru among Fore people. The disease has progressively disappeared from the younger age-groups up to the adult ones. No new Kuru patients have been recorded as born after 1959, and prospective evaluations estimate that Kuru will disappear by the end of the twentieth century.

Transmission and Tissue Tropism

The natural (human-to-human) mode of transmission is not totally understood, but ritual cannibalism has been the probable mode of propagation and maintenance of the disease. This is because the brain tissue, with which the officiating women contaminated both themselves and all their infants and toddlers, contained over ten infectious doses per gram, with self-inoculation occurring through the eyes, nose and skin as well as by mouth.

Experimental transmission of Kuru was first demonstrated in a chimpanzee by intracerebral inoculation of brain homogenate of a Kuru patient; since then, experimental transmission studies of Kuru were conducted in several animal species (other nonhuman primates and various small laboratory rodents).

Studies in cell cultures derived from tissues of patients and animals with Kuru have been performed, inoculating nonhuman primates by the intracerebral route. Primary cell lines that maintain the infectious Kuru agent did not largerly differ in appearance from neuronal cultures derived from brains of non-Kuru cases. Some of these cell cultures became infected with Kuru and the persistence of Kuru infection was demonstrated for 170 days in human cultures and for 215 days in animal cultures. It has never been clearly proved that the Kuru agent replicates *in vitro*.

Kuru has a selective neurotropism; in fact, histological lesions are found only in the central nervous system, involving neurons as well as astrocytes. In about 10% of Kuru cases there is an accumulation and deposition of typical amyloid plaques. Lesions have never been described outside nervous tissue. It is likely that, as in other subacute spongiform encephalopathies of humans and animals, the etiological agent penetrates the lymphoreticular system, reaching the midthoracic level of the spinal cord and then spreading towards the central nervous system, resulting in the clinical appearance of the disease.

Pathogenicity

The etiological agent of Kuru has not yet been isolated; the agent produces a disease which is always fatal for the host and it is regularly detected in the brain tissue where the infectivity titer reaches 10^8 infectious doses per gram. In extraneural tissues, such as liver and spleen, Kuru agent has been found only rarely at death and with lower titers. Infectivity has never been detected in blood, urine, leukocytes, cerebrospinal fluid, placenta or embryonal membranes originating from patients with Kuru.

A pathological amyloidotic protein, PrPres (resistant), has been systematically found in the brains of patients dead from Kuru. PrPres is a distinctive pathological hallmark of Kuru and other spongiform encephalopathies of animals and humans; however, whether this pathological protein represents an important component of the infectious agent or is a by-product of the infection is still a matter of controversy.

Clinical Features of Infection

There is considerable consistency in the clinical characteristics of Kuru, suggesting genetic stability of the agent. In fact, Kuru is constantly characterized by cerebellar ataxia and a shivering-like tremor and its clinical course is remarkably uniform, with cerebellar symptomatology progressing to total inability and death, usually within 3–9 months. Generally, patients complain of joint pain, with the subsequent appearance of walking difficulties prior to clinical onset. During the clinical course of the

disease, some patients develop neurological signs of cognitive impairment, mainly related to damage to the frontal lobes, but most Kuru patients show signs of dementia only in the late stages of the disease. During the progression of the disease, truncal ataxia and shivering tremor become so severe that patients are not able to walk without assistance. At least a third of Kuru patients show clinical signs of basal ganglia impairment, with rigidity and cogwheeling.

Pathology and Histopathology

Macroscopically, the cerebral hemispheres appear normal but the cerebellum regularly shows atrophy, often especially severe in the phylogenetically old paleocerebellum, i.e. the vermis and flocculonodular lobe. Microscopically, the lesions are almost homogenous and no large variations are noted that could be related to differences in age, sex or duration of the disease. The most regular and striking degeneration always occurs in the cerebellum, where there is a loss of Purkinje and granule cells. At the level of the molecular layer, masses of microglial cells are usually found. A diffuse and severe proliferation of astrocytes is observed throughout all layers of the cerebellar cortex. Amyloid plaques, a distinctive neuropathological feature of Kuru, are abundant in more than 80% of cases and are seen within the granular and molecular layers of the cerebellum. These plaques are morphologically characterized by a multicentric core with radiating filamentous deposits. The core consists of granular or homogenous substances of various sizes which are densely stained with periodic acid–Schiff reaction, birefringent with Congo red staining and fluorescent with thioflavin staining.

Immunohistochemical staining with antibodies specifically raised against the pathological protein PrPres shows an intense positive reaction in the core and the periphery of these multicentric amyloid 'Kuru' plaques. Immunocytochemistry of some Kuru brains has been recently carried out in the light of potential similarities with the amyloid plaques deposited in the brain of cases of the new variant CJD (nvCJD), recently reported in young British patients. The conclusion of these studies using antiprion protein immunocytochemistry shows that the pathology, including immunomorphology of PrP deposition, is within the lesion spectrum of CJD, although plaques are unusually prominent and the topography of PrP deposition parallels that of spongiform change and/or astrogliosis, while it seems that Kuru does not share the neuropathological hallmarks of nvCJD. The cerebellar white matter shows no signs of a primary demyelination. Spongiform changes associated with proliferation of reactive astrocytosis and some degree of neuronal loss are diffusely observed throughout the cerebral cortex. In the striatum, many large neurons show a severe and multilocular vacuolation. Other changes are variably distributed in the rest of the basal ganglia and are most frequently observed in the anterior nuclear group of the thalamus.

Immune Response

There is no recognizable inflammatory/immune-mediated response during the clinical course of Kuru, as is the case in all the other subacute spongiform encephalopathies.

Prevention and Control

The most likely mode of natural propagation and maintenance of the infection appears to be contamination during ritualistic cannibalistic ceremonies; this has been confirmed by the dramatic decrease of the number of new cases of Kuru since the cessation of cannibalistic rituals in the Fore region. This decline in Kuru incidence occurred during the period of transformation from a Stone Age cultural enviroment, in which the endocannibalistic ritual consumption of dead relatives was regularly practiced, to a modern society organized with a cash economy. The decline in the incidence of Kuru victims has therefore followed the cessation of cannibalism, and the disease has progressively disappeared from the youngest age group (4–9 years) up to the adult age groups.

The number of Kuru cases has steadily declined and each year the youngest patients have been older than those in the previous year. Now, only two or three cases are occurring annually, none younger than 40 years of age. According to prospective estimates it will probably take only a few years before the appearance of the last Kuru case.

Yeast and Fungi

Marie-Lise Maddelein, Herman Edskes, Kim Taylor and **Reed B Wickner**, Laboratory of Biochemistry and Genetics, National Institute of Diabetes Digestive and Kidney Diseases, National Institutes of Health, Bethesda, Maryland, USA

History

The notion that a protein could be infectious without a nucleic acid as part of the infectious material arose from studies of scrapie of sheep, kuru and Creutzfeldt–Jakob disease (CJD) of man, and the equivalent diseases of other mammals. These diseases are called transmissible spongiform encephalopathies because the diseased brain has a spongy appearance due to loss of neurons and accumulation of vesicles in others. The transmissibility requires injection or feeding of the diseased tissues.

Origin of the infectious protein concept

Gajdusek showed in the 1960s that the inherited and spontaneous forms of CJD were infectious for monkeys, just like the infectious form. He believed that CJD (and scrapie) was due to a slow virus. Studies by Tikva Alper showed that the scrapie agent was remarkably UV-resistant, compared with viruses and bacteriophage. She proposed that scrapie may be infectious without a nucleic acid. Griffith proposed that an infectious protein might be an altered form of a cellular protein that had acquired the ability to change the normal form of the protein into the altered form by forming an oligomer with it. This 1967 proposal is precisely what the transmissible spongiform encephalopathies are widely believed to be today.

In 1975, Dickinson identified a critical gene involved in scrapie of mice that he named *Sinc*, for *s*crapie *inc*ubation period. Prusiner purified the scrapie agent and found that it contained a protease-resistant protein (named PrP). Weissmann and Chesebro cloned the PrP genes of hamster and mouse, respectively, and found they were normal cellular genes. In fact, the PrP gene was the same as Dickinson's *Sinc* gene. Weissmann showed that PrP was necessary for the propagation of scrapie, as mice deleted for the gene were immune to the disease. Prusiner showed that mice transgenic for the hamster gene had now become sensitive to the hamster scrapie agent. Although these studies have not yet proven that scrapie is due to an infectious protein, the concept was widely circulated in this connection.

The definition of 'prion'

The term 'prion' was coined by Prusiner in 1982 to mean simply the scrapie agent. In view of its unusual properties, scrapie was considered to be a new type of entity. It was suggested that if scrapie were an infectious protein, without a nucleic acid, it could be transmitted via 'reverse translation' or 'protein-dependent protein synthesis', but infectious protein was not part of the definition of the word prion. Indeed, many current authors use 'prion' as a synonym for 'scrapie agent'.

We have perhaps confused matters by using the word 'prion' to mean 'infectious protein' and have treated the question of whether there are such things as a separate issue. We continue that usage here.

Expected properties of a yeast or fungal infectious protein

If there were an infectious protein of yeast, it would be expected, like yeast viruses, to spread to other cells via the cell fusion that accompanies mating. Thus, it would appear as a nonchromosomal genetic element.

We proposed three genetic criteria that should distinguish an infectious protein (a prion) from the majority of non-chromosomal genetic elements, which are plasmids or viruses (**Fig. 1**).

1. If one can cure a prion, it should be possible for it to arise again in the cured strain (reversible curability).
2. Overproduction of the normal form of the protein should increase the frequency with which the prion form arises.
3. Recessive mutations of the chromosomal gene for the protein should produce the same phenotype as the presence of the prion, because both result in absence of the normal form of the protein. Deletion of the chromosomal gene should also result in loss of the prion.

Note that scrapie is not known to satisfy any of these criteria.

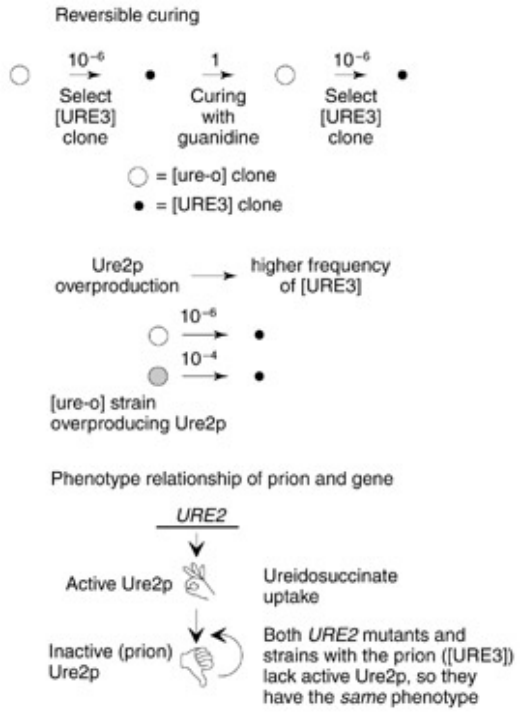

Figure 1 Genetic properties expected of a prion. We proposed that a prion should be reversibly curable, that overexpression of the normal form should increase the *de novo* appearance of the prion form and that the presence of the prion and the absence of the normal form should have similar phenotypes (if the prion phenotype comes from absence of the normal form). From Wickner RB (1994) with permission.

[URE3], an Infectious Form of Ure2p, a Regulator of Nitrogen Metabolism

[URE3] satisfies the three genetic criteria for a prion

[URE3] is a nonchromosomal genetic element identified by Lacroute in 1971 in his search for yeast mutants able to take up ureidosuccinate in the presence of a good nitrogen source, such as ammonia. Ureidosuccinate is an intermediate in uracil biosynthesis, the product of aspartate transcarbamylase (**Fig. 2**). It is taken up by Dal5p, the permease for allantoate, which is structurally similar to ureidosuccinate. Allantoate is a poor, but usable nitrogen source for yeast, but genes needed for allantoate utilization (such as *DAL5*) are repressed when a good nitrogen source is available. This 'nitrogen catabolite repression' is mediated in part by Ure2p, which blocks the positive transcription regulator, Gln3p, when a good nitrogen source is at hand. Gln3p is necessary for transcription of *DAL5* and other nitrogen-regulated genes.

Lacroute found that both the chromosomal *ure2* mutants and strains with the nonmendelian element [URE3] could take up ureidosuccinate. But Aigle and Lacroute found that *ure2* mutants could not propagate the [URE3] genetic element. This is criterion (3) above. [URE3] may be cured by growing cells in the presence of low concentrations of guanidine, but we found that from the cured strains can again be isolated strains that have spontaneously developed [URE3]. This is reversible curability (criterion (1) above). Finally, overproduction of Ure2p results in a 20–200-fold increase of the frequency with which [URE3] arises (criterion (2)).

Further evidence that [URE3] is a prion form of Ure2p

Not only can overproduction of Ure2p induce appearance of [URE3] in a normal strain, but it can do the same thing in a strain which was initially deleted for *URE2*. This argues against [URE3] being the altered form of a virus or plasmid present in the normal strains, as the putative normal replicon should depend on the same chromosomal genes (i.e. *URE2*).

If [URE3] is an infectious protein form of Ure2p, it should be possible to show some difference in Ure2p in [URE3] strains compared with normal strains. Indeed, Ure2p is more protease resistant in [URE3] strains, than in either the parent strain or in a cured strain.

One type of nonnucleic acid 'genetic element' is a sort of regulatory circuit that is self-maintaining. Since Ure2p is a transcription regulator, it is critical to show that this is not the case here. Several lines of evidence show that the regulatory capacity of Ure2p and its ability to undergo or induce the [URE3] change are distinct. Moreover, the [URE3] genetic element can be equally well propagated under conditions of nitrogen derepression or repression.

Molecular biologic proof that Ure2p is infectious

We have shown that it is actually the overproduction of the Ure2 protein, not the *URE2* mRNA or the *URE2* gene in high copy, that induces the appearance of [URE3]. This may be viewed as the molecular biological equivalent of purifying Ure2p from [URE3] strains and showing that it is infectious.

Mechanism of [URE3] generation and propagation

The Ure2 protein may be divided into an N-terminal 65-residue prion domain and a C-terminal nitrogen regulation domain. The prion domain is sufficient when overproduced to induce appearance of [URE3] at a frequency over 1000 times the spontaneous rate. It is also necessary for a Ure2p molecule to have a

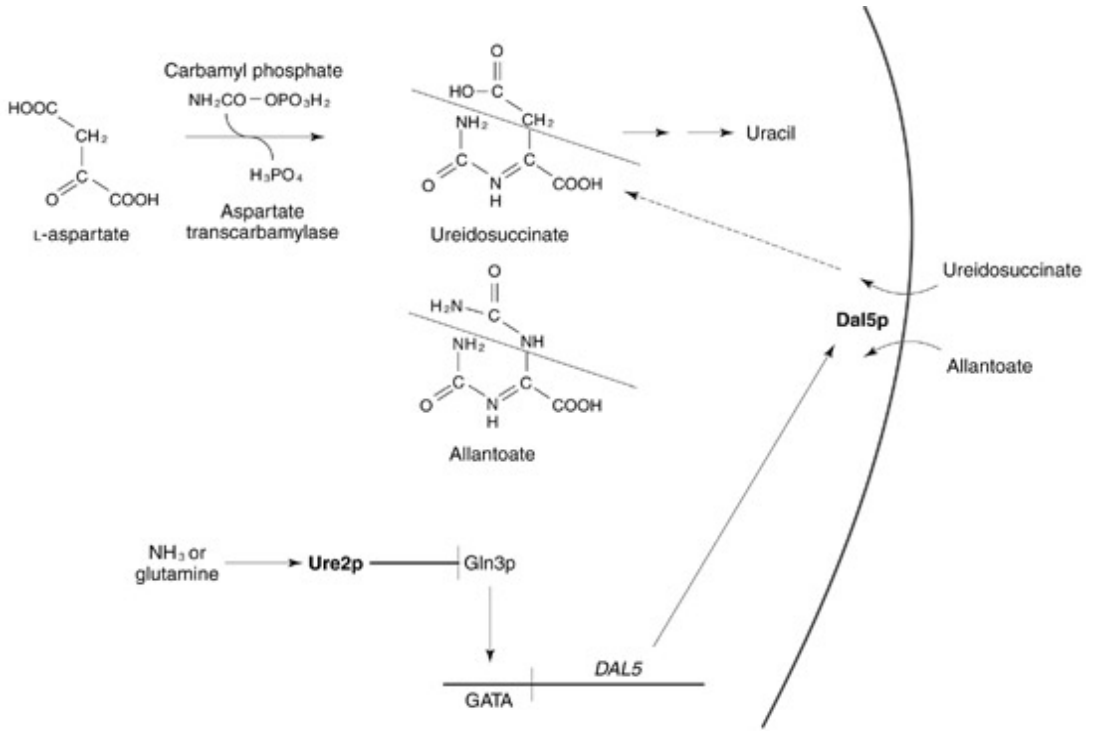

Figure 2 Nitrogen regulation affects uptake of ureidosuccinate through Ure2p. In the presence of a good nitrogen source (ammonia or glutamine) the Ure2p protein prevents the Gln3p protein from activating transcription of genes whose products are involved in utilization of poor nitrogen sources. Dal5p is such a protein, a transporter for allantoate, a poor nitrogen source structurally similar to ureidosuccinate. Ureidosuccinate is an intermediate in uracil biosynthesis.

covalently attached prion domain in order for it to be subject to the prion change as transmitted from another molecule (**Fig. 3**). Indeed, the N-terminal prion domain can transmit [URE3] in the complete absence of the C-terminal part of the Ure2 molecule. Likewise, the C-terminal part of the molecule can regulate nitrogen without the N-terminal domain.

Although the N-terminal prion domain and the C-terminal nitrogen regulatory domain of Ure2p can each act in the absence of the other, there are several lines of evidence that they have specific functional interaction: (1) the C-terminal domain must be overproduced to regulate nitrogen as well as the full-length protein, suggesting that the N-terminal domain somehow helps in this activity; (2) deletions in the C-terminal domain *increase* the frequency with which the molecule converts to the prion form, suggesting that the C-terminal domain stabilizes the N-terminal domain in the normal form; and (3) attaching the prion domain to β-galactosidase does not make that enzyme subject to inactivation by the introduction of [URE3].

The precise mechanism by which the prion domain inactivates the C-terminal nitrogen regulation domain is not yet known. It is possible that this involves a specific interaction, or that the aggregation of Ure2p in [URE3] strains prevents Ure2p from entering the nucleus, where it acts to modulate Gln3p activity.

[PSI], an Infectious Form of Sup35p, a Translation Release Factor

[PSI] as a infectious form of Sup35p

[PSI] was discovered in 1965 by Cox as a nonchromosomal genetic element that increased the strength of chromosomal suppressor mutations (suppressor tRNAs). Weak suppressors became strong and strong suppressors became lethal. Even [PSI] by itself had some weak suppressor activity. [PSI] could affect any nonsense mutation.

[PSI] can be cured by growth of strains in high osmotic strength medium, or by guanidine. But from the cured strains could again be isolated strains that had developed [PSI]. This is reversible curability. *Sup35* mutants, like [PSI], have 'omnipotent suppressor' activity, working on UAA, UGA and UAG codons. Moreover, [PSI] fails to propagate in certain *sup35* mutant strains. This is the relation expected if [PSI] is a prion form of Sup35p (**Fig. 3**). Finally, overproduction of Sup35p results in a 100-fold increase of the frequency with which [PSI] appears.

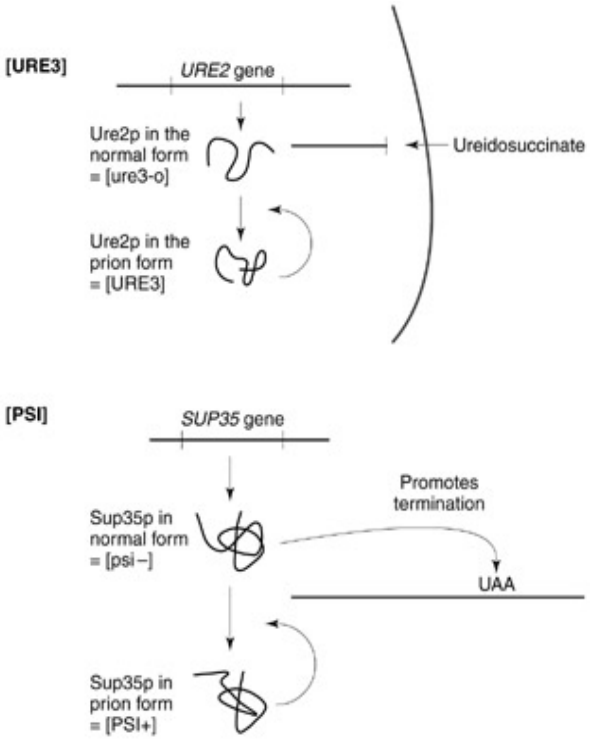

Figure 3 [URE3] and [PSI] as prion forms of Ure2p and Sup35p. If an altered protein can convert the normal form into the same altered form, this altered form can be a prion if it has a means to pass from cell to cell, or individual to individual. We proposed that [URE3] and [PSI] are altered forms of Ure2p and Sup35p, respectively.

Thus, [PSI] has the three genetic properties expected if it is an infectious protein form of Sup35p. Sup35p is a subunit of the translation release factor. It is to be expected that a change of Sup35p that partially inactivates it (or completely inactivates some proportion of the Sup35p molecules) would make translation termination less active and less able to compete with a suppressor tRNA.

Support for [PSI] being a prion

In normal strains, Sup35p is a soluble protein, complexed with the other subunit of the translation release factor, Sup45p, as a heterodimer. In extracts of [PSI] strains, most of Sup35p is present as an aggregate. The Sup35p in extracts of [PSI] strains is resistant to digestion with protease, perhaps because it is in this aggregated form.

Prion domain of [PSI]

Ter-Avanesyan and coworkers examined various deletion mutants of Sup35p and showed that the C-terminal domain is essential for cell growth, presumably the translation termination domain. They found that the N-terminal 114 residues were dispensable for cell growth, but were necessary for the propagation of [PSI]. This region has a series of repeats of an eight amino acid motif and is rich in glutamine and glycine residues. PrP also has an octapeptide repeat near its N-terminus, but transgenic mouse studies indicate that this repeat is not necessary for the propagation of scrapie.

Hsp104 is necessary for [PSI] propagation *and* can cure [PSI]

Chernoff and coworkers isolated a high-copy plasmid that cured [PSI] and found that it encoded Hsp104, a heat shock protein known to disaggregate proteins which had been denatured by heat. Overproduction of Hsp104 by other means also results in loss of [PSI]. Surprisingly, underproduction of Hsp104, for example, by deletion of the gene, also results in loss of [PSI].

The fact that a protein renaturing factor can eliminate [PSI] supports the notion that [PSI] is a conformationally altered form of a normal protein. At the same time, this important result suggests an avenue to approach the treatment of CJD and other transmissible spongiform encephalopathies. That [PSI] propagation requires Hsp104 could suggest that Hsp104 is actually involved in the conversion of Sup35p from the normal to the altered form (along with the altered form of Sup35p itself). Another possibility is that in the absence of Hsp104 there is essentially a single aggregate of Sup35p in [PSI] strains, and that when the cell divides, only one of the daughter cells will receive this aggregate (and thus receive [PSI]). Perhaps normal levels of Hsp104 breaks the aggregates into several peices, at least one of which goes to each daughter cell, insuring the stable propagation of [PSI].

In vitro propagation of [PSI]

Recently, Paushkin *et al* have reported an *in vitro* system in which soluble Sup35p, isolated from a wild-type strain, is converted to the aggregated form by addition of highly purified Sup35p aggregates from a [PSI] strain. A small aliquot of the product can prime the aggregation reaction of a new batch of soluble Sup35p. This reaction can apparently be continued as long as there is a supply of fresh normal Sup35p. The reaction requires the same N-terminal domain of Sup35p that has been shown to be critical for propagation of [PSI]. This is a remarkable confirmation of the prion model for [PSI].

[Het-s] as a Prion Form of the *het-s* Protein of *Podospora*

Heterokaryon incompatibility in fungi

A colony of the filamentous fungus, *Podospora*, is not really a collection of cells. Rather, the cells of the colony are interconnected, separated by incomplete cell walls and septae. Thus, each colony is a single multinuclear cell, a syncytium. When two colonies of a single fungal strain grow toward each other, the cellular processes (called hyphae) of the two colonies fuse, forming what is, in effect, one colony. The nuclei migrate between what was the two colonies so that a 'heterokaryon' is formed – a combination of the two colonies in which each 'cell' may have a mixture of the two kinds of nuclei, one kind from one parent colony, and one from the other. When these colonies fuse, a virus or plasmid present in one colony will spread throughout the other as well. Many fungal viruses and plasmids are quite debilitating to their hosts. For this reason, it is believed, most fungi have a system that limits with what strains it will carry out this 'hyphal fusion' (or heterokaryon formation). This system limiting heterokaryon formation is called 'heterokaryon incompatibility'.

Genetic control of heterokaryon incompatibility

Sexual mating, leading to meiosis, is a process designed to create diversity by shuffling the genetic cards. Thus, sexual mating requires *differences* between the individuals at one or more loci (the mating type loci). Heterokaryon formation, as described above, is designed to allow cooperation (e.g. sharing of nutrients) between genetically identical individuals, and so heterokaryon formation only occurs between strains identical at each of several genes, called *het* genes in the case of *Podospora*.

One of the *Podospora het* genes is called *het-s*, and it can have two alleles, *het-S* and *het-s*. Two *het-s* or two *het-S* strains readily fuse and form healthy heterokaryons with each other. But when a *het-s* strain meets a *het-S* strain, hyphal fusion is followed quickly by death of fused hyphae and the formation of a barrier to further fusion between the two colonies.

Genetic properties of *het-s* suggest a prion

The *het-s* strains can have either of two phenotypes, one showing the incompatibility described above, and another 'neutral' phenotype in which cells form heterokaryons equally well with *het-s* and *het-S* cells. This difference is controlled by a nonmendelian genetic element, called [Het-s], whose presence leads to the incompatibility phenotype, and whose absence results in the neutral phenotype (**Fig. 4**). [Het-s] can be cured, but then spontaneously reappears at a low frequency ('reversible curability'). Begueret and coworkers have recently found that overproduction of the *het-s* protein results in an increase of the frequency with which [Het-s] appears. Deletion of the *het-s* gene results in inability to propagate [Het-s], but the deleted strains show the same neutral phenotype as is found in the absence of [Het-s], so this does not specifically point to [Het-s] being a prion (although it is not against this conclusion). Finally, the *het-s* protein shows increased resistance to protease digestion in extracts of [Het-s] strains compared to strains lacking [Het-s].

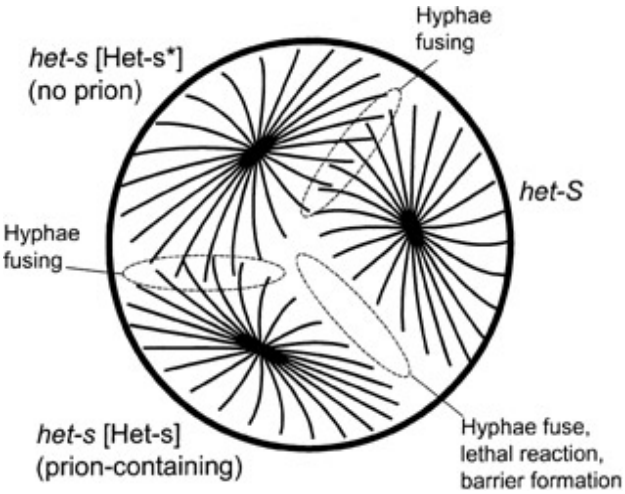

Figure 4 Heterokaryon incompatibility in *Podospora* and the [Het-s] prion. A *het-s* strain shows heterokaryon incompatibility with a *het-S* strain only if the former carries a nonmendelian genetic element, called [Het-s]. Begueret and coworkers have presented evidence that [Het-s] is a prion form of the *het-s* protein.

These results all point to [Het-s] being a prion form of the *het-s* protein. This is the first case in which a prion appears to be facilitating a normal cellular function. Heterokaryon incompatibility is a phenomenon found in most filamentous fungi, and in the many other cases examined genetically, there is no evidence of any unusual genetic features suggestive of prions.

Features of the *het-s* protein

The *het-s* and *het-S* alleles differ by only 14 amino acids in a 289 amino acid open reading frame. A single difference at residue 33 is sufficient to convert *het-s* to *het-S* behavior. These proteins have no similarity to any other proteins in the databases, including the other putative prion proteins, PrP, Ure2P and Sup35p.

Table 1 Comparison of the putative prion systems

Prion	*Protein*	*Phenotype of prion*	*Function of normal protein*	*Structure of protein*
Scrapie	PrP	Ataxia, dementia, death	Unknown	Normal – α helix; prion – β sheet
[URE3]	Ure2p	Nitrogen derepression	Nitrogen repression	Asparagine-rich prion domain
[PSI]	Sup35p	Translation readthrough	Translation termination	Glutamine and asparagine rich
[Het-s]	*het-s* protein	Heterokaryon incompatibility	None known	??

Comparison of the Putative Prion Systems (Table 1)

Although the evidence certainly suggests that the scrapie agent is an altered form of PrP, there is other data that calls this into question. Although PrP can be made in large amounts in bacterial or yeast cells, sometimes as protease-resistant material with high β-sheet content, it has never proven infectious. Moreover, there are several reports of dissociation between the finding of abnormal PrP and appearance of infectivity. Finally, the genetic criteria proposed for fungal prions have not yet been satisfied for PrP and scrapie.

The yeast and fungal systems, because of the ease with which they may be studied genetically, have already produced some important results:

- The fungal systems have provided evidence that there can be such a thing as a prion – evidence of a type not yet available for scrapie and PrP.
- These systems show that an inherited trait can be a prion: a prion can be a 'gene'.
- The role of chaperones in prion propagation has long been speculated, but is first shown for [PSI]. It is expected that these systems will soon lead to the definition of other factors affecting prion generation and propagation.
- [Het-s] shows that a normal cellular function can be determined by a prion.
- The definition of prion domains in Ure2p and Sup35p is beginning to contribute to our understanding of how a prion arises and is propagated.
- The *in vitro* system for [PSI] is the best available for any prion to date.

We expect that many more prions will be discovered, some causing pathologic conditions of animals, plants or microorganisms, while others mediate normal cellular functions. The genetic approaches to identifying prions that have proven useful in yeast and filamentous fungi will probably continue to be valuable in identification of other prions.

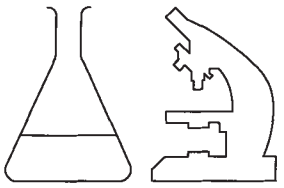
PROPAGATION OF VIRUSES



Contents

Animal

Steffen Faisst, Novo Nordisk AIS, Soeborg, Denmark

Introduction

Viruses exist in two functionally distinct forms. The viral particle, referred to as virion, represents the static extracellular form without any metabolic activity, serving as a vehicle for the viral genetic material. The second, the dynamic form, consists of the viral genetic material itself once it is uncoated in a host cell. This active form of a virus uses the host cell biosynthesis machinery and energy supplies to multiply and to generate progeny virions. Hence, virus multiplication exploits host cells in a parasitic way. This results in the disturbance of normal cellular functions in many virus-infected cells, one of the basic mechanisms of viral diseases.

Virus propagation under defined laboratory conditions provides an important experimental tool in basic research in virology, allowing studies of virus multiplication, virus–host cell interactions and viral pathogenesis. Furthermore, virus propagation provides the basis for diagnoses of viral disease and vaccine production, as well as the generation of recombinant viruses for potential use in gene therapy.

Here, the mechanisms of intracellular virus multiplication are summarized, and techniques used for virus propagation, purification and titration are described.

The Virus Multiplication Cycle

To multiply, a virus has to enter a living cell. Thereafter, the viral genome is released from the capsid, and interacts with the host cell in order to replicate and to produce viral proteins. New capsids are assembled, and the newly synthesized genomes are packaged into these capsids either concomitant with or after their assembly. This results in progeny virions, which are released from the cell in order to transfer the viral genome to new host cells.

The initial step of virus–cell contact, referred to as adsorption, is mediated by the binding of a viral protein, located at the virion surface, to a receptor at the cell surface. Cellular receptors of many viruses have been identified. Most viruses adsorb to cell surface proteins that have specific metabolic functions, and that are expressed only in a subset of differentiated cells. Rabies virus, for example, binds to the acetylcholine receptor, and accordingly adsorbs to nerve cells. Human immunodeficiency virus adsorbs to CD4 molecules of T lymphocytes and macrophages, but needs co-receptors for viral entry into these cells. These co-receptors have been identified recently, and belong to the family of chemokine receptors. It should also be noted that carbohydrates have been shown to act as virus receptors. For example, polyomavirus, Sendai virus and vaccinia virus adsorb to sialyloligosaccharides of glycoproteins and glycolipids, which can be found on the surface of many cell types.

After adsorption, viruses have to cross the plasma membrane in order to enter a cell. The mechanism of penetration differs from virus to virus, depending on the respective virion structure. Adsorption to cell receptors brings viruses into intimate contact with the plasma membrane. Subsequently, viruses with a membranous envelope may directly inject the viral capsid into the cytoplasm by membrane fusion. However, the virus–receptor complex can also be internalized by coated pit-mediated endocytosis and delivered to endosomes. Subsequent fusion of viral and endosome membranes leads to the release of the viral capsid into the cytoplasm.

Viruses lacking an envelope also enter cells by coated pit-mediated endocytosis, but entry of the capsid into the cytoplasm obviously cannot occur via membrane fusion. For the non-enveloped adenovirus, evidence has been presented that capsid proteins induce the lysis of endosomes, thus releasing the capsid into the cytoplasm.

Once within the cytoplasm, the viral genome has to be liberated from the capsid and transported to the appropriate intracellular site for transcription or replication. This event is referred to as uncoating.

For RNA viruses, cellular factors like proteases are thought to dismantle the virus capsids immediately after entry, releasing the viral RNA into the cyto-

plasm, where it is replicated and translated. Also poxviruses, which contain a double-stranded DNA genome, replicate in the cytoplasm, using a virus-encoded DNA polymerase. Only retroviruses transcribe their RNA genome in DNA, which subsequently translocate to the nucleus and integrate into the cellular genome. The integrated retroviral genome serves as a template to synthesize new RNA genomes.

For nuclear-replicating DNA viruses, the capsid is supposed to be translocated along the cytoskeleton to the nuclear pores. At the nuclear pores, the viral DNA is released into the nucleus, where it is replicated.

When the viral genome is delivered to its appropriate intracellular site, it has to interact with the host cell biosynthesis machinery in order to get amplified and transcribed into mRNAs allowing the synthesis of viral (capsid and noncapsid) proteins. Thereafter, cellular and viral factors mediate the assembly of the capsids, and the packaging of the viral genome into these capsids. These steps are referred to as capsid maturation. The assembly of capsid proteins of nonenveloped viruses occurs either in the nucleus (e.g. parvoviruses, adenoviruses and papovaviruses) or in the cytoplasm (e.g. reoviruses). Most of the nonenveloped viruses rely on host cell lysis for their egress.

The assembly of the capsids of enveloped viruses also takes place either in the cytoplasm (most RNA viruses, poxviruses), or in the nucleus (herpesviruses), but the last step in virion assembly is linked to the release of the virions. Most RNA viruses egress by budding through the plasma membrane. Herpesviruses have been shown to leave the nucleus by budding through the inner nuclear membrane. They are then released from the cells by transport through the endoplasmic reticulum. Poxviruses may be released from the cells either by budding through the Golgi apparatus, or by cell disruption, resulting in enveloped and nonenveloped particles, respectively. Both enveloped and nonenveloped particles are infectious. Once progeny virus has been released, new cells can become infected, and further multiplication cycles are initiated.

Cytopathic Effect

Different types of interaction between viruses and host cells can be observed. Many viruses kill or morphologically modify their host cells when they multiply. This is called the cytopathic effect (CPE), and the respective virus is said to be cytopathogenic.

Generally, cytopathogenic viruses code for proteins that shut off synthesis of cellular macromolecules, or that are cytotoxic. Furthermore, the capsid proteins of nonenveloped viruses seem to be implicated in cell lysis, on which these viruses may rely for their egress. Enveloped viruses may additionally insert viral proteins into the cell membrane, which also may impair the viability of the target cells. Cell death within a few days is the result of productive infection with many types of viruses, such as togaviruses, picornaviruses or autonomous parvoviruses. Infection with poxviruses, reoviruses or adenoviruses also leads to cell death, but less rapidly.

Another type of CPE is the induction of cell fusion by viruses such as paramyxoviruses, human immunodeficiency viruses and herpesviruses. Induction of cell fusion is also due to the insertion of viral proteins into the host cell membrane, and results in the formation of syncytia (giant cells with up to several hundred nuclei).

As a result of mild CPEs, a balance between cell growth and virus production can sometimes be observed (e.g. after paramyxovirus infections). Such 'carrier cultures' may be seen as the cell culture counterparts of chronic infections in animals. Several RNA viruses that are not cytopathogenic (like arenaviruses and most retroviruses) may also provoke such steady-state infections.

Host Range, Permissiveness and Susceptibility

Any cell that can be infected by a virus is said to be susceptible. However, infection of a susceptible cell does not necessarily result in a productive infection. Productive infections occur only in cells able to support a complete viral multiplication cycle. Such cells are said to be permissive. In terms of cell cultures, the spectrum of permissive cells makes up the host range of a virus. However, the host range may also define the animal species that support a productive infection.

The host range of viruses may be wide, but it may also be very limited. For example, the host range of the parvovirus H-1 comprises humans, monkey, hamster and rat as animal species, and most cell types (fibroblasts, keratinocytes, lymphocytes) of human, monkey, hamster or rat origin. On the other hand, the host range of B19, another parvovirus, is restricted to humans and human erythroid precursor cells.

Infections of susceptible, but nonpermissive cells do not result in virus production. Three distinct types of such nonproductive infections have been described, and are referred to as abortive, latent and restrictive infections, respectively.

An abortive infection occurs in susceptible cells, which sustain some, but not all steps of the viral multiplication cycle. As stated earlier, after successful

entry of a virus into a cell, the viral genome has to become uncoated, amplified and expressed. Newly synthesized genomes have to be packaged into progeny particles that need to be released from infected cells.

Virus multiplication can be blocked at all stages of this cycle in susceptible, but nonpermissive cells. For example, the polyoma virus multiplication cycle is blocked at the stage of DNA replication and transcription in embryonal carcinoma cells lacking specific DNA-binding proteins. Similarly, the multiplication of the parvoviruses H-1 and MVM is blocked at the level of DNA and RNA synthesis in some cells that are refractory to virus propagation. Furthermore, some diploid cell strains infected with parvovirus H-1 are proficient in capsid assembly, but no DNA is packaged, and no particles are released from the cells. Cellular functions implicated in these last stages of infection have not yet been identified.

It should also be stated that infection of a permissive cell with a defective virus, lacking one or several essential viral functions, results in an abortive infection. During abortive infections, the virus may exert different cytopathic effects, depending on the viral functions that the host cells allow to be expressed. Hence, an abortive infection may result in cell death, if the virus was able to express its cytotoxic proteins, but may also be inapparent.

A latent infection consists of the persistence of viral genomes in infected cells for many cell generations. The viral genomes may persist in an integrated or in an episomal state or both. For example, retroviruses have been found as 'endogenous viruses' in human cells, and have been calculated to persist in these cells since approximately 40 million years. Such latent infections do not lead to host cell killing, but may nevertheless influence biologic characteristics of the cells. As an extreme example, persistence of tumor viruses is associated with cellular transformation leading to increased growth rates, abnormal cell morphology, altered cell metabolism and chromosomal aberrations.

Most viruses establishing latent infections can be rescued from their host cells, provided they have not become defective. Latent infections that can become productive are called persistent infections. To convert a latent into a productive infection, specific treatments have to be applied. For example, superinfection with adenovirus results in a productive infection of persistent adeno-associated viruses, and treatment with phorbol esters activates the multiplication cycle of persistent human immunodeficiency virus type 1 in the human macrophage cell line U1.

Finally, a rare type of nonproductive infection is the restrictive infection, that is observed in cell cultures where only a small subset of the cell population is permissive, or where the cells are only transiently permissive.

Virus Propagation in Whole Organisms

In initial studies in virology, the experimental tools for virus propagation and purification were whole laboratory animals or embryonated hen's eggs. Laboratory animals can be infected using the natural route of virus entry. To achieve this, the virus must be brought into contact with either the skin (e.g. papillomaviruses), the digestive tract (e.g. enteroviruses), the respiratory tract (e.g. orthomyxoviruses) or the conjunctiva (e.g. herpes simplex virus). Viral replication may be confined to the site of entry, or progeny virions may spread through the body (generally via the blood or lymphatic stream) with subsequent targeting to specific organs. Laboratory animals also can be infected by injecting the virus directly into specific organs (e.g. the brain for rabies virus). Several days or weeks after infection, the animals are killed, and cell-free extracts from the organs sustaining virus multiplication are used as a source of virus.

Furthermore, fertilized hen eggs can be infected after several days of incubation (depending on the stage of embryonic development required). Most viruses can be grown in the embryonic membranes of fertilized eggs, i.e. the yolk sac (e.g. herpesviruses), the chorion (e.g. poxviruses), the allantois (e.g. influenza virus) and the amnion (e.g. mumps virus). Although laboratory animals or embryonated eggs are still the most appropriate propagation systems for some viruses (animals for arboviruses, coxsackieviruses and rabies virus; eggs for orthomyxoviruses), they tend to be replaced by cell cultures, which are much more convenient to handle. For present-day virology, the use of animals is restricted mostly to research on viral pathogenesis and for production of vaccines.

Virus Propagation in Cell Culture

Multiplicity of infection, defective-interfering particles

The term 'cell culture' refers to *in vitro* cultures derived from dispersed cells taken from original tissues by enzymatical, mechanical or chemical disaggregation. Cultured cells may serve as hosts for the propagation of a number of viruses, provided these cells express all the factors allowing a complete viral replication cycle.

The first cells to be cultured were primary cells freshly isolated from animal tissues. The growth of

these cultures is restricted to five to ten cell generations at most, which limits their value for routine virus propagation. Such primary cultures contain a variety of cell types providing a broad viral spectrum. Thus, they represent a system in which as yet uncharacterized viruses can be propagated and isolated with a high probability of success, and are therefore valuable in virus diagnosis.

Cell lines derived from cancer tissues, capable of indefinite growth in culture, and strains of diploid cells prepared from human or animal tissues (in particular from embryos), capable of growing in culture up to 100 cell generations, contain cells of a specific type and allow the propagation of viruses under defined conditions. The choice of the most suitable cell line to propagate a virus will depend mainly on the host range and tissue specificity of the virus investigated. Continuous cell lines are useful for the propagation of viruses such as adenoviruses and rhinoviruses. Insect viruses (e.g. baculoviruses) can be propagated *in vitro* in immortal insect cells (e.g. SF cells, derived from *Spodoptera frugiperda* pupal ovarian tissue). Other viruses, like herpesviruses or enteroviruses, may preferentially be propagated in diploid cell strains of finite life.

However, attempts to propagate a series of viruses in cultured cells failed. This is mainly due to differences in cell behavior between cultured cells and their counterparts *in vivo*. Many of these differences stem from the dissociation of cells from a three-dimensional geometry and the lack of several systemic compounds involved in homeostatic regulation *in vivo*. As a consequence, cellular metabolism may not be truly representative of the tissue from which the cells were derived (see also below, 'Virus Propagation in Three-Dimensional Cell Culture Systems'). Hepadnaviruses, for example, require liver-specific receptor(s) to enter their host cells. In cell culture, only primary liver cells fulfill this requirement. Continuous hepatoma cell lines, however, do not express these receptor(s) in culture and therefore prohibit hepadnavirus propagation *in vitro*. Most data on the hepadnavirus replication cycle have therefore been obtained by genetic approaches using transfection of terminally redundant hepadnavirus DNA constructs, directing the synthesis of the RNA pregenome, into cultured hepatoma cells. This method allows only a single round of virus production, and precludes the study of early steps of the viral replication cycle such as the uncoating of the viral genome and its conversion into covalently closed circular DNA. Recently, receptor(s) required for internalization of hepadnavirus particles have been identified and cloned. The availability of cloned receptor genes now will allow cultured hepatoma cells to be genetically engineered in order to induce constitutive expression of these molecule(s) on their surface. Such cells subsequently may represent an efficient *in vitro* system for hepadnavirus propagation.

To obtain the best yield of progeny virus, it is important to determine the optimal conditions for the initial infection of the culture. One important parameter is the ratio of the number of cells to the number of infectious particles inoculated. This ratio is called multiplicity of infection (moi). A multiplicity of infection of two (moi = 2) defines an infection with an average of two infectious virus particles per exposed cell.

Most, if not all, viruses generate defective genomes, and, consequently, defective particles during their multiplication. This defectiveness is due to deletions in the viral genome, which render the virus incapable of expressing all the functions needed for a productive infection. These particles can arise because their defectiveness is complemented by genes of co-infecting 'wild-type' viruses. Therefore, the formation of defective particles is favored by infections at high moi. Adenovirus or parvovirus preparations may contain up to 1000 defective particles per infectious virion. In order to generate as few defective particles as possible, the standard protocol for the propagation of many viruses involves an initial infection at moi of 1×10^{-3} (i.e. one infectious virion per 1000 cells).

Infections are usually performed under cell culture conditions (37°C, pH 7.4, 5% CO_2) for 30 min to 1 h. The volume of the solution in which cells and viruses are brought together should be as small as possible in order to enhance the probability of host cell–virus contact. The presence of cations facilitates the adsorption process of most viruses. After infection, cell cultures are maintained at 37°C, except in the case of infections with viruses such as rhinoviruses or coronaviruses, which multiply best at 33°C, the temperature encountered in the nasal mucosa. After one or several multiplication cycles, progeny virus can be purified from the infected cultures.

Virus propagation in three-dimensional cell culture systems

As mentioned above for hepadnaviruses, papillomaviruses also cannot be propagated in conventional cell cultures. *In vivo,* papillomaviruses infect basal epithelial cells and establish their genomes as extrachromosomal elements. Following cell division, infected daughter cells migrate from the basal region and begin the process of differentiation. Upon terminal differentiation, papillomavirus genome amplification, late gene expression and virion assembly

are induced. Hence, attempts to propagate papillomaviruses in conventional cell cultures, which do not allow the cells to terminally differentiate, have not been successful, but were facilitated by the utilization of three-dimensional (3D) cell cultures (also called organotypic cultures or raft cultures). In organotypic cultures, cells of different lineages are recombined in a 3D matrix in spatial relationships and in experimentally determined ratios to recreate a component of the organ under study. Organotypic cultures of epithelial cells, for example, recreate important features, both morphological and physiological, of epithelial differentiation *in vitro* by raising the cells to an air–liquid interface, and even allow the achievement of terminal differentiation after treatment with 12-*O*-tetradecanoyl phorbol-13-acetate (TPA). When epithelial cells containing extrachromosomal papillomavirus genomes were grown in raft cultures, differentiation-dependent viral late gene expression, genome amplification and virion biosynthesis were observed.

Virus Purification

Viruses are purified from tissue (culture) homogenates, using various fractionation procedures. Different methods can be used depending on the physicochemical properties of the virions to be purified. Most virions are very sensitive to inactivation by heat, acid, alkali and lipid solvents. Accordingly, in most purification protocols, the virus is maintained at neutral pH and 4°C.

Generally, the supernatant of infected cell cultures provides a relatively clean virus suspension, but in some instances, viruses must be released by breaking up the cells by sonication, homogenization, or repeated freeze–thaw cycles. Thereafter, viruses can be concentrated and partially purified from cellular debris by adsorbing viral particles to erythrocytes, DEAE cellulose, aluminum hydroxide or ion-exchange resins. Subsequently, virions are eluted with buffers of specific pH and ionic strength. Viruses may also be precipitated with ammonium sulfate.

These partially purified viruses can be further separated from contaminants by physical methods, in particular by centrifugation. Differential centrifugation, which consists of multiple centrifugation cycles at increasing speed, is used to pellet first the contaminants and then the virions. Centrifugation through a cushion of a dense sucrose solution or through a preformed sucrose gradient (rate zonal centrifugation) separates viruses from contaminants based on their size and shape, i.e. their sedimentation coefficient. Equilibrium centrifugation in cesium chloride or potassium tartrate solutions is used to purify viruses as a function of their buoyant density.

Since virus purification aims at the elimination not only of cellular debris but also of defective viral material, equilibrium centrifugation may be the method of choice. This method allows the separation of infectious virions, defective particles, and empty capsids, which generally band at distinct densities (for example, infectious, defective and empty particles of the parvovirus H-1 have a density of 1.41, 1.38 and 1.32 g ml^{-1}, respectively). Before equilibrium centrifugation, it may be useful to treat the virus suspension with DNase, since contaminating cellular or viral DNA stick to some viruses and therefore would be copurified.

Virus preparations can be concentrated by ultracentrifugation, freeze-drying or dialysis against hydrophilic agents such as polyethylene glycol. Generally, concentration will be the last step of a purification protocol, but may be useful before centrifugation steps. Most viruses are heat labile. Therefore, virus preparations should be stored as cold as possible. As a rule, the half-life of many (enveloped) viruses will be years at −196°C, months at −70°C, days at 4°C and only hours at 20°C or minutes at 37°C.

Virus Titration

There is a variety of ways to determine the amount of virus in a preparation. Two types of methods should be distinguished: (1) infectivity assays that measure the amount of infectious virions in a preparation; and (2) particle assays that determine the number of all virus particles.

For lytic viruses, the most commonly used infectivity assay is the plaque assay. Monolayers of highly permissive cells are infected with serial dilutions of the virus suspension to be tested. After infection, the cells are overlaid with a semisolid agarose gel containing the culture medium, in order to restrict spread of progeny virus to cells next to the initially infected cells. Each infectious particle will give rise to a focus of infected cells, which can be seen as an area of CPE. The number of areas of CPE (plaques) within a cell monolayer can be easily counted after staining of the cell monolayer with a vital dye such as neutral red. Living cells stain red, and the areas of CPE appear as clear plaques against a red background (**Fig. 1**). From the number of plaques detected by this method, the number of infectious particles in a virus suspension can be calculated, and is expressed in terms of plaque-forming units (PFU) per milliliter.

To determine the titer of noncytopathogenic viruses, *in situ* hybridization assays can be used. Prerequisites for this test are the identification of permissive cells allowing the amplification of the viral

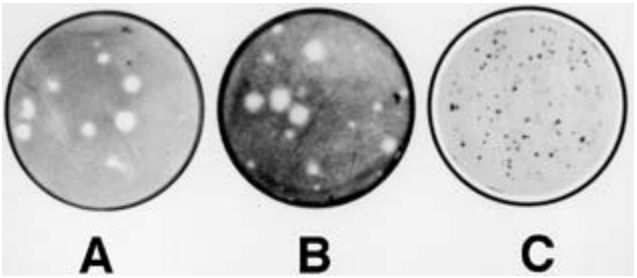


Figure 1 Virus titration. Plaque assay of the papovavirus simian virus type 40 (SV40) yieding clear-cut plaques (**A**) and of the parvovirus minute virus of mice (MVM) yielding more diffuse plaques (**B**). Areas of virus-induced cytopathic effect appear as clear plaques within the cell monolayer which has been stained with the vital dye Neutral Red. (**C**) An *in situ*-hybridization assay of an MVM-infected cell monolayer in which single cells containing amplified viral DNA appear as black dots. From the number of plaques (**A, B**) and dots (**C**), respectively, the total number of infectious particles in the virus suspension used for infection can be calculated. For more details see text.

DNA by factors of more than 200, and the availability of corresponding viral DNA that can be used as a probe. After infection of the cells, at the time when DNA amplification is maximal but before release of progeny virus, the monolayer is transferred to a nitrocellulose membrane. Cells attached to the membrane are subsequently lysed by alkali treatment, and the DNA (cellular and viral) is fixed to the membrane. A single cell that was infected and the viral DNA amplified, can be detected by autoradiography after hybridization of the filter-bound DNA with the corresponding radioactively labeled viral DNA (**Fig. 1**). Viral titers determined by this method give the number of viral particles within a virus suspension which can infect and replicate in a host cell, irrespective of whether this infection is productive or not.

Particle assays are much faster and simpler to handle. Two methods are widely used: the hemagglutination assay and particle counting by electron microscopy. Hemagglutination assays are based on the capacity of many viruses to adsorb to erythrocytes. Serial dilutions of a virus suspension are incubated with red blood cells. The viruses can bridge red blood cells, preventing them from precipitating. The virus dilution no longer capable of agglutinating erythrocytes gives a measure of the particle content of the suspension, and is expressed in terms of hemagglutinating units (HAU). This test is not very sensitive and reflects the presence of all the viral particles capable of binding to red blood cells, including defective particles and empty capsids.

Virus particles can also be counted directly by electron microscopy after negative staining. A known volume of virus suspension is deposited on a formvar-coated or carbon-coated copper grid, water and salts are removed, and viruses are subsequently negatively stained and counted. Since some virus may be lost during the washing and staining processes, it is convenient to add a marker to the virus suspension, e.g. in the form of a known concentration of latex particles. The number of latex particles counted enables the determination of particle loss during preparation and therefore allows the original virus particle concentration to be determined.

Bacteria

Gail E Christie, Department of Microbiology and Immunology, Virginia Commonwealth University, Richmond, Virginia, USA

Introduction

Bacterial viruses, or bacteriophages, consist of a genome, either DNA or RNA, encapsidated in a protein coat. Occasionally this nucleoprotein capsid may also be surrounded by a membrane, derived from that of the host cell. The virus particle, or virion, serves to protect the nucleic acid and deliver it into a susceptible bacterial host. Expression of the viral genome results in infection of the host cell and production of new progeny phages. Bacteriophage multiplication depends upon the macromolecular synthetic machinery and energy generating systems of the infected bacterial cell. There are different outcomes of bacteriophage infection, depending on the nature of the interactions of a particular type of phage with the bacterial host. Virulent phages are those which invariably follow a lytic cycle of multiplication, resulting in the destruction of the infected cell and release of progeny phages. Temperate phages can undergo a similar lytic cycle, but also have an alternative mode of propagation in which their

Bacteria

Gail E Christie, Department of Microbiology and Immunology, Virginia Commonwealth University, Richmond, Virginia, USA

Introduction

Bacterial viruses, or bacteriophages, consist of a genome, either DNA or RNA, encapsidated in a protein coat. Occasionally this nucleoprotein capsid may also be surrounded by a membrane, derived from that of the host cell. The virus particle, or virion, serves to protect the nucleic acid and deliver it into a susceptible bacterial host. Expression of the viral genome results in infection of the host cell and production of new progeny phages. Bacteriophage multiplication depends upon the macromolecular synthetic machinery and energy generating systems of the infected bacterial cell. There are different outcomes of bacteriophage infection, depending on the nature of the interactions of a particular type of phage with the bacterial host. Virulent phages are those which invariably follow a lytic cycle of multiplication, resulting in the destruction of the infected cell and release of progeny phages. Temperate phages can undergo a similar lytic cycle, but also have an alternative mode of propagation in which their

genome can be maintained stably for many generations within the bacterial host. Filamentous phages and some mycoplasma viruses establish an ongoing infection within a bacterial cell, leading to the continuous production and release of progeny phage without killing the host.

Bacteriophages are generally grown under environmental conditions that are optimal for the host bacterium. Susceptibility of a bacterial strain to infection by a particular phage is determined primarily by the presence of the appropriate receptors on the bacterial cell surface. Other factors that can play a role in host range include restriction/modification systems, immunity or resistance encoded by resident prophages or plasmids, and the availability of specific bacterial enzymes required by the phage for replication or gene expression. In the case of satellite phages, lytic growth requires the presence of a suitable helper phage, usually present as a prophage in the bacterial host.

This entry summarizes mechanisms involved in the different modes of bacteriophage propagation and provides an overview of basic methods used in the quantitative study of bacteriophage infection and in preparation of bacteriophage stocks from infected cells.

Virus Multiplication Cycle

Adsorption and infection

Viral infection is initiated by the adsorption of the infecting particle to a bacterial cell. This attachment involves highly specific interactions between specialized phage structures and receptors on the bacterial cell surface. Most bacteriophages are tailed, and use tail fibers or tail spikes for adsorption. Other phages may use apical spikes or special attachment proteins; some lipid-containing phages adsorb by their envelopes. A variety of bacterial cell wall components are known to be exploited as bacteriophage receptors. Outer membrane proteins involved in uptake systems for other molecules may be used. For example, phage T1 binds to proteins involved in the transport of ferrichrome, while λ adsorption requires proteins involved in maltose transport. O-antigen side chains and residues in the lipopolysaccharide core of Gram-negative bacteria and complexes of peptidoglycan with carbohydrate or teichoic acid in Gram-positive bacteria have also been identified as receptors. Capsules or extracellular slime are used as the initial site of adsorption by certain phages, as are pili and flagella. Adsorption to the plasma membranes of mycoplasmas has also been documented. Cofactors may be required for adsorption. Ca^{2+} is the most frequently required cofactor, followed by Mg^{2+}. These divalent cations sometimes also play a role in stabilizing the phage particle. Other known cofactors include NaCl, in the case of some marine phages and cyanophages, and L-tryptophan, which is required by some T-even phages for proper unfolding of the tail fibers.

Following adsorption, the bacteriophage genome enters the cell and initiates infection. The protein coat generally remains outside the cell, although in the case of the fd-type filamentous phages and cystovirus φ6 the capsid has been shown to penetrate the cell wall but does not enter the cytoplasm. Occasionally, specific viral proteins are also injected; examples of this include the spike protein of φX174, N4 RNA polymerase, and the T4 *alt* gene product. Phages that adsorb to porins or other specific outer membrane receptors are thought to take advantage of the solute transport channels of these membrane complexes during DNA penetration. Electron microscopy of infected cells indicates that the tails or tail cores of some phages penetrate the cell wall and provide a channel for DNA entry. Structural components of some phage baseplates also possess lysozyme activity. Adhesion zones between the inner and outer membranes have been proposed as possible entry sites for some phages. Even in well-studied bacteriophages, however, the process of nucleic acid penetration is still poorly understood.

Lytic cycle

Expression of functions encoded by the bacteriophage genome results in the takeover of the host biosynthetic machinery for viral replication. Host DNA, RNA and protein synthesis are shut off to varying degrees by different phages. Phages with large genomes depend less on host functions than those with small genomes, and may encode redundant functions, particularly for nucleic acid metabolism. Phage gene expression is regulated largely at the transcriptional level, except in the case of the single-stranded (ss) RNA phages, in which gene expression is regulated by the secondary structure of the viral RNA. Transcription generally occurs in discrete temporal stages, reflecting the order in which the various phage functions are required during infection. Genes expressed early in infection encode proteins needed for phage replication and shut-off of host functions, while those expressed late are involved in phage assembly and lysis of the bacterial host. For some of the larger phages with more complicated regulatory circuitry, temporal expression is further subdivided into additional classes, while some small phages, such as φX174, express all genes more or less simultaneously. With few exceptions, early transcription is carried out by the host RNA polymerase while

later phases of transcription use phage-encoded RNA polymerases or phage-modified forms of the host transcriptional machinery. Phages N4 and PBS2, however, coinject phage-encoded RNA polymerases into the host cell that are used immediately for phage-specific transcription.

Phage nucleic acid replication depends on host functions, although certain bacteriophages encode their own polymerases or replicase subunits. Modes of bacteriophage genome replication vary widely, depending on the phage. Phages with single-stranded DNA or RNA genomes first synthesize a complementary strand. Replicating templates can be linear or circular, and replication may be uni- or bidirectional. The product of replication that is used as the packaging substrate may be a unit-length genome or a concatemer of multiple genomic copies.

Bacteriophage maturation is a highly regulated process in which the structural proteins (and in a few instances lipids) of the phage particle are assembled and the nucleic acid is packaged. The tailed phages assemble heads and tails in separate pathways; these components are then attached after encapsidation of the DNA. Entry of phage nucleic acid into preformed capsids or shells has also been shown to occur in most of the cubic phages. In the case of the ssRNA phages, however, coat protein aggregates around the viral RNA. Encapsidation is also quite different in the filamentous phages and plasmaviruses, as discussed below.

The lytic cycle, as its name implies, ends with the release of progeny phage by lysis of the infected cell. Tailed phages generally employ a two-component system involving a murein hydrolase that breaks down either glycosidic or peptide bonds in the peptidoglycan and a transmembrane holin that promotes access of the endolysin to the peptidoglycan across the cytoplasmic membrane. This strategy leads to total cellular destruction, accompanied by a characteristic loss of turbidity in a liquid culture of infected cells. The microvirus ϕX174 encodes a single lysis function that appears to form septal lesions in the cell wall which allow release of the cytoplasmic contents, leaving behind rod-shaped, nonrefractile ghosts. The RNA phages also encode a single lysis protein that is thought to be a transmembrane protein rather than a lysozyme, but the mechanism of action is not understood. For plasmaviruses and filamentous phages, infected cells are not killed and progeny phage are released by budding or extrusion, respectively.

Lysogenic cycle

The ability to undergo a stable association with a bacterial host, termed lysogeny, is a property exhibited by many phages. Bacteriophages capable of establishing lysogeny are called temperate. Most temperate phages are tailed phages with double-stranded (ds) DNA genomes, although at least one filamentous phage and one plasmavirus have also been reported to form lysogens. Following adsorption and entry of the phage nucleic acid, a temperate phage undergoes a choice between two alternate pathways. It can either enter the lytic cycle, in which the genome is replicated and progeny phage are produced, or the phage can establish a latent prophage state, in which the bacteriophage genome is replicated indefinitely along with the bacterial chromosome. Many temperate phages integrate their genomes into the bacterial chromosome during the establishment of lysogeny; for most of these phages the integration occurs at specific locations, called attachment sites. There are also examples of phages that replicate in the prophage state as either circular or linear plasmids; these include P1, satellite phage P4 and N15.

The prophage state is maintained by a phage-encoded immunity repressor that prevents expression of lytic phage functions. Synthesis of this repressor, which is usually a protein but can also be a regulatory RNA, confers upon the lysogenic bacterium immunity to superinfection by homologous phages. Prophages frequently encode additional functions that impart novel properties in addition to superinfection immunity to a lysogenic host, a phenomenon called lysogenic conversion. Examples of new properties that may be acquired by lysogenic bacteria include resistance to other unrelated phages, production of toxins, alterations in colony morphology, production of new surface antigens or receptors, and resistance to antibiotics. These properties persist as long as the cell retains the prophage.

Prophage loss occurs spontaneously at a low rate. If a prophage escapes repressor control, it can undergo vegetative replication and lyse the bacterial host. Cultures of lysogenic bacteria frequently contain a small number of free phages due to spontaneous release from a few cells in which lytic multiplication has occurred. Many prophages can also be induced, most commonly by agents that cause direct DNA damage or interfere with DNA replication and activate the RecA-dependent SOS pathway in the bacterial host.

Nonlytic multiplication

Filamentous phages of Gram-negative bacteria do not cause bacterial cell lysis. Phage replication is tightly controlled and the infected cells continue to grow and divide, albeit more slowly than usual. Assembly of filamentous phage particles, which contain a long

loop of circular single-stranded DNA surrounded by multiple copies of the major coat protein, occurs as the phage is secreted from the cell. Coat protein is inserted into the inner membrane of the infected cell via a signal sequence that is subsequently removed. Newly synthesized intracellular phage DNA, covered by a phage-encoded ssDNA binding protein, is drawn to the inner surface of the cytoplasmic membrane, where assembly begins. As the growing filament is extruded from the cell, the ssDNA binding protein is shed and replaced by a helical array of subunits of the major coat protein. The two ends of the filament are capped by structures formed by minor coat proteins that are present in 4–5 copies per phage particle. Bacteria infected by filamentous phages produce progeny phage on a continual basis, at a rate of several hundred phage per cell per generation.

Plasmaviruses are spherical enveloped viruses that infect mycoplasmas. Following infection, there is a latent period of up to 2 hours followed by a 'rise' period of 4–6 hours during which progeny viruses are released from an infected cell. Infected cells grow more slowly than uninfected cells, but the infectious cycle does not kill the bacteria. The plasmavirus DNA acquires an envelope by budding of the cell membrane. The plasmavirus genome can also integrate into the host chromosome during the rise period, leading to the establishment of lysogeny. A second group of mycoplasma viruses, the plectroviruses, also has a nonlytic infectious cycle. These viruses encapsidate their ssDNA genomes in a short rod-shaped particle. Virus assembly and release by extrusion through the cell membrane are coincident, similar to what is seen in the filamentous phages, but details of the process are not known. Progeny phage are produced continuously throughout the infectious cycle, which lasts for several hours.

Plating, Titration and Measurement of Growth Parameters

The plaque assay is a critical tool for phage isolation and quantitation. The number of infectious phage particles in a sample is measured in 'plaque-forming units' or pfu. Titration of a phage suspension is carried out by mixing serial dilutions of the sample with aliquots of sensitive bacteria. This mixture is plated in a soft agar overlay on a petri dish containing the appropriate nutrient agar and incubated, usually overnight. Individual infected cells release phages that infect the surrounding cells in the bacterial layer, and multiple rounds of infection continue until growth of the bacteria on the plate ceases due to nutrient depletion. At suitable phage dilutions, this will lead to the appearance of individual holes, or plaques, in an otherwise confluent bacterial lawn. Since each plaque is derived from a single viable phage, counting the number of plaques allows calculation of the number of plaque-forming units in the original suspension.

Plaque purification is used for the isolation of pure phage populations. Individual plaques can be picked (with a sterile toothpick or pasteur pipette), resuspended and replated prior to large-scale growth to ensure that the resulting phage preparation is genetically homogeneous.

A particular phage will exhibit a characteristic plaque morphology. Virulent phages produce clear plaques, and the plaques formed by phages with large genomes tend to be smaller than the plaques formed by phages with small genomes. Temperate phages give rise to turbid plaques, due to the growth of surviving lysogenic bacteria within the zone of lysis. Growth of lysogens is often heavier in the center of the plaque, with a surrounding clear margin. Plaques formed by filamentous phages and the mycoplasma viruses that have nonlytic infectious cycles are also turbid in appearance; these plaques are actually foci of infected cells that are growing more slowly than the surrounding bacteria and may disappear upon prolonged incubation of the plates. Plaques with a turbid appearance may also result from partially lysed cells or accumulation of plasma membranes, rather than growth of surviving bacteria. Phages infecting bacteria that produce slime or capsule often form plaques surrounded by halos due to the breakdown of capsule in the surrounding cells. Plating conditions can affect plaque size: a low moisture content in the agar or a dense bacterial inoculum will reduce the size of the plaques.

The parameters of latent period and burst size are often used to describe bacteriophage growth. The latent period is the time interval between the initial infection and the release of progeny phages. The burst size is the number of new phages released by a single infected cell. Both of these parameters can be measured by a one-step growth experiment, in which phage production by synchronously infected bacteria is monitored. A culture of exponentially growing bacteria is infected with phages, incubated for a short time to allow adsorption, and then diluted or treated with phage-specific antiserum to prevent further infection by unadsorbed phages. The diluted culture is then incubated further and samples are removed at various time intervals and assayed for plaque-forming units. The number of plaque-forming units will remain constant for a certain time interval; this corresponds to the latent period. There is then a period during which the phage titer rises rapidly, followed by a plateau when no further increase in

plaque-forming units occurs. The increase in titer corresponds to the burst, and the ratio of the final titer at the plateau to the initial titer of phage-infected bacteria is the average burst size. Those phages that are released from infected cells continuously by extrusion or budding will not yield a discrete burst, but the number of progeny viruses released from individual infected cells as a function of time has still been estimated using this method.

Preparation of High-Titer Stocks

To obtain a high yield of progeny phage, culture conditions that are optimal for the bacterial host should be used. Sensitive bacteria must be actively growing when infected, and at a sufficiently low density to allow multiple rounds of phage infection before the culture reaches stationary phase. Any necessary cofactors for adsorption or phage stabilization (e.g. Ca^{2+} or Mg^{2+} salts) must also be added. Bacteriophages can be propagated on solid media or in liquid culture, and there are commonly used techniques employing both approaches.

Propagation on solid media involves plating a mixture of bacterial cells, at a concentration that will result in a uniform lawn, in a soft agar overlay with just enough phages to give confluent or nearly confluent lysis after a suitable incubation time (generally overnight, although for phages of some slow-growing bacterial species it will take longer). Once lysis has occurred, the top agar is scraped off and suspended in a small volume of appropriate buffer. Alternatively, a small volume of buffer can be added to the plate, allowed to stand for a period of time to allow diffusion of the phage particles into the buffer, and then collected. The phage suspension must then be centrifuged at low speed to sediment agar and cell debris. This centrifugation is not generally sufficient to sterilize the phage stock. A common practice is the addition of a few drops of chloroform to the lysate to kill any remaining bacteria; while this works well for certain phages it is risky as a general practice because many phages are chloroform sensitive. Further purification of the phage suspension to ensure that it contains no viable bacteria can be accomplished by filtration through membrane filters with a pore size of 0.45 μm.

Propagation in liquid media is the method of choice for large-scale phage production. The optimum ratio of infecting phage to sensitive cells (multiplicity of infection) will vary, depending on the particular phage and host, but the bacterial culture should be young and actively growing. Following an adsorption step, the infected cells are allowed to grow for several cycles of infection under culture conditions that support good bacterial growth. Visible lysis of the culture may or may not occur, depending on the phage. Release of intracellular phages from unlysed cells can be accomplished in some cases by treatment with chloroform, trypsin or lysozyme. For phages that require divalent cations for adsorption, phage yield can be improved by adding EDTA or EGTA before harvesting to block adsorption to cell debris. If the phage requires Mg^{2+} for stabilization, EGTA is preferable since it will chelate Ca^{2+} but not Mg^{2+}. Cultures of lysogenic bacteria can be grown to mid-log phase and then induced; in this case nearly all cells are simultaneously infected by the induced prophages, and progeny are released after a single round of infection. Phages released by budding or extrusion are harvested from the culture medium after a suitable period of bacterial growth.

Concentration and Purification

Once most of the bacteria and debris have been removed from a lysate by low speed centrifugation, phages are generally further concentrated and purified. Direct ultracentrifugation can be used for small-scale phage preparation; the lysate is frequently treated with DNase and RNase prior to ultracentrifugation to degrade bacterial DNA and RNA released during lysis. Centrifugation at 50 000–60 000 *g* appears to be adequate for most phages. Precipitation is used to concentrate phages from large volumes of lysate. Polyethylene glycol 6000 (PEG) is an agent that appears to work for virtually all phages; ammonium acetate has also been used in some cases. For PEG precipitation, NaCl (up to 0.5 mol l^{-1}) and PEG (most commonly at a final concentration of about 10%) are dissolved in the lysate, and the PEG is then allowed to precipitate at 4°C, usually overnight. The PEG precipitate, which contains the phages as well as any remaining bacteria and bacterial debris present in the lysate, is collected by low speed centrifugation. Extraction of the PEG pellet with a small volume of buffer yields a concentrated phage suspension. Phages can be purified further by density gradient centrifugation. Equilibrium sedimentation in CsCl is commonly used. Lipid-containing phages are sensitive to CsCl, however, and are purified on sucrose gradients. After density gradient centrifugation, phages are dialyzed against a suitable storage buffer, often containing Mg^{2+} to help stabilize the phage particles. Lysates and purified phage stocks are usually stored at 4°C.

Choice of Propagative Host

One of the most important factors to consider when designing a method for virus propagation is the choice of plant material. Although many viruses are named for the plant from which they were isolated, often this is not the best host for virus propagation. When the virus is known, it is likely that literature is available to suggest suitable propagative hosts. If the virus has not been identified or is not well characterized, it will be necessary to passage the virus to a number of host plants to decide which will be suitable local lesion and propagative hosts. Local lesion hosts are particularly important when the virus may be a mixture of strains or even different viruses. Individual lesions are believed to represent infections originating from a single infectious unit. Consequently, strains can be separated from one another by establishing new infections in systemic hosts from individual lesions. Similarly, mixed viruses, and sometimes multiple strains of the same virus, can be separated from one another by inoculation to different hosts. Some standard hosts, such as *Nicotiana* spp., *Chenopodium* spp. and others, have proven useful for diagnosing and separating strains from a number of viruses.

In choosing a propagative host, the plant should be capable of being infected systemically by the virus, and should accumulate virus to high concentrations without becoming severely stunted. If possible choose a host with large, soft, spongy leaves, as such leaves produce more sap, resulting in greater virus yield. *Nicotiana* spp. are an excellent example, and work well for many viruses. Hosts which contain high levels of substances that interfere with virus purification and/or bind the virus should be avoided, particularly those with high levels of tannins, gums, waxes and phenolic compounds. Any host which contains excessive amounts of these substances can result in poor recovery of virus.

Once a host is chosen, some preliminary experiments should be conducted to identify the appropriate temperature and lighting conditions for virus propagation. A virus may prefer different conditions in different hosts, possibly reflecting the physiological variation among hosts. Virus strains may also exhibit variation dependent upon environmental conditions. Some cauliflower mosaic virus (CaMV) strains, for example, infect solanaceous hosts under conditions of low light intensity, but not high. Other strains are not affected by lighting conditions. Certain viruses, such as cucumber mosaic virus, exhibit a phenomenon known as cycling, in which virus concentration increases for several days, then declines fairly quickly. Cycling can be a host-specific phenomenon, occurring in some hosts, but not others. As a result, it is important to determine the amount of time necessary to achieve optimal virus concentration before virus titers begin to decline. Simple time-course experiments can be designed to address when and under what conditions optimal virus concentration can be achieved.

Virus Transmission

In order to propagate a plant virus effectively, it must first be passaged from the initially infected plant to the propagative host. This requires obtaining infectious virus from the original plant, and introducing it to the propagative host such that the virus is in the presence of all necessary components for infection.

Although mechanical transmission is not possible with some viruses, mechanical transmission is the simplest and most direct method of virus transmission available. A number of different methods can be used to transmit viruses mechanically, ranging from sap inoculation, to inoculation with purified virions, to inoculation with viral nucleic acid. Mechanically transmissible viruses which accumulate to reasonably

Choice of Propagative Host

One of the most important factors to consider when designing a method for virus propagation is the choice of plant material. Although many viruses are named for the plant from which they were isolated, often this is not the best host for virus propagation. When the virus is known, it is likely that literature is available to suggest suitable propagative hosts. If the virus has not been identified or is not well characterized, it will be necessary to passage the virus to a number of host plants to decide which will be suitable local lesion and propagative hosts. Local lesion hosts are particularly important when the virus may be a mixture of strains or even different viruses. Individual lesions are believed to represent infections originating from a single infectious unit. Consequently, strains can be separated from one another by establishing new infections in systemic hosts from individual lesions. Similarly, mixed viruses, and sometimes multiple strains of the same virus, can be separated from one another by inoculation to different hosts. Some standard hosts, such as *Nicotiana* spp., *Chenopodium* spp. and others, have proven useful for diagnosing and separating strains from a number of viruses.

In choosing a propagative host, the plant should be capable of being infected systemically by the virus, and should accumulate virus to high concentrations without becoming severely stunted. If possible choose a host with large, soft, spongy leaves, as such leaves produce more sap, resulting in greater virus yield. *Nicotiana* spp. are an excellent example, and work well for many viruses. Hosts which contain high levels of substances that interfere with virus purification and/or bind the virus should be avoided, particularly those with high levels of tannins, gums, waxes and phenolic compounds. Any host which contains excessive amounts of these substances can result in poor recovery of virus.

Once a host is chosen, some preliminary experiments should be conducted to identify the appropriate temperature and lighting conditions for virus propagation. A virus may prefer different conditions in different hosts, possibly reflecting the physiological variation among hosts. Virus strains may also exhibit variation dependent upon environmental conditions. Some cauliflower mosaic virus (CaMV) strains, for example, infect solanaceous hosts under conditions of low light intensity, but not high. Other strains are not affected by lighting conditions. Certain viruses, such as cucumber mosaic virus, exhibit a phenomenon known as cycling, in which virus concentration increases for several days, then declines fairly quickly. Cycling can be a host-specific phenomenon, occurring in some hosts, but not others. As a result, it is important to determine the amount of time necessary to achieve optimal virus concentration before virus titers begin to decline. Simple time-course experiments can be designed to address when and under what conditions optimal virus concentration can be achieved.

Virus Transmission

In order to propagate a plant virus effectively, it must first be passaged from the initially infected plant to the propagative host. This requires obtaining infectious virus from the original plant, and introducing it to the propagative host such that the virus is in the presence of all necessary components for infection.

Although mechanical transmission is not possible with some viruses, mechanical transmission is the simplest and most direct method of virus transmission available. A number of different methods can be used to transmit viruses mechanically, ranging from sap inoculation, to inoculation with purified virions, to inoculation with viral nucleic acid. Mechanically transmissible viruses which accumulate to reasonably

high titers in the infected host can usually be prepared by grinding a small amount of infected tissue with a mortar and pestle in a suitable buffer. If the inoculation is being performed directly from triturated sap, the favored method is to dip an index finger directly in the inoculum, then gently spread the inoculum over the leaf surface, while supporting the leaf with the opposite hand. Pass over each portion of the leaf only once, otherwise excessive damage may result. Inoculation performed with gloved hands reduces the potential for contamination. Glove-free hands are more sensitive to the delicate nature of leaves, but this increases the potential for contamination. If gloves are not used, it is important to remember that hands must be thoroughly washed between inoculations to prevent cross-contamination with other inoculum. All equipment in contact with the inoculum must be free of contaminating virus. When many inoculations are to be performed, glass rods, cotton swabs or pestles also work well.

Effective inoculation usually requires that leaves be abraded by means of either carborundum dust or by Celite (diatomaceous earth) suspended in the inoculum. Carborundum is a fine metal powder that creates microwounds in leaves when rubbed on the leaf surface, allowing virus to enter through the wounds. Leaves are usually dusted with carborundum before inoculation, then washed briefly to prevent carborundum remaining on the leaves from producing scars or more wounds as the plant grows. Celite is also a fine powder, but is usually suspended with liquid inoculum and applied during inoculation to create wounding. Although Celite is more gentle on plant tissue than carborundum, it too should be washed from leaves after inoculation. Inoculation occurs almost immediately upon rubbing a leaf with a virus suspension; therefore, rinsing leaves with water soon after inoculation will not affect transmission. Although more difficult, some phloem-limited viruses can also be transmitted mechanically through stem slashing. Stem slash inoculation is performed by dipping a scalpel or razor blade in inoculum, then using the blade to make several consecutive horizontal cuts approximately halfway through one side of the stem of the plant to be inoculated. The procedure deposits virus directly in the phloem tissue of the inoculated plant. Care should be taken to avoid girdling the plant when this approach is implemented.

Some viruses are not mechanically transmissible, and must be passaged by insect, fungal or nematode vectors, or through direct vascular connections. Such connections can be established by grafting a portion of the source plant to the plant being infected. Depending on the plant, a number of grafting techniques are possible. The main advantage of grafting is to permit a direct vascular connection between the source plant and the plant being inoculated. Historically, some viruses have been transmitted through the use of the parasitic plant, dodder (*Cuscuta* spp.). Dodder establishes a vascular connection with plants, allowing virus to pass from one plant to another through its vasculature. If dodder is used, it must be from a source known to be free of contaminating viruses. Although virus transmission through dodder is no longer a common practice, dodder can facilitate movement of virus between hosts when other methods fail.

It is important to remember that any vector-transmitted virus should be passaged by the vector. Frequent mechanical transmission of vector-transmitted viruses often leads to loss of vector transmissibility. This does not mean such viruses should not be transmitted mechanically, rather that vector transmission should be performed at regular intervals to avoid selection against vector transmissibility during virus propagation. Some viruses, such as barley yellow dwarf virus which circulates in its aphid vector, require an intimate connection with the vector, as well as with plant hosts. If possible, it is best to routinely maintain and transmit all such viruses in the manner by which they are transmitted in nature.

Preserving Infectivity During Transmission and Isolation

Many mechanically transmitted viruses can be successfully transmitted by simply grinding infected tissue in 50–100 mmol l^{-1} sodium or potassium phosphate buffer with a pH between 7.0 and 8.0. This is a common buffer, used effectively for mechanical transmission of a large number of viruses. Experimentation has determined that the inclusion of phosphate in the inoculation buffer increases infectivity of the inoculum for many viruses. Although phosphate buffers of neutral pH are suitable for passaging many plant viruses, it is important to remember that each virus has unique properties, and the conditions which favor transmission of one virus may inhibit or decrease the efficiency of transmission of another. Some viruses are adversely affected by phosphate. It is sometimes possible to transmit these viruses through sap in phosphate buffer, but longer extraction procedures require alternative buffers such as sodium borate or sodium citrate. The pH of the buffer is also critical. If the pH of the buffer is not suitable, virions may swell and become unstable, or they may dissociate altogether, resulting in free nucleic acid and rapid degradation. A number of viruses require the addition of divalent cations in

specific concentrations, while still others require chelating agents, such as ethylenediaminetetra-acetic acid (EDTA), to bind such cations.

Most plant tissues contain phenolic compounds which are released upon tissue maceration and reduce infectivity. Many mechanically transmissible viruses can be prepared in buffer of the appropriate pH, and rubbed on leaves of a suitable propagative or local lesion host without substantial loss of infectivity. Other viruses are not so stable and require special care. Young leaves generally contain fewer phenolic compounds and are routinely used to avoid phenolics when these become a problem. To protect virions from degradation during processing, extraction should be performed at temperatures near 0°C, and reducing agents such as 2-mercaptoethanol, thioglycolic acid, diethyldithiocarbamate or sodium sulfite should be included in tissue grinding buffer to prevent enzymatic inactivation of inoculum during tissue homogenization. These measures are usually quite effective at preserving infectivity during virus purification. The addition of polyvinyl pyrrolidone (PVP) of varying molecular weights has also proven useful in maintaining the infectivity of some viruses. PVP complexes with tannins to prevent their interaction with the virus particle, and consequently enhances infectivity.

Virus Isolation from Propagative Hosts

Once a virus has reached optimal concentrations in the propagative host, as determined through experimentation, it can either be collected in tissue or isolated from the propagative host. In the case of the former, virus in infected leaf tissue can be collected and frozen. Some viruses are quite stable for many months when stored as frozen tissue. A more stable inoculum preservation method, however, is to freeze-dry the tissue in a lyophilizer. Leaf tissue can be cut into small pieces, frozen and dried until all moisture is removed. When the tissue is not fully dried, samples often lose infectivity more rapidly in storage. Once dried, the virus can be stored at 4°C, or −20°C. Many viruses are stable for several years when stored in this manner. Others are much less stable and may need to be stored as purified virions frozen in glycerol, or as frozen nucleic acid.

To obtain purified virions, tissue must be homogenized. This is usually performed in a blender because large volumes of tissue can be ground rapidly and effectively. Some researchers do not advocate the use of blenders for viruses which are composed of long rod-shaped particles, as these particles may be sheared by the blender. Long rods are protected well by grinding tissue in a mortar with liquid nitrogen, then adding buffer to the pulverized tissue. This procedure also works well for extraction of many phloem-limited viruses. Others claim, however, that blenders, particularly Virtis top-driven blenders, actually facilitate extraction of infectious long flexuous rods from phloem-limited viruses. As discussed above, the grinding buffer must not only allow the virus to be separated from host materials, but also preserve infectivity. Large-scale extraction of virus allows virions to be exposed to inactivating compounds for long periods of time, much longer than during a simple sap transmission. Consequently, all factors affecting infectivity must be considered in designing a suitable virus purification buffer.

Nonionic detergents are helpful in some extraction buffers. Certain viruses, such as CaMV, form inclusion bodies in the host, which contain large quantities of virus and would sediment at low speed if not disrupted. When a small amount of detergent is added to the extraction buffer, these inclusions dissociate more readily. Such detergents also facilitate removal of host membranes.

The best advice when developing a buffer for virus extraction is to begin with the simplest buffer possible. This could be a 50–100 mmol l^{-1} phosphate solution with a pH of 7.5, and a reducing agent. Add other components or change components as necessary, until a suitable amount of infectious virus is obtained. The suspension is then clarified with a low-speed centrifugation, and the supernatant is collected and filtered through cheesecloth or Miracloth™. If virus yields are low, precipitation with polyethylene glycol (PEG) can be used to concentrate the virus prior to high-speed centrifugation. With some viruses, PEG precipitation is performed as an alternative to high-speed centrifugation, as the latter can disrupt virions or create pellets which are difficult to resuspend. However, high-speed or ultracentrifugation remains the preferred method for isolating most plant viruses.

Ultracentrifugation of the supernatant at high speeds for an extended period of time removes virions from the supernatant, forming a tight pellet on the bottom of the tube. A cushion of concentrated sucrose in extraction buffer is often used during ultracentrifugation to prevent excessive debris from sedimenting with virions, resulting in a cleaner virus pellet. If pellets are difficult to resuspend, a small amount of a nonionic detergent included in the grinding buffer may ease resuspension. Following resuspension of the pellet, the concentrated virions can be inoculated to a host or purified further.

It is sometimes useful to have a highly purified source of inoculum, in which case the resuspended high-speed pellet or a PEG precipitated fraction can

be run on a sucrose density gradient. The viral band can be extracted from the gradient to obtain highly purified virions. Such purifications are not necessary for most virus transmissions, although they can be useful in determining the precise amount of inoculum administered to plants, as concentration can be determined on a spectrophotometer following gradient purification. In addition, gradient-purified virions can be mixed with glycerol and frozen for long-term storage. Infectivity of virions stored in this manner varies.

The most important aspect of virus propagation is to understand that each virus has unique characteristics and specific interactions with each host plant it infects. Although a great deal of literature is available on propagation and maintenance of known plant viruses, effective methods for propagation and maintenance of each newly discovered virus must be determined experimentally. Suggestions can be obtained from literature on similar viruses, but this cannot replace experimentation.

PSEUDORABIES VIRUS (*HERPESVIRIDAE*)

Saul Kit, Novagene Inc., Houston, Texas, USA

History

Aujeszky's disease (AD), also known as infectious bulbar paralysis and as pseudorabies (PR) because of its clinical similarity to rabies, was one of the first virus diseases to be recognized. In 1902, Aujeszky recovered the causative agent from infected oxen, cats and dogs, and transmitted it to rabbits and guinea pigs, in which it produced the pruritis and central nervous system (CNS) signs characteristic of naturally occurring PR disease. AD was probably present in the United States as early as 1813, but it was not until 1931 that Richard Shope established that 'mad-itch' disease of Iowa cattle was serologically identical to AD, and that a mild and usually unrecognized disease of swine was produced by the mad-itch agent, that is, PR virus (PRV). Shope showed that PRV was infectious for adult swine and was transmitted through skin abrasions to cattle pastured with infected swine. In 1933, minced rabbit brain and testicles were first used by Traub to cultivate PRV *in vitro*. A year later, Sabin reported that the virus was immunologically related to herpes simplex virus (HSV-1) and herpes B. virus and PRV was classified into the herpesvirus group. In the 1940s and 1950s, established mouse cell cultures were used to serially propagate the virus. Virus isolations are now routinely made in sensitive rabbit cell cultures and propagated in a variety of vertebrate (porcine, bovine, monkey, chick, etc.) cell lines.

Taxonomy and Classification

PRV (swine herpesvirus-1) is a member of the family *Herpesviridae*, subfamily *Alphaherpesvirinae*, genus *Varicellovirus*. PRV particles are about 150–180 nm in diameter and consist of an enveloped nucleocapsid (about 105–110 nm) that surrounds the genomic DNA. The DNA of PRV is a linear double-stranded, class 2 herpesvirus DNA molecule, approximately 90×10^6 Da (135 kbp) in size and encodes about 80 genes (**Tables 1** and **2**). Many of these genes are not required for replication in cultured cells. It is composed of two components, L and S. The S component consists of a short unique (U_S) sequence bracketed by large (about 10^7 Da) inverted repeats. (T_R/I_R). High-frequency inversion of the U compo-

nent, but not the L component, is observed during virus growth, so that the S genome is found in two isomeric forms. The ends of the PRV genome are unique; no terminal redundancy is present. Antigenic differences have not been detected among strains of PRV, but strain differences demonstrable by restriction endonuclease fingerprinting are common and have been used for epidemiological studies and control programs. Deletion mutations in the U_S region of the PRV genome occur 'spontaneously' following passages in chick cells.

Molecular Biology

The PRV genome is, for the most part, colinear with the I_L arrangement of the HSV-1 genome. However, a peculiarity of the PRV genome is the presence of an inversion in the middle of the unique long (U_L) region (0.07 and 0.39 map units) compared to HSV-1 and other alpha herpesviruses. On one side, the inversion occurs between the *UL27* and *UL26* genes (**Tables 1** and **2**). It appears that PRV lacks a sequence homologous to the HSV-1 *UL45* gene at the *Bam*HI-9 junction downstream of *UL44* (gC). Due to the fact that in PRV the *UL26* and *UL44* genes are adjacent and their ends are conserved, the right border of the inversion must lie within their intergenic region. Most of the PRV genes are conserved relative to those of HSV-1, but there are notable differences. Some genes present in HSV-1 [*UL56, UL48 (VP16), UL45, US5 (gJ), US10, US11* and *US12*] have not been detected in PRV, whereas the PRV gene, *UL3.5,* has also been found in the varicella-zoster virus (VZV), bovine herpesvirus 1 (BHV1) and equine herpesvirus 1 (EHV1) alpha herpesvirus genomes, but not in that of HSV-1. Also, the PRV *US2* gene is not colinear with the *US2* gene of HSV-1.

PRV genes are expressed during lytic infection as three groups, immediate early (IE), early and late, in a coordinately regulated and sequentially ordered cascade. The IE genes are transcribed by the host cell RNA polymerase in the absence of *de novo* viral protein synthesis. Early genes are dependent upon IE proteins for their transactivation and can be transcribed in the absence of viral DNA synthesis. Late genes consist of two subclasses depending on their requirement for viral DNA synthesis. Inhibition of viral DNA synthesis moderately decreases the accumulation of quasi-late $\gamma 1$ transcripts but totally prevents formation of $\gamma 2$ late transcripts. $\gamma 1$ quasi-late genes reach maximum expression levels after DNA synthesis starts. Most late gene products are virion structural proteins.

The PRV genome contains only one IE gene, IE180, but since this IE gene is located in the T_R/I_R region of the PRV genome, there are two copies per genome. The IE gene is homologous to the HSV-1 $\alpha 4$ gene, and specifies an unspliced 5.1 kb transcript which is translated to a protein of about 180 kDa. The PRV IE gene is required for continuous transcription of early and late PRV genes and for shutting off the synthesis of its own RNA. The PRV IE gene contains five to six different consensus sequences in its promoter region and is capable of *trans*-activating a variety of viral and cellular class II and class III promoters by interacting with host transcription factors and specific promoter sites. Unlike PRV, HSV-1 encodes several IE genes. Homologous genes found in PRV and presumed to have regulatory gene functions include *EP0* and *RSp40,* homologues of the IE HSV-1 genes, *ICP0* and *ICP22,* respectively, but these PRV genes are early genes rather than IE genes. The PRV *UL54* gene encodes a protein homologous to the HSV-1 IE *ICP27* gene, but the mode of regulation of PRV *UL54* has not been elucidated.

A latency-associated transcription unit (LAT) overlaps the PRV IE gene. This transcription unit is at least 11.8 kb long, extends from the U_L region to

the T_R/I_R region of the PRV DNA (0.69–0.77 map units), and is transcriptionally active in the trigeminal ganglia of latently infected swine. The LAT transcription unit is spliced to a large latency associated transcript (LLT), an 8.5 kb poly(A^+) transcript, and to smaller 4.5–5.5 kb and 1.0–2.0 kb RNA species. The first and second exons of the LLT are antiparallel to and overlap the genes for EP0 in U_L and IE180 in the I_R. The roles of the LAT transcripts in the maintenance of or reactivation of PRV from the latent state have not as yet been delineated.

Early PRV genes encode proteins functioning in DNA metabolism and include the nonessential genes encoding thymidine kinase (*UL23*), ribonucleotide reductase (*UL39*, *UL40*), uracil–DNA glycosylase (*UL2*) and dUTPase (*UL50*). Some other PRV genes are essential for viral DNA replication and include *UL9* (origin binding protein), *UL30* (DNA polymerase) and the *UL5*, *UL8* and *UL52* helicase/primase complex, and probably *UL29* (major DNA binding protein).

Replication of PRV DNA occurs in two phases. In the first phase, the viral DNA enters the cell nucleus and circularizes by ligation of the ends of the linear DNA molecules. This process does not appear to require expression of virus functions. The first rounds of replication are associated with these circular structures. The main origin of replication is located in the BamHI-4 fragment in the middle of the U_L region. Replication probably proceeds by a rolling circle mechanism. Later in the replication process, concatamers in head-to-tail alignment are generated. Cleavage of concatameric DNA to generate mature, genome-sized linear molecules requires the expression of UL21 and UL28 and possibly other viral proteins and involves site-specific cleavages from signals present on both ends of the PRV genome. Both cleavage and packaging are intimately linked to capsid assembly. UL19 (major capsid protein), UL18 and UL38 have been identified as PRV capsid proteins. Genes encoding tegument and envelope proteins have also been identified (**Tables 1** and **2**). The molecular structure of latent PRV DNA in the trigeminal ganglia is uncertain, but appears to be concatameric or circular, and is presumably generated during an abortive DNA replication cycle.

Geographic Distribution

PR is enzootic in swine in most parts of the world, except Australia, Canada and Norway. PR has been a consistent source of significant losses in swine and cattle due to increased mortality, reproductive failures and lower growth performance. The cost of PR outbreaks has been estimated to be about $10 000 per year per outbreak, with a total annual cost in the US of from 30 to 72 million dollars. In most states in the US, PR diagnosis in a herd results in a quarantine of the swine with movement limited directly to a slaughter facility.

Host Range

Domestic and feral swine are the only identified reservoir hosts in which PR transmission is maintained. All other species are considered to be 'dead-end' hosts (i.e. the virus dies within the host without passing infection to other animals). PRV causes an acutely fatal infection in many nonporcine species, such as cattle, sheep, dogs, cats, raccoons, opossum, rats, mice and chicks. These species become infected after comingling with pigs or ingesting infected meat. The development of PR in carnivores may often be the first indication that the disease exists in swine on a farm. Reports of infection of humans have been rare and have not been substantiated.

Epidemiology

From 1902 to 1930 only single outbreaks of PRV were reported, predominantly in cattle and dogs. Pseudorabies in pigs was described in 1920 and the first enzootic in pigs appeared in 1931. In the following years, sporadic outbreaks occurred in several European countries, the USA, North Africa and Turkey. In areas where small pig farms predominated, PRV appeared suddenly and involved the majority of susceptible pigs. After that, there was no subsequent outbreak of disease on the premises for many years. The epidemiological pattern changed in the 1950s and 1960s with the development of large swine units. PRV became enzootic in the big farrowing and fattening farms in Eastern and Southeastern Europe and in the middle west of the USA. By the mid-1970s, PRV had spread to Central and Western Europe and Southeast Asia and had become a worldwide disease of great economic importance. Serologic surveys of swine sent to slaughter in the US revealed an increase in the PR-positive herds from 0.56% in 1974 to 8.78% in 1984. Until 1977, only 2–24 PR outbreaks in pigs were recorded in the then Federal Republic of Germany, but from 1977 onwards, their numbers increased, reaching 2000 recorded outbreaks in 1987. PRV was first isolated from New Zealand pigs on the North Island in 1976. PR was first reported in central Japan in 1981 and has been spreading rapidly throughout that country.

The increase and spread of PR disease may be, at least in part, attributed to the emergence of more virulent PRV strains or variants. A more significant

cause is the changed management within the swine industry. PR disease is most prevalent in areas that employ intensive swine housing practices and where swine are most concentrated. In Iowa in 1984/1985, only 2% of herds with fewer than 50 sows were seropositive for PRV, whereas the herd prevalence rate for herds with more than 100 sows was 55%. The incidence of PRV is highest in Europe in those areas with cold climates and intensive hog industries, such as Holland, Belgium, France and Hungary, and is less of a problem in countries with less intensive hog production.

A salient factor in the spread of PR disease is the capacity of PRV to establish latent infections in sensory ganglia of infected swine. A small percentage of these latently infected animals sporadically shed virus in saliva and nasal discharges, so that licking, biting and aerosols can cause transmission. Losses from overt disease in swine occur when nonimmune pregnant sows, or swine less than 3 months old born to nonimmune sows, are infected. When breeding sows have adequate antibody levels, overt clinical disease in their progeny may be greatly reduced, but the baby pigs may nevertheless become latently infected and later develop clinical signs of disease and/or transmit infectious virus. On farms where breeding, farrowing, nursery, growing and finishing operations are conducted separately, significant losses may occur when weaned swine from several sources are brought together into a growing–finishing facility.

Transmission and Pathogenesis

PR is usually transmitted by acutely infected pigs, which produce large amounts (10^4 PFU) of infectious PRV, or by latently infected animals, which sporadically shed small amounts of virus even though they may not show signs of disease. The primary source of virus spread is intimate nose-to-nose contact involving expelled body fluids of oronasal origin. Often, PRV is transmitted by pregnant sows to their highly susceptible newborn offspring. Latently infected pigs may be experimentally induced to excrete PRV by stress-related factors, simulated by the drug, dexamethasone. Factors influencing infection include the movement of swine (e.g. the introduction into a breeding herd of latently infected sows from outside the farm), swine and wildlife density, housing and ventilation design, access of other animals and wildlife to swine, dead pig disposal, and the source and handling of swine feed. Airborne transmission of droplets containing virus between farms can play a role in initiating disease outbreaks. The airborne transmission over a distance of 15–80 km of PRV originating in northern Germany caused the recurrent epizootics of 1984 to 1988 in both conventional and specific pathogen-free Danish herds. Contamination of feed, water, bedding and floors may likewise provide susceptible pigs with access to virus. After successful transmission, virus replication occurs in the tonsillar and pharyngeal tissues and in the olfactory epithelium. From these sites, the virus spreads to the medulla by way of the olfactory nerve system and the epineural lymph of the trigeminal and glossopharyngeal nerves, and on further replication reaches the brain. Multiplication of virus in the respiratory tract of swine facilitates its spread within the body, since macrophages and leukocytes become infected and may carry the virus to various body organs, particularly to the placenta in which it may multiply and subsequently invade the fetus. PRV can be isolated from buffy coat cells, providing further evidence of absorption on or within leukocytes. Feces and urine are not considered significant sources of infection. Most swine infected with virulent virus shed infectious virus for from 12 to 21 days. By contrast, most wildlife and domestic species excrete virus for only 1 to 2 days before death and in amounts insufficient for transmission of infection.

PRV, like other herpesviruses, is extremely labile, so that experimental virus stocks must be stored at −70°C. The virus can, however, survive in damp bedding for 140 days at 4°C and for 40 days at 37°C, for 5 weeks on shelled corn and for 3 weeks on moist meal. The virus has a very short survival time on clean concrete, green plants or well-cured hay. Heat, direct sunlight and dry conditions quickly inactivate PRV. PRV can survive in ground flesh for weeks. Dead baby pigs or infected placentas that are ingested by cats and dogs or wildlife, cause fatal infections. Dogs have become fatally infected with PRV after fighting with feral pigs. Cattle can become infected through contaminated feed or when secretions from infected pigs are introduced through existing bovine skin abrasions. Simultaneous wound contamination at the time of bite infliction also occurs, particularly in the rear limbs of cattle. To avoid fatal outbreaks of PR, it is essential that cattle on farms be isolated from swine. Iatrogenic infections, involving accidental injections of conventional, inadequately attenuated PRV vaccines into lambs and chicks, have caused fatal infections on several occasions.

Clinical Features of Infection

Generally, after infection of pigs, two different disease patterns may be seen depending on the age of the animal and the virulence of the virus strains. In piglets, the CNS is heavily affected whereas in older pigs, mostly respiratory symptoms are seen.

Young pigs infected with PRV exhibit a high morbidity, high mortality, fever, vomiting, diarrhea and CNS signs. The CNS signs include tremors, incoordination and pronounced muscle spasms, circling and intermittent convulsions accompanied by excess salivation. Death occurs by 8 days after infection. Maternal antibodies protect piglets from signs of disease, but not infection. Older (feeder) pigs show a high morbidity, variable mortality, fever, anorexia, constipation, vomiting, depression, growth arrest, listlessness, coughing and sneezing, labored breathing and CNS signs. In pregnant sows, mortality may be low, but respiratory and gastrointestinal signs are common, as are reproductive problems. Infection of sows before day 30 of gestation may result in death and resorption of the embryos. Infection after day 30 of pregnancy may terminate in abortion, or by the delivery of stillbirths and mummified fetuses. PR in cattle assumes a rapid and fatal course. Death often occurs by 2 days after the first signs of illness appear. The first sign is a decrease in milk yield followed by violent licking of parts of the body. As pruritis increases in intensity, the cow becomes frenzied, bites and gnaws at the skin and rubs its head and neck against hard objects. Rabbits, cats and dogs are among the most vulnerable of species. Subcutaneous injection of 1 PFU of PRV can be lethal to rabbits. In dogs, pruritis is accompanied by drooling of saliva and plaintive howling simulating true rabies. In cats, the disease may progress so rapidly that pruritis is not observed.

Pathology and Histopathology

Following primary oronasal infection of swine, virus replicates in the oropharynx. At 24 h after infection, viral antigens and DNA can be detected in cells of the nasal epithelium. After 48 h, areas of the epithelium become necrotic and the infection reaches the stroma killing many cells. Enveloped virus particles are detectable by electron microscopy in and around infected epithelial cells and fibroblasts. The stroma of the oronasal epithelium contains many blood vessels and neuronal axons of the trigeminal, olfactory and vegetative nerves, through which the virus can travel via the axoplasm to cranial nerve ganglia and the medulla and pons. Virus may establish latency in the nuclei of neurons, in which case production of infectious virus ceases, but the viral genome itself is maintained in a portion of the cells, or the virus may continue to spread within the CNS producing ganglioneuritis, meningoencephalitis, perivascular cuffing and focal gliosis associated with extensive necrosis of neuronal and glial cells. A common finding in severely infected swine is congestion of the nasal mucosa and pharynx, tonsillitis and rhinitis. Pulmonary congestion and edema are frequently observed in such cases. In the larger air passages, viral capsids and viruses may be seen in bronchial and bronchiolar epithelium, lymphocytes and alveolar macrophage. Swine that recover from PR may shed virus sporadically in their nasal secretions. Others from which virus cannot be isolated by conventional means may yield virus after cocultivation of tonsillar or trigeminal ganglia with susceptible cells. That recovered swine are latently infected may also be shown by demonstrating PRV DNA or RNA in trigeminal ganglia. *In situ* hybridization techniques with polymerase chain reaction-generated probes are particularly useful for this purpose.

Immune Response

One highly sulfated, secreted glycoprotein [gG (90–98 kDa)] of unknown function, eight Class I structural membrane glycoproteins [gB, gC, gD (gp50), gE, gI (gp63), gH, gL and gN], and five multiple membrane spanning Class III proteins [UL11, UL20, UL43, UL53 (gK) and UL10 (gM, 45 kDa)] are synthesized in PRV-infected cells (**Tables 1** and **2**). The gB glycoprotein is a complex of homodimeric molecules that are post-translationally cleaved by a cellular protease residing in the trans-Golgi into two subunits per monomer (72–78 kDa and 50–58 kDa) that remain linked via disulfide bond. gE (115–122 kDa) and gI (63 kDa) are noncovalently complexed with each other as are gH (95 kDa) and gL (20 kDa). Of the PRV glycoproteins, only four (gB, gH, gL and gD) are essential for virus replication. These glycoproteins are involved in virus penetration of host cells and cell-to-cell spread. The other glycoproteins are nonessential for PRV replication in cultured cells. Indeed, a quadruple deletion mutant lacking gE, gI, gG and gC is viable. The structural glycoproteins are found embedded in the nuclear and cellular membranes of infected cells as well as on the surface of mature enveloped viruses, and are major antigens that interact with the host immune system to elicit humoral and cell-mediated immune responses. Glycoprotein gC (92–98 kDa), although nonessential, has a primary role in virus attachment to host cells through a heparan sulfate proteoglycan receptor on the cell surface. However, in the absence of gC, PRV can attach to cells by an alternative pathway not mediated by the heparan sulfate receptor and virus infection, though retarded still occurs. Polylysine enhances the adsorption of gC-negative PRV mutants. In addition, PRV gC functions as a complement C3 receptor, thereby providing the virus with an immunoevasion mechanism that prevents complement-mediated cell lysis and virus

neutralization. Glycoproteins gE and gI influence the release of infectious virions from infected cells and promote cell-to-cell spread (as measured by plaque size). In animals, gE and gI are also important for efficient infection of the central nervous system and for neurovirulence. Glycoprotein gK is a virion structural component involved in virus release, but is not required for entry. gK mutants exhibit a dramatic reduction in the ability to form plaques by cell to cell spread on noncomplementing vero cells. A PRV mutant lacking gM displayed reduced infectivity and was delayed in penetration, indicating that the virion component, gM, though nonessential, has a modulatory role in the initiation of PRV infection.

PRV glycoproteins gG, gD, gI and gE map in the U_s region of the viral genome and are flanked on the left by a protein kinase gene and on the right by the genes encoding 11 and 28 kDa proteins. Glycoproteins gB, gC, gH, gL, gN, and gM map in the U_L region of the viral genome (**Tables 1** and **2**).

Until recently, it was accepted that most viruses have only one protein or glycoprotein that is important for induction of immune responses and protection in the host. However, it is now clear that several herpesvirus glycoproteins can induce protection. Convalescent sera from animals infected with PRV have antibodies to gD, gB and gC, which can neutralize viruses outside cells and destroy virus-infected cells by antibody-dependent cellular cytotoxicity or antibody-dependent, complement-mediated cytolysis. In pigs, monoclonal antibodies against gE, gB, gC and gD all neutralize virus, while passive immunization of mice or pigs with these monoclonal antibodies protects them from lethal virus challenge. The level of antibodies in pigs does not, however, correlate with protection against virulent virus infection, indicating that major histocompatibility complex-restricted (MHC) cytotoxic T lymphocytes and natural killer cells are also important. Unfortunately, data on these cellular immune elements are as yet limited. It is known that gE, gB and gC are important targets, but not the only targets, for cytotoxic lymphocytes. PRV downmodulates the expression of MHC Class I antigens in porcine and murine cells. Since MHC Class I antigens are critical for recognition of infected cells by virus-specific cytotoxic T lymphocytes (CTL), it is logical to suppose that suppressed Class I expression would reduce CTL activity and facilitate viral immunoevasion. The specific viral regulatory genes involved in downregulating the MHC Class I antigens have not been identified. The fact that the PRV envelope is composed of several glycoproteins is, in a sense, fortunate from the point of view of the host. Mutagenic alterations in a single viral glycoprotein do not abrogate the defense mechanisms of the host. Indeed, although almost all of the modified-live PRV vaccines harbor deletion mutations in viral glycoproteins, they are highly protective.

Prevention and Control of Pseudorabies

The strategy selected to control PR has depended on: (1) the type of operation carried out by the producer (farrow-to-finish, seedstock, feeder pig producer, feeder pig finisher); (2) financial considerations; (3) availability of suitable replacements; (4) the disease profile of the herd and; (5) PRV status in the area. Slaughter of an entire herd and repopulation is considered with single isolated outbreaks in non-infected districts, but may also be necessary when disease is detected in seed stock operations. Slaughter is performed on quarantined pigs after they reach market weight of 220–260 pounds. This is done to save the meat and market value of the animals. Hence, it may take 6 months to slaughter an entire herd. The slaughter strategy is expensive and disruptive, results in the loss of valuable blood lines, and is impractical if the source of infection cannot be identified or if the reinfection risk is high. Offspring segregation has been used to produce PRV-seronegative gilt replacements from positive sow herds. Serological testing and the culling of seropositive pigs has been recommended in low-prevalence areas when the proportion of seropositive individuals in the herd was about 20% or less and when there was no evidence that virus was circulating between the sows of the breeding herd and their offspring. Seropositive pigs were then replaced with seronegative gilts. Factors impeding control through test and slaughter are the expense of repeated serologic testing, large herd size and the density at which pigs are maintained, especially if they are housed in proximity to other infected farms. Test and slaughter programs in England and Denmark have greatly decreased PR outbreaks but have not completely eliminated them.

Vaccination has been used alone or together with other strategies for over 25 years to stop PR outbreaks, to reduce virus shedding by infected pigs, to minimize clinical disease and mortality, to reduce losses from secondary bacterial infections and to reduce the incidence of latent infections. Both killed and modified-live virus (MLV) vaccines have been used, but despite frequent vaccination with conventional vaccines, the incidence of PR outbreaks in areas of intense husbandry has continued to increase, principally because it has hitherto been impossible to identify pigs latently infected with virulent PRV in a vaccinated herd. This situation has now changed with the identification of several nonessential viral

genes that contribute to virulence. The thymidine kinase (*TK*) of PRV and other herpesviruses is one of the most important genes contributing to virus virulence. Therefore, irreversible deletion mutations in the *TK* gene have been engineered by recombinant DNA techniques to significantly attenuate the virus and greatly increase vaccine safety. All current genetically engineered PRV vaccines have deletion mutations in the *TK* gene. The elucidation of glycoprotein genes also led to an understanding of the action of conventional vaccines and the finding that some glycoprotein genes can be deleted. This motivated the development of differential diagnostic tests and provided the basis for PRV eradication programs.

Conventional MLV PRV vaccines, as illustrated by the Bucharest vaccine strains, were obtained by repeatedly passing PRV on the chick CAM and in cultured chick embryo fibroblast cells. gE deletion mutations were induced in most, but not all, of the Bucharest derived vaccine variants. It was shown, retrospectively, that the gE deletion mutations could account for much of the reduced neurovirulence of Bucharest vaccine strains. Other conventional PRV vaccines, such as the Bartha and NIA4 vaccines also harbored gE deletions, but in addition, the Bartha vaccine had a deletion in the *gI* gene and mutations in the *UL21* gene and in the promoter region of the glycoprotein *gC* gene. A partially attenuated, but gE-positive Bucharest variant was the first PRV strain used by the author to develop a genetically engineered TK-deleted PRV vaccine, but virulent Iowa, Aujeszky and NIA3 PRV strains have also been used by others as the starting material for TK-deleted PRV vaccines. In addition, deletion mutations have been engineered in the gC gene, the gE gene or the gG gene of TK-deleted vaccines to produce diagnostic markers by which vaccinated pigs could be distinguished serologically from pigs harboring virulent PRV.

Diagnosis

The clinical signs of PR are sufficiently characteristic to permit a preliminary diagnosis which may be verified by PRV isolation, the fluorescent antibody staining of frozen tissue sections, and serum neutralization (SN) tests. Screening ELISA and latex agglutination tests are, however, more rapid and more sensitive than SN tests. With the advent of gene-deleted marker vaccines, differential blocking ELISA diagnostic tests are now being used. Marker-specific differential diagnostic tests have been developed for each of the gC-, gE and gG deleted vaccines. When pigs are vaccinated with the OMNIMARK vaccine, a TK-deleted gC-deleted vaccine, for example, they develop antibodies to various PRV proteins, but not to gC. Wild-type PRV-infected pigs develop antibodies to most PRV proteins, including gC. Hence, a differential blocking ELISA test, which uses gC as the antigen to coat microtiter wells and a gC-specific monoclonal antibody conjugated to horseradish peroxidase to react with the antigen, distinguishes serologically between OMNIMARK-vaccinated and wild-type virus-infected pigs. Undiluted test sera are used with this gC-blocking ELISA test. The specificity of the test approaches 100% and the sensitivity is about the same as that of screening ELISA and latex agglutination tests. gC antibodies can be detected by about 7–10 days after pigs vaccinated with OMNIMARK become infected with wild-type virus and for a year or more after pigs are latently infected with wild-type PRV. SN antibody tests are often negative under these conditions. The wild-type virus-infected pigs identified by the differential diagnostic test can be removed during herd clean-up. Vaccinated swine that are negative in the differential tests are classified by the USDA as PRV-negative and their interstate and intrastate movement is permitted.

Future Perspectives

The availability of gene-deleted marker vaccines for PRV has stimulated new efforts for the control and eradication of PR disease. Such eradication and control programs are now in progress in the USA, Cuba, Mexico, Jamaica, Hungary, France, Germany, Bulgaria, the Czech and Slovakian republics, The Netherlands, Norway, Sweden, Rumania, the former USSR republics, Yugoslavia, Japan and Viet Nam. It has also been recognized that latent PRV infection is prevalent in free-roaming feral swine, which may come in contact with and transmit PR disease to domestic swine and other livestock. The US Animal Health Association has therefore recommended that serological surveillance of feral swine be expanded and that procedures for their vaccination (oral?) with marker PRV vaccines be developed.

Finally, it should be emphasized that attenuated, gene-deleted marker vaccines are promising candidates for live vaccine vectors, which can confer protection against both PR and other swine diseases. Model experiments in which foreign DNA sequences have been inserted at several sites in the PRV genome have recently been carried out. In one such experiment, a live, attenuated PRV expressing the envelope glycoprotein of hog cholera virus (classical swine fever) was prepared and its efficacy in protecting swine against both PR and hog cholera investigated, with promising results. Many more such PRV vector-based subunit vaccines may be anticipated.

Q

QUASISPECIES

Esteban Domingo, Centro de Biología Molecular "Severo Ochoa" (CSIC-UAM), Universidad Autónoma de Madrid, Cantoblanco, Madrid, Spain

Origins of the Concept

Quasispecies describes a type of population structure in which collections of closely related genomes are subjected to a continuous process of genetic variation, competition and selection. Quasispecies has become very important in virology because it provides an interpretation for the extensive plasticity, both genetic and phenotypic (of biological features), displayed by many viruses, in particular RNA viruses. The quasispecies concept originated in theoretical studies on early informational macromolecules by Eigen and colleagues, and in experimental work on bacteriophage $Q\beta$ by Weissmann and colleagues. Eigen was the first to elaborate a quantitative treatment of the generation of error copies of simple replicating molecules (replicons) as those that probably populated the earth at the early stages of life. This treatment represented a link between principles of information theory and Darwinian evolutionary concepts, and was inspired to a great extent by experiments on evolution of simple RNA molecules replicating *in vitro* carried out by Spiegelman and his associates in the 1960s.

Eigen, Schuster and their colleagues defined the quasispecies as an organized, steady-state distribution of error copies of self-replicating macromolecules (nucleic acids). It represents a rated distribution of mutants (mutant spectrum) centered around one or several master sequences (**Table 1** and **Fig. 1**). The copying fidelity with which replication occurs determines the fraction of progeny molecules which will be identical to the parental replicon. This theoretical concept assumes a selection equilibrium in the distribution whose evolution can be described by a system of ordinary differential equations. This selection equilibrium is metastable in that it will collapse when an advantageous mutant appears in the distribution. The previous quasispecies will then be substituted by a new one, characterized by a new master sequence and a new mutant spectrum. The stability of a quasispecies depends on the complexity of the genetic information contained in the genome, the copying fidelity and the superiority of the master sequence. This is expressed mathematically in an error threshold relationship which limits the amount of genetic information that can be transmited when copying fidelity is limited (**Table 1**).

Quasispecies has a physical, a chemical and a biological definition. Physically a quasispecies distribution of genomes can be regarded as a cloud in sequence space. Sequence space refers to all possible sequences that theoretically could be occupied by a genome (**Table 2**). Viral quasispecies can be viewed as clouds that occupy tiny portions of such theoretical space. Occupation of sequence space by viruses is restricted by multiple genetic and functional constraints. The clouds have, at any given time, a defined population structure dependent on the distance of each point to the consensus sequence (that could be taken as the center of the distribution), and on the relative fitness values of the different mutant components. The distance or number of mutated positions between a given sequence and the best adapted one (the master sequence) is called the Hamming distance. This term is also used to indicate the number of mutations between two sequences.

Chemically, the definition of quasispecies is the one most familiar to virologists: a rated distribution of related, nonidentical genomes. Biologically, quasispecies are the target of selection. It is not easy to imagine an ensemble rather than an individual genome is the actual target of selection. However, individual RNA genome sequences may have a fleeting existence, and there are now a number of cases documenting that the evolutionary fate of an individual viral genome is strongly influenced by the mutant spectrum surrounding it.

Table 1 Important equations in quasispecies

• *Basic differential equation describing quasispecies evolution*

$$\frac{dx_i}{dt} = (A_i Q_i - D_i)x_i + \sum_{k \neq i} w_{ik} x_k + \phi_i$$

dx_i/dt = variation of concentration of mutant i as a function of time
x_i = concentration of mutant i
A_i = velocity constant for the replication of i
Q_i (quality factor) = probability that replication of i produces i
D_i = velocity of decomposition of i
W_{ik} x_k = velocity of formation of i as a result of erroneous replication of any other molecule k
ϕ_i = Constant that corrects for changes of concentration of i as a result of flux of molecules

• *Error threshold relationship*

$$\nu_{max} < \ln \sigma_o / (1 - \bar{q})$$

ν_{max} = the maximum length of the sequence (genetic complexity) that can be maintained during replication
σ_0 = selectivity or superiority of the master sequence relative to its mutant spectrum
$\bar{q}$ = average copying fidelity. The average error rate is $(1 - \bar{q})$. (Different positions of a replicating nucleic acid often show different copying fidelities. In this case $\bar{q}$ is the geometric mean of the copying fidelity value at each position.) The expected number of errors in a sequence of length ν replicating with a fidelity of $\bar{q}$ is $\nu\ (1 - \bar{q})$

The quasispecies theory was aimed at interpreting self-organization and evolutionary optimization of primitive genetic material. It was recognized that error rates lower than about 10^{-2} misincorporations per nucleotide and round of copying would be difficult to attain without participation of catalytic functions contained in some types of protein and RNA structures. This gave rise to the extended notion of catalytic hypercycle which combined the coding ability of nucleic acids (types of molecules well suited as a repository of genetic information) with the catalytic potential of proteins (more complex molecules that can combine multiple active surfaces to accelerate a variety of biochemical reactions).

Real Virus Quasispecies

The second origin of the quasispecies concept was experimental. It had long been suspected that RNA viruses were genetically unstable, as suggested by the abundance of mutants in viral stocks and by the difficulty of maintaining some mutants (conditional lethal, plaque-type) free of wild-type revertants. The first evidence that an RNA virus depicted features of quasispecies was obtained by Weissmann and associates in Zürich working with bacteriophage Qβ. Upon replication in its host *Escherichia coli*, a clone of bacteriophage Qβ generated error copies with high frequency. Quantification of the reversion of a site-specific mutant, and of its growth rate relative to the parental wild-type Qβ, allowed an estimate of the mutation rate for a specific purine transition: about 10^{-4} per round of copying, a value about 10^5-fold larger than that estimated for the mutation rate of DNA genomes. Furthermore, genomic RNA from many phage clones was analyzed by T1-oligonucleotide fingerprinting (rapid nucleotide sequencing techniques were not yet available). The results indicated that, assuming a random distribution of mutations among the genomes analyzed, each infectious RNA differed in 1–2 positions from the average or consensus sequence in the population. Interestingly, the T1-oligonucleotide map of the RNA from the uncloned phage population remained unchanged during 50 serial infections, a fact that must be kept in mind before considering stability of a consensus sequence as evidence against quasispecies. A highly dynamic mutant spectrum can nevertheless produce the same average sequence over many generations of viral replication. Weissmann and colleagues concluded that: 'The genome of Qβ phage cannot be described as a defined unique structure, but rather as a weighted average of a large number of different individual sequences.'

Subsequent studies with many human, animal and plant RNA viruses, or viruses which include an RNA

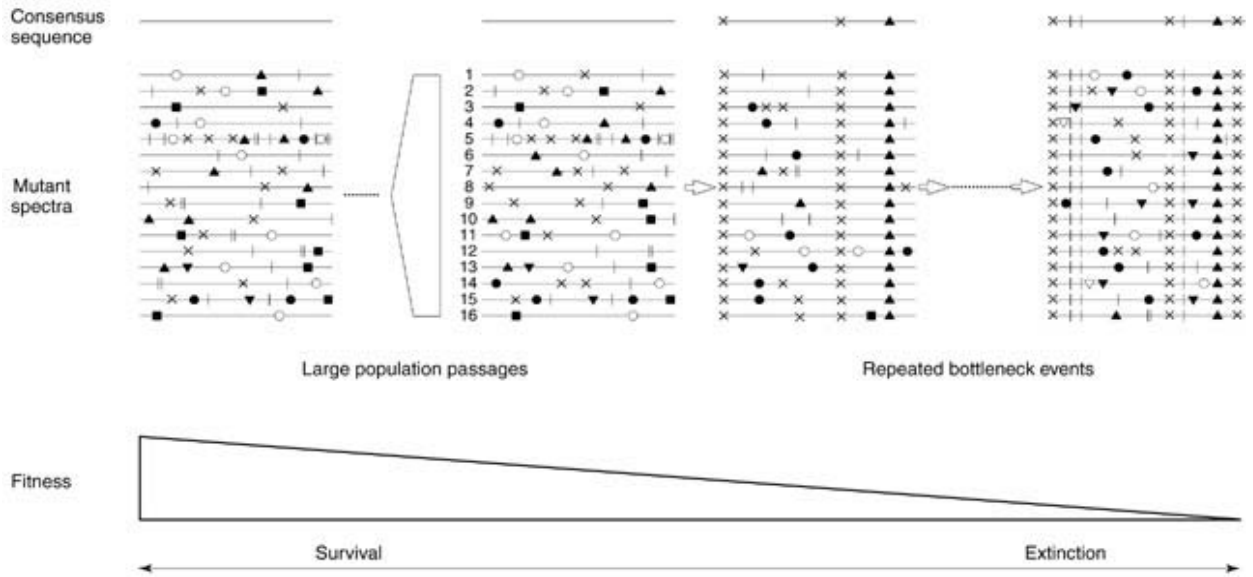

Figure 1 Representation of quasispecies and of possible outcomes of their evolution. Horizontal lines represent individual genomes, and symbols on the lines represent mutations. Large population passages (left) in a constant environment generally lead to fitness gains. The average sequence may or may not be modified as a result of replication. Repeated bottleneck events (right, small arrows) generally result in accumulation of mutations and average fitness losses that may drive viral populations near extinction. For a mathematical expression of quasispecies and definition of terms see **Tables 1** and **2**.

Table 2 Definition of some terms frequently used in the literature of quasispecies

- *Consensus or average sequence (of nucleotides or amino acids)* The sequence that results from taking for each position the most frequent residue (nucleotide or amino acid) found at the corresponding position in a set of aligned sequences. The consensus sequence may not exist physically as a component of the mutant distribution
- *Fitness* A parameter that describes the adaptation of an organism to its environment. For viruses, relative fitness values are quantitated as their ability to produce infectious progeny relative to a reference virus, in a defined environment
- *Master sequence* The dominant sequence in a quasispecies. It often shows the highest selection value among the mutant sequences present, but it may or may not coincide with the consensus or average sequence of the population
- *Mutant spectrum* The ensemble of mutant genomes that constitute a quasispecies
- *Mutation frequency* The proportion of mutants (average for an entire sequence or specific for a defined site) in a genome population
- *Mutation rate* The frequency of occurrence of a mutation event during genome replication
- *Population number* The number of individuals in a population. For viruses, it is the number of infectious genomes replicating in a given biological niche (cell, tissue, organ, organism). The number of genomes quantitated in an infected host is also termed the viral load
- *Rate of fixation of mutations* The frequency of mutations in the viral genome which become dominant per unit time in an infected host or among a set of infected hosts. This rate is generally not constant. The assumption of a molecular clock is not justified for RNA viruses
- *Sequence space* A theoretical representation of all possible variants of a genomic sequence. The sequence space is n^{ν} in which n is the number of symbols in an informational macromolecule and ν is the complexity (total number of residues) of the macromolecule. For a single-stranded RNA virus of 10 000 residues in length the sequence space is $4^{10\,000}$

as a replication intermediate, have documented that they all share high mutation rates or frequencies, and the dynamics of competition and selection predicted by the quasispecies model. The genetic plasticity of RNA replicons led Holland and colleagues to emphasize the multiple biological and evolutionary implications of such a highly dynamic RNA world parasitizing the relatively static DNA world of differentiated organisms.

A generalized quasispecies concept is now used by virologists to describe dynamic distributions of nonidentical but closely related mutant and recombi-

nant viral genomes subjected to a continuous process of genetic variation, competition and selection, and which act as a unit of selection.

Environmental Perturbations and Occupation of Sequence Space

Real virus quasispecies, such as those replicating in the course of acute or chronic infections of differentiated organisms, are permanently perturbed by a complicated array of environmental influences. One is compartmentalization of virus replication within infected organisms: viruses may replicate in disparate cell types, such as epithelial cells of the upper respiratory tract, lymphocytes or brain cells. Different sites within an infected organism will be subjected to different kinds of selective pressures derived either from variations in the internal environment (immune responses, metabolic or nutritional alterations, temperature, etc.) or from externally applied influences such as the presence of antiviral agents. Competition among components of the mutant spectrum will be established within each infected cell. Virus progeny from different cells may engage in subsequent rounds of competition (for entry into target cells, for effective replication, etc.). Such rating events may involve many genomes in the case of acute, systemic infections in which viruses may reach up to 10^{12} infectious units at a given time in the entire organism, and viral RNA loads composed of infectious and noninfectious genomes may reach exceedingly high levels. Evolving mutant distributions are easily shaped by selective forces and perturbed by random sampling events (**Fig. 1**), providing a genetic flexibility that could not be reached if mutations were rare events. Adaptability is facilitated by the limited genome size (generally between 3×10^3 and 3×10^4 nucleotides) and large population numbers. All possible single and double mutants, and decreasing proportions of triple, quadruple, etc. mutants are potentially present in many viral populations. In contrast, only a minute fraction of all possible single mutants is present at any given time in populations of cellular organisms. That is, the ability to explore their allotted share of sequence space is vastly superior for small, abundant replicons than for complex DNA genomes. Furthermore, one or a few nucleotide (or amino acid) replacements are often sufficient to trigger biologically relevant changes (alterations in cell tropism, virulence, escape from immune surveillance, resistance to antiviral inhibitors, etc.). Variant genomes with few mutations have a high probability of occurrence within the mutant spectra of evolving quasispecies. Of course, clouds of mutants are far from being symmetrical, as even single point mutants may have reduced fitness and may not be represented, or represented with low frequency, in the mutant spectra. Mathematical extensions of the initial theoretical quasispecies concept have been developed to cope with some of the perturbations undergone by real virus quasispecies; however, such treatments are complex and difficult to apply to experimental observations with viruses.

Multiple Biological Implications

Quasispecies represents a new description of the population structure of RNA viruses, and it has numerous implications for the biology of this important group of pathogens (**Table 3**). Particularly relevant to viral disease control is the pre-existence and selection of mutants completely or partially resistant to antiviral agents. Examples are influenza virus A mutants resistant to amantadine (1-aminoadamantane) and rimantadine (α-methy-1-adamantane methylamine), human rhinovirus mutants displaying low- or high-level resistance to disoxaril, 5-[7-[4-(4,5-dihydro-2-oxadozolyl)phenoxy]heptyl]-3-methyl-isoxazole, or other related compounds, and, more recently, human immunodeficiency virus mutants resistant to reverse transcriptase and protease inhibitors.

The frequency of antibody-resistant mutants of RNA viruses is generally high (10^{-4}–10^{-6} per infectious genome) both in cell culture and *in vivo*. The frequency of cytotoxic T lymphocyte-escape mutants is more difficult to determine but variations at specific T cell epitopes permitting virus escape *in vivo* have been documented in several systems, such as human hepatitis C virus, human immunodeficiency virus and lymphocytic choriomeningitis virus.

RNA viruses may use a number of alternative receptors or coreceptors for entry into cells, and shifts in receptor specificity may be triggered by amino acid replacements at surface residues on the viral capsid or viral envelope. Mutant viruses able to use either alternative receptors or altered forms of a standard receptor occur in nature and have also been selected in cell culture.

Virulent (disease-causing) variants may be generated in populations of avirulent viruses, or may be present as minority components of attenuated viral preparations. Beck, Levander and associates described that an avirulent coxsackievirus B3 became cardiopathic upon replication in selenium- or vitamin E-deficient mice, as a result of repeated selection of six specific mutations scattered along the viral genome. It is likely that such a phenotypic modification was facilitated by the impaired immune responses, and the larger ensuing viral loads, in infected hosts bearing

Table 3 Some implications of the quasispecies structure of viral populations

- It offers a general and highly effective adaptive strategy
- In particular, it explains the pre-existence and selection in viral populations of mutants with altered phenotypic properties:
  - resistant to antiviral agents
  - antibody and cytotoxic T lymphocyte escape
  - with altered cell receptor specificity
  - with different ability to induce interferon
  - with increased virulence
- It implies the existence of thresholds for phenotypic expression
- There is a possible association between the pathogenic potential of a virus and its mutant spectrum complexity

some nutritional deficiencies. Chumakov and colleagues quantitated the presence of virulent poliovirus in the mutant spectrum of attenuated poliovirus used for vaccine preparation. When the proportion of virulent poliovirus variants in the vaccine exceeded a certain value, the virulent phenotype was manifested and the vaccine failed the safety tests in monkeys. This, and additional results with other viral systems, have established that expression of a variant phenotype encoded in a subset of genomes from the mutant spectrum depends on their proportion in the mutant distribution. These results agree with theoretical predictions on the behaviour of viral quasispecies in that the fate of each individual component of the mutant spectrum is strongly dependent on the mutant cloud surrounding it.

Recent evidence suggests that the complexity of the mutant spectrum may influence the outcome of viral infections. The complexity of the coronavirus mouse hepatitis virus quasispecies may contribute to its pathogenic potential. Likewise, the nonresponse to treatment with interferon α in chronic hepatitis C virus infections may relate to the number of viral molecular species detected in the infected patients. Model experiments with the animal pathogen foot-and-mouth disease virus showed that indeed the repertoire of viral mutants that became dominant in an evolving quasispecies depended on the population size of the virus. Thus, it is not surprising that both the population size and the complexity of the mutant spectrum may be important determinants of the pathogenic potential of some viruses, although the number of well-documented cases is still limited.

Connections with Population Genetics and with Current Concepts of Complexity

The main departure of the quasispecies concept from previous models of population genetics is the emphasis on mutation (or, more generally, in genetic variation) to the point of invalidating the concept of the wild type as a defined genomic sequence. RNA viral genome sequences are statistically defined, but individually indeterminate. Recognition of such indetermination, together with the emphasis on continuous mutant generation, contributed to the success of quasispecies, rather than other quantitative models of population biology, as a descriptor of RNA viruses.

The rapid evolution of RNA viruses has been used to explore some principles and theories of population biology. A concept of increasing interest in virology is fitness (**Table 2**). This is a complex parameter which has been the object of considerable research and debate in biology. Fitness of a virus is measured as its relative ability to produce infectious progeny under a defined set of environmental conditions. Relative fitness values have been determined in tissue culture and in some cases in laboratory mice or other hosts. Cells or organisms are co-infected with the virus to be tested together with a genetically or phenotypically marked reference virus. The progeny virus is passaged for several transfers and the quantification of the proportion of the two viruses relative to the initial mixture yields a relative fitness value. Using this assay a number of observations on the dynamics of viral quasispecies have been made.

When large populations of RNA viruses are allowed to replicate in a defined environment, fitness gains are generally observed when measured in the same environment (**Fig. 1**). However, adaptation of virus to one environment (for example one cell type) may result in profound fitness losses in another environment. Two vesicular stomatitis virus clones with similar relative fitness competing in serial infections coexisted for many passages. However, in a rather unpredictable manner, one of the clones abruptly displaced the other and became dominant in the population. This observation agrees with the competitive exclusion principle of population genetics that states that unless there is a niche differentiation, one of two competing species will eventually outcompete the other. In such competitions both the

Table 4 Some practical implications of the quasispecies structure of RNA viruses

- Vaccines must be multivalent (multiple B and T epitopes)
- Antiviral agents must be used in combination (directed to independent targets; the number depends on viral population size and genome turnover)
- Completely new antiviral strategies should be explored (drugs capable of throwing viral replication into error catastrophe)
- The use of virulent RNA viruses as pest control agents should be avoided

winners and the losers gained fitness in such a manner that their relative position in the fitness landscape was similar at the end and at the start of the competition. This agrees with the Red Queen hypothesis of population biology, as, in the words of the Red Queen in Lewis Carroll's *Through the Looking Glass*, 'it takes all the running you can do, to keep in the same place'.

In contrast to large population passages, repeated bottleneck events such as those mediating serial plaque-to-plaque transfers, resulted in stochastic fitness losses (**Fig. 1**). This is known as the 'Muller's ratchet' effect, according to which asexual populations of organisms will tend to incorporate deleterious mutations in a rather irreversible fashion unless compensatory mechanisms such as recombination can restore the initial, better adapted, genomes. For well-adapted viral quasispecies, repeated plaque isolations will tend to deviate successive mutant distributions from the optimal one, resulting in average fitness losses (**Fig. 1**). The transmission population size needed to maintain viral fitness is dependent on the initial fitness of the viral clone tested. The higher the initial fitness the larger the transmission pool must be to avoid fitness losses. Studies with foot-and-mouth disease virus have documented that viral clones subjected to serial plaque-to-plaque transfers accumulate unusual mutations, providing insight into the types of low-frequency mutants that populate viral quasispecies.

RNA viruses in their evolutionary dynamics constitute attractive experimental systems of complex adaptive behaviour. They display a highly indeterminate fine structure as well as a rather unpredictable behavior. Indetermination arises from the stochastic nature of mutagenesis, in conflict with the need of the system to ensure genetic continuity. Adaptability stems from the variable degrees of success of subsets of genomes. The indetermination of mutagenesis, together with the directionality of selective forces, situate RNA viruses in a subtle border between reproducibility of some observations and unpredictability of others. Thus, RNA virus quasispecies may also become interesting model systems for studies on complexity.

Strategies for Disease Prevention and Control

The great adaptability of viral quasispecies creates difficulties for viral disease control, and may also contribute to the emergence of new viral pathogens. When quasispecies was recognized as the most adequate descriptor of pathogenic RNA viruses, the need to adjust antiviral strategies to the new findings became apparent to some scientists. These recommended strategies (**Table 4**) are not yet generally followed, probably because of an inherent tendency of thinking of RNA viruses still as genetically defined entities. If a single selective pressure is applied to limit virus replication, the highly dynamic mutant spectrum is likely to provide variants capable of overcoming the selective constraints. Research on entire new antiviral strategies, such as the possibility of displacement of virus replication into error catastrophe, seems justified in view of accumulating evidence that the copying fidelity properties of viral replicases can be modified by structural alterations of the enzymes.

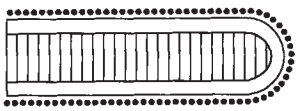
RABIES VIRUS (*RHABDOVIRIDAE*)



George M Baer and **Noël Tordo**, Laboratorios Baer, Mexico City, Mexico

History

The dramatic clinical signs of rabies have been recorded from early times: hyperexcitability, increased tendency of animals to bite, jaw paralysis, changed facial expression, and transmission of the disease to other animals and, eventually, humans. One of the earliest references to the disease is from the third millenium BC, in the Eshnunna Code preceding the Code of Hammurabi:

> If a dog is mad and the authorities have brought it to the attention of the owner; if he does not keep it in and it bites a man and causes his death, then the owner shall pay 40 shekels of silver. If it bites a slave and causes his death he shall pay 15 shekels of silver.

Rabies in dogs and its transmission to man were well recognized by the time of Aristotle. Pliny and other writers referred to the influence of the dog-star Sirius, including the increased susceptibility of dogs to rabies during the so-called 'dog-days' of summer.

Outbreaks of rabies in dogs, foxes and wolves were reported from most European countries throughout the Middle Ages, predating the current European outbreak in foxes which began in the early 1940s. The first cases in the United States were reported in Virginia foxes in 1753. Bites by rabid wolves (animals often reported rabid in Iran, Afghanistan and the Soviet Union) still rank as the most dangerous source of the disease for humans. Mortality rates after wolf bites are well over 50%, although dogs still cause over 90% of human rabies deaths world-wide; in many developing countries the numbers of deaths still reach many thousands annually.

Rabies in vampire bats was first suggested by chronicles of Spanish conquistadores in the sixteenth and seventeenth centuries and confirmed in Brazil, Argentina and Trinidad in the early 1900s. Vampire rabies is still a major animal health problem in most Latin American countries, with hundreds of thousands of cattle deaths yearly. Insectivorous bats are a sporadic problem in North America, Latin America and Europe.

The classic studies of Pasteur beginning in 1881 showed that the central nervous system was the principal site of rabies virus replication, that the virus could be passaged in experimental animals, and that vaccines could be prepared from virus thus passaged. These studies led to his first preparing and then administering human vaccine in 1885. It is surprising that the same vaccine was not used for mass dog vaccination programs until 1921 when Umeno and Doi initiated urban control programs in Japan.

The first specific diagnostic tool, the 'Negri body', was discovered by Adelchi Negri in 1903. This rather insensitive tool was commonly used until the fluorescent antibody technique replaced it in the late 1950s.

Taxonomy and Classification

Rabies viruses belong to the family of RNA viruses *Rhabdoviridae*. These viruses have nonsegmented negative-strand RNA genomes enclosed in a lipid envelope derived from the host cell. The bullet-shaped virions are all composed of a nucleocapsid or ribonucleoprotein (RNP) core and an envelope in the form of a lipoprotein bilayer membrane closely surrounding the RNP core. The outer glycoprotein (G) coat is responsible for the induction of neutralizing (anti-G) antibodies. The virion RNP core is tightly wound into coils. Extending from the outer surface of the envelope is an array of spike-like G projections. The rabies-like viruses cross-react serologically with rabies nucleoprotein (N) antisera to varying degrees and include Lagos bat, Mokola, Duvenhage, Obodhiang and kotonkan viruses.

Geographic and Seasonal Distribution

Human rabies occurs world-wide, except in certain islands and peninsulae where the disease has never occurred (Australia and a number of small Caribbean islands) or where it has been eliminated (England, Ireland, Japan, Taiwan, Spain, Portugal). The infected countries can be divided into those that have controlled canine rabies with effective canine vaccination programs (but where wildlife rabies remains) such as all the western European countries, Canada, the US and some Latin American countries, and those countries where canine rabies is still endemic such as most of the African and Asian countries.

Genetics

Since 1981 the molecular genetics of rabies virus has followed two distinct strategies, work with viral messenger RNAs and work with the genome itself; the latter has permitted simultaneous analysis of the intergenic regions. Complete sequence is known for the PV and SAD strains of rabies and the rabies-related Mokola virus. The sequence data have helped to locate the glycosylation sites as well as the signal and transmembrane peptides on the G protein. The potential phosphorylation sites have also been characterized on the N and M1 (NS or phospho-protein). In addition, the important regions in eliciting humoral and T cell-mediated immunity were mapped along the G, M1 and N polypeptides.

Evolution

Conservation of the elements involved in transcription and replication

A comparative analysis of rabies virus strains, rabies-related viruses, rhabdoviruses in general, and paramyxoviruses indicate that strong selective pressure has stressed the following major elements controlling the gene expression: (1) the start and stop transcription signal bordering each cistron; (2) the promoters for RNA synthesis and encapsidation at the 3′ and 5′ genomic ends, respectively; (3) the RNA-dependent RNA polymerase (L protein), by far the most conserved polypeptide; it exhibits six highly conserved domains separated by variable areas, a distribution in agreement with the notion of independent functions (RNA synthesis, capping, polyadenylation and phosphorylation) concatenated within the polypeptide.

An intermediate place of unsegmented negative-strand RNA virus evolution

Proteins other than the L polymerase are poorly conserved. The G protein, although maintaining limited sequences around the main glycosylation site, has varied a great deal, as might be expected for the polypeptide that mediates the first contact with the host. The N protein has also retained small sequence stretches most likely involved in direct interaction with the genomic backbone. The M1 phosphoproteins and M2 matrix proteins are highly varied, as are the untranslated genomic areas.

The G–L intergene is of particular interest because of its large size and its inability to encode substantial peptides. In the same genomic location a fish rhabdovirus (infectious hematopoietic necrosis virus or IHNV) encodes an mRNA of similar size, as do the paramyxoviruses for the HN hemagglutinin protein. The rabies G–L intergene is presumed to be a remnant gene, baptized ψ for pseudogene. It places rabies virus in an intermediate position in the evolution of unsegmented negative-strand RNA viruses, between the rhabdoviruses with condensed genomes (vesicular stomatitis virus, for instance, shows the dinucleotide GA between the G and L), IHNV virus and the paramyxoviruses. The L protein homology studies independently confirm that rabies virus was closer to paramyxoviruses than to VSV.

The rabies ψ pseudogene: the best thermometer of evolution

Since it is a nonprotein coding region highly susceptible to mutation, changes in the rabies ψ pseudogene are more likely to represent the natural evolution of the virus outside any external selective pressure, and this site may therefore be a suitable target for

epidemiologic studies. By use of the polymerase chain reaction (PCR) technique directly from brain samples it was shown that:

- There is up to 18% divergence in the ψ pseudogene of different vaccine strains, most of which are derived from the original Pasteur strain.
- Wild isolates from a given geographic area are clearly related, with less than 2.5% divergence.
- Wildlife isolates differ by approximately 15% from vaccine strains (but complete cross-protection by those vaccines is still achieved).
- In West Africa (Ivory Coast, Cameroon, Niger and Morocco) where vaccine failures have often been noted, there is a greater (25–40%) divergence from the vaccine strains.
- European bat isolates tend to be completely different from vaccine strains at the ψ pseudogene. At the G and N gene, those known to be important in initiating the immune response, the divergence between isolates from European bats and isolates from vaccine strains is comparable to the difference vs Mokola virus (against which rabies vaccines are ineffective).

Serologic Relationships and Variability

The lyssavirus genus includes a wide variety of rabies viruses, both laboratory-adapted and naturally occurring 'street' viruses, almost all of which can be differentiated through the use of antinucleoprotein monoclonal antibodies. Monoclonal antibody analysis of various rabies variants indicates a remarkable stability in their pattern over many years, with a bat virus from all Mexican freetail bat, for instance, giving the same pattern in the early 1980s and the early 1990s. The analysis of variants also shows that the predominant virus circulating in a given epidemiologic area or 'niche' (such as raccoon rabies in eastern US) is also found in the animals that raccoons bite such as skunks and groundhogs; bat viruses tend to give a different pattern. The common rabies vaccines prepared from 'fixed' viruses such as LEP (low egg passage Flury), HEP (high egg passage Flury), ERA, PM and PV virus strains protect against all rabies 'street' viruses.

Within the lyssavirus genus there are also 'rabies-like' viruses, originally isolated in Africa and markedly different from the rabies viruses in their NP pattern. They include a virus isolated from a bat in Nigeria (Lagos bat), from a human bitten by a bat in South Africa (Duvenhage), or from shrews in Nigeria (Mokola). Common rabies vaccines do not protect against these virus strains.

Epidemiology

Rabies is endemic world-wide, either in dogs or in wild animals, except in those limited areas of the world (mostly islands) where rabies has never existed or where it has been eliminated. Most developing countries of Asia, Africa and Latin America have many cases of rabies in dogs which result in many human antirabies vaccinations and many human deaths. In most of these countries the approximate rate of human antirabies vaccination is 1:1000 population annually.

The picture is quite different in regions where rabies in dogs has been controlled and the disease is prevalent in a variety of wild animals, such as red foxes (western and eastern Europe and Ontario, Canada), arctic foxes (all circumpolar areas), skunks (midwest US), raccoons (eastern US), mongooses (Asia, South Africa, Cuba, Puerto Rico, the Dominican Republic, Haiti and Grenada), wolves (Iran, Afghanistan and the former USSR), vampire bats (northern Mexico to northern Argentina), insectivorous bats (Latin America, the US, Canada and, rarely, western Europe), and frugivorous bats (South America and the Caribbean). In those areas rabies is mostly transmitted within one species and rarely outside, with, for instance, rabies transmitted freely within skunk populations but only occasionally to other animals they bite, such as cows. Rabies rarely 'crosses over' and begins an outbreak in a species bitten by the original species involved.

But rabies in Latin America is almost always transmitted by one species of bat, the common vampire *Desmodus rotundus*, an animal that feeds solely on blood, mostly cattle blood. Every year there are hundreds of thousands of rabies deaths in cattle bitten by vampire bats; rare human outbreaks have also been reported, mostly in Trinidad, Brazil and Peru. Rabid insectivorous bats, on the other hand, rarely infect other species such as humans, cats and wild animals.

Transmission and Tissue Tropism

Rabies is almost always transmitted by saliva via bites or scratches. In rabid animals the submaxillary salivary glands (the most commonly involved extraneural organ) are infected about 75% of the time, with levels of virus often exceeding 10^8 infectious doses (mouse or tissue culture) per ml. After its introduction by a bite the virus stays at the local site for a variable incubation period, usually several weeks, then advances up the peripheral nerves to the central nervous system; it often reaches the brain and the salivary glands before changes in the behavior of the animal occur. There is, then, a dangerous

preclinical period of virus excretion in which the animal can infect other animals or humans without exhibiting any clinical abnormality such as jaw paralysis, excitation or changes in locomotion. During the terminal centrifugal spread of the disease (again by peripheral nerves) a variety of organs are commonly infected, including salivary glands, skin, lungs, kidneys and gonads.

Pathogenicity

Rabies viruses differ in their pathogenicity, but those differences have been difficult to measure. Certain laboratory adapted viruses (i.e. 'fixed' viruses) are highly invasive when injected either intracerebrally or intramuscularly. The invasiveness (as measured by the difference in mortality after intracerebral or intramuscular injection) of two 'street' isolates from one species in one geographic area can differ by as much as a thousandfold; it is not clear what factors this difference is due to, but it may include some factor in the saliva, the number of defective-interfering particles in the sample, and the particular characteristics of the virus. The pathogenicity also depends on the species of animal bitten, some species such as foxes being exquisitely susceptible to the virus, while others, such as the opossum, are much more resistant. Humans are quite resistant to rabies, with the expected mortality in persons bitten by rabid animals yet untreated being far below 50%; in observations made in the late 1800s, before rabies treatments were initiated, it was noted that 15% of persons died after severe and multiple hand bites by rabid dogs, while 85% survived without any treatment.

Clinical Features of Infection

Rabies in humans usually begins with mild and nonspecific symptoms which lead to an initial diagnosis of a common and minor bacterial or viral infection. A specific symptom often noted during the progression of the disease is pain or paresthesia at the bite site (usually the hand or foot). The acute neurological period begins with obvious nervous dysfunction, often including hyperactivity and, later, paralysis. Fever, nuchal rigidity, muscle fasciculation, convulsions, hyperventilation and excess salivation may be seen. The majority of agitated patients ('furious rabies') develop marked anxiety or agitation, sometimes accompanied by hydrophobia and aerophobia; during periods of agitation the patient's mental state fluctuates between periods of increasingly severe agitation and periods of normal behavior or depression. This acute period ends after 2–7 days. 'Paralytic rabies', with paralysis dominating the symptoms, is seen in about 20% of patients. Coma follows a transition period which begins with apneustic breathing; death is thought to be caused by respiratory arrest.

Pathology and Histopathology

There is little gross pathology in humans or animals that die of rabies; congestion of the meningeal vessels may occasionally be noted. The most common histologic change is perivascular infiltration, especially in the brainstem (the pons and medulla) as well as the spinal cord, basal ganglia and cerebral cortex. The neuronal degeneration and other inflammatory changes are variable. Negri bodies, specific (pathognomonic) cytoplasmic inclusions, are found in approximately 75% of rabid animals; these inclusions are most notable in the Purkinje cells of the cerebellum and in the hippocampal gyri (Ammon's horn). The absence of these inclusions does *not* rule out the diagnosis of rabies.

Geographic and Seasonal Distribution

The geographic distribution of the disease is summarized in the Epidemiology section. Rabies in dogs appears to have a somewhat seasonal character, with an increase in cases during the summer months; this was early attributed to the influence of the dog-star Sirius, but actually may be due to heat cycles in female dogs which lead to fighting among male dogs and an eventual increase in subsequent rabies cases. Rabies in terrestrial wild animals has not been reported to be seasonal; bat rabies, however, is distinctly seasonal in nontropical areas.

Host Range and Virus Propagation

Rabies virus infects a very broad array of animal species, perhaps the widest range of any animal virus. Commonly infected are dogs, wolves, foxes, jackals, skunks, raccoons, raccoon dogs, vampire bats, insectivorous bats and mongooses; the animals bitten by these species develop sporadic cases of rabies (these include cats, cows, horses, badgers and woodchucks) although the virus in those species rarely becomes enzootic. Humans are mostly infected after bites by rabid dogs.

Propagation is almost always by bite. Virus appears in the saliva of infected animals either when they are symptomatic, or for days or weeks before clinical signs appear. The presymptomatic excretion of virus in saliva is a very important epidemiologic characteristic for virus survival, and a crucial piece of information for physicians who judge whether an exposure has occurred in persons bitten by rabid (or possibly rabid) animals.

Experimental hosts include mice (the animal most commonly injected for confirmatory laboratory diag-

nosis), hamsters and rats (often used for pathogenesis studies), dogs (pathogenesis, vaccine efficacy), raccoons and skunks (oral vaccination). Suckling (1–3 day old mice) have been used for human and animal rabies vaccine production in many countries, mainly in Latin America, since their myelin content is much lower than that of adult animals, and virus titers in these young animals tend to be very high. Embryonating eggs have been used for propagation of attenuated vaccines (LEP and HEP). Street rabies viruses can be grown on mouse neuroblastoma cells with relative ease, and those cells are the most sensitive for confirming an initial diagnosis by fluorescent antibody. Tissue culture-adapted viruses grow to high titers on BHK cells. Other cells such as VERO, human diploid, chick and duck embryo cells are also commonly used for vaccine preparation.

Immune Response

Animals or humans vaccinated with classic rabies vaccines respond with a rise in neutralizing antibodies, the level reached generally being proportional to the potency of the vaccine. Neutralizing antibodies arise in direct response to the glycoprotein (G) gene; recombinant vaccines constructed with the cDNA of rabies virus glycoprotein also give rise to neutralizing (anti-G) antibodies. Animals with neutralizing antibodies, even at low levels, almost always survive subsequent challenge with 'street' rabies virus. Recently the protective role of the N gene has been recognized in experimental animals, although its significance in vaccinated animals (or humans) is not known. The cellular immune response after vaccination involves a wide array of cells. Serum neutralizing antibodies in individuals (humans or animals) that sicken with rabies are rarely noted before the eighth day of illness; antibodies appear in the cerebrospinal fluid 1 or 2 days later.

Prevention and Control of Rabies

Rabies may be controlled at three levels: human, domestic animal and wild animal. Until widespread canine vaccination programs were initiated in the late 1940s rabies was controlled only at the human level, with hundreds of thousands of persons vaccinated world-wide for exposure to rabid animals, mostly dogs. Rabies in dogs was controlled when potent animal vaccines became available (especially after the advent of proper vaccine potency tests) along with effective dog vaccination programs (those resulting in the immunization of at least 70% of community dogs) and stray dog control. This stopped dog-to-dog rabies transmission as well as serving as a barrier between infected wild animals and human populations. Recently an additional step has been taken involving the oral rabies vaccination of wild animals (foxes, raccoons) to eliminate rabies in those populations.

Future Perspectives

Many issues remain unsolved in rabies: what causes 15% of persons bitten in the hand by rabid dogs to die, while 85% survive without treatment? Where is the virus during the long incubation periods? What makes the virus break away at the end of that period? Why do some outbreaks in wild animals fade away after a few decades while others 'simmer' for much longer periods? Is there a better and less expensive treatment for exposed humans than that now administered (antiserum – or globulin – and vaccine)?

As the examination of molecular aspects of rabies permits the unravelling of the mysteries of pathogenesis we should see more investigation of antiviral substances and the development of more effective and less lengthy human treatments. Examination of viral isolates from various areas of the world will permit examination of the viral genomes of more and more rabies viruses, and clarify whether some are so far from the 'classic' strains as to require separate vaccines for the protection of humans and animals. The future should also bring a better understanding of just how effective vaccines can be delivered to unvaccinated animals such as wild animals, or, more important, community dogs in developing countries.

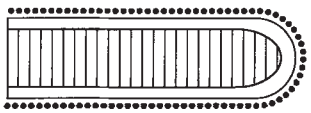
RABIES-LIKE VIRUSES (*RHABDOVIRIDAE*)



Robert E Shope, Center for Tropical Diseases, University of Texas Medical Branch, Galveston, Texas, USA

History

Rabies virus was thought to be a single serotype without relatives until 1969. That year workers at Yale University and the Centers for Disease Control in Atlanta, Georgia discovered that two viruses from Africa were bullet-shaped like rabies, and were related serologically to rabies virus. One of these, Lagos bat virus had been isolated in 1956 by L.R. Boulger and James Porterfield from brains of *Eidolon helvum* fruit bats captured on Lagos Island, Nigeria. The second, Mokola virus, was isolated by Graham Kemp in 1968 from the organs of shrews of the genus *Crocidura* captured in the Mokola District of Ibadan, Nigeria. Subsequently, it was discovered that the virus Obodhiang, isolated by Jack Schmidt in 1963 from *Mansonia* mosquitoes in the Sudan, and another virus isolated in 1967 by Graham Kemp and Vernon Lee from *Culicoides* midges in Ibadan, Nigeria and named kotonkan virus, were distant serologic relatives of rabies virus. The mosquito and midge viruses have not been recovered from naturally infected vertebrate animals and may be insect viruses.

The full significance of the finding in 1969 that viruses from Africa were related to rabies virus was not realized at the time. In 1971, however, Mokola virus was isolated from a fatal human case of central nervous system disease in Ibadan, Nigeria.

In 1970, a South African farmer was bitten on the lip by a bat. He later died of what was clinically thought to be rabies. The virus isolated from his brain was recognized as a new rabies-related virus and was named Duvenhage virus.

Lagos bat virus has since been isolated from a cat and a bat in South Africa, from a bat in Central African Republic, and from a rabid dog in Ethiopia, but has not been associated with human illness. Mokola virus has been subsequently isolated from apparently rabid dogs and a cat in Zimbabwe, and from a rabid dog in Ethiopia. Both Lagos bat and Mokola viruses have thus demonstrated their potential for rabies-like pathogenicity; Mokola virus was also isolated from shrews in Cameroon and from a rodent, *Lophuromys* in the Central African Republic. The most striking finding, however, was the discovery of viruses most closely related to Duvenhage virus in bats in Germany. In 1985, a bat biologist died of this virus (since named European bat lyssavirus) infection. It is now clear that close relatives of Duvenhage virus are widely distributed in bats throughout Europe, and represent a hazard to human health.

A lyssavirus was recovered from the brains of flying foxes (fruit bats) *Pteropus alecto* and *P. scapulatus* found in New South Wales and Queensland, Australia in 1995 and 1996. These are the first reports of enzootic lyssavirus infection in Australia. A fatal human case in a woman who took care of bats occurred in 1996. Preliminary serological studies indicate that the Australian bat lyssavirus is neutralized by rabies antibody, although it is not identical to rabies in its reactivity with monoclonal antibodies. It is provisionally considered a member of the classic rabies serotype 1. A partial sequence is 92% homologous with rabies virus at the amino acid level.

Charles Calisher and his colleagues in 1989 tested 89 rhabdoviruses for antibody crossreaction by immunofluorescence and found that 19 reacted with the known rabies-related viruses or with rhabdoviruses that in turn reacted with the known rabies-related viruses. Other than rabies, Mokola, Lagos bat, Duvenhage virus and European bat lyssavirus, none of these rabies relatives has been implicated as a cause of rabies-like disease in people or domestic animals. Here, the properties of the rabies-related lyssaviruses that cause rabies in domestic animals and/or people are described, whereas kotonkan, Obodhiang, and the 19 other rhabdoviruses that have distant serological relationships to members of the genus *Lyssavirus* are not detailed.

Taxonomy and Classification

The rabies-related viruses belong to the genus *Lyssavirus* of the family *Rhabdoviridae* of RNA viruses. These viruses have nonsegmented negative-strand RNA genomes enclosed in a lipid envelope derived from the host cell. The particles are covered by glycoprotein (G), a layer of spikes contained in the envelope, which endows the particles of at least two of the viruses, Mokola and Lagos bat, with the ability to agglutinate avian red blood cells. Beneath the lipid envelope is a membrane phosphoprotein designated P associated with a helical complex containing the

nucleoprotein (N) and the polymerase protein (L). A matrix (M) protein forms the inner lining of the lipid envelope. The viruses in the genus are bullet-shaped; Obodhiang and kotonkan resemble bovine ephemeral fever virus with mostly cone-shaped particles whereas the other members are indistinguishable from rabies particles. They have parallel sides, one flat end and one hemispherical end, and are approximately 180 nm in length and 65 nm in diameter.

The lyssaviruses are classified in five serotypes: serotype 1, rabies; serotype-2, Lagos bat (Lag); serotype-3, Mokola (Mok); serotype-4, Duvenhage (Duv) and serotype-5, European bat lyssavirus (EBL). These types were historically distinguished by neutralization test using polyclonal sera. Serotypes are currently typed and subtyped using a battery of anti-N monoclonal antibodies by immunofluorescence, and anti-G monoclonal antibodies by neutralization test. The serotypes correspond to genotypes except that EBL has two recognized genotypes, EBL1 and EBL2.

Geographic and Seasonal Distribution

Rabies-related viruses are geographically limited to Africa, except for European bat lyssavirus which is found in Europe. European Bat lyssaviruses are recognized throughout Europe from Spain to Russia and Ukraine. The rabies-related virus distribution is almost certainly a function of the range of reservoir hosts. There is no pattern of seasonality recognized.

Host Range and Virus Propagation

The reservoir hosts of Lagos bat, Mokola, Duvenhage, and European bat viruses are inferred from knowledge of sources of virus in nature. Lagos bat virus has been isolated at least nine times from bats. Where the bats were identified, these were fruit-eating bats: *Eidolon helvum* in Nigeria and Senegal, *Micropterus pusillus* in the Central African Republic, and *Epomophorus wahlbergi* in South Africa. The virus has presumably spilled over into domestic animals. It caused rabies in cats in South Africa and Zimbabwe, and in a dog in Ethiopia.

The reservoir of Mokola virus is believed to be the shrew, *Crocidura* spp., from which it has been isolated in Nigeria and Cameroon. A single isolation was made from a rodent, *Lophuromys sikapusi* in Central African Republic. The virus was recovered from rabid dogs in Zimbabwe and Ethiopia, and from rabid cats in Zimbabwe and South Africa indicating spillover into the domestic animal population. A fatal human case was recorded in Nigeria.

Insectivorous bats are implicated as the reservoir host of Duvenhage virus. The virus has been isolated repeatedly from *Eptisicus serotinus* throughout Europe, and once from *Nycteris thebaica* in Zimbabwe. The bat that bit the lip of the South African farmer who died of Duvenhage virus infection in 1970 was not identified.

European bat virus has been isolated repeatedly from *Eptisicus serotinus* (genotype EBL1) and *Myotis dasycneme* and *M. daubentonii* (genotype EBL2).

Lagos bat, Mokola, and Duvenhage viruses kill baby and adult mice following intracerebral inoculation. The three viruses induce plaques in Vero cells, and Duvenhage virus was readily adapted to form plaques in BHK-21 cells.

Wild-caught *Crocidura flavescens manni*, the African giant shrew, were inoculated in the laboratory with Mokola virus. Many of these became infected, including shrews exposed orally. Virus was recovered from brain, salivary glands, kidney, pancreas, lung and mouth swab. Virus was also sometimes detected in blood. Some animals became sick. They tended to save their food without eating it, to be more aggressive than uninfected animals, and to develop flaccid hind-limb paralysis. Shrews attack other animals in nature. Both sick and apparently healthy infected shrews transmitted Mokola virus to laboratory mice by bite.

Rhesus monkeys and beagle dogs were inoculated experimentally with Lagos bat and Mokola viruses. Animals inoculated intracerebrally invariably developed encephalitis indistinguishable from rabies and either died, or were killed. Dogs inoculated intramuscularly (i.m.) survived without illness as did the majority of monkeys inoculated i.m. One of five monkeys inoculated i.m. with Lagos bat virus developed unilateral paresis, but survived. One of five monkeys inoculated i.m. with Mokola virus developed tremors and died on day 19 postinoculation. Thus, Mokola and Lagos bat viruses are less pathogenic after i.m. inoculation than street rabies virus.

Mokola virus was passaged sequentially in baby mice, *Aedes albopictus* mosquito cells, and Vero cells. This passage material was found to infect *Aedes aegypti* mosquitoes by intrathoracic inoculation and was maintained by sequential passage in mosquitoes for 340 days. The virus was found in salivary glands, but in higher titer in nervous tissue of the mosquitoes. Mokola virus was transmitted transovarially in the mosquito, but infection of mice by mosquito bite was not demonstrated. Whether Mokola virus can be transmitted by arthropods in nature is still not known.

Genetics

The RNA of Mokola virus was cloned and the cDNA sequenced. The genome is very similar in length and

organization to rabies virus. The length is estimated at 12 000 nucleotides. The genes, designated by the proteins they code, are arranged as follows: 3′-N-P-M-G-L-5′. The 3′ and 5′ end sequences of Mokola virus are highly conserved when compared to the PV strain of rabies virus, and the Mokola end sequences appear to be complementary.

Evolution

Rabies and the other lyssaviruses are postulated to have evolved initially on the African continent. This hypothesis is based on the known African distribution of nearly all lyssaviruses described. Sequence analysis of the gene coding for the N protein of the European bat lyssavirus shows that EBL1 and EBL2 have probably evolved from a progenitor on the African continent. The worldwide distribution of rabies virus can be explained by transport with people of domesticated dogs which were infected and carried extensive distances by sailing ships from Africa during the long incubation period of the virus. For this hypothesis to be credible, one also needs to postulate that rabies virus spread in the Americas, Asia, and Australia from dogs to sylvatic animals such as the skunk, fox, raccoon and bat, and that further divergent evolution occurred in these hosts.

Serologic Relationships and Variability

Serologic relationships among lyssaviruses have been measured by complement fixation, neutralization and immunization challenge tests. The N protein plays a major role in complement fixation. By this method, rabies, Mokola, Lagos bat and Duvenhage viruses differ among themselves by two- to 16-fold in each direction in reciprocal tests. This degree of closeness indicates a relative conservation of the N protein antigens.

The neutralization test measures the surface G antigen. When undiluted hyperimmune sera are tested against various dilutions of infectious virus in the baby mouse, the four lyssaviruses are very closely related. However, the same test done with constant virus dose and various dilutions of antibody shows almost no relationship among the viruses except with undiluted antibody. When the test is done in cell culture using plaque reduction and varying dilutions of antibody, Duvenhage virus is most closely related to rabies, and Mokola virus is quite distinct.

The immunization challenge test is the most likely method to indicate the utility of a rabies vaccine to protect against challenge with other lyssaviruses. Mokola and Lagos bat crossreact minimally with rabies virus; a rabies vaccine with solid homologous protection, yields only a 1.5 log protection index against Duvenhage virus challenge. If these same relationships hold in human infection, there is some rationale for use of rabies vaccines to protect against Duvenhage infection, but the efficacy would not be expected to be optimal.

Batteries of monoclonal antibodies are used to determine the variability in reactivity by immunofluorescence of the G and N antigens. The monoclonal antibodies reactive with the G antigens have also been tested for neutralization. On the basis of reactivity with these batteries, subtypes of lyssaviruses have been recognized. Lagos bat virus has three proposed subtypes (Lagos, Central African Republic and South Africa). Duvenhage and Mokola viruses have only one each, but there is some evidence that the Ethiopian Mokola virus is different from the Nigerian. European bat lyssavirus is still under study, but is considered at this time to be a single antigenic subtype (with two genotypes).

Epidemiology

Lyssaviruses related to rabies are maintained in transmission cycles of terrestrial wildlife or bats. Each serotype is found in one or a relatively limited number of related species. It is believed that transmission to humans or domestic animals represents spill-over from the wildlife cycle. These spill-over events are rare. They may occur when people intrude into wildlife habitats, such as a Finnish spelunker who was infected in 1985 with EBL, or when the wildlife enter houses such as may have happened in Ibadan, Nigeria in 1971 when a 6-year-old girl was infected fatally with Mokola virus.

There is no evidence that epidemics or epizootics occur. Animals and people may survive infection with Duvenhage, Lagos bat and Mokola viruses. Survival of experimentally infected dogs and monkeys following Lagos bat and Mokola virus infection is documented. Mokola virus was reportedly isolated from a child that recovered from poliomyelitis-like disease in Nigeria, although the patient did not develop antibody during convalescence and the validity of the isolation is in doubt. The seasonality, carrier rates, sex and age susceptibility are not known for animals or people.

Transmission and Tissue Tropism

Experimentally, Mokola virus is transmitted by bite of shrews, and there is anecdotal evidence that a bat transmitted Duvenhage virus to a person by bite. Aerosol transmission has not been eliminated as a possible mechanism of spread. Mokola virus was

adapted to mosquitoes in the laboratory, but there appears to be no need to postulate mosquito transmission to explain maintenance in nature.

The limited data available from autopsy and infection of experimental animals indicate that Mokola, Lagos bat and Duvenhage viruses are neurotropic. The brain is the prominent target organ, as in rabies, and virus is also found in salivary glands late in infection.

Pathogenicity and Clinical Features of Infection

The range of pathogenicity of different strains of rabies-related viruses is not known. The clinical features of Mokola and Duvenhage virus infections are recorded in three patients; all presented with central nervous system disease. Duvenhage is associated with Guillain–Barré ascending paralysis and radiating pain in the arm and neck, followed later by agitation, increased respiration rate, muscle spasms, then coma and death. Diabetes insipidus with polyuria complicates the course. The child who died of Mokola virus infection had a prodromal illness of fever and vomiting, then flaccid paralysis of the limbs, progressing to deep coma before death.

Pathology and Histopathology

Specific lesions in the child who died of Mokola virus infection after a 9-day illness were limited to the brain. There were lymphocytic perivascular cuffing, neuronal changes of chromatolysis, eosinophilic necrosis, and nuclear pyknosis most marked in the midbrain and basal ganglia. Eosinophilic cytoplasmic inclusion bodies were found clustered in degenerating neurons. There were several lytic changes in the brain of the Finnish case of EBL. Rabies-reactive antigen was found in central nervous system neurons postmortem.

Immune Response

The very limited observations of patients infected with Mokola and Duvenhage viruses failed to show a specific serological response. The Finnish case of EBL infection was followed through 23 days of illness.

Prevention and Control of Disease Caused by Rabies-related Viruses

Prevention of human infection with rabies-related viruses is based on elimination of exposure in Europe and Africa, contact with bats should be avoided. Sick animals or those with abnormal behavior should be handled only with protective gloves. There is no vaccine available for Mokola or Lagos bat viruses. Commercial rabies vaccine and immune globulin may give limited protection against Duvenhage and EBL infection. Thus persons with bat bites and other bat exposures should receive classic rabies postexposure treatment, but should not expect complete protection. Persons whose occupations lead to exposure to bats should receive pre-exposure rabies vaccination.

Vaccines prepared from Mokola, Duvenhage and European bat lyssaviruses would be useful biologicals, but with the very low attack rates, it is not likely that such vaccines will be developed commercially.

Future Perspectives

The finding in Zimbabwe and Ethiopia of dogs and cats infected with Lagos bat and Mokola viruses is cause for concern. Human exposure and disease may be prevalent and not diagnosed. Active surveillance in Africa for Lagos bat, Mokola and Duvenhage viruses is needed.

Likewise, the threat posed by European bat lyssavirus is not yet completely appreciated. The scientific community needs to maintain vigilance for possible human cases, and needs increased research on the prevalence in bats, the possible spread to species other than serotine bats, and the extent to which terrestrial wildlife and domestic animals are exposed and infected.

RECOMBINATION OF VIRUSES

Jozef J Bujarski, Northern Illinois University, Plant Molecular Biology Center, Montgomery Hall, DeKalb, Illinois, USA

Introduction

Biochemically, recombination is a process of creating new genomic molecules by combining or substituting pieces of nucleic acids. Genetically, recombination could be defined as physical exchange of fragments among the parental genetic material. The results of recombination are progeny genomes that contain genetic information in nonparental combinations. Recombination was recognized as an important factor producing the genetic diversity upon which natural selection can operate.

Recombination events can occur in both RNA and DNA viruses. Since the molecular events behind DNA and RNA recombination differ in many aspects, they are described separately below.

Recombination in DNA Viruses

Recombination in many DNA viruses is believed to be accomplished by cellular enzymatic activities. There are two general types of genetic DNA recombination in the cell: homologous recombination (general recombination) and nonhomologous recombination. Nonhomologous or site-specific recombination occurs relatively rarely and requires special proteins that recognize specific DNA sequences to promote recombination. Homologous recombination occurs between two DNA sequences that are the same or very similar in the region of crossovers. Homologous recombination probably occurs in every DNA-based organism and it happens much more often than nonhomologous recombination.

There is plenty of information on the biochemical pathways responsible for crossovers in DNA. Besides sequence identity the requirements of general recombination include complementary base-pairing between double-stranded DNA molecules, recombination enzymes and the formation of heteroduplex within the regions of complementary base-pairing between the two recombining DNA molecules. Studies of the enzymology of DNA recombination in bacteria (and in particular of RecA, RecBCD proteins of *Escherichia coli*) have led to a large amount of literature, including many general reviews. Related recombination activities have been found and studied in eucaryotic sources, including yeast, insect, mammalian and plant cells.

Some DNA viruses encode their own proteins that function during recombination processes. In fact some DNA viruses serve as model systems for the study of recombination. For instance, certain bacteriophages encode the recombination pathways in order to avoid dependence on host systems. Such recombination can be used for repairing damaged phage DNA and for exchanging DNA between related phages to increase their diversity. High-frequency illegitimate recombination was observed at the replication origin of bacteriophage M13 in the *E. coli* host. The crossovers occurred at the nucleotide adjacent to the nick at the replication origin, by joining to a nucleotide elsewhere in the genome. This implied a breakage-and-reunion mechanism of illegitimate recombination, operating in *E. coli*.

Many of the phage recombination activities are analogous to those present in the host bacteria and studies on bacterial recombination systems were influenced by studies on phage systems. These pathways include Rec proteins of phages T4 and T7 (analogous to host RecA, RecG, RuvC or RecBCD proteins), RecE pathway in the rac prophage of *E. coli* K-12, or the phage 1 *red* system. In phage lambda there is another recombination system that can substitute for the RecF pathway components in *E. coli*. Models illustrating functions of RecA protein, RecBCD enzyme and Ruv proteins are shown in **Fig. 1**. A cartoon of the correlation of different stages of DNA recombination with transcription and DNA replication during bacteriophage T4 growth cycle is shown in **Fig. 2**.

Analogies between selected phage and *E. coli* host recombination functions are shown in **Table 1**.

Recombination between viral DNA and host genes was first observed in transducing bacteriophages in procaryotes and for retroviruses in eucaryotes. In some cases this represents a useful way for DNA viruses to acquire cellular genes. Among interesting examples of acquisition of cellular genes by DNA viruses are tRNA genes present in bacteriophage T4. These genes contain introns indicating that bacteriophage T4 must have passed through a eucaryotic host during evolution.

Genetic methods that rely on the use of mutants have been one of the most popular approaches for studying genetic recombination of DNA viruses. In viruses that have a single-component DNA genome,

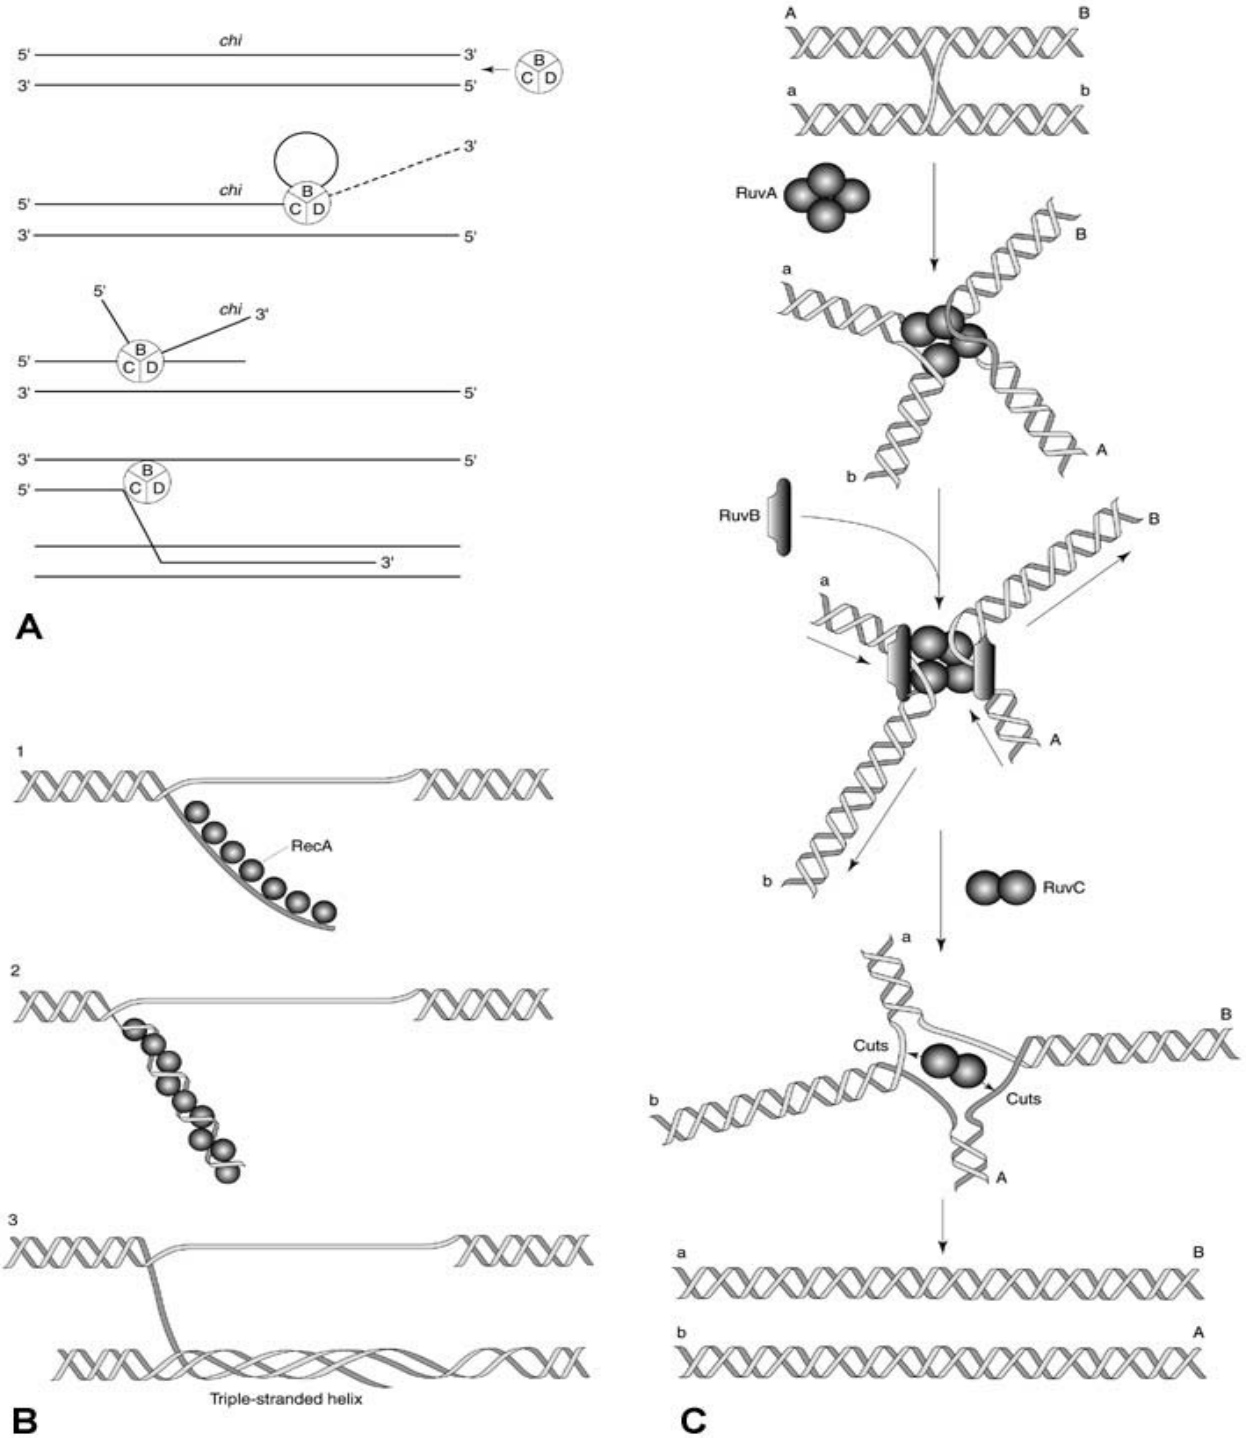

Figure 1 (**A**) Model for promotion of recombination initiation at a *chi* site by the RecBCD enzyme. The RecBCD enzyme loads on to the DNA at a free end or at a double-strand break internal to the DNA. It then moves along the DNA, displaces a loop, and the 3′ end is degraded by the exonuclease activity of the RecBCD enzyme (dotted line). The exonuclease activity is inhibited at a *chi* site, the 3′ end is no longer degraded and can thus invade another DNA molecule. (**B**) Synapse formation between two homologous DNAs by RecA protein. In steps 1 and 2, the RecA protein binds to the single-stranded end and forces it into an extended helical structure. In step 3, the helical single-stranded DNA can pair with a homologous double-stranded DNA in its major groove to form a stable extended triple helix. (**C**) Model for the mechanism of action of the Ruv proteins. RuvA binds to the Holliday junction. Note that the figure starts with one turn of blue-gray heteroduplex. Then RuvB binds to RuvA, and the junction migrates, deriving energy from ATP cleavage. RuvC cleaves two strands of the Holliday junction to resolve the junction into separate DNA molecules. Note the three turns of heteroduplex after junction migration. (Reproduced with permission from *Molecular Genetics of Bacteria* (1997) ASM Press.)

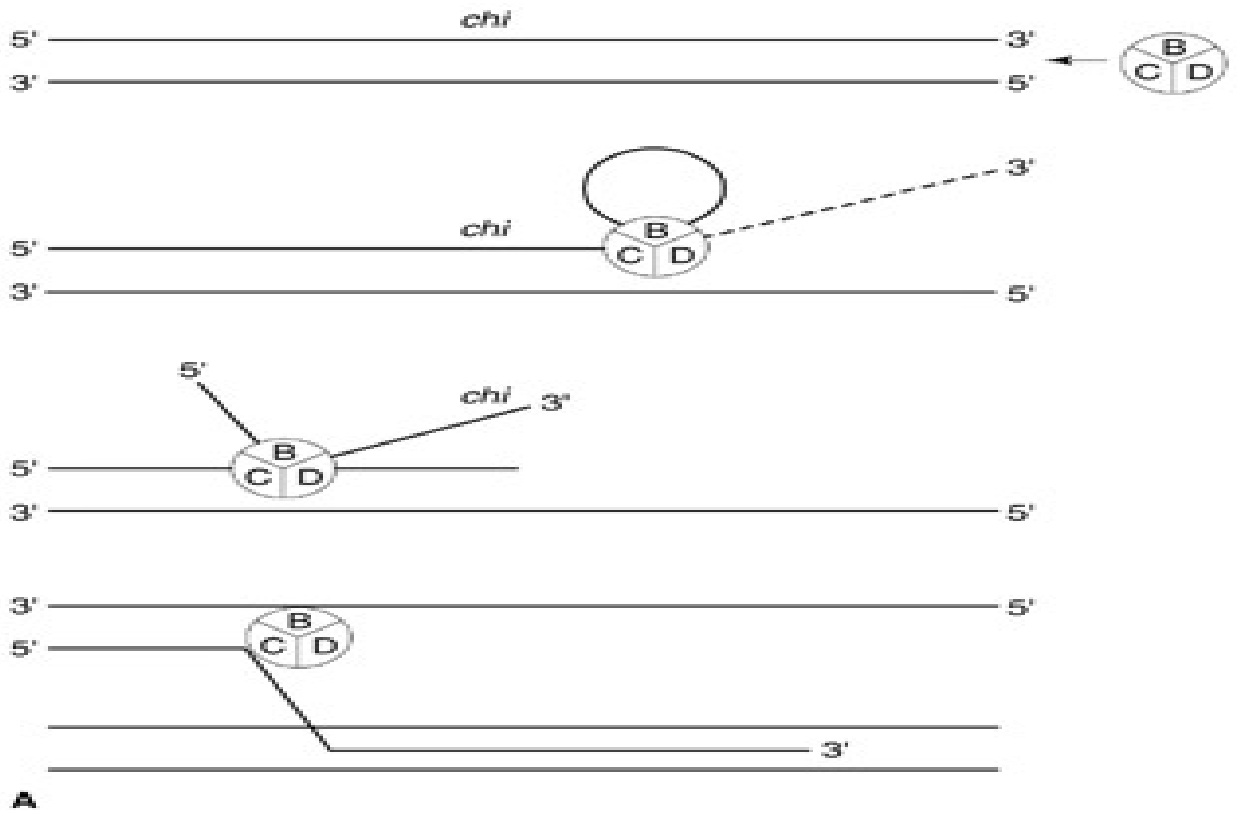

Figure 2 Cartoon showing the correlation between T4 recombination, and transcription and replication processes during bacteriophage T4 life cycle. The upper panel shows early (a), middle (b), and late (c) promoters recognized by forms of the host RNA polymerase that is modified by ADP-ribosylation of the α subunits and by T4-encoded accessory proteins. (d) shows a ribosome-binding site (RBS) of the mRNA for a late protein (Endo VII) that can be sequestered in a long early transcript but is free to initiate protein synthesis from a late transcript. The lower panel illustrates different stages of DNA replication and recombination in the context of the transcriptional program. (e) represents two T4 DNA molecules infecting a bacterium. (f) depicts bidirectional origin of replication cycle. (g) shows a replication–recombination pathway that becomes essential when the RNA polymerase modifications prevent further origin initiation. It is hypothesized that late after infection proteins required to initiate Okazaki pieces become limiting and that some join-cut-copy recombination requiring endonuclease VII occurs (h and i). Packaging proteins finally compete with replication and early recombination proteins for the recombinational intermediates, the concatamers are debranched, cut to headfull lengths, and packaged. (Reproduced with permission from *Molecular Biology of Bacteriophage T4* (1994) ASM Press.)

recombination can involve the exchange of DNA fragments. In contrast, in segmented DNA viruses, in addition to exchanges within each DNA component, the genome segments can be reassorted. This has implications for the recombination behavior observed among mutants. Recombination analyses are most easily performed using conditional-lethal type. The cells are mixedly infected with two mutants at permissive conditions and then the nonpermissive conditions are applied to select for recombinants. The so called two-factor crosses are performed through simple pairwise infections. For single-segmented DNA viruses this approach allows the mutants to be ordered into complementation groups and the relative positions of mutations to be placed on a linear map. For segmented genome DNA viruses, however, due to the reassortant factors, the data obtained in two-factor crosses do not allow mutants to be ordered on to a linear map. Three-factor crosses involve the use of three mutations, with one of them being kept unselected during selection of recombinants between the other two. These crosses are useful for determining linkage relationships between mutants and for establishing the order of marker mutations. Due to reassortment the three-factor crosses are of less use in segmented viruses.

Recombination in DNA viruses of eucaryotes was observed for both animal and plant viruses. The recombination frequencies among pairs of temperature-sensitive mutants (two-factor crossings) were studied in herpes simplex virus. A linear dependence upon the distance between mutations and the fre-

quency was observed, suggesting the lack of specific signal sequences responsible for crossover events in this virus.

Three-factor crosses were performed using herpes simplex virus. Here, a syncytial plaque morphology mutation was used as an unselected marker for ts mutations. In the case of adenoviruses the host range determined by the helper function of two mutations has been used as a third marker between ts mutants.

Epstein–Barr virus (EBV), a member of the gamma herpesvirus family, is a DNA virus with a long double-stranded DNA genome which shows a high degree of variation among strains. This variation takes the form of single base changes, restriction site polymorphism, insertions and deletions. It was found that some EBV variants arose by DNA recombination events.

Homologous genetic recombination was observed in vaccinia virus (VV) and other poxviruses. This is evident from the high frequency of intertypic crossovers, the ease of the marker rescue and the isolation of viral recombinants. Recombination of VV DNA occurs both intra- and intermolecularly, and is dependent on DNA target size. A function of the viral DNA polymerase or viral DNA replication itself has been implicated and viral proteins with DNA strand transfer activity have been identified.

Intertypic crosses between ts mutants were selected for adenoviruses. Analysis of the segregation patterns of DNA fragments and their restriction enzyme polymorphism has allowed the specific ts mutations to be mapped on adenovirus genomes.

General recombination in somatic cells was observed for SV40 (a papovavirus). The authors tested recombination events from artificially constructed recombinant circular oligomers. While this type of recombination was high, homologous recombination in this type of DNA tumor viruses was rare.

The geminiviruses are a unique group of single-stranded plant DNA viruses. Intermolecular recombination between geminivirus DNAs has frequently been observed using various combinations of mutants. Likewise, intramolecular homologous recombination between tandem repeats of a geminivirus genome was found in agro-infected tobacco plants. Both homologous recombination model and replication-based recombination model were proposed to explain the observed events. In addition, deletions, insertions and other rearrangements have frequently been detected in geminivirus infections. These illegitimate recombination processes may rely on aberrant breakage–fusion events as well as errors of DNA replication, and may be inter- or intramolecular in nature.

Cauliflower mosaic virus (CaMV) is a plant DNA virus. It belongs to the pararetroviruses, which replicate through a reverse transcription step. A high recombination rate was observed *in vivo* for CaMV. The replication cycle of CaMV offers a variety of possibilities for recombination: recombination at the DNA level, which occurs in the nucleus, and at the RNA level, which occurs during reverse transcription in the cytoplasm. In general, it is difficult to decide by which recombination route a CaMV recombinant is obtained. However, such features as recombinational hot spots and apparent mismatch repair might be indicative. Namely, the presence of hot spots reflects replicative (RNA) recombination, while mismatch repair can occur during formation of heteroduplex intermediates and is thus indicative of DNA recombination. Recombination between CaMV strains and CaMV transgene mRNA was observed. It is believed that this type of recombination represents an RNA–RNA recombination event (during reverse transcription).

Recombination in RNA Viruses

RNA viruses utilize RNA as their genetic material. The potential for variation of the RNA genome is very large owing to a high mutation rate (during copying by RNA-dependent RNA polymerase) and to recombination. The terms of classic population biology do not describe RNA viruses. Instead, a term of quasispecies was proposed to reflect the nature of RNA virus populations. The processes of genetic recombination in plus-stranded RNA viruses probably do occur at the RNA level, as these viruses most likely do not go through DNA steps in their replication cycles. RNA recombination processes are generally categorized as either homologous or nonhomologous. In 1992, Lai postulated three classes of RNA recombination: homologous, aberrant homologous and nonhomologous. Homologous recombination occurs between two related RNA molecules at corresponding sites, although homologous RNA

recombination can also occur within a common region shared by otherwise unrelated RNA sequences. Aberrant homologous recombination involves crossovers between related RNAs, but does not occur at corresponding sites, leading to sequence insertions or deletions. Nonhomologous recombination occurs between unrelated RNA molecules. Slightly different definitions, based on mechanistic models and considerations, were proposed recently by several authors.

Although genetic recombination in RNA viruses such as influenza virus and poliovirus has been described, it has not been found in Newcastle disease virus. The complete nucleotide sequences of the genomic RNAs of a large number of RNA viruses belonging to different virus groups have been obtained. This revealed the relatedness of various animal, plant and other RNA viruses and allowed the definition of sequence rearrangements in the viral RNA genome.

Sequence rearrangements were found in the following animal plus-strand RNA viruses: picornaviruses: poliovirus and foot-and-mouth-disease virus (FMDV); in coronaviruses: mouse hepatitis coronavirus (MHV); Sindbis alphavirus (SIN); flock house nodavirus (FHV); and in bacteriophages $Q\beta$, and MS-2. Recombinants were found in bunyaviruses. Genetic rearrangements were also observed in other types of RNA viruses, including influenza virus, a minus-strand RNA virus, in retroviruses, and in double-stranded $\Phi 6$ bacteriophage. The following genomes of plant RNA viruses reveal RNA rearrangements: alfalfa mosaic virus (AlMV), beet necrotic yellow vein virus (BNYVV), bromoviruses (see below), hordeiviruses, luteoviruses, nepoviruses, tobamoviruses, tobraviruses, tombusviruses and turnip crinkle carmovirus (TCV).

Recombination by reassortment was observed for multisegmented animal RNA viruses, including influenza virus and double-stranded reoviruses and orbiviruses. The reassortment mechanism functioning in reoviruses is reflected by the fact that the interpretation of two-factor crosses (using for instance temperature-sensitive mutations) appears to be difficult: the mutants cannot be ordered on to a self-consistent linear map and quite often no linkage between mutants could be detected.

The examples in which host-derived sequences have recombined with viral RNAs include an ubiquitin-coding sequence of bovine diarrhea virus, a sequence from 28S rRNA inserted in the hemagglutinin gene of an influenza virus, and a tRNA sequence in Sindbis virus RNA. For plant viruses, several potato leafroll virus isolates contain sequences homologous to an exon of tobacco chloroplast. Acquisition of chloroplast sequences during RNA recombination was observed for brome mosaic virus.

The use of transgenic plants expressing viral RNA sequences has confirmed that plant RNA viruses are able to recombine with host mRNAs. This was shown for cowpea chlorotic mottle bromovirus (CCMV), red clover necrotic mosaic virus (RCNMV), potato virus Y potexvirus (PVY) and plum pox potyvirus (PPV).

Studies on the molecular mechanism of RNA recombination have progressed when experimental systems that supported the high frequency of crossovers were established. The available data on rearrangements in picornaviruses suggest a mechanism of template switching that occurs during minus-strand RNA synthesis. These rearrangements may be facilitated by the existence of identical or completely dissimilar signal sequences between the recombining RNA substrates.

Certain RNA viruses can produce both homologous and nonhomologous RNA recombinants. The molecular mechanism involved in the formation of homologous and nonhomologous recombinants was tested using an efficient recombination system of brome mosaic virus (BMV). A partially debilitating BMV RNA3 mutant was repaired *in vivo* by exchanges with the sequences of other BMV RNA components. Low recombination frequency was overcome by construction of RNA3-based recombination vectors, where recombinationally active sequences could be inserted and analyzed. It appeared that short base-paired regions between the two BMV RNA recombination substrates can target efficient nonhomologous recombination crossovers. A model invokes the formation of local RNA–RNA heteroduplexes to be responsible for targeting the RNA crossovers as a result of: (1) bringing the RNA substrates into a close proximity; and (2) slowing down or stalling the approaching replicase enzyme complex (**Fig. 3**).

Similarly, homologous RNA recombination was studied by inserting a BMV RNA2-derived sequence into the recombination vector. Both precise and imprecise crossovers were observed. Other RNA sequences revealed that the frequency of RNA2–RNA3 homologous crossovers depends upon sequence composition and tends to occur at hot spot regions that contain stretches of GC-rich alternating with AU-rich sequences. Such nucleotide composition may act as recombination activators during switching between RNA templates by the RNA replicase enzyme (**Fig. 4**). Overall, the data on BMV RNA recombination suggest that molecular mechanisms involved in the two types of crossovers in BMV differ from each other.

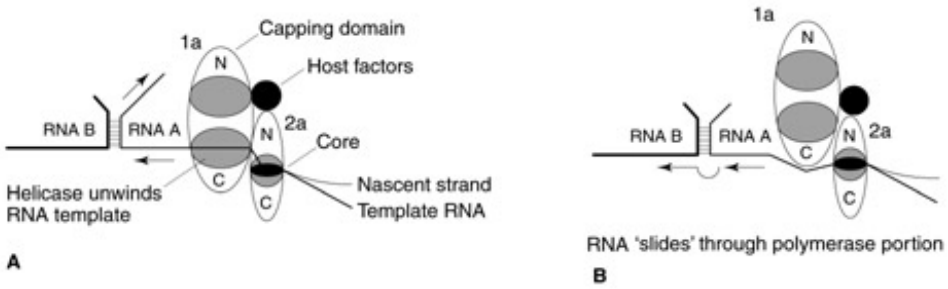

Figure 3 The model of strand switching by BMV replicase. The replicase is composed of the interacting host (smaller black circles) and viral (represented by ellipses) proteins. Functional domains of nucleotidyl transferase (capping enzyme), helicase and core RNA polymerase on proteins 1a and 2a are represented by smaller shaded ellipses. At the replication mode (**A**) the enzyme copies the original template through the double-stranded region (represented by a short 'ladder') due to the helicase action. During recombinational mode (**B**), the polymerase 'slides' under the double-stranded regions and changes the templates from RNA A to RNA B. The arrows indicate the direction of replicase migration. (Reproduced from Bujarski and Nagy (1994) Genetic RNA–RNA recombination in positive-stranded RNA viruses of plants. In: Paszkowski J (ed.) *Homologous Recombination and Gene Silencing in Plants.* Kluwer Academic.)

The term 'recombinosome' was proposed to describe a complex between the recombining RNAs, the replicase proteins and other (putative) factors involved in template switching events. The participation of replicase proteins of BMV in recombination was studied using a temperature-sensitive 1a of BMV protein mutant. This revealed a *5′* shift in crossover sites within the RNA1–RNA3 heteroduplex, suggesting that the helicase domain of 1a participates in heteroduplex-mediated crossovers. Likewise, a single amino acid mutation within the core domain of 2a protein and mutations within the N-terminal portion of 2a, the polymerase component of the replicase, inhibited the frequency of nonhomologous recombination in BMV. These studies confirm the participation of replicase proteins in recombination.

The role of replicase enzyme in RNA recombination was also studied in TCV, a small single component RNA virus that is associated with a number of subviral RNAs, such as satellite RNA D and chimeric RNA C. High frequency recombination was observed *in vivo* between RNAs C and D. A template switching model was proposed where viral replicase utilizes the nascent plus-strand of RNA D to reinitiate RNA elongation at a hairpin structure on the acceptor minus-strand RNA C template (**Fig. 5**).

The participation of TCV replicase in RNA recombination was studied *in vitro* with a TCV replicase preparation and a chimeric RNA template containing the *in vivo* hot spot region from RNA D joined to the hot spot region from RNA C. This demonstrated roles for a priming stem sequence in the RNA C portion and the TCV RNA-dependent RNA polymerase (RDRP) binding hairpin, also from the RNA3 portion. It probably reflects such late steps of the *in vivo* RNA recombination as strand transfer and primer elongation.

For coronaviruses, the animal RNA viruses containing a large RNA genome, recombination has been demonstrated between coronavirus genomes and defective-interfering RNAs, and it was postulated to account for the diversity in the genomic structure of these viruses. The mechanistic considerations suggest the nonprocessive nature of the coronavirus RNA polymerase, which might be responsible for recombination. Similarly, RNA recombination in nodaviruses, two-partite RNA viruses, occurs between RNA segments at a site, where the nascent strand could form a base-paired region with the acceptor template. Such factors as template secondary structure and the similarity of the crossover sites to an origin of replication seem to influence the choice of recombination site. A model of recombination where the polymerase interacts directly with the acceptor nodavirus RNA was postulated.

A copy-choice template switching mechanism was also suggested for recombination in a double-stranded bacteriophage Φ6. Here, the crossovers occur inside the virus capsid structure. Apparently, the crossovers can occur in regions that share little sequence similarity and the frequency of recombinants can be enhanced by conditions that prevent the minus-strand synthesis.

The bacteriophage Qβ has emerged as a unique RNA virus system for the study of RNA recombination both *in vivo* and in cell-free systems. It was demonstrated for the first time in this virus that RNA recombination can occur not by polymerase template switching events but rather via a splicing-type RNA recombination mechanism.

Genetic RNA recombination has been observed in retroviruses. Here, the efficient recombinant jumpings are secured by reverse transcriptase. In fact, the retrovirus system represents a well-established model

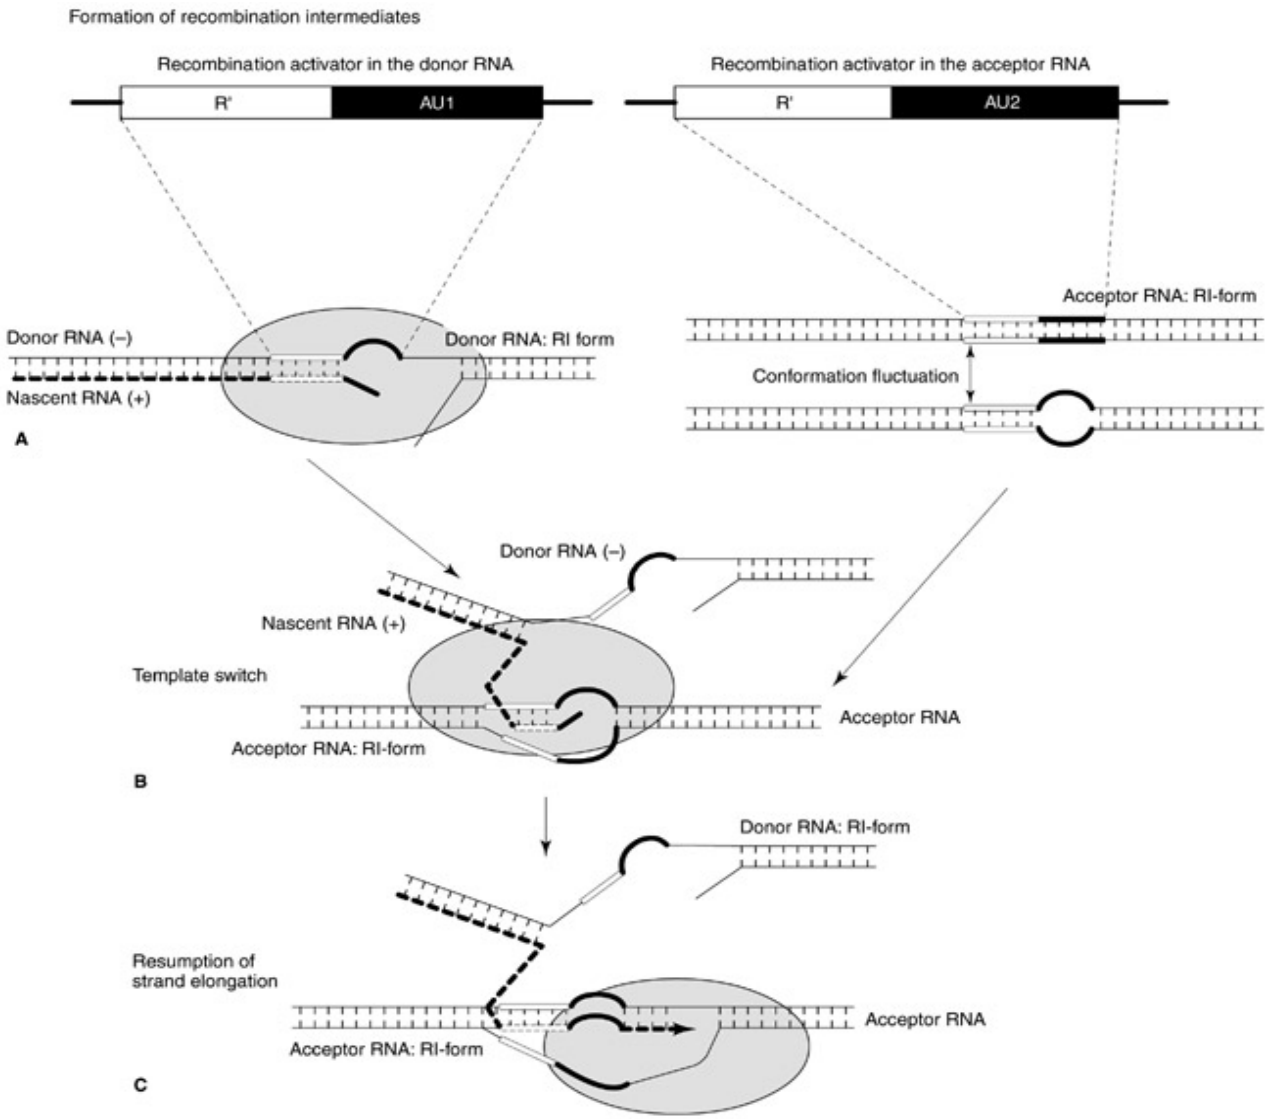

Figure 4 Processive template switching model explaining the formation of homologous recombination hot spots within the recombination activator sequences. (**A**) Template switching of the BMV replicase occurs during positive-strand synthesis. Although localized double-stranded replicative intermediates (RIs) are shown, the existence of single-stranded RNAs with negative polarity is also possible (not shown). The weak base pairing within the AU-rich region (shown on the left side of the diagram with a black line) can facilitate the release of the 3′ end of the incomplete nascent RNA. The weak base pairing within the AU-rich region can also facilitate the temporary formation of a bubble structure in the RI of the acceptor strand (gray line on the right side). The replicase (large shadowed ellipse) pauses on the donor strand at the UA-rich region, and the very 3′ end of the nascent strand disengages from the original template strand. (**B**) The released 3′ end of the nascent strand hybridizes to the acceptor strand facilitated by the bubble structure. Hybridization of the upstream located R′ (shown by empty boxes) stabilizes the recombination intermediate. (**C**) The viral replicase resumes chain elongation on the acceptor strand (shown by an arrowhead). This leads to the formation of homologous recombinant RNA3s. (Reproduced with permission from a paper by Nagy and Bujarski (1997) *J. Virol.* 71(8): 3808.)

of the polymerase/template switching reactions both *in vivo* and *in vitro*. Apparently, the virally encoded reverse transcriptases are evolutionarily selected to secure jumping during reverse transcription reactions. The recombinant jumpings are responsible for both inter- and intramolecular template switching, and for

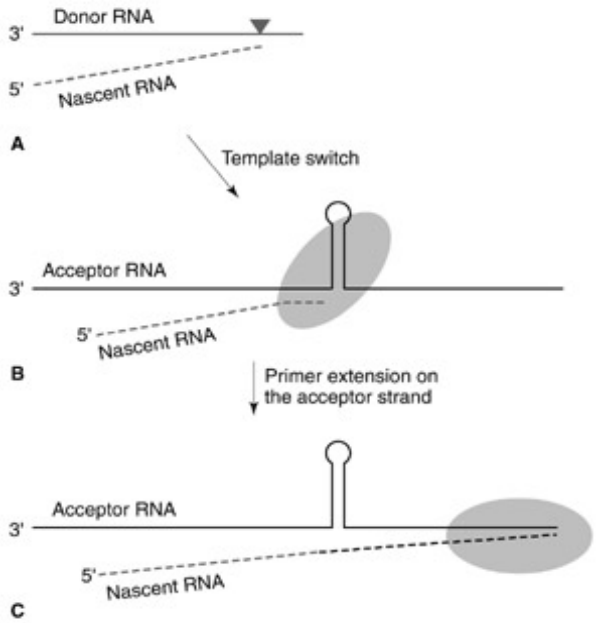

Figure 5 Model for RNA recombination in the turnip crinkle virus (TCV) system. (**A**) The TCV RDRP copying minus-strand sat-RNA D either reaches the natural 5′ end or pauses at some positions (mainly 13 nucleotides from the 5′ end, as indicated by a triangle) likely due to the presence of a protein-binding site. (**B**) The TCV RDRP, which is still associated with the nascent sat-RNA D strand, switches to the acceptor template (minus-strand sat-RNA C or TCV) facilitated by either the motif I or motif III hairpins. Hybridization between the nascent strand and the acceptor strand may stabilize the recombination intermediate. (**C**) The TCV RDRP reinitiates RNA synthesis using the 3′ end of the nascent sat-RNA D as a promoter. Further copying of the acceptor RNA by the RDRP results in a recombinant RNA molecule. (Reproduced with permission from Simon *et al* (1996) *Semin. Virol.* 7: 373.)

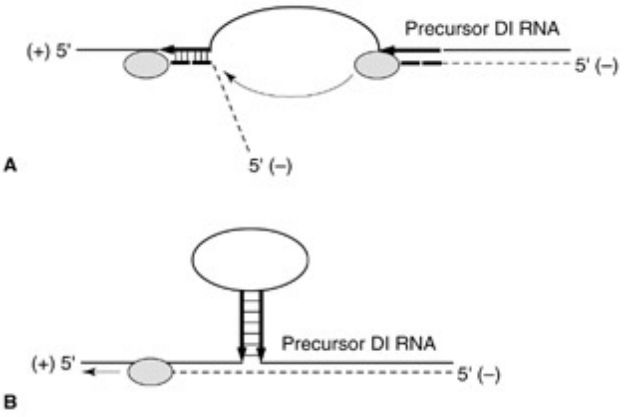

Figure 6 Proposed replicase-mediated model for deletion of segments from precursor DI RNAs. RNA templates are depicted as solid lines while nascent strands are shown as dashed lines. The viral replicase is represented by shaded ovals and its path is indicated by thin arrows. Deletion of segments from precursor DI RNA molecules may be facilitated by tracts (bold arrows) of sequence (**A**) identity or (**B**) complementarity, as discussed in the text. (Reproduced with permission from White A (1996) Formation and evolution of Tombusvirus defective interfering RNAs. *Semin. Virol. 7:* 409.)

the formation of defective retroviral genomes. They contribute significantly to genetic variability of retroviruses.

Defective-Interfering RNAs

Defective-interfering (DI) RNAs are subviral RNA molecules derived from the helper virus genomic RNA and typically interfere with helper virus accumulation and affect symptoms produced by the helper virus. Paul von Magnus was first (in 1954) to report DI RNAs in influenza virus. Later, DI RNAs were observed in a majority of animal and in many plant RNA virus infections. Naturally-occurring DI RNAs have been identified during infection with several coronavirus species. These molecules appear to arise by a polymerase strand-switching mechanism. In fact the DI RNAs were used in coronavirus research, to study the mechanism of high-frequency, site-specific RNA recombination events that progress through leader acquisition during RNA replication, and as vehicles for the generation of targeted recombinants of the parental virus genome.

For plant tombusviruses and carmoviruses the DI RNAs reveal a consistent pattern of rearranged mosaic-type sequences flanked by unmodified terminal regions. Analysis of these DI RNAs suggests that in some cases the base-pairing between an incomplete replicase-associated nascent strand and the acceptor template can mediate the selection of the rearrangement sites (**Fig. 6**).

Single deletion-type DI RNAs were isolated from infections with several viruses, including beet necrotic yellow vein furovirus (BNYVV), soil-borne wheat mosaic furovirus (SBWMV), peanut clump furovirus (PCV), clover yellow mosaic potexvirus (CYMV), sonchus yellow net rhabdovirus (SYNRV), and tomato spotted wilt tospovirus (TSWV). Such factors as the length of the defective RNA or its coding capacity seem to affect the selection of DI RNAs during infection.

For broad bean mottle bromovirus (BBMV) the naturally existing DI RNAs were found to be derived by single deletions in the RNA2 component. A secondary structure-mediated model for BBMV DI RNAs, where local complementary regions bring the remote parts of RNA2 together to facilitate the crossover events, has been proposed (**Fig. 5**). Similar to BBMV, single deletion-type DI RNAs have been found associated with cucumoviruses. Overall, it

seems likely that the mechanisms leading to DI RNA generation are similar to those of RNA recombination.

The closteroviruses are the RNA viruses of plants that have the longest known RNA genome. Recently, multiple species of citrus tristeza closterovirus (CTV) defective RNAs, which resulted from the recombination of a subgenomic RNA with distant parts from the 5′ end of the viral genomic RNA, were identified. This suggests that closteroviruses can utilize subgenomic RNA as factors for the modular exchange and rearrangement of their genomes.

Defective-interfering particles were also found in negative-strand RNA viruses. Namely, for vesicular stomatitis virus (VSV) *cis*-acting terminal sequence elements play an important role during RNA replication. The formation and accumulation of certain classes of DI RNA molecules were observed: the majority of DI RNAs were of the 5′ copy-back class, reflecting the mechanisms involved in DI RNA generation.

In the case of RNA viruses both homologous and nonhomologous recombination events were observed. Various types of copy-choice mechanisms were proposed to explain the formation of RNA recombinants, and the role of special RNA signal sequences and viral proteins in recombination was observed. In some cases a mechanism of RNA breakage and religation cannot be excluded and was experimentally demonstrated for bacteriophage Qβ. Further studies are required to obtain a more general picture of genetic recombination pathways available for viruses, especially for RNA viruses.

Conclusions

Genetic recombination can be found in many groups of DNA and RNA viruses. Both the observed natural sequence rearrangements and the data obtained with the use of experimental systems demonstrate that recombination plays an important role in providing the genetic diversity during virus infections. The molecular mechanisms involved in genetic recombination depend on the class of viruses. DNA viruses utilize mechanisms of homologous (general) recombination available in the host cells, although some DNA viruses encode their own recombination proteins. Also, site-specific (nonhomologous) recombination events were found for certain classes of DNA viruses.

REOVIRUSES (*REOVIRIDAE*)

Contents

General Features

Kenneth L Tyler, Neurology Department, B-182, University of Colorado Health Sciences Center, Denver, Colorado, USA

History

In 1959, AB Sabin proposed the designation reovirus (respiratory enteric orphan virus) for a subgroup of respiratory and enteric viruses not known to be associated with human disease (hence orphan) with particular distinguishing characteristics. The distin-

guishing features of reoviruses included: (1) their size, which at ≥75 nm was larger than other known enteric viruses; (2) their capacity to produce cytoplasmic inclusions in monkey kidney cells in tissue culture; (3) their pathogenicity for newborn but not adult mice; and (4) their capacity to hemagglutinate human type O erythrocytes. All of the viruses that would subsequently be designated the prototypes for the three reovirus serotypes (see below) were originally isolated in the 1950s from the stools of children. The first reovirus was isolated by NF Stanley and colleagues in 1951 from an aboriginal child and subsequently named hepatoencephalomyelitis virus. An enteric virus isolated by M Ramos-Alvarez and AB Sabin in 1953 from the stool of a baby named Lang initially became the prototype virus for ECHO 10, and subsequently for reovirus serotype 1 (reovirus serotype 1 strain Lang). The prototype for reovirus serotype 2 was isolated by Ramos-Alvarez and Sabin from the stool of a child named Jones with a summer diarrheal illness (reovirus serotype 2 strain Jones) in 1955. Viruses isolated by Ramos-Alvarez and Sabin in 1955 from the stool of a child named Dearing and by L Rosen in 1957 from an anal swab from a baby named Abney became the prototype strains for serotype 3 (reovirus serotype 3 strains Dearing and Abney).

Taxonomy and Classification

The genus *Orthoreovirus*, of which the mammalian reoviruses are the prototypes, is one of the nine genera belonging to the family *Reoviridae*. Viruses belonging to this family are nonenveloped spherical viruses of 60–85 nm diameter, whose genome consists of 10–12 discrete segments of double-stranded RNA (dsRNA) that is contained in two or three concentric protein capsids with icosahedral symmetry. Members of different genera can be distinguished by differences in relative size, capsid number and structure, genome segment number, nature and number of structural proteins, and patterns of reactivity with antisera. Viruses belonging to different genera also differ substantially in their host range and pathogenesis. (*See also*: **Orbiviruses and Coltiviruses, Phytoreoviruses, Rotaviruses.**) Nucleotide sequence data indicate that members of the *Orthoreovirus* genus are highly divergent from other *Reoviridae* genera (e.g. *Orbivirus, Rotavirus*) including those known to infect humans and other mammals. Members of the *Orthoreovirus* genus have 10 segments of dsRNA contained in two concentric protein capsids of approximately 85 nm diameter (**Table 1**).

The mammalian orthoreoviruses, which form the subject of this chapter (subsequently referred to as 'reoviruses'), are further classified into three serotypes (designated serotypes 1, 2, 3) on the basis of their patterns of reactivity with typing antisera and differences in their capacity to hemagglutinate human and bovine erythrocytes. Classically, serotyping was performed by hemagglutination–inhibition assay on human type O erythrocytes using serotype-specific antisera. Serotyping can also be accomplished by evaluating the capacity of serotype-specific antisera to produce neutralization as measured in plaque reduction neutralization assays. Genetic studies with reassortant viruses derived from crosses between the prototype strains for different serotypes indicate that the $\sigma 1$ protein, which is encoded by the S1 dsRNA segment, is the major serotype-specific determinant. Accurate serotyping can also be accomplished by evaluating the capacity of serotype-specific sigma 1 monoclonal antibodies to neutralize infectivity of test isolates. The most accurate information concerning the relationship between different reovirus strains can be accomplished by comparison of nucleotide and amino acid sequence variability between their cognate gene segments and encoded proteins. Detailed phylogenetic analyses of the evolutionary relationship between a number of reovirus strains based on the nucleotide sequence of their S1, S2, S3 and S4 gene segments have now been published (**Fig. 1**). Interestingly, the phylogenetic trees of individual viral strains differ depending on the dsRNA segment chosen for comparison, indicating that reassortment of reovirus gene segments occurs under natural circumstances.

Other members of the *Orthoreovirus* genus include a large group of viruses isolated from birds, the avian reoviruses, and several currently incompletely categorized viruses isolated from the flying fox (Nelson Bay virus), baboons and several species of snakes. These viruses all have basic similarities in the nature of their genomic organization (10 dsRNA segments), protein coding pattern and general virion structural organization. Reassortment between these various groups of reoviruses has not been demonstrated and their cognate gene segments and corresponding proteins are extremely divergent in their nucleotide and protein sequences. It is likely that mammalian reoviruses, avian reoviruses, and perhaps some of these other currently uncharacterized reoviruses are independent quasispecies.

Geographic and Seasonal Distribution

Reoviruses are ubiquitous in their geographic distribution. Studies of variation in the seasonal pattern of infection are extremely limited. As noted, many of the initial isolates of reoviruses from humans were made from infants and children with summer diarrheal illnesses. Studies of the prevalence of child-

Table 1 Properties of the mammalian reoviruses

Genome
Double-stranded RNA
10 gene segments in three size classes (L, M, S)
Total size 23 500 bp
Gene segments encode either one or two proteins each
Gene segments are transcribed into full-length mRNAs
Plus strands of gene segments have 5′ caps
Nontranslated regions at segment termini are short
Gene segments can undergo reassortment between virus strains
Particles
Spherical, with icosahedral (5:3:2) symmetry
Nonenveloped
Total diameter 85 nm (excluding σ1 fibers)
Two concentric protein capsids: outer capsid subunits in $T = 13$ lattice, arrangement of inner capsid subunits unknown
8 structural proteins: 4 proteins in outer capsid (λ2, μ1 (mostly as cleavage fragments μ1N and μ1C), σ1, and σ3) and 4 proteins in inner capsid (λ1, λ3, μ2, and σ2)
Subviral particles (ISVPs and cores) can be generated from fully intact particles (virions) by controlled proteolysis.
Cell-attachment protein σ1 can extend from the virion and ISVP surface as a long fiber.
Protein λ2 forms pentamers that protrude from the core surface.
Replication
Fully cytoplasmic
Sialic acid can serve as cell surface receptor for recognition by cell-attachment protein σ1.
Proteolytic processing of outer capsid proteins σ3 and μ1/μ1C is essential to infection and can occur either extracellularly or in endo/lysosomes.
Uncoating of parent particles is incomplete: genomic dsRNA does not exit particles to enter the cytoplasm.
Transcription and capping of viral mRNAs occur within particles and are mediated by particle-associated enzymes.
Segment assortment and packaging involves mRNAs.
Minus-strand synthesis occurs within assembling particles.
Mature virions are inefficiently released from infected cells by lysis.

hood illnesses associated with reovirus type 2 infection suggested an increased incidence in summer months (June–September).

Host Range and Viral Propagation

Evidence of infection as documented by virus isolation or the presence of antireovirus antibodies, has been found in an enormous variety of animal species including humans, a wide variety of nonhuman primates, swine, horses, cattle, sheep, goats, dogs, cats, rabbits, rats, mice, guinea pigs, voles, bats, a large number of marsupials and several avian species. The clinical syndrome produced by natural reovirus infection in animals includes predominantly respiratory, enteric and neurological disease. Among the more commonly described diseases are conjunctivitis, rhinitis, other upper respiratory tract infections, and pneumonia in horses, cattle, sheep and pigs. Dogs and cats can develop neurological illnesses including encephalitis and 'ataxia' in addition to respiratory and enteric illness. In birds, infection may produce arthritis, enteritis and hepatitis.

Reoviruses can be propagated in a variety of cultured cells. Cytopathic effects (CPE) can be seen in a wide variety of cell types derived from different animal species and tissues including mouse strain L clone 929 cells ('L cells' 'L929 cells', ATCC CCL1), human HeLa cells (ATCC CCL2), African green monkey kidney cells (CV-1, ATCC CCL70), and human embryonal kidney cells (HEK). Growth of virus for preparation of viral stocks, purification of virions, and quantification of viral titer by plaque assay is most commonly performed in L929 cells.

Genetics

The genome of reoviruses consists of equimolar quantities of ten discrete segments of dsRNA which can be divided into three size classes: large (dsRNA

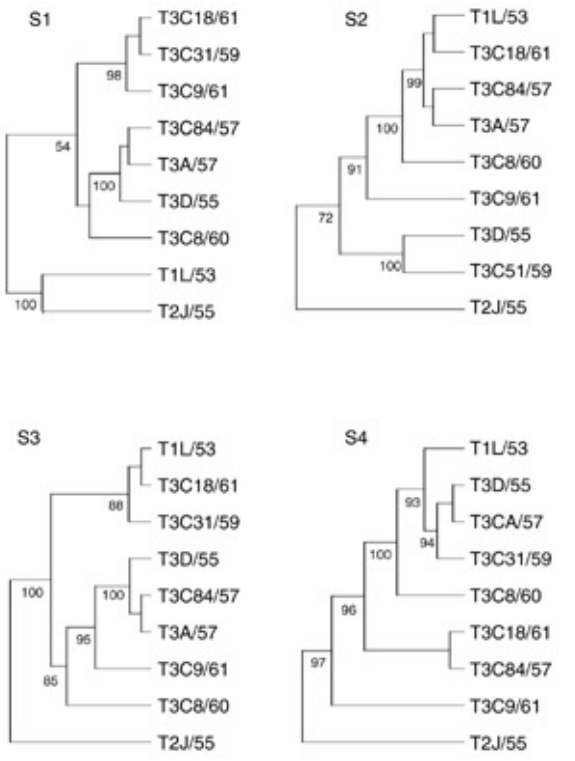

Figure 1 Phylogenetic trees indicating the potential evolutionary relationship and degree of diversity or relatedness between reovirus strains based on the nucleotide sequences of the reovirus S1, S2, S3, and S4 dsRNA segments. Each tree is rooted at the midpoint of its longest branch. (Reproduced with permission from Virgin *et al* (1997).)

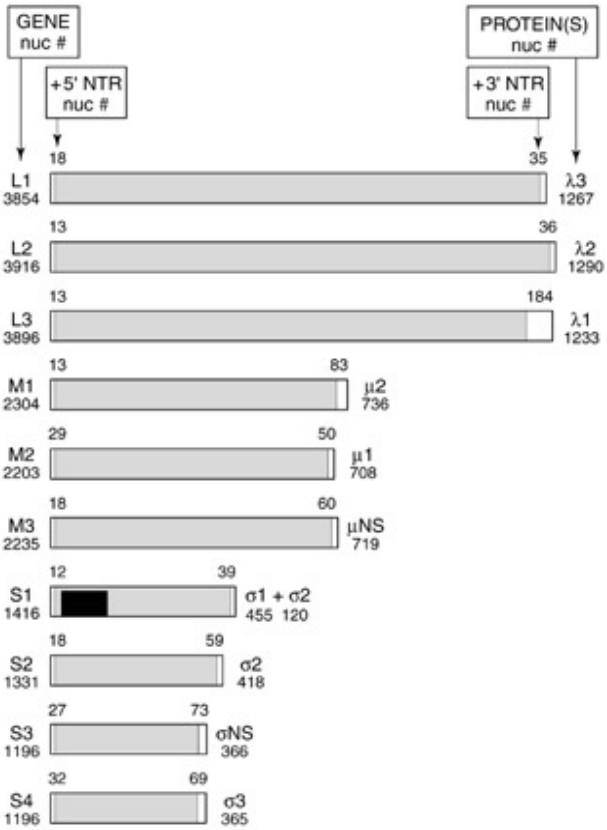

Figure 2 Coding strategies of the ten reovirus gene segments. The names of the individual reovirus dsRNA segments are shown on the left, along with their length in nucleotides. The name and size of the protein(s) encoded by each dsRNA segment are shown on the right. The lengths of the nontranslated regions (in nucleotides) are also indicated. Note that each dsRNA segment encodes a single protein with the exception of the S1 dsRNA segment. The S1 dsRNA segment encodes two proteins from different but overlapping open reading frames. (Reproduced with permission from Nibert *et al* (1996).)

segments L1, L2, L3), medium (M1, M2, M3) and small (S1, S2, S3, S4). dsRNA segments belonging to the three size classes can be distinguished on the basis of their different mobility patterns when subjected to polyacrylamide gel electrophoresis (PAGE). The cognate dsRNA segments of different reovirus strains often have different mobility patterns. Differences in the PAGE mobility pattern of gene segments derived from reoviruses belonging to different strains or serotypes has facilitated identification of the derivation of individual genes in reassortant viruses derived from co-infection of cells or animals with two distinct reoviruses (see below).

Nucleotide and derived amino acid sequence information is available for each of the ten dsRNA segments from at least one strain of reovirus (**Fig. 2**). The nucleotide sequence of the genome of the prototype strain T3D is 23.55 kilobase-pairs (kbp) in length. Individual dsRNA segments range in size from 1196 bp (S4) to 3916 bp (L2). The 5′-nontranslated regions (NTR) are extremely short, the largest being only 32 nucleotides. The longest 5′-NTR, that of the L3 segment, is 184 nucleotides. All other dsRNA segments have 5′-NTR of $\leq$83 nucleotides. The gene segments encode protein ranging in size from 365 amino acids (S4) to 1290 amino acids (L2). dsRNA segments are typically transcribed into a full-length mRNA from a single open reading frame (ORF). Each mRNA is translated into a single protein species. An exception to this scenario involves the S1 dsRNA segment which encodes two proteins (σ1, σ1s) from separate initiator sites in different, but overlapping, reading frames. Further details on the properties of the reovirus genome and reovirus replication are contained in the following entry on Reoviruses: Molecular Biology.

A number of mutants of reovirus have been identified or created in the laboratory. Temperature-sensitive (ts) mutants, defined by their reduced capacity to replicate at nonpermissive (39°C) com-

pared to permissive (31°C) temperatures, have been created by chemical mutagenesis with nitrous acid, nitrosoguanidine, or proflavin. These ts mutants have been classified into ten ts groups (tsA–tsJ) representing mutations involving each of the ten reovirus dsRNA segments. Several intra- and extragenic suppressor mutants resulting in reversion of the ts− to the ts+ phenotype have also been identified. Additional reovirus mutants have been generated and selected based on their resistance to inactivation by physicochemical agents such as ethanol, or by their resistance to neutralization by monoclonal antibodies specific for the $\sigma 1$ protein. Reovirus mutants, including deletion mutants, can also be identified in high passage viral stocks. These deletion mutants typically contain deletions involving the L1, L2, L3 and M1 dsRNA segments. Mutant viruses have also been selected based on their capacity to generate persistent infections (PI viruses), by selecting revertant viruses from hemagglutination-negative (HA−) T3 strains which have regained the capacity to bind to bovine erythrocytes or murine erythroleukemia (MEL) cells, and by serial passage through the brains of neonatal mice.

Evolution

Comparison between the complete nucleotide and derived amino acid sequences from the S1, S2, S3 and S4 dsRNA segments of a large number of reovirus strains has allowed the construction of phylogenetic trees indicating potential evolutionary relationships between various reovirus strains (**Fig. 2**). Of these four gene segments, the S1 dsRNA segment shows the most extreme diversity between viruses belonging to different serotypes. Within strains belonging to a particular serotype the degree of diversity in the S1 dsRNA segment is considerably less than the diversity between serotypes. It has been suggested that there were originally three 'progenitor' S1 genes representative of the current three viral serotypes, which have subsequently diverged to produce the differences seen between strains of virus belonging to the same serotype.

Comparison of the evolutionary relationships between reovirus strains differ strikingly depending on which dsRNA segment is used for analysis (**Fig. 2**). This provides strong evidence that reoviruses can and have reassorted their dsRNA segments in nature. Reovirus reassortants can be easily generated *in vitro* by co-infection of susceptible cells with two distinct strains of virus. Reassortant viruses can also be isolated from mice simultaneously co-infected with two different reovirus strains. These studies provide experimental support for the feasibility of reassortment.

In distinction to the evidence supporting reassortment of dsRNA segments between reovirus strains is the absence of evidence indicating that recombination occurs between either homologous or heterologous dsRNA segments.

Serologic Relationships and Variability

As discussed above, reoviruses are classified into three serotypes on the basis of reactivity with type-specific polyclonal or monoclonal antibodies in reactions including hemagglutination inhibition and plaque-reduction neutralization. Each serotype is represented by one or more prototype strains including reovirus serotype 1 Lang (T1L), serotype 2 Jones (T2J), and serotype 3 Dearing (T3D) and Abney (T3A). In addition to the prototype viruses, many additional strains have been isolated, characterized to varying degrees, and classified according to serotype. Variability between viruses belonging to different serotypes and/or strains has been analyzed based on variability in the nucleotide and derived amino acid sequence of their cognate dsRNA segments (see above).

Epidemiology

The majority of individuals have developed detectable serum antireovirus antibodies against all three reovirus serotypes by late childhood. Seroepidemiological studies suggest that less than 25% of children ≤ 1 year-old are seropositive for reovirus antibodies, but that by ≥ 3 years of age over 70% of individuals are seropositive. The majority of cases of reovirus infection in humans appear to be sporadic in nature, although outbreaks of infection caused by reovirus serotype 1 have been described. Age-related susceptibility to reovirus infection has also been observed in both natural and experimental infections in non-human animals. Calves, foals, piglets, and neonatal mice all appear more susceptible to reovirus infection than their adult counterparts. Experimental studies in mice indicate that the host's immune status is another important factor in determining the nature and outcome of reovirus infection. Immunocompetent adult mice develop an immune response but do not show clinical or pathological evidence of disease following reovirus infection. By contrast, after reovirus infection SCID (severe combined immunodeficient) mice develop prominent and often lethal hepatic disease. SCID mice, and mice with targeted disruptions of the transmembrane exon of IgM (i.e. antibody and B cell deficient mice), show altered

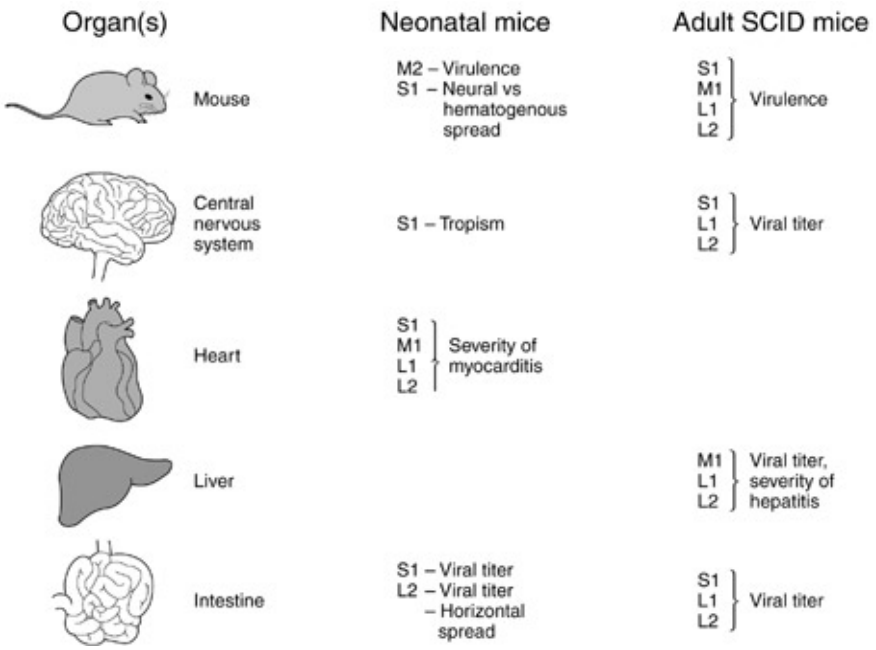

Figure 3 Reovirus dsRNA segments shown to have a role in determining organ-specific virulence in mice. (Reproduced with permission from Virgin *et al* (1997).)

patterns of viral clearance following peroral inoculation of reovirus.

Transmission and Tissue Tropism

Reoviruses are respiratory and enteric viruses whose transmission ('horizontal spread') under natural circumstances involves respiratory aerosols and secretions and fecal–oral transmission. Following oral inoculation in mice reovirus strains differ in their capacity to grow in intestinal tissue. There is an excellent correlation between the capacity of reoviruses to grow in the intestine, the amount of virus subsequently shed in the stool, and the efficiency with which an infected animal transmits disease to its uninfected litter mates. Genetic studies using reovirus reassortants derived from strains exhibiting high and low transmission efficiency indicate that the viral *L2* gene, which encodes the core spike protein λ 2, is the primary determinant of the efficiency of viral transmission following peroral inoculation. Both the *L2* and the *S1* genes influence growth and survival of reovirus in intestinal tissue (**Fig. 3**).

Transmission is also influenced by the capacity of the virus to survive in the environment after being shed from an infected host. Most reoviruses are generally stable at temperatures below room temperature, although at higher temperatures strain-specific differences in thermostability become apparent. One index of thermostability is the time required for a viral stock to lose 50% of its infectivity at 37°C. Reovirus T1L has $t_{1/2}$ of 19 h compared to 2.6 h for T3D. Reoviruses are also stable in aerosols, especially in the presence of high relative humidity. Studies of the genetic basis of physicochemical inactivation of reoviruses indicate that the viral outer capsid proteins are the major determinants of virion stability.

The basic steps in the pathogenesis of reovirus infection have been extensively studied in experimental animals including mice and rats. After peroral or intratracheal inoculation reoviruses adhere to the surface of epithelial M (microfold) cells. These cells overlie collections of lymphoid tissue in the small intestine and bronchi that form part of the systems of gut-associated lymphoid tissue (GALT) and bronchus-associated lymphoid tissue (BALT). In the intestinal lumen virions are partially digested by proteases into intermediate subviral particles (ISVPs). ISVPs lack the major outer capsid protein σ3, contain a partially cleaved form of the major outer capsid protein μ 1C, and contain the cell attachment protein σ1 in an extended conformation. It appears that, at least in the intestine, ISVPs are the form of virus particles that bind to M cells. After binding to M cells ISVPs and/or virions are transported across these cells to the underlying intestinal lymphoid tissue. Studies

of intestinal infection suggest that replication may occur in macrophages within mucosal lymphoid tissue.

Spread of virus from the site of primary infection to distant tissues and organs results in systemic disease. Reoviruses are capable of spreading in the host by means of the lymphatic system, through the bloodstream, or via axoplasmic transport within neurons. Reovirus strains differ both in their capacity to generate and sustain viremia and the efficiency with which they utilize neuronal transport. Following footpad or intramuscular infection in neonatal mice, reovirus T1L spreads to the central nervous system (CNS) primarily through the bloodstream, whereas T3D spreads predominantly through neural pathways. Studies of this pathway of spread using T1L × T3D derived reassortant viruses indicate that the viral *S*1 gene determines the pathway of spread used by reoviruses in the infected host (**Fig. 3**). Similarly, studies of the spread of reoviruses to extraintestinal organs following peroral inoculation into mice also indicate that the viral *S*1 gene is the major determinant of the extent of extraintestinal spread in this experimental model.

Depending on the viral strain, the route of inoculation and host factors such as the age and immune status of the host, reoviruses can produce injury in a variety of target tissues. Among the most extensively studied targets of viral infection in murine model systems are the CNS, the lung, the heart, the hepatobiliary system and the gastrointestinal tract. The specific pathology induced in these various organ systems is discussed extensively in the references included at the end of this chapter.

Reovirus strains often show striking differences in their pattern of organ and tissue tropism. These differences are particularly, but not exclusively, evident in reovirus infection of the CNS. For example, the prototype T3D strains infects neurons and retinal ganglion cells whereas the prototype T1L strain infects ependymal cells, and cells in the anterior lobe of the pituitary gland. Using T1L × T3D reassortant viruses it has been shown that differences in the tropism of reoviruses in the brain, the pituitary gland and the retina are all determined by the viral *S*1 gene. This gene encodes the virus cell attachment protein as well as a small nonstructural protein (σ1S). Studies with monoclonal antibody resistant σ1 variants of T3D, indicate that even single amino acid substitutions within this protein are sufficient to alter the neurovirulence, CNS growth and pattern of CNS tropism of reoviruses.

Tropism is obviously influenced by the nature and distribution of viral receptors on host cells. The nature of the reovirus receptor(s) on cells is only incompletely understood, and the nature of the reovirus receptor(s) on host cells remains controversial. Reoviruses appear to utilize different receptors on different types of cells. Sialic acid residues appear to be important for the binding of reoviruses to a variety of cultured cells and for their capacity to hemagglutinate erythrocytes. Studies with anti-idiotypic antibodies have suggested that reovirus binds to a surface receptor complex that contains components of M_r 65 kDa (p65) and 95 kDa (p95). It has been suggested that the p65 receptor component has structural similarity to the family of receptors that include the β-adrenergic receptor and that the p95 component either has or is associated with a tyrosine kinase activity. Interestingly, the state of tyrosine kinase activity in target cells has also been shown to influence the severity of reovirus-associated cytopathic effects in certain target cells. It is clear that if reoviruses bind to members of the β-adrenergic receptor family they do so without triggering any of the usual pharmacologic activities associated with β-adrenergic receptor binding (e.g. stimulation of adenylate cyclase activity). Reoviruses can also bind to the epidermal growth factor receptor (EGF-R), and the activity of this receptor may influence the efficiency of reovirus infection in certain cultured cells. Additional candidate reovirus receptor proteins that appear to be distinct from either sialic acid residues or the p65/p95 receptor complex have been identified on some cells.

Clinical Features and Infection

Reoviruses remain as much human orphan viruses as when they were first described (**Table 2**). Seroepidemiological studies indicate that human infection occurs during early childhood. The clinical correlates of this infection are difficult to determine accurately. It would appear that the overwhelming majority of human infections are either asymptomatic or produce mild symptoms of upper respiratory or intestinal infection or in some cases exanthema with fever. The predominant symptoms in children during an outbreak of T1 infection included rhinorrhea (81%), pharyngitis (56%) and diarrhea (19%), although the extent to which these were attributable exclusively to the reovirus infection itself is unclear. Over half the children shed reovirus in the stool for at least one week, and 21% shed virus for at least two weeks. The longest reported duration of stool shedding of virus was five weeks. Deliberate inoculations of adult human volunteers with reoviruses produces similar patterns of infection to those that appear to occur under natural circumstances. Reovirus seronegative volunteers nasally inoculated with T1L are typically

Table 2 Reovirus as a possible human pathogen

asymptomatic. Approximately one-third of individuals develop symptomatic infection lasting 4–7 days and beginning 24–48 h after viral challenge. The predominant symptoms include fever, headache, coughing, sneezing, rhinorrhea and generalized malaise. Infection is associated with shedding of virus in the stool and seroconversion. Challenge with T2J has not been associated with clinical illness in volunteers, but is associated with seroconversion and shedding of virus in stools. Individuals challenged with T3D are also generally asymptomatic or develop mild rhinitis. Infected volunteers shed virus in the stools and show seroconversion. In general, individuals with preexisting antireovirus antibody prior to challenge with reoviruses do not develop signs of clinical disease and do not shed significant amounts of virus in stool.

Reovirus infection of mice produces a disease whose clinical and pathological features resemble human extrahepatic biliary atresia (EHBA). Attempts to link reovirus infection to human EHBA have produced conflicting results. Some serologic studies show a higher frequency or higher titers of antireovirus antibodies in children with EHBA as compared to controls, whereas other studies do not. Reovirus has not been directly isolated from pathological specimens obtained at biopsy, surgery or autopsy from patients with EHBA nor has reovirus antigen been detected in liver or biliary tissues of EHBA patients by immunocytochemistry. However, reovirus nucleic acid corresponding to the L1 gene segment is detectable by polymerase chain reaction (PCR) with significantly greater frequency in liver and biliary tissues of patients with extrahepatic biliary atresia and choledochal cysts compared with liver and biliary tissues from patients with other liver diseases.

There are occasional reports of an association between reovirus infection and human diseases including meningitis, encephalitis, keratoconjunctivitis, and pneumonia. These cases are sufficiently rare and unusual as to suggest that if reovirus is involved in the production of these diseases it must be an exceedingly unusual event. It is important to recognize that currently available studies suggest that reoviruses are only responsible for a vanishingly small percentage of the total number of cases of these various illnesses.

Pathology and Histopathology

Pathological studies of material from humans infected with reovirus are exceedingly rare. Most of our current knowledge of the pathology of reovirus infection comes from studies of experimental infection in animals, notably mice. A detailed description of the pathology of reovirus infection in different organs is beyond the scope of this chapter, and interested readers should consult the references for further reading. As noted, in mice the brunt of reovirus infection and injury involves the CNS, the lungs, the heart, the liver and biliary tree, and the intestinal tract. The nature and severity of injury depends on the strain of virus, route of inoculation, and host factors include the age and immune status of the infected animals. The pattern of injury shows considerable variation. In some cases virus induces significant destruction of tissue with minimal or absent early inflammatory response. This pattern of infection can be seen in the CNS after intracerebral inoculation of T3D, and in the heart after intramuscular inoculation of reovirus 8B. Conversely, reovirus can also generate more prominent perivascular and parenchymal inflammation with less tissue injury. This pattern is often seen in skeletal muscle following intramuscular inoculation of T1L.

Recent studies indicate that reoviruses can produce apoptosis in infected L929 and MDCK cells in culture. Reovirus strains differ in this capacity with T1L strains producing less apoptosis than T3 strains. Studies using reassortant viruses derived from apoptotic-inducing (APO+) and non-inducing (APO−) strains (e.g T1L × T3D or T1L × T3A) indicate that the viral *S1* gene is a major determinant of the capacity of these viruses to induce apoptosis. Recent studies indicate that apoptosis also occurs *in vivo* in the CNS following intracerebral inoculation with T3D. Virus-infected (antigen positive) and apoptotic cells (TUNEL positive) colocalize to the regions of the brain that show the brunt of neuropathological

injury. At a cellular level, colocalization studies suggest that apoptotic cells may be either virus-infected or 'bystander' cells in proximity to virus-infected cells.

Immune Response

Following natural or experimental reovirus infection antibodies specific for a variety of reovirus structural and nonstructural proteins are produced. The bulk of both the immunoglobulin (Ig)A and IgG antibody response appears to be directed against viral structural proteins. There is no evidence that reovirus infection results in production of antibodies against nonprotein viral antigens (e.g. nucleic acid). The majority of the antibody response is not serotype specific, as would be expected by the high degree of homology between most reovirus proteins between viruses belonging to different serotypes. Serotype-specific immune responses are directed against the reovirus $\sigma 1$ protein, which is the least conserved of the reovirus proteins. Currently available monoclonal antibodies directed against the $\sigma 1$ protein (e.g. 9BG5, 5C6) are serotype-specific and show minimal if any crossreactivity between viruses belonging to different serotypes. Monoclonal antibodies directed against the reovirus outer capsid proteins $\sigma 3$ and $\mu 1$ are all crossreactive between reoviruses belonging to different serotypes, although in some cases they may show differing degrees of reactivity to viruses belonging to different serotypes or to individual viral strains within a serotype.

The nature of the reovirus-specific antibody response is influenced by the route of viral inoculation. Following peroral inoculation of reovirus T1L there is an increase in the number of reovirus-specific IgA-producing cells in intestinal Peyer's patches and in the spleen. Enteric infection is also associated with the induction of IgG antibody, predominantly of the IgG_{2a} and IgG_{2b} subclasses. Intradermal inoculation of reovirus does not result in significant IgA production, but instead induces predominantly reovirus-specific antibody belonging to the IgG_{2a} and IgG_{2b} subclasses. Variations in the dominant reovirus-specific IgG antibody subclass are influenced both by the route of virus inoculation and the strain of mouse: for example, IgG_1 antibodies are induced in some strains of mice following intradermal inoculation of virus.

T cell responses are induced during reovirus infection. Following peroral inoculation of reovirus, virus-specific major histocompatibility complex (MHC)-restricted cytotoxic T lymphocytes (CTLs) can be found in Peyer's patches and among the intraepithelial intestinal lymphocyte population. These cells are CD8+, bear the alpha/beta T cell receptor (TCR), and are capable of MHC-restricted lysis of reovirus-infected target cells. The number of these reovirus-specific intraepithelial CTLs increases dramatically after intestinal infection with reoviruses. Studies of $V\beta$ TCR usage indicate that reovirus infection is associated with increases in CTLs bearing $V\beta$ 7, 12, 14 and 17 TCRs, suggesting that reovirus infection is associated with oligoclonal expansion of specific TCR subpopulations.

Both serotype-specific and nonspecific CTL responses occur following reovirus infection. Serotype-specific CTL responses are directed against products of the *S*1 gene. As noted, this gene encodes the viral cell attachment protein $\sigma 1$ and a small nonstructural protein $\sigma 1S$. Nonserotype-specific CTL responses are presumably directed against epitopes on proteins other than $\sigma 1$ or on conserved epitopes within the $\sigma 1$ protein. The exact peptide epitopes recognized by MHC class I or class II restricted reovirus-specific T-cells have not yet been identified.

The role of antibody and T-cells in protection against reovirus infection has been investigated by passive transfer experiments, by selective depletion of B cells and T-cell subsets in mice, and in immunodeficient mice. Both antibody and reovirus-specific lymphocytes can protect mice against challenge with a variety of reovirus strains and from infection by a variety of different routes. Although direct comparisons are difficult, it appears that passively transferred reovirus-specific immune cells are more effective than antibody in controlling viral replication at primary sites, although systemic IgG antibody does permit viral clearance from mucosal surfaces. Conversely, antibody may be more effective than immune cells in controlling growth and spread of virus within certain tissues or organs including the CNS.

Studies with monoclonal antibodies indicate that passive protection can be conferred by antibodies specific for each of the reovirus outer capsid proteins ($\sigma 1$, $\mu 1C$, $\sigma 3$). *In vitro* studies suggest that protective antibodies may act at a variety of steps in the reovirus replication cycle including inhibition of viral binding to cell surface receptors, penetration of host cell plasma membranes, and inhibition of the intralysosomal proteolytic processing of virions to ISVPs. Similarly, *in vivo* protection can be associated with inhibition of viral replication at primary sites, spread of virus through nerves or the bloodstream to critical target tissues such as the CNS, and growth and spread of virus within these tissues.

Studies with passively transferred reovirus-specific T cells indicate that both CD4 and CD8 cells are required for optimal production and that depletion of either subset results in a significant loss of protective

capacity of transferred cells. There is currently no evidence that intestinal intraepithelial γ/δ TCR+ T cells, as opposed to α/βTCR+ T cells, play a significant role in immunity to reovirus infection. As noted earlier, both SCID mice, and antibody and B cell-deficient mice show increased susceptibility to reovirus infection and diminished capacity to clear viral infection. Adult SCID mouse, unlike their congeneic immunocompetent counterparts, develop lethal hepatitis after peroral infection with reovirus T1L or T3 clone 9. Similar results have been found in immunocompetent neonatal mice depleted of CD4 and/or CD8 T cells. This suggests, that at least in certain organs, T cells play a critical role in controlling reovirus infection.

Studies of experimental reovirus-induced pulmonary infection in rats indicate that there are serotype-specific differences in the capacity of reoviruses to induce cytokine gene expression and cellular inflammatory responses. T3D is associated with significantly greater neutrophil influx into the lung than T1L. T3D-induced pulmonary neutrophilia correlates with the capacity of T3D to induce expression of tumor necrosis factor alpha (TNFα) and macrophage inhibitory protein 2 (MIP 2) mRNAs and proteins. Peroral and intradermal infection with reovirus T1L in mice is associated with the production of interferon gamma (IFN-γ), and low levels of interleukin 5, although the magnitude of these responses varies significantly among different strains of mice. Reovirus strains differ in their capacity to induce IFN-γ following infection of cultured cells, with T3D typically inducing higher levels than T1L. In mice, the level of IFN-γ induction also varies with the strain of mouse infected. Induction of IFN-γ is associated with enhanced MHC I expression.

Reovirus strains differ in their sensitivity to IFN-γ, and this effect may vary in different cell types. Reovirus T3D appears to be generally more sensitive to the effects of IFN-γ than T1L. Therefore the amounts of IFN-γ induced and the effects of this induction on reovirus replication, involve a complex interplay between the nature of the infecting viral strain, the species of animal, and the particular tissue involved. Given this complexity it is perhaps not surprising that the role of IFN-γ in the pathogenesis of reovirus infection *in vivo* remains to be established. In the case of reovirus-induced myocarditis, there is an excellent correlation between the myocarditic potential of reovirus strains and the level of viral RNA produced by these strains in infected cells. Since dsRNA is a potent inducer of IFN-γ, this raises the possibility that differences in the amount of IFN-γ induction could potentially play a role in determining the severity of reovirus-induced myocarditis.

Prevention and Control

Because reoviruses are not important human pathogens, investigations of the prevention and control of reovirus infection are limited. In experimental models of infection protection can be conferred by passive transfer of both reovirus specific antibodies and immune cells. Several reovirus vaccines have been developed for veterinary use and appear to be reasonably effective in inducing reovirus-specific antibody responses and in preventing symptomatic infection. Most veterinary vaccines against reovirus utilize either formalin or β-propiolactone-killed virus. Protease inhibitors, which can prevent the conversion of reovirus virions into ISVPs, can protect against reovirus infection after peroral inoculation. In this experimental model, ISVPs appear to be the critical form of virus responsible for initiating infection and blockage of the digestion of virions into ISVPs by intestinal proteases prevents infection. Reovirus infection *in vitro* can be inhibited by ribivarin, acivicin and cicloxolone; but none of these agents has been tested against reovirus infection *in vivo*. These agents have a variety of mechanisms of action. For example, ribivarin is a guanosine analogue, acivicin is a glutamine analogue and cicloxolone is a monesin-like Golgi apparatus inhibitor.

Future Perspectives

Future studies of reoviruses are likely to provide more detailed information at the atomic level of the structure of the reovirus particle and the mechanisms by which the various structural proteins interact. Many aspects of the reovirus replication cycle remain obscure, particularly as they relate to the methods by which equimolar quantities of the ten dsRNA segments are correctly packaged in the virion. Increased understanding of the viral replication cycle may facilitate the development of experimental systems that allow gene segments to be modified and reinserted into virions. Many fundamental aspects of the interaction between reovirions and host cells remain to be delineated. This includes clarification of the nature of the reovirus receptor(s) on specific host cells, the nature of and mechanisms by which reovirus infection affects host cell signal transduction pathways, and the precise biochemical processes that lead to reovirus-induced inhibition of host cell macromolecular synthesis and ultimately cell death. A major theme of future reovirus research will certainly continue to be the effort to understand the molecular and genetic basis for specific steps in viral pathogenesis. Many areas of reovirus biology and pathogenesis remain to be explored. For example, the nature of the

age-related susceptibility to reovirus infection remains unknown. Many aspects of the fundamental immunology of reovirus infection remain obscure, such as the exact nature of the specific peptide epitopes recognized by reovirus-specific antibodies and immune cells, and the role played by cytokines in host defense against reovirus infection. Finally, the role, if any, of reoviruses as agents of human disease remains as mysterious now as it was 40 years ago.

Introduction

Reoviruses (*Re*spiratory entero) are members of the genus *Orthoreovirus* of the family *Reoviridae,* which also includes five other genera, namely, *Rotavirus* and *Orbivirus,* both of which are also viruses of vertebrates, *Cypovirus* of insects and *Phytovirus* and *Fijivirus,* both of which are plant viruses. The common characteristic features of all these genera are a basically similar particle morphology and size, and double-stranded RNA (dsRNA)-containing genomes that comprise 10, 11 or 12 genome segments.

Reoviruses are ubiquitous among mammals in which they usually do not cause overt disease. Mammalian reoviruses fall into three serologic subgroups or serotypes (ST1, ST2 and ST3), members of each of which are not neutralized by antisera against the other two.

Reoviruses have also been isolated from other vertebrates such as birds and reptiles, as well as from invertebrates, such as insects and molluscs. None of these viruses have been studied in biochemical or molecular terms except the avian reoviruses which fall into five serotypes. In contrast to mammalian reoviruses, they cause disease [the viral arthritis syndrome (VAS) and the stunted growth syndrome (transient digestive system disorder, TDSD)], as well as pericarditis/myocarditis, hepatitis and nephritis.

Most of our knowledge concerning the biochemistry and molecular biology/genetics of orthoreoviruses derives from studies of the mammalian reoviruses.

The Reovirus Particle

Reovirus particles consist of a core some 55 nm in diameter which is surrounded by an outer capsid shell that is about 12.5 nm thick (**Fig. 1**). Since the thickness of the core shell is about 7.5 nm, the central cavity accounts for about 12.5% of the reovirus particle volume, and the core for about 33%.

Both the outer capsid and the core shell are composed of capsomers which are arranged with icosahedral symmetry. The reovirus particle surface reveals 600 protrusions, presumably capsomers, arranged with $T = 13l$ symmetry in the form of shared hexamer rings around 120 holes. The core shell also possesses $T = 13l$ symmetry elements, but the arrangement of capsomers in them is difficult to discern (**Fig. 2**). However, cores possess 12 icosahedrally located columnar projections or spikes which are about 10 nm in diameter, possess central channels 5 nm in diameter, and project about halfway through the outer capsid shell in which they are visible as depressions or craters. The spikes, which can be removed from cores by incubating them at pH 11.4 at 4°C for 15 min, are pentamers of protein $\lambda 2$ and appear to be partially covered by 3 nm-thick 'lids' which appear to be trimers of protein $\sigma 1$ (see below).

The outer capsid shell is stable at high and physiological salt concentrations, but loses capsomers on storage at low ionic strength. It is readily digested by chymotrypsin to which the core shell is completely resistant. Virus particles and cores are readily separated by density gradient centrifugation; their sedimentation coefficients are about 630 and 470S, respectively, and their densities in cesium chloride density gradients are 1.36 and 1.43 g ml^{-1}, respectively.

age-related susceptibility to reovirus infection remains unknown. Many aspects of the fundamental immunology of reovirus infection remain obscure, such as the exact nature of the specific peptide epitopes recognized by reovirus-specific antibodies and immune cells, and the role played by cytokines in host defense against reovirus infection. Finally, the role, if any, of reoviruses as agents of human disease remains as mysterious now as it was 40 years ago.

Introduction

Reoviruses (*Re*spiratory entero) are members of the genus *Orthoreovirus* of the family *Reoviridae,* which also includes five other genera, namely, *Rotavirus* and *Orbivirus,* both of which are also viruses of vertebrates, *Cypovirus* of insects and *Phytovirus* and *Fijivirus,* both of which are plant viruses. The common characteristic features of all these genera are a basically similar particle morphology and size, and double-stranded RNA (dsRNA)-containing genomes that comprise 10, 11 or 12 genome segments.

Reoviruses are ubiquitous among mammals in which they usually do not cause overt disease. Mammalian reoviruses fall into three serologic subgroups or serotypes (ST1, ST2 and ST3), members of each of which are not neutralized by antisera against the other two.

Reoviruses have also been isolated from other vertebrates such as birds and reptiles, as well as from invertebrates, such as insects and molluscs. None of these viruses have been studied in biochemical or molecular terms except the avian reoviruses which fall into five serotypes. In contrast to mammalian reoviruses, they cause disease [the viral arthritis syndrome (VAS) and the stunted growth syndrome (transient digestive system disorder, TDSD)], as well as pericarditis/myocarditis, hepatitis and nephritis.

Most of our knowledge concerning the biochemistry and molecular biology/genetics of orthoreoviruses derives from studies of the mammalian reoviruses.

The Reovirus Particle

Reovirus particles consist of a core some 55 nm in diameter which is surrounded by an outer capsid shell that is about 12.5 nm thick (**Fig. 1**). Since the thickness of the core shell is about 7.5 nm, the central cavity accounts for about 12.5% of the reovirus particle volume, and the core for about 33%.

Both the outer capsid and the core shell are composed of capsomers which are arranged with icosahedral symmetry. The reovirus particle surface reveals 600 protrusions, presumably capsomers, arranged with $T = 13l$ symmetry in the form of shared hexamer rings around 120 holes. The core shell also possesses $T = 13l$ symmetry elements, but the arrangement of capsomers in them is difficult to discern (**Fig. 2**). However, cores possess 12 icosahedrally located columnar projections or spikes which are about 10 nm in diameter, possess central channels 5 nm in diameter, and project about halfway through the outer capsid shell in which they are visible as depressions or craters. The spikes, which can be removed from cores by incubating them at pH 11.4 at 4°C for 15 min, are pentamers of protein $\lambda 2$ and appear to be partially covered by 3 nm-thick 'lids' which appear to be trimers of protein $\sigma 1$ (see below).

The outer capsid shell is stable at high and physiological salt concentrations, but loses capsomers on storage at low ionic strength. It is readily digested by chymotrypsin to which the core shell is completely resistant. Virus particles and cores are readily separated by density gradient centrifugation; their sedimentation coefficients are about 630 and 470S, respectively, and their densities in cesium chloride density gradients are 1.36 and 1.43 g ml^{-1}, respectively.

The reovirus genome

The reovirus genome consists of ten segments of dsRNA, all of which have been cloned and sequenced (**Table 1**). They fall into three size classes termed L, M and S, members of which are about 3900, 2250 and 1300 bp long, respectively. The total length of the reovirus genome is 23 549 bp; it is one of the largest and therefore most complex of RNA-containing genomes. Small-angle x-ray diffraction studies indicate that the RNA segments exist within the central cavity in tight well-ordered packing arrangement with adjacent helices aligned locally parallel to each other rather like the DNA in T even bacteriophages.

Each of the ten reovirus genome segments possesses a major open reading frame (ORF) which varies in length from 365 to 1289 codons. Most of them also contain short ORFs in other reading frames at least one of which, in S1, is translated in infected cells (see below). The 5′-untranslated regions are all short (12–32 nucleotides); those at the 3′-ends are longer, but still (with one exception, L3 (182 nucleotides)) less than 85 nucleotides long. The four 5′-terminal and five 3′-terminal base pairs of all ten genome segments are identical (5′-GCUA- and -UCAUC-3′ for the plus-strands).

Reovirus oligonucleotides

Reovirus particles also contain about 3200 oligonucleotides of which about 2400 are 5′-G-terminated and are the products of abortive reiterative transcription catalyzed by the reovirus transcriptase (see below), and about 800 are oligoadenylates from 2 to 20 residues long. The latter may represent either an untemplated polymerase activity of the reovirus transcriptase committed to transcribe but unable to move along its template, or slippage transcription of the three genome segments (L2, M3 and S3) the 3′

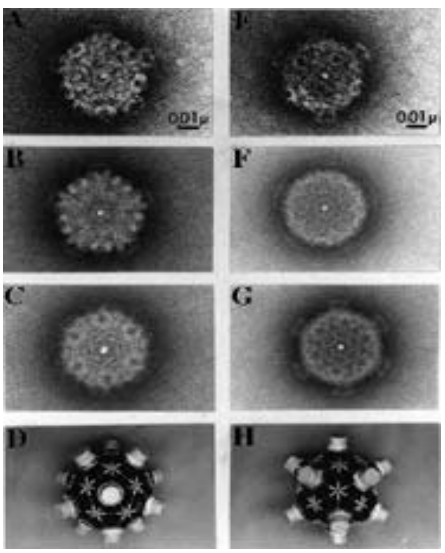

Figure 2 Two reovirus core particles the central axis of which passes through either a presumptive fivefold (**A**) or threefold (**E**) vertex. Enhancement of the five peripheral spikes of (**A**) was achieved by an $n = 5$ rotation (**B**), but not by an $n = 6$ rotation (**C**). (**D**) Model that depicts the spike orientations when the central axis is through a fivefold vertex. Enhancement of the six peripheral spikes (**E**) was exhibited with an $n = 6$ rotation (**G**), but not an $n = 5$ rotation (**F**). (**H**) Model with the central axis through a threefold vertex. The particles were stained with 2% uranyl acetate. (From Luftig RB, Kilham S, Hay AJ, Zweerink HJ and Joklik WK (1972) *Virology* 48: 170.)

ends of the minus-strands of which are CGAUUU- (see below).

Enzymes in reovirus cores

Since host cells do not contain enzymes capable of generating mRNA from dsRNA templates, reovirus particles contain the enzymes necessary for this purpose. Since reovirus mRNAs are capped at their 5′ ends, this involves possession of a transcriptase or RNA polymerase, an RNA triphosphatase to convert the 5′-terminal ppp groups generated by the transcriptase to the pp groups required by the guanylyltransferase, the guanylyltransferase itself and two methyltransferases to methylate the 7 position of the cap G and the 2′-O position of what was the 5′-terminal ribose of the uncapped RNA.

In core form the transcriptase is very stable and functions for long periods of time (more than 24 h) at elevated temperatures (up to 50°C), transcribing the genome segments many times.

The reovirus proteins

The various reovirus proteins are listed in **Table 1**. All reovirus proteins except μ1 have been isolated in native form from cells infected with recombinant vaccinia viruses with TK (thymidine kinase) genes containing reovirus genome segments inserted under the control of powerful promoters like the T7 polymerase promoter or the cowpox virus A-type inclusion body protein gene promoter.

The core shell components λ1 and σ2 The core shell consists of an inner layer of 120 or 180 molecules of protein σ2 and an outer layer of 120 molecules of protein λ1. The two proteins associate with each other *in vitro* and in cells infected with recombinant vaccinia viruses expressing them, core-like particles are formed. Protein λ1 possesses a nucleotide-binding site –TKGKSSG– starting at residue 8; a zinc finger motif centered around residue 194 (λ1 is a zinc-binding metalloprotein); and a weak dsRNA-binding site upstream of the zinc finger. It possesses two enzymic activities; it is a helicase and, as suggested by genome segment reassortant analysis, an RNA triphosphatase/ATPase. This enzyme activity may function in preparing transcripts for capping or to provide energy for the helicase-mediated unwinding of the dsRNA genome segments required for the transcription of their minus strands. Protein σ2 also binds dsRNA weakly and possesses a region that bears a striking similarity to a region in the β subunit of *Escherichia coli* DNA-dependent RNA polymerase.

The spike component λ2 Protein λ2, in the form of pentamers, is the reovirus spike. It is also the reovirus guanylyltransferase, that is, it is the capping enzyme. Protein λ2 exhibits strong epitopes that are exposed on the reovirus particle surface, are identical or very similar on all three (ST1, ST2 and ST3) λ2 proteins, and elicit the formation of group-specific antibodies. It possesses strong affinity for proteins σ1, λ1 and λ3. There is some evidence that is possesses SAM-

utilizing methyltransferase activity, but such an activity has not yet been demonstrated for isolated protein λ2.

The minor core components λ3 and μ2 Reovirus cores contain about 12 copies of each of two proteins, λ3 and σ2, that possess no apparent structural functions, but play very important roles in two key enzymic activities. One is protein λ3 which possesses several amino acid sequences or motifs that are present, and similarly spaced, in all positive strand- and dsRNA-dependent RNA polymerases, such as DxxxxxD, GxxxTxxx(N/E)(S/T) and GDD; the genome segment that encodes it, namely L1, controls the pH optimum of the transcription of dsRNA genome segments into mRNAs by cores; and is a poly(C)-dependent poly(G) polymerase. It is very likely, therefore, that it is the catalytic component of the reovirus RNA polymerase/transcriptase, specificity being supplied by another component, most likely μ2. It should be pointed out, however, that these two proteins exhibit no affinity for each other *in vitro*. However, it is also true that the intracore concentrations of these two proteins are very high (of the order of 0.1 M), so that high affinity may not be required for them to be capable of interacting. The second enzymic activity is the nucleoside triphosphatase activity. As pointed out above, this activity has been linked to protein λ1; but genome segment reassortant analysis has also linked it to protein μ2. Either there are two such activities in cores, or protein λ1 is its catalytic subunit and protein μ2 provides specificity or some other required function.

The outer capsid shell The reovirus outer capsid shell consists of 600 μ1C–σ3 complexes, with the former -SS- bonded and internal to the latter. The cleavage of μ1, which is myristoylated at its N-terminus, to μ1C and μ1N, its 42 amino acid-long myristoylated N-terminal fragment, occurs when μ1 associates with σ3 well before the insertion of the resulting complexes into the outer capsid shell; most μ1 in cells is free, whereas most μ1C is associated with σ3. Interestingly, most μ1N remains associated with μ1C and is also present in virus particles, as is a small amount of μ1 (about one-twentieth of the amount of μ1C). The presence of myristoyl groups in the reovirus outer capsid shell raises interesting questions concerning their function in the assembly and structural stability of the outer capsid shell, as well as during the uptake and entry of reovirus particles into cells (in analogy with the presence of myristoyl groups on picornavirus and other viral proteins).

Protein μ1C accounts for almost 40% of the reovirus protein complement. Antibodies against it neither precipitate virus particles, nor neutralize infectivity. Not surprisingly, protein μ1C plays a major role in specifying how reovirus particles interact with their environment. On the one hand, it controls sensitivity to chemical reagents like ethanol and phenol; on the other, it controls some aspects of tissue tropism because susceptibility of μ1C to proteolytic cleavage controls activation of the transcription of mRNA as the first step of the reovirus replication cycle (see below). It therefore specifies the extent to which reovirus replicates in the intestine, which in turn determines the extent to which it spreads to the central nervous system; it thus controls neurovirulence. It also plays a role in inducing serotype-specific immunologic tolerance and delayed-type hypersensitivity responses. Finally, there is evidence that μ1 is cytotoxic, apparently damaging membranes; and that it is one of the two reovirus proteins, the other being σ1, that inhibits cellular DNA replication and induces apoptosis in infected cells.

The second major component of the reovirus outer capsid shell is protein σ3 which has a variety of functions. First, it possesses a Zn-binding site in a zinc finger that encompasses residues 45–72 inclusive. Interestingly, residues 45–53 inclusive are very similar to a region in picornavirus proteases. Since σ3 is strongly implicated in the cleavage of μ1 to μ1C (see above), it was at first thought that this sequence might be involved; but it turns out that μ1 is cleaved even when it complexes with σ3 variants that lack this sequence. Rather the association of σ3 with μ1, which does not proceed in the absence of the zinc finger, causes conformational changes in μ1 that cause the cleavage to be autocatalytic. Second, σ3 possesses a strong dsRNA-binding site centered around residue 265, a remarkable property for an outer capsid shell component. However, sigma 3 also binds to ssRNA transcripts in vivo very soon after they are formed (see below), which suggests that its affinity is not for dsRNA per se, but for regions of ssRNA with dsRNA character such as hairpins (stem-loops) or intermolecular complementary regions.

Protein σ1 Protein σ1 is a reovirus particle component that exists in the form of 12 trimers inserted into the spikes that are composed of pentamers of λ2 (see above). Normally σ1 appears to form a lid that covers the channel of these spikes, but mild heat causes σ1 to assume the form of 48 nm-long 4–6 nm-wide fibers topped by 9.5 nm-diameter globular heads that extend from the surface of the virus particles, the heads containing the cell attachment site. Most of the N-terminal one-third of σ1 is made up of a series of about 20 tandemly arranged heptads in which the first and fourth amino acids are hydrophobic. This type of

sequence results in an alpha-helical coiled coil type structure in which the hydrophobic residues form the interfaces beween alpha-helices. It is these sequences that cause the trimerization of $\sigma 1$ which in turn generates the signals for its association with insertion into the spike channels.

Although present in reovirus particles to the extent of 36 molecules (only 3 of which are essential, that is, virus particles that possess only one $\sigma 1$ trimer are about one-half as infectious as virus particles that possess all twelve), protein $\sigma 1$ plays an extremely important role in specifying the interactions between reovirus particles with host cells and intact hosts. Protein $\sigma 1$ is the cell attachment protein (and the hemagglutinin); thus is specifies tissue tropism and is therefore the major factor in reovirus pathogenesis. It also elicits the formation of three forms of neutralizing antibodies that crossreact minimally, if at all; that is, $\sigma 1$ is the reovirus type-specific antigen. Protein $\sigma 1$ also induces delayed-type hypersensitivity, generates suppressor T cells and cytolytic T lymphocytes, and is recognized by cytotoxic T lymphocytes. Finally, genome segment reassortant analysis suggests that $\sigma 1$ inhibits cellular DNA synthesis and induces apoptosis in infected cells, and it plays a crucial role in the maintenance of persistment infections.

The nonstructural reovirus proteins Reovirus encodes three nonstructural proteins that are not virus particle components. Two are encoded by genome segments M3 and S3 and are produced in large amounts. The former, muNS, is produced in two forms, one of which is translated from the entire M3 ORF, whereas the other, designated muNSC because it was at first thought to be a cleavage product of muNS, is translated in the same reading frame but starting at AUG at codon position 42. Protein muNS has a very high alpha-helix content and in its C-terminal region shares a periodic sequence similarity pattern with various myosins. It rapidly complexes with newly-transcribed mRNAs with which it remains associated until they are transcribed into minus-strands to form progeny genome segments (see below). It possesses affinity for elements of the cytoskeletal framework which may play an important role in morphogenesis.

Protein σNS is another ssRNA-binding protein. Like proteins muNS and $\sigma 3$ it forms complexes with reovirus mRNA molecules very soon after they are transcribed. Proteins muNS and σNS possess affinity for each other as demonstrated by the fact that antibodies against either also precipitate the other.

The third nonstructural reovirus protein is the basic protein σ1S, encoded by the minor ORF in S1, which is formed in infected cells in small amounts. It localizes to the cytoplasm and to nucleoli where it could interfere with both DNA and RNA synthesis and/or expression. Its actual function may only be discovered by examining the phenotypes of knock-out mutants.

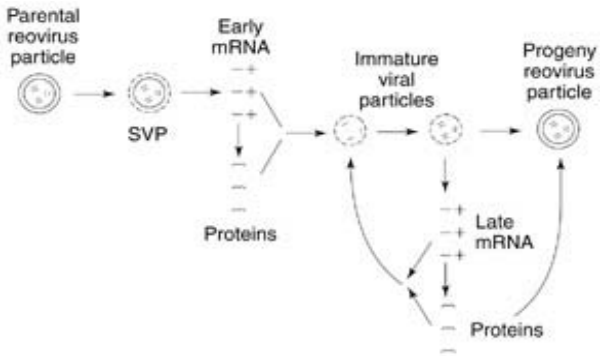

Figure 3 The reovirus multiplication cycle. SVP, subviral particle.

Reovirus Replication

Strategy

Reovirus multiplication exhibits two unusual features, both consequences of the fact that the reovirus genome is dsRNA, which means that a virus associated polymerase is required to generate mRNA, and the fact that it is segmented. As a result, parental genomes are not uncoated to naked RNA, and a highly complex mechanism functions to assort the ten genome segments into complexes that contain one, and one only, of each (**Fig. 3**).

Reovirus particles adsorb to specific receptors (see below) and internalized in endoplasmic vesicles that fuse with lysosomes within which the reovirus capsid shell is extensively degraded: a 12 kD fragment is cleaved from the C-terminal portion of μ1C to generate the 60 kDa protein δ, and proteins $\sigma 3$ and $\sigma 1$ are lost. The resultant particles, which are cores covered by an outer shell that consists only of protein δ and which are known as viral particles (SVPs), are liberated into the cytoplasm. The major functional difference between reovirus particles and SVPs is that the former genome segments are not transcribed into mRNA, whereas in the latter they are transcribed. The mRNAs are then translated into the various reovirus proteins and, after a certain interval, generally at about 3 h after infection, they begin to be transcribed into minus-strands with which they remain associated, thereby generating the progeny dsRNA-containing genome segments; and at the same time equimolar amounts of them are assorted into complexes. These complexes, or particles, then

transcribe the dsRNA molecules back into plus-strands, which are again either translated and/or used as templates for the generation of further ds genome segments. This cycle represents the multiplication phase of reovirus replication. As more dsRNA-containing complexes (dsRCCs) are generated and more reovirus proteins are formed, the protein complement of the dsRCCs is modified in stepwise fashion to generate first core-like particles and eventually complete, mature reovirus particles.

The nature of the reovirus receptor

There are several reovirus receptors that differ in their affinity for the cell-attachment sequences on the $\sigma 1$ proteins. Protein $\sigma 1$ itself possesses highest affinity for a 67 kDa glycoprotein and somewhat lower affinity for several other glycoproteins. The reovirus receptor on erythrocytes is glycophorin. The minimal essential receptor is the sialic acid residue at the ends of the carbohydrate prosthetic groups of glycoproteins. Presumably the remainder of the carbohydrate moiety and the protein modulate affinity and specificity.

All this evidence suggests a relatively nonstringent requirement for reovirus receptor recognition which is consistent with its very wide host range and its ability to bind to and infect a variety of cell types in the body.

The activation of the reovirus transcriptase

Reovirus particles do not transcribe mRNA; SVPs do so. This is not due to the fact that the transcriptase is inactive in virus particles; on the contrary, transcription initiation proceeds normally in virus particles, but transcription ceases before transcripts are more than four to six residues long and then reinitiates. The products of this abortive reiterative transcription are 5′-triphosphorylated – and also often capped – oligonucleotides, the sequence of most of which is $GCUA_n$ or $GCUAU_n$ where n is 1–4, and which remain associated, at least temporarily, with reovirus particles, in which they make up the bulk of the approximately 2400 5′-G-terminated oligonucleotides that they contain (see above).

SVPs, by contrast, are capable of transcribing full-length mRNA molecules, although for them also the majority (of the order of 90%) of transcripts are abortive transcripts. Clearly, what is activated is not the transcriptase, but rather the movement of template segments relative to the transcriptase catalytic site. Exactly what is involved in this release of movement is not known. Physicochemical evidence indicates that the conversion of reovirus particles to SVPs or cores triggers a conformational change in the dsRNA.

Transcription and translation of reovirus mRNA

Under optimal conditions of NTP and Mg^{2+} concentration, reovirus cores transcribe all ten genome segments at the same rate, that is, in amounts inversely proportional to their sizes. In infected cells, the relative proportions of the various species of mRNAs that are formed generally differ in two respects: there is usually a deficiency in the relative amounts of the *l* size class species, and during the early phase of the multiplication cycle, before progeny dsRNA genome segments have been formed, several species of mRNA (*l*1, *m*3, *s*3 and *s*4) appear to be formed in amounts larger than the rest. The basis of this effect, which is variable – often it is the *m*2, *s*3 and *s*4 species that are formed in relatively higher proportions, and often the effect is not limited to the early period – is not known.

Whereas these effects on the relative transcription frequencies are variable and quantitatively minor (that is, the excess transcription efficiencies are no more than two- to threefold), the relative translation efficiencies of the ten species of reovirus mRNAs differ enormously. The most efficiently translated mRNA species is usually species *s*4, followed by *m*2 (relative translation efficiency 0.67), *s*2 and *s*3 (slightly less than 0.5), *m*3, *l*2 and *l*3 (0.25–0.33), *s*1 (0.1) and *l*1 and *m*1 (0.01). These differences in relative translation efficiencies are due to differences in the sequences that surround and lie upstream of the initiation codons. Not only does the well-known Kozak rule apply, namely, positions −3 and +4 relative to the first nucleotide of the initiation codon must be G or A, but the nature of nucleotides at least as far upstream as position −8 also profoundly affects translation efficiency, depending on the nature of the nucleotides in positions −1 to −3. There is also an optimal length of the 5′-untranslated region (about 14 nucleotides), and there are also secondary structure constraints: the 5′-upstream sequence, including the initiation codon, must not be part of a stable stem-loop, and the 5′-cap must be accessible, that is, it also must not be part of or too close to, a stem-loop.

The fact that reovirus cores contain enzymes that catalyze the entire capping reaction indicates that capping is very important for reovirus mRNA translation. Some studies have suggested that late reovirus mRNAs are uncapped and that reovirus infection modifies the host cell translational machinery, so that late uncapped viral mRNAs are translated preferentially over capped cellular mRNAs, or that a factor in reovirus-infected cells stimulates translation of late uncapped reovirus mRNAs. Other studies have found that reovirus-infected cells can translate both uncapped and capped mRNAs, which confirms earlier studies that indicated that possession of a cap facili-

tates translation, but is not essential. It has also been suggested that the preferential translation of reovirus mRNAs in infected cells is mediated at the level of competition between mRNAs for a limited amount of a message-discriminatory factor. The resolution of all this conflicting evidence may lie in the finding that, like infection with many other viruses, infection with reovirus activates, via the generation of dsRNA or of short sequences in ssRNA with a locally dsRNA-like character, a cellular protein kinase that phosphorylates the α subunit of protein synthesis initiation factor eIF-2, thereby inactivating it and inhibiting protein synthesis, including the synthesis of reovirus proteins; and that protein $\sigma 3$, by virtue of its affinity for dsRNA (see above), prevents this activation. Thus protein $\sigma 3$ itself may be the factor that is essential for the efficient translation of late reovirus mRNAs.

The assortment of genome segments into reovirus genomes

The mechanism responsible for assorting the ten genome segments into genomes containing one of each is one of the most fascinating problems of reovirology; and very little is known about it. Since it is much easier to imagine how ssRNA molecules can be recognized by each other and by proteins than dsRNA molecules, it has always been assumed that assortment proceeds at the level of ssRNA. However, such ssRNA-containing complexes (ssRCCs) cannot be found. Rather it appears that the plus-strands associate with three viral proteins very soon after they are formed: the nonstructural protein μNS, the nonstructural protein σNS and $\sigma 3$. The resultant complexes contain one molecule of RNA and 15–30 molecules of these three proteins, depending on their length; most of them contain μNS, as well as σNS and/or $\sigma 3$. Presumably the binding is sufficiently reversible not to interfere with the RNAs being translated. The relative amounts of the various ssRNA species in the populations of these complexes reflect the relative frequencies with which they are transcribed (see above). Very significantly, however, even the first double-stranded RNA-containing complexes (dsRCCs) that can be detected (and which contain $\lambda 2$ as a major component as well as, presumably, $\lambda 3$) contain strictly equimolar amounts of all ten genome segments. This suggests that the generation of dsRNA genome segments and their assortment into genome sets are functionally linked and concomitant events; and it focuses attention on the RNA polymerase $\lambda 3$ as a key effector of assortment.

Infectious reovirus RNA

Since the only molecular links between parental and progeny virus particles are the plus-strands transcribed by SVPs, infectious reovirus should in theory be formed in cells into which the ten species of plus-stranded RNA are introduced. Conditions have indeed been found recently under which reovirus RNA is 'infectious' in this sense. The basic system consists of lipofecting into cells all ten species of ST3 ssRNA together with rabbit reticulocyte lysates in which all ten species of ST3 ssRNA have been translated for 60 min, and infecting these cells 4–8 h later with ST2 reovirus. When analyzed for their virus content 24 h later, ST3 virus is found to be present in these cells to the extent of 10^3 to 10^4 plaque-forming units (PFU)/10^6 cells. If ST3 dsRNA is also lipofected at the same time, the virus yields are 100 times higher; and most of the increased amount of virus can be shown to be the progeny of the ssRNA, not the dsRNA, the function of which is therefore to enhance the infectivity of the former.

This system is very important because it permits identification of the signals that are required for the introduction of heterologous, that is, novel, genetic information into the reovirus genome. Clearly there must be recognition signals on incoming, that is, to-be-accepted, genome segments because orbivirus or rotavirus genome segments, for example, are not accepted. What is very unexpected, however, is that there are also acceptance signals: thus the reovirus ST3 genome will not accept novel genome segments like, for example, ST2 genome segments, unless the S4 genome segment of the accepting ST3 genome is a variant of the normal wild-type S4 genome segment that contains two point mutations, one of which causes an amino acid change, whereas the other does not. The discovery of these acceptance signals permits the introduction of novel genetic information into the reovirus genome, permits identification of the nature of recognition signals, permits the construction of reovirus strains with desired properties such as, for example, highly efficient and nonpathogenic vaccine virus strains (this would be of great importance for orbiviruses and rotaviruses which, in contrast to reoviruses, include important human and domestic animal pathogens and to which this technology should be transferable), and opens the way for the development of the nonpathogenic reovirus as a highly efficient expression vector for clinical application in the fields of gene therapy, on the one hand, and cancer therapy, on the other.

Effect of reovirus infection on infected cells

There is no special mechanism for the release of reovirus progeny; reovirus particles are released when cytopathic effects have progressed sufficiently for cell necrosis to result in cell lysis. In cells infected with

reovirus, masses of granular material develop in areas scattered throughout the cytoplasm which eventually move toward the nucleus and coalesce, forming characteristic inclusions or 'viral factories'. These inclusions are easily identified with fluorescein-labeled antibodies against reovirus proteins; they represent the areas where viral assembly proceeds, and quasicrystalline arrays of reovirus particles are often associated with them. Microtubules appear to extend throughout these viral factories and appear to be covered with viral protein; in particular, proteins $\sigma 1$ and μNS possess affinity for elements of the cytoskeleton (CSK), which suggests that they may play a role in facilitating or mediating reovirus morphogenesis. However, microtubules *per se* are not essential, since colchicine does not inhibit reovirus multiplication or assembly. Like infection with all lytic viruses, reovirus infection causes progressive disruption of the CSK organization, but it is not known which reovirus protein(s) cause(s) this effect.

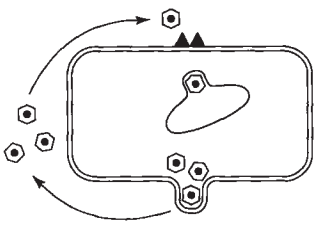
REPLICATION OF VIRUSES

V Gregory Chinchar, Department of Microbiology, University of Mississippi Medical Center, Jackson, Mississippi, USA



Introduction

Viruses are obligate intracellular parasites that replicate only within living animal, plant, or bacterial cells. Of the 71 taxonomically defined virus families, 24 contain members that infect vertebrates, and these families will be the focus of this overview. Among the smallest vertebrate viruses, the virion consists only of the viral genome and a closely associated protein coat (nucleocapsid), whereas larger viruses possess, in addition to the nucleocapsid, a variety of catalytic, regulatory and structural proteins, and in some cases a host-derived lipid membrane (envelope) containing one or more virus-encoded glycoproteins. In animal cells, virus replication is complete within several hours to at most a few days, and results in the synthesis of 10^3–10^5 virions per cell. Virus replication will be discussed in three stages: (1) early events (attachment to susceptible cells, penetration and uncoating), (2) viral biosynthetic events (replication of the viral genome, transcription and translation) and (3) virion assembly. However, because of space limitations, early events and mechanisms of virion assembly will be dealt with briefly so that viral biosynthetic strategies can be considered in greater detail.

Early Events

Attachment

Infection begins with the attachment of a virion, via capsid or envelope proteins, to specific cell-surface macromolecules (viral receptors). Because of the specificity of this interaction, the host range (tropism) of a given virus is determined primarily by the presence of viral receptor molecules on the cell surface. As a group, viruses utilize a variety of proteins, lipids and oligosaccharides as receptors. One class of receptors includes cellular macromolecules involved in ligand binding, endocytosis and cell recognition. For example, the receptors for poliovirus, human rhinovirus (ICAM-1), human immunodeficiency virus type 1 (CD4) and Epstein–Barr virus (CD21) are members of the immunoglobulin superfamily of proteins. In contrast, the receptor for Mahoney leukemia virus is an amino acid transporter and sialic acid-

reovirus, masses of granular material develop in areas scattered throughout the cytoplasm which eventually move toward the nucleus and coalesce, forming characteristic inclusions or 'viral factories'. These inclusions are easily identified with fluorescein-labeled antibodies against reovirus proteins; they represent the areas where viral assembly proceeds, and quasicrystalline arrays of reovirus particles are often associated with them. Microtubules appear to extend throughout these viral factories and appear to be covered with viral protein; in particular, proteins $\sigma 1$ and μNS possess affinity for elements of the cytoskeleton (CSK), which suggests that they may play a role in facilitating or mediating reovirus morphogenesis. However, microtubules *per se* are not essential, since colchicine does not inhibit reovirus multiplication or assembly. Like infection with all lytic viruses, reovirus infection causes progressive disruption of the CSK organization, but it is not known which reovirus protein(s) cause(s) this effect.

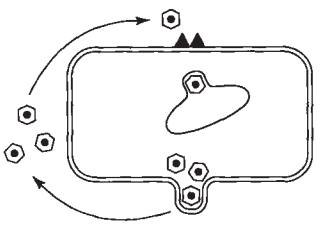
REPLICATION OF VIRUSES

V Gregory Chinchar, Department of Microbiology, University of Mississippi Medical Center, Jackson, Mississippi, USA



Introduction

Viruses are obligate intracellular parasites that replicate only within living animal, plant, or bacterial cells. Of the 71 taxonomically defined virus families, 24 contain members that infect vertebrates, and these families will be the focus of this overview. Among the smallest vertebrate viruses, the virion consists only of the viral genome and a closely associated protein coat (nucleocapsid), whereas larger viruses possess, in addition to the nucleocapsid, a variety of catalytic, regulatory and structural proteins, and in some cases a host-derived lipid membrane (envelope) containing one or more virus-encoded glycoproteins. In animal cells, virus replication is complete within several hours to at most a few days, and results in the synthesis of 10^3–10^5 virions per cell. Virus replication will be discussed in three stages: (1) early events (attachment to susceptible cells, penetration and uncoating), (2) viral biosynthetic events (replication of the viral genome, transcription and translation) and (3) virion assembly. However, because of space limitations, early events and mechanisms of virion assembly will be dealt with briefly so that viral biosynthetic strategies can be considered in greater detail.

Early Events

Attachment

Infection begins with the attachment of a virion, via capsid or envelope proteins, to specific cell-surface macromolecules (viral receptors). Because of the specificity of this interaction, the host range (tropism) of a given virus is determined primarily by the presence of viral receptor molecules on the cell surface. As a group, viruses utilize a variety of proteins, lipids and oligosaccharides as receptors. One class of receptors includes cellular macromolecules involved in ligand binding, endocytosis and cell recognition. For example, the receptors for poliovirus, human rhinovirus (ICAM-1), human immunodeficiency virus type 1 (CD4) and Epstein–Barr virus (CD21) are members of the immunoglobulin superfamily of proteins. In contrast, the receptor for Mahoney leukemia virus is an amino acid transporter and sialic acid-

containing glycoproteins serve as receptors for paramyxo- and orthomyxoviruses.

Penetration and uncoating

Following attachment, the virion must enter the cell (penetration) and release its genome (uncoating). The process by which many viruses accomplish this dual task is termed receptor-mediated endocytosis and is the same mechanism used by the cell to import growth factors and other large molecules to which the plasma membrane is not permeable. Virions, bound to their cognate receptors, are transported laterally within the plasma membrane to clathrin-coated pits and enter the cell as the clathrin-coated pit invaginates. Subsequently, this vesicle fuses with an endosome and, within this acidic compartment, uncoating takes place. The acidic pH of the endosome is critical and agents that raise the intraendosomal pH (e.g. NH_4Cl, chloroquine, etc.) block virus uncoating. For enveloped viruses, uncoating involves fusion of the viral envelope with the endosomal membrane followed by release of the nucleocapsid into the cytoplasm. In the case of influenza virus, it is thought that low pH changes the conformation of the hemagglutinin (HA) allowing the hydrophobic fusion peptide to interact with target cell membranes. In addition, among negative-stranded viruses, the acidic environment within the endosome promotes release of the matrix (M) protein from the nucleocapsid, a step necessary for subsequent transcription. Nonenveloped viruses also appear to utilize receptor-mediated endocytosis, although here uncoating does not involve membrane–membrane fusion. For example, following attachment of poliovirus to target cells, one of the capsid proteins (VP4) is released exposing hydrophobic residues buried inside the virion. Interaction of these residues with the endosomal membrane may provide a pore through which viral RNA is extruded into the cytoplasm. In the adenovirus system, low endosomal pH induces conformational changes in the capsid which rupture the endosomal membrane at virion–membrane contact points. After its release into the cytoplasm, adenovirus is transported via microtubules to nuclear pores where viral DNA enters the nucleus. In contrast to the above mechanism, several viruses (e.g. paramyxoviruses, herpesviruses and human immunodeficiency virus type 1 [HIV]) do not require an acidic environment for uncoating and enter cells by fusion at the plasma membrane.

Although the presence of viral receptors is a primary determinant for infectivity, not all cells carrying the appropriate receptor are susceptible to infection. In several 'restrictive' systems, the synthesis of infectious progeny is blocked at a postattachment step. For example, some mammalian cell lines bind influenza virus and support the synthesis of all viral macromolecules, yet do not generate infectious virions because they lack the protease required to cleave the hemagglutinin precursor (HA_0) and generate activated (i.e. fusion-competent) HA_1 and HA_2. Conversely, some cells that lack the appropriate viral receptor can nonetheless support a productive infection if the viral genome is introduced into the cell by transfection.

Synthesis of Virus-specific Macromolecules

The 24 families of vertebrate viruses, although differing in genomic make-up, virion morphology, and their repertoire of viral-encoded enzymes, can be ordered on the basis of replicative mechanisms. However, before examination of different replication strategies, several common themes need to be addressed.

Viral transcription and genome replication

Viral nucleic acid synthesis is catalyzed by both viral and host enzymes, the relative contribution of which is determined by the type of virus and the specific molecule. Viruses with RNA genomes, except for the retroviruses, synthesize mRNA and replicate their genomes using virus-encoded RNA-dependent RNA polymerases. In contrast, retroviruses synthesize a double-stranded complementary DNA (cDNA) copy of their single-stranded RNA genome using a virion-encoded RNA-dependent DNA polymerase (reverse transcriptase). In subsequent steps, the retroviral cDNA is integrated into the host chromosome and transcribed by host-encoded DNA-dependent RNA polymerase II (pol II) to yield viral messages and genomic RNA. DNA viruses, except for poxviruses, also use host-encoded pol II to transcribe their messages. Poxviruses, because they replicate in the cytoplasm and do not have access to pol II, assemble a novel transcriptase composed of multiple poxvirus-specific (and possibly one or more host-derived) subunits. Most DNA virus families (e.g. *Poxviridae, Iridoviridae, Herpesviridae, Adenoviridae*) synthesize a virus-encoded DNA-dependent, DNA polymerase. However, two families (i.e. *Parvoviridae* and *Papovaviridae*) utilize host DNA polymerase, and the *Hepadnaviridae* replicate viral DNA through an RNA intermediate using a virus-encoded reverse transcriptase.

Gene regulation

Viruses have evolved a variety of mechanisms to control gene expression and maximize efficiency. In

some systems, viral gene expression is divided into temporal phases in which catalytic and regulatory proteins are synthesized early in infection, whereas the synthesis of structural proteins is limited to late times. Alternatively, the expression of viral genes may be controlled by differences in the transcription rate of specific genes (e.g. rhabdoviruses and paramyxoviruses), the translational efficiency of different viral messages (e.g. reovirus) or the replication of transcriptional templates (e.g. influenza virus). Moreover, it is likely that, even within a single virus family, multiple mechanisms regulate gene expression. At the molecular level, gene expression is controlled by both *cis*- and *trans*-acting signals. In some cases, the nucleotide sequence of viral messages and transcriptional templates may be the primary factor in determining how efficiently a given sequence is translated or transcribed. For example, the differential synthesis of the various coronavirus mRNAs is thought to be controlled by interaction between *trans*-acting coronavirus leader RNA and *cis*-acting sequences located at the beginning of each gene. Furthermore, transcription and genome replication among DNA viruses (and retroviruses) is regulated by the (often) combined action of *trans*-acting viral- and host-encoded factors with *cis*-acting viral nucleotide sequences. For example, herpesvirus immediate-early gene transcription requires, aside from pol II, both host- (OTF-1) and virus-encoded (α-TIF) transcription factors. Lastly, in several families (e.g. *Orthomyxoviridae, Poxviridae, Herpesviridae* and *Iridoviridae*), there are hints that viral gene expression is also regulated at post-transcriptional and translational levels.

Viral protein synthesis

Viral protein synthesis is completely dependent on the cell's translational machinery (i.e. ribosomes, tRNAs, initiation factors, etc.). Reflecting that dependence, viral mRNAs, despite some prominent exceptions (e.g. picornaviruses), are similar in overall structure to host messages, i.e. they are capped and methylated at their 5′ terminus and polyadenylated at their 3′ end. Viral mRNAs are monocistronic and are translated as are other eucaryotic transcripts. However, in some systems, viral proteins are synthesized as part of a larger precursor (polyprotein) which is cleaved to generate the final products. This mechanism overcomes the inability of eucaryotic ribosomes to translate polycistronic messages and allows one viral mRNA to code for several proteins. Viruses have also developed several ways to utilize the same nucleotide sequence to encode one or more proteins:

1. HIV-1 and influenza A virus use alternative splicing to generate additional transcripts encoding novel proteins;
2. measles virus and other paramyxoviruses generate a novel P-related protein (V) by RNA editing, a process in which one or more nontemplated nucleotides are added at a site within the 3′ end of some P transcripts;
3. Sendai virus synthesizes five proteins from its P transcript by using alternative translational initiation codons;
4. retroviruses use frameshifting or read-through mechanisms to circumvent a stop codon lying between the capsid and polymerase coding regions of the gag-pol transcript.

Finally, following their translation, viral proteins, like their cellular counterparts, are post-translationally modified (e.g. glycosylated, phosphorylated, etc.) using cellular enzymes.

As infection progresses, viral protein synthesis often supplants cellular translation. In some cases, this simply reflects the increased abundance of viral messages, whereas in others viral messages appear to initiate translation at a higher rate than host messages. Alternatively, virus infection may actively inhibit host translation by (1) proteolytically inactivating or covalently modifying initiation factors required solely or preferentially by cellular messages, (2) selectively degrading host messages, or (3) altering the intracellular ionic environment to favor viral over host translation. Furthermore, because infection can lead to the phosphorylation and functional inactivation of eucaryotic initiation factor 2 (eIF-2), several virus families (*Poxviridae, Reoviridae, Orthomyxoviridae, Adenoviridae* and *Picornaviridae*) have evolved mechanisms to block eIF-2 phosphorylation. Virus infection also blocks host cell RNA and DNA synthesis. Although transcriptional shut-off may be the direct result of inactivating specific transcription factors, the inhibition of cellular DNA synthesis is likely due to the earlier inhibition of protein synthesis.

Cytoskeleton

In addition to providing the biochemical components required for replication, the cell also supplies the virus with an intracellular highway to facilitate infection and assembly. There is growing evidence that the transport of infecting virions to the nucleus and the transport of viral proteins into assembly sites takes place along the various fibers of the cellular cytoskeleton.

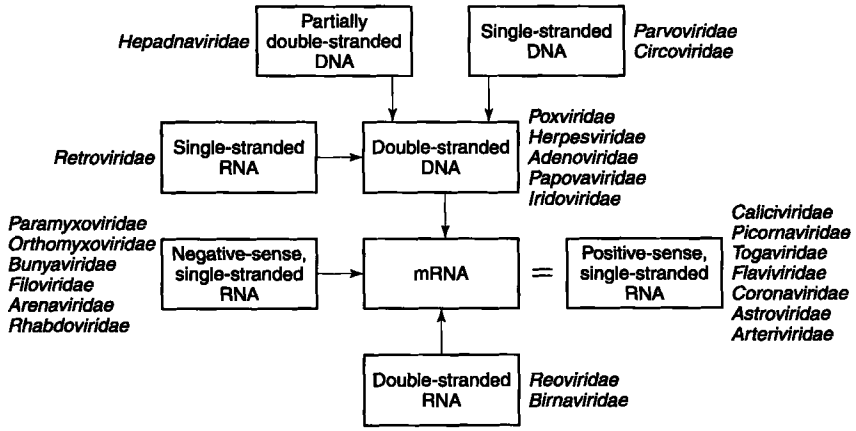


Figure 1 Strategies for the production of viral mRNA utilized by 24 families of viruses infecting humans and other animals. (Updated from Baltimore D (1971) *Bacteriol. Rev.* 35: 235.)

RNA Viruses

RNA-containing viruses are discussed in the light of four basic transcriptional strategies (**Fig. 1**). These strategies encompass viruses with message-sense (positive-strand viruses) and antisense genomes (negative-strand viruses), viruses that package their replicative form as genome (double-stranded RNA viruses) and viruses that utilize 'reverse transcription'. Although this approach is conceptually useful, not all viruses within a class conform precisely to the prototypic replication strategy. Despite this caveat, representative examples will be cited to illustrate the replication mechanism.

Positive-strand RNA viruses

Positive-strand viruses contain a single-stranded, message-sense RNA genome which is translated immediately after uncoating. To simplify this discussion, poliovirus (family *Picornaviridae*; genus *Enterovirus*) will be used as a prototype because it is the most extensively studied positive-strand virus and provides a clear view of this strategy (**Fig. 2**).

Following uncoating, the poliovirus genome is translated to yield an ~200 000 mol. wt polyprotein. Initial cleavage of the polyprotein occurs cotranslationally and is mediated by the autocatalytic activity of a virus-encoded protease, polypeptide 2A. Subsequent cleavages, catalyzed by viral protease 3C, yield structural (capsid) and catalytic (polymerase) proteins. As infection proceeds, translation of capped host mRNAs is blocked due to the virus-induced degradation of the large subunit (eIF-4G) of the mRNA cap recognition factor (eIF-4F). In contrast, viral messages, which are uncapped and possess a highly structured 5′-nontranslated region (5′-NTR), escape shut-off because the 40S ribosomal subunit binds to an internal sequence within the 5′-NTR. The ability of the 40S ribosomal subunit to bind internally, in contrast to the usual scenario in which the 40S ribosome binds at the 5′ end of the message and 'scans' until a start codon is encountered, is termed

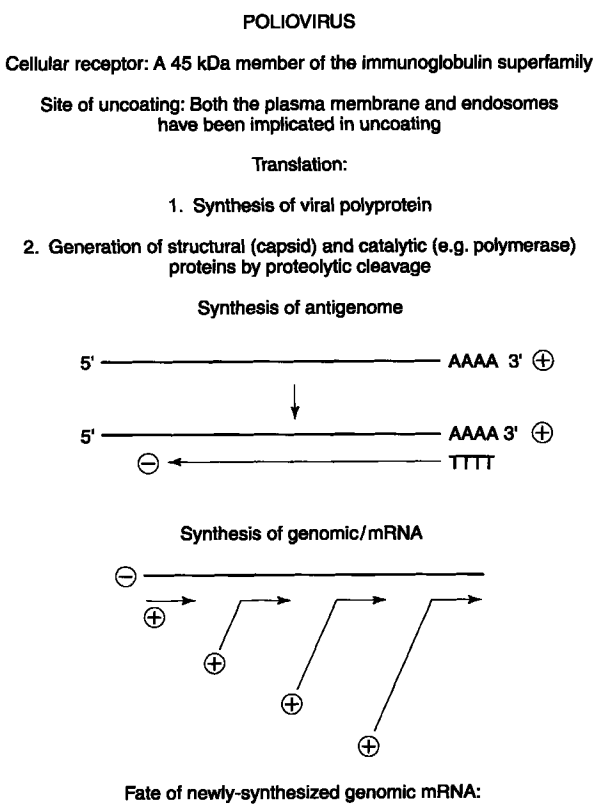

Figure 2 Replication strategy of a representative positive-stranded RNA virus.

'internal ribosome entry'. Thus cap-independent initiation and internal ribosome entry allow poliovirus messages to be selectively translated under conditions where translation of capped messages is progressively compromised.

Following its synthesis, the viral RNA-dependent RNA polymerase catalyzes the synthesis of a full-length negative-sense copy of the genome. Subsequently, the negative-strand serves as template and directs the synthesis of multiple plus-strands. Early in infection, when the concentration of viral structural proteins is low, newly synthesized positive-strands most likely are translated and serve to amplify the synthesis of viral proteins. Later when the concentration of virion precursors is high, newly synthesized plus-strands are encapsidated to generate infectious virus particles. A small virus-encoded protein (VPg) is covalently linked to the 5′ end of all picornavirus RNAs except message. VPg is thought to play a role in RNA synthesis, but it is unclear whether VPg functions as a primer or in some other capacity.

Negative-strand RNA viruses

Because the genome of negative-sense RNA viruses cannot be translated, the first virus-specific biosynthetic event following uncoating is the synthesis of viral mRNA by a virion-associated RNA-dependent RNA polymerase using the viral genome as template. Negative-stranded viruses are divided into two classes: those with unsegmented (monopartite) genomes (i.e. the order *Mononegavirales* containing the families *Paramyxoviridae, Rhabdoviridae* and *Filoviridae*) and those with segmented (multipartite) genomes (i.e. the families *Orthomyxoviridae, Bunyaviridae* and *Arenaviridae*). Although each class uses the negative-strand strategy, they possess unique attributes and will be dealt with separately.

The replication of monopartite viruses is discussed using vesicular stomatitis virus (VSV), a rhabdovirus, as the prototype (**Fig. 3**). Immediately after uncoating, the VSV genome is transcribed to yield a short nontranslated 'leader' RNA followed, in decreasing molar amounts, by five capped, methylated and polyadenylated viral mRNAs. Transcription occurs within the nucleocapsid, a structure containing the viral genome and multiple copies of three virus-encoded proteins. Aside from the nucleocapsid (N) protein, which tightly encloses the genome and is present in ~2000 copies/nucleocapsid, two catalytic proteins are also present within the nucleocapsid. The polymerase, polypeptide L (mol. wt ~200 000), is present in about 50 copies per nucleocapsid and catalyzes transcriptional initiation and elongation, as well as capping, methylation and polyadenylation.

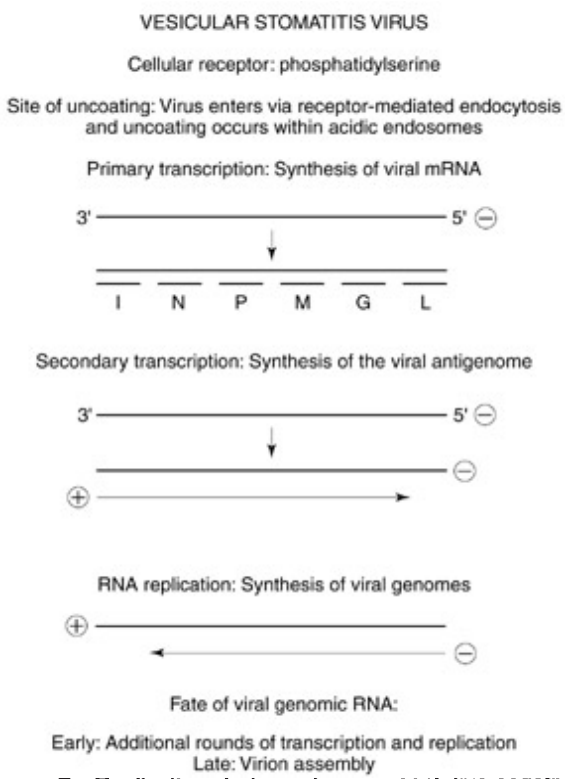

Figure 3 Replication strategy of a representative negative-stranded RNA virus.

The phosphoprotein P, present in about 500 molecules per nucleocapsid, plays a variety of roles in RNA synthesis. It binds L to the nucleocapsid, maintains the solubility of free N and may function in chain elongation. The viral transcriptase binds genomic RNA at its 3′ terminus and initiates transcription. At each intergenic junction (with the exception of the leader-N junction), a poly(A) tract is added to the newly synthesized mRNA by repetitive copying ('stuttering') of an oligo(U) sequence present at the end of the gene. After synthesis of the poly(A) tract, transcription terminates, releasing newly synthesized mRNA, but maintaining the transcriptase on its template. Re-initiation at the next gene downstream occurs via a conserved start sequence present at the beginning of each gene. However, because re-initiation does not take place every time, downstream genes (i.e. those coding for the envelope and polymerase proteins) are transcribed less frequently than upstream ones encoding the nucleocapsid, phosphoprotein and matrix proteins. Thus viral gene expression is controlled by transcriptional polarity.

Viral genome replication, i.e. the synthesis of a full-length positive-sense copy of the genome and the subsequent generation of progeny negative-strands, is catalyzed by the same polymerase that directs transcription. The switch between the transcriptive

and replicative modes appears to be controlled by the concentration of the nucleocapsid protein. When N reaches a critical concentration, it binds newly synthesized RNA within the leader sequence and allows the polymerase to readthrough intergenic regions and synthesize full-size positive-strands (i.e. antigenomes) which will serve as templates for virion RNA synthesis.

Segmented viruses encode their genetic information in multiple molecules of negative-sense RNA. In the case of influenza A virus (*Orthomyxoviridae*), the genome is composed of eight unique segments of virion RNA. In contrast to most RNA virus families, orthomyxoviruses require a functional cell nucleus for replication. This requirement reflects the fact that the orthomyxovirus polymerase complex can neither initiate transcription *de novo* nor cap and methylate viral mRNAs. Instead, the complex 'pirates' the capped and methylated 5′ terminus from a selected set of newly synthesized host messages and uses these to prime viral transcription. Once initiated, transcription continues until an oligo(U) tract, about 22 nucleotides from the end of virion RNA, signals addition of the 3′ poly(A) tail by repetitive copying. Because of this, viral genomic and mRNAs are not completely complementary, but differ at both their 5′ and 3′ ends. As with unsegmented viruses, the trigger controlling the transition from transcription to replication may be the concentration of nucleocapsid protein.

Other negative-stranded viruses possess additional molecular surprises. Some bunyaviruses (tripartite genome) and all arenaviruses (bipartite genome) possess 'ambisense' genomic RNA, in which non-overlapping subgenomic messages are transcribed from the 3′ ends of both virion RNA and its full-length complement. Furthermore, in what may be the prototype of a new family within the *Mononegavirales*, Borna disease virus replicates and transcribes its genome within the nucleus and utilizes RNA splicing to generate its messages.

Double-stranded RNA (dsRNA) viruses

Animal viruses with dsRNA genomes are segmented and can be viewed as a variant of the negative-sense strategy in which the virion encapsidates the replicative form of the genome. Genomic dsRNA is transcribed within partially uncoated ribonuclease-resistant viral cores by the virion-associated polymerase to yield viral mRNAs. Early in infection, some progeny plus-strands function as translational templates whereas others associate with nonstructural proteins and form complexes which are transcribed once to yield dsRNA. Newly synthesized dsRNA serves as template for the synthesis of additional viral mRNA which amplifies the replication cycle. Later, as the concentration of core and capsid proteins increases, the dsRNA–protein complex exchanges nonstructural for structural proteins and forms mature virus particles.

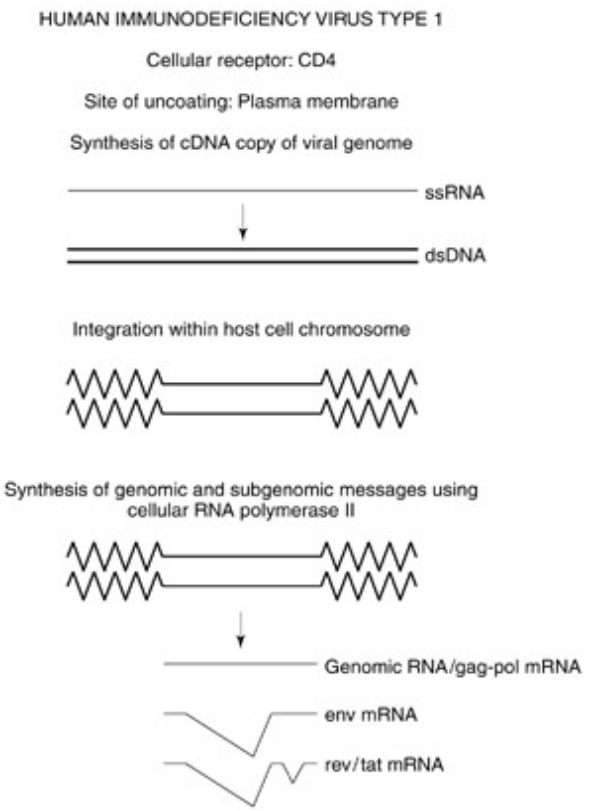

Figure 4 Replication strategy of a complex retrovirus.

RNA viruses that utilize a reverse transcription strategy

Retroviruses replicate their genome and transcribe mRNA using a dsDNA copy of viral genomic RNA as template (**Fig. 4**). This unconventional mechanism, in which single-stranded virion RNA is used as a template for dsDNA synthesis, is catalyzed by a virion-associated, RNA-dependent DNA polymerase (reverse transcriptase). After viral entry, the virion capsid is partially uncoated and a complementary DNA copy of the RNA genome is synthesized using reverse transcriptase. An endonucleolytic activity, integral to the reverse transcriptase, degrades the RNA template and second-strand DNA synthesis begins. Completion of second-strand synthesis results not only in a dsDNA copy of virion RNA, but also generates a unique structure termed the long terminal

repeat (LTR). The LTR flanks the viral cDNA and is composed of unique sequences from the 5′ and 3′ ends of the genome and a repeat element common to both ends. Following cDNA synthesis retrovirus DNA is integrated into the host chromosome, and, in this form, is termed the 'provirus'. Subsequently, the provirus is transcribed by pol II to yield full-length progeny RNA and one or more subgenomic mRNAs. The upstream LTR plays a very important role in retrovirus gene expression because it contains enhancer elements which regulate pol II-catalyzed transcription. (The downstream LTR is not involved in viral gene expression, but may activate host oncogenes and play a role in cell transformation.)

Full-length genome-sized RNA can either be packaged within virions or serve as messenger for the capsid and catalytic viral proteins. Translation of retrovirus genomic RNA yields two classes of polyproteins. The majority (~95% of the total) encode the capsid, core and matrix proteins and result when translation terminates immediately after the coding region of the nucleocapsid gene. However, a minor population, encoding the aforementioned structural proteins as well as the protease, reverse transcriptase, and integrase results when the stop codon at the end of the capsid/core region is bypassed either by frameshifting or read-through. Envelope glycoproteins are translated from a singly-spliced subgenomic mRNA containing sequences primarily from the 3′ end of the genome, whereas lentiviruses, such as HIV-1, utilize doubly spliced subgenomic mRNAs to direct the synthesis of TAT, REV and several other regulatory proteins.

TAT and REV are the two best-studied of the HIV-1 regulatory proteins. TAT is a *trans*-acting protein that binds to a sequence present at the 5′ end of all HIV-1 mRNAs and enhances HIV-1 gene expression by relieving a block in transcriptional elongation or by increasing transcriptional initiation. REV mediates the switch between the synthesis of regulatory proteins (i.e. TAT and REV) and the generation of structural and catalytic proteins by binding to *cis*-acting sequences within viral mRNA and directing the transport into the cytoplasm of unspliced genomic RNA and singly-spliced envelope message.

DNA Viruses

With the exception of parvoviruses and hepadnaviruses, the genomes of which are respectively single-stranded and partially double-stranded, DNA-containing animal viruses possess a dsDNA genome. However, even in these two families, viral mRNA is ultimately transcribed from a dsDNA template using cellular DNA-dependent RNA polymerase (**Fig. 1**). In place of a detailed discussion of each family, broader issues of viral DNA replication will be discussed. To begin with, DNA viruses differ greatly in their genetic content ranging in size from 5 kbp (*Parvoviridae*) to greater than 120 kbp (*Herpesviridae, Poxviridae* and *Iridoviridae*). Thus the small DNA viruses are about as genetically complex as a typical RNA virus, whereas the larger DNA viruses encode 100 or more proteins. Not unexpectedly, the degree to which virus replication is dependent on cellular functions reflects the genetic complexity of the virus. Thus, parvoviruses and papovaviruses require extensive host involvement to support viral biosynthetic events (including DNA synthesis), whereas other families are progressively more independent.

Among herpes-, pox- and iridoviruses, viral genes are expressed in a coordinated temporal sequence of immediate early, early and late genes. Generally immediate early genes code for proteins required to initiate virus replication, early genes encode catalytic functions (e.g. the viral DNA polymerase), and late genes specify structural proteins. Furthermore, immediate early genes activate early and late gene transcription, whereas specific early and late genes downregulate immediate early and early gene expression respectively. Aside from specific regulatory proteins, full late gene expression also requires viral DNA synthesis, thus inhibitors of viral DNA replication block late gene expression despite the presence of functional immediate early and early activators.

Because DNA polymerase requires a primer with an available 3′-OH to initiate DNA synthesis, all viruses with a linear DNA genome have evolved specialized features that allow them to maintain intact termini during replication. For example, adenoviruses solve the 'end-problem' by using a nucleotide-linked terminal protein to initiate DNA replication, herpesviruses replicate through a rolling circle mechanism, and poxviruses and parvoviruses utilize a self-priming mechanism to ensure replication of their termini. In contrast to other DNA viruses, hepadnaviruses possess a circular, partially single-stranded DNA genome that is replicated through an RNA intermediate using virus-encoded reverse transcriptase. Upon entry into the cell the gaps are repaired and dsDNA is transcribed in the nucleus by host polymerase to yield viral mRNAs and pregenomic RNA. The latter is encapsidated and transcribed into complementary DNA using virus-encoded protein P both as the primer and the reverse transcriptase. As with retroviruses, the RNA template is degraded and second-strand DNA synthesis takes place. However, before its completion, the virion is exported from the cell leaving genomic DNA partially single-stranded.

Unlike other DNA viruses, poxviruses replicate solely within the cytoplasm in morphologically distinct viral 'factories'. Reflecting their metabolic independence from the host cell, poxviruses synthesize unique DNA and RNA polymerases, and their virions contain all the proteins needed to transcribe the earliest class of viral mRNAs. Furthermore, viral transcriptional promoters and termination sequences are unique and are regulated by virus-specific factors.

Iridoviruses, occupying a taxonomic middle-ground between poxviruses and the nuclear DNA viruses, possess several distinctive features. Viral DNA replication takes place in two distinct compartments (genome-length progeny DNA is synthesized in the nucleus, followed by the synthesis of concatemeric DNA in the cytoplasm), whereas virion assembly is confined to cytoplasmic viral 'assembly sites'. Viral DNA is highly methylated with nearly 25% of cytosine residues present as methylcytosine. Methylation is catalyzed by a virus-encoded enzyme and, as in some bacteriophage systems, appears to function as part of a restriction–modification system. Surprisingly, despite the high content of methylcytosine, host RNA polymerase II has been implicated in at least the early rounds of viral transcription. However, it is not known whether unmodified pol II transcribes viral DNA late in infection or whether viral-encoded proteins modify pol II and alter its specificity.

Virus Assembly

Once sufficient stores of viral nucleic acid and protein have accumulated in the infected cell, nucleocapsid formation and virion assembly begin and continue as long as the cells are metabolically competent. Despite the large number of vertebrate virus families, only three types of nucleocapsids are found: complex, helical and icosahedral (spherical). The nucleocapsids of poxviruses do not conform to the geometric symmetry found among the helical and icosahedral viruses and are considered to be 'complex'. Little is known about the molecular mechanisms controlling their assembly. Helical nucleocapsids (which, among vertebrate viruses, enclose only RNA genomes) form as viral proteins bind to nascent RNA transcripts and encapsidate them. During virus assembly, helical nucleocapsids migrate to cellular membranes where viral glycoproteins have concentrated. There, through concerted interaction between the nucleocapsid and viral glycoproteins, the nucleocapsid is enveloped by the cellular membrane in a process termed 'budding'. Host proteins are excluded from the membrane and the resulting envelope contains only virus-encoded glycoproteins. Moreover, because envelopment is not a precise process, dual infections with different strains of the same multipartite virus (e.g. influenza virus A) lead to high-frequency genetic reassortment. Although virion envelopment takes place commonly at the plasma membrane (e.g. among the *Paramyxoviridae, Orthomyxoviridae* and *Rhabdoviridae*), intracellular membranes (e.g. those of the Golgi, endoplasmic reticulum and, in the case of DNA viruses, the nucleus) are used by other virus families. In contrast to viruses with helical nucleocapsids, icosahedral nucleocapsids enclose both DNA and RNA genomes. It is thought that nucleocapsids form spontaneously when the concentration of capsid proteins reaches a critical level. In some families, nucleocapsids are not enveloped (i.e. virion equals nucleocapsid), whereas in others nucleocapsids are enveloped as described above. Enveloped icosahedral viruses are released from infected cells by budding, whereas non-enveloped icosahedral virions are liberated by cell lysis.

RESPIRATORY SYNCYTIAL VIRUS – HUMAN (*PARAMYXOVIRIDAE*)

Peter L Collins, Laboratory of Infectious Disease, National Institute of Allergy and Infectious Disease, National Institutes of Health, Bethesda, Maryland, USA

History

Human respiratory syncytial virus (RSV) was isolated in 1956 from a laboratory chimpanzee with upper respiratory tract disease. Shortly thereafter, an apparently identical virus was recovered from children ill with pneumonia or croup and was identified as a virus of humans. RSV is now recognized as the leading viral agent of pediatric respiratory tract disease worldwide. It also is gaining recognition as a significant cause of disease in the elderly and in immunocompromised individuals. Its poor growth *in vitro* and instability have impeded research. RSV lacks an approved vaccine or highly effective antiviral therapy.

Taxonomy and Classification

RSV is a member of the Order *Mononegavirales*, the nonsegmented negative-strand RNA viruses (**Table 1**). These are enveloped viruses that have as genome a single strand of protein-coated negative-sense RNA. Vesicular stomatitis and Sendai viruses are the most extensively characterized members of the group.

RSV is the type species for genus *Pneumovirus* in the subfamily *Pneumovirinae* of the family *Paramyxoviridae*. There also are bovine (BRSV), caprine (CRSV) and ovine (ORSV) versions which are related to human RSV. BRSV is one of several respiratory tract pathogens associated with shipping fever, an important disease of cattle. Pneumonia virus of mice (PVM) is a somewhat more distant relative. There is a turkey pneumovirus, formerly called turkey rhinotracheitis virus (TRTV) but now called avian pneumovirus (APV), which is sufficiently distinct (see below) so that it has been placed in a second genus, *Metapneumovirus*.

Virion Structure and Viral Proteins

RSV virions include spherical particles of 80–350 nm in diameter (**Fig. 1**) and filamentous particles of 60–100 nm in diameter and up to 10 μm in length. The nonuniform nature of the particles and the presence of large amounts of cell debris lends uncertainty as to the exact size and shape of the infectious particle. The virion contains a helical nucleocapsid (diameter 12–15 nm, compared to 18 nm for other paramyxoviruses) packaged in a lipoprotein envelope acquired from the host cell plasma membrane during budding. The genome and antigenome (positive-sense replicative intermediate) are found only in nucleocapsid form. The virion surface has spike-like glycoprotein projections of 11–20 nm spaced at intervals of 6–10 nm. RSV lacks a hemagglutinin and a neuraminidase; the former is present in all members of *Paramyxovirinae* and the latter in all but the morbilliviruses. But PVM has a hemagglutinin, and thus its absence is not a characteristic of the pneumoviruses.

RSV encodes 11 proteins (**Fig. 1, Table 2**). Four are nucleocapsid proteins, N, P, L and M2-1. The N protein binds tightly along the entire length of genomic RNA. L is the major polymerase subunit. P is thought to associate with free N and L to maintain them in soluble form and might also participate as a cofactor in RNA synthesis. N, P and L are necessary and sufficient to direct RNA replication (synthesis of antigenome and genome), whereas transcription involves in addition an elongation factor, the M2-1 protein. Although the polypeptide components of the viral polymerase are packaged in the virion, as is characteristic of the Order, virion-associated polymerase activity has not been directly demonstrated.

There are three transmembrane virion proteins, F, G and SH, which assemble separately into homo-oligomers that make up the membrane spikes; F and G assemble into either trimers or tetramers, and SH might be a pentamer. The F glycoprotein mediates membrane fusion, which is responsible for viral penetration and syncytium formation. It has a cleaved N-terminal signal sequence and a membrane anchor near the C-terminus. F is synthesized as a precursor, F_0, which is cleaved intracellularly by a furin-type cellular protease into the two subunits which remain disulfide-linked and constitute the biologically active form: NH_2-F_2-S-S-F_1-COOH.

The G glycoprotein mediates viral attachment. It is anchored in the membrane by a signal/anchor sequence near the N-terminus such that the large C-terminal domain is extracellular. G contains several *N*-linked carbohydrate side chains and approximately 24 or 25 *O*-linked chains (the ectodomain contains

Table 1 Order *Mononegavirales*, the nonsegmented negative-strand RNA viruses

Family	*Subfamily*	*Genus*	*Example(s)*
Rhabdoviridae		*Vesiculovirus*[a]	Vesicular stomatitis virus
Filoviridae		'Marburg-like viruses'	Marburg virus
		'Ebola-like viruses'	Ebola virus
Paramyxoviridae	*Paramyxovirinae*	*Respirovirus*	Parainfluenza virus types 1 and 3, including Sendai virus
		Rubulavirus	Mumps virus and parainfluenza virus types 2 and 4 including simian virus type 5
		Morbillivirus	Measles virus
	Pneumovirinae	*Pneumovirus*	RSV, animal RSVs, and pneumonia virus of mice (PVM)
		Metapneumovirus	Avian pneumovirus (APV) (formerly turkey rhinotracheitis virus)
Bornaviridae		*Bornavirus*	Borna disease virus

[a] Four other genera of rhabdoviruses exist which are not shown.

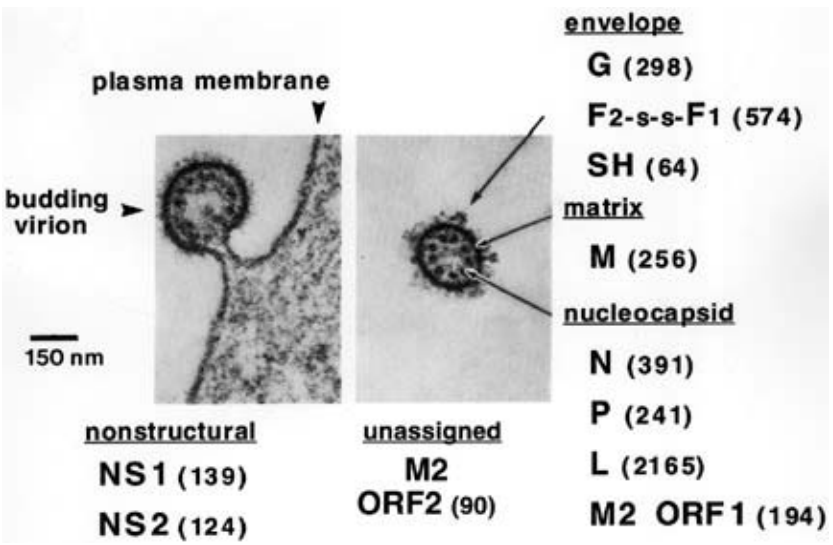

Figure 1 Locations of the RSV proteins, as illustrated on electron micrographs of thin layer sections of (left) a spherical-type RSV virion in the final stage of budding from the plasma membrane of an infected cell, and (right) a free spherical virion. Note the continuity between the envelope of the budding virus and the cell plasma membrane. Virion spikes are visible as a fringe on the exteriors of the virions, and the dense round structures in the virion interior represent cross-sections of the nucleocapsid. The amino acid lengths of the viral proteins are indicated. (The electron micrographs are adapted from Kalica *et al* (1973) *Arch. Gesamte Virusforsch.* 41: 248–258.)

more than 70 potential acceptor sites). It is speculated to have an extended, heavily glycosylated, mucin-like structure. In the middle of the ectodomain there is a predicted disulfide-linked tight turn that coincides with a conserved sequence segment presumed to be a domain important in attachment activity. Remarkably, recombinant RSV lacking the G protein gene can grow in cell culture, implying that an alternative attachment activity exists.

The function of the small SH protein is unknown. Remarkably, recombinant RSV lacking the gene in its entirety is fully viable in cell culture and chimpanzees. SH is anchored in the membrane by a centrally located signal/anchor sequence such that the C-terminal third of the molecule is extracellular. The first two methionine codons in the translational open reading frame (ORF) are alternative translational start sites, and the SH protein accumulates in a variety

Table 2 RSV proteins[a]

Protein	*Function/comments*	*Comments on expression, post-translational modifications*
Nucleocapsid-associated		
N	Binds tightly to genomic and antigenomic RNA	
P	Maintains free N and L proteins in soluble form. Polymerase cofactor	P is the most heavily phosphorylated RSV protein
L	Major polymerase subunit	
M2-1	Transcription elongation factor	Encoded by 5′-proximal ORF of M2 mRNA
Envelope-associated		
G	Transmembrane surface attachment protein. Major neutralization and protective antigen. Antigenic and sequence divergence in G defines the antigenic subgroups. Recombinant RSV lacking the G protein gene can grow in cell culture	Contains several *N*-linked sugar side chains and extensive *O*-linked glycosylation: the M_r of the unglycosylated form is 32.5 kDa and that of the fully-glycosylated form is 90 kDa. Translational initiation at the second methionine in the ORF yields an N-terminally-truncated form which, following additional N-terminal proteolytic trimming, is secreted
F	Transmembrane surface protein. Fusion activity mediates viral penetration and syncytium formation. Major neutralization and protective antigen	Synthesized as an *N*-glycosylated, 70 kDa precursor, F0, which is cleaved by a furin-type intracellular protease into two disulfide-linked subunits, F2 (amino acids 1–130, 19 kDa) and F1 (amino acids 137–574, 50 kDa)
SH	Transmembrane surface protein. Function unknown. Recombinant 'knock-out' virus lacking SH is fully viable	Translational initiation at first and second methionines of the ORF yields full length (SH0) and N-terminally-truncated (SHt) forms. Some of SH0 receives an *N*-linked sugar to form SHg, and some of the SHg is modified by the addition of polylactosaminoglycan to the *N*-sugar to yield SHp
M	Unglycosylated internal protein. Mediates virion assembly	
Nonstructural		
NS1[b]	Putative negative regulatory factor for replication and transcription. Recombinant 'knock-out' virus lacking NS1 is viable in cell culture but exhibits reduced synthesis of progeny virus	
NS2[b]	Recombinant 'knock-out' virus lacking NS2 is viable in cell culture but exhibits delayed synthesis of progeny virus	Unstable, with a half-life of 30 min
Newly-described, unassigned		
M2-2	Putative negative regulatory factor for replication and transcription	Encoded by the second, internal ORF of the M2 mRNA. Much less abundant than the other viral proteins

[a] Proteins known to be virion structural components: N, P, L, M2-1, SH0, SHp, G, F, M.
[b] Although the calculated molecular weight of NS1 (15 567) is greater than that of NS2 (14 674), it typically has a greater electrophoretic mobility.

of forms due to differing degrees of glycosylation. The multiplicity of forms seems to be a conserved feature, but its significance is unknown.

The nonglycosylated matrix M protein is thought to be located on the inner surface of the envelope and to have a central role in organizing the envelope and directing packaging of the nucleocapsid.

NS1 and NS2 are small proteins thought to be nonstructural. NS1 inhibits transcription and RNA replication in a minireplicon system (see below),

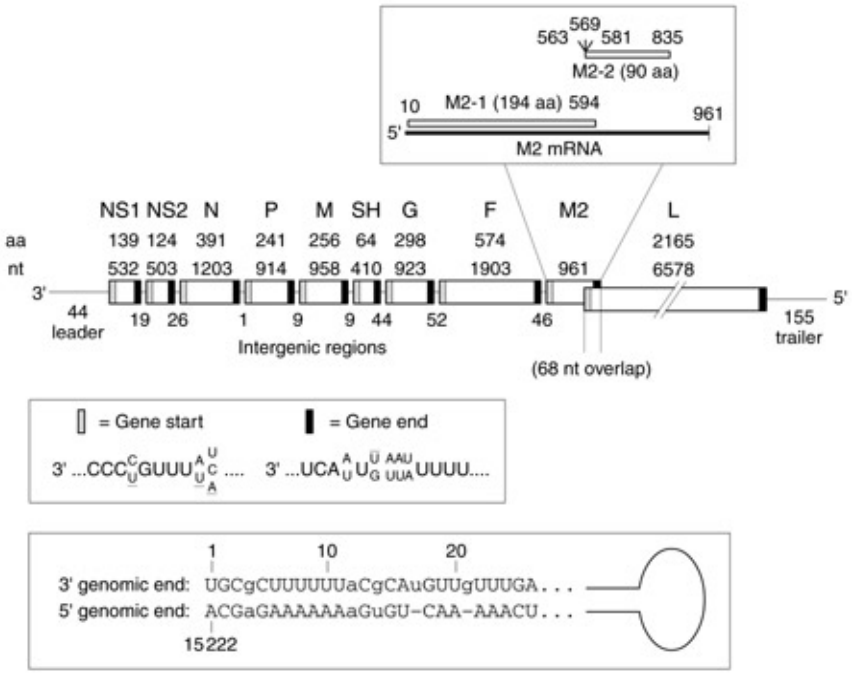

Figure 2 Gene map of RSV strain A2 (not to scale). The 15 222 nt genomic RNA is shown 3′ to 5′. Each box corresponds to an encoded mRNA, with the shaded and filled regions identifying the gene-start and gene-end signals respectively. For the gene-start signal, the first nine genes are identical for the first nine nucleotides of the 10 nt signal, whereas that of the L gene has differences indicated by underlining. The gene-end signal is more variable. For both signals, variable nucleotides (or a gap representing three gene-end sequences which are each one nucleotide shorter) are listed vertically in decreasing order of prevalence. The nucleotide (nt) length of each mRNA (exclusive of nontemplated polyadenylate) is indicated immediately over its box, and the amino acid (aa) length of the encoded protein is indicated above that. An expanded drawing of the M2 mRNA illustrates the two ORFs, shown as open rectangles over the line representing the mRNA, with potential translational start and stop codons numbered according to their positions in the 961 nt M2 mRNA. The extragenic leader, intergenic and trailer regions are drawn as thin lines, with nucleotide lengths shown underneath. The complementarity between the 3′ and 5′ ends is illustrated at the bottom; complementary nucleotides are in capitals and the dashes indicate single-nucleotide gaps introduced to maximize the alignment. These sequences are 81% complementary, after which the degree of relatedness is insignificant.

suggesting that it is a negative regulatory factor. Recombinant RSV lacking the NS1 or NS2 gene is viable in cell culture but replicates less well than wild type. Thus, the NS1 and NS2 genes encode nonessential accessory proteins. The M2 mRNA has a second ORF (**Fig. 2**), encoding the M2-2 protein, a nonabundant species which has been detected in preliminary experiments. Expression of the M2-2 ORF inhibited transcription and RNA replication by an RSV minireplicon, suggesting that M2-2 is a negative regulatory factor.

Genome Organization, Transcription and Replication

The RSV genome is a single, negative strand of RNA that encodes ten mRNAs (**Fig. 2**). Nucleotide lengths for three different RSV genomes sequenced to date are: 15 222 (strain A2 of antigenic subgroup A; see below for a description of the antigenic subgroups), 15 225 (strain B1 of antigenic subgroup B) and 15 133 (BRSV strain A51908). The RSV gene order is conserved within genus *Pneumovirus* but, interestingly, that of APV has two differences: it lacks the NS1 and NS2 genes, and part of its gene order has a different arrangement: 3′-F-M2-SH-G-5′ (**Fig. 3**).

As is the case with the Order in general, RNA replication involves the synthesis of a complete positive-sense replicative intermediate that is called the antigenome and serves as the template for the synthesis of progeny genomic RNA. Genomic RNA contains extragenic 3′ 'leader' and 5′ 'trailer' regions of 44 and 155 nt, respectively (**Fig. 2**). The first 26 nucleotides at the 3′ end of genomic RNA have 81% complementarity with the last 24 nucleotides at the 5′ end (**Fig. 2**). One possibility is that this complementarity allows the two ends to interact. However, an alternative and more likely possibility is that the complementarity reflects sequence conservation at the 3′ ends of the genome and antigenome due to the

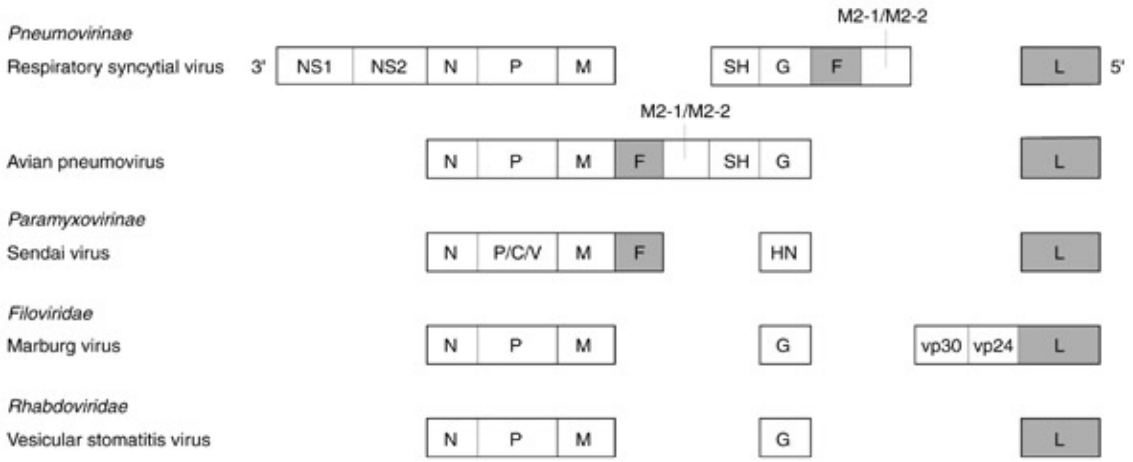

Figure 3 Comparison of the gene maps (not to scale) of the two paramyxovirus subfamilies, *Pneumovirinae* and *Paramyxovirinae*, with those of the filovirus and rhabdovirus families. Each box represents a separate mRNA, with the encoded protein(s) indicated; for mRNAs which contain more than one ORF, the encoded proteins are separated by slashes. The maps were drawn to align analogous proteins vertically when possible. The F and L proteins are shaded to indicate that each exhibits sequence relatedness among the different families. RSV and APV also share sequence relatedness for other proteins, but only F and L have unambiguous relatedness extending beyond the pneumoviruses. The identification of the filovirus P and M proteins is preliminary.

presence of a conserved promoter in each. Also, the conserved 5′ ends might each contain a conserved signal for initiating encapsidation of the nascent RNA. Studies with minireplicons indicate that the RNA signals required for replication are contained in their entirety within the 33–40 nucleotides at the 3′ and 5′ ends of genomic and antigenomic RNA. While certain viruses like Sendai and measles viruses have the remarkable requirement that the genome length be an even multiple of six for efficient replication, there is no such requirement for RSV.

As is characteristic of the Order, RSV transcription initiates at the 3′ genomic promoter and copies the genes by a sequential stop–start mechanism that yields subgenomic mRNAs. Each gene begins with a conserved 10 nt gene-start motif that directs initiation of transcription and encodes the 5′ end of the mRNA, and ends with a 12–13 nt gene-end motif that directs polyadenylation and release of the mRNA (**Fig. 2**). These motifs are self-contained signals that switch the polymerase between transcribing and nontranscribing modes. The first nine RSV genes are separated by intergenic regions, which are of various lengths (1–52 nt for strain A2) and lack apparent conserved sequences. The intergenic regions do not appear to have a significant role in gene expression. In human and animal RSVs, but not in PVM or APV, the last two genes (M2 and L) overlap by 67 (BSRV) or 68 (RSV) nucleotides (**Fig. 2**) and are expressed as separate mRNAs which each contain the overlap sequence. The mechanism for transcribing overlapped genes is not known but does not appear to involve independent internal polymerase entry.

As is typical of this Order, transcription is polar: promoter-proximal genes are transcribed more frequently than downstream ones due to polymerase fall-off. This provides a gradient of transcription thought to be the major factor determining the relative amounts of expression of the various genes. There is no evidence of temporal regulation of gene expression. During transcription, there is a low frequency of readthrough of the gene-end signals, such that 5–10% of the total mRNA consists of readthrough transcripts each representing two or more adjacent genes.

The RSV mRNAs contain a virally-encoded methylated 5′ cap [$m^7G(5')ppp(5')Gp$] and 3′ polyadenylate typical of eucaryotic mRNA, the latter produced by reiterative copying by the viral polymerase on a tract of 4–7 U residues at the downstream side of each gene-end signal. Each mRNA encodes a single major viral protein except for the M2 mRNA, which contains two overlapping ORFs (**Fig. 2**) present in all pneumoviruses. The two ORFs are expressed as separate proteins, although the mechanism for translation of the internal ORF is unknown.

The synthesis of mRNA and antigenome ostensibly occur on the same template, and the factors which regulate the two processes are unknown. The M2-1 elongation factor does not appear to regulate tran-

scription and RNA replication, nor does encapsidation of the nascent RNA by the N protein shift synthesis from that of mRNA to antigenome.

Genetics

Nonsegmented negative-strand viruses in general do not undergo recombination, apart from the polymerase jumping which is involved in the production of short helper-dependent defective-interfering RNA. The differences in the gene orders of RSV and APV (**Fig. 3**) suggest that recombination to yield nondefective infectious genomes can occur, but presumably is very rare.

Negative-sense genomic RNA is not directly infectious alone. However, infectious recombinant RSV can be produced in cultured cells by expression from transfected plasmids of a complete antigenomic RNA and the N, P, L and M2-1 proteins. These components presumably assemble into a nucleocapsid that initiates a productive infection. This method can be used to introduce predetermined changes into infectious virus through the cDNA intermediate.

An alternative genetic system that is very useful for basic studies involves short, internally-truncated, cDNA-encoded genome or antigenome analogues, or minireplicons, in which the viral genes have been replaced with one or more reporter genes under the control of RSV transcription signals. When complemented in *trans* by the appropriate mix of plasmid-encoded RSV proteins, the minireplicons are transcribed, replicated and packaged into virus-like particles which can be passaged to fresh cells. Identification and analysis of the functions of *cis*-acting RNA signals and *trans*-acting proteins using these systems is an active area of research.

Antigens and Antigenic Subgroups

Postinfection human or animal serum contains antibodies to various viral proteins, notably the F, G and N proteins. The F and G proteins are by far the major antigens for neutralizing antibodies, but have markedly different antigenic properties. Many of the available F-specific monoclonal antibodies (MAbs) efficiently neutralize RSV *in vitro,* whereas those for the G protein neutralize weakly or not at all. However, polyclonal antibodies to G neutralize efficiently. The high content of *O*-linked carbohydrate in the G protein is likely to be a factor in its antigenic properties, and indeed the sugars have been shown to be important, directly or indirectly, for the binding of many, but not all, MAbs. Since the sugar side chains are host-specific, they might mask the virus-specified polypeptide chain. Microheterogeneity in the placement of side chains among the many potentially available acceptor sites might result in subpopulations of molecules among which epitopes are variably altered or masked.

RSV is monotypic serologically, with up to four-fold differences between disparate strains in cross-neutralization *in vitro* by postinfection serum. However, binding studies with MAbs showed that RSV isolates can be segregated into two distinct antigenic subgroups designated A and B. Epitopes for F MAbs tend to be conserved, whereas those for G are not, such that antigenic relatedness between the two subgroups is greater than 50% for the F protein, compared with only 5% for the G protein. Comparably distinct antigenic subgroups also have been described for BRSV and APV.

The amino acid sequences of the various RSV proteins are 87% or more identical between the two subgroups, except for the extracellular domains of the SH and G proteins which are only 50% and 43% conserved, respectively. Potential acceptor sites in the G protein for *N*- and *O*-linked sugars also are poorly conserved. These sequence differences provide a structural basis for the observed antigenic dimorphism. The amount of sequence variation between strains within a given subgroup is considerably less, although the G protein is more variable than the others, with as much as 12% amino acid difference. While the presence of antigenic dimorphism in circulating virus is thought to be one mechanism for mitigating host immunity, RSV has not been observed to undergo significant antigenic divergence on the time scale of months or a few years.

RSV infection also generates virus-specific CD4+ helper T cells (Th) and CD8+ cytotoxic T cells (CTLs). Depending on the host and genetic background, various viral proteins have been shown to be T cell antigens. The G protein seems to be a relatively poor antigen for CTLs, perhaps a consequence of its high content of sugar side chains.

Antigenic and Sequence Relatedness of RSV to Other Viruses

Antigenic crossreactivity has been observed between RSV and BRSV for most of the proteins, and between RSV and PVM for the N and P proteins. The amount of sequence divergence between BRSV and RSV is approximately two times greater than between the two RSV subgroups. (For example, the N and F proteins are, respectively, 7% and 19% divergent between RSV and BRSV, compared with 4% and 9% divergence between the RSV subgroups.) As would be expected, the BRSV G protein is the most divergent relative to RSV, being 70% divergent with RSV,

compared with 47% divergence between the G proteins of the RSV subgroups. As an example of the divergence of PVM and APV relative to RSV, the PVM or APV N protein is 40% or 59% divergent, respectively, from its RSV counterpart.

RSV lacks antigenic relatedness with paramyxoviruses outside of its subfamily. The F protein has low but significant sequence relatedness with the F proteins of the other paramyxoviruses. The L protein has low but significant relatedness with L proteins within the Order and contains sequence motifs conserved among a wide range of polymerases and thought to represent catalytic domains. Although the other RSV proteins lack obvious, unambiguous sequence relatedness with their nonpneumovirus counterparts, it is likely that functional similarity (and evolutionary relatedness) exists between these viruses for proteins such as N, P and M (**Fig. 3**).

Virus Infection in Cell Culture and Animals

RSV initiates infection by binding to a cellular receptor(s) which remains to be identified, and the viral envelope fuses with the plasma membrane. Genome expression and replication are entirely cytoplasmic. Progeny virus buds at the plasma membrane in areas of coalesced viral envelope proteins.

RSV can be grown in a variety of cultured cells of human, simian or bovine origin, and can also be adapted to grow in chick cells. The human epidermal HEp-2 or the African green monkey kidney Vero cell lines are the most commonly used. During infection with strain A2 at an input multiplicity of 5, the intracellular production of viral proteins and nucleic acids can be detected by 6–10 h postinfection and reaches maximum at 15–24 h. Virus release begins by 10–16 h and is maximal by 29 h; syncytia become evident by 20–30 h, and extensive cytopathology and destruction of the monolayer occurs at 30–48 h. Host cell macromolecular synthesis does not appear to be inhibited except by the indirect effects of cytopathology. Although most cells infected in culture are killed, persistent infection *in vitro* can be readily established. Much of the progeny virions remain cell-associated and are released by freeze–thawing or sonication. RSV is very labile to inactivation during unfrozen storage or freeze–thawing, although stability can be greatly improved if the harvested culture supernatants are adjusted to pH 7.5 and to contain 0.1 M magnesium sulfate. Virus yield is 10^5 to 5×10^8 PFU ml^{-1} depending on the cell, strain and growth conditions. A yield of 10 PFU per cell is typical, indicating that the production of infectious virus is inefficient indeed. The instability and size heterogeneity of the virion reduces the efficiency of purification and concentration.

The only hosts that are fully permissive for RSV are the human and the chimpanzee. RSV also can replicate in the respiratory tract of several species of monkey as well as in hamsters, guinea pigs, ferrets, mice, and cotton rats. But in these animals the infection is semipermissive: the titer of recoverable virus is 100–1000-fold lower than in the fully-permissive chimpanzee, and disease either does not occur or is greatly reduced in severity.

RSV buds from the apical surface of polarized cultured cells. *In vivo*, RSV infection is generally restricted to the superficial layers of the respiratory tract epithelium; however, it can spread to secondary organs under conditions of immunosuppression or immunodeficiency, indicating that systemic spread is normally restricted by host immunity rather than a viral factor. Infection of monocytes and macrophages has been reported but is of unknown significance. While individuals can shed virus for sustained periods, there is no evidence of persistent infection *in vivo*. RSV inoculated intramuscularly undergoes a single cycle of replication without the production of infectious virus.

Epidemiology and Clinical Factors

RSV is worldwide. It causes yearly epidemics centered in the winter months in temperate climates or in the rainy season in the tropics. It is highly contagious. It is an important cause of nosocomial infection. Spread involves inoculation of conjunctival or mucosal surfaces by hand or aerosolized particles containing respiratory secretions. Essentially everyone is infected by 1–2 years of age, with the greatest incidence of serious disease occurring between 6 weeks and 6 months of age. The relative sparing of newborns is thought to be due to the transient protective effects of maternally-derived serum IgG. The higher incidence of serious disease in young infants probably reflects in part the greater susceptibility of smaller airways to obstruction by edema and secretions. RSV regularly accounts for more than 20% of pediatric hospitalizations due to respiratory tract disease. In developed countries, mortality is very low for normal children. However, infants and children with bronchopulmonary dysplasia, congenital heart disease or immunodeficiency are at special risk for serious, life-threatening RSV disease. In these cases, mortality can be as high as 30%. In the USA, RSV causes an estimated 91 000 hospitalizations and 4500 deaths annually. In developing countries the infant death rate from respiratory disease can exceed 2000 per 100 000 births,

and it is estimated that 20–25% of these would be due to RSV, which can be extrapolated to one million deaths per year worldwide.

During natural infection, RSV has an incubation period of 4–5 days. It causes upper respiratory tract disease, with symptoms of a common cold. Between 25 and 40% of primary infections progress to the lower respiratory tract and cause bronchitis, bronchiolitis or pneumonia. Symptoms include rhinorrhea, middle-ear disease, fever, coughing and wheezing. Seriously ill infants have increased coughing and wheezing, rapid respiration and hypoxemia, requiring the administration of humidified oxygen. The duration of illness is 7–12 days. Virus is shed in large amounts (10^4–10^6 PFU ml^{-1} nasal wash) throughout infection and sometimes during recovery.

RSV infection can be diagnosed rapidly and efficiently by the detection of viral antigens by immunofluorescence of exfoliated cells or enzyme-linked immunosorbent assay (ELISA) of respiratory secretions. Other methods in common use include isolation of the virus in cell culture or detection of an increase in RSV-specific antibodies during convalescence.

RSV is unusual in that it can infect young infants despite the presence of maternally-derived virus-neutralizing serum IgG. This reflects the inefficiency with which serum IgG moves by transudation on to the respiratory tract mucosa and indicates the importance of local immunity in restricting virus replication in the upper respiratory tract. It is not clear why RSV is more infectious under these conditions than are other viruses of the respiratory tract. Another striking feature of RSV is its ability to reinfect repeatedly during childhood and throughout life. Certainly the transient nature of local secretory immunity and the relative ineffectiveness of serum antibodies in accessing the luminal surface of respiratory mucosa are factors in frequent reinfections. But it is not clear why reinfections are so much more frequent with RSV than with other viruses of the respiratory tract. The two antigenic subgroups have been described as alternating in local prevalence from year to year, supporting the idea that the degree of antigenic variation can contribute to reinfection. That the G protein, one of the two protective antigens, might be sheathed in sugar, might exhibit microheterogeneity in side-chain location and structure, and is produced in part as a secreted form, presents other possible mechanisms for mitigating the effectiveness of host immunity. Although the virus can reinfect, serious disease is associated mostly with first or second infection. Sparing during subsequent infections is due to immunological restriction of virus replication in the lower respiratory tract, and indicates that immunoprophylaxis is feasible.

Much of the pathogenesis of RSV is the direct result of destruction of epithelial cells by virus replication and the concomitant edema, mucus secretion and influx of lymphocytes and macrophages. Pathogenesis can probably also be influenced by additional immune factors, such as antibody-mediated or cell-mediated hypersensitivity, which remain to be elucidated. In some individuals, airway reactivity in RSV disease might involve an allergic-type reaction mediated by IgE. The ability of immune factors to profoundly influence RSV pathogenesis is illustrated by the enhancement of RSV disease associated with immunization with a formalin-inactivated RSV vaccine (see below). A long-term reduction in pulmonary function is a common sequel to serious RSV disease, but it is not clear whether this is due to the infection or whether such individuals already had underlying pulmonary deficiencies which predisposed them to serious RSV infection.

Immunity

The major mechanisms for resolving primary infection appear to be innate immune mechanisms, CTLs and antibodies. In naive mice, the reduction in pulmonary RSV replication coincided with the appearance of RSV-specific CD8+ CTLs and was inhibited by prior depletion of that subset. Children deficient in cell-mediated immunity experience more serious disease and have difficulty resolving infection. Studies in calves and humans indicated that the appearance of secretory antibodies is coincident with viral clearance. The late appearance of serum antibodies suggests that they are less important in resolving the primary infection.

In experimental animals immunized with individual RSV proteins, antigens which elicited predominantly either (1) neutralizing antibodies or (2) RSV-specific CTLs could induce resistance to subsequently challenge virus replication. However, the resistance induced by CTL antigens was short-lived compared with that afforded by neutralizing antibodies. This suggests that, while CTL clearly have an important role in resolving infection, the long-term resistance to virus replication that develops from prior infection or immunization is more likely to be mediated by antibodies. The F and G proteins are the major RSV antigens which induce virus-neutralizing antibodies and protection. Secretory IgA antibodies are important mediators of resistance in the upper respiratory tract but are relatively short-lived. Virus-neutralizing serum antibodies alone can restrict virus replication in the lower respiratory tract, an effect due to their transudation, albeit inefficient, on to the respiratory epithelium.

Immunoprophylaxis and Treatment

Because natural RSV infection does not provide complete, long-lasting resistance to reinfection, it seems unlikely that a vaccine will do so. None the less, early immunization could reduce the incidence of serious disease associated with the first one or two infections of life. It is likely that natural infections would not be prevented, but their consequences would be reduced in severity and would have the desirable effect of boosting immunity. Very young infants, who would be the targets for immunization, have been shown to have reduced immune responses to RSV infection owing to immunologic immaturity. Also, maternally-derived serum antibodies can suppress the induction of antibodies and CTLs, although this effect can be abrogated to a considerable extent by direct immunization of the respiratory tract. Recent vaccine trials suggest that very young infants can mount a satisfactory immune response against live attenuated RSV administered intranasally.

Vaccine safety is a major consideration. A vaccine made from formalin-inactivated, concentrated RSV and tested in 1966 failed to prevent natural infection and, paradoxically, primed the vaccinees for an increased frequency and severity of disease upon subsequent natural infection. The lack of protective efficacy was probably due to denaturation of neutralization epitopes, and the disease enhancement appears to be due to an exaggerated Th response, perhaps one imbalanced in favor of a Th2-type response instead of the Th1-biased response typical of natural infection. The elucidation of this phenomenon, and the testing of RSV vaccines in general, is complicated by the semipermissive nature of RSV infection in convenient experimental animals like the mouse.

Live attenuated RSV strains for immunization by intranasal infection are under development and might represent the safest, most effective vaccine. Recombinant vaccinia and adenoviruses which express the F or G glycoproteins have been tested in experimental animals as prototype vaccines but, to date, have not been sufficiently immunogenic. Purified F and G glycoproteins for intramuscular immunization have been produced from cultured mammalian cells infected with RSV or from cultured insect cells infected with recombinant baculoviruses. The noninfectious nature of a subunit vaccine might be especially appropriate for immunization of the very young. But these purified antigens appear to induce antibodies with low neutralizing activity, perhaps due to denaturation during preparation, and there are indications that they, like the formalin-inactivated vaccine, prime for immune-mediated pathology upon subsequent infection.

Ribavirin treatment of hospitalized normal or high-risk infected children is well established, although debate as to its level of efficacy has continued. The administration of aerosolized ribavirin to children who were seriously ill and supported by mechanical respirators is associated with improvement and reduced hospital stay. As another approach, the systemic or topical application of RSV-neutralizing antibodies (either polyclonal serum antibodies or murine MAbs) to infected experimental animals was shown to be efficacious both in immunoprophylaxis and therapy. This concept led to the recent development of a strategy in which a pooled human serum antibody preparation with high RSV-neutralizing activity (RespiGam^{TM}) is administered intravenously to high-risk children as a method of passive immunoprophylaxis. A further improvement will be to increase the specific antiviral activity by replacing the preparation of serum antibodies, of which only a small component is RSV-specific, with humanized or human RSV-specific MAbs. Also, application of antibodies directly to the respiratory tract of infected individuals might be effective in curtailing infection and disease.

RESPIRATORY VIRUSES

David O White and **Lorena E Brown**, Department of Microbiology and Immunology, The University of Melbourne, Parkville, Victoria, Australia

Introduction

The respiratory tract is a major portal of entry for pathogenic organisms; infections at this site are the most common afflictions of humans. Children contract up to half a dozen respiratory illnesses each year, adults perhaps two or three, and most of these are caused by viruses. Though trivial colds and sore throats account for the majority of respiratory disease, their impact on communities is significant; millions of lost working hours and a considerable proportion of all visits to family physicians can be attributed to this type of infection. More serious lower respiratory tract infections tend to occur at the extremes of life, and in those with pre-existing pulmonary conditions. The most important human respiratory viruses are influenza and respiratory syncytial viruses (RSV), the former killing mainly the aged and the latter the very young. Of the estimated 5 million deaths from respiratory infections in children annually worldwide, at least one million are viral in origin.

Altogether, there are over 200 human respiratory viruses, falling mainly within six families: orthomyxoviruses, paramyxoviruses, picornaviruses, coronaviruses, adenoviruses and herpesviruses (see corresponding entries elsewhere in this text). Here we shall confine ourselves to those that enter the body via the respiratory route and cause disease confined largely to the respiratory tract. Many other 'respiratory' viruses become disseminated via the bloodstream to produce a more generalized disease, as is the case with most of the human childhood exanthems such as measles, rubella and varicella, or rinderpest and foot-and-mouth disease in cattle. Yet other viruses, entering by nonrespiratory routes, can reach the lungs via systemic spread, and pneumonia may represent the final lethal event, e.g. in overwhelming infections with herpesviruses or adenoviruses in immunocompromised neonates or patients with the acquired immune deficiency syndrome (AIDS).

Epidemiology

By definition, respiratory viruses are transmitted via the respiratory route. Virions are shed from the respiratory tract of an infected human or animal, particularly during sneezing, coughing, talking or barking. A sneeze generates an aerosol comprising up to a million tiny droplets less than 10 μm in diameter that quickly evaporate to yield droplet nuclei which remain suspended in the air for several minutes. This particulate material containing virions transmits infection following inhalation by someone nearby. Larger droplets (up to 100 μm) contain more virions but fall to ground within seconds. They are a danger to anyone directly in the line of fire. Alternatively, respiratory infections can spread by direct contact, e.g. kissing, or by transfer of nasal or oral secretions via hands to nose or mouth. At the height of a common cold such secretions are particularly copious and readily find their way on to handkerchiefs, towels, toothbrushes, eating utensils, doorknobs and so on, as well as hands.

Enveloped viruses such as orthomyxoviruses, paramyxoviruses and coronaviruses tend to be rather susceptible to inactivation by desiccation or by summer temperatures, but icosahedral viruses such as adenoviruses and picornaviruses are more stable; for example, certain outbreaks of foot-and-mouth disease have been attributed to virus carried in the wind for 100 km.

We associate respiratory infections with cold, wet weather but there is no evidence that the winter incidence of the common cold, or indeed any other respiratory disease, is attributable to cold or wet *per se*. Colds are not common in Arctic or Antarctic explorers, for example. It seems more likely that the striking winter peaks of respiratory disease caused by influenza and RSV (**Fig. 1**) are a reflection of our predilection during that season for avoiding the invigorating outdoor climate and shutting ourselves away in ill-ventilated centrally-heated buildings and vehicles, in close apposition to others of like mind. This hypothesis is supported by the observation that in the tropics, where summer and winter are replaced by 'wet' and 'dry' seasons, respiratory infections are more prevalent during the monsoonal rains when people spend more time indoors, exchanging parasites in crowded, often squalid conditions. An additional factor in the less developed world is the domestic air pollution (smoke) generated by the ever-present fire, lit for cooking and warmth inside poorly ventilated huts. Outbreaks of influenza often occur in boarding

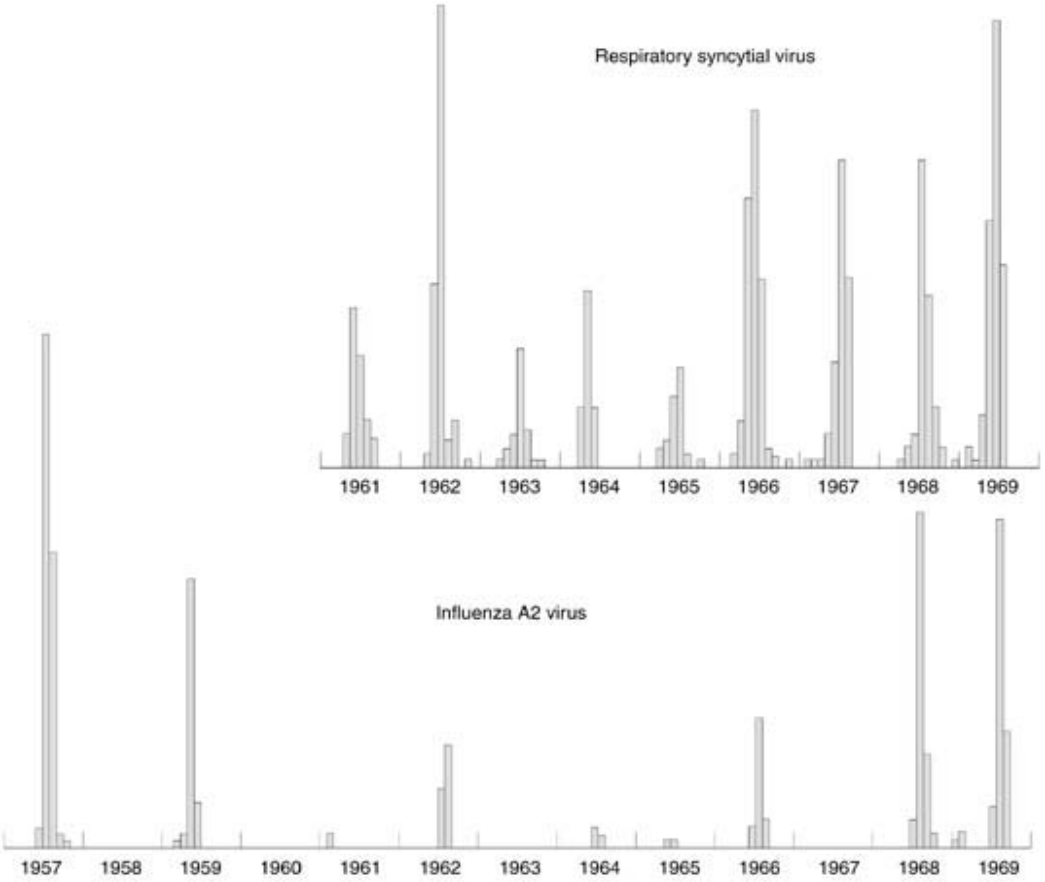

Figure 1 Epidemic occurrence of influenza A and respiratory syncytial viruses. The histograms show the monthly isolations of these two viruses from patients admitted to the Fairfield Hospital for Infectious Diseases, Melbourne, over the periods indicated. Compare the regular winter epidemics of RSV (causing significant disease mainly in infants) with the less regular winter epidemics of influenza. There were major peaks of influenza in 1957 (first appearance of the new human influenza subtype H2N2, known as 'Asian flu') and then again in 1968 (marking the emergence of the novel subtype H3N2, known as 'Hong Kong flu'). (Data courtesy of Drs A. A. Ferris, F. Lewis and I. D. Gust. From Fenner F and White DO (1976) *Medical Virology* 2nd edn. New York: Academic Press.)

schools, army camps, nursing homes, etc.; similarly, nosocomial spread of RSV is common in hospital nurseries. Livestock such as cattle are particularly vulnerable when crowded together in feed-lots or transport vehicles, e.g. shipping fever.

Respiratory viruses spread with great facility and speed, albeit not with the explosive onset that characterizes certain 'common source' outbreaks of enteric viruses when feces contaminate food or water supplies. First, respiratory diseases have a very short incubation period, usually 2–7 days. Second, very large numbers of virions (10^3–10^9 per ml of respiratory secretions) are shed, commencing even before symptoms develop, and peaking around the time the patient is coughing or sneezing with greatest abandon. A single infectious particle may infect a susceptible contact. Typically, a young child picks up the latest virus at school, brings it home and passes it on to the rest of the family and perhaps to the neighbours' children. Within 2 or 3 months up to half the population of a city may have contracted the infection and developed immunity to the virus. As the proportion of uninfected susceptibles in the community falls, the epidemic burns itself out (**Fig. 1**).

Respiratory viruses may evolve quite rapidly in the field. RNA viruses in particular display a very high rate of mutation, because their RNA polymerase is error prone and lacks the error-correcting capability that accompanies DNA replication. Any spontaneously arising mutant that is capable of replicating in the presence of antibody against the wild-type virus will have a growth advantage. Eventually mutants emerge that contain amino acid substitutions in most or all of the immunodominant antigenic domains on the critical surface protein of the virion. Such multiple mutants, no longer neutralizable by wild-type antibody, are designated a new strain and may initiate another epidemic. This phenomenon is known as

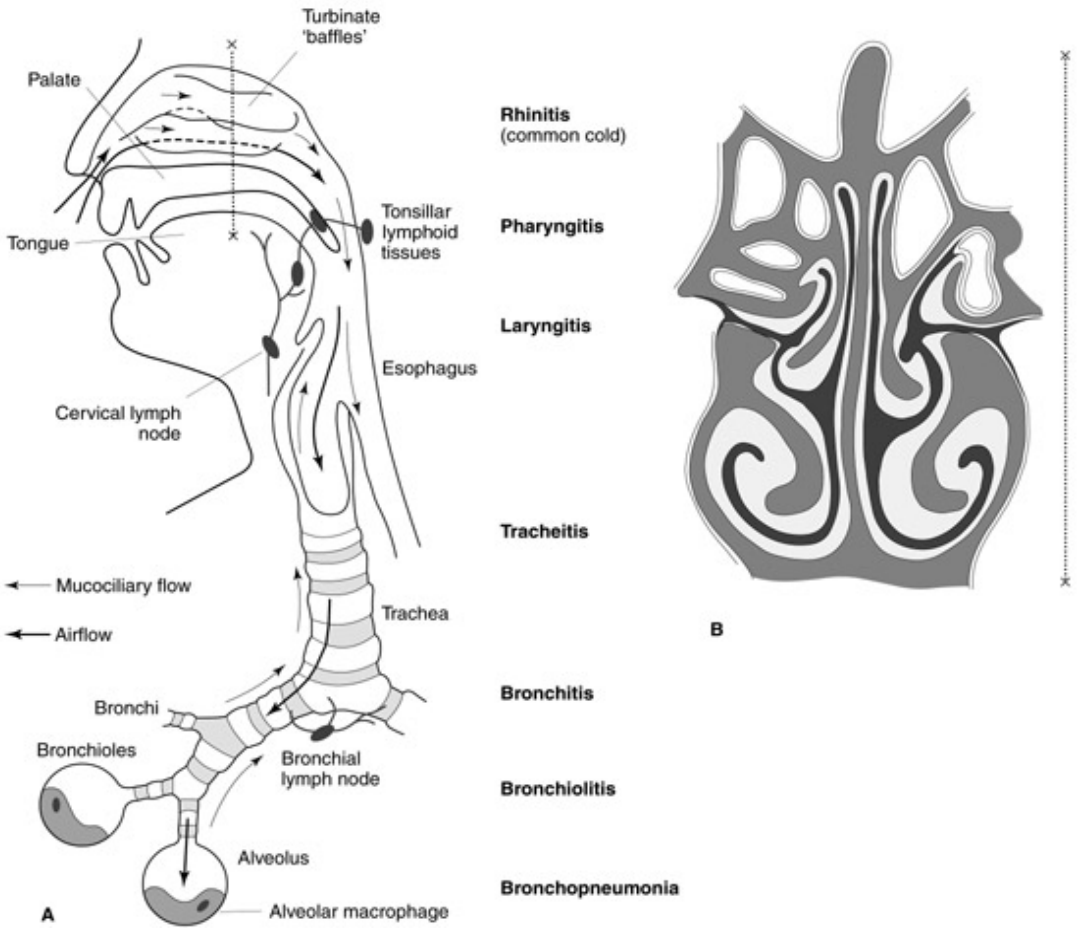

Figure 2 (**A**) Pathways of infection and mechanical protective mechanisms in the respiratory tract. On the right, clinical syndromes produced by infection at various levels of the respiratory tract. (**B**) Section of the turbinates (X—X) magnified 2.5 times, showing the narrow and complicated pathway of inspired air, and thus the ease with which slight swelling 'blocks the nose'. (From White and Fenner (1994), as modified from Mims CA and White DO (1984) *Viral Pathogenesis and Immunology*. Oxford: Blackwell Scientific.)

antigenic drift. While best characterized for influenza, it is presumably the mechanism that has also given rise to the dozens of known serotypes of rhinoviruses, enteroviruses, adenoviruses, and so on. A second, more dramatic type of change, known as antigenic shift, is observed in RNA viruses with segmented genomes that can undergo genetic reassortment. Novel subtypes of human influenza A viruses, capable of initiating pandemics that can infect the majority of the world's population within a year, arise every generation or so as a result of reassortment following co-infection of, say, a pig with a human and an avian influenza virus simultaneously.

Pathogenesis and Immunity

Inhaled droplets of more than 10 μm in diameter are trapped in the turbinates of the nose (**Fig. 2**), whereas those measuring 5–10 μm often reach the trachea and bronchioles. Many of these particles become trapped in the layer of mucus that blankets the ciliated epithelium and are carried by ciliary action to the pharynx, where they are swallowed or coughed out. Smaller particles still can be inhaled directly into the lung and some may reach the alveoli. Here, virus may be phagocytosed and destroyed by alveolar macrophages (although some viral species undergo an abortive cycle of replication and others have developed the capacity to replicate in macrophages). A few virions will succeed in attaching to susceptible epithelial cells via the appropriate ligand–receptor pairing and thereby initiate infection. Progeny virions will be released a few hours later, often by budding from the apical surface of the cell into the lumen of the respiratory tract, and then initiate a second cycle of infection in adjacent or more distant cells. Some of the enveloped species of respiratory viruses are dependent upon a particular cellular protease to

cleave the appropriate viral envelope glycoprotein, e.g. influenza HA, or RSV F protein, otherwise the progeny are noninfectious. Moreover, mucus contains glycoprotein inhibitors which can neutralize the infectivity of certain viruses, e.g. influenza. Mannose-binding lectins such as those in lung surfactant can also neutralize virus. Interferon, synthesized by and secreted from virus-infected cells, binds to interferon receptors on nearby uninfected cells and protects them by inhibiting viral replication.

If specific neutralizing antibodies of the IgA class are already present in the mucus coating the respiratory tract as a result of previous infection or vaccination, they will bind to the corresponding epitopes on the surface of the virion and neutralize its infectivity by blocking attachment or fusion of viral envelope with plasma membrane or endocytic vesicle, thus preventing uncoating of the viral genome. In the absence of pre-existing antibody, however, infection can progress because primary antibody synthesis does not become significant for several days. Additional mechanisms are brought into play to control viral replication during this early period, with the first cells to be mobilized being the natural killer (NK) cells from bone marrow, which become activated by interferon (IFN) to lyse virus-infected cells. Shortly thereafter, the relevant clones of T lymphocytes are activated. Helper T (Th) cells (CD4+) recognize peptides generated from endocytosed virions by proteolysis and presented in the peptide-binding groove of the class II major histocompatability complex (MHC) molecules on the surface of antigen-presenting cells (dendritic cells and macrophages) and are triggered to proliferate and to secrete a range of lymphokines that mediate inflammation by attracting macrophages and other leukocytes to the site, and by upregulating macrophages, B cells and T cells. Cytotoxic T cells (CD8+), on the other hand, see endogenous viral peptides generated by proteolysis of newly synthesized viral proteins and bound to class I molecules on the surface of infected cells.

A major mechanism of recovery from viral infection is lysis of infected cells by activated CD8+ T lymphocytes, preferentially but not exclusively by a perforin/granzyme-mediated process. Children with a congenital T cell deficiency may die from measles or RSV infection; conversely, influenza virus-infected athymic mice may be saved by adoptive transfer of virus-specific CD8+ T cells. CD4+ T cells also contribute to the process of recovery by secretion of cytokines such as IFN-γ and through provision of help to B cells in the developing humoral response. Specific antibodies may act by (1) neutralizing virus, (2) complement-mediated lysis of infected cells, or (3) antibody-dependent cell-mediated cytolysis (ADCC). In addition, IgA, during its active passage through respiratory epithelial cells, may combine with viral proteins produced within these cells, resulting in reduced output of infectious progeny.

Whereas the immune response to respiratory infection is instrumental in recovery, it can also, paradoxically, exacerbate the disease itself. CD4+ Th1 cells may induce such a strong inflammatory response (delayed-type hypersensitivity or DTH) as to cause lethal consolidation of the lung (pneumonia). Furthermore, responses orchestrated by the type 2 cytokines IL-4 and IL-5, namely IgE production and eosinophil degranulation, can precipitate a life-threatening attack of asthma in a young infant infected with RSV. Other factors may also contribute to RSV bronchiolitis: virus infection not only enhances bronchial reactivity to antigen but also destroys the ciliated epithelial cells responsible for mucociliary clearance, thus allowing the infant's narrow bronchioles to become plugged with mucus, inflammatory cells and necrotic cell debris, while bronchoconstriction may also be triggered by vagal nerve reflexes or by release of mediators by inflammatory cells. Blockage of airways causes hypoxia and a pathophysiologic cascade that leads to acidosis and uncontrollable fluid exudation into airways.

Superinfection with bacteria, typically *Streptococcus pneumoniae, Haemophilus influenzae* or *Staphylococcus aureus*, often complicates viral pneumonitis, and without chemotherapy can lead to a fatal outcome. The very young and very old are particularly at risk, as are the immunocompromised, and premature or malnourished infants.

Systemic viral infections such as measles generate a strong memory response and prolonged production of IgG antibodies, which protect against reinfections for life. In contrast, viruses that cause infection localized to the respiratory tract, with little or no viremia, e.g. RSV or rhinoviruses, induce only a relatively short-lived mucosal IgA antibody response, and reinfections with the same or a somewhat different strain can recur repeatedly throughout life. In addition, numerous strains arising by antigenic drift may cause sequential episodes of the same disease in a single individual.

Viral Diseases of the Human Respiratory Tract

While some viruses have a predilection for one particular part of the respiratory tract, most are capable of causing disease at any level and the syndromes to be described below overlap somewhat (**Fig. 3**). Nevertheless, for ease of description we will

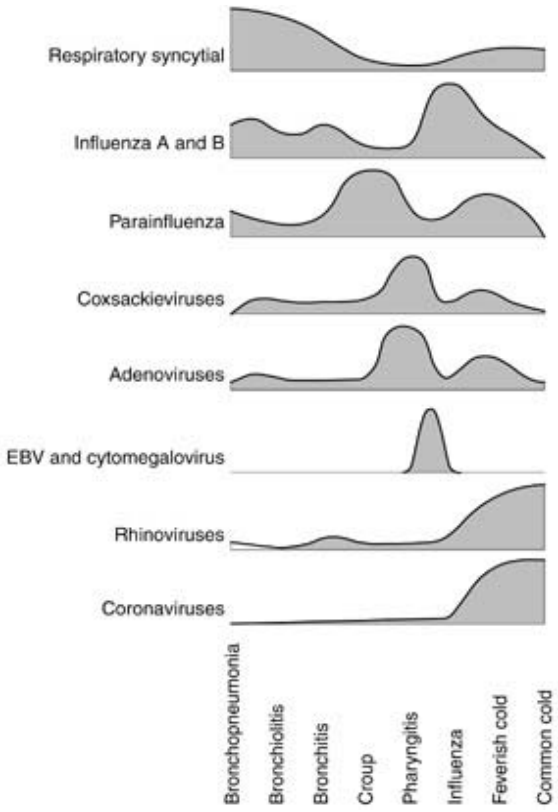

Figure 3 Frequency with which particular viruses produce disease at various levels of the human respiratory tract. (Data courtesy of Dr D. A. J. Tyrrell. From White and Fenner (1994).)

designate six basic diseases of increasing severity as we descend the respiratory tract: rhinitis, pharyngitis, croup, bronchitis, bronchiolitis and pneumonia (Table 1).

Rhinitis (common cold)

The classical common cold (coryza) is marked by copious watery nasal discharge and congestion, sneezing, and perhaps a mild sore throat or cough, but little or no fever. Rhinoviruses are the major cause, several serotypes being prevalent all year round and accounting for about half of all colds. Coronaviruses are responsible for about another 15%, mainly those occurring in the winter months. Certain enteroviruses, particularly coxsackieviruses A21 and A24, and echoviruses 11 and 20 cause febrile colds and sore throats in the summer. In children, RSV, parainfluenza viruses and the lower-numbered adenoviruses are between them responsible for up to half of all upper respiratory tract infections (URTI or URI).

Otitis media or sinusitis sometimes complicate URI. Bacterial superinfection is generally involved, but viruses have also been recovered from the effusion. Respiratory infections with RSV, influenza, parainfluenza, adenovirus or measles viruses predispose to otitis media. Indeed, repeated viral infections can precipitate recurrent middle ear infections, leading to progressive hearing loss.

Pharyngitis

Most pharyngitis is of viral etiology. URI with any of the viruses just described can present as a sore throat, with or without cough, malaise, fever and/or cervical lymphadenopathy. Influenza, parainfluenza and rhinoviruses are common causes throughout life, but other agents are prominent in particular age groups: RSV and adenoviruses in young children; herpesviruses in adolescents and young adults. Adenoviruses, though not major pathogens overall, are estimated to be responsible for about 5% of all respiratory illnesses in young children, often presenting as pharyngoconjunctival fever. Primary infection with herpes simplex virus (HSV), if delayed until adolescence, presents as a pharyngitis and/or tonsillitis rather than as the gingivostomatitis seen principally in younger children; the characteristic vesicles, rupturing to form ulcers, can be confused only with herpangina, a common type of vesicular pharyngitis caused by coxsackie A viruses. Infectious mononucleosis (glandular fever) is usually marked by a very severe pharyngitis, often with a membranous exudate, together with cervical lymphadenopathy and fever; this syndrome is generally caused by Epstein–Barr (EB) virus in 15–25-year-olds, and less commonly by cytomegalovirus.

Laryngotracheobronchitis (croup)

Croup is one of the serious manifestations of parainfluenza and influenza virus infections. A young child presents with fever, cough, inspiratory stridor and respiratory distress, sometimes progressing to complete laryngeal obstruction and cyanosis. Parainfluenza viruses are responsible for about half of all cases, type 1 being more common than type 2. Influenza and RSV are important causes during winter epidemics.

Bronchitis

Influenza, parainfluenza and RSV are the main viral causes of acute bronchitis. There is also evidence that chronic bronchitis, which is particularly common in smokers, may be exacerbated by acute episodes of infection with influenza viruses, rhinoviruses or coronaviruses.

Table 1 Human respiratory viral diseases

	Virus	
Disease	*Common*	*Less common*
Rhinitis (common cold)	Rhinoviruses	RSV, parainfluenza, influenza
	Coronaviruses	Adenoviruses
		Coxsackie A21, 24; echo 11, 20
Pharyngitis	Parainfluenza 1–3	Rhinoviruses
	Influenza	Adenoviruses 1–7
	Herpes simplex	RSV
	EB virus	Cytomegalovirus
	Coxsackie A	
Laryngotracheobronchitis (croup)	Parainfluenza	RSV
	Influenza	
Bronchiolitis	RSV	Influenza
	Parainfluenza 3	
Pneumonia	RSV	Adenoviruses 3, 7
	Parainfluenza 3	Cytomegalovirus
	Influenza	Measles
		Varicella

Bronchiolitis

RSV is the most important respiratory pathogen during the first year or two of life, being responsible, during winter epidemics, for about half of all bronchiolitis in infants. Parainfluenza viruses (especially type 3) and influenza viruses are the other major causes of this syndrome. Breathing becomes rapid and labored, and is accompanied by a persistent cough, expiratory wheezing, cyanosis, a variable amount of atelectasis, and marked emphysema visible by x-ray. The disease can develop with remarkable speed and is one of the causes of sudden infant death syndrome (SIDS), where an infant may die overnight.

Pneumonia

Whereas viruses are relatively uncommon causes of pneumonia in adults, they are very important in young children. RSV and parainfluenza (mainly type 3) are between them responsible for 25% of all pneumonitis in infants in the first year of life. Influenza also causes a considerable number of deaths during epidemic years. Adenoviruses 3 and 7 are less common but can be severe; long-term sequelae such as obliterative bronchiolitis or bronchiectasis may permanently impair lung function. Up to 20% of pneumonitis in infants has been ascribed to perinatal infection with cytomegalovirus (CMV). CMV may also cause potentially lethal pneumonia in immunocompromised patients, as may measles, varicella and adenoviruses. Moreover, viral pneumonia not uncommonly develops in adults with varicella, and in military recruits involved in outbreaks of adenovirus 4 or 7, while measles is often complicated by bacterial pneumonia, especially in malnourished children in Africa and South America. In the elderly, and particularly in those with underlying pulmonary or cardiac conditions, influenza is a major cause of death, either via influenza pneumonitis or more commonly via secondary bacterial pneumonia.

Viral pneumonitis often develops insidiously following URI and the clinical picture may be atypical. The patient is generally febrile, with a cough and a degree of dyspnea, and auscultation may reveal some wheezing or moist rales. Unlike typical bacterial lobar pneumonia with its uniform consolidation, or bronchopneumonia with its streaky consolidation, viral pneumonitis is usually confined to diffuse interstitial lesions. The radiological findings are not striking; they often show little more than an increase in hilar shadows or, at most, scattered areas of consolidation.

Space does not permit a discussion of veterinary diseases, but **Table 2** lists some of the most important respiratory viral diseases of farm and companion animals. Most of these agents are relatively specific to a single animal species, or to closely related species, and do not infect humans. Influenza is occasionally transmitted to humans following close contact with

Table 2 Major respiratory viral diseases of animals

Host	*Disease (virus)*	*Virus family*
Cattle	Infectious bovine rhinotracheitis	*Herpesviridae*
Cattle	Respiratory syncytial virus	*Paramyxoviridae*
Cattle, swine	Foot-and-mouth disease	*Picornaviridae*
Horse	Equine rhinopneumonitis	*Herpesviridae*

Dog	Canine distemper	*Paramyxoviridae*
Chicken	Infectious laryngotracheitis	*Herpesviridae*
Chicken	Avian infectious bronchitis	*Coronaviridae*
Birds	Newcastle disease	*Paramyxoviridae*
Birds, horses, swine	Influenza	*Orthomyxoviridae*

pigs or birds infected with a swine or avian influenza virus respectively, but generally fails to spread beyond the first human case. At the time of writing an avian influenza strain has caused a small number of deaths in Hong Kong residents recently in contact with infected chickens. The greater danger in such a situation is the possibility of genetic reassortment occurring between the avian strain and a human strain already well adapted to human–human transmission. A recently discovered paramyxovirus, known as equine morbillivirus because it was responsible for the death from pneumonia of several racehorses as well as their well-known trainer, now appears to be native to Australian fruit-eating bats.

Laboratory Diagnosis

The etiology of respiratory viral infection can be established in the laboratory by identifying the virus itself, viral antigen or the viral genome. The most appropriate specimen is generally a throat swab or, better still, mucus aspirated from the nasopharynx, taken early in the disease. Because enveloped respiratory viruses with helical nucleocapsids are notoriously labile, the specimen is kept cold and moist, transported promptly to the laboratory and processed as soon as practicable.

Enzyme immunoassay (EIA) is the method of choice for the rapid detection of antigen in respiratory secretions. Diagnostic kits, based on appropriate monoclonal antibodies for antigen-capture and detection respectively, and often incorporating a biotin–avidin readout system, are now available for all common human respiratory viruses and many of the important animal pathogens. EIA is replacing immunofluorescence (application of fluorescein-labeled monoclonal antiviral antibody to infected cells aspirated from the throat). Multiple target (multiplex) polymerase chain reaction (PCR) for the amplification of the viral genome, followed by its identification using an appropriate nucleic acid probe, is fast becoming popular as a diagnostic technique for respiratory infections and in epidemiologic investigations.

Most of the known respiratory viruses can quite readily be cultivated in appropriate cell lines from the corresponding host species, e.g. diploid lung fibroblasts or HUT-292 cells for human viruses. Growth of the virus is detected by cytopathic effects and/or hemadsorption or immunofluorescence, and the virus recovered from the supernatant is then typed using any of a variety of serological techniques. However, this sequence is so time consuming and expensive that isolation and identification of virus is today undertaken mainly by reference laboratories requiring a large supply of the virus for further characterization, for research, or for antigen or vaccine production. Viral culture nevertheless remains a vital first step in the identification of agents responsible for newly emerging diseases.

'Serology', i.e. identification and quantification of antibody in the patient's serum, is also far too slow to be of value in influencing the management of the patient, hence it is used principally in seroepidemiological surveys to assess the immune status of populations. IgM-capture EIA does provide a rapid diagnosis but fills only a limited role in the routine diagnostic laboratory.

Vaccines and Chemotherapy

Very successful live attenuated vaccines are in general use against certain 'respiratory' viruses like measles, mumps and rubella, which, though naturally trans-

mitted via the respiratory route, are absolutely dependent upon viremic spread to their target organs elsewhere in the body. In contrast, it is a much more challenging assignment to develop effective vaccines against viruses whose pathogenicity is essentially confined to the respiratory tract. The major reasons for this are that (1) secretory IgA memory is relatively short-lived, and (2) numerous antigenically distinct strains or serotypes are capable of causing the same clinical syndrome. Thus, a common cold vaccine might need to contain dozens of different serotypes of rhinoviruses (± coronaviruses). An inactivated vaccine is used to protect the aged and other risk groups against the currently prevalent strains of influenza, but its composition must be updated regularly to keep abreast of antigenic drift and shift and, even so, its efficacy in the aged is only of the order of 50–80%. The incorporation into vaccines of mucosal adjuvants, e.g. low-toxicity mutants or individual subunits of cholera toxin and *Escherichia coli* heat-labile toxin, is being examined in the hope of stimulating potent antiviral mucosal IgA responses. Improved antigen-delivery strategies, many of which utilize the size and multivalent antigen presentation properties of the viruses themselves, are also being investigated. Immunostimulatory complexes or 'ISCOMs', which are small adjuvant- and lipid-containing particles into which viral proteins can be inserted, already form the basis for an equine influenza vaccine. Live 'cold-adapted' mutants, for many years licensed as influenza vaccines in Russia, replicate only at the low temperature of the nose and are generally avirulent. Although it has proven difficult to walk the tightrope between genetic stability of avirulence on the one side, and adequate replication (hence immunogenicity) on the other, there is currently considerable interest in re-exploring the potential of such viral mutants for intranasal vaccination in other parts of the world. Another potentially exciting vaccine strategy is the use of recombinant DNA encoding the vaccine antigen, delivered in the form of a plasmid by syringe or 'gene gun'. Such vaccines, encoding the nucleoprotein and hemagglutinin of influenza A virus, have successfully elicited protective responses in animals. Subsequent efforts in this area include methods for enhancing the efficiency of transfection of host cells to increase the feasibility of application in humans.

In the long term another source of hope may lie with antiviral chemotherapeutic agents (see Antivirals), although significant barriers still remaining are (1) the multiplicity of viruses involved and the specific antiviral spectrum of available agents; (2) difficulties with drug delivery, efficacy and toxicity; (3) the fact that high titers of virus may be produced even before the onset of symptoms; and (4) emergence of drug-resistant mutants. Since the discovery of interferon in 1957, the field of antiviral chemotherapy has moved slowly. Although IFN-α is effective when given intranasally shortly before or after virus exposure, its use is not practical because of cost of production, frequency of doses required and problems with local bleeding and discharge. The only agents currently in use against respiratory viruses are (1) amantadine and its methylated derivative rimantadine, which display activity against influenza A if given prophylactically and act by interfering with the ion flux mediated by the M2 channel-forming protein of the virus, thereby inhibiting its uncoating; and (2) ribavirin, a nucleoside analogue, which may be of value in severely ill infants with RSV bronchiolitis/pneumonia when administered as a small-particle aerosol. More recently, thanks to x-ray diffraction and cryoelectron microscopy techniques, sites on viral proteins essential for interaction with the host cell receptor or otherwise critical to the infectious process can be visualized. From this has blossomed the age of computer-aided drug design for the development of antivirals. Among the compounds already in clinical trial are those that block the enzyme active site of influenza neuraminidase, a glycoprotein whose role is to facilitate the release of progeny virions from infected cells and prevent self-aggregation of the virus. Others target a small hydrophobic pocket within the canyon region of the coat proteins of rhinoviruses; these drugs stabilize the coat proteins, thereby preventing uncoating and release of viral RNA for replication. Viral mutants resistant to these drugs can be derived in the laboratory but their significance *in vivo* remains to be established.

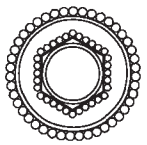
RETICULOENDOTHELIOSIS VIRUSES (*RETROVIRIDAE*)



Radmila Hrdlickova, **Jiri Nehyba** and **HR Bose**, Department of Microbiology and Institute for Cellular and Molecular Biology, University of Texas, Austin, Texas, USA

Introduction

The reticuloendotheliosis (RE) viruses constitute a small group of avian retroviruses which are genetically and immunologically unrelated to the avian leukosis-sarcoma viruses (ALSV) complex. Interesting aspects of RE viruses include their evolution, tumorigenicity, and the immunosuppression they induce.

Taxonomy, Classification and Evolution

RE viruses belong to the *Retroviridae*, a large family of RNA viruses that replicate through a DNA intermediate. Seven genera of retroviruses are recognized and the RE viruses belong to the same genus (*Betaretrovirus*) as the murine leukemia viruses (MLV). The RE group includes the acutely transforming reticuloendoendotheliosis virus, strain T (REV-T), its helper virus, reticuloendotheliosis associated virus (REV-A), spleen necrosis virus (SNV), chicken syncytial virus (CSV), duck infectious anemia virus (DIAV), and other isolates from chickens, ducks, geese, pheasants and turkeys. A total of 26 replication-competent RE virus isolates have been biologically cloned. Only one acutely transforming replication-defective member (REV-T) has been identified. Three antigenic subtypes of RE viruses are distinguished on the basis of their reactivity with monoclonal antibodies, but all RE viruses belong to a single interference group. No endogenous RE viruses have been recognized.

Nucleotide sequence analysis has demonstrated that the RE viruses are more related to mammalian retroviruses than to the other avian retroviruses. The *gag* and *pol* sequences of RE viruses are closely related to gibbon ape leukemia virus (GALV), a primate type C retrovirus, whereas, the nucleotide sequences of *env* gene are approximately 50% identical at the amino acid level to those of simian type D retroviruses and two type C retroviruses – feline endogenous virus (RD114) and baboon endogenous virus (BAEV). All of these viruses share a common receptor. However, the *env* sequence of RE viruses also shares 30% identity at the amino acid level with the *env* sequence of GALV. The receptor of GALV appears to be a ubiquitous permease protein. It is likely, therefore, that the receptor for RE and primate type D oncoviruses is also a permease.

It has been proposed that a common ancestor of BAEV and RE viruses existed and was related to GALV (**Fig. 1**). This ancestor evolved an envelope protein which recognizes a new cellular receptor. From this retrovirus arose the RE virus group as a result of adaptation to avian species. The subgroup D primate viruses evolved by a recombination event between the proposed common ancestor of BAEV and the RE virus which provided the *env* gene and a subgroup B retrovirus. This recombination explains why the subgroup D primate viruses and RE viruses have a similar *env* sequence and share a common receptor.

Virion Structure, Genome and Proteins

RE virus particles have C-type particle morphology resembling MLV more closely than ALV virions. The viral particles are about 100 nm in diameter and are covered with surface projections approximately 6 nm long and 10 nm in diameter. The density of RE virions in sucrose is 1.16–1.18 g ml^{-1}, and RE viruses can be distinguished from those of the ALSV complex by morphology and by density gradient centrifugation. Cell-free stocks of RE viruses may be stored for long periods at −70°C. These viruses are relatively stable

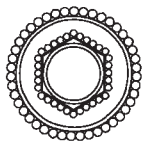
RETICULOENDOTHELIOSIS VIRUSES (*RETROVIRIDAE*)



Radmila Hrdlickova, **Jiri Nehyba** and **HR Bose**, Department of Microbiology and Institute for Cellular and Molecular Biology, University of Texas, Austin, Texas, USA

Introduction

The reticuloendotheliosis (RE) viruses constitute a small group of avian retroviruses which are genetically and immunologically unrelated to the avian leukosis-sarcoma viruses (ALSV) complex. Interesting aspects of RE viruses include their evolution, tumorigenicity, and the immunosuppression they induce.

Taxonomy, Classification and Evolution

RE viruses belong to the *Retroviridae*, a large family of RNA viruses that replicate through a DNA intermediate. Seven genera of retroviruses are recognized and the RE viruses belong to the same genus (*Betaretrovirus*) as the murine leukemia viruses (MLV). The RE group includes the acutely transforming reticuloendoendotheliosis virus, strain T (REV-T), its helper virus, reticuloendotheliosis associated virus (REV-A), spleen necrosis virus (SNV), chicken syncytial virus (CSV), duck infectious anemia virus (DIAV), and other isolates from chickens, ducks, geese, pheasants and turkeys. A total of 26 replication-competent RE virus isolates have been biologically cloned. Only one acutely transforming replication-defective member (REV-T) has been identified. Three antigenic subtypes of RE viruses are distinguished on the basis of their reactivity with monoclonal antibodies, but all RE viruses belong to a single interference group. No endogenous RE viruses have been recognized.

Nucleotide sequence analysis has demonstrated that the RE viruses are more related to mammalian retroviruses than to the other avian retroviruses. The *gag* and *pol* sequences of RE viruses are closely related to gibbon ape leukemia virus (GALV), a primate type C retrovirus, whereas, the nucleotide sequences of *env* gene are approximately 50% identical at the amino acid level to those of simian type D retroviruses and two type C retroviruses – feline endogenous virus (RD114) and baboon endogenous virus (BAEV). All of these viruses share a common receptor. However, the *env* sequence of RE viruses also shares 30% identity at the amino acid level with the *env* sequence of GALV. The receptor of GALV appears to be a ubiquitous permease protein. It is likely, therefore, that the receptor for RE and primate type D oncoviruses is also a permease.

It has been proposed that a common ancestor of BAEV and RE viruses existed and was related to GALV (**Fig. 1**). This ancestor evolved an envelope protein which recognizes a new cellular receptor. From this retrovirus arose the RE virus group as a result of adaptation to avian species. The subgroup D primate viruses evolved by a recombination event between the proposed common ancestor of BAEV and the RE virus which provided the *env* gene and a subgroup B retrovirus. This recombination explains why the subgroup D primate viruses and RE viruses have a similar *env* sequence and share a common receptor.

Virion Structure, Genome and Proteins

RE virus particles have C-type particle morphology resembling MLV more closely than ALV virions. The viral particles are about 100 nm in diameter and are covered with surface projections approximately 6 nm long and 10 nm in diameter. The density of RE virions in sucrose is 1.16–1.18 g ml^{-1}, and RE viruses can be distinguished from those of the ALSV complex by morphology and by density gradient centrifugation. Cell-free stocks of RE viruses may be stored for long periods at −70°C. These viruses are relatively stable

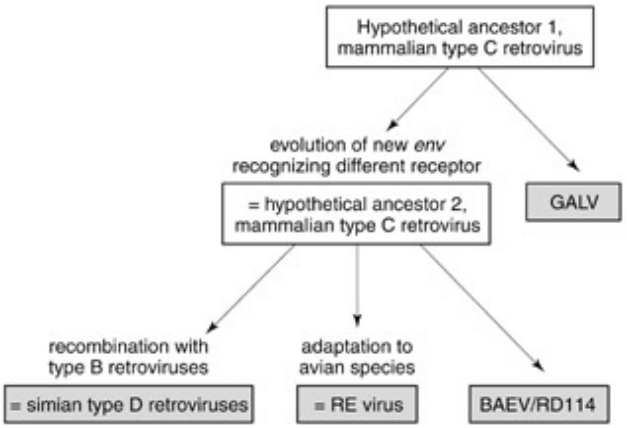


Figure 1 The suggested evolutionary relationship of RE viruses with GALV, BAEV/RD114 and simian type D retroviruses. The shaded boxes indicate currently existing retroviruses. The white boxes indicate hypothetical viral ancestors.

at 4°C but 50% of the infectivity is lost within 20 min when incubated at 37°C.

The genomic RNA of RE viruses consists of a 60–70S complex composed of two identical single-stranded (ss) RNA subunits about 3.9×10^6 Da. The genome of replication-competent RE viruses is approximately 8–9 kilobases (kb) and consists of *gag*, *pol* and *env* genes. The *gag* gene of RE viruses encodes five structural proteins, p10, p12, pp18/pp20 and p30. The *pol* gene encodes a protease (p15), a reverse transcriptase (p84) which is related to the Mn^{2+}-dependent group C mammalian retroviruses and an integrase which facilitates proviral integration (p44). The *env* gene encodes two glycoproteins – a gp90 surface unit and a gp20 transmembrane peptide. REV-T, which is replication-defective, has a genome about 5.7 kb since it contains extensive deletions in the *gag*, *pol* and *env* genes. The transforming gene of REV-T, v-*rel*, has been inserted into *env* sequences.

Replication

Entry of RE viruses is mediated by the envelope glycoproteins which bind to specific receptors on the cell surface. Entry of SNV is pH independent and may involve the direct fusion between the viral envelope and the cell membrane. Shortly after attachment and penetration of the virions, viral DNA is synthesized in the cytoplasm of the infected cell by the reverse transcriptase in uncoated viral cores. Linear as well as circular DNA copies of the retroviral RNA genome are found in the infected cells and the linear DNA serves as the immediate precursor for proviral integration. Two size classes of RNA – genomic-length and spliced subgenomic – are transcribed from the integrated provirus. Translation of genomic-length viral RNA results in the synthesis of two polyprotein precursors: the *gag* and *gag-pol* polyproteins (**Fig. 2**). The *gag* and *pol* genes are in the same reading frame and separated by a stop codon. Expression of the *gag-pol* polyprotein is dependent on stop codon suppression. The *gag* and the *gag-pol* polyproteins are proteolytically cleaved into mature *gag* and *pol* proteins by the virally encoded p15 protease. *Env* proteins are expressed from spliced viral RNA. The primary polyprotein precursor $gPr77^{env}$ is glycosylated and myristoylated and is converted into a second polyprotein precursor $gPr115^{env}$, which is rapidly proteolytically processed by a cellular protease to form gp90 and gPr22(E). A final modification of gp22(E), the transmembrane glycoprotein precursor, to mature gp20 occurs after its incorporation into the virion. The nucleocapsid is assembled in the cytoplasm as a ribonucleoprotein complex and acquires an envelope by budding through the plasma membrane. Release of virus particles begins approximately 24 h after infection.

Hosts and Tissue Tropism

RE viruses have been isolated from chickens, ducks, geese, Japanese quail and turkeys. They can replicate in a wide range of avian cells but specific species or a tissue tropism has not been described. RE viruses are also able to infect certain mammalian cells, including primate cells (HeLa and COS-7). Human cells transfected by SNV produce low levels of infectious virus. Although antibodies against p30 have been detected in human tissue, the health significance of these findings remains to be evaluated.

Immune Response

RE viruses are generally strongly immunosuppressive and the immunosuppression they induce may contribute to their virulence (see below, *Nonneoplastic diseases*). However, most birds are able to develop a strong immune response which efficiently controls the infection.

Humoral immunity

Birds infected at hatching or later develop a 'non-tolerant' infection characterized by a transient viremia and antibody synthesis. Some birds develop a persistent virus infection which can be detected in peripheral blood lymphocytes in the absence of a viremia. Infection of embryos with RE viruses results in a 'tolerant' infection characterized by the lack of antibody production and by a viremia that can persist for 2 years. Also, neonatal bursectomy leads to the

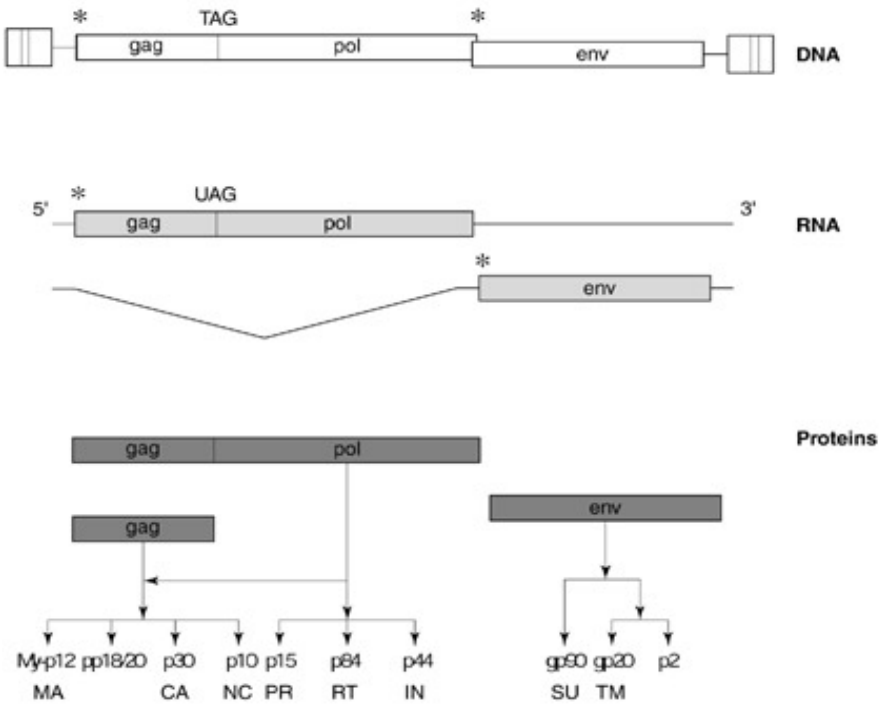

Figure 2 Genome structure, RNA splicing pattern and polyprotein processing pattern of RE viruses. White boxes indicate the genomic regions encoding proteins. Lightly colored boxes represent coding regions in genomic and spliced RNA and dark boxes represent translated proteins. Asterisks indicate the ATG/AUG codons known to be used in initiation of translation. The *gag* stop codon TAG/UAG is shown. The polyproteins and mature processed proteins derived from the *gag, pol* and *env* genes of RE viruses are shown. Proteins are designated according to molecular weight (kDa). The following designations are used: My-p, myristoylated protein; p, protein; pp, phosphoprotein, gp, glycoprotein; MA, *gag* matrix protein; CA, *gag* capsid protein; NC, *gag* nucleocapsid protein; PR, protease; RT, reverse transcriptase; IN, integrase; SU, *env* surface unit; TM, *env,* transmembrane protein. pp18/20 proteins are two differentially post-translation modified proteins encoded by the same *gag* sequence.

establishment of a tolerant infection, which suggests that B lymphocytes are involved in the elimination of the viremia. Tolerance to RE viruses does not depend on immunodepression. In contrast to nontolerantly infected chicken, tolerantly infected dams transmit the virus to their progeny but at low efficiency.

Cell-mediated immunity

Thymectomy increases the mortality of REV-T-infected birds suggesting the involvement of cell-mediated immunity in the elimination of RE virus-infected cells. Cytotoxic T lymphocytes (CTL) lyse virus-infected cells which present viral antigens in conjunction with the major histocompatibility complex (MHC) class I molecules. CTL are induced 7 days after infection with RE viruses and may persist at least 21 days. The CTL response against RE viruses is mediated by $\gamma\delta$ T CD8+, CD4− cells which express MHC class I and II molecules. RE viruses do not appear to activate natural killer cells.

Transmission, Diagnosis, Prevention and Control

Despite the fact that RE viruses are widespread in commercial poultry flocks, they do not create a real economical problem. However, the contamination of vaccines against Marek's disease virus (MDV) by RE viruses has been associated with a runting disease and chronic neoplasia. In addition, occasional outbreaks of neoplastic diseases in turkeys have also been described.

Both vertical and horizontal routes of transmission have been observed but at low levels in the viremic birds. Vertical infections may occur when viruses released from the mother contaminate the egg resulting in the infection of the embryo. Alternatively, infectious virus may be transmitted to the offspring from the semen of a viremic male. RE viruses are transmitted horizontally by contact and may also be transmitted by insects.

RE virus epidemics are prevented by testing commercial vaccines for contamination by these

viruses. RE viruses can be detected by the presence of the viral genome, viral antigens, reverse transcriptase or the induction of a cytopathic effect by some strains. The sensitive polymerase chain reaction (PCR) and reverse transcriptase PCR can be used for detection of viral genomes. RE viruses specific antigens may be detected by immunofluorescence, complement fixation assays or enzyme immunoassays. Antibodies to RE viruses may be monitored by immunofluorescence, virus neutralization, agar-precipitation, Western blot analysis, enzyme immunoassays and pseudotype neutralization tests.

A commercial vaccine is not available since RE viruses do not create a significant economic impact. It is, however, feasible to develop an effective vaccine against RE viruses. Fowlpox virus recombinants expressing the *env* gene of SNV induce neutralizing antibodies and reduce the viremia and runting disease in infected chickens.

Pathogenesis

Nonneoplastic diseases

All replication-competent RE viruses induce to some degree a rapid and severe immunosuppression, in which T cells fail to undergo a blastogenic response to antigens or mitogens. This immunosuppression probably facilitates expression of the oncogenic potential of the virus and is responsible for the increased susceptibility of RE virus-infected birds to other pathogens. Other nonneoplastic disease syndromes include a runting disease syndrome, enlarged peripheral nerves, abnormal feather development, bursal and thymic atrophy and anemia. Several of these syndromes may be the direct or indirect consequence of the immunosuppression. These syndromes develop during the first month after infection and may either be transient or result in death.

The induction of nonneoplastic diseases by RE viruses correlates with their ability to induce a cytopathic response in cultured cells. The replication-competent RE viruses induce an acute infection characterized by an extensive cytopathic effect and cell killing. Large amounts of unintegrated and integrated proviral DNA accumulate in the infected cell during this acute phase. Surviving cells which replicate and become persistently infected contain much lower levels of both unintegrated and integrated proviral DNA. The correlation between the transient accumulation of large numbers of proviral DNA and the transient development of a cytopathic effect suggests that cell death results from the toxic effect of this DNA or proteins coded by this DNA.

The primary determinants of the runting disease syndrome have been mapped to distinct regions in the structural genes of RE viruses by comparing highly pathogenic REV-A with the less pathogenic CSV. Both *env* and *gag* sequences were necessary for the full expression of the pathogenic effect of REV-A. The *env* genes of REV-A and CSV encode the immunosuppressive peptide (ISP) which is conserved in a number of mammalian retroviruses including human T-cell leukemia virus (HTLV) I and II, feline leukemia virus, MLV and GALV. The murine env protein which contains the ISP, suppresses the proliferation of an interleukin-2-dependent cytotoxic T lymphocytes cell line, the mixed lymphocyte response of T and B cells, the respiratory burst of monocytes, immunoglobulin production, the cytolytic activity of natural killer cells, monocyte-mediated tumor cell killing and the production of γ-interferon by peripheral blood lymphocytes. Interestingly, ISP is an inhibitor of protein kinase C and this may explain its profound suppressive effect on immune cells. However, the sequence of ISP is conserved in both CSV and REV-A and, therefore, the other regions of the *env* genes of REV-A and CSV must be responsible for the difference in pathogenicity of these viruses. These *env* sequences may influence how the ISP immunosuppressive region is exposed on the virion surface accounting for the difference in pathogenicity between REV-A and CSV. The *gag* sequences may directly influence the replication efficiency of the virus. The matrix region of *gag* is responsible for the increased replication efficiency of REV-A in some cell types relative to other replication-competent RE viruses. Therefore, the cytopathogenicity and immunosuppressive ability of RE virus is most likely determined by *env*. By increasing replication ability, the *gag* sequence of REV-A also enhances the virulence of the virus.

Syncytia formation has also been observed in certain cell lines infected by RE viruses. The viral envelope glycoproteins expressed on the surface of the infected cell may interact with cellular receptors of neighboring cells, resulting in fusion and syncytia formation. This phenomenon may contribute to the pathology induced by RE viruses.

Chronic neoplasia

Two types of chronic neoplasia induced by replication-competent RE viruses have been described. In the first type, RE viruses induce B cell lymphomas after a relatively long latent period (17–35 weeks). Tumor induction may be prevented by surgical or chemical bursectomy. This type of disease is indistinguishable from lymphoid leukosis induced by ALV. As is the

case with ALVs, RE proviruses are integrated upstream from the second exon (the first exon is a noncoding exon) of the c-*myc* locus in the same transcriptional orientation in these tumor cells. Invariably these RE proviruses have deleted the 5′ LTR and/or large parts of the viral genome. When the 5′ LTR is lacking, the 3′ LTR becomes transcriptionally active leading to constitutive expression of c-*myc* RNA.

The second type of neoplasia induced by replication-competent RE viruses is a T cell lymphoma which develops after a shorter latent period (6 weeks) and does not involve the bursa. This lymphoma involves the thymus, but also the liver, spleen, heart and peripheral nerves. Induction of this T cell lymphoma is also associated with insertional activation of c-*myc*, but one half of the proviruses are oriented in the opposite transcriptional direction from the c-*myc* gene. Whereas some of the proviruses in these T cell lymphomas use the 3′ LTR promoter to transcribe the downstream c-*myc* gene, others apparently activated a cryptic promoter located in the first intron of c-*myc*. This insertion pattern contrasts with that observed in B cell lymphomas induced by the same virus. The proviral integration pattern in these T cell lymphomas induce lower levels of c-*myc* and it has been suggested that T cell lymphomas can be induced at lower levels of c-*myc* than the B cell lymphomas.

Interaction with herpesvirus

Recently, the recombination of RE viruses with Marek's disease virus (MDV) an avian herpesvirus, has been described. This interaction represents the first example of genetic recombination between an RNA and a DNA virus. This phenomenon has important biological consequences for the transmission of RE viruses into cells which would otherwise not be susceptible to RE virus infection. The presence of RE viral sequences in MDV also alters MDV gene expression and pathogenesis. Co-infection of avian cells with MDV and RE viruses frequently leads to the integration of RE proviral sequences within the MDV genome. Although usually only the LTR sequences become stably integrated into the MDV genome, a complete infectious RE provirus has been detected in one case.

REV-T induced neoplasia

REV-T was initially isolated from a lymphoma of a turkey in 1958. Subsequently, it was discovered that the original isolate contains both REV-T which is a replication-defective virus encoding the v-*rel* oncogene and a replication-competent helper virus REV-A. In experimentally infected avian species REV-T induces tumors in the liver, spleen and other visceral organs and causes death within 2 weeks. REV-T transforms a number of cell types at different stages of differentiation including B and T cells, macrophage-like cells and dendritic cells and birds die from a lymphoproliferative disease. REV-T can transform these cell types *in vitro* and also morphologically transforms avian fibroblasts. REV-T-transformed fibroblasts have a distinct morphology, prolonged life-span and induce sarcomas in susceptible birds. REV-T(REV-A) can infect mammalian cells but fails to transform them. Transgenic mice which constitutively express the v-*rel* gene under the control of the *lck* promoter in T cells develop thymic lymphomas in approximately 10 months. However, these murine T cell tumors grow poorly in culture and they do not induce tumors in syngenic mice.

The role of v-*rel* mutations in transformation REV-T induces an acute neoplastic disease due to the expression of the v-*rel* oncogene. v-*rel* arose as a result of the transduction of the c-*rel* proto-oncogene into envelope sequences of REV-A. c-Rel is a member of the Rel/NF-κB family of transcription factors, a ubiquitously expressed group of proteins which participate in the control of cell proliferation, differentiation and apoptosis. The transduction of c-*rel* resulted in the deletion of 2 N-terminal and 118 C-terminal amino acids. Since c-*rel* was transduced into envelope sequences, translation of the v-*rel* subgenomic RNA results in the formation of an oncogene fusion protein with 11 amino acids of envelope protein at the N-terminus and 18 out-of-frame envelope sequences at the C-terminus. Two critical functions of c-Rel were lost or modified during the initial transduction event. The loss of the C-terminal amino acids of c-Rel removed sequences responsible for cytoplasmic anchoring allowing v-Rel increased nuclear access. The C-terminal deletion also removed a significant portion of the sequences involved in transactivation. v-Rel, therefore, activates transcription of some genes less efficiently than c-Rel. One of the genes immediately activated when Rel/NF-κB complexes translocate to the nucleus is IκB-α. IκB-α inhibits the ability of Rel/NF-κB complexes to regulate target genes through cytoplasmic retention and displacement of Rel/NF-κB complexes from DNA. v-Rel, because it has deleted a portion of its transactivation domain induces the transcription of IκB-α much more weakly and with reduced kinetics relative to c-Rel. Decreased IκB-α synthesis may lead to the constitutive activation of v-Rel in transformed cells.

Following the initial transduction event, v-*rel* sustained multiple mutations many of which altered the amino acid sequence of v-Rel and contribute directly to its oncogenicity. These mutations are

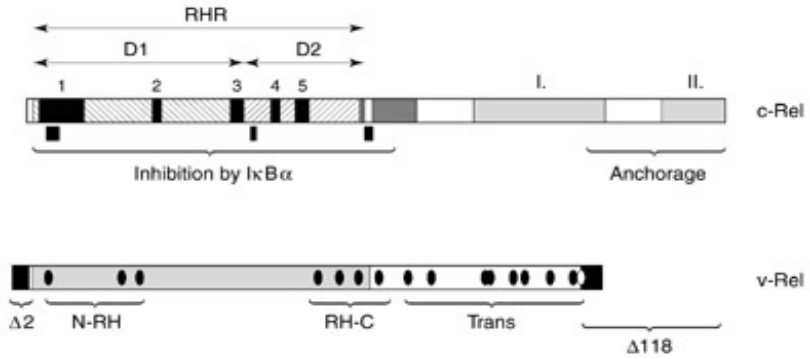

Figure 3 The functional domains of c-Rel and the position of mutations in v-Rel. The Rel homology region (RHR) consists of two domains D1 and D2. The five loops in the RHR that contact DNA directly are indicated by black boxes and numbered above. Loop 1 contains the major DNA recognition motif RxxRxRxxC. A hinge-like loop 3 connects domains D1 and D2. The region flanking D2 on the C-terminal side (white diagonals on black background) contains the nuclear localization signal indicated by the white box. The region of c-Rel that is both necessary and sufficient for inhibition of DNA binding of c-Rel by IκB-α is shown (Inhibition by IκBα). Small black boxes identify the amino acids believed to be in contact with IκB-α. Two transactivation domains (light gray boxes) and a cytoplasmic anchorage region (Anchorage) are present in the C-terminus. The RHR of v-Rel is represented by an intermediate color pattern. Mutated amino acids in v-Rel are indicated. Deletions of 2 N-terminal and 118 C-terminal amino acids resulting from the transduction of c-*rel* into REV-A are indicated below (Δ2, Δ118). The black boxes represent amino acids encoded by *env*-derived sequences which are fused to the truncated N- or C-termini. Internal mutations are identified by black or white ellipses. These mutated amino acids can be divided into three groups: N-RH, RH-C and Trans mutation clusters. The groups contain mutations that may affect a similar structural/functional domain. The N-RH and RH-C mutation clusters are situated at N- and C-termini of the RHR and contain, respectively, three and four single amino acid substitutions. A group of mutations designated Trans contains six single amino acid substitutions and three internal deletions of one or two amino acids. The majority of the Trans mutations are situated in the transactivation domain. (Adapted from Nehyba J, Hrdlickova R and Bose HR, Jr (1997) Differences in κB DNA-binding properties of v-Rel and c-Rel are the result of oncogenic mutations in three distinct functional regions of the Rel protein. *Oncogene* 14, 2881.)

located in several functional regions of v-Rel (**Fig. 3**). Two clusters of mutations are located in the N-terminus (N-RH) and C-terminus (RH-C) of the Rel homology region (RHR). The RHR is conserved among all members of the Rel/NF-κB family of transcription factors. This region contains the sequence responsible for DNA binding, dimerization, nuclear localization and IκB-α association. A third cluster of mutations (Trans) maps to the sequences in the C-terminus of v-Rel with the majority of them present in the transactivation region. The mutated amino acids in v-Rel are located in regions normally involved in the regulation of c-Rel. The functions of c-Rel including DNA-binding activity, the ability to form dimeric complexes as well as transcriptional activity are required for v-Rel to be transforming. The conversion of c-Rel into a highly oncogenic protein is due, therefore, to alterations which modify rather than eliminate the functional domains of c-Rel which are responsible for interacting with other proteins and/or DNA. The amino acid substitutions in the N-terminal part of RHR inside of or near the DNA contact motif are responsible for the altered DNA-binding specificity of v-Rel. Amino acid changes in the C-terminal portion of RHR, in the region responsible for dimerization, enables v-Rel to escape IκB-α-mediated inhibition of DNA binding. Finally, alteration in the amino acid sequence in the extreme C-terminal region of v-Rel may be responsible for altered transcriptional activity or may modulate the DNA-binding activity of v-Rel. These changes created an oncogenic protein which is no longer responsive to normal cellular regulatory constraints.

Altered gene expression in v-*rel* transformed cells Disruption of the ability of v-Rel to bind DNA abolishes its oncogenicity indicating that v-Rel must bind κB sites and directly alter gene expression in order to induce transformation. Although the role of some v-Rel mutations in the activation of the transformation potential of c-*rel* are known, how altered regulation of gene expression by v-Rel results in transformation remains largely unknown. Numerous genes have been identified in which the expression pattern is altered in cells transformed by REV-T. To date, all the genes which display an altered pattern of transcription in REV-T transformed cells are regulated by the Rel/NF-κB family members. These genes are listed in **Table 1**.

A few of the genes altered by v-*rel* expression are known to contribute to the transformed phenotype of v-Rel infected cells. The expression of the gene

Table 1 Genes induced by v-Rel. The genes are grouped into classes with similar function of their protein products. All genes were detected in avian cells unless indicated otherwise

Functional groups	*Genes induced by v-Rel*
Rel/NF-κB family	*nfkb1, nfkb2, Ikba*
Cell surface receptors	The MHC genes class I and II, DM-GRASP[a], the interleukin-2 receptor, p75 membrane protein, *sca-2*
Cytokines	*mip-1β*, *ctca*, CEF-4 (avian homologue of interleukin-8), interleukin-6[b], tumor necrosis factor-α[b]
Transcription factors	c-*fos*, c-*jun*, *fra*-2, interferon response factor 1 and 3, interferon consensus sequence-binding protein, the high-mobility-group protein 14b
Inhibitors of apoptosis	ch-IAP1
Structural proteins	δ-crystallin, vimentin, type I collagen α, β-tubulin
Proteins of oxidative metabolism	Mitochondrial cytochrome *b*
Chaperons	GRP-78

encoding the cell surface receptor DM-GRASP and the cytokine *mip-1β* are altered in v-Rel transformed cells. Antibody against the DM-GRASP inhibits the *in vitro* proliferation of v-*rel*-transformed cells. The overexpression of *mip-1β* induces limited colony formation in soft agar and prolongs the life span of avian fibroblasts. Activation of an inhibitor of apoptosis, ch-IAP1, contributes to the immortalization of lymphocytes transformed by v-Rel. Expression of exogenous ch-IAP1 in temperature-sensitive v-Rel mutant transformed lymphocytes inhibits apoptosis of these cells at nonpermissive temperature. The fos/jun family of transcription factors also plays an important role in the Rel transformation pathway. v-Rel binds to the c-*jun* promoter inducing the constitutive expression of c-*jun* in transformed cells. Sup*jun*, a dominant inhibitor of c-*jun* significantly reduces the transformation efficiency by oncogenic Rel proteins.

v-Rel directly up- or downregulates genes which are normally under the control of c-Rel, but with different efficiencies. For example, the c-*jun* promoter is transactivated by v-Rel more efficiently than by c-Rel. The *Ikba* promoter is transcriptionally upregulated by both v-Rel and c-Rel, however, v-Rel is a much weaker inducer than c-Rel. To date, no genes have been identified which are activated by c-Rel but inhibited by v-Rel or the reverse. v-Rel, therefore, functions as constitutively activated c-Rel but modulates gene expression in a qualitatively different way than c-Rel. The differences in the DNA-binding specificity of v-Rel versus c-Rel may be partly responsible for this behavior. This suggestion is in agreement with the fact that v-Rel binds to the c-*jun* κB site with a higher affinity than c-Rel.

Retroviral Vectors

REV-A and SNV-based retroviral vectors have been successfully used to study retrovirus replication, recombination, cell transformation and to establish transgenic chickens. Moreover, several properties of RE viruses make them candidates for human gene therapy. The use of retroviral vectors for human therapy must address potential safety concerns. It is desirable to avoid homologous recombination which could reconstitute a replication-competent virus. Therefore, RE viruses are produced from packaging cell lines which express genes encoding structural retroviral proteins under the control of nonretroviral promoters. After transfection by the plasmid form of the retroviral vector which encodes only the desired therapeutic protein controlled by its own promoter, the viral RNA is packaged into virions. Unlike other retroviral vectors, RE vectors have no homology with structural genes coded by the packaging cell lines, therefore, replication-competent viruses are not produced. Also, it is essential that the retroviral vectors used in gene therapy are unable to undergo homologous recombination with endogenous viruses in target cells. Human cells do not contain endogenous RE virus sequences. The integration of the strong retrovirus LTR promoter/enhancer element into the DNA of target cells which could influence the transcription of neighboring genes must also be avoided. The construction of SNV-derived self-

inactivating vectors which produce proviruses lacking LTRs addresses this safety concern.

The delivery of retrovirus vectors into specific cell types is also required for human therapy. The envelope protein of RE viruses contains multiple binding domains and, therefore, can tolerate the extensive modification associated with the introduction of cell specific targeting sequences. Retroviruses that recognize specific target cells have been generated by the incorporation of sequences encoding antigen binding sites into the *env* gene of SNV. These targeted SNV-derived vectors are very efficient at infecting specific human cell types.

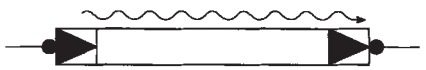
RETROTRANSPOSONS OF FUNGI



Jef D Boeke, Department of Molecular Biology and Genetics, Johns Hopkins University, Baltimore, Maryland, USA

History

Transposable elements in eucaryotes can nearly all be classified into three basic types. The first type, typified by the Ac elements of plants and the P elements of *Drosophila,* resemble bacterial transposons in that they bear short inverted repeat termini; the available evidence strongly suggests that this type of element transposes directly via a DNA intermediate. However, most eucaryotic transposons differ from the bacterial elements in that they encode a reverse transcriptase (RT) or RT-like protein. Two basic types of these 'retrotransposons' are known – the LTR (long terminal repeat)-containing type, which are structurally highly reminiscent of retroviruses, and the poly(A)-type, which lack LTRs and usually (but not always) contain an oligo(A), poly(A) or similar sequence tract at their extreme 3′ end. These two types of retrotransposon are shown in **Fig. 1.** Both classes of retrotransposons are now known from organisms as phylogenetically distinct as fungi, trypanosomes, insects and mammals. Hence this brief review will focus on what is currently known about fungal retrotransposons, principally the retrotransposons that are more retroviral-like and are distinguished by the presence of LTRs. Thus, only a small and highly selective glimpse of the total picture of retrotransposons is provided.

Structural Features

The structural features of the known fungal retrotransposons are summarized in **Table 1.** LTR-containing retrotransposons isolated from fungi resemble retroviral proviruses in structure. They contain LTR sequences of a few hundred base pairs long flanking a central coding region that contains one or two open reading frames (ORFs), called *gag* and *pol* by analogy to the retroviral counterparts. As is the case with proviruses and DNA-based transposons, target site duplications of a fixed length flank the elements. These vary greatly in sequence and are presumably generated during the integration process

inactivating vectors which produce proviruses lacking LTRs addresses this safety concern.

The delivery of retrovirus vectors into specific cell types is also required for human therapy. The envelope protein of RE viruses contains multiple binding domains and, therefore, can tolerate the extensive modification associated with the introduction of cell specific targeting sequences. Retroviruses that recognize specific target cells have been generated by the incorporation of sequences encoding antigen binding sites into the *env* gene of SNV. These targeted SNV-derived vectors are very efficient at infecting specific human cell types.

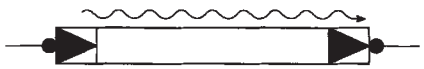
RETROTRANSPOSONS OF FUNGI



Jef D Boeke, Department of Molecular Biology and Genetics, Johns Hopkins University, Baltimore, Maryland, USA

History

Transposable elements in eucaryotes can nearly all be classified into three basic types. The first type, typified by the Ac elements of plants and the P elements of *Drosophila,* resemble bacterial transposons in that they bear short inverted repeat termini; the available evidence strongly suggests that this type of element transposes directly via a DNA intermediate. However, most eucaryotic transposons differ from the bacterial elements in that they encode a reverse transcriptase (RT) or RT-like protein. Two basic types of these 'retrotransposons' are known – the LTR (long terminal repeat)-containing type, which are structurally highly reminiscent of retroviruses, and the poly(A)-type, which lack LTRs and usually (but not always) contain an oligo(A), poly(A) or similar sequence tract at their extreme 3′ end. These two types of retrotransposon are shown in **Fig. 1**. Both classes of retrotransposons are now known from organisms as phylogenetically distinct as fungi, trypanosomes, insects and mammals. Hence this brief review will focus on what is currently known about fungal retrotransposons, principally the retrotransposons that are more retroviral-like and are distinguished by the presence of LTRs. Thus, only a small and highly selective glimpse of the total picture of retrotransposons is provided.

Structural Features

The structural features of the known fungal retrotransposons are summarized in **Table 1**. LTR-containing retrotransposons isolated from fungi resemble retroviral proviruses in structure. They contain LTR sequences of a few hundred base pairs long flanking a central coding region that contains one or two open reading frames (ORFs), called *gag* and *pol* by analogy to the retroviral counterparts. As is the case with proviruses and DNA-based transposons, target site duplications of a fixed length flank the elements. These vary greatly in sequence and are presumably generated during the integration process

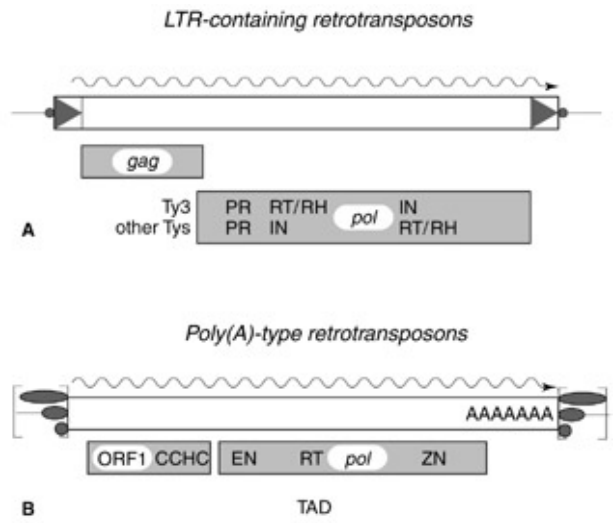


Figure 1 Retrotransposon types in fungi. All elements found to date in the yeasts, *Saccharomyces cerevisiae* and *Schizosaccharomyces pombe* are LTR-containing transposons (**A**). PR, protease; IN, integrase; RT, reverse transcriptase; RH, RNase H. Boxed triangles represent the LTRs; wavy line represents the transcript; shaded circles represent fixed-length target site duplications. Note that the order of functional domains differs between Ty3 (*Metaviridae*) and the other yeast elements (*Pseudoviridae*). (**B**) Two elements of the 'poly(A)' type have been found in the filamentous fungi (see **Table 1**). Note that unlike almost all members of this class of elements, TAD does not contain the 3′ poly(A) tract, but instead contains an AT-rich sequence. Abbreviations and symbols as above except: CCHC, retroviral Gag Zn-finger-like sequence; EN, endonuclease domain; FZN, zinc-finger-like domain found in *pol* genes of this class of elements; bracketed shaded ovals represent variable-length target site duplications.

by a transposon-encoded integrase function. In the cases where the RNA has been examined, it resembles retroviral genomic RNA in that it extends from LTR to LTR and is terminally repetitious, allowing definition of U3, R and U5 regions of the LTR sequence in a manner formally analogous to that used by retrovirologists. The elements with two ORFs clearly contain the equivalents of *gag* and *pol*, but no analogue of retroviral *env*. The elements with single ORFs, Tf1 and Tf2, (and possibly also Ty5) apparently translate a Gag/Pol fusion protein only. In all cases, the primary translation products are then cleaved into smaller final products by the element encoded aspartyl protease.

The elements with LTRs fall into two basic classes, distinguishable by the order of the functional domains in pol (see **Fig. 1**). In the class typified by Ty3, the RT domain precedes the IN domain, as it does in retroviruses. This family of elements has recently been classified as the *Metaviridae*. In the other type, typified by Ty1 and the other yeast elements except Ty3, the order of these domains is reversed. This family of elements has recently been classified as the *Pseudoviridae*.

Thus far there is only one report in the literature of a fungal retrotransposon that lacks LTRs, the TAD element from the filamentous fungus *Neurospora crassa* Adiopodoume strain, although structurally similar elements have now been isolated from other filamentous fungi. As these elements are much less retroviral-like, they are not reviewed here.

Transposition Mechanism

There is probably more known about the LTR-containing retrotransposons of fungi than about those of any other species. By far the most heavily studied elements are the Ty1 and Ty3 elements of *Saccharomyces cerevisiae*, and the Ty5 elements of the related species *Sac. paradoxus*, and the Tf1 elements of *Schizosaccharomyces pombe*. The life cycles of these

Table 1 Fungal retrotransposons

Host[a]	*Element name*	*Type*	*ORFs*	*Target site duplication (bp)*	*LTR length (bp)*	*Primer (−) strand*
Sac. cerevisiae	Ty1	LTR	2	5	334	$tRNA^{Met}_i$
Sac. cerevisiae	Ty2	LTR	2	5	334	$tRNA^{Met}_i$
Sac. cerevisiae	Ty3	LTR	2	5	340	$tRNA^{Met}_i$
Sac. cerevisiae	Ty4	LTR	2	5	371	$tRNA^{Asn}$
Sac. paradoxus	Ty5	LTR	1	5	250	$tRNA^{Met}_i$
Sch. pombe	Tf1,2	LTR	1	5	358	self-priming
N. crassa	TAD	polyA	2	14, 17	N.A.	?
M. grisea	MAGGY	LTR	2		253	
A. fumigatus	Afut	LTR	2	5	282	

[a] Generic abbreviations: *M., Magnaporthe; Sac., Saccharomyces; Sch., Schizosaccharomyces; N., Neurospora; A., Aspergillus.*

are quite similar. In contrast, except for the presence of a cytoplasmic transposition intermediate, and evidence for reverse transcription during its transposition, relatively little is yet known about TAD transposition. This is because these poly(A)-type elements are generally less well known (and retroviral analogies are uncertain at best). Thus the discussion below applies to yeast Ty elements specifically, and to LTR retrotransposons generally.

A transposon copy (usually studied in the laboratory in the form of a *GAL* promoter/Ty element fusion) produces a transcript that extends from a point in the 5′ LTR to a different, downstream point in the 3′ LTR. Thus, a terminally redundant RNA is generated. This RNA is polyadenylated and exported to the cytoplasm, where it can have two different fates; it can serve (1) as an mRNA for Gag and Gag-Pol protein products and/or (2) as genetic material for transposition.

Translation of Ty elements is somewhat unconventional. Gag is produced directly by conventional translation of this mRNA, whereas Pol is expressed as a Gag-Pol fusion protein (readthrough protein); this 'frameshifting' process is mediated at a special sequence within the region of overlap of *gag* and *pol*. Both the Ty1 and Ty3 frameshifts differ from those of more conventional retroviruses in that they are +1 frameshifts rather than −1 frameshifts, and the intrinsic mechanism used to effect the frameshift is different. In the −1 frameshifts used by retroviruses, coronaviruses, and the yeast killer double-stranded RNA virus, a 'slippery site' allows for a simultaneous slip of the ribosome during the translational step in which the ribosomal P and A sites are simultaneously occupied. Stem–loop structures or pseudoknots that are often found just downstream of the slippery site are thought to cause ribosomal pausing and perhaps even to induce the ribosome to slip backwards. In contrast, the Ty1 element appears to utilize a completely different mechanism. There appears to be no requirement for any special RNA secondary structure; rather the frameshifting appears to be sequence-mediated, because a seven nucleotide sequence from the overlap region readily confers frameshifting on a heterologous reporter gene. Ribosomal pausing, thought to be required for frameshifting, is apparently caused by limiting amounts of a rare tRNA, $tRNA^{Arg}_{CCU}$. The stalled ribosome, which unlike the retroviral case, has an empty A site, has the P site occupied by a specific $tRNA^{Leu}$ that recognizes all six Leu codons. The stall caused by low $tRNA^{Arg}$ levels allows time for the slippage event to occur; the $tRNA^{Leu}$ slips to an overlapping Leu codon in the +1 (*pol*) frame. This then exposes a Gly codon recognized by an apparently abundant tRNA in the A site, allowing translation to continue in the *pol* frame. This mechanism results in an efficiency of frameshifting that varies somewhat with context, but on average is about 10–20%.

Once sufficient Ty protein products, in the form of intact Gag and Gag-Pol readthrough proteins, are produced, an assembly process that is not yet well understood begins. What follows is a working model for this assembly process, although this is based largely on interpretations of the limited experiments that have been done on Ty assembly and by analogy with retroviral systems and models. Ty RNA is apparently selectively packaged, together with at least one specific tRNA, the primer tRNA, into a capsid initially consisting of a coassemblage of unprocessed Gag and Gag-Pol proteins. Presumably, these coassemble via Gag-Gag interactions, and these are made in such a way that the C-termini of the proteins, and the RNA, reside in the internal cavity of the virus-like particle (VLP). The aspartyl protease encoded within *pol*, presumably activated by a dimerization process facilitated by the high protein concentration involved in the assembly process, then cleaves the precursor Gag proteins and Gag-Pol proteins to their mature, presumably physiologically relevant forms. This results in a change in the morphology of the VLPs, as well as an apparent activation of the endogenous reverse transcriptase activity.

Once reverse transcriptase is activated, the initial DNA products, corresponding to the left end of the transposon are synthesized, using a cellular tRNA as primer. This primer was recently shown to be $tRNA^{Met}_{i}$ for Ty1. Eventually, a full-length double-stranded (ds) DNA is made through a series of priming and DNA strand transfer events. In the Ty5 element, the same tRNA is apparently cleaved to form a half-molecule; the 5′ half-molecule is then used to prime reverse transcription. The identity of the enzyme that effects this cleavage is unknown.

In the Tf elements of *Sch. pombe*, a different type of reverse transcriptase priming occurs – self priming. In these unusual elements, the primer for reverse transcription is a piece of the retrotransposon RNA itself. The 5′ end of the RNA folds into a complex secondary structure, and an 11 nucleotide (nt) fragment is then released, apparently by the RNase H activity associated by the reverse transcriptase. A number of other retroelements from fungi and other organisms are thought to use a similar mechanism.

The dsDNA remains associated with Gag and Pol proteins such as reverse transcriptase inside the cell. These DNA-containing VLPs (isolated as a mixture of RNA-containing and DNA-containing VLPs) have been shown to contain all the macromolecular factors needed to carry out an *in vitro* transposition

(integration) reaction. Like retroviral core particles, which have this same activity, these VLPs require only a divalent cation for activity. The Ty DNA is apparently synthesized inside VLPs inside the cytoplasm. It is interesting to consider how and in what form this DNA is delivered to the nucleus. This is a particularly interesting question to ask in yeast, because fungi, unlike mammalian cells, undergo a 'closed mitosis' in which the nuclear membrane does not break down and reform during each mitosis, but apparently remains intact. Recent experiments implicate a small basic amino acid sequence at the C-terminus of the integrase in this process. This 'nuclear localization signal' may be responsible for delivering not only the integrase but also the DNA to the nucleus.

Once the Ty DNA and Ty integrase enter the nucleus, a concomitant cleavage of host DNA and joining to transposon ends similar to that occurring during retroviral integration occurs. Ty3 is extremely selective for its integration, and apparently inserts only at the transcription initiation sites for RNA polymerase III. Ty1 also targets tRNA genes, but probably by recognizing a unique chromatin structure associated with their 5′ ends. Ty5 elements appear to target 'silenced' chromatin. All of these mechanisms tend to ensure that these Ty elements will not destroy host genes, as most of the Ty targets do not encode genes, or at least not essential ones.

Virus-like Particles: Evolutionary Vestige or Transposition Intermediates?

The presence of VLPS in Ty elements has often raised the question of the evolutionary relationship between retroviruses and LTR-containing retrotransposons. Is the VLP a degenerate leftover of some decaying retrovirus? Or are LTR-containing retrotransposons a family of modern-day descendants of the precursor of the retroviruses? Presumably all retroelements descended ultimately from a 'cellular reverse transcriptase gene' as originally proposed by Temin. This gene may be ancient, and its original product may have been the molecule that archived the genetic information of the RNA world into DNA. Examination of the spectrum of modern-day retroelements from this perspective, reveals a natural progression from the simple to the very complex, as follows: starting with a simple RT gene (perhaps represented by modern-day telomerase?), to the poly(A)-type retrotransposons, which contain a second ORF in addition to RT, to the LTR-containing retrotransposons, which have the above plus LTRs, to the simple retroviruses, which have acquired a third ORF, *env*, and on to the most elaborate of all, the lentiviruses, with multiple additional regulatory reading frames in addition to the basic three. Since all LTR-containing retrotransposons studied appear to involve a VLP intermediate (that is, all examined to date have many properties of a transposition intermediate), the implication is that, as is the case in all complex biological reactions, a structure is built to ensure (1) high local concentration of numerous macromolecules required for the reaction and (2) appropriate orientations/conformations of these macromolecules to allow the reactions to proceed appropriately. The strongest support for this idea comes from studies on Ty1, which suggest that the VLP is a direct, functional transposition intermediate. Thus, if LTR-containing retrotransposons predated retroviruses, and their VLP structure evolved in response to selection for this organizing function, it does not stretch the imagination too far to suggest that these elements were 'preadapted' for subsequent selection for infectivity. In fact, one may see such transitional forms within the *gypsy* family of LTR-containing retrotransposons, in which some family members resemble the Tys in having two ORFs, but a few elements have

Table 2 Host genes affecting Ty1

Gene name	*Normal function/product*	*Function for Ty1*	*Found by*
Transcriptional effect genes			
SPT3, 7, 8	Transcription factor	Transcription initiation	Suppression of Ty- or LTR-induced mutation
SPT4, 5, 6	Chromatin factors	Transcription initiation	Suppression of Ty- or LTR-induced mutation
SPT10, 21	Repressor and activator	Repress 3′ LTR	Suppression of Ty- or LTR-induced mutation
Post transcriptional effect genes			
IMT1-4	Translation initiation, $tRNA^{Met}_{i}$	Prime reverse transcription	Intentional mutagenesis of genes to reveal interaction
(none)	$tRNA^{Arg}_{CCU}$	Low level causes ribosome stalling, frameshifting	Search for genes which interfere with transposition when overexpressed
DBR1	Debranch intron lariats (2′-5′ phosphodiesterase)	Unknown	Search for chromosomal mutations that interfere with transposition

a third *env*-like ORF in the appropriate genomic position.

Host Functions in Retrotransposition

The Ty1 system has provided some insights into the roles of host-encoded proteins and RNAs on the retrotransposition process, and it is anticipated that many more remain to be discovered. A large number of host genes that play roles in Ty and host gene transcription have been uncovered genetically; these are called *SPT* genes because they were originally identified by mutations that *sup*pressed the effect of *T*y or LTR insertions. Although some of these affect Ty transcription, they do not affect the production of GAL/Ty mRNA. The development of sensitive assays for transposition of GAL/Tys *in vivo* has led to the identification of a number of host factors that are important for transposition at a post-transcriptional level; these are reviewed in **Table 2.**

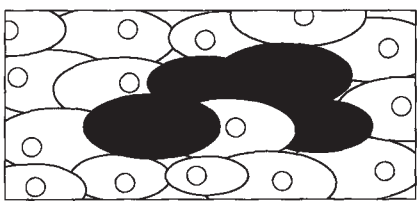
RETROVIRAL ONCOGENES



Paula J Enrietto and **Gabriela Maldonado-Codina**, Genomica Corporation, Boulder, Colorado, USA

Michael J. Hayman, Department of Molecular Microbiology and Genetics, SUNY at Stony Brook, Stony Brook, New York, USA

Introduction

The role of viruses in the etiology of cancer was suggested by the work of Peyton Rous who isolated the first acutely transforming retrovirus, Rous sarcoma virus (RSV), from a chicken sarcoma. These viruses are highly oncogenic and induce malignant transformation of cells because of the presence of cellular sequences, oncogenes (v-*onc*) within the viral genome. The cellular sequences from which viral oncogenes are derived, proto-oncogenes, are cellular genes converted into oncogenes by mutation, rearrangement or deletion. Retroviral oncogenes are generally mutated versions of their respective proto-oncogene. These changes result from the transduction process and additional changes are acquired during viral replication. Consequently, the oncogenic potential of the viral oncogene is significantly enhanced when compared to the cellular oncogene.

In this entry we will focus on retroviral oncogenes, which will be discussed in functional groups. The description of oncogenes within each group is meant to be broad. Specific details have been excluded but can be found in the references listed at the end.

Nuclear Oncogenes

ErbA

V-*erbA* is found in the avian erythroblastosis virus, AEV-ES4 and -R strains, isolated in 1934 by Englebreth-Holm. AEV transduced two different oncogenes, v-*erbA* and v-*erbB*. V-*erbB* is a homologue

a third *env*-like ORF in the appropriate genomic position.

Host Functions in Retrotransposition

The Ty1 system has provided some insights into the roles of host-encoded proteins and RNAs on the retrotransposition process, and it is anticipated that many more remain to be discovered. A large number of host genes that play roles in Ty and host gene transcription have been uncovered genetically; these are called *SPT* genes because they were originally identified by mutations that suppressed the effect of Ty or LTR insertions. Although some of these affect Ty transcription, they do not affect the production of GAL/Ty mRNA. The development of sensitive assays for transposition of GAL/Tys *in vivo* has led to the identification of a number of host factors that are important for transposition at a post-transcriptional level; these are reviewed in **Table 2.**

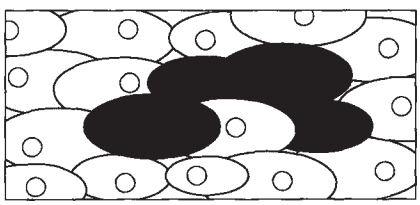
RETROVIRAL ONCOGENES



Paula J Enrietto and **Gabriela Maldonado-Codina**, Genomica Corporation, Boulder, Colorado, USA

Michael J. Hayman, Department of Molecular Microbiology and Genetics, SUNY at Stony Brook, Stony Brook, New York, USA

Introduction

The role of viruses in the etiology of cancer was suggested by the work of Peyton Rous who isolated the first acutely transforming retrovirus, Rous sarcoma virus (RSV), from a chicken sarcoma. These viruses are highly oncogenic and induce malignant transformation of cells because of the presence of cellular sequences, oncogenes (v-*onc*) within the viral genome. The cellular sequences from which viral oncogenes are derived, proto-oncogenes, are cellular genes converted into oncogenes by mutation, rearrangement or deletion. Retroviral oncogenes are generally mutated versions of their respective proto-oncogene. These changes result from the transduction process and additional changes are acquired during viral replication. Consequently, the oncogenic potential of the viral oncogene is significantly enhanced when compared to the cellular oncogene.

In this entry we will focus on retroviral oncogenes, which will be discussed in functional groups. The description of oncogenes within each group is meant to be broad. Specific details have been excluded but can be found in the references listed at the end.

Nuclear Oncogenes

ErbA

V-*erbA* is found in the avian erythroblastosis virus, AEV-ES4 and -R strains, isolated in 1934 by Englebreth-Holm. AEV transduced two different oncogenes, v-*erbA* and v-*erbB*. V-*erbB* is a homologue

of the epidermal growth factor receptor tyrosine kinase (see below).

The two *erb* genes are inserted between *gag* and *env* and are separated by an *erbB* intron sequence, which encodes the C-terminal four amino acids and termination codon of v-*erbA*. The 11 preceding Erb-A amino acids are encoded by *env* sequence. At the N-terminus a substitution of 254 amino acids encoded by the viral *gag* gene is also apparent. Giving rise to the protein product of v-ErbA, $p75^{gag\text{-}erbA}$, v-ErbA is derived from c-ErbA, the thyroid hormone receptor α (THRA1). V-ErbA is a mutated form of chicken THRA1. In addition to deletions resulting from transduction (nine amino acid N-terminal deletion and a 13 amino acid C-terminal deletion), V-ErbA has two point mutations in the DNA-binding domain and 11 in the hormone-binding domain. These changes result in the loss of hormone-binding capacity but do not abrogate sequence-specific DNA binding. The $p75^{gag\text{-}erbA}$ protein is localized to the nucleus. $P75^{gag\text{-}erbA}$ is phosphorylated on Ser16/17 by protein kinase A or protein kinase C. Mutation of the Ser16/17 phosphorylation site releases the block of erythroid differentiation exerted by v-ErbA.

THRA1 is a zinc-finger transcription factor, which binds to the response element TCAGGTCATGACCTGA, repressing its promoter activity. V-ErbA suppresses transcription of several genes, including avian erythrocyte anion transporter (band III), carbonic anhydrase II and β-globin genes. Transcriptional repression of erythrocyte-specific genes correlates with the biological properties of v-Erb-A and requires formation of heterodimeric complexes with retinoid X receptor (RXR).

V-ErbA is not tumorigenic but cooperates with v-Erb-B to cause avian erythroleukemia and fibrosarcomas. *In vitro*, v-ErbA blocks erythroid differentiation in cooperation with v-ErbB and other sarcoma-inducing oncogenes in transformation. V-ErbA stimulates chicken embryo fibroblast (CEF) growth and enhances the tumorigenicity of v-ErbB transformed fibroblasts.

Ets

The avian retrovirus E26, which carries the *ets* oncogene, was isolated in 1962 at the Bulgarian Academy of Sciences from a case of avian erythroblastosis. The E26 genome consists of deleted viral *gag* and *env* genes, a truncated version of *myb*, and *ets* (δgag-v-myb-v-ets-δenv). The *myb-ets* junction was created by an aberrant splice between a cryptic donor in *myb* and the normal splice acceptor in *ets* exonα. The result is the generation of five additional amino acids at this junction (HGTSE). Comparison of c-Ets (ETS-1) with v-Ets reveals amino acid substitutions at Ala285 and Ile445, which are replaced by Val in v-Ets. The 13 C-terminal residues of c-Ets have been replaced by 16 amino acid residues in v-Ets, 13 of which are derived from an inverted Ets-1 sequence. This results in a contiguous Gag-Myb-Ets open reading frame encoding a protein of 135 kDa, $p135^{gag\text{-}myb\text{-}ets}$ that is in the nucleus.

V-Ets is a member of a family of transcription factors that bind to DNA motifs containing (C/A)GGA (A/T) through a conserved 85 amino acid region called the Ets domain. V-Ets has less stringent target sequence requirements than c-Ets and binds to a broad spectrum of DNA sequence motifs, suggesting that v-Ets transforms cells by altering expression of tightly regulated genes with nonconsensus Ets binding sites.

The predominant disease induced by E26 in chickens is erythroblastosis. *In vitro*, both myeloid and erythroid cells can be transformed by E26, reflecting the fact that E26 also contains the myeloid-specific oncogene, v-Myb (see below). E26 transforms quail fibroblasts, NIH-3T3 cells, immature erythroid cells, and stimulates proliferation of CEF.

Fos

The *fos* oncogene is carried by the Finkel–Biskis–Jinkins (FBJ-MSV) and Finkel–Biskis–Reilly (FBR-MSV) murine osteogenic sarcoma viruses. Dr Miriam Finkel isolated both viruses from mice with ^{90}Sr-induced osteosarcomas. A virus isolated from an avian nephroblastoma, NK24, also contains the *fos* gene. The genome structures of FBJ and FBR-MSV differ significantly. FBJ-MSV contains v-*fos* and has no additional viral structural gene information, whereas FBR-MSV v-*fos* is fused to *gag* and non-*fos* sequences from the *fox* gene.

FBJ-MSV has five amino acid changes compared to c-Fos. A 104 bp deletion shifts the reading frame resulting in a C-terminus with 49 novel amino acids. Comparison with c-Fos reveals that FBJ-MSV v-Fos has lost 24 amino acids at the N-terminus (replaced with 310 gag amino acids) and 98 C-terminal amino acids (replaced with eight amino acids from fox). There are two C-terminal in frame deletions of 13 and 9 amino acids. The NK24 virus expresses an unaltered Fos protein linked to the gag encoded sequence.

The FBJ-MSV Fos protein product is 39 kDa, whereas the FBR-MSV fusion protein is $p75^{gag\text{-}fos\text{-}fox}$. Fos is a member of the helix–loop–helix/leucine zipper transcription factor superfamily. Each member of the family contains a basic domain, a leucine zipper, two homology boxes (HOB1 and HOB2) within a transac-

tivation domain, and a *trans*-repression domain. FBJ-MSV and FBR-MSV both lack the *trans*-repression domain at the C-terminus. Both FBJ and FBR-MSV v-Fos proteins are localized in the nucleus.

FBR-MSV v-Fos, but not FBJ v-Fos, is myristylated at the N-terminus. Both proteins are phosphorylated on serine and threonine residues but not to the same extent as c-Fos, as the predominant phosphorylation sites on c-Fos are within the C-terminal sequences deleted from v-Fos. A basic motif, KCR, is conserved in the Fos family and redox-regulation of the cysteine residue mediates DNA binding. All Fos proteins display DNA binding activity at a site (TGAc/GTCA) termed either activating protein-1 site (AP-1) or TPA response element (TRE) and form heterodimers with Jun proteins. These function as positive or negative transcription regulators binding to DNA via the basic domain.

FBJ, NK24 and FBR-MSV transform fibroblasts *in vitro*. FBR immortalizes murine cells in culture, while FBJ does not. Transforming ability appears to correlate with the presence of a C-terminal transactivation domain.

Jun

Avian sarcoma virus 17 (ASV17), which contains V-Jun, was isolated from a chicken sarcoma in 1987; 220 viral Gag residues (p19 and δp10) are joined in frame to 296 Jun-encoded amino acids. Comparison to c-Jun reveals a 27 amino acid deletion in the N-terminus of v-Jun and three nonconservative substitutions in the C-terminal half; two of which are in the DNA binding domain. The v-Jun protein product $p65^{gag\text{-}jun}$ is localized in the nucleus and has several domains: the A1 activator domain, two homology box regions, HOB1 and HOB2, the ε region and δ region (the region of 27 amino acids deleted in v-Jun), A2 activation domain, and a Pro/Gln-rich ancillary DNA-binding domain. The primary DNA-binding domain, a basic region and leucine zipper, are in the C-terminal 110 residues. This region and the activation domain are necessary for transformation by Jun. V-Jun forms heterodimers with members of the Fos family and Fos-related antigens (FRA1 and FRA2) and binds with high affinity to a TPA response element (TGAc/gTCA), TRE.

Oncogenic activation of c-Jun results from 27 amino acid deletion in the N-terminus. This region contains a MAP kinase site allowing for control of c-Jun activity by phosphorylation. V-Jun is not subject to control by phosphorylation. Two of the three nonconservative amino acid substitutions may be important functionally. A Ser222 to Phe mutation prevents the glycogen synthase kinase-3 phosphorylation of a negative regulatory site. Mutation of Cys248 to Ser disrupts the oxidation of Cys248, inactivating DNA binding.

V-Jun induces tumors when injected into the wing web of young chicks. *In vitro,* v-Jun transforms chicken embryo fibroblasts.

Maf

The v-*maf* oncogene was identified in an avian retrovirus, AS42, isolated from a spontaneous musculoaponeurotic fibrosarcoma of chicken. The v-*maf* gene is inserted into the viral genome in the *gag* gene and v-*maf* encodes a 42 kDa basic region/leucine zipper protein, which is localized in the nucleus. The coding region of v-*maf* has only two structural changes when compared to *c-maf*.

V-Maf and other Maf family members form homodimers and heterodimers with each other and Fos and Jun. The DNA target sequence to which Maf binds is termed the Maf response element (MARE). It is a 13 or 14 bp element that contains a core TRE or CRE palindrome.

In vitro v-Maf transforms avian fibroblasts. *In vivo* the virus induces musculoaponeurotic fibrosarcomas.

Myb

The v-*myb* oncogene is found in two acutely transforming avian retroviruses, avian myeloblastosis virus (AMV) and E26. AMV v-*myb* replaces 26 codons at the 3′ end of *pol* and most of *env*. There are 6 *gag*-coded amino acids at the N-terminus and 11 *env* amino acids at the C-terminus. E26 v-*myb* is fused in frame with v-*ets*, see above. Comparison of *AMV* v-*myb* with c-*myb* revealed extensive 5′ (71 N-terminal amino acids) and 3′ (198 C-terminal amino acids) deletions and 11 point mutations. E26 v-Myb lacks 80 N-terminal and 278 C-terminal amino acids of c-Myb and has one point mutation.

The AMV v-Myb protein product is $p45^{v\text{-}myb}$. The E26 v-Myb protein product is $p135^{gag\text{-}myb\text{-}ets}$. Both proteins are nuclear. C-Myb contains a DNA-binding domain with three repeat regions, R1, R2, R3, transactivation domain, leucine zipper, *trans*-repression domain and a conserved domain in the C-terminus. N-terminal deletions in AMV v-Myb remove most of the R1. The C-terminal conserved region is also deleted. E26 v-Myb lacks almost all of R1, the leucine zipper region, the MAPK/CDC2 site, and the conserved domain. All Myb related genes contain a Cys residue at position 65.

Phosphorylation of a casein kinase II site at the N-terminus decreases c-Myb DNA binding. This site is absent in both E26 and AMV v-Myb. A MAPK/CDC2 site in the C-terminus of c-Myb is not

phosphorylated in AMV v-Myb. V-Myb binds directly to double stranded DNA and regulates transcription through a consensus site YAACT/(C)/GGYCA. V-Myb regulates the expression of mim-1 and c-Myb.

AMV induces myeloid leukemia in chickens. *In vitro,* AMV transforms macrophage precursors (monoblasts). E26 transforms fibroblasts, myeloid and, as a result of the presence of ets, erythroid cells.

Myc

The v-*myc* gene was first identified in avian myelocytomatosis virus, MC29, but was subsequently found in four other virus isolates, CMII, OK10, MH2 and FH3. All the v-*myc* genes are highly homologous and contain only eight single nucleotide changes when compared with c-*myc*. MC29 contains deleted *gag*, 422 v-*myc* amino acids, no *pol* and a complete *env* gene. CMII contains deleted *gag*, 421 v-*myc* amino acids, and complete *pol* and *env* genes. OK10 contains all of *gag*, 426 v-*myc* amino acids, deleted *pol* and *env* genes. $P58^{\delta gag\text{-}myc}$ is a second Myc protein product translated from a subgenomic RNA, which contains a small piece of *gag* sequence at the N-terminal end. MH2 contains deleted *gag* and *env* genes and 417 v-*myc* amino acids and a second oncogene, *mil*, which is homologous to v-*raf*. FH3 contains deleted *gag* gene and 421 *myc* amino acids.

All v-*myc* genes are expressed as fusion proteins with viral structural information. MC29: $P110^{\delta gag\text{-}myc}$; CMII: $P90^{\delta gag\text{-}myc}$; OK10: $P200\text{-}gag^{\delta pol\text{-}myc}$, $P58^{\delta gag\text{-}myc}$; MH2: $P57^{\delta gag\text{-}myc}$; FH3: $P145^{\delta gag\text{-}myc}$. Several functional domains have been defined in the Myc family. A central acidic region influences the transforming host range of v-Myc proteins. Two nuclear localization signals have been defined. The C-terminus contains elements essential for DNA binding, a basic region, a helix–loop–helix motif and a leucine zipper. All v-Myc proteins are localized to the nucleus except $P200^{gag\text{-}\delta pol\text{-}myc}$, which is found in the cytoplasm and the nucleus. The Ser62 is phosphorylated by MAP kinases, lies in a highly-conserved proline-rich region and carries transcriptional activation capacity.

Myc forms a sequence specific (CACGTG) DNA binding heterodimer with a helix–loop–helix protein, Max. The leucine zipper and the helix–loop–helix region are required for heterodimer formation. Both positive and negative regulation of gene expression has been associated with Myc family members.

In vivo, MC29, CMII or FH3 cause myelocytomatosis. MC29, MH2 or OK10 cause liver and kidney carcinomas. *In vitro,* MC29, CMII, OK10, MH2 or FH3 transform immature macrophages or fibroblasts. Primary fibroblasts are immortalized by v-Myc but are rendered tumorigenic only when an activated Ras is also expressed.

Rel

V-*rel*, the oncogene in avian reticuloendotheliosis virus strain T (REV-T), was isolated from a turkey with lymphoid leukosis. V-Rel is a member of the NF-κB family of transcription factors. Incorporation of c-*rel* into the viral genome resulted in truncation of *gag*, *pol* and *env*. Using the *env* initiation codon, v-*rel* begins with 12 *env* amino acids and ends with 18 amino acids which are out of frame with respect to *env*. Comparison of v-Rel and turkey c-Rel revealed that v-Rel has lost two N-terminal amino acids and 118 amino acids at the C-terminus. V-Rel has 14 amino acids changes, ten of which are nonconservative, and three sites of deletion where a total of five amino acids are deleted.

The protein product of v-*rel* is $p59^{v\text{-}rel}$, which is localized to both the cytoplasm and nucleus of infected cells. At the N-terminal end of v-Rel is the Rel homology domain, a DNA-binding domain conserved in all members of the NF-κB family. This region also specifies nuclear localization and protein–protein interaction. C-Rel contains sequences in the C-terminus important for cytoplasmic retention and transcriptional activation which are deleted from v-Rel. In the cytoplasm, v-Rel exists in a complex with several other cellular proteins, including the inhibitor IκB. Dissociation of IκB from this complex allows translocation of v-Rel to the nucleus. V-Rel forms heterodimers with other members of the NF-κB family and binds to NF-κB motifs ($NGGNN^{A}$/TTTCC). In most cells, v-Rel represses gene expression; however, in transformed avian cells v-Rel activates transcription of MHC class I, HMG 14b, NF-κB, macrophage inflammatory protein-1 and an interleukin (IL)-8 related gene.

In vivo, REV-T causes acute reticuloendotheliosis. *In vitro,* v-Rel transforms a bone marrow-derived dendritic cell precursor, spleen-derived lymphoid cells, and fibroblasts.

Qin

The *qin* oncogene is the cell-derived insert in the genome of the avian sarcoma virus, ASV31. V-Qin is fused to Gag sequences at the N-terminus and eight cell coded amino acids link the cellular *qin* coding domain with the viral *gag* domain. Comparison of v-Qin with chicken c-Qin demonstrated several differences between the two. There are two non-conservative amino acid substitutions in the Qin coding region, a truncation in the C-terminus of the

viral protein due to a premature stop codon. V-Qin is a nuclear protein.

V-Qin contains two domains: a winged helix domain and a repression domain. Regions between residues 74–141 and 383–395 are required for transformation. Qin is a member of the winged helix transcription factor family which function as important regulators of embryonal development and tissue differentiation in vertebrates and invertebrates, regulating expression of a number of genes. It is most closely related to brain factor-1. Qin also functions as a transcriptional repressor.

In vivo ASV31 induces fibrosarcomas in chickens. *In vitro,* the virus transforms avian fibroblasts.

Ski

V-ski is the oncogene found in the Sloan–Kettering viruses, SKV. Inially two molecular weight forms of v-Ski proteins were described. A 125 kDa form, in which the *ski* sequence was inserted into the *gag* gene, and a 110 kDa form, which was derived from the former via deletion of *gag* sequence 3′ to the *ski* gene resulting in a Gag-Ski-Pol fusion protein. Both proteins are located in the nucleus of infected cells. By comparison to the c-Ski protein, v-Ski is truncated at both the N- and C-terminus. Both v-Ski and c-Ski can transform fibroblasts and so these truncations do not seem to be essential for oncogenic activity.

Ski has several protein motifs, including two amphipathic helices which are required for transforming activity. Ski can both transform cells and induce differentiation of muscle cells. The exact function of ski is unknown. However it appears to be capable of acting as a repressor of retinoic acid-induced transcription and this may be important for hematopoietic cell transformation. It can also activate transcription and this may be important for its effects on differentiation.

In vivo ski can effect the differentiation of muscle cells. It can also cause fibrosarcomas and stem cell leukemia when coexpressed with the v-*sea* oncogene. *In vitro* it can transform fibroblasts and hematopoietic cells.

Growth Factors

Sis

The v-*sis* oncogene is the transforming oncogene of the simian sarcoma virus. The oncogenic sequences of the Parodi–Irgens (PI) FSV are homologous with the v-*sis* sequences of the simian sarcoma virus but very little is known about this feline virus-encoded protein. The v-*sis* oncogene product is a protein of 28 kDa, which shares 92% homology with the platelet-derived growth factor (PDGF) B chain. *V-sis* is presumed to transform cells via autocrine activation of the endogenous PDGF receptor. The location of these autocrine interactions between the v-Sis protein and PDGF receptors remains somewhat controversial; however, it is thought that internal autoactivation of PDGF receptors may be essential for transformation by v-Sis. V-Sis can transform fibroblasts in culture and causes fibrosarcomas *in vivo*.

Protein Tyrosine Kinases

Abl

The v-*abl* oncogene was originally found in the Abelson murine leukemia virus. Subsequently the Hardy–Zuckerman 2, HZ2, feline sarcoma virus was also found to have transduced the feline *abl* gene. The protein encoded by the murine v-*abl* oncogene is a 160 kDa fusion protein, p160, which contains N-terminal gag sequences and is a truncated version of the cellular *c-abl* gene. A 120 kDa protein encoded by a variant Abelson MuLV has been described, in which 263 codons have been deleted from the middle of the p160 sequence. The feline v-Abl protein is a fusion protein of 110 kDa, which is comprised of N-terminal Gag sequences followed by Abl sequences and then sequences from the viral *pol* gene. The c-Abl protein is composed of several structural motifs. An SH3 domain is located close to the N-terminus, followed by an SH2 domain, then the tyrosine kinase domain, and a DNA-binding domain followed by an F-actin-binding domain has been located at the C-terminus. The murine p160 v-Abl protein contains all of these domains, apart from the N-terminal SH3 domain. In contrast, the feline v-Abl protein contains the SH3, SH2 and kinase domains, but lacks the C-terminal DNA-binding and actin-binding domains. A model has been proposed in which association of the N-terminal SH3 domain with C-terminal sequences keeps the tyrosine kinase activity of the c-Abl protein in an inactive state. This model would predict that the murine v-Abl protein would be an active kinase due to the loss of the SH3 domain, and the feline v-Abl protein would also be active owing to the loss of the C-terminal sequences. Consistent with this model, both v-Abl proteins are constitutively active tyrosine kinases and this activity is essential for their transforming abilities.

The v-Abl protein is located at the plasma membrane of the cell by virtue of the myristylated N-terminus provided by the Gag sequences. This is in contrast to the cellular Abl protein, which is primarily found in the nucleus of the cell. These myristylation sequences not only direct membrane localization but

also activate tyrosine phosphorylation and are necessary for cell transformation. *In vivo* the murine Abelson MuLV causes lymphocytic leukemias, whereas the feline HZ2 virus causes multicentric sarcomas. *In vitro* v-Abl can transform fibroblast cell lines and also transforms hematopoietic cells of the myeloid and lymphoid lineages. The transformation of these hematopoietic cells is of particular interest as the *c-abl* gene is rearranged by a balanced translocation between chromosomes 9 and 22, (t9;22)[q34;q11], in over 95% of the human malignancy chronic myelogenous leukemia (CML). This translocation forms a fusion protein between Bcr and Abl that gives rise to a constitutively active tyrosine kinase similar to the v-Abl proteins.

ErbB

The v-*erbB* oncogene was originally identified in the replication-defective avian erythroblastosis virus AEV-ES4. This retrovirus also contains the *erbA* oncogene (see above, Nuclear Oncogenes). The AEV-H strain of avian erythroblastosis virus also contained the *erbB* oncogene but did not contain any other oncogenes. This identified *erbB* as the oncogene that was primarily responsible for the induction of disease. In addition to erythroblastosis, AEV-ES4 and AEV-H also caused fibrosarcomas. A specific strain of chickens, L15, is very susceptible to erythroblastosis induced by avian leukosis virus, and analysis of these diseased birds demonstrated that the *erbB* oncogene was activated by retroviral insertions into the *c-erbB* gene. Furthermore the *erbB* sequences were frequently transduced into the retroviral genomes, giving rise to new strains of avian erythroblastosis viruses that encoded v-ErbB proteins. These proteins have sustained the N-terminal truncations but not the C-terminal truncations. Upon further passage, AEVs acquire the ability to cause other tumors in addition to erythroblastosis, for example fibrosarcomas and angiosarcomas. This increase in oncogenic potential is associated with point mutations and deletions within the cytoplasmic region of the ErbB protein.

The *erbB* oncogene is a truncated version of the epidermal growth factor receptor (EGFR). The EGFR is a member of the tyrosine kinase family of growth factor receptors. In comparison to the EGFR, the different forms of ErbB have been truncated at the N-terminus and frequently they are also truncated at the C-terminus. The N-terminal truncations all involve deletion of the ligand-binding domain of the EGFR and this results in constitutive activation of tyrosine kinase activity. The v-ErbB proteins of AEV-ES4 and AEV-H are glycoproteins of approximate molecular mass 74 kDa, which are located at the plasma membrane. Kinase activity and membrane localization are necessary for full oncogenic potential. The EGFR can induce mitogenic signals, which are accompanied by tyrosine phosphorylation of several cellular substrates. Presumably the constitutive activation of v-ErbB leads to the activation of similar substrates. V-ErbB is a much more powerful oncogene than the EGFR, thus the possibility exists that the mutations have somehow altered the specificity of v-ErbB for some substrates. To date no novel substrates for v-ErbB have been identified. Potential substrates identified in v-ErbB transformed include caldesmon, the catenin-like protein p120cas, Shc and Stat5b. In addition, the Grb2 adapter protein binds to v-ErbB and the mitogen-activated protein kinase pathway is constitutively active.

Eyk (ryk)

The v-*eyk* oncogene was found in the avian retrovirus RPL30. It was originally termed v-*ryk*, but the name was changed to avoid confusion with another gene that had been previously termed *ryk*. The v-*eyk* sequences are 1.39 kb in length and code for a tyrosine kinase domain that is fused in frame to the gp37 Env sequences. Unlike other acute transforming retroviruses, the transduction of the v-*ryk* gene did not result in the loss of viral sequences. The v-Eyk protein is first synthesized as a 150 kDa precursor Env-Eyk fusion protein. This protein undergoes the normal proteolytic processing of the *env* gene product to release the Env protein gp85 and a gp69 fusion protein containing gp37 and Eyk sequences. The gp69 protein is located in the membrane of transformed cells and possesses tyrosine kinase activity. C-Eyk encodes a receptor-type tyrosine kinase of 974 amino acids, which is a member of the UFO/Axl/Ark subfamily of receptors. The v-Eyk sequences are truncated by comparison to c-Eyk and have lost the regions that encode the extracellular and transmembrane domains; in addition there are two amino acid changes. RPL30 causes fibrosarcomas when injected into chickens and the cloned *eyk* gene can transform chicken embryo fibroblasts *in vitro*.

Fes/fps

The *fes/fps* oncogene has been isolated from both avian and feline sarcoma viruses. It was identified in the avian viruses: Fujinami sarcoma virus, Poultry Research Center viruses II and IV, PRCII, PRCIV, University of Rochester virus 1, UR1 and 16L. The name *fps* was derived from *F*ujinami-*P*RCII *S*arcoma, as these were the first two viruses described to contain this gene. The cognate oncogene *fes* was found in the Snyder–Theilen, Gardner–Arnstein and Hardy–

Zuckerman 1 strains of feline sarcoma viruses and the name is derived from *f*eline *s*arcoma. The c-*fps/fes* oncogene encodes a cytoplasmically located 98 kDa protein tyrosine kinase that contains an SH2 domain. All of the viral Fps/Fes forms are fusion proteins between N-terminal Gag sequences and fps sequences. The v-Fps/Fes sequences have lost the N-terminus of Fps/Fes but retain the SH2 domain and the tyrosine kinase domain. The v-Fps/Fes proteins are of varying sizes: Fujinami sarcoma virus v-Fps is 140 kDa; PRCII v-Fps is 105 kDa; PRCIV v-Fps is 150 kDa; 16L v-Fps is 142 kDa; UR1 v-Fps is 150 kDa; ST-FSV v-Fes is 85 kDa; GA-FSV v-Fes is 95 kDa; and HZ1-FSV v-Fes is 100 kDa.

The fusion of the Fps/Fes sequences to Gag is sufficient to activate the transforming potential. This fusion seems to be important for the activation of the tyrosine kinase and membrane location of the virally-encoded proteins. Although the feline proteins have lipid modification, there is no evidence of myristylation for any of the avian proteins. *In vitro* the v-Fps proteins can transform fibroblasts and *in vivo* these viruses cause fibrosarcomas and/or myxosarcomas. The tyrosine kinase activity of the Gag-fusion proteins is essential for transformation, and the identity of several cellular substrates is known. These include the GTPase-activating protein, the Shc adapter protein and fibronectin receptor proteins. A key pathway involved in transformation appears to be the Ras pathway, as microinjection of anti-Ras antibody blocks Fps-induced transformation. Interestingly the Bcr protein, which is fused to the Abl oncoprotein in CML, has recently been identified as a substrate of the Fps/Fes kinase. Phosphorylation of BCR provides a docking site for Grb-2 and in this way links Fps/Fes to Ras activation.

Fgr

The v-*fgr* oncogene was first identified in the Gardner–Rasheed feline sarcoma virus, GR-FSV and was subsequently found in the Theilen–Petersen feline sarcoma virus, TP1-FSV. Fgr encodes a cytoplasmic tyrosine kinase activity and is a member of the Src family. In the GR-FSV virus the *fgr* sequences are expressed as a fusion between Gag, followed by γ-actin and then the Fgr sequences to generate a 70 kDa protein. In the TP1-FSV the Gag sequences are fused to the Fgr sequence to generate an 83 kDa protein. The Gag sequences are myristylated and this explains the plasma membrane location of the v-Fgr protein. There is no actin domain in the TP1 v-Fgr protein, and in fact deletion of this region from the GR-FSV v-Fgr protein actually increases both tyrosine kinase activity and transformation.

In vitro Fgr has been shown to transform most mammalian fibroblasts. *In vivo* the GR-FSV causes fibrosarcomas and rhabdosarcomas upon infection of kittens. The c-Fgr protein is a 55 kDa protein tyrosine kinase that is most abundantly expressed in hematopoietic cells. c-*fgr* mRNA levels are increased up to 50-fold in Epstein–Barr virus-associated lymphoproliferative disease; however, viral infection does not readily lead to tumors of hematopoietic cells.

Fms

The *fms* oncogene is the transforming oncogene of the Susan McDonough (SM-FSV) and Hardy–Zuckerman 5 strains of feline sarcoma virus. C-Fms is a growth factor receptor tyrosine kinase that is activated by the ligand, macrophage colony-stimulating factor, CSF-1. V-Fms protein is initially synthesized as a Gag-Fms fusion protein in which the Gag sequences are rapidly removed upon cleavage at the Fms-signal peptide sequence. V-*fms* and c-*fms* encode mature glycoproteins of approximately 140 kDa in size that differ in a few scattered amino acids and at the C-terminus, where in the SM-FSV encoded protein the last 50 amino acids of c-Fms have been replaced by 14 residues that come from c-*fms* 3′ untranslated sequences. This substitution has removed a C-terminally-located tyrosine residue, which plays a role in activating the oncogenic potential of v-Fms. V-Fms is a constitutively activate tyrosine kinase and, of the scattered amino acid changes, the substitution of two serine residues in the extracellular domain seems to be particularly important in activating the tyrosine kinase. Membrane localization and tyrosine kinase activity are necessary for transformation. V-Fms-transformed cells contain similar tyrosine phosphorylated substrates to those seen following c-Fms activation, for example PI3-kinase. Interestingly, tyrosine residue 809 is involved in Myc gene expression and this seems to be key for mitogenesis induced by Fms.

In vivo SM-FSV causes fibrosarcomas and does not normally induce hematopoietic malignancies in spite of the fact that v-Fms is derived from the receptor for CSF-1; however *in vitro* v-fms can induce the growth factor-independent growth of CSF-1 dependent cell lines in addition to transforming fibroblast cell lines.

Kit

V-*kit* is the oncogene found in Hardy–Zuckerman 4 feline sarcoma virus, HZ4-FSV. V-Kit is derived from the tyrosine kinase growth factor receptor for stem cell factor, c-Kit. V-*kit* is expressed as a Gag-Kit fusion protein of 80 kDa. V-*kit* contains sequences encoding the tyrosine kinase domain from c-*kit*

(residues 558–925). The N-terminal sequences, which include the extracellular domain and the transmembrane domain, are deleted, and 50 amino acids from the C-terminus of c-Kit are replaced by five unrelated residues. Thus the v-Kit protein is not a transmembrane glycoprotein like its cellular homologue. However the $P80^{gag\text{-}kit}$ protein is myristylated, which suggest that it is membrane associated and it was shown to display a tyrosine-specific autophosphorylation activity.

Comparison of the v-Kit and c-Kit sequences revealed, in addition to the deletions mentioned above, three additional v-Kit mutations: deletion of Tyr569 and Val570, and the exchange of Asp at position 761 to Gly. Examinations of the consequences of the deletion of Tyr569 and Val570 revealed significant enhancement of transformation. Tyr568 and Tyr571 in c-Kit are a potential binding site for Src family members. Thus the repositioning of Y571 by this two-codon deletion has been postulated to play a role in the enhancement of v-Kit oncogenic activity.

In vitro v-Kit can transform the murine NIH3T3 fibroblast cell line. *In vivo* HZ4-FSV has been reported to cause fibrosarcomas in cats.

Ros

Ros is the transforming oncogene of the University of Rochester UR2, replication-defective avian sarcoma virus. It is derived from c-Ros, which is an orphan growth factor receptor that has similarity in overall structure to the drosophila sevenless protein. C-Ros is a large glycoprotein of 260 kDa. In contrast v-Ros is a 68 kDa protein that is expressed as a Gag-fusion protein. V-Ros contains the transmembrane and the tyrosine kinase domain of c-Ros, and has lost C-terminal sequences that have been replaced by 12 amino acids. In addition the transmembrane sequence in v-Ros contains a three amino acid insertion compared to c-Ros which seems to increase the transforming ability of v-Ros. This Gag-Ros fusion protein is a transmembrane protein in which the Gag moiety protrudes extracellularly. This Gag-Ros fusion protein is an active tyrosine kinase, is autophosphorylated and is found in a complex with phospholipase Cγ. In addition the mitogen-activated protein kinase pathway is activated in v-Ros transformed cells.

In vitro the UR2 virus can transform fibroblasts and *in vivo* cause fibrosarcomas.

Src

V-*src* is the transforming oncogene of the avian Rous Sarcoma virus, RSV. RSV is unique amongst acutely transforming retroviruses in being a replication competent virus in which the v-*src* sequence is located between the *env* gene and the 3′ end of the viral genome.

C-Src is a cytoplasmic protein tyrosine kinase and is the founding member of the Src superfamily of kinases, which includes Blk, Fgr, Fyn, Hck, Lck, Lyn, Src and Yes. All of these kinases have been implicated to some extent in oncogenesis and Src, Fgr and Yes have viral homologues. The cellular proteins are N-terminally myristylated and are membrane located. They contain a tyrosine kinase domain and Src-homology 2 and 3 domains (SH2 and SH3). In addition the cellular proteins have a C-terminal Tyr, which is important for regulation of the tyrosine kinase activity. In c-Src this tyrosine is Tyr527 and its phosphorylation *in vivo* inhibits the tyrosine kinase activity. In v-Src this tyrosine is deleted and thus v-Src has a constitutive tyrosine kinase activity which is essential for its transforming ability.

In vivo Src causes fibrosarcomas that are rapid and fatal in young birds. *In vitro* v-Src is capable of transforming several different cell types including fibroblasts, chondrocytes and hematopoietic cells. V-Src transformed cells have very high levels of tyrosine phosphorylation and over 30 different proteins are reported to be phosphorylated on tyrosine. The contributions to the transformed phenotype by these proteins are not always clear. However the activation of proteins in the MAP kinase pathway and cytoskeletal proteins clearly have roles in the uncontrolled growth and morphological changes associated with v-Src transformation.

Sea

V-*sea* is the transforming oncogene of the S13 avian erythroblastosis virus. The cellular c-Sea protein is a member of the hepatocyte growth factor (HGF) receptor family, which is comprised of Met, Ron and Sea. V-Sea is expressed as a fusion protein between the viral *env* gene and the cytoplasmic sequences from the c-*sea* gene. The Env-Sea fusion protein is initially synthesized as a precursor molecular weight of 155 kDa, which is then subject to proteolytic cleavage at the normal site in Env to give rise to a disulfide-linked complex comprising the Env protein gp85 and a gp37-Sea fusion protein called gp70. The Env protein sequences provide the extracellular domain and transmembrane domain and serve to oligomerize this complex. Oligomerization activates the tyrosine kinase activity. Oligomerization, plasma membrane localization and tyrosine kinase activity are all necessary for transformation by v-Sea.

The HGF family of receptors all have two tyrosine located near to the C-terminus of the receptor which are autophosphorylated and serve as a multifunctional binding site for SH2-domain signaling proteins. The v-Sea protein has retained this site and it has been shown to be essential for transformation. *In vitro* v-Sea can transform chicken and rat fibroblasts and also chicken erythroid progenitor cells. *In vivo* infection of young chicks by the S13 virus causes sarcomas, erythroblastosis and anemia.

Yes

V-*yes* is the transforming oncogene of the avian sarcoma viruses Y73 and Esh. The name derives from these two strains, *Y*73 and *Esh*. C-Yes is a member of the Src family of protein tyrosine kinases and encodes a 61 kDa protein. V-*yes* is expressed as Gag-Yes fusion proteins in both Y73 and Esh of molecular weights 90 kDa and 80 kDa respectively. In the Yes sequences in the Y73 virus the C-terminal eight amino acids of c-Yes are replaced by three amino acids, which are encoded by the avian leukemia virus *env* gene. This alteration changes the position and context of a tyrosine residue in $p61^{c\text{-}yes}$. In addition, there are the six amino differences between v-Yes and c-Yes sequences. Based on the importance of the C-terminal sequences in regulating Src protein kinase family members, it is thought that the differences at the C-terminus of v-Yes are important for the activation of the tyrosine kinase. The c-Yes protein is found associated with the plasma membrane and also with the cell cytoskeleton. V-Yes is more diffusely distributed and, in a similar manner to v-Src, is also found associated with adhesion plaques.

Analysis of proteins phosphorylated on tyrosine in v-Yes transformed cells has identified multiple substrates as in Src transformed cells. These substrates include proteins associated with the cytoskeleton proteins and those involved in adhesion, such as integrins, $p130^{cas}$, and focal adhesion kinase as well as PI3 kinase.

In vitro the Y73 and Esh viruses can transform chicken embryo fibroblasts and *in vivo* they cause fibrosarcomas.

Cytokine Receptors

Cytokine receptors do not possess intrinsic tyrosine kinase activity; however, upon ligand activation cytoplasmic tyrosine kinases are activated. Although this is a very large gene family, to date only one member has been found as a retrovirally encoded oncogene, and this is v-*mpl*.

Mpl

V-*mpl* is the transforming oncogene of the murine myeloproliferative virus, MPLV. C-Mpl has been recently identified as being the receptor for the cytokine, thrombopoietin, and plays a role in the growth and differentiation of cells into megakaryocytes. V-*mpl* encodes a transmembrane protein that is expressed as an Env-Mpl fusion gene and is a truncated form of the c-Mpl receptor. The v-Mpl protein contains 100 amino acids of Env followed by 184 amino acids derived from c-Mpl, which contains the transmembrane and cytoplasmic sequences.

In vivo MPLV causes an acute hematological disorder characterized by the rapid growth of cells from several lineages. In contrast to most acutely transforming retroviruses, MPLV does not transform fibroblasts but *in vitro* infection of bone marrow cells will lead to the rapid outgrowth of immortalized cells from several lineages.

Adapter Proteins

Recently a class of proteins has been identified that has no intrinsic biochemical activity but they serve as linker molecules to connect proteins in key signaling pathways. These proteins are known as adapter molecules and they possess structural motifs that allow for protein–protein interaction. They also frequently serve as targets for tyrosine protein kinases, and upon phosphorylation can act as scaffolding molecules that bind to several downstream effector molecules. Two such molecules have been identified in acute transforming retroviruses; these are the *cbl* and *crk* oncogenes.

Cbl

Cbl is the transforming oncogene of the murine Cas NS-1 virus. The c-Cbl protein is a cytoplasmic protein of approximately 120 kDa. V-Cbl is a Gag-fusion protein of 100 kDa, which contains only 355 amino acids from the N-terminus of c-Cbl. V-Cbl is found in the nucleus of transformed cells. C-Cbl is associated with the Grb2 adapter protein and is phosphorylated upon tyrosine residues following growth factor stimulation. C-Cbl is related to the *Caenorhabditis elegans* gene Sli-1, which is a negative regulator of growth factor signaling. The N-terminal region of c-Cbl contains a putative phosphotyrosine binding domain and a ring-finger motif. Cbl is thought to function as a scaffold protein and associates with several SH2 and SH3 domain-containing molecules, including the Crk adaptor family and Vav. The deletion of C-terminal sequences up to the ring-finger

motif, as found in v-Cbl, causes Cbl to become oncogenic. This deletion is suggested to generate a structural alteration, allowing the oncogenic forms of v-Cbl to displace wild-type c-Cbl from the receptor complex and in doing so to abrogate c-Cbl's negative regulatory function.

The Cas NS-1 murine retrovirus induces lymphomas and leukemias *in vivo*.

Crk

V-*crk* is the transforming oncogene of the avian sarcoma viruses, CT10 and ASV-1. C-Crk is an adapter protein of molecular weight 28 kDa that contains both an SH2 and two SH3 domains. Although the CT10 virus was isolated in the 1920s and the ASV-1 virus in 1983, the v-crk sequence in these viruses is virtually identical and is a Gag-fusion protein of 47 kDa. Although v-Crk does not possess a tyrosine kinase domain, fibroblasts transformed by v-Crk have greatly elevated levels of tyrosine phosphorylated proteins. This is thought to be due to the activation of a cellular tyrosine kinase by v-Crk and potentially also the stabilization of tyrosine phosphorylation upon association of tyrosine phosphorylated proteins with v-Crk. Abl is a candidate for a tyrosine kinase that may be regulated by v-Crk, as it forms a stable complex with v-Crk via the SH3 domain of v-Crk. Src-family members have also been implicated as being regulated by v-Crk. V-Crk is associated with several proteins in transformed cells. These include the proteins paxillin and p130Cas, which bind to Crk SH2 domain, and are thought to play roles in adhesion. The C3G protein, a guanine nucleotide exchange protein for Rap1, was shown to be bound to Crk SH3 domains. The SH3 domain of Crk also binds to Sos, and Eps15. The nature of the proteins bound to Crk implies that Crk influences the activities of effector proteins that are included in pathways involving cell morphology and growth.

V-Crk transforms fibroblasts *in vitro* and infection of birds with the AVS-1 and CT10 viruses causes fibrosarcomas.

Serine/Threonine Kinases

Akt

V-*akt* is the transforming oncogene of the acute transforming retrovirus AKT8 which was isolated from a spontaneous mouse T-cell lymphoma. V-*akt* has two human cellular homologues, AKT1 and AKT2, also known as protein kinase B. These genes encode protein kinase C-related serine/threonine kinases.

V-*akt* arose by recombination between MuLV and *c-akt*, 785 nucleotides downstream of the Gag ATG codon and 60 nucleotides upstream of the ATG codon in the 5′ untranslated region of the *c-akt* protooncogene. The 60 base pairs of 5′ *c-akt* noncoding sequence and the entire coding and 3′ untranslated regions are fused to viral Gag giving a 763 amino acid, 105 kDa fusion phosphoprotein of structure (p12, p15, Δp30)-X-*c-akt*, where X is 21 amino acids that result from the translation of the 60 *c-akt* 5′ noncoding nucleotides plus three additional nucleotides inserted at the junction between *Gag* and *c-akt*. The Akt protein sequence of v-Akt is identical to c-Akt. V-Akt and c-Akt contain a pleckstrin homology domain and a serine/threonine homology domain.

C-Akt kinase activity is positively regulated by phosphorylation at a Thr residue in the T-loop and Ser473 in the C-terminal regulatory domain. The PIP3-dependent kinase 1 (PDK1) is responsible for phosphorylation at Thr308. Currently the kinase that phosphorylates the Ser473 residue is unknown. C-Akt is activated by growth factors, including platelet-derived growth factor. Akt interacts directly, via its pleckstrin homology domain, with PI(3,4)P2 and PIP3, promoting a conformational change, a change in localization from the cytoplasm to the plasma membrane, as well as an increase in kinase activity. Although Akt is a serine/threonine kinase, part of its regulatory region is similar to the Src homology domain (SH2), a characteristic of cytoplasmic tyrosine kinases that function in protein–protein interactions. Possible c-Akt targets include glycogen synthase kinase 3 (GSK3), ribosomal protein S6 kinase $p70^{S6K}$ and the Bcl-2 family member BAD, phosphorylation of which makes it unable to inhibit the survival activity of proteins like Bcl-2.

Fusion of Gag sequences to Akt provides a myristylation site at the N-terminus of the v-Akt protein that mimics the pleckstrin homology domain, anchoring the protein to the membrane. Localization of v-Akt is unregulated as dependence on PIP3 formation is lost. As a result of its permanent presence at the plasma membrane, v-Akt kinase activity is unregulated.

Raf

V-*raf* is the transforming oncogene of the murine retrovirus 3611-MSV derived from the mouse *Raf-1* proto-oncogene. The avian homologue of *Raf-1*, v-*mil* (originally termed v-*mht*), occurs in the Mill Hill 2 (MH2) virus isolated from a spontaneous ovarian tumor in chickens.

The 3611-MSV genome structure is 5′ *gag*(Δp15, p12, Δp30)-v-*raf*-Δ*pol*-*env*-3′. The 5′ v-*raf* junction has 12 nucleotides identical to the 3′ end of mouse *Raf-1* exon 9 and differs from MuLV $p30^{gag}$ by only one nucleotide. At the 3′ end, eight nucleotides of v-*raf*, MuLV and mouse *Raf-1* exon 17 are identical. V-*raf* is a truncated version of *Raf-1* starting with a few nucleotides of exon 9 and ending with part of exon 17 coding for amino acids 326–648 from full length Raf-1. The N-terminal regulatory conserved regions 1 and 2 (CR1 and CR2) are deleted in v-*raf*. Therefore, the kinase domain (CR3) is joined to viral *gag* sequences. The resulting protein is cytosolic like its cellular counterpart, and is phosphorylated and myristylated. The v-*mil* oncogene of the MH2 virus begins in exon 7 and encodes the last 380 amino acids of chicken *Mil* (*Raf*) with 19 amino acid substitutions and one deletion. None of these mutations appear critical for transformation.

C-Raf is positively regulated by serine/tyrosine phosphorylation, which occurs mainly in response to mitogenic signals. Serine phosphorylation may also exert a negative effect, as phosphorylation of Ser357 and Ser359 in the ATP-binding domain of Raf-1 may inhibit Raf-1 activity. C-Raf is a serine/threonine kinase, which activates MAP kinase-kinase (MAPK-K), which in turn stimulates the mitogen-activated protein kinases ERK1 and ERK2. V-Raf has constitutive kinase activity and consequently MAPK-K, ERK1 and ERK2 are constitutively active in v-*raf* transformed cells. The ΔGag-v-Raf and ΔGag-v-Mil proteins have autophosphorylating protein kinase activity, which is essential for transforming activity. These oncoproteins *trans*-activate expression of genes driven by AP-1, ETS and NFκB binding motifs.

V-*raf* induces fibrosarcomas, erythroblastosis and occasionally erythroleukemia *in vivo*. Raf-induced tumors are more frequent in the hematopoeitic cell lineages, followed by pancreatic epithelium and connective tissues. Raf and Myc act synergistically to transform cells of all hematopoeitic lineages.

Ras

The v-H-*ras* and v-K-*ras* oncogenes, found in Harvey and Kirsten murine sarcoma virus (Ha-MuSV and Ki-MuSV), are derived from H-*ras* and K-*ras* cellular oncogenes, members of the Ras superfamily of transforming small G proteins. These viruses were isolated from rats infected with mouse leukemia viruses, Mo-MuLV and Ki-MuLV. Following the induction of leukemia, plasma from these animals was injected into BALB/c mice, which rapidly developed solid tumors. BALB-MuSV, AF-1 and Rasheed-MuSV viruses have also acquired Ras genes.

The viral genomes of Ha-MuSV (5.5 kb) and Ki-MuSV (6.5 kb) are composed of three types of nucleotide sequences: sequences homologous to MuLV (0.2 kb at the 5′ end and 1 kb at the 3′ end), sequence homologous to rat retrovirus-like 30S RNA, and the oncogene sequences which are 1.5 kb in Ha-MuSV and 1.75 kb in Ki-MuSV inserted towards the 5′ end of the 30S RNA.

V-H-*ras* and v-K-*ras* both encode full-length proteins with two and four point mutations, respectively. The v-H-Ras point mutations are Lys12 to Gly and Lys143 to Gln. The v-K-Ras point mutations are Gly12 to Ser, Glu37 to Gln, Ala59 to Thr, Ile100 to Leu. The v-H-*ras* and v-K-*ras* oncogenes encode a 189 amino acid protein, $p21^{ras}$. Ras proteins are modified by polyisoprenylation and palmitoylation, and as a consequence bind tightly to the inner surface of the plasma membrane. Ras-encoded proteins are GTPases that are activated by a variety of growth factors. Normal $p21^{ras}$ molecules hydrolyze GTP and exist in an equilibrium between active (GTP bound state) and inactive states (GDP bound). Two other proteins are involved in determining the state of the Ras proteins: GAPs (GTPase activating proteins), which catalyze the GDP bound state; and GEFs (guanine nucleotide exchange factor), which catalyze the release of bound GDP, thereby activating the protein. Three residues are critical for activating oncogenic potential: Gly12, Ala59 and Gln61. Gly12 and Ala59 are assumed to interfere with the action of the Gln61 side chain that forms a complex with the γ-phosphate in GTP. All inhibit GTP hydrolysis by diminishing GTPase activity or modulating the rate of nucleotide exchange (Ala59). Oncogenic mutations allow the GTP.$p21^{ras}$ complex to remain active, thereby stimulating cell growth. Ras activates a cascade of serine/threonine protein kinases that include c-Raf, MAP kinase kinase (MAPK-K) and extracellular signal-regulated kinases (ERKs or MAP kinases). Via this cascade v-Ras activates FOS, JUN and other AP1 components and therefore modulates transcription, which eventually results in DNA synthesis.

Injection of mice with Ha-MuSV and Ki-MuSV gave rise to sarcomas. It is important to note that activating mutations of Ras have been detected in a wide variety of human tumors. Normal fibroblasts are not transformed by v-Ras unless coinfected with viruses containing immortalizing oncogenes such as Myc. However, cell lines such as NIH3T3 can be transformed by v-Ras. Ras oncogenes can efficiently transform murine erythroid, myeloid and mast cells *in vitro*.

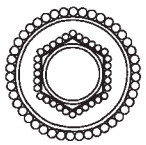
RETROVIRUSES – TYPE D (*RETROVIRIDAE*)



Maja A Sommerfelt, Department of Microbiology and Immunology, Gades Institute, University of Bergen, Bergen, Norway

Eric Hunter, Department of Microbiology, University of Alabama at Birmingham, Birmingham, Alabama, USA

History

The first type D retrovirus described was isolated in 1970 from a spontaneous mammary carcinoma of an 8-year-old rhesus macaque. This virus, named Mason Pfizer monkey virus (M-PMV), has since become the prototype for an enlarging family of both endogenous and exogenous viruses (**Table 1**). Although isolated from a mammary carcinoma, M-PMV is not oncogenic; instead, infected primates succumb to a severe and often fatal immunosuppressive disease, which is distinct from that caused by the simian immunodeficiency viruses (SIVs) that are lentiviruses. Simian acquired immune deficiency disease (SAIDS-D) was first defined in 1983 as a disease entity caused by type D viruses. The precise mechanism of type D virus-induced immune suppression is not known, but the syndrome is currently restricted to the genus *Macaca* (subfamily Cercopithecinae) of old world monkey.

Approximately 12 years after the discovery of M-PMV, several additional horizontally transmitted type D viruses were isolated. They were called simian AIDS D-type (SAIDS-D) viruses together with the primate center of origin (for example, the virus from the New England Primate Center was named SAIDS-D/NE; **Table 1**). Based on the observation that the type D viruses could be divided into distinct neutralization groups, a new nomenclature was devised to distinguish these viruses from each other and to differentiate them from the HIV-like AIDS-inducing SIV. Members of the group are now named simian retrovirus (SRV) followed by the serological type. Serotypes 1–3 have all been molecularly cloned and sequenced. SRV-2, isolated at the Washington and Oregon primate centers, in addition to causing immune suppression, is directly associated with a severe retroperitoneal fibromatosis (RF). SRV-1–5 correspond to the exogenous type D viruses. It is presently unclear whether SRVPc isolated from an Ethiopian baboon at the Washington primate center represents an accidental laboratory infection or a new serotype. Two endogenous viruses have been isolated, one endogenous to the New World squirrel monkey *Saimiri sciureus* (squirrel monkey retrovirus SMRV) and the other to the Old World spectacled langur *Presbytis obscurus* (PO-1-Lu). An endogenous virus considered to be ancestral to the exogenous type D retroviruses has been recently identified in baboon genomic DNA. There have been reports of type D viruses isolated from human permanent cells lines: Hep-2V and PMFV, but these appear to be contaminants as only certain cell stocks carried the virus. The host species of origin for the exogenous type D viruses has not yet been defined.

Taxonomy and Classification

Type D retroviruses, classified in the family *Retroviridae*, are members of the *Betaretrovirus* genus. These are positive-strand RNA viruses that replicate by reverse transcription to form a proviral DNA intermediate which can integrate covalently into the host chromosomal DNA. M-PMV has a morphogenesis similar to that of the type B mouse mammary tumor virus (MMTV), in that it preassembles immature capsids (referred to as intracytoplasmic A-type particles (ICAPs)) within the infected cell cytoplasm.

The morphology of the mature extracellular virion is different, in that it has a centrally located nucleoid similar to type C retroviruses and a much less dense fringe of glycoprotein than MMTV. Being of primate origin with these differences, a new morphological class of retrovirus was designated type D.

Properties of the Virion

Type D viruses assemble an immature capsid in the cytoplasm. These intracellular spherical particles, 60–95 nm in diameter, migrate to the plasma membrane, where they acquire, during release by budding, an envelope containing virus-encoded glycoproteins (**Fig. 1A, 1B**). These particles have a diameter of 100–120 nm. Following release, a proteolytic event termed 'maturation' results in a morphological change in the virion from an electron-lucent core to an electron-dense core (**Fig. 1C**). Surface projections corresponding to the viral glycoproteins can be seen in negatively stained preparations (**Fig. 1D, 1E, 1F**). Type D viruses exhibit a buoyant density of $1.17\,g\,ml^{-1}$ in sucrose, and $1.21\,g\,ml^{-1}$ in cesium chloride. The three-dimensional structure of the virion remains to be determined.

Properties of the Genome

The genome of type D retroviruses that have been sequenced to date is composed of two identical positive-sense, single-stranded RNAs of approximately 8 kb in length (7943 nt for M-PMV). The RNA molecules are proposed to be hydrogen-bonded to each other and to a host $tRNA^{lys}$. This diploid structure of about 5.3×10^6 Da (70 S) is denatured by heat (80°C for 2.5 min) or 40% formamide to 2.65×10^6 Da (35 S). Like eucaryotic mRNA, the retroviral RNA genome is capped at the 5′ end with a 7-methyl GTP, polyadenylated at the 3′ end and internally methylated on scattered adenosine residues.

As with any replication-competent retrovirus genome, coding regions of type D viruses are flanked at both ends by 5′- and 3′-terminal sequences that are important for virus replication and regulation of gene expression. The 5′ sequences include a binding site for a host $tRNA^{lys}$ which serves as a primer for the synthesis of negative-strand DNA by the viral reverse transcriptase enzyme, and an untranslated region preceding the coding regions. The RNA splice donor-site (AAGUAAGU) for subgenomic mRNAs is located 21 nucleotides upstream of the *gag* AUG for M-PMV. A packaging signal sequence for encapsidation of genomic RNAs into virions is also present. The 3′-terminal sequences contain at least two transcriptional elements: the AUUAAA signal sequence for poly(A) addition, and the UAUAUAAG sequence corresponding to the TATA box as promoter for viral RNA synthesis.

Properties of the Proteins

Four genes, arranged as 5′-*gag-pro-pol-env*-3′, encode type D virus proteins. The most detailed information is available for the prototype virus M-PMV. Viral

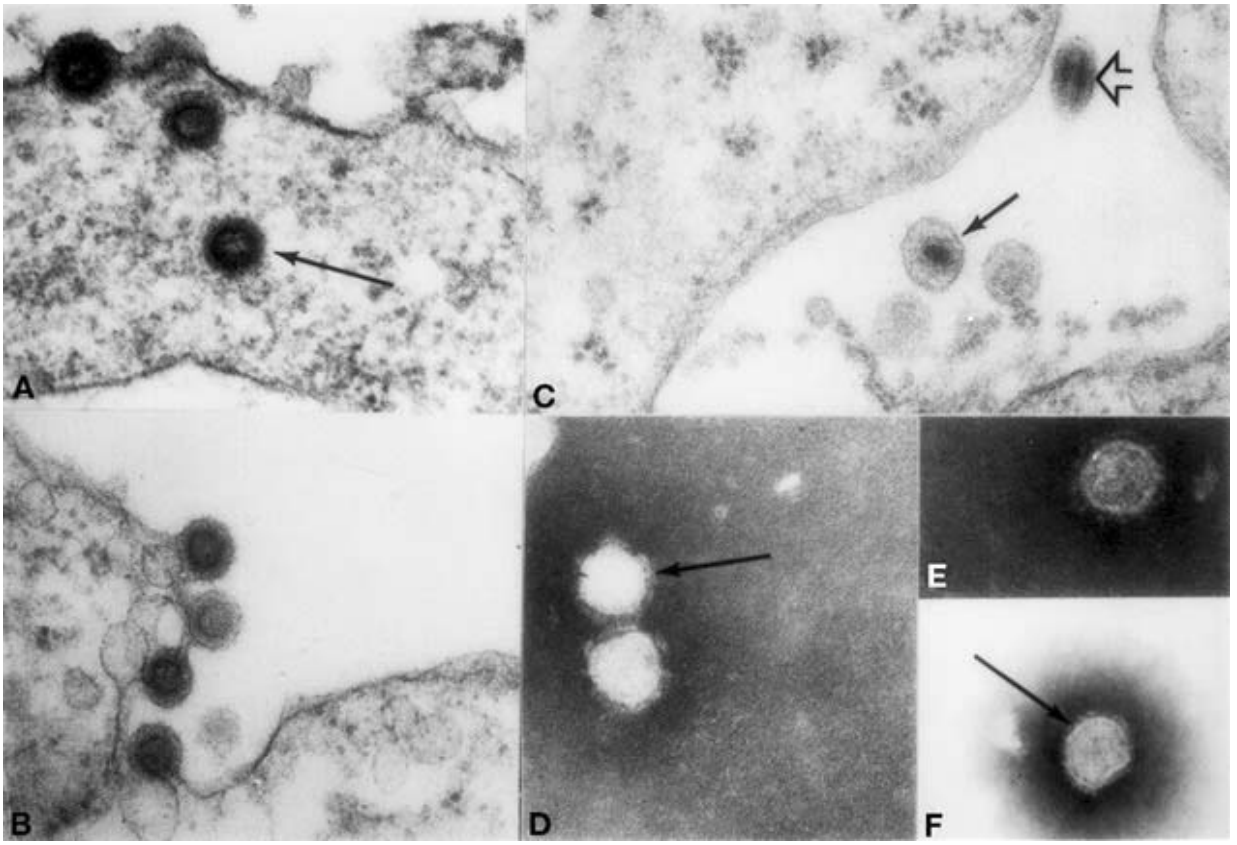

Figure 1 Electron micrographs of M-PMV-infected cells and M-PMV virions. (**A**) Thin section of an M-PMV-infected cell showing immature capsids deep in the cytoplasm (arrow) and in process of budding. (**B**) Immature capsids at a late stage of budding. (**C**) Mature virions showing electron-dense core (arrow) and section through cylindrical core (open arrow). (**D–F**) Negatively-stained virions showing glycoprotein surface projections (arrows).

genes are expressed as polyprotein precursors: Pr78 is encoded by *gag*, and Pr95 by *gag-pro* through a −1 frameshift event at the end of *gag*. The *pol* gene is similarly expressed as a Pr180 *gag-pro-pol* product that is generated from two −1 frameshifts, one at the end of *gag* and a second at the end of *pro*. The envelope glycoprotein is translated from a spliced mRNA as a Pr86 precursor. This polyprotein is comprised of the surface (SU) glycoprotein gp70 that interacts with receptors on susceptible cells, and the transmembrane (TM) glycoprotein gp22, which spans the viral membrane and catalyzes the process of membrane fusion. During virus maturation the gp22 is cleaved to gp20 by the viral protease, a process which appears to activate the fusogenic potential of the glycoprotein complex.

Immature intracytoplasmic A-type particles are composed of Pr78, Pr95 and Pr180 in an approximate 80:15:5% ratio. Expression of the precursor proteins in an *in vitro* translation system results in assembly of these immature capsids in a process that is dependent on ATP hydrolysis. During maturation, the Pr78 precursor is cleaved, by the virus-encoded protease, to yield six internal structural proteins in the order NH_2-p10(MA)-pp24/16-p12-p27(CA)-p14(NC)-p4-COOH (**Fig. 2**). The 10 kDa matrix protein (MA) forms the envelope-associated outer shell of the mature particle and is modified with myristic acid. The 27 kDa polypeptide capsid protein (CA) is the major structural component of the mature capsid, while the 14 kDa nucleic acid binding protein (NC) presumably functions in genomic RNA packaging and dimer formation. The exact functions of the 12 kDa (p12), 4 kDa (p4) proteins and the phosphorylated 24/16 protein remain to be determined. However, the p12 domain of Pr78 is critical for immature capsid assembly both in infected cells and *in vitro*, and a proline-proline-proline-tyrosine (PPPY) motif in pp16/24 is critical for the final stage of virus budding from the cell. SMRV particles contain a major capsid protein p35, which is likely to represent a fusion protein of p12 and p27.

The protease gene of M-PMV could potentially encode a protein of 314 amino acids, fused to the Gag

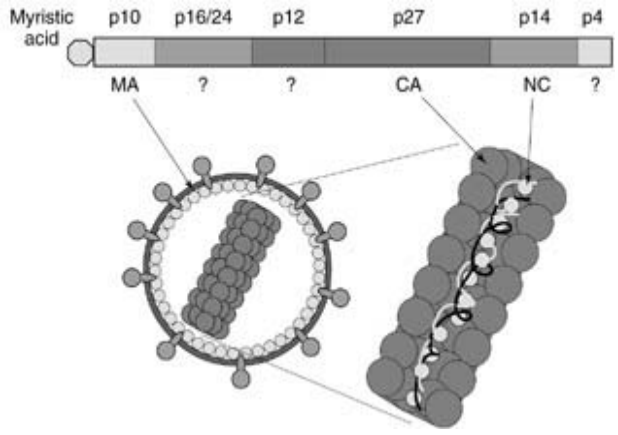

Figure 2 M-PMV *gag* gene-encoded precursor showing the organization of the mature products and their location within the mature virion. A section through the core shows the association of the NC protein with the diploid RNA genome.

precursor that is truncated at the frameshifting site. This *pro*-encoded region is cleaved by the viral protease to two proteins of 17 kDa; the N-terminal protein has dUTPase activity, while the C-terminal portion has protease activity and can be further cleaved to a 12 kDa protein with protease activity. The protease is an aspartyl protease, which remains inert while it is part of the Pr95 and Pr180 precursors within the cell. It is activated by an unknown mechanism following virus release. The importance of dUTPase activity in the virus life cycle is unknown.

The reverse transcriptase enzyme (80–90 kDa) for all the type D retroviruses has a divalent cation preference for magnesium in contrast to manganese, which is utilized by many of the nonhuman mammalian type C viruses. This enzyme also has RNase H and integrase activity.

Physical Properties of the Virion

Type D virions are rapidly inactivated when exposed to high temperature (56°C for 30 min) and are also sensitive to lipid solvents and detergents. The mature virions of M-PMV are easily disrupted in mild detergent concentration (0.5% Triton X-100), whereas immature intracytoplasmic capsid particles remain stable under these conditions. Recent evidence from cryoelectron microscopy indicates that the immature capsids, despite their assembly in the absence of membranes, are not icosahedral and exhibit a broad distribution of sizes.

Although retroviruses are quite resistant to UV light or gamma irradiation, UV irradiation of M-PMV results in inhibition of virus-induced syncytial formation in rhesus monkey embryonic lung cells.

Type D viruses are composed of approximately 60–70% protein, 30–40% lipid, 2–4% carbohydrate and 1% nucleic acid by weight.

Strategy of replication of the nucleic acid

In common with other retroviruses, the type D retroviral RNA genome is reverse transcribed within the infected cytoplasm to form a double-stranded DNA intermediate. The nascent DNA migrates to the nucleus and integrates covalently into the host chromosomal DNA, where it exists as a provirus. Transcription of the provirus results in messenger RNA that will function to produce virus-specific polyprotein precursors, and also genomic RNA that will be packaged into assembling virions.

Characterization of Transcription

Cellular RNA polymerase II transcribes the integrated type D provirus genome into RNA. In the cytoplasm of infected cells, two classes of viral RNA transcripts are detected. A genomic-sized mRNA (8 kb), which is either translated into polyprotein precursors or encapsidated into progeny virus particles, and a 3 kb mRNA representing subgenomic-spliced mRNA which is translated into Env polyproteins. Transport of the unspliced genomic RNA from the nucleus to the cytoplasm is dependent on the presence of a short (~200 nucleotide) element called the constitutive transport element (CTE) that is located between the *env*-gene and the 3′ long terminal repeat (LTR). This element forms a hairpin structure that is presumably recognized by a host protein(s) capable of diverting the genome-length RNA from the splicing machinery and out of the nucleus.

Characterization of Translation

Genome-length RNAs are translated on free polysomes into the Gag polyprotein and, as a result of ribosomal frameshifting, into the Gag-Pro and Gag-Pro-Pol polyproteins. The heptanucleotide sequence motifs for the −1 frameshift have been localized in both M-PMV and SRV-1 genomes: GGGAAAC for Gag-Pro fusion and AAAUUUU for Pro-Pol fusion. Due to the frequency of frameshifting, the majority of precursor proteins are Gag polyproteins, approximately 15% are Gag-Pro polyproteins and around 5% are Gag-Pro-Pol polyproteins.

The spliced subgenomic *env* mRNA is translated on polysomes associated with the endoplasmic reticulum. The cotranslationally glycosylated product is transported via the secretory pathway of the cell to

the plasma membrane, where it is anchored and oriented as a type I glycoprotein.

Post-translational Processing

Cellular enzymes post-translationally modify the Gag-containing polyproteins. The N-terminal methionine residue is cotranslationally removed and myristic acid is added to the new N-terminal glycine residue. The polyproteins are also phosphorylated following translation, but the significance of this modification is not clear.

Following entry into the endoplasmic reticulum of the cell, Env polyproteins form an oligomeric structure (estimated to be a trimer), which is the transport-competent form of the precursor. During transport to the cell surface through the secretory pathway, core oligosaccharide side chains on the SU domain of M-PMV Env polyproteins are processed to complex oligosaccharide chains. The single high-mannose oligosaccharide chain added to the TM domain during translation is maintained in an unmodified form. In a late Golgi compartment the Pr86 polyprotein is cleaved into the two mature glycoproteins, gp70(SU) and gp22(TM), by a furin-like cellular endopeptidase. The gp22 is further processed, by a C-terminal cleavage event, to gp20 during virus maturation by the viral aspartyl protease.

Assembly Site, Release and Cytopathology

Type D viruses are characterized by the assembly of immature intracytoplasmic A type particles (ICAPs). These are assembled from uncleaved precursor proteins and migrate to the plasma membrane, where they are released by budding. They acquire an outer membrane, which is derived from the host cell plasma membrane and contains virus-specific envelope glycoproteins, during this process. The assembly of immature capsids appears to occur at a site in the cytoplasm where precursors congregate in sufficient quantities to allow self-assembly. A signal, which directs the proteins to the intracytoplasmic assembly site, has been identified in the MA protein of M-PMV. Immature capsids appear to contain a full complement of genomic RNA. As with other retroviruses, RNA packaging requires a sequence (psi) found within the 5′ end of genomic RNA. This region has been shown to fold into a specific secondary structure that is presumably recognized by the Gag precursor protein during capsid assembly.

Although the pathway of intracytoplasmic transport has not been defined, the transport of immature capsids to the membrane requires a specific protein-mediated targeting process, in addition to the presence of myristic acid, which is also required for intracellular transport. During the budding process, immature capsids associate with the plasma membrane, presumably via the MA protein, and are extruded from the cell. It has been postulated for M-PMV that there is an interaction between the cytoplasmic domain of the TM glycoprotein, gp22, and the matrix protein, which directs incorporation of envelope glycoproteins into the virion. As with other retroviruses, the viral glycoproteins are not essential for virion release but are required for virus infectivity.

Other Subjects Relevant to Virus Group

Type D viruses are capable of inducing cell fusion *in vitro*. This is mediated by the interaction of virus envelope glycoproteins expressed at the cell surface with available receptors present on adjacent uninfected cells and has provided a method for titrating the virus in culture.

Geographic Distribution

The primates that are infected with exogenous type D viruses primarily comprise the *Macaca* (Cercopithecinae) genus of Old World monkey which naturally inhabit India and Southeast Asia (**Table 2**). Studies of seropositivity to type D retroviruses in feral macaques is limited. At present the disease spectrum of this virus group has mainly been associated with primate research centers in the USA, although seropositivity to type D infection in imported or wild caught monkeys has been noted in primate centers in Europe and China. The spectacled langur, which harbors the endogenous virus PO-1-Lu, inhabits India and Southeast Asia and the squirrel monkey, harboring SMRV, inhabits central and southern America.

Host Range and Virus Propagation

Viruses enter cells following attachment to specific cell surface receptors. These viruses enter cells by a pH-independent pathway, suggesting that they penetrate cells at the plasma membrane. Type D virus receptors appear to be constitutively expressed on human cells. The same receptor moiety appears to be used by all the type D viruses, as well as two related mammalian type C viruses, RD114 (an endogenous virus of cats) and baboon endogenous virus (BaEV), as well as the type C avian reticuloendotheliosis viruses (REV). Viruses within this group exhibit receptor interference where cells chronically infected with one virus will be resistant to superinfection by a second in the group. The receptor gene has been

Table 2 Primates from which exogenous SRVs have been isolated

Genus and species	*Common name*	*Primate center*
Macaca mulatta	Rhesus macaque	California, New England

Papio cunocephales	Ethiopian baboon	Washington

[a] Seropositivity confirmed by western blotting, no reported virus isolation.

assigned to human chromosome 19q13.1–13.3. The distinct neutralization specificities suggest that the type D retroviruses utilize distinct epitopes of the same cell surface receptor. Exploiting the neutralization epitope of SRV-2, a molecule of 60 kDa has been identified as a putative receptor on Raji cells. Further work is required to confirm a receptor function for this molecule. Type D viruses are not considered to be cytopathic; instead, they integrate into the cell genome and persist as a chronic infection where the cells do not die but continuously shed virus.

The *in vivo* host range of SRV-1–5 is broad, infecting many tissue types, including lymph nodes, salivary gland, spleen, thymus and brain. There have been reports that the SRVs may remain latent in the brain.

The *in vitro* host range of SRV-1–5 is extensive and includes a variety of human lymphoblastoid (H9, Raji) and nonlymphoblastoid cell lines (HeLa and HOS). Mink, chimp lung, African green monkey (COS), horse epithelial and dog thymus cells are also susceptible. Cells that appear to be resistant to productive infection include hamster, rat and mouse.

The endogenous viruses have a more restricted *in vitro* host range. PO-1-Lu infects only human and bat lung cells. It cannot infect langur cells, indicating that it has a xenotropic host range typical of endogenous viruses. SMRV has a broader xenotropic host range infecting cells of dog, chimp, mink, rhesus, human, marmoset, owl monkey and howler monkey, but not baboon. Simian endogenous retrovirus (SERV) has only been studied as cloned DNA. It is present in all *Papio* and *Cercopithec* species, but genomic DNA from African or Asian members of the Colobinae has not yet been analyzed. As no infectious SERV has been isolated, the *in vitro* and *in vivo* host range of this member remains to be determined.

Genetics

The type D retroviruses, in common with other retroviruses, contain two identical RNA genomes; this diploidy allows for genetic recombination.

SRV-1, -2 and -3 have been fully sequenced and show a high degree of both nucleotide and amino acid identity. They have slightly different restriction endonuclease patterns but are uniform within each group. The difference between the SRV genomes probably results from basepair mutations over time rather than large recombinational events. The exogenous SRVs have been described as variants of M-PMV. The major differences are found in regions encompassing the Gag phosphoproteins, the p12 proteins and the envelope glycoproteins. SRV-1 and SRV-3 (M-PMV) appear to be more related than SRV-2, which is also associated with RF.

The viral genome is comprised of four genes in the order *5′-gag-pro-pol-env-3′*, where *gag* encodes the structural components of the capsid, *pro* encodes the viral aspartyl protease, *pol* encodes the polymerase enzyme (reverse transcriptase) and integrase and *env* encodes the surface envelope glycoproteins. The type D retroviruses have neither regulatory genes, found in the immunosuppressive primate lentiviruses, nor oncogenes, found in members of the avian and mammalian type C retroviruses.

Evolution

The type D viruses such as M-PMV exhibit immunological crossreactivity in their envelope glycoproteins to two related endogenous type C retroviruses, namely baboon endogenous retrovirus (BaEV) and RD114. In contrast, the Gag and Pol proteins of the type D viruses are unrelated to these type C viruses.

The genomic organization, reverse transcriptase and Gag proteins of type D viruses are related to those of the B-type MMTV and the intracisternal A-type particles (IAPs). The type D viruses may therefore have arisen as a recombinational event in which the *env* gene was acquired from a virus ancestral to the C-type BaEV, and the capsid and reverse transcriptase genes were derived from a retrovirus ancestral to MMTV or the IAPs.

Early hybridization studies with tissues of different monkey species showed that M-PMV and SRV-1 DNA hybridized more readily to langur DNA (in the subfamily Colobinae) than to rhesus DNA, suggesting that M-PMV may have been derived from a virus similar to that endogenous in the langur monkey. Recently an endogenous type D retrovirus (SERV) genome was isolated from a baboon (*Papio cynocephalus*) genomic library. DNA sequence analysis showed that the *gag*, *pro*, *pol* and *env* (gp20 region) genes were similar to SRV-1, -2 and -3, whereas the gp70-encoding region was more closely related to that of BaEV. No analysis of langur DNA for SERV sequences has yet been undertaken.

The Jaagsiekte sheep retrovirus (JSRV) associated with ovine pulmonary carcinoma (OPC) of sheep, shows both antigenic and proviral DNA sequence similarity to M-PMV in the *gag-pro-pol* genes, while the *env* gene is similar to the prototype type B retrovirus MMTV and may represent a novel recombinant.

The presence of type D retroviral sequences in both Old and New World primates clearly shows that these viruses are ancient. Tracing their evolution is complicated by their potential for extensive recombination and zoonoses.

Serologic Relationships and Variability

There are five different serotypes, each with distinct neutralization epitopes, among the exogenous SRVs. These neutralization epitopes lie in the external envelope glycoproteins, which may show variability because of adaptation to different macaque species. The viruses can also be distinguished using antibodies to the smaller Gag proteins, p10 and p12. In addition to these type-specific determinants, the type D retroviruses demonstrate a high level of antigenic cross-reactivity within the major capsid protein. The type D envelope glycoproteins appear conserved for each serotype and do not show the same degree or kinetics of variation as the human and simian immunodeficiency viruses (HIV/SIV) and SIV. Minor variations are present in each serotype depending on the host species of isolation. Studies addressing sequence variability following infection have not been undertaken.

Epidemiology

Type D retroviruses have been targeted in the development and maintenance of specific-pathogen-free (SPF) colonies of rhesus macaques. Seroepidemiological surveys have shown that up to 20% of captive macaques at US primate centers and commercial suppliers are infected with SRV. Seropositivity to type D retroviruses has also been reported in China in wild-caught macaques (**Table 2**). Since certain infected macaques fail to make detectable antibody, or exhibit a long interval between infection and seroconversion, serologic testing alone is not sufficient for epidemiological studies. The polymerase chain reaction (PCR) provides a rapid means of detecting type D proviral DNA. However, PCR is limited to the detection of viruses for which DNA sequence information is available. Type D retrovirus infection is undoubtedly widespread, although its distribution in primate holding facilities worldwide, in zoos or in the wild has not been fully investigated.

Transmission and Tissue Tropism

Transmission of the exogenous SRVs requires close physical contact and is probably spread by saliva and blood through biting, grooming and fighting – the way such primates establish a social hierarchy. Unlike HIV, SRV transmission does not appear to be via sexual contact. High titers of virus can be found in infected macaque saliva, allowing entry to the bloodstream of a recipient individual following trauma.

The virus can be experimentally transmitted by inoculation of primates, as was done to prove the disease association of these viruses. The *in vivo* tissue tropism shows a broad host range for both lymphoid and nonlymphoid organs. Perinatal transmission and *in utero* transmission of the exogenous type D viruses appears to be infrequent. SRV can be recovered from peripheral blood lymphocytes, saliva, urine, feces and breast milk of viremic animals.

Transmission of the endogenous viruses occurs vertically as inherited genetic elements.

Pathogenicity

SAIDS-D is a naturally occurring, experimentally reproducible infection, where infected rhesus monkeys show a broad spectrum of clinical and pathological abnormalities (**Table 3**). Following infection of juvenile rhesus macaques, the animals may die within 1 year. The course of infection can result in fulminating viremia and death, a relatively mild acute

Table 3 Clinical features of SAIDS-D infection

Immune deficiency
Chronic wasting/ weight loss (>10%)
Persistent diarrhea unresponsive to appropriate therapy
Splenomegaly
Neutropenia
Lymphopenia or histologic lymphoid depletion
Abnormal peripheral blood lymphocytes
Mesenchymal proliferative disorders
Noma
Increased incidence of tumours
Opportunistic infections including:
Disseminated cytomegalovirus infection
Bacterial pneumonia
Progressive generalized lymphadenopathy (PGL)
Anemia
Bone marrow hyperplasia

phase of disease resulting in a chronic carrier state, or recovery from both viremia and latent infection.

The endogenous viruses are not associated with any pathogenic effects in their hosts.

Clinical Features of Infection

Infection of macaques with all of the SRVs isolated to date is associated with a severe and often fatal immune suppression (**Table 3**.) There is a decrease in both T and B cell populations and a low response of peripheral blood lymphocytes to mitogens, together with an increased incidence of tumors. Virus can be isolated from persistently infected animals from saliva, peripheral lymph nodes, plasma, peripheral blood leukocytes and exfoliated cells in milk.

One feature unique to SRV-2 is that this virus is also associated with retroperitoneal fibromatosis, which has been compared to Kaposi's sarcoma in humans. However, RF tissue is infected with SRV-2, unlike Kaposi's sarcoma and HIV. Particularly prevalent in Celebes and pigtailed macaques, RF is a highly vascular mesenchymal proliferative lesion that commonly originates in the subserosa of the intestine at the ileocecal junction and which can aggressively spread throughout the abdominal and thoracic cavity. A cutaneous form of RF has also been recognized in a small number of animals; immunohistochemical studies show a factor VIII-related antigen in endothelial cells and scattered fibroblast-like cells throughout the RF lesions, similar to those described for human Kaposi's sarcoma. RF is restricted to the Oregon and Washington regional primate centers.

Pathology and Histopathology

Typical type D virus particles can be found in the salivary gland acinar cells (secretory cells), mucosal epithelial cells, macrophages, lymph nodes, Langerhans cells, peripheral blood lymphocytes, thymus and spleen, but not in muscle or brain. Viral nucleic acid can be found in brain parenchyma, suggesting that the virus may remain latent in this organ. Neuropathy, however, is not a characteristic of SAIDS-D. Brain cells may thus present a post-transcriptional block to SRV replication. The tissue localization of SRV-1 is also dependent on the severity of the disease. In severe SAIDS-D, virus is present in a higher percentage of cells of the salivary gland, as well as in the sinusoidal cells lining the spleen, and the stellate cells of the thymus. If the primate presents with persistent generalized lymphadenopathy or splenomegaly, virus antigen is not as prevalent, being limited to germinal centers of lymphoid organs and scattered salivary gland acinar cells. There have been reports that some virus may also be found in other secretory cells, e.g. sweat glands, mammary glands and pancreatic acinar cells.

The histology of RF associated with SRV-2 infection reveals thymic atrophy and follicular and paracortical atrophy of the lymph nodes, as well as variable myeloid and lymphoid hyperplasia in the bone marrow.

Immune Response

Infection usually results in an overall decline in both B and T lymphocytes. Unlike in human AIDS, hypergammaglobulinemia is not a feature of SAIDS-D. Impairment of B cell function has been demonstrated by a diminished antibody response to antigenic stimulation, *in vivo* and *in vitro*, and progressively decreasing levels in the serum of all immunoglobulin subclasses. Secondary immune responses may be impaired with no switch from IgM to IgG. Complement C3 and C4 levels remain intact or are slightly elevated through the course of the disease. Antibodies are mounted predominantly to the Gag antigens. Resistance to type D infection corresponds to the presence of high levels of neutralizing antibodies directed against the envelope glycoproteins.

Prevention and Control

Effective vaccines have been generated against SRV-1, SRV-2 and SRV-3. Juvenile macaques inoculated with formalin-inactivated SRV-1 generate neutralizing antibodies that are protective upon challenge. Recombinant vaccinia virus expressing the envelope glycoproteins of SRV-1, SRV-2 and SRV-3 protect

against the respective virus challenge, even years later, demonstrating that the envelope glycoproteins alone are sufficient to elicit a protective immune response. These vaccines have limited crossprotection: SRV-3 vaccinated animals were protected from SRV-1 challenge but no crossimmunity has been observed between the SRV-1 and SRV-2 serotypes. Vaccines are useful for limiting the spread of SRV infection. Control of infection *in vitro* has also been successful using zidovudine (AZT) or 9-(2-phosphonylmethoxyethyl)adenine (PMEA), which inhibit the reverse transcriptase, as well as inhibitors of the HIV proteinase.

Future Perspectives

Although type D virus-induced immunosuppression has been a problem at primate centers in the USA, effective screening measures are possible to identify infected primates. Polyvalent vaccines may eventually be generated to protect primates from all the different serotypes identified to date. A report of the isolation of a type D virus, highly related to M-PMV, from an AIDS patient suffering from lymphoma raised the possibility of human infections by type D viruses; however, human seropositivity to type D antigens remains controversial. Recently, a DNA sequence of 932 bp with similarity to type B/D retroviruses was identified in patients with Sjögren's syndrome. This sequence appears to represent an acquired genome that has been provisionally called human retrovirus 5. Further research is required to establish the significance of this finding.

History, Taxonomy and Classification

The *Drosophila melanogaster gypsy virus* has been recently classified in the family *Metaviridae* of the genus *Errantivirus*. However, in context of the earlier classification, this virus is referred to as a retrovirus. Gypsy was first described as a transposable element present in the genome of *Drosophila melanogaster*. Although its structure is very much similar to that of vertebrate retroviruses (see below and **Fig. 1**), it was considered as a long terminal repeat (LTR)-containing retrotransposon. Infectious properties were demonstrated in 1994.

Control of Gypsy by the Host Genome

The transposition and infective properties of Gypsy are controlled by a host gene called *flamenco*. This gene is located on the X chromosome. Restrictive *flamenco* alleles repress Gypsy transposition and infectivity; permissive alleles allow high rates of

Control of Gypsy by the Host Genome

The transposition and infective properties of Gypsy are controlled by a host gene called *flamenco*. This gene is located on the X chromosome. Restrictive *flamenco* alleles repress Gypsy transposition and infectivity; permissive alleles allow high rates of

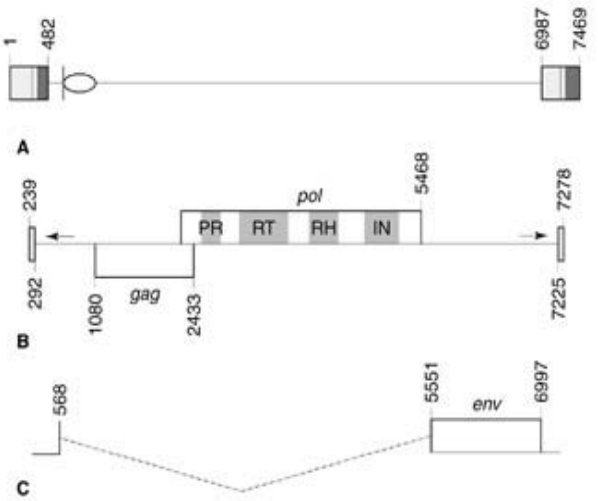

Figure 1 Gypsy proviral structure and transcription (**A**) Structure of a *D. melanogaster* Gypsy provirus. Numerical designations refer to coordinates (in nucleotides) from the first sequence deposited in the databank. Boxes represent the proviral long terminal repeats (LTRs), including U3, R and U5 (light shading, open box and dark shading, respectively). The oval and the vertical bar represent two DNA-binding regions, the SU(HW)-binding site and the downregulating palindrome, respectively. (**B**) Structure of the full-length transcript and its coding potential. The viral RNA is bounded at either end by the short direct repeat R. The U5 and U3 LTR sequences are unique in the transcript. The leftwards and rightwards arrows indicate respectively the positions of the primer binding site (PBS), including nucleotides 482–492, and of the polypurine tract (PPT), including nucleotides 6977–6986. The coordinates of the *gag* first AUG codon and of the *gag* and *pol* stop codons are given. The *pol* open reading frame begins at nucleotide 2363. Position of *pol* domains is as follows: PR, protease; RT, reverse transcriptase; RH, RNAse H; IN, integrase. (**C**) Structure of the *env* subgenomic RNA. The splicing event is figured by the broken line. The vertical bar at position 568 corresponds to the two first nucleotides of the AUG initiator codon which are spliced to a G at position 5551. The 5′ end of this RNA has not been precisely mapped.

transposition and the expression of its infective properties. Transposition only occurs in the progeny of females homozygous for the permissive *flamenco* alleles, indicating that this gene has a maternal effect on Gypsy activity.

Overview of the Strategy of Replication

The typical retroviral replication cycle mainly consists of the following sequence of events: (1) transcription of the provirus; (2) translation; (3) RNA packaging; (4) reverse transcription; and (5) integration as a proviral DNA into the chromosome of the infected host. There is already a wealth of evidence showing that most, if not all, of these steps are involved in the biology of Gypsy. Moreover, like a typical endogenous retrovirus, Gypsy is a germline parasite which can therefore just rely on the chromosome DNA replication machinery for its proviruses to be passively transmitted from generation to generation. Unlike endogenous retroviruses in vertebrates, however, the proviral copy number can dramatically increase in permissive *Drosophila* genotypes. This results from very efficient transfer from the soma towards the germen. Requirement of the infectious potential of Gypsy for this transfer has yet to be demonstrated.

Sequence of the Proviral Genome

Three Gypsy proviruses have been thoroughly sequenced to date in *D. melanogaster*. Despite some differences, these sequences all display the same three open reading frames (ORFs), each of which show at least some similarities to either of the main three genes, *gag, pol* and *env,* shared by all retroviruses (**Fig. 1**). Near the C-terminus of the *gag* homologue gene, an arginine-rich region, conserved in proviruses isolated from two other *Drosophila* species (*D. virilis* and *D. subobscura*), was described as a putative ARM RNA binding motif. The protein putatively encoded by the second ORF is highly homologous to the enzymatic activities, protease, reverse transcriptase, RNAse H and integrase, encoded by other retroviruses. Translation of the third ORF produces a *bona fide* retroviral envelope with a 32 amino acid intracellular domain.

Cis sequences involved in the retroviral replication cycle can also be found: (1) there are two LTRs; (2) adjacent to 5′ LTR, complementarity to $tRNA_1^{Lys}$ discloses a minus-strand primer binding site (PBS); (3) an oligopurine stretch just upstream of 3′ LTR, assumed to be resistant to RNAse H, should be able to prime synthesis of the plus-strand DNA.

Gypsy is not framed by the typical TG...CA nucleotides. Instead, the inverted repeats AGTTA... $TAA^{T}/_{C}T$ are found at the LTR ends.

Transcription

Basal transcriptional activity requires a TATA-less upstream element, located between nucleotides −38 and −24, the TCAGTT Inr sequence at the start site and a downstream sequence between +13 and +60. Polyadenylation of the viral RNA occurs in the 3′ LTR downstream of the Inr sequence, thus leaving short direct repeats (R) which flank unique LTR regions at the 5′ (U5) and 3′ (U3) ends (**Fig. 1B**). A subgenomic RNA (**Fig. 1C**) has been partially characterized in adult females and in Schneider-2 tissue cell cultures; it only seems to differ from the

full-length transcript by the splicing of a 5 kb sequence removing the end of the leader and the *gag* and *pol* ORFs. This splicing event generates a putative initiator codon for ORF 3.

No transcription initiation has ever been described from the 3′ LTR. By contrast, insertion of Gypsy in direct orientation into introns of the *forked* gene may result in mutant phenotypes when polyadenylation of the readthrough transcript occurs in the 5′ LTR before the intron plus the insertion have been spliced.

In addition to the two major transcripts, a rather abundant population of transcripts of various sizes is assumed to originate from the subfamily of defective proviruses, in particular as a result of readthrough transcription in either orientation.

Transcriptional Regulation

The molecular basis of the precise patterns of developmentally regulated Gypsy expression is not yet known. The two following transregulators are currently being studied:

- The product of the *flamenco* gene reduces the accumulation of Gypsy transcripts, especially that of the subgenomic transcript (see below, Transmission and Tissue Specificity). As judged from the ability of a transcriptional fusion to be repressed by *flamenco*, all the relevant *cis*-regulatory sequences must be located within a region encompassing the 5′ LTR and the leader sequence.
- The Gypsy leader region (**Fig. 1A**) contains two elements which bind proteins from nuclear extracts. One is an imperfect palindrome having some homology with the *lac*-operator of *Escherichia coli*. The other contains 12 copies of the binding site ($5'\text{PyPu}^{T}/_{C}\text{TGCATA}^{C}/_{T}\text{PyPu}$) for the *Drosophila* zinc-finger protein SU(HW). When binding of the ubiquitous SU(HW) factor is prevented, Gypsy transcription is uniformly reduced in every tissue. It can act both as an insulator and as a tissue-specific enhancer. This insulating ability is responsible for the SU(HW)-dependent mutant phenotypes induced by Gypsy insertions in the regulatory regions of various genes.

Translation and Post-translational Processing

Very little is known about the ORF 1 and ORF 2 products. From sequence analogy with retroviruses, ORF 2 is assumed to be translated by a −1 frameshifting process. An anti-IN monoclonal antibody failed to detect the GAG-POL fusion protein. Only a 50 kDa polypeptide was lighted up, whereas a 40 kDa IN subunit is expected. In preparations containing extracellular Gypsy particles from the supernatant of *Drosophila* cell cultures (see below, Characteristics of the Viral Particles), a 37 kDa polypeptide was shown to have some specific affinity to Gypsy nucleic acids.

Products of the *env* gene can be detected in ovary extracts of permissive *flamenco* females (see below, Transmission and Tissue Specificity). Treatment by endoglycosidase F reduces the apparent molecular mass of the 66 kDa ENV precursor such that it comigrates with the product of ORF 3 translated *in vitro*. This glycosylated precursor is cleaved into a 34 kDa surface polypeptide (SU) and a 28 kDa transmembrane subunit (TM). Transfection of *Drosophila* cell cultures by the *env* gene under control of the *actin* promoter results in accumulation of the ENV products in the cell membranes.

Characteristics of the Viral Particles

Particles containing Gypsy RNA were first described in the supernatant of *Drosophila* cell cultures (*D. melanogaster* 67j25D and *D. virilis* 79f9 cell lines). Later, fractionation by sucrose density gradients of permissive *flamenco* female extracts produced low-density fractions characterized by the co-occurrence of the ENV product and an endogenous reverse transcriptase activity able to synthetize Gypsy DNA without addition of any Gypsy template. On immunoelectron microscopic and negative staining pictures of these fractions, one can surmise particle-like structures about 100 nm in diameter, the outside of which tends to be decorated by the anti-ENV monoclonal antibodies. In the follicle cells of the same females, much smaller intracytoplasmic particles (40–45 nm in diameter, see **Fig. 2**), lighted up by a Gypsy DNA probe, were found to accumulate close to the membrane domains where ENV is targeted. Neither budding nor enveloped extracellular virions could be observed, as if the replication cycle of this type D-like retrovirus was somewhat abortive in this tissue.

Reverse Transcription

The sophisticated process of reverse transcription of LTR retroelements results in production of DNA with LTRs starting from an RNA template flanked with short terminal repeats. Reconstruction of the complete Gypsy LTR DNA was actually documented in *Drosophila* cultured cells transfected with Gypsy constructs missing the 5′ U3 sequence.

This process is due to the ability of reverse transcriptase to switch templates several times, involving formation of several distinct molecular

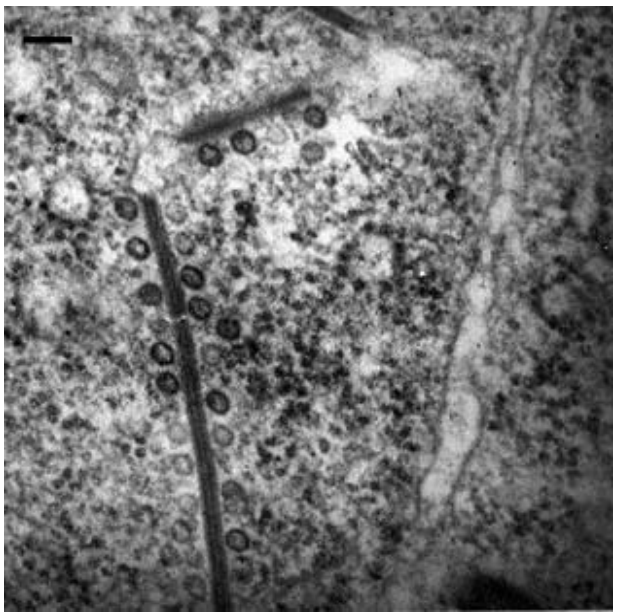

Figure 2 Localization and ultrastructure of Gypsy particles inside *flamenco* permissive follicle cells. In transverse sections, the cellular membranes appear connected together, from place to place, by some junction-like dense material. In immunoelectron microscopic experiments, not shown here, these particular membrane domains were specifically decorated by the anti-ENV antibodies. The picture also shows that these specific membrane domains are covered internally by numerous 40–45 nm particles which, in another experiment, were shown to hybridize with a Gypsy probe. Bar = 100 nm.

forms composed of the template RNA and the nascent DNA strands, organized in a highly specific fashion. Such RNA–DNA hybrids (including the 'minus strong-stop DNA', associated to an RNA primer, the 'plus strong-stop DNA' and full-length minus-strand cDNAs with one or two LTRs), could be actually identified, after oligo(dT) chromatography of nucleic acids extracted from the cell line 67j25d, as permanent cellular ingredients in the absence of exogenous retroviral infection. Similarly, Gypsy strong-stop DNAs are to be found even in females where neither particles nor insertions can be detected, suggesting that they result from the incomplete reverse transcription cycle of the endogenous Gypsy transcripts.

Integration and Excision

In the absence of any external infection, the insertion frequency of germinal proviruses ranges from 10^{-4} to 10^{-1} per haploid genome per active provirus, depending on the host genetic background. In the few insertional mutations analyzed so far, the PyPuPyPu*PyPu consensus sequence – (Py) pyrimidine; (Pu) purine; (*) insertion site – was used as a target, the first four nucleotides being duplicated at both ends of the insertion.

Three different insertional mutations were reported to revert at a frequency of 5×10^{-4} as a result of precise Gypsy excision. The mechanism of this amazing phenomenon is not yet understood.

Transmission and Tissue Specificity

Gypsy is generally transmitted vertically through the germline as a provirus and is not contagious in normal breeding conditions. However, infectious properties of Gypsy were demonstrated by experiments in which crude extracts of pupae issued from a *flamenco* permissive strain containing a high copy number of active Gypsy were put in contact with permissive larvae lacking active Gypsy. Using a genetic assay (based on the screening of mutations due to *de novo* insertion of Gypsy), new sites of Gypsy insertion were observed in the progeny of the flies subjected to the extracts. These results suggest that Gypsy can be efficiently transmitted to the germline of permissive individuals.

The regulation of Gypsy by the *flamenco* gene is tissue-specific. The Gypsy RNAs and ENV proteins accumulate in the ovaries of *flamenco* permissive females. This accumulation takes place near the apical membrane of the somatic follicle cells that surround the oocyte, whereas no derepression occurs in the germline which gives rise to the progeny where integration occurs. This pattern of accumulation is reminiscent of the targeting of enveloped viruses to membrane domains of epithelial cells.

Gypsy ORF 3 is expressed from a spliced messenger RNA that encodes a membrane glycoprotein containing a signal peptide and an endopeptidase cleavage site characteristic of retroviral ENV protein. Direct evidence of Gypsy ENV infectious properties was obtained using a Moloney murine leukemia virus-based retroviral vector pseudotyped by the Gypsy ENV protein. Such particles, produced in the 293GP human cell line, can infect *Drosophila* cells. *Drosophila* cell receptors for Gypsy entry remain to be determined.

Distribution

Southern blot experiments using the Gypsy sequence as a probe have shown that Gypsy-related sequences are widespread in the *Drosophila* genus.

Sequences homologous to Gypsy from *D. subobscura* (Gypsy*Ds*) and *D. virilis* (Gypsy*Dv*) were cloned and entirely sequenced. The sequenced Gypsy*Ds* and Gypsy*Dv* ORF 3s do not have the coding capacity for

Table 1 Insect endogenous retroviruses containing an *env*-like gene.

Element	*Host species*	*env-like spliced RNA*	*ENV protein*	*Infectivity*

Osvaldo	*D. buzzatii*	?	?	?

functional envelopes because they contain several stop codons generating truncated proteins. The phylogenetic relationship of these three elements is not consistent with the phylogeny of the three host species, suggesting horizontal transfer(s) of the Gypsy elements across species.

All *D. melanogaster* strains contain defective Gypsy proviruses located in pericentromeric heterochromatin. The strains caught in the wild studied so far contain a few additional putatively active Gypsy proviruses (fewer than five) located in euchromatin.

Putative endogenous retroviruses are common in insects. Gypsy is not the only endogenous retrovirus found in insects. Many other envelope-containing insect elements have a similar ORF 3 (**Table 1**) but Gypsy is the only invertebrate retroelement for which infectivity has been shown.

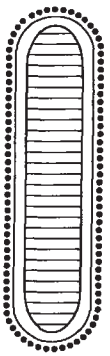
RHABDOVIRUSES (*RHABDOVIRIDAE*)



Contents

Plant Rhabdoviruses

Andrew O Jackson, Michael Goodin, Ignacio Moreno, Jennifer Johnson and **Diane M Lawrence**, Department of Plant and Microbial Biology, University of California, Berkeley, California, USA

Introduction

Plant viruses have traditionally been included in the Rhabdovirus family based on their distinctive enveloped bacilliform or bullet-shaped particles. These large complex particles can be distinguished readily from the constituents present in uninfected tissue by electron microscopy of extracts or thin sections of infected tissue. Therefore, numerous putative rhabdoviruses have been described in many different plant families. Microscopy of infected cells reveals that plant rhabdoviruses can be distinguished depending on whether the viruses elicit inclusions in the nucleus, bud from the inner nuclear envelope, and accumulate in the perinuclear spaces, or whether they undergo morphogenesis from cytoplasmic membranes and accumulate in the cytoplasm. Thus, the cytopathology of most plant rhabdoviruses differs in several respects from that of the prototype animal rhabdovirus, vesicular stomatitis virus (VSV), which replicates in the cytoplasm and undergoes morphogenesis at the plasma membrane.

Plant rhabdoviruses infect a large number of monocot and dicot plant species (**Table 1**). In some instances, serious disease outbreaks occur on economically important crop plants, some of which result in substantial losses on a recurring basis. The most serious pathogens include maize mosaic virus (MMV), lettuce necrotic yellows virus (LNYV), rice transitory yellowing virus (RTYV) which may be identical to rice yellow stunt virus (RYSV), strawberry crinkle virus (SCV), potato yellow dwarf virus (PYDV), and barley yellow striate mosaic virus (BYSMV). A number of other rhabdoviruses also have considerable disease potential that can be affected by agronomic practices and biological variables of the insect vectors that facilitate their transmission.

Most plant rhabdoviruses are highly dependent on transmission by phytophagous insects, so their prevalence and distribution is influenced to a large extent by the ecology and host preferences of their vectors. Virus–vector interactions are highly specific, and in all cases where known vectors have been carefully examined, they have been shown to support the replication of the plant rhabdoviruses they transmit. Although some rhabdoviruses can be transmitted mechanically by abrasion of leaves, this mode of transmission does not contribute significantly to natural spread in nature due to the labile nature of the virion. Moreover, seed or pollen transmission of plant rhabdoviruses has not been described; thus, aside from vegetative propagation, direct plant to plant transmission is unlikely to be a major factor in the ecology or epidemiology of these pathogens.

Taxonomy and Classification

The International Committee on Taxonomy of Viruses used subcellular distribution patterns to assign plant rhabdoviruses into the *Cytorhabdovirus* and the *Nucleorhabdovirus* genera (**Table 1**). Individual members within these groups have also been shown to be distinct based on host range, vector transmission, serology and nucleic acid hybridization analyses. Presently, eight viruses (BYSMV, broccoli necrotic yellows virus (BNYV), festuca leaf streak virus (FLSV), LNYV, northern cereal mosaic virus (NCMV), sonchus virus (SV), SCV, and wheat American striate mosaic virus (WASMV)) are assigned to the *Cytorhabdovirus* genus. The *Nucleorhabdovirus* genus has seven members (Datura yellow vein virus (DYVV), eggplant mottled dwarf virus (EMDV), MMV, PYDV, RTYV, sonchus yellow net virus (SYNV), and sowthistle yellow vein virus (SYVV)). Of these viruses, SYNV and LNYV have been the most extensively characterized in terms of sequence analysis.

Table 1 List of plant rhabdoviruses and their host and insect specificity

Virus	*Host*	*Vector*	*Virus*	*Host*	*Vector*

Euonymus fasciation virus (EFV)	D		*Zea mays* virus (ZMV)	M	

Names in brackets are synonomous to those immediately above. Host: D = Dicot, M = Monocot. (*) indicates ability to be mechanically transmitted. Vectors: A = Aphid, L = Leafhopper, LW = Lacewing, M = Mite, P = Planthopper. Blank spaces indicate that no insect vector has been defined.

Most other plant rhabdoviruses have not been investigated in much detail beyond cursory infectivity studies, crude physicochemical analyses of virus particles, and electron microscopic observations of morphogenesis. Consequently, nearly sixty rhabdoviruses await assignment to a genus (**Table 1**). Moreover, sufficient comparative information to determine whether individual descriptions from disparate hosts are due to distant, closely related, or identical viruses is not available from many preliminary descriptions. Hence, more definitive morphological, serological and molecular studies need to

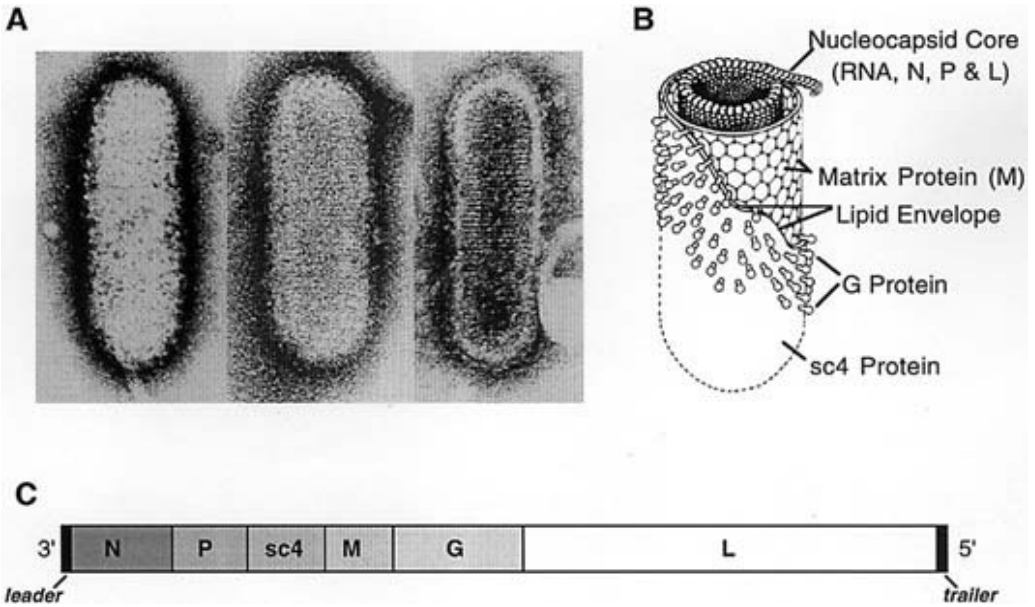

Figure 1 Plant rhabdovirus morphology and depiction of the sonchus yellow net virus genome. (**A**) Electron micrographs of negatively stained particles of SYNV. The panel on the left shows a lightly stained particle illustrating the hexagonal subunit associations at the surface of the virion. The slightly more intense negative stain in the center highlights the surface glycoprotein spikes surrounding the particle. The right panel illustrates a particle with deeper penetration revealing the internal striated nucleocapsid core. (**B**) Depiction of the architecture of the virus particle. The nucleocapsid core is composed of the minus-sense genomic RNA, the nucleocapsid protein (N), the phosphoprotein (P), and the polymerase protein (L). The matrix protein (M) is involved in the attachment of the nucleocapsid core to the envelope. The membrane lipids are host-derived and are interspersed with an orderly array of the glycoprotein (G) spikes. The location of the sc4 protein has not been precisely defined, but it is solubilized by nonionic detergent treatment of virions. (**C**) Depiction of the genome organization of SYNV. The 13 720 nucleotide minus-strand genomic RNA from 3′ to 5′ consists of the leader sequence, the N, P, sc4, M, G and L protein genes and the trailer sequence. The relative sizes of the genes are proportional to the size of the viral RNA. Adapted from Jackson and Wagner (1998).

be carried out to establish reliable criteria for the taxonomic grouping of plant rhabdoviruses, and to more readily verify their roles as causal agents of specific diseases. Additional biological data also need to be acquired with numerous poorly characterized rhabdoviruses whose host range, vector relations and distribution have received only cursory attention. Nevertheless, even though taxonomy assignments and our understanding of the relatedness of the rhabdoviruses are presently rudimentary, modern molecular and cell biological methodology provides great potential for identifying and characterizing unassigned plant rhabdoviruses, and developing additional criteria to better appreciate stages in their evolution.

Virion Morphology and Composition

Plant rhabdoviruses are normally bacilliform after careful fixation, but are bullet-shaped in unfixed preparations (**Fig. 1A**). Estimates of the sizes of virus particles range from 45 to 100 nm in width and 130 to 350 nm in length; however it is very difficult to determine accurately the sizes of the virus particles due to swelling of the fragile virions, shrinking of the nucleocapsid core, and other artifacts. Electron microscopy of particles reveals three distinct layers of varying electron density whose composition has been determined for several viruses by particle disruption, gel electrophoresis and RNA analyses. The outer layer containing 5–10 nm spike-like surface projections is composed of the G protein (**Fig. 1B**). The spikes appear to be arranged as hexamers on the surface and, by analogy with animal rhabdoviruses, G protein trimers may participate in forming the surface lattice. The middle layer consists of a host-derived membrane penetrated by the G protein. The striated inner core, with a periodicity of 4–5 nm, is composed of a helical ribonucleoprotein consisting of the genomic RNA, the nucleocapsid protein (N), the phosphoprotein (P), and the L polymerase protein (**Fig. 1 A, B**). The exact location of the matrix protein (M), has not yet been clearly determined, but it probably participates in coiling of the nucleocapsid and interacts with the G protein to stabilize the particle. A sixth protein (sc4) found in SYNV

particles has no known function, but it can be solubilized from membrane components on treatment with nonionic detergents.

The overall chemical composition (~70% protein, 2% RNA, 20–25% lipid, and a small amount of carbohydrate associated with the G protein) of the plant and animal rhabdoviruses is similar. The minus-sense RNA genomes of plant rhabdoviruses range in size from ~11 to 14 kb based on sedimentation and gel electrophoretic analyses, and are slightly larger than those of most described animal rhabdoviruses. The lipids of plant and animal rhabdoviruses have differences in fatty acid and sterol composition that are related to their respective hosts and sites of morphogenesis. Two nucleorhabdoviruses, SYNV and PYDV, have been examined in the most detail, and the results indicate that a variety of fatty acids, free and esterified sterols are present in purified virus particles. Four sterols predominating in SYNV closely approximate the sterols of the nuclear envelope, whereas those of NCMV, a cytorhabdovirus, are more typical of cytoplasmic membranes.

Figure 2 Alignment of the intergenic regions of selected plant and animal rhabdoviruses. The rhabdovirus consensus sequence is shown at the top followed by the sequences of sonchus yellow net virus (SYNV), lettuce necrotic yellows virus (LNYV), vesicular stomatitis virus (VSV) and rabies virus (RV). The intergenic sequences ('gene-junction' sequences) are separated into three elements: element I constitutes the poly(U) tract at the 3′ end of each gene on the genomic RNA; element II is a short sequence that is not transcribed during mRNA synthesis; element III constitutes the start site for transcription of each mRNA. The bold type in the viral sequences indicates the consensus nucleotides, P_y indicates pyrimidine, $(N)_x$ corresponds to a variable number of nucleotides.

Genomic Structure and Organization

The nucleotide sequence of SYNV RNA and genome mapping studies of LNYV show that both viruses encode six proteins, but otherwise, their genome organization is similar to those of VSV, which encodes five genes. The gene order for SYNV is 3′-leader-*N*-*P*-*sc4*-*M*-*G*-*L*-trailer-5′ (**Fig. 1C**), and the order for LNYV is 3′-leader-*N*-*4a*-*4b*-*M*-*G*-*L*-trailer-5′ (where 4a is thought to represent a phosphoprotein derivative and 4b an undefined extra gene). The coding regions of SYNV and LNYV are flanked by leader sequences at the 3′ end of the minus-sense genomes, and by a noncoding trailer sequence at the 5′ end of the genomes. The leader and trailer sequences of the plant rhabdoviruses have complementary regions, as is the case with other minus-strand viruses, and both sequences are considerably longer than those of animal rhabdoviruses. Another difference is that the transcribed leader RNA of SYNV is polyadenylated, which may represent an adaptation to facilitate its nuclear mode of replication.

The leader and trailer genes of SYNV have little obvious sequence relatedness to those of LNYV or other animal rhabdoviruses. In contrast, the intergenic 'gene-junction' sequences of SYNV and the animal rhabdoviruses are generally highly conserved (**Fig. 2**). These intergenic regions can be grouped into three components constituting a poly(U) tract at the 3′ end of each gene on the genomic template (element I), a short nontranscribed element which separates each gene (element II), and a conserved element located at the beginning of each subsequent gene (element III). The SYNV 'gene junctions' are very similar to the intergenic region following the N gene of the nucleorhabdovirus, RYSV. LNYV also has some similarity to other rhabdoviruses in element I, but elements II and III diverge substantially. Element 1 (AUUCUUUUU) of SYNV is also nearly identical to the analogous regions (AUUCUUUUUU) of Ebola virus, suggesting that some conservation of regulatory regions may extend to the *Filoviridae*. Sequence similarities in this region are also found in paramyxoviruses and in borna disease virus. Thus, intergenic regions of the genome that play an important role in regulating mRNA transcription and replication appear to have been stringently conserved. However, the leader and trailer genes and the genes encoding the proteins appear to have undergone extensive evolution to accommodate diverse host requirements.

Properties of the Encoded Proteins

The structural properties of plant rhabdovirus proteins deduced from nucleotide sequence analyses are presented below in the order of their appearance from the 3′ end of the genome (**Fig. 1C**). Only rudimentary biochemical analyses have been conducted on the proteins and these are mostly confined to SYNV and LNYV. Overall, the plant rhabdovirus proteins appear to have very little sequence relatedness to analogous proteins of animal rhabdoviruses, with the exception of the L protein which has conserved motifs common to those of most rhabdoviruses. A descrip-

tion of these proteins and their probable functions is outlined below.

The nucleocapsid protein (N)

The N protein functions to encapsidate the genomic and antigenomic RNAs and it is a component of the viroplasms and of the polymerase complex that can be isolated from nuclei of SYNV-infected plants. The N protein genes of the nucleorhabdoviruses, SYNV and RYSV, and the cytorhabdovirus, LNYV, have been sequenced. The deduced proteins of these viruses have no extensive sequence relatedness to animal rhabdovirus proteins, although their hydropathy patterns have some similarity. However, the SYNV and RYSV N proteins have limited regions of weak homology that are more closely related to each other than to analogous regions of the N protein of LNYV. The 475 amino acid SYNV N protein contains a nucleoplasmin-like nuclear localization signal close to the carboxy terminus that has some involvement in mediating the nuclear localization of the N protein. A related consensus element is also present in the RYSV N protein, but this element is lacking in the cytorhabdovirus, LNYV. The SYNV, LNYV and RYSV N proteins all contain regions located approximately two-thirds of the way towards the carboxy termini that appear to be weakly conserved with that of VSV.

The phosphoprotein (P)

Sequence information for the P protein and the remaining encoded genes are available only for SYNV. The P gene encodes a 362 amino acid protein with no direct amino acid sequence relatedness to the P proteins of other rhabdoviruses. However, the SYNV P protein appears to have functions similar to those of other rhabdoviruses because it is a component of the viral nucleocapsid core and the nuclear associated replicase complex. The P protein is also capable of forming complexes *in vivo* with the N and L proteins that are analogous to N:P and P:L complexes found in VSV-infected cells that may function in transcription and replicase recycling. The amino terminal half of the SYNV P protein is negatively charged, as is the case with the other rhabdoviruses, but little charge similarity or sequence resemblance is present at the carboxy terminus. The SYNV P protein is phosphorylated *in vivo* at threonine residues and hence differs from the VSV P protein, which is phosphorylated at serine residues. The SYNV P protein accumulates in the nucleus and a basic region approximately 150 amino acids from the amino terminus may have some karyophilic properties.

The sc4 protein

The sc4 protein appears to be associated with the SYNV envelope because nonionic detergent treatments can facilitate its release from virus particles. sc4 does not contain an obvious transmembrane domain or a nuclear localization signal. However, it could be associated with membranes by acylation through attachment of palmitic acid residues found in the viral envelope and thioester (cysteine) or ester (serine or threonine) linkages. Recent studies suggest that sc4 may be phosphorylated *in vivo*. Analysis of the sequence reveals that 16% of the amino acids are serine or threonine residues and that four potential consensus casein kinase II phosphorylation sites are present. The sc4 protein also contains a motif related to an aspartic protease site found in α-amylases and cellular and acid proteases. The function of sc4 has not been elucidated, but it may play a role in aphid transmission or in cell to cell movement. However, irrespective of its function, sc4 appears to be unique to plant rhabdoviruses because its predicted sequence has no similarity to sixth genes encoded by infectious hematopoietic necrosis virus, Sigma virus, Flanders virus, or bovine ephemeral fever virus.

The matrix protein (M)

The 286 amino acid M protein is basic and is thought to function in nucleocapsid coiling and interactions with the G protein, as is the case with other rhabdovirus M proteins. Multiple alignments of the M protein fail to reveal conserved consensus motifs, but short stretches of amino acids display some similarities in composition to the M proteins of other rhabdoviruses. A hydrophobic region of 67 amino acids extending almost to the middle of the protein could be involved in membrane–lipid interactions with the G protein. Recent studies suggest that the SYNV M protein is phosphorylated *in vivo* at both threonine and serine residues.

The glycoprotein (G)

The G protein forms the glycoprotein virion spike. The 632 amino acid sequence deduced for the G protein has no significant homology to G proteins of other rhabdoviruses, but it does contain putative signal sequences, a transmembrane anchor domain, and glycosylation signals. In addition, the SYNV G protein contains a putative nuclear targeting signal near the carboxy-terminus which could be involved in transit to the inner nuclear membrane prior to morphogenesis. Glycosylation inhibitors interfere with G protein *N*-glycosylation and the protein is stable in tunicamycin-treated cells. This treatment blocks SYNV morphogenesis and results in striking

arrays of condensed nucleocapsid cores that fail to bud and accumulate in the nuclei.

The polymerase protein (L)

The SYNV *L* gene encodes a 2116 amino acid protein that is present in low abundance within the nucleocapsid. The L protein is required for polymerase activity, because antibodies raised against a fragment containing the GDNQ (polymerase) motif inhibit transcription. As is the case with other rhabdoviruses, the L protein is positively charged and contains polymerase and RNA binding domains. Alignment of the L protein sequence with polymerases of several other nonsegmented negative-strand RNA viruses reveals conservation within 12 motifs that appear sequentially in the protein. A cluster dendrogram derived from the L protein alignments suggests that SYNV is more closely related to animal rhabdoviruses than to paramyxoviruses, and that animal rhabdoviruses have diverged less from each other than from SYNV.

Polymerase Activity

A viral RNA-dependent RNA polymerase is activated after treatment of LNYV and BNYV cytorhabdovirus virions with mild nonionic detergents. This activity cosediments with the 40–45S loosely coiled nucleocapsid filaments that are released from virions by detergent treatment. The transcribed products are complementary to the genome, as expected of mRNAs. Thus, the described polymerases of these plant rhabdoviruses appear to be similar to the extensively studied polymerase of the animal rhabdovirus prototype, VSV.

In contrast, no appreciable polymerase activity is evident in dissociated preparations of SYNV and other nucleorhabdovirus members. In this regard, the negligible levels of activity are similar to those obtained from rabies virus preparations. However, an active polymerase can be recovered from the nuclei of plants infected with SYNV. The polymerase activity is associated with a nucleoprotein complex consisting of the N, P, and L proteins, and it cosediments with SYNV nucleocapsid cores. The complex can be precipitated in an active form by P protein antibodies, and L protein antibody inhibition experiments show that the L protein is a functional component of the polymerase. Kinetic analysis of transcription products also reveals that the complex is capable of sequentially transcribing a polyadenylated plus-sense leader RNA, and polyadenylated mRNAs corresponding to each of the six SYNV-encoded proteins. Potential replication intermediates consisting of short incomplete minus-strand products homologous to the genomic RNA are also transcribed. These results thus support the hypothesis that polymerases of cytorhabdoviruses are present in an active form in virions and that released cores are capable of initiating primary transcription immediately upon uncoating. Nucleorhabdovirus particles differ by containing an inactive polymerase that appears to require activation by host components early in infection.

Defective Interfering RNAs

Animal rhabdoviruses passaged at high multiplicities of infection commonly accumulate defective-interfering (DI) particles. These DIs are dependent on the wild-type virus for their replication, and their presence results in a substantial decrease in the titer of the helper virus. The RNA molecules associated with DIs are typically internally deleted forms of the wild-type viral genomic RNA that retain the complementary 3′ and 5′ terminal sequences.

Formation of plant rhabdovirus DIs has been observed with PYDV and SYNV. PYDV passaged at high multiplicities of infection developed DIs after 30 successive mechanical transfers. The slowly sedimenting particles appeared not to be infectious in local lesion assays, but their protein composition was similar to those of the parental virus. In addition, the presence of the DIs decreased the amount of PYDV that could be isolated from infected plants. In the case of SYNV DIs, calyx tissues of *Nicotiana edwardsonii* examined 5 months after inoculation were shown to contain a high proportion of particles approximately three quarters as long as those of wild-type SYNV. Purified short particles were not infectious when inoculated alone, but when coinoculated with wild-type virions, short particles predominated upon reisolation. RNA isolated from these short particles was approximately 25% shorter than RNA from complete virions. The DI RNAs were able to hybridize to SYNV cDNA probes, but additional information about their structure has not been reported. From these results, the appearance of plant rhabdovirus DIs appears to be an uncommon occurrence that contrasts with the high frequency of animal rhabdovirus DIs.

Cytopathology and Replication

Unlike the animal rhabdoviruses which replicate and assemble in the cytoplasm, the plant rhabdoviruses vary profoundly in their sites of replication and morphogenesis (**Fig. 3**). The nucleorhabdoviruses, typified by SYNV, replicate in the nucleus, bud in

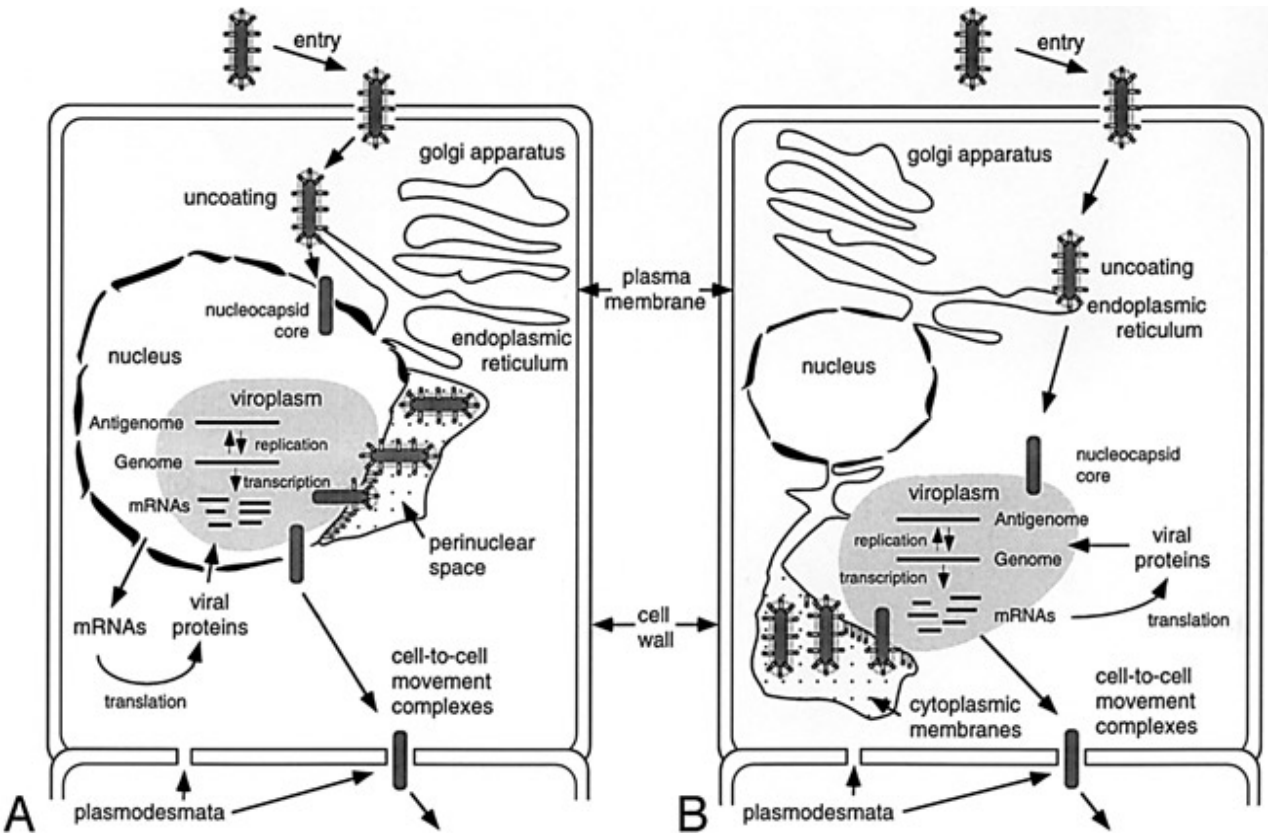

Figure 3 Model for the replication cycle of plant nucleorhabdoviruses (**A**) and cytorhabdoviruses (**B**). See text for details.

association with the inner nuclear envelope, and accumulate in enlarged perinuclear spaces formed between the inner and outer envelopes. Considerable attention has been focused on SYNV, and these studies support the model illustrated in **Fig. 3A.** The early entry and uncoating events are obscure, but based on observations with SYNV-infected protoplasts, it has been hypothesized that during entry into the cell, virus particles associate with the endoplasmic reticulum to release the nucleocapsid cores into the cytoplasm. It is thought that the cores utilize the host nucleocytoplasmic transport machinery to facilitate movement and entry into the nucleus via the nuclear pore complex. During the early stages of infection the virion-associated polymerase probably is activated by host components to produce an active transcriptase that participates in primary transcription. The transcribed mRNAs are transported to the cytoplasm and translated. The newly translated N, P and L polymerase core proteins are transported to the nucleus where they participate in multiple rounds of replication of antigenomic and genomic RNAs and secondary rounds of mRNA transcription. As replication proceeds, the nuclei increase dramatically in volume, and granular electron-dense viroplasms form discrete foci that appear near the periphery of the nuclei. Several recent lines of evidence show that SYNV viroplasms contain the N, P and L proteins, suggesting that the viroplasms are the source of the polymerase activity that can be recovered from nuclei. During the late stages of replication, the matrix protein is thought to participate in coiling of nucleocapsid cores containing the minus-sense RNA genome. These cores then associate with G protein concentrated at sites on the inner nuclear envelope that are in close proximity to the viroplasms. Virus budding apparently requires G protein glycosylation because tunicamycin interrupts budding and causes the appearance of large numbers of the nucleocapsid cores around the periphery of the nucleus. During normal budding, numerous enveloped particles accumulate in perinuclear spaces between the inner and outer nuclear envelope, but in some instances, a few virus particles are present in cytoplasmic vesicles. Since the outer nuclear envelope is continuous with the endoplasmic reticulum and is part of the endomembrane system, this observation is not surprising. However, it does indicate that assignments to the nucleorhabdovirus group need to be based on several different types of ultrastructural evidence. Such evidence should include use of virus specific probes for *in situ* hybridization, immunochemical

localization of nucleocapsid proteins, and high resolution immunoelectron microscopy to probe virus morphogenesis at different stages of infection.

The cytorhabdoviruses appear to replicate in the cytoplasm, bud in association with the endoplasmic reticulum, and accumulate in endoplasmic reticulum-derived vesicles (**Fig. 3B**). Two variations have been proposed based on extensive electron microscopic observations of LNYV and BYSMV cells. During the early stages of LNYV infection, indirect evidence suggests that LNYV may undergo a nuclear phase because the outer nuclear membrane blisters and develops small vesicles that contain some virus particles. However, later in the life cycle masses of thread-like viroplasms appear in the cytoplasm and these are in close proximity to dense networks of the endoplasmic reticulum. These membranes serve as sites for morphogenesis of the majority of virus particles which bud into vesicles that appear to be derived from the proliferated host membranes. A slightly different scenario lacking a nuclear phase has been outlined for BYSMV. In this case, membrane-bound viroplasms appear in the cytoplasm and virus particles are found exclusively in association with cytoplasmic membranes that proliferate in close proximity to the viroplasms. Unfortunately, both of the cytorhabdovirus models have been derived solely from ultrastructural observations, and none of these studies have utilized specific antibodies to individual virus proteins or viral-specific probes for *in situ* hybridization. Clearly more direct cell biological studies must be conducted with such reagents before detailed models of the replication cycles of these viruses can be proposed.

Vector Relationships, Distribution and Evolution

Many members of the rhabdoviruses are transmitted by insects and other arthropods in which they also multiply, so it is possible that members of the rhabdovirus family radiated from a primitive arthropod. This mode of transmission more than any other property, may have been responsible for the widespread occurrence of the rhabdoviruses within the plant and animal kingdoms. Although some plant rhabdoviruses have no known vector, most are transmitted by aphids (*Aphidae*), leafhoppers (*Jassidae*), or planthoppers (*Delphicidae*). Two poorly characterized putative rhabdoviruses, beet leaf curl virus and coffee ringspot virus, have lacebug and mite vectors, respectively, but these viruses need to be examined more rigorously before they can be unambiguously accepted as members of the *Rhabdoviridae*.

Several general patterns indicate that host–vector relationships have profoundly affected plant rhabdovirus distribution. For example, leafhoppers, planthoppers and aphids are prevalent on both monocots and dicots, but rhabdoviruses causing diseases of the *Gramineae* are all transmitted by leafhoppers or planthoppers. Except for PYDV and CBDV, which have leafhopper and planthopper vectors, respectively, the rhabdoviruses infecting dicots are commonly transmitted by aphids. The available evidence indicates that rhabdovirus–vector interactions are highly specific and that generally, a single rhabdovirus is transmitted by closely related species of the same genus. In all cases of insect transmission that have been carefully examined, the rhabdovirus is persistently transmitted in a propagative fashion. Comprehensive transmission trials conducted with PYDV in leafhoppers and SYVV in aphids, as well as less extensive studies with several other leafhopper and aphid transmitted rhabdoviruses, are all consistent with replication in the vector. Indirect evidence for replication is that long latent periods are required before transmission occurs, that virus is often retained throughout the life of the insect, and that transovarial passage can be observed through eggs and nymphs. More persuasive results have been obtained by continued transmission after repeated serial dilution passages from insect to insect. Strain specific infection of tissue culture lines and explants and serological detection of virus in vectors provides additional proof that rhabdoviruses replicate with high specificity in leafhopper and aphid vector cells.

Genetic experiments with PYDV have shown that highly efficient and inefficient leafhopper vectors can be selected. Continuous passage of PYDV by serial injection of insects can also result in isolates that are unable to infect plants. Additional studies have shown that strains that have lost their capacity to be insect transmitted can be recovered after protracted passage in plants. This phenomenon could provide a mechanism for evolution of vectorless rhabdoviruses particularly in cases where infections were established in vegetatively propagated hosts. Rhabdoviruses normally have the capacity to infect a greater range of hosts than the narrow range of species colonized by their vectors, because experimental host ranges usually can be extended considerably by mechanical transmission. One appropriate example is transmission of SCV, which is restricted in nature to cultivated and native strawberry due to feeding preferences of its aphid vector. SCV is very difficult to transmit mechanically from strawberry (**Table 1**). However, alternate solanaceous hosts can be infected by surrogate nonvector aphids injected with extracts

from the strawberry aphid, and the virus can then be mechanically transmitted from these plants. In addition, cowpea protoplast infectivity experiments with the grass rhabdovirus FLSV and with SYNV show that both viruses are able to infect legume protoplasts, but they are unable to infect cowpea plants. These results indicate that plant rhabdoviruses have the ability to infect cells of hosts that are quite distantly related to their native hosts, but that vector feeding and requirements for systemic movement constrain their host specificity.

Plant rhabdoviruses are faced with two major evolutionary challenges of a fundamentally different nature brought about by the necessity to alternately infect plants and insects. In each host, the virus must utilize different entry methods and accommodate distinct cellular and defense mechanisms. Establishment of effective vector relations requires nonpathogenic infections of the insect without substantial interference with longevity, fecundity or normal feeding activities necessary for efficient virus dispersal. Rhabdovirus acquisition by the vector probably necessitates attachment to specific receptors at the surface of cells in the digestive system and active invasion of the reproductive organs, fat bodies and salivary glands. It is highly likely that vector specificity is regulated at the entry stages of infection via receptors on the surface of the host alimentary system. This hypothesis is supported by experiments showing that aphid vector specificity can be extended if the gut barrier is avoided by direct injection of virus. Very different barriers must be circumvented to establish systemic infections of plants. In order to establish a primary infection focus, the cell wall must first be breached by mouthparts of the insect, the virus must be regurgitated into the cell, uncoated and replicated. Then, to establish systemic invasions, the virus must move from cell to cell through very small plasmodesmatal connections, into the phloem cells of the vascular system and throughout the plant. Because the plasmodesmata normally restrict movement of macromolecules, viruses generally move to adjacent cells via mechanisms that increase the permeability of the plasmodesmatal openings. Many plus-strand RNA viruses encode specific nucleic acid binding proteins that function to enlarge plasmodesmata, bind viral RNA and shuttle the genome through the plasmodesmata to neighboring cells. Plant rhabdoviruses face a special challenge at this stage of infection because the approximately 3 nm plasmodesmata are at least an order of magnitude smaller in diameter than virus particles. Therefore, transit of intact viruses would require enormous plasmodesmatal alterations that ought to be easily visible by electron microscopy. Moreover, since the naked genomic RNA of minus-strand viruses is not infectious, the polymerase proteins must accompany the infectious derivative. These constraints probably mandate that rhabdovirus-encoded gene products facilitate enlargement of the plasmodesmata, and that nucleocapsid cores function in cell to cell and vascular movement. These movement activities may well require functions of the sixth genes that have been identified by mapping of SYNV and LNYV.

Epidemiology and Disease Control

Plant rhabdoviruses have been identified in most major crops throughout the world. Although the factors affecting their dispersal have not been investigated extensively, several studies suggest that transmission depends on a delicate balance of interactions involving vector–host plant associations. These include the specificity of the virus–vector relationship, the dependence on insect vectors for local and long distance spread, and possible pathological effects of rhabdovirus infections on the insects. The ecology of host plant and insect vector interactions also has a major role in distribution and spread of plant rhabdoviruses. Therefore, a number of interacting factors, including changes in vector species and weed host populations could affect rhabdovirus ecology and disease cycles. In Berkeley, California, an interesting example resulting in a marked decline of SYVV in natural sowthistle populations has been attributed to the displacement of the aphid vector (*Hyperomyzus lactucae*) with an aggressive invader aphid (*Uroleucon sonchi*) that is not a vector for SYVV. Other obvious components affecting the biology of plant rhabdoviruses and their capacity to cause disease are virus reservoirs in weed hosts or volunteer crop plants that bridge the season between crops, and vectors that survive from one crop generation to the next. An additional element that often is not considered is that synergistic or antagonistic interactions with other viruses may affect viral ecology. One possibility of such interactions comes from a correlation of the presence of bidens mottle virus (BMoV), a potyvirus, in all beggarticks (*Bidens* sp.) harboring SYNV. Potyviruses often act synergistically with a number of viruses, including SYNV; thus it is likely that BMoV may serve to facilitate high levels of SYNV that aid in aphid acquisition.

Several additional interactions also contribute to disease outbreaks. These include populations of viruliferous aphids early in the growing season that can establish infection foci when crops are most susceptible to invasion. After initial infections have been established, rapid distribution of the virus probably is most dependent on a sufficient density

of host plants capable of supporting the vector and transmission of virus to juvenile insects. Concurrently, environmental conditions conducive to short incubation periods after acquisition feeding by vectors, and optimal for rapid disease development in plants after virus transmission will facilitate efficient dissemination of the virus. Consequently, seemingly minor changes in climate, agronomic practices, crop varieties or vector populations may alter virus spread and disease development profoundly, and manipulation of these factors can lead to reductions in yield losses.

For these reasons, rhabdovirus disease control has emphasized a broad range of different strategies. Agronomic or cultural controls applied with some success include elimination of natural weed reservoirs, spraying to reduce vector populations, and production of virus-free vegetative stocks. However, the efficacy of these measures relies on the particular host/virus/vector relationships, and no common method suitable for rhabdovirus disease control has yet been described. In particular, the reported successes indicate that development of effective control measures requires a detailed knowledge of the ecology of the particular virus under consideration, the biology of the host plant and the natural vector reservoirs.

Major factors that can affect rhabdovirus disease incidence are external agents that alter the ecology of host/vector interactions. An interesting anecdotal description of such a situation relates to the epidemiology of LNYV outbreaks in lettuce that occurred in Australia in the early 1960s. These epidemics have been speculated to coincide with the introduction of myxomatosis in Australia to control rabbit populations. The reduced rabbit populations permitted increases in sowthistle plants that constitute a natural reservoir for LNYV and its aphid vector, *Hyperomyzus lactucae*. This combination resulted in disease epidemics due to invasion of newly planted lettuce by large numbers of viruliferous aphids that had increased on viruliferous sowthistle. Fortunately, elimination of weeds for a short distance around fields reduced the entry of vectors into the lettuce crops and provided acceptable disease control. Elimination of rhabdoviruses from vegetatively propagated crops also has considerable potential for disease control. Certification strategies to produce disease-free stock by selection of strawberry propagules free of SCV are proving to be beneficial in California. In other cases, production of virus-free stock, combined with insecticide applications, can provide disease control. Infections of PYDV, which caused serious yield losses before the 1940s in the northeastern United States, appear to have been reduced to a very low frequency as a serendipitous consequence of combinations of insecticides and elimination of the virus from seed potatoes.

Incorporation of disease resistance into crop plants normally provides more effective, durable and economical control than any other measure. Two notable examples of the employment of this strategy exist in rhabdoviruses. The first relates to MMV in Hawaii, where up to 100% losses have been observed in maize lacking disease resistance genes. Useful control is obtained by incorporation of a single gene for tolerance into cultivars, which ameliorates the disease. Another example exists for infections with raspberry veinal chlorosis virus, an unassigned plant rhabdovirus. Raspberries possessing this form of resistance appear to be immune because resistant scions can not be infected by graft inoculation.

The major problem with application of disease resistance is identification of useful genes. Traditionally, such genes have been isolated by screening wild species found near centers of origin of crop plants. However, two major advances in biotechnology provide optimism that resistance can be more widely applied for disease control. Disease resistance genes with specificity to viruses, bacteria and fungi have been cloned from several crops, and some of these genes retain their function when transferred to distantly related species. The evidence also suggests that the recognition motifs of these genes can be engineered to produce novel sources of resistance. A second approach involves engineering synthetic sources of pathogen-mediated resistance by producing transgenic plants expressing portions of the viral genome. Although both strategies have enormous potential for disease control, neither has yet been applied to plant rhabdoviruses. Thus, these approaches represent an important challenge for the future.

Ungrouped Mammalian, Bird and Fish Rhabdoviruses

Bishnu P De and **Amiya K Banerjee**, Department of Molecular Biology, The Lerner Research Institute, The Cleveland Clinic Foundation, Cleveland, USA

Introduction

The family *Rhabdoviridae* comprises a diverse collection of viruses linked by a common bullet-shaped or bacilliform morphology. They are among the most widely distributed viruses in nature, infecting vertebrates, invertebrates and many plants. A large number are included so far in five genera: *Vesiculovirus, Lyssavirus, Ephemerovirus, Cytorhabdovirus* and *Nucleorhabdovirus*. Many others are virtually uncharacterized and, because of the lack of any serological relatedness to other viruses, they remain ungrouped. This entry deals with those ungrouped rhabdoviruses, including Gossas virus, Klamath virus, Navarro virus, and fish rhabdoviruses. Except for the fish rhabdoviruses, very little is known about these ungrouped viruses. The mammalian and bird rhabdoviruses are grown in most common laboratory cell lines, e.g. BHK-21, Vero, etc., while fish rhabdoviruses are grown in some special cell types such as epithelioma papulosum cyprini (EPC) cells. In common with other rhabdoviruses, mammalian and bird rhabdoviruses readily infect newborn or weanling mice when injected intracerebrally. No human disease is known for any of these viruses.

Gossas Virus

The Gossas virus was originally isolated in 1984 by Bres from the salivary glands of an adult bat (*Tadarida* sp.) caught in Dakar, Senegal. Neither the pathology of infection nor the neutralizing antibody was detected in the bat at that time. However, in laboratory infections antibody can be detected in mice as well as rabbits. The virus did not crossreact antigenically with many other viruses, including Sindbis, Semliki Forest, West Nile or blue tongue virus. Like vesicular stomatitis virus (VSV), the virus grows in BHK-21 and also in Vero cells. Oita rhabdovirus, another ungrouped virus, was isolated from bat by Oya in Japan. No other information is available on this virus.

Klamath Virus

Klamath virus was originally isolated in 1965 by Johnson from a 3-month-old (immature) meadow vole (*Microtus montanus*) collected at Klamath Falls, Oregon. The virus was subsequently detected in Alaska at Dot Lake (red-backed mice, *Clathrionomys rutilus*) and at the University of Alaska (meadow vole, *Microtuseconomus*). The virus is bullet-shaped (167 × 80 nm) in morphology, typical of a rhabdovirus. When inoculated intracerebrally into newborn mice, infectious virus was detected in the lung and brain. The virus grows in chicken embryonated eggs as well as laboratory cell lines. In infected cells, cytoplasm contains the nucleocapsids and matured virions found around the cisternae of endoplasmic reticulum. Antigenic crossreactivity tests using 154 different viruses indicate that Klamath virus is antigenically distinct.

Navarro Virus

The Navarro virus was isolated in 1984 by the Cali Virus Laboratory (Cali, Colombia) from the spleen of an adult wild turkey vulture (*Cathartes aura*) shot in Navarro, Colombia. The known properties of the virus are very similar to the Klamath virus.

Fish Rhabdoviruses

The rhabdoviruses that infect fish are particularly interesting because their hosts live in a wide variety of habitats and include such diverse fish as salmon, trout, cod, carp, pike, perch, etc. These viruses were initially designated as members of either the *Lyssavirus* or *Vesiculovirus* genera on the basis of electrophoretic migration of their proteins. Recently, it has been recognized that these classifications require modification, and the fish rhabdoviruses are now classified as 'unassigned' (formerly known as *Lyssavirus*) and 'vesiculo-like' (formerly known as *Vesiculovirus*) in accordance with the sixth report (1995) of the International Committee on Taxonomy of Viruses (ICTV). The members of the 'unassigned'

Introduction

The family *Rhabdoviridae* comprises a diverse collection of viruses linked by a common bullet-shaped or bacilliform morphology. They are among the most widely distributed viruses in nature, infecting vertebrates, invertebrates and many plants. A large number are included so far in five genera: *Vesiculovirus, Lyssavirus, Ephemerovirus, Cytorhabdovirus* and *Nucleorhabdovirus*. Many others are virtually uncharacterized and, because of the lack of any serological relatedness to other viruses, they remain ungrouped. This entry deals with those ungrouped rhabdoviruses, including Gossas virus, Klamath virus, Navarro virus, and fish rhabdoviruses. Except for the fish rhabdoviruses, very little is known about these ungrouped viruses. The mammalian and bird rhabdoviruses are grown in most common laboratory cell lines, e.g. BHK-21, Vero, etc., while fish rhabdoviruses are grown in some special cell types such as epithelioma papulosum cyprini (EPC) cells. In common with other rhabdoviruses, mammalian and bird rhabdoviruses readily infect newborn or weanling mice when injected intracerebrally. No human disease is known for any of these viruses.

Gossas Virus

The Gossas virus was originally isolated in 1984 by Bres from the salivary glands of an adult bat (*Tadarida* sp.) caught in Dakar, Senegal. Neither the pathology of infection nor the neutralizing antibody was detected in the bat at that time. However, in laboratory infections antibody can be detected in mice as well as rabbits. The virus did not crossreact antigenically with many other viruses, including Sindbis, Semliki Forest, West Nile or blue tongue virus. Like vesicular stomatitis virus (VSV), the virus grows in BHK-21 and also in Vero cells. Oita rhabdovirus, another ungrouped virus, was isolated from bat by Oya in Japan. No other information is available on this virus.

Klamath Virus

Klamath virus was originally isolated in 1965 by Johnson from a 3-month-old (immature) meadow vole (*Microtus montanus*) collected at Klamath Falls, Oregon. The virus was subsequently detected in Alaska at Dot Lake (red-backed mice, *Clathrionomys rutilus*) and at the University of Alaska (meadow vole, *Microtuseconomus*). The virus is bullet-shaped (167 × 80 nm) in morphology, typical of a rhabdovirus. When inoculated intracerebrally into newborn mice, infectious virus was detected in the lung and brain. The virus grows in chicken embryonated eggs as well as laboratory cell lines. In infected cells, cytoplasm contains the nucleocapsids and matured virions found around the cisternae of endoplasmic reticulum. Antigenic crossreactivity tests using 154 different viruses indicate that Klamath virus is antigenically distinct.

Navarro Virus

The Navarro virus was isolated in 1984 by the Cali Virus Laboratory (Cali, Colombia) from the spleen of an adult wild turkey vulture (*Cathartes aura*) shot in Navarro, Colombia. The known properties of the virus are very similar to the Klamath virus.

Fish Rhabdoviruses

The rhabdoviruses that infect fish are particularly interesting because their hosts live in a wide variety of habitats and include such diverse fish as salmon, trout, cod, carp, pike, perch, etc. These viruses were initially designated as members of either the *Lyssavirus* or *Vesiculovirus* genera on the basis of electrophoretic migration of their proteins. Recently, it has been recognized that these classifications require modification, and the fish rhabdoviruses are now classified as 'unassigned' (formerly known as *Lyssavirus*) and 'vesiculo-like' (formerly known as *Vesiculovirus*) in accordance with the sixth report (1995) of the International Committee on Taxonomy of Viruses (ICTV). The members of the 'unassigned'

subgroup include infectious hematopoietic necrosis virus (IHNV), viral hemorrhagic septicemia virus (VHSV) and hirame rhabdovirus (HIRRV). The members in the 'vesiculo-like' subgroup include spring viremia of carp virus (SVCV) and pike fry virus (PFV). These viruses may also be classified into two divisions reflecting their host: salmonoid and nonsalmonoid. The IHNV and VHSV are examples of salmonoid fish rhabdovirus, whereas SVCV and PFV belong to the nonsalmonoid group. Because of rapid progression of infection and high mortality, these viruses represent a major threat to aquaculture. Unlike other rhabdoviruses, the fish rhabdoviruses infect and cause disease at characteristically low temperatures (12–15°C), probably due to adaptation to colder aquatic habitats. In the laboratory, these viruses grow in standard cell lines such as BHK-21 and WI-38 and also some poikilothermic cell lines such as FHM, RTG-2 and STE-137. In all cases, the optimum temperature for growth and virus stability is 15–18°C. Like other rhabdoviruses, ultrastructurally they display a bullet-shaped morphology with glycoprotein spikes projecting from the viral envelope. Like VSV, the SVCV and PFV virions have been shown to contain protein kinase activity. Specific characteristics of individual fish rhabdoviruses are described below.

Infectious Hematopoietic Necrosis Virus

The IHNV is enzootic in the sockeye salmon population on the west coast of North America. In recent years, another major host for IHNV was found to be rainbow trout. The infectious hematopoietic necrosis disease was introduced into Japan in 1977 and it appeared in Europe in 1987. The IHNV-infected disease now represents a major threat to aquaculture all over Europe. The virus infection and the disease appear to be cold-dependent, with the characteristic of epizootics at 13°C which disappears at a higher temperature (above 15°C). Two other viruses, namely Oregon sockeye salmon disease virus (OSDV) and Sacramento River Chinook disease virus (SRCDV), are antigenically similar to IHNV and produce diseases with nearly identical symptoms.

Clinical features and pathology

An epizootic of IHNV usually begins with a sudden rise in mortality. Clinical signs are the appearance of dark color, loss of appetite, anemia, exophthalmia, distension of the abdomen with ascites, general viremia and fecal casts. Petechial hemorrhages occur near the base of the fins and on the mesenteries surrounding the viscera. Necrosis of the hematopoietic tissues in the anterior kidney and spleen can be detected by histological examination. With increasing severity of the disease, necrosis is also detected in liver, pancreas, and granular cells in the wall of the alimentary tract.

Fish infected with SRCDV and OSDV do not feed and have symptoms similar to those produced by IHNV. Extensive subcutaneous hemorrhaging occurs, accompanied by the appearance of red blotches on the skin and the gills turning pale. Like IHNV, infection with these viruses also causes necrotic lesions in kidney, pancreas, spleen and adrenal cortex. Virus particles are detected in the interstitial spaces of the infected organs and in some cases in the cytoplasmic vacuoles.

Transmission

The IHNV is transmitted through water, either by feeding on infected carcasses or by exposure to eggs from infected fish. Gills and gastrointestinal tracts are the most probable route of entry of the virus. Transmission also occurs from adult carriers to fry. The virus is readily detected in ovarian or seminal fluid of the infected fish. In the laboratory, defective interfering (DI)-like particles are produced when the cells are infected at higher multiplicity of infection (m.o.i).

Molecular aspects

The morphology and genome size (11 kb) of IHNV is identical to VSV. However, several differences are observed among IHNV and other rhabdoviruses. IHNV specifies six mRNAs rather than five mRNAs as is found in VSV. The five mRNAs encode the viral structural proteins RNA polymerase (L, 225 kDa), envelope glycoprotein (G, 59 kDa), nucleocapsid protein (N, 42 kDa) and two matrix proteins (M1, 26 kDa and M2, 22 kDa. Like P protein of VSV, the M1 protein is phosphorylated and believed to function in transcription, similar to other rhabdoviruses. The sixth mRNA encodes a unique nonstructural protein (NV) that is expressed in infected cells but is not present in purified virions. Recently, the complete nucleotide sequence of the genome of IHNV has been determined. This represents the first complete nucleotide sequence of a fish rhabdovirus genome. The genome organization is 3′-N-M1-M2-G-NV-L-5′. The intergenic region contains the conserved sequence 5′-AGAYAG/C-3′ (antigenomic polarity) which is followed by a stretch of seven adenosine residues. This sequence is present at the end of every sizeable open reading frame found in the IHNV genome and is similar to that found in the intergenic region of VSV.

Viral Hemorrhagic Septicemia Virus

History

VHSV was initially isolated from the rainbow trout (*Oncorhynchus mykis*) in the Egtved region of Jutland (Denmark) in 1950. It represents a major threat to the fish farming industry in continental Europe, causing devastating viral disease in fish. Brown trout (*Salmo trutta*) and brook trout (*Salvelinus fontinalis*) were found to be immune to the disease; however, they could be infected experimentally. Recently, both the geographical distribution and host range of the virus were shown to be wider, as VHSV was isolated in routine control of other species of fish in the USA. The antigenic crossreactivity and the electrophoretic pattern of the viral structural proteins indicate that these viruses are similar to those originating in Europe. The North American isolates, however, were not associated with any specific clinical condition, and no experimental overt infection could be obtained with these strains.

Clinical features and pathology

Infected trout appear black, especially on the head and abdomen, and show exophthalmia of the eyes (sometimes with protruding eyeballs giving a popeye effect due to the hemorrhages in the connective tissues of the eye pit), distended abdomen and severe anemia. The gills appear pale pink or greyish white. Acute hemorrhages are seen at the base of the pectoral fins. At the lateral line they are less frequent or may be entirely absent. In some cases the fish also show neurological and motor disorders, such as spiral swimming at the bottom of the pond, tilted swimming and darting through and out of water. Death occurs within several days.

The most prominent pathological changes are the scattered hemorrhages in skeletal muscles, mouth cavities and sex organs. Histology of the liver and kidney shows necrotic foci with hepatocytes including cytoplasmic vacuoles, karyolysis and pyknosis. Lymphoid and spleen tissues show accumulation of mononucleated and immune erythrocytes.

Immunology and interferon production

Neutralization studies of 76 natural isolates of VHSV from Danish, Norwegian and Swedish rainbow trout showed that 72 of them were essentially identical to the F1 strain, suggesting that the four others may represent different serotypes. However, in cell cultures all were recognized by fluorescein isothiocyanate-conjugated anti-F1 antibody. Diagnosis of the disease is made by immunofluorescent staining of tissue or by direct isolation of the virus from tissue homogenates.

Experimental infection of rainbow trouts with VHSV has been shown to produce interferon that reaches a maximal level (about 2800 units ml^{-1}) at 3 days postinfection. Physicochemical properties of fish interferon have been determined as the molecular mass of about 26 kDa, sedimentation coefficient of 2.5 S and isoelectric point of 4.5–6.2. It has been suggested that the production of interferon may play a role in the antiviral response of the fish at temperatures above 15°C.

Molecular aspects

The VHSV genome, like IHNV, encodes five structural proteins: the nucleocapsid protein N (41 kDa), the polymerase-associated protein M1 (28 kDa) similar to the P protein of VSV, the matrix protein M2 (24 kDa) similar to the M protein in VSV, the glycoprotein G (74 kDa), the polymerase protein L (~150 kDa) and a nonstructural protein NV (14 kDa). By direct sequencing VHSV genome organization was confirmed to be 3′-N-M1(P)-M2(M)-G-NV-L-5′. The NV protein has no significant sequence similarity to the NV protein of IHNV or any other known protein. The predicted sequence of the M1 and M2 proteins are rich in Ser and Thr residues and both are phosphorylated. The RNA polymerase activity of all fish rhabdoviruses, including VHSV, have a lower optimum temperature (15–20°C), as opposed to 30–32°C in VSV. Also, unlike other rhabdoviruses, the RNA polymerase activity of VHSV is stimulated by Mn^{2+} rather than Mg^{2+}.

Spring Viremia of Carp Virus

SVCV belongs to the vesiculo-like genus of the family *Rhabdoviridae*. The infectious dropsy of carp (*Cyprinus carpio*) was originally reported in Europe as early as 1930, but the origin of the disease remained unknown until 1950. Now it is clearly established that SVCV is the causative agent of hemorrhagic swimbladder inflamation and infectious dropsy in common carp. Clinical signs of the virus infection are external and internal hemorrhages, peritonitis and ascites. The symptoms of the disease, however, vary depending on the form of the disease: acute, chronic, asymptomatic or latent. In an overt disease, the central nervous system and peripheral nerves are affected. The fish becomes hyperactive, with the appearance of ulcerative dermal vesicles (carp erythrodermatitis). The kidneys and spleen become enlarged and contain the highest titer of the virus. Peak viremia appears on the 6th day postinfection and again on the 9th and 10 days. Excretion of the virus in

feces and mucus occurs on the 11th day, and finally the fish dies around the 20th day. Since the first isolation of the virus several other fish hosts have been reported, suggesting that SVCV has a wider host range than the carp family. The virus causes significant mortality in both juvenile and adult fish, and therefore it has a large economic impact on the fish farming industry in Europe. In experimental infections, fingerling carp, pike fry and the larvae and carp fry are also susceptible.

Pike Fry (Rhabdo) Virus

The PFV belongs to the vesiculo-like genus of the *Rhabdoviridae* family. It is involved in two diseases of fry of the northern pike (*Esox lucius* L.): a 'head disease' identified by swelling or lumps on the body, or a 'red disease' identified by swelling and reddish color of large areas of the body. These diseases were first seen in the Nieuw-Vennep hatchery in The Netherlands around 1959. Both diseases have a high mortality rate. The hydrocephalus associated with the 'head disease' makes the fish lose equilibrium and swim erratically near the surface of the water. Clinical symptoms are poor growth, hemorrhages in the brain, spinal cord, spleen and pancreas, and degenerative necrotic changes in kidney tubules. The 'red disease' is characterized by pale gills, hemorrhages in trunk and muscle connective tissue, and red swollen areas above the pelvic fins. The virus is detected in the hematopoietic tissues of the kidney. At the molecular level, the PFV is similar to VSV, encoding the structural proteins, N, P, M, G and L.

Hirame Rhabdovirus

The HIRRV is a member of the 'unassigned' genus of the *Rhabdoviridae* family. It was first isolated from Japanese flounder (*Paralichthys olivaceus*) and from ayu fish (*Plecoglossus altivelis*), both of which are valuable cultured fish species in Japan. The clinical signs of HIRRV infection are similar to those caused by SVCV. Crossreactions in serological studies have suggested that HIRRV is related to the well-characterized North American fish pathogen IHNV. The genes of the two matrix proteins (M1 and M2) and the glycoprotein (G) of HIRRV have been sequenced. Sequences of all of the internal gene junctions have also been determined. The matrix protein genes have been shown to share a high amino acid similarity (81.5% for M1 and 86.0% for M2) with the respective genes of IHNV. The G protein shared the highest sequence identity (74.3%) and similarity (83.3%) with the G protein of IHNV.

RHINOVIRUSES (*PICORNAVIRIDAE*)

Glyn Stanway, Department of Biological Sciences, University of Essex, Colchester, Essex, UK

History

Rhinoviruses are the major cause of the familiar, mild, upper respiratory tract infection known as the common cold and are among the most frequent human pathogens. References to colds are found from earliest times and both Hippocrates and Pliny the Younger discussed possible therapies. Although long suspected, their infectious nature was formally demonstrated in the early 1900s by Kruse, Foster and Dochez, who transmitted colds from donors to recipients using filtered nasal secretions. It was not until the advent of organ and tissue culture that rhinoviruses were first isolated, initially in the laboratories of Pelon and Price. When culture conditions were modified, notably by using temperature and pH similar to those found in the nose, the number of identified rhinovirus serotypes grew rapidly.

Taxonomy and Classification

Viruses designated rhinoviruses have been isolated from humans and cattle. Human rhinoviruses (HRVs) comprise by far the largest group, with over 100 serotypes (HRV-1A, HRV-1B and HRV-2 to HRV-100) and will be the exclusive focus for this discussion. There are three bovine rhinoviruses. All are members of *Picornaviridae* and are classified in the rhinovirus genus. Two viruses isolated from horses, currently named equine rhinoviruses 1 and 2, are also picornaviruses, but sequence analysis shows them to be more similar to members of the aphthovirus genera.

Serotypes are defined in terms of neutralization by antisera and absence of crossreactivity. Several attempts have been made to further divide the large number of HRVs, the most useful being on the basis of receptor tropism. Around 90% of rhinoviruses (the major receptor group) use the membrane protein, intercellular adhesion molecule 1 (ICAM-1) as their cell receptor, whereas most of the rest (the minor group) use members of the low density lipoprotein (LDL) receptor family. A single serotype (HRV-87) apparently recognizes a sialoprotein. Analysis using antivirus agents shows that rhinoviruses can be divided into two classes, but these do not correspond directly to the receptor groups (**Table 1**).

Properties of the Rhinovirus Virion

Electron microscopy reveals the typical picornavirus appearance of spherical, largely featureless particles approximately 30 nm in diameter. The particles are nonenveloped, of icosahedral symmetry and made up of genomic RNA, surrounded by 60 copies each of four capsid proteins, VP1–4. An intermediate in capsid assembly is the protomer, composed of one copy of VP1, VP3 and VP0, a precursor in which VP4 and VP2 are covalently linked. Five protomers, arranged symmetrically about a fivefold axis, give another important intermediate, the pentamer, which will form one of the 12 corners of the icosahedron. Twelve pentamers come together to form the protein coat. Cleavage of VP0 is the final step of assembly and may be related to encapsidation of the nucleic acid and stabilization of the mature particle. One or two

[a]The major rhinovirus receptor group are the serotypes which recognize ICAM-1, the minor group recognize the LDL receptor, and HRV-87 binds to a sialoprotein.

[b]Depending on their response to a panel of antivirus agents which bind to a hydrophobic pocket beneath the canyon, rhinoviruses can be divided into two groups, A (serotypes shown in bold type) and B. Structural and sequencing studies suggest that this reflects a fundamental difference between these viruses.

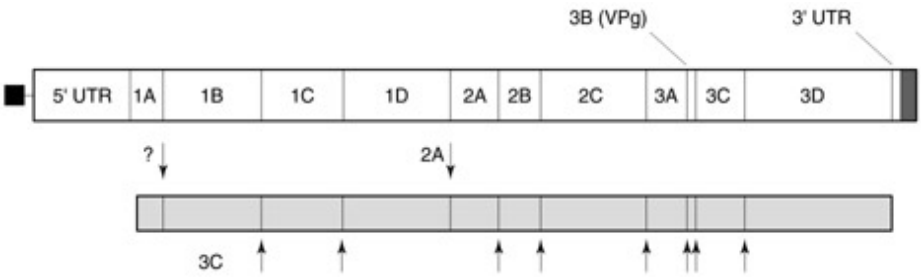

Figure 1 The rhinovirus genome (top) and the polyprotein which it encodes. The single-stranded, positive sense genome has a small protein, VPg, attached to the 5′ terminus (shown as a black box) and is polyadenylated at its 3′ terminus (hatching). Genes are named 1A–3D according to their genomic location. The polyprotein is cleaved by proteases encoded by the 2A and 3C genes and by an unknown activity, at the positions shown by arrows, giving the individual proteins.

copies of VP0 remain uncleaved, but the significance of this is not known.

Our understanding of rhinoviruses has been greatly advanced by work done in the laboratory of Rossmann, where the three-dimensional structures of a number of rhinoviruses have been solved to high resolution. These studies have shown that VP1, VP2 and VP3 are structurally similar, each being composed of an eight-stranded β barrel, and differing mainly in the loops and elaborations which join or project from the β strands making up this core structure. This basic structure for the capsid proteins is seen in all picornaviruses, as is their relative position in the virus particle. At the surface, the area surrounding the fivefold axis of the pentamer is composed primarily of VP1, while VP2 and VP3 are arranged side by side at a greater distance from this axis. VP4 has an extended configuration and is located internally, underneath the other proteins. The pentamer is stabilized by interactions involving the N and C termini of VP1 and VP3, while adjacent pentamers are held together largely by hydrogen bonds between parts of VP2 and VP3. The loops between the β strands of VP1–VP3 are the location of the regions of antigenic importance and they form much of the surface of the virus. The amino acid sequences of these regions are highly variable between serotypes and this is presumably the origin of the many rhinovirus serotypes.

Properties of the Rhinovirus Genome

Rhinovirus genetic information is carried by a single-stranded RNA molecule, the 5′ terminus of which is covalently linked to a small, virus-encoded protein, VPg (**Fig. 1**). The RNA has positive polarity and functions directly as a message, encoding a single polyprotein which is cleaved post-translationally by virus-encoded proteases to give the final products. Several rhinoviruses have been sequenced and they have a genome 7100–7200 nucleotides in length, the shortest known for picornaviruses. This is made up of a 600 nucleotide 5′ untranslated region (UTR), an open reading frame of approximately 2150 codons, a 3′UTR of around 40 nucleotides and a 3′ poly(A) tract. All rhinoviruses have a characteristic nucleotide composition with a preponderance of A and U, particularly in the third position of codons.

Properties of Rhinovirus Proteins

The rhinovirus proteins are numbered 1A(VP4), 1B(VP2), 1C(VP3), 1D(VP1), 2A, 2B, 2C, 3A, 3B, 3C, 3D, according to their location in the initial polyprotein. In addition to these 11 proteins, several precursors, for example 3AB and 3CD, have a significant half-life and are functionally active. The capsid proteins were discussed earlier, and much of our knowledge of the nonstructural proteins is inferred from other picornaviruses. The largest nonstructural proteins, 2C and 3D, together with 3AB, are known to be involved in RNA replication. 2C has amino acid sequence motifs seen in nucleotide binding proteins and, by analogy with other positive-stranded virus proteins, may have a helicase function. 3D has been shown to be the RNA-dependent RNA polymerase and contains motifs (YGDD for instance) which are seen in other polymerases. 2A and 3C are cysteine proteases involved in processing the polyprotein and both are structurally homologous to the trypsin group of proteases. The three-dimensional structure of the HRV-14 3C protease has been solved and this has given insights into the processing mechanism and the additional involvement of 3C, as part of the precursor 3CD, in interacting with the virus RNA during RNA replication. 2A also has other functions, since it is involved in host cell protein synthesis shut off and seems to interact with the 5′UTR to influence translation. The other proteins are not well understood, but 2B may alter host cell

membrane permeability, enhancing virus release, and mutations in this protein have been seen to give changes in cell tropism.

Physical Properties

Rhinoviruses have a buoyant density in CsCl of 1.38–1.42. The characteristic feature which distinguishes them from the similar pathogens, enteroviruses, is their lability below pH 6.0. In contrast, they are relatively thermostable, surviving for days at 20–37°C and this may be an important factor in their spread. As they do not have a lipid envelope, they are resistant to organic solvents such as ether and are unaffected by the detergent sodium deoxycholate. Alcohol/phenol disinfectants are effective virucidal agents.

Replication

Strategy and early events

In common with other viruses, the replication of rhinoviruses requires several steps, including attachment, penetration, uncoating, protein synthesis, RNA replication and assembly. The extent of our knowledge of these steps varies considerably and the study of the first step, attachment, has probably advanced the furthest. Structural analysis by Rossmann has revealed the presence of deep depressions, often termed 'canyons', running at a constant radius around each of the fivefold axes and these contain the sites at which most, if not all, rhinoviruses interact with their cellular receptor. ICAM-1, used by the major receptor group, is an immunoglobulin-like molecule which is sufficiently narrow to penetrate the canyon. The involvement of the canyon has been demonstrated by mutational analysis and by cryoelectron microscopy of HRV-16/ICAM-1 complexes.

The interaction with the receptor, possibly together with exposure to the low pH of endosomes during internalization, is believed to trigger conformational changes. These are centered on the fivefold axis, where a channel through the capsid and the endosomal membrane opens, due to the exposure of hydrophobic domains of VP1 and VP4, allowing the RNA to be released into the cytoplasm.

Translation

Rhinoviruses have a positive sense genome and the first step in macromolecular synthesis is translation, to enable the production of virus-specific proteins. The 5′UTR is very similar to that of enteroviruses, in terms of sequence and predicted secondary structure and translation proceeds in the same manner, i.e. following internal ribosomal entry within the 5′UTR. Similarly, rhinoviruses also shut off host cell protein synthesis, by inactivating the cap binding complex, and their cap-independent, internal ribosome entry allows them to circumvent this inactivation.

Post-translational processing

Synthesis of a single virus polyprotein necessitates cleavage to give the mature proteins and this is brought about by at least two proteolytic activities encoded by the virus itself. $3C^{pro}$ carries out the majority of cleavages, usually at peptide bonds between the dipeptides QG, QS, QA, QT or QM. The amino acids P, A, T or V are often found close to the cleavage site and these, with other features, probably help in its definition. $2A^{pro}$ performs the first cleavage event of processing, liberation of the capsid protein precursor, P1. $2A^{pro}$ usually cleaves between AG, VG or YG residues in rhinoviruses and upstream sequences add specificity to this process. Details of the cleavage of VP0 to VP4 and VP2, which does not occur until the new virus particles are assembled, are not yet fully known.

RNA synthesis

The nature of the genetic material requires that an RNA-dependent RNA polymerase is present and this is virally encoded as no host enzyme exists. Once the first rounds of translation and processing are complete, the synthesized polymerase ($3D^{pol}$), together with other virus products and host proteins, forms a membrane-associated complex. This uses the genomic-sense RNA as a template for producing negative-sense copies which in turn act as templates for genomic-sense RNA synthesis. Some of these act as messages, whereas others are packaged into virus particles. RNA secondary structural elements in both the 5′ and 3′UTR are critical in this process and appear to act as binding sites for host and virus proteins.

Assembly, Release and Cytopathology

Assembly of rhinovirus particles is via the protomers and pentamers already described and takes place in association with membranes. The determinants important in RNA packaging and the details of this process are not known. The gross effect on the cell (the cytopathic effect) probably stems from the inhibition of cellular protein and RNA synthesis, together with the accumulation of virus components. It is also possible that infection triggers apoptosis. Recent evidence suggests that one of the functions of the 2B protein is to affect membrane permeability of the cell, which enhances virus release.

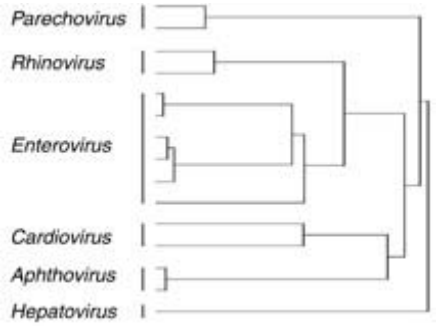

Figure 2 Genetic relationships, based on amino acid identity of the 2C protein, between selected picornaviruses, representing each of the six currently recognized genera. The dendrogram shows that rhinoviruses and enteroviruses are close relatives.

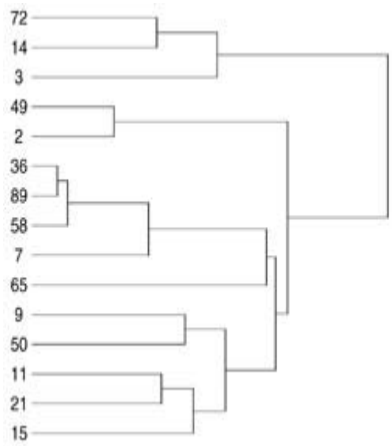

Figure 3 Genetic relationships between a number of HRV serotypes, based on the sequence of part of VP2. The data show that some rhinoviruses, for example HRV-36, HRV-58 and HRV-89 are very closely related. Two distinct molecular groups can be observed and these correlate with those defined on the basis of antivirus drug susceptibility. HRV-3, HRV-14 and HRV-72, which form one molecular group, are all drug group A members, whereas the other serotypes belong to drug group B.

Geographic and Seasonal Distribution

HRVs infect individuals living under all climatic conditions, from arctic to tropical. Infections occur throughout the year, but in temperate countries there is an increased occurrence of HRV colds in September and less markedly in May. These may be correlated with summer/autumn and spring/summer changes in the weather.

Host Range, Virus Propagation and Detection

HRVs exhibit a restricted host range, a major factor probably being the lack of receptors in nonhuman organisms. They cannot be transmitted to any commonly used laboratory animals, and, although some serotypes can infect chimpanzees and gibbons, no symptoms are observed.

Tissue cultures useful for HRV isolation are mainly of human origin and include fetal kidney and tonsil as well as continuous cell lines. Human diploid lung fibroblasts are commonly used for primary isolation, and MRC-5 and HRV-sensitive strains of HeLa (e.g. Ohio-HeLa) give excellent results. Several tissue culture systems need to be used to maximize HRV recovery from clinical samples.

In addition to using virus propagation, routine diagnosis can be performed by polymerase chain reaction (PCR) detection, which is much more rapid and is highly sensitive. PCR employs primers which bind to highly conserved sequences, found in the 5′UTR of all HRVs.

Genetics and Evolution

Rhinoviruses are typical picornaviruses in terms of structure and genome organization. The genetic information is carried on one piece of RNA, precluding reassortment, and the major evolutionary mechanism is the accumulation of point mutations, which occurs at high frequency due to the lack of $3D^{pol}$ proof-reading activity. Recombination has been demonstrated in some picornaviruses and may play a role in rhinovirus evolution, although there is no direct evidence for this. Sequence comparisons with other picornavirus genera shows that rhinoviruses are closely related to enteroviruses and these two genera share features not seen in other picornaviruses, e.g. detailed folding of the 5′UTR and a trypsin-like $2A^{pro}$ (**Fig. 2**). Little is known about rhinovirus evolution on a contemporary time-scale, although antigenic variants can be isolated during an outbreak. Some serotypes, for example HRV-36, HRV-58 and HRV-89, are very closely related at the RNA sequence level, suggesting that they have diverged relatively recently (**Fig. 3**). The existence of intertypes, with antigenic properties intermediate between two serotypes, strengthens the conclusion that some currently known rhinoviruses have a recent common ancestor.

Serological Relationship and Variability

A major factor in the incidence of rhinovirus infection is the large number of serotypes; additionally, several of these can cocirculate within the community. Although there is evidence of an increase in the frequency with which higher numbered and therefore more recently identified serotypes are isolated, many lower-numbered rhinoviruses are still prevalent.

Thus, many serotypes seem to coexist within the human population. The multiplicity of serotypes is in contrast to two other medically important picornaviruses, the polioviruses (three serotypes) and hepatitis A virus (a single serotype). Several serotypes fall into groups on the basis of low-level immunological crossreactivity with hyperimmune serum (HRV-36, HRV-58 and HRV-89; HRV-2 and HRV-49 for example), but it is not known whether this plays any role in protection from heterologous serotypes. These antigenic groups seem to correlate with close molecular relationships (**Fig. 3**).

Epidemiology

Rhinoviruses are a major cause of morbidity and economic loss. They have been implicated in 10–40% of cases of acute respiratory disease, a category accounting for around half of all acute illnesses in the developed world. Thus, although the common cold is less severe than some respiratory diseases, rhinoviruses are responsible for a significant proportion of working days lost in industry, commerce and education.

Rhinovirus infections are most common in young children and babies and the infection rate decreases with age, possibly due to prior exposure to a growing number of serotypes. Estimates of the average incidence of rhinovirus colds have varied, but it is probably at least 0.5 per adult per year. It is agreed that the rate in babies and infants is approximately three times that in adults. Once an individual is infected, the virus often spreads to other members of the family, the home being a major site of transmission. Young children are frequently causes of introduction into the family unit and other young children and the mother the most frequent recipients. The infection rate in mothers possibly reflects greater exposure to infected individuals, although other factors may be involved as it has been shown that the susceptibility to colds varies with the stage of the menstrual cycle. Schools and preschool groups also facilitate rhinovirus transmission.

Transmission and Tissue Tropism

Two routes may be important in rhinovirus spread: direct contact and airborne transmission. People with colds contaminate their hands and environmental surfaces with virus from nasal secretions. The hands of uninfected individuals can then become contaminated by direct contact with the person with a cold or by touching the contaminated surface. The virus can enter the body when the hand is used to rub an eye or pick the nose, common features of human behavior. In experiments which exclude this route, some transmission still occurred, suggesting that contaminated airborne particles or aerosols may also be important. Transmission in the family context correlates with time of exposure to the infected individual, severity of their symptoms and titer of rhinovirus in nasal secretions.

Once introduced into the body, the primary and major site of infection is the epithelial surface of the nasal mucosa. Rhinoviruses thus show a restricted tissue tropism, which may be correlated, among other factors, with their optimum growth temperature (33°C). Clinical manifestations are therefore largely limited to common-cold-like symptoms. Sometimes though, rhinoviruses infect other tissue, particularly the lower respiratory tract, the maxilliary sinus and the middle ear.

Pathogenicity and Clinical Features of Infection

Rhinovirus infections are usually relatively trivial and not life-threatening. Extensive work has been performed on their etiology and pathogenesis using human volunteers. These studies show that a rhinovirus infection can be initiated by less than one $TCID_{50}$ (50% tissue culture infectious dose) of virus, if it is administered to the nasopharynx. Virus shedding can be detected within 24 h and reaches a maximum after 2–3 days, coinciding with the onset of symptoms. Virus titers thereafter fall rapidly but may remain detectable for 3 weeks.

Rhinovirus infection is accompanied typically by the symptoms of a common cold. These vary with the individual and possibly the particular rhinovirus, but usually include nasal discharge and obstruction, often with sneezing, coughing and sore throat. Fever and malaise are less commonly seen than in infections with other respiratory viruses, but gastrointestinal disorders are not uncommon, particularly in children.

Although limited largely to the upper respiratory tract, rhinovirus infections are believed to predispose some individuals to bacterial sinusitis and otitis media. In addition, rhinoviruses can produce serious and debilitating lower respiratory infections, particularly in the elderly, young children and patients with existing disorders, such as cystic fibrosis and bronchopulmonary dysplasia. Up to 40% of exacerbations of chronic bronchitis may be due to rhinovirus infections. Respiratory infections are known to increase the severity and frequency of asthma attacks in susceptible individuals and rhinoviruses are the most important pathogens associated with increased asthma.

Pathology and Histopathology

Physical examination of patients with a rhinovirus infection usually reveals nasal obstruction and discharge, the nasal mucosa being pale and edematous. Elevated levels of bradykinin found locally, possibly contribute to this edema. Neutrophil infiltration is observed in the common cold and this may be caused by rhinoviruses inducing the expression of interleukin 8 (IL-8), a neutrophil chemoattractant. IL-8 may also be involved in asthma exacerbation, which is characterized by rhinovirus-induced enhancement of allergic inflammation and responsiveness to histamine.

The detailed histopathology of rhinovirus infections is not well documented. Nasal mucosa biopsies reveal few histological abnormalities, although shed, virus-containing, columnar epithelial cells can be detected in nasal secretions, suggesting that the epithelial surface of the nasal mucosa is primarily involved. Infection of bovine tracheal organ cultures with bovine rhinovirus leads to the shedding of large numbers of ciliated epithelial cells, leaving a smooth epithelial surface.

Immune Response

Rhinovirus infection stimulates the production of type-specific IgA, IgG and IgM antibodies in up to 90% of individuals. These are detectable within 2–3 weeks in serum and nasal secretions and their levels rise for 5–6 weeks. Most immunoglobulin in nasal secretions is IgA and this is probably a major factor in protection against re-infection (or at least reduction of disease symptoms) by the homotypic rhinovirus. Serum and secretory antibody persist for several years after infection, although their levels decline. As antibody appears late in the infection, it probably plays little part in recovery but it may be involved in final virus clearance. Other mechanisms, including interferon involvement, may therefore be involved in the recovery process. T cell responses which are serotype-crossreactive have been observed, but their contribution to subsequent protection is not known.

Prevention and Control

At present, there is no generally available means of protecting against or treating common colds produced by rhinoviruses. The large number of serotypes apparently precludes conventional vaccines and few attempts have been made to pursue this approach. Most effort has been expended on the development of chemical antivirus agents, but of the many shown to have antirhinovirus activity *in vitro,* none has yet proved clinically useful, although some are currently at the clinical trials stage. An alternative approach is interferon, produced in large amounts by recombinant DNA means. High, intranasal doses, initiated several days before virus challenge, have proved to be effective in preventing illness. However, side effects limit long-term use and as symptoms are only reduced if treatment is commenced before virus infection, interferon has limited applicability. It may prove useful in the family context when it is important to prevent virus spread to specific individuals, e.g. asthmatics and bronchitics. In these cases, it may also be possible to use what we know about the properties of rhinoviruses and their mode of transmission to limit spread. Interrupting transmission by avoiding direct contact with the infected person and by frequent hand-washing is sensible. Furthermore, experiments have been performed in which paper tissues impregnated with virucidal agents (mild acid to exploit rhinovirus lability at low pH) were used for frequent nose-blowing and hand-wiping by infected and uninfected individuals kept together under confined conditions for prolonged periods. The tissues were effective in preventing infection. One semi-empirical approach is the regular topical application of warm, moist air to the upper respiratory tract. Its beneficial effect may be due to the temperature increase in the nose, making it less conductive to rhinovirus replication, although the stimulation of host mechanisms may also be involved. In the absence of specific antivirus agents, proprietary treatments which reduce symptoms are widely used. In addition, both large amounts of vitamin C and zinc acetate tablets have been reported to reduce the severity and duration of colds, although their efficacy have been frequently questioned.

Future Perspectives

The past few years have seen major advances in the study of rhinoviruses, particularly the determination of three-dimensional structures and the identification of receptors. Several nucleotide sequences have been determined, revealing conserved regions which have been exploited by PCR-based systems for rapid detection. These are an improvement on virus isolation procedures for detection and are giving a more complete picture of the role of rhinoviruses in human disease, for instance the recognition of their importance in asthma exacerbation. Rhinovirus serotype diversity means that broadly reactive prophylactic or therapeutic approaches must be devised. The economic and social significance of the common cold continues to stimulate research and our knowledge of the structure of the virus particle, the determinants of antigenicity and cellular receptors, together with

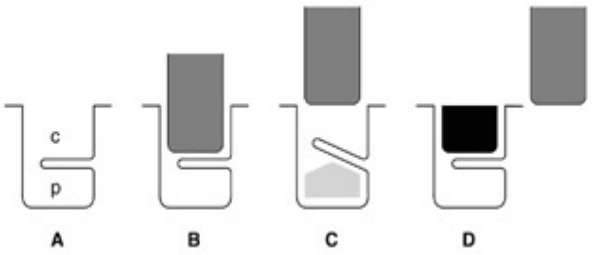

Figure 4 Targets for antirhinovirus therapeutic agents. (**A**) Underneath the canyon (c), which is the site for receptor binding, there is a hydrophobic pocket (p). (**B**) The receptor (gray) docks with the canyon. (**C**) A class of effective antirhinovirus compounds binds strongly to the pocket. This distorts the canyon floor, preventing receptor binding and/or uncoating. (**D**) An alternative approach is to saturate the receptor binding domains with a soluble form of the receptor, thus preventing receptor binding.

other advances, will contribute greatly to the development of rational approaches. It still seems unlikely that a vaccine can be produced, although the ability to pin-point areas of antigenic importance means that it may become possible to construct molecules which can mimic the antigenicity of several serotypes and thus reduce the complexity of the antigenic diversity problem. Even so, several components to the vaccine would be necessary and there may be a reluctance to use such a vaccine, with possible side effects, against what is usually a mild pathogen.

The antirhinovirus drug route may prove more feasible and there are at least three potential targets. Best studied are agents which bind within a hydrophobic pocket located underneath the canyon, blocking virus attachment to cells and/or uncoating (Fig. 4). They have high specificity and efficacy against rhinoviruses *in vitro* and seem to lack toxicity. As the pocket is well conserved, the drugs are potentially broadly reactive and it is possible that one, or a small number, of agents would be effective against all rhinovirus serotypes. Following success with inhibitors of the HIV-1 protease, agents (e.g. peptidyl-aldehydes) which specifically interfere with processing by inhibiting the rhinovirus $3C^{pro}$ are being widely studied. A third approach is to use soluble ICAM-1 to block early virus/cell interactions. However, even such highly specific reagents are likely to suffer from problems which may limit their usefulness. For example, in common with other RNA viruses, rhinoviruses have a high mutation rate and drug-resistant mutants can appear rapidly *in vitro*. Furthermore, maximal benefit from most agents tested is possible only if they are administered before infection. Thus, despite improvements in understanding, rhinovirus infections may continue to be a familiar feature of our lives.

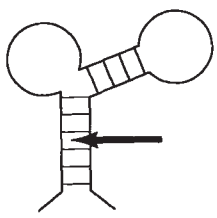
RIBOZYMES



Robert H Symons, Department of Plant Science, University of Adelaide, Glen Osmond, South Australia, Australia

History

Ribozymes are catalytic RNA molecules, first identified in the early 1980s. They have the intrinsic ability to break and form covalent bonds in RNA molecules. In many ways they can be compared to the protein enzymes which catalyze cleavage of peptide bonds in other proteins or peptides. However, ribozymes can

Table 1 RNAs involved in RNA-catalyzed splicing/cleavage reactions

RNA present in	*Reaction in vivoz*	*End groups on cleaved RNAs*	*Nucleotide cofactor*	*Mechanism*
Ribonuclease P	Processing tRNA precursors	5′-P,3′-OH	No	Hydrolysis
Group I introns	Self-splicing of ribosomal introns	5′-P,3′-OH	Yes	Transesterification
Group II introns	Self-splicing of organelle introns	5′-P,3′-OH	No	Transesterification
Three plant viroids, four circular (virusoids) and four linear satellite RNAs	Cleavage of oligomeric precursors	5′-OH,2′,3′-cyclic phosphate	No	Transesterification
Hepatitis delta virus (HDV) RNA	Cleavage of oligomeric precursors	5′-OH,2′,3′-cyclic phosphate	No	Transesterification
Newt satellite II RNA transcript	Unknown	5′-OH,2′,3′-cyclic phosphate	No	Transesterification
Neurospora mitochondrial plasmid transcript VS RNA	Unknown	5′-OH,2′,3′-cyclic phosphate	No	Transesterification

also be *cis*-acting since the ribozyme component of an RNA molecule can cleave at a specific site in another part of the same molecule. All except one of the naturally occurring ribozymes (**Table 1**) are of the latter type.

In 1983, Altman and his colleagues described the first, and so far the only, truly naturally occurring catalytic ribozyme. The bacterial ribonuclease P is involved in the processing of precursor transfer RNA (tRNA) by specific cleavage of a 5′-terminal sequence (**Fig. 1A**). The enzyme consists of one molecule of protein and one molecule of single-strandard RNA; the isolated RNA can carry out the same processing reaction in *trans* as in the holoenzyme with multiple turnover and without being changed in the reaction.

The term ribozyme was first used by Cech and his colleagues in 1982 to describe the self-splicing activities of an intervening sequence (IVS) of ribosomal RNA precursor sequences in the protozoan *Tetrahymena* (**Fig. 1B**). This is an intramolecular reaction and the ribozyme component only catalyzes a single turnover and is modified during the reaction. It can, therefore, be considered to be acting in a quasicatalytic manner. All introns which self-splice as in **Fig. 1B** are called Group I introns. The molecular aspects of this self-splicing reaction continue to be extensively investigated.

In 1986, three groups reported a new type of intron self-splicing as in **Fig. 1C** and such introns are called Group II introns. They are less common than Group I introns and are found in organellar and bacterial genomes. They exist in fungal mitochondria, plant mitochondria and chloroplasts, algae and bacteria.

Also in 1986 two new ribozymes were identified in small circular plant pathogenic RNAs which were subsequently called the hammerhead and hairpin ribozymes. They both carry out the reaction summarized in **Fig. 1D**. A total of 14 plant pathogenic RNAs have so far been identified which can carry out either the hammerhead or hairpin ribozyme reaction or both the reactions (**Table 1**). Interestingly, only one nonpathogenic RNA has been reported to carry out the hammerhead reaction, the RNA transcripts from satellite DNA of the newt, and none have been reported for the hairpin ribozyme.

The only animal RNA pathogenic RNA known so far to undergo self-cleavage was reported in 1988 for hepatitis delta RNA which is essentially a satellite RNA dependent on hepatitis B virus for its replication. Both plus and minus forms of the approximately 1700 nt circular RNA self-cleave via a pseudoknot structure.

And, finally, a second nonpathogenic RNA was reported in 1990 to undergo the self-cleavage reaction of **Fig. 1D**; this was an 881 nt transcript of a circular mitochondrial DNA plasmid of *Neurospora*. Two-dimensional structural models around the self-cleavage site are different from other known self-cleavage structures.

It is perhaps surprising that all currently known types of self-processing or self-cleaving naturally occurring RNAs in **Table 1** were identified between 1982 and 1990. It remains to be seen whether any new types of reactions will be found from 1998 onwards.

Ribozymes of Non-viral Origin

Since the emphasis in this encyclopedia is on Virology, the nonviral ribozyme systems are only considered briefly here; the newt hammerhead ribozyme system is considered in the following section.

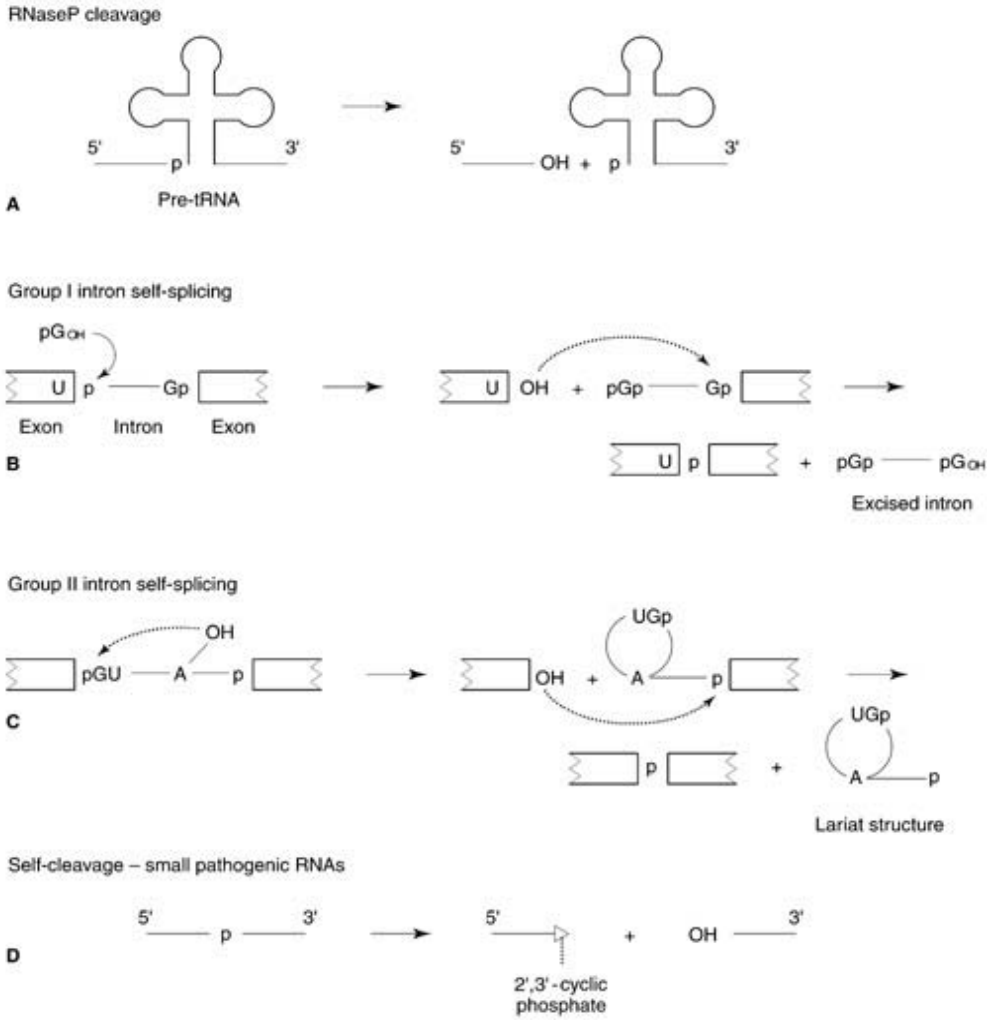

Figure 1 RNA processing reactions that are naturally RNA catalysed. See text and Tables 1 and 2 for further details.

Ribonuclease P (RNase P)

The reaction carried out by this ribozyme is summarized in **Fig. 1A**. RNase P is an endoribonuclease which cleaves precursor tRNAs at their 5′ ends to give the mature 5′ termini of tRNAs (**Fig. 1A**). The best characterized enzymes are those from the eubacteria *Escherichia coli* and *Bacillus subtilis*. The RNase P holoenzyme is composed of one basic protein subunit of approx. M_r 14000 (119 amino acids) and one single-stranded RNA molecule of 377 nucleotides (*E. coli*) or 401 nucleotides (*B. subtilis*). The RNAs make up 90% by weight of these enzymes and are not covalently coupled to the protein component.

The purified RNAs of bacterial RNase P can carry out the same reaction as the holoenzyme but high ionic strength is required in the reaction mixture. This result indicates that, *in vivo*, the catalytic component of RNase P is the RNA moiety.

The nucleotide sequences of the substrate tRNAs are not conserved around the cleavage sites for RNase P; hence there must be common structural features which allow specific recognition. The basic substrate requirements for RNase P activity are shown in **Fig. 2**; a base paired stem, one strand of which contains the eventual 3′ terminal–NCCA of the tRNA and the other strand the cleavage site. Hence, the RNA component of RNase P can act as a true ribozyme in *trans* to specifically cleave pre-tRNAs as well as unrelated RNAs which contain the basic sequence and structural requirements of **Fig. 2**.

Group I introns as ribozymes

The best characterized Group I system is that of the 413 nucleotide intervening sequence (IVS) in the nuclear rRNA precursor from *Tetrahymena thermophila*. The intron can be excised and the two exons

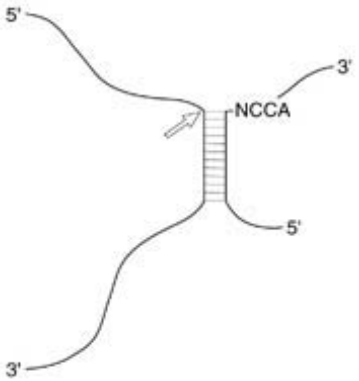

Figure 2 Basic structural and sequence requirements of a substrate for specific cleavage (site indicated by arrow) by RNase P or its RNA.

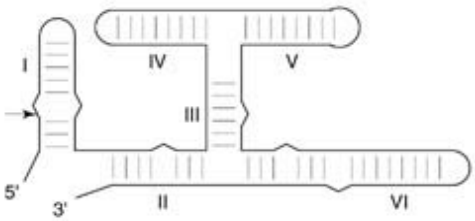

Figure 3 Secondary structure model of part of the 881 nt *Neurospora* VS RNA required for self-cleavage. The minimal sequence required contains 154 nt with only 1 nt 5′ to the self-cleavage site indicated by an arrow.

ligated in the complete absence of protein but there is a requirement for guanosine or a guanosine nucleotide as a cofactor as indicated in **Fig. 1B**. Hence, the IVS catalyzes only its own excision and is modified during the process. The released intron can then undergo further RNA-catalyzed cyclization and cleavage reactions that remove a total of 19 nucleotides from the 5′ end to produce an intron core (L-19 IVS) of 395 nucleotides.

The L-19 IVS RNA can be used *in vitro* in a classical enzymatic fashion in several in *trans* reactions, catalyzing the turnover of more than one substrate molecule and remaining unchanged. One of these reactions is a sequence-specific endonuclease.

Group II introns as ribozymes

Group II introns are found in eubacteria and eubacterial-derived organellar genomes of plants, mitochondria and chloroplasts. They have never been reported in the nucleus of eukaryotes. The overall self-splicing of Group II introns (**Fig. 1C**) involves the initial nucleophilic attack by a 2′-hydroxyl near the 3′

Table 2 Plant and animal pathogenic RNAs with *cis*-ribozyme activity

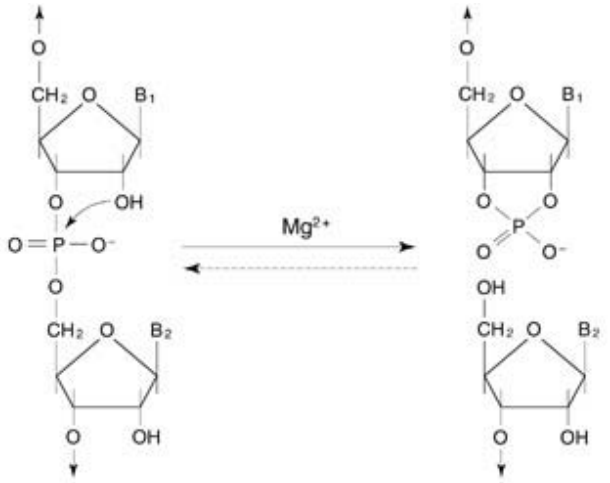

Figure 4 The self-cleavage reaction of RNA catalysed by Mg^{2+} or other divalent cations. This nonhydrolytic, transesterification reaction is theoretically reversible.

end of the intron on the 5′-terminal phosphate of the intron followed by the two steps of **Fig. 1C** to give the ligated exons and the released intron as a lariat structure. The splicing of intron-containing pre-mRNAs follows the same route but it occurs in the nucleus and requires the assistance of the spliceosome complex.

Demonstration of self-splicing of Group II introns *in vitro* requires very unphysiological conditions of high concentrations of salt and of Mg^{2+} and higher than normal temperatures. Only a minority of Group II introns have been shown to have ribozyme activity *in vitro*. Hence, progress in characterizing this ribozyme activity has lagged behind that of the Group I introns.

Neurospora VS RNA can self-cleave

VS RNA is a self-cleaving 881 nt RNA transcript of a mitochondrial DNA plasmid of *Neurospora*. Only 154 nt is required for self-cleavage and a potential two-dimensional structure is shown in **Fig. 3**. As for the hepatitis delta ribozyme (see below), only a single nucleotide 5′ to the cleavage site is required for activity. The RNA can be divided into a two component in *trans* ribozyme system. Even though VS RNA is present at high concentrations in mitochondria, its function is unknown.

Ribozymes of Viral Origin

The plant and animal pathogenic RNAs which have been shown so far to undergo self-cleavage *in vitro* are listed in **Table 2**. In all cases, this self-cleavage activity involves the divalent metal ion-catalyzed nucleophilic attack of the oxygen of the 2′-hydroxyl group at the cleavage site on the phosphate of the internucleotide linkage (**Fig. 4**). The cleavage products contain a 3′ end terminal 2′,3′-cyclic phosphate and a 5′-hydroxyl. The reaction is theoretically reversible.

Experimental evidence, at least for some of the RNAs of **Table 2**, indicates that this self-cleavage reaction is an essential step in their rolling circle replication (**Fig. 5**). Where both the plus RNAs (the dominant form *in vivo*) and the minus RNAs (the minor form) self-cleave, replication follows (**Fig. 5A**). The circular plus strand is copied by a host or viral-coded RNA-dependent RNA polymerase to produce a multimeric minus strand which is processed into unit length minus monomers. These are circularized by a host RNA ligase and the circular molecules copied by the RNA polymerase to give a multimeric plus strand which is cleaved specifically to monomers. These are then circularized to give the progeny circular RNAs, the dominant form found *in vivo*.

Of the RNAs in **Table 1**, only three plant satellite RNAs follow the replication cycle of **Fig. 5B** where the dominant plus form undergoes self-cleavage and the multimeric minus strand is copied directly to give

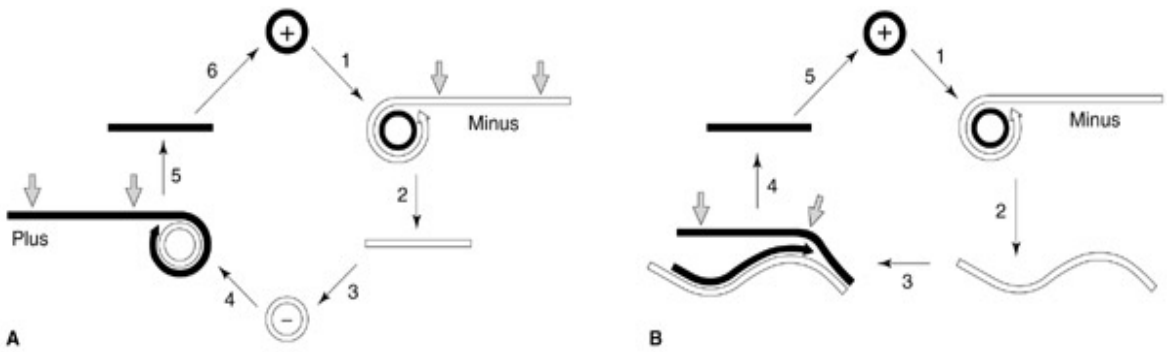

Figure 5 Two routes for the rolling circle replication of small, circular pathogenic RNAs, by an RNA polymerase. (**A**) Six-step pathway where both the multimeric minus and plus linear RNAs self-cleave (open arrows) to give monomers which are ligated *in vivo* to the circular forms. (**B**) Five-step pathway where only the multimeric plus RNA self-cleaves.

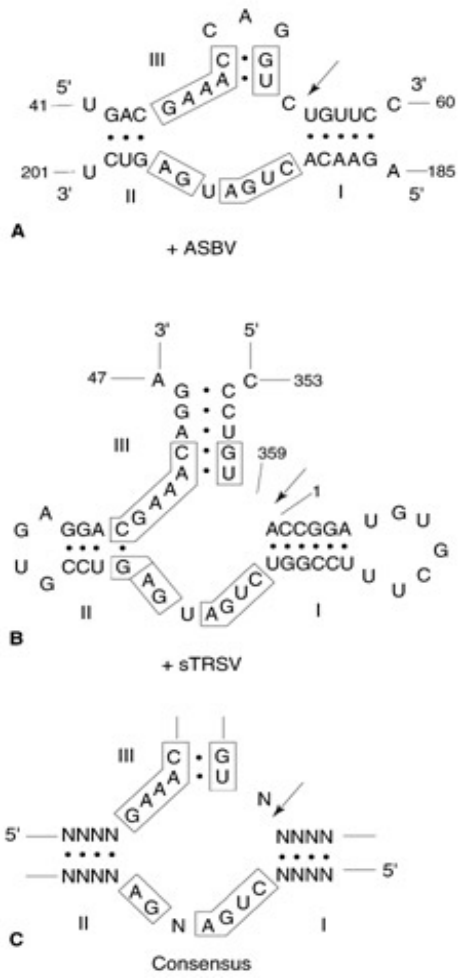

Figure 6 Two-dimensional hammerhead structures in self-cleaving RNAs. (**A**) Hammerhead structure that can form from opposite strands in the 247 nt rod-like structure of plus ASBV. (**B**) Hammerhead structure in the plus strand of the 359 nt satellite RNA of tobacco ringspot virus. (**C**) Consensus hammerhead structure for RNAs in Table 2. Self-cleavage site indicated by arrow. The 13 nucleotides that are highly conserved in all RNAs which cleave by the hammerhead structure are boxed.

the plus strand which self-cleaves to monomers which are then circularized.

Only the three viroids listed in **Table 2**, out of 27 so far identified, undergo self-cleavage *in vitro*. Viroids are single-stranded circular RNAs which vary in size from 246 to 463 nucleotides and infect a wide range of plant species. Many are of agricultural importance. Most of the remaining self-cleaving RNAs in **Table 2** are satellite RNAs in that they are dependent on a helper virus for their replication, including the only animal virus member, the hepatitis delta virus RNA which depends on hepatitis B virus. Two other self-cleaving plant pathogenic RNAs have yet to be characterized at the biological level.

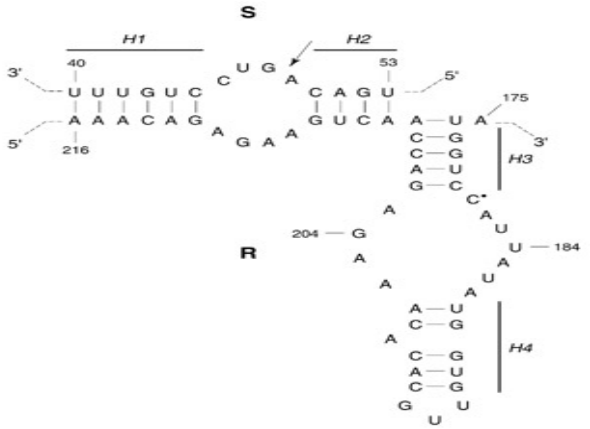

Figure 7 Standard convention for numbering the residues in a hammerhead structure.

So far only three types of two-dimensional structural motifs have been identified at the self-cleavage sites of the 14 pathogenic RNAs of **Table 2**. These are the hammerhead, hairpin and pseudoknot structures.

Hammerhead ribozyme

The hammerhead self-cleavage motif was first recognized in the plus and minus self-cleaving RNAs of avocado sunblotch viroid (ASBV) and of the satellite RNA of lucerne transient streak virus (sLTSV) and the plus form of the satellite RNA of tobacco ringspot virus (sTRSV). The original hammerhead structures predicted around the self-cleavage sites of (+)ASBV and (+)sTRSV together with the highly conserved nucleotides (boxed) in all hammerhead structures are given in **Fig. 6** together with the consensus hammerhead structure for all naturally occurring RNAs. *In vitro*, the RNA sequences in **Fig. 6** are all that are required to ensure efficient self-cleavage in the presence of Mg^{2+}. Hence, such RNAs can be considered as ribozymes since they catalyze a single turnover, intramolecular (*cis*) cleavage reaction.

In addition to the well-studied plant viroids and satellite RNAs in **Table 2**, there are two other naturally occurring circular RNAs where both plus and minus strands self-cleave via the hammerhead structure but which have yet to be characterized in detail at the biological level. One of these is the 275-nt circular RNA from carnation and named carnation small viroid-like RNA (CarSV RNA) which has a dsDNA counterpart in the form of head-to-tail monomers. The other self-cleaving viroid-like RNA is the 451 nt cherry small circular RNA which is associated with a series of double-stranded RNAs of putative viral origin in cherry trees showing the cherry chlorotic rusty spot disease.

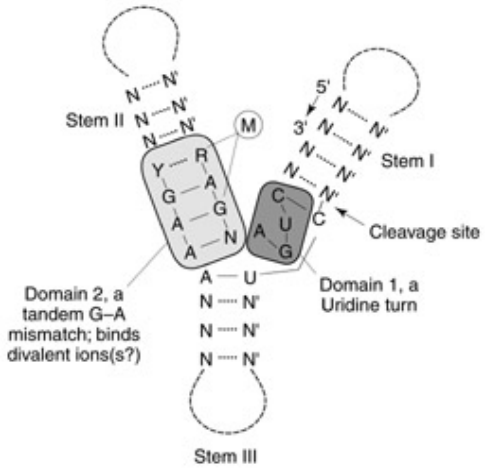

Figure 8 Schematic drawing of the structure of the hammerhead as determined by x-ray crystallography. (Reproduced with permission from McKay (1996).)

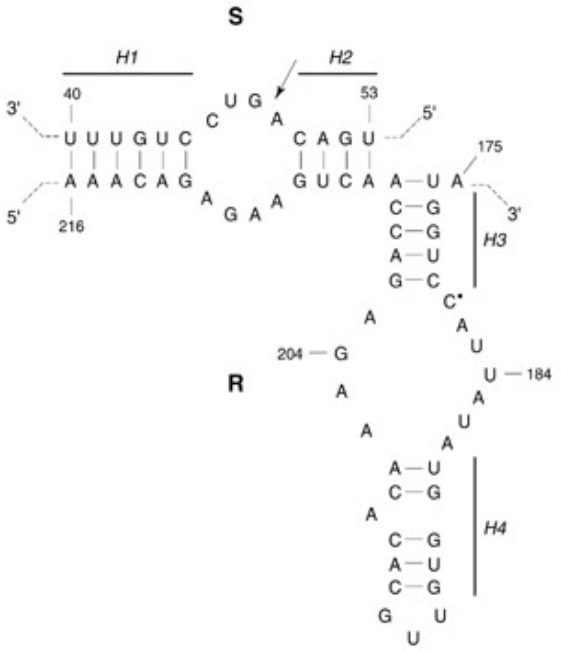

Figure 9 Secondary structure model of the hairpin ribozyme of the minus strand of the satellite RNA of tobacco ringspot virus ((−)sTRSV). The model is divided into a ribozyme component R and a substrate component S which form part of the 359nt sTRSV. The self-cleavage site between G48 and A49 is indicated by an arrow; note that the residue numbering is of the plus strand so that the numbering increases in the 3′ to the 5′ direction. Helices are numbered H1 to H4. UV irradiation of the ribozyme leads to cross-linking between G204 and U184.

In 1987, Epstein and Gall reported that *in vitro*-produced transcripts of tandemly repeated 330bp satellite II DNA of the newt self-cleaved by a hammerhead structure. This is the only non-viral RNA identified so far which self-cleaves via the hammerhead structure; the role of this reaction *in vivo* is unknown.

The small size of the hammerhead structure has led to its extensive characterization and manipulation. To aid in the description of various hammerhead constructs, a standard numbering system was introduced in 1992 (**Fig. 7**) and is now widely used.

Hammerhead reaction in *trans*

The plus and minus hammerhead structures of ASBV as identified in the native rod-like molecules are constituted from sections of the top and bottom RNA strands in the 247 nucleotides viroid. This led Uhlenbeck in 1987 to demonstrate hammerhead self-cleavage in *trans* using a 19nt ribozyme to catalyze cleavage with multiple turnover of a 24nt substrate as well as to cleave sequences embedded in a number of different RNAs. Haseloff and Gerlach in 1988 extended this approach by the design of small riboyzmes for the cleavage of specific sites in native RNA molecules *in vitro*, an approach which is now extensively used *in vitro* and *in vivo*.

Crystal structure of the hammerhead

The first crystal hammerhead structure was reported by McKay in 1994; it consisted of a 34-ribozyme and a 13-mer deoxynucleotide substrate. This was soon followed by Klug in 1995 and 1996 with crystal structures of an all RNA hammerhead. The three-dimensional structures developed from the three approaches are essentially the same (**Fig. 8**). Stem III of the hammerhead forms the stem of a Y-shaped structure where the arms are formed by stems I and II. Stems II and III are nearly collinear.

The hairpin ribozyme

This ribozyme (**Fig. 9**) has it origins in a 359nt linear satellite RNA of tobacco ringspot virus (sTRSV) which is encapsidated within viroids of the helper virus. Circular forms of sTRSV are found *in vivo* in infected plants but these are not encapsidated, in contrast to the encapsidation of the circular viroid-like satellite RNAs or virusoids associated with the Sobemoviruses (**Table 2**). The dominant plus form of sTRSV self-cleaves via the hammerhead structure and the minus form via the hairpin structure. Only three satellite RNA examples of the hairpin ribozyme have been identified, all within the Nepovirus group and having hammerhead self-cleavage in the plus strand.

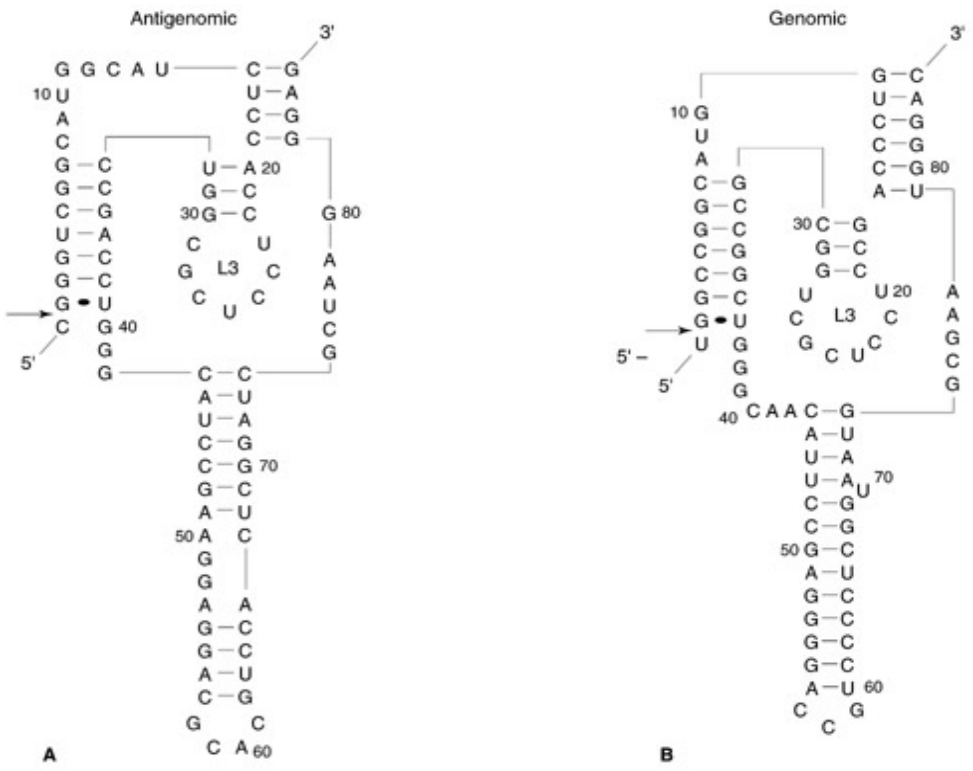

Figure 10 Secondary pseudoknot structures of the (**B**) genomic and (**A**) antigenomic ribozymes of hepatitis delta virus. The self-cleavage site in each ribozyme is indicated by an arrow. Only one nucleotide is needed 5′ to the self-cleavage site for cleavage to occur *in vitro*.

As for the hammerhead sequences in plus and minus ASBV, the nucleotide sequences required for self-cleavage of minus sTRSV are from two well-separated regions of the RNA molecule (**Fig. 9**). This allowed the demonstration of self-cleavage in *trans in vitro* and the manipulation of the hairpin ribozyme to target unrelated RNAs *in vitro* and *in vivo*. This work is at an early stage as compared to the application of the hammerhead ribozyme.

The pseudoknot riboyzme of hepatitis delta virus RNA

Hepatitis delta virus (HDV) is a subviral satellite virus of hepatitis B virus (HBV). The approx. 1680 nt circular genomic RNA is encapsidated in HBV-coded proteins and can fold into an unbranched rod-like structure as can the nonencapsidated complementary antigenomic RNA found *in vivo*. The antigenomic RNA contains an open reading frame coding for a 195 amino acid protein called the delta antigen which is essential for HDV RNA replication. At one end of these molecules there is a viroid-like domain containing the ribozyme domains required for the processing of multimeric intermediates during the rolling circle replication of HDV RNA. There are no known coding regions on the genomic RNA.

The two-dimensional structures of genomic and antigenomic riboyzmes are given in **Fig. 10** and each contain approx. 85 nt. By common usage they are referred to as pseudoknot structures. There is a high conservation of sequence between the two structures. The naturally occurring *cis* ribozyme activity can be converted into in *trans* ribozyme activity by splitting the structures in **Fig. 10** in at least two single-stranded regions to give ribozyme and substrate fragments.

RINDERPEST AND DISTEMPER VIRUSES (*PARAMYXOVIRIDAE*)

Tom Barrett, Institute for Animal Health, Pirbright Laboratory, Pirbright, Surrey, UK

History

Rinderpest virus

Rinderpest (or cattle plague) is one of the oldest known plagues of domestic livestock, with recognizable descriptions dating back to the fourth century AD. It is of ancient Asiatic origin but in more recent times devastating plagues of rinderpest swept across Europe in the eighteenth and nineteenth centuries. In 1711 the disease entered Europe through Venice and had spread as far as Britain by 1714. The economic effect of the subsequent European plagues was so drastic that it led to the establishment of veterinary schools to deal specifically with the problems of animal health, the first being the veterinary school at Lyon in France in 1762. A vigorous slaughter and quarantine policy succeeded in controlling the disease and by the beginning of the twentieth century Europe was free of rinderpest. Subsequently there have been periodic introductions through importation of live infected animals; the last serious outbreak in domestic cattle occurred in Belgium in 1920 and was caused by infected zebu cattle in transit from India to Brazil mixing with local cattle at the docks. Following the 1920 outbreak in Europe, the Office International des Epizooties (OIE) was set up in Paris to deal with matters concerning animal health in relation to international trade. The last known case reported in Europe was in an imported zoo animal in Rome in 1949. Isolated cases of rinderpest have occurred in Brazil (1920) and Australia (1924), again in association with importation of live infected cattle.

In 1889 a catastrophic outbreak of rinderpest occurred in Africa and was caused by the importation of infected cattle from India to feed Italian soldiers engaged in a military campaign in Abyssinia (Ethiopia). The subsequent panzootic spread to nearly all parts of the continent, reaching South Africa by 1897. Over 90% of domestic cattle, along with other highly susceptible wild animals such as buffalo (*Syncerus caffer*), eland (*Taurotragus* spp.), kudu (*Tragelaphus imberbis*), giraffe (*Giraffa* spp.) and wildebeest (*Connochaetes* spp.), were wiped out (**Table 1**). At the time most transport relied on oxen and, as the South African railway system had not been fully established, the economic consequences were devastating. In Kenya the Masai tribe suffered greatly and many people starved. Descriptions at the time stated that the East African Plains were so littered with dead carcasses that the vultures were unable to clear the carrion. Previously rinderpest was only seen in Africa in Egypt and parts of Senegal, where it was periodically introduced from Europe or the Middle East.

A similar plague in small ruminants, peste des petits ruminants, was first described in West Africa in 1942 by Gargadennec and Lalanne. This disease is

Table 1 Susceptibility of wildlife to rinderpest

Susceptibility	*Animals*
Very high	Buffalo, eland, kudu, warthog
High	Giraffe, bushbuck, bushpig, sitatunga, Uganda cob, bongo, wildebeest
Moderate	Reedbuck, topi, gemsbok, blesbok, bontbok, oribi, impala, springbok

RINDERPEST AND DISTEMPER VIRUSES (*PARAMYXOVIRIDAE*)

Tom Barrett, Institute for Animal Health, Pirbright Laboratory, Pirbright, Surrey, UK

History

Rinderpest virus

Rinderpest (or cattle plague) is one of the oldest known plagues of domestic livestock, with recognizable descriptions dating back to the fourth century AD. It is of ancient Asiatic origin but in more recent times devastating plagues of rinderpest swept across Europe in the eighteenth and nineteenth centuries. In 1711 the disease entered Europe through Venice and had spread as far as Britain by 1714. The economic effect of the subsequent European plagues was so drastic that it led to the establishment of veterinary schools to deal specifically with the problems of animal health, the first being the veterinary school at Lyon in France in 1762. A vigorous slaughter and quarantine policy succeeded in controlling the disease and by the beginning of the twentieth century Europe was free of rinderpest. Subsequently there have been periodic introductions through importation of live infected animals; the last serious outbreak in domestic cattle occurred in Belgium in 1920 and was caused by infected zebu cattle in transit from India to Brazil mixing with local cattle at the docks. Following the 1920 outbreak in Europe, the Office International des Epizooties (OIE) was set up in Paris to deal with matters concerning animal health in relation to international trade. The last known case reported in Europe was in an imported zoo animal in Rome in 1949. Isolated cases of rinderpest have occurred in Brazil (1920) and Australia (1924), again in association with importation of live infected cattle.

In 1889 a catastrophic outbreak of rinderpest occurred in Africa and was caused by the importation of infected cattle from India to feed Italian soldiers engaged in a military campaign in Abyssinia (Ethiopia). The subsequent panzootic spread to nearly all parts of the continent, reaching South Africa by 1897. Over 90% of domestic cattle, along with other highly susceptible wild animals such as buffalo (*Syncerus caffer*), eland (*Taurotragus* spp.), kudu (*Tragelaphus imberbis*), giraffe (*Giraffa* spp.) and wildebeest (*Connochaetes* spp.), were wiped out (**Table 1**). At the time most transport relied on oxen and, as the South African railway system had not been fully established, the economic consequences were devastating. In Kenya the Masai tribe suffered greatly and many people starved. Descriptions at the time stated that the East African Plains were so littered with dead carcasses that the vultures were unable to clear the carrion. Previously rinderpest was only seen in Africa in Egypt and parts of Senegal, where it was periodically introduced from Europe or the Middle East.

A similar plague in small ruminants, peste des petits ruminants, was first described in West Africa in 1942 by Gargadennec and Lalanne. This disease is

Table 1 Susceptibility of wildlife to rinderpest

Susceptibility	*Animals*
Very high	Buffalo, eland, kudu, warthog
High	Giraffe, bushbuck, bushpig, sitatunga, Uganda cob, bongo, wildebeest
Moderate	Reedbuck, topi, gemsbok, blesbok, bontbok, oribi, impala, springbok
Low	Waterbuck, dukier, orynx, Grant's gazelle, dikdik, hartebeest
Very low	Thomson's gazelle, hippopotamus, gerenuk

also caused by a virus and is known as kata in West Africa. At first it was thought to be a variant of rinderpest virus adapted to grow in sheep and goats; however, it was subsequently shown to be an immunologically distinct virus with a separate epizootiology in areas where both viruses were enzootic. A disease of small ruminants, which was almost certainly caused by peste des petits ruminants virus, was first described in Senegal in 1871.

Canine distemper virus

Canine distemper virus is also a disease with a long history. Edward Jenner studied its neurological symptoms but it was Carré in 1906 who first showed that it was caused by a virus. In French the virus is known as 'la maladie de Carré'. In the summer of 1988 a large number of harbour seals (*Phoca vitulina*) died in the Baltic Sea and on the North Sea coasts of Northern Europe with clinical signs very similar to canine distemper in dogs. The epizootic was eventually shown to have been caused by a virus, at first thought to be canine distemper. Monoclonal antibody analyses and nucleic acid hybridization showed that it was a new virus distinct from canine distemper and it is now named phocid distemper virus. A disease with similar clinical signs caused mass mortality in Siberian seals (*Phoca sibirica*) in Lake Baikal in the winter of 1987. There was no obvious link between the virus outbreaks in the two seal populations and subsequent work showed that, in contrast to the European situation, the Russian epizootic was caused by a virus indistinguishable from canine distemper. The source of virus in this outbreak is thought to have been lakeside dogs which were suffering from canine distemper at that time. So, in addition to a wide range of land mammals, canine distemper virus can also infect aquatic carnivores.

In 1990 large numbers of striped dolphins (*Stenella coeruleoalba*) in the Mediterranean Sea were found dying from a virus infection which was referred to as the dolphin morbillivirus. Two years previously a virus had been isolated from porpoises (*Phocoena phocoena*) which was then found to be very closely related to the new dolphin virus. They were shown to be genetically distinct from other morbilliviruses, including phocid distemper virus. Serological evidence of infection with this virus was subsequently found in many other cetacean species in the Atlantic Ocean and the term cetacean morbillivirus has been suggested as a suitable name.

Taxonomy and Classification

Rinderpest was first shown to be a filtrable agent in 1902 and, along with the other viruses described above, is classified in the *Morbillivirus* genus (from the latin *morbus* meaning disease) within the *Paramyxoviridae* family. Antigenically the animal morbilliviruses are closely related to human measles virus, the type virus of the genus. Morbilliviruses are large enveloped viruses with a negative-strand RNA genome of about 16 kb. The virus particles are pleomorphic with an average diameter of around 200–300 nm. Measles virus is the only member of the group which has been shown to haemagglutinate red blood cells reproducibly. Unlike other members of the *Paramyxoviridae*, neuraminidase activity is generally not found in morbilliviruses; however, a highly substrate-specific neuraminidase activity has recently been demonstrated in rinderpest and peste des petits ruminants viruses.

Geographic Distribution

Rinderpest is enzootic on the Indian subcontinent and in parts of the Middle East and Eastern Africa. Sporadic outbreaks occur in countries bordering the enzootic regions. Peste des petits ruminants is enzootic in parts of West Africa but in the past few years it has spread across a broad belt of sub-Saharan Africa and eastwards through the Middle East and to southern Asia as far as Bangladesh (**Fig. 1**). It was thought until recently that India was free from peste des petits ruminants virus and that the morbillivirus-like disease prevalent in small ruminants was caused by rinderpest virus. However, in 1988 its presence in southern India was confirmed using specific cDNA hybridization probes.

Canine distemper has a worldwide distribution but is not found in very hot, arid regions. The development of an attenuated vaccine for canine distemper virus in the 1950s greatly reduced the incidence of disease in domestic dogs. However, many wild-life species are susceptible to the disease and can act as reservoirs of infection.

The origin of the European seal morbillivirus is unknown but it appears to be enzootic in Arctic waters, as sera collected from Greenland seals dating back to the early 1980s have been shown to be positive for morbillivirus antibodies. Arctic harp seals (*Phoca groenlandica*) show a high seropositivity and, unlike seals in European waters, are present in sufficient numbers to maintain the disease. The morbilliviruses isolated from porpoises and dolphins were probably transmitted by contact with another cetacean species in which the virus is enzootic. The most likely candidate in this case is the pilot whale (*Globicephalus melas*), which is gregarious and present in sufficient numbers to maintain the virus.

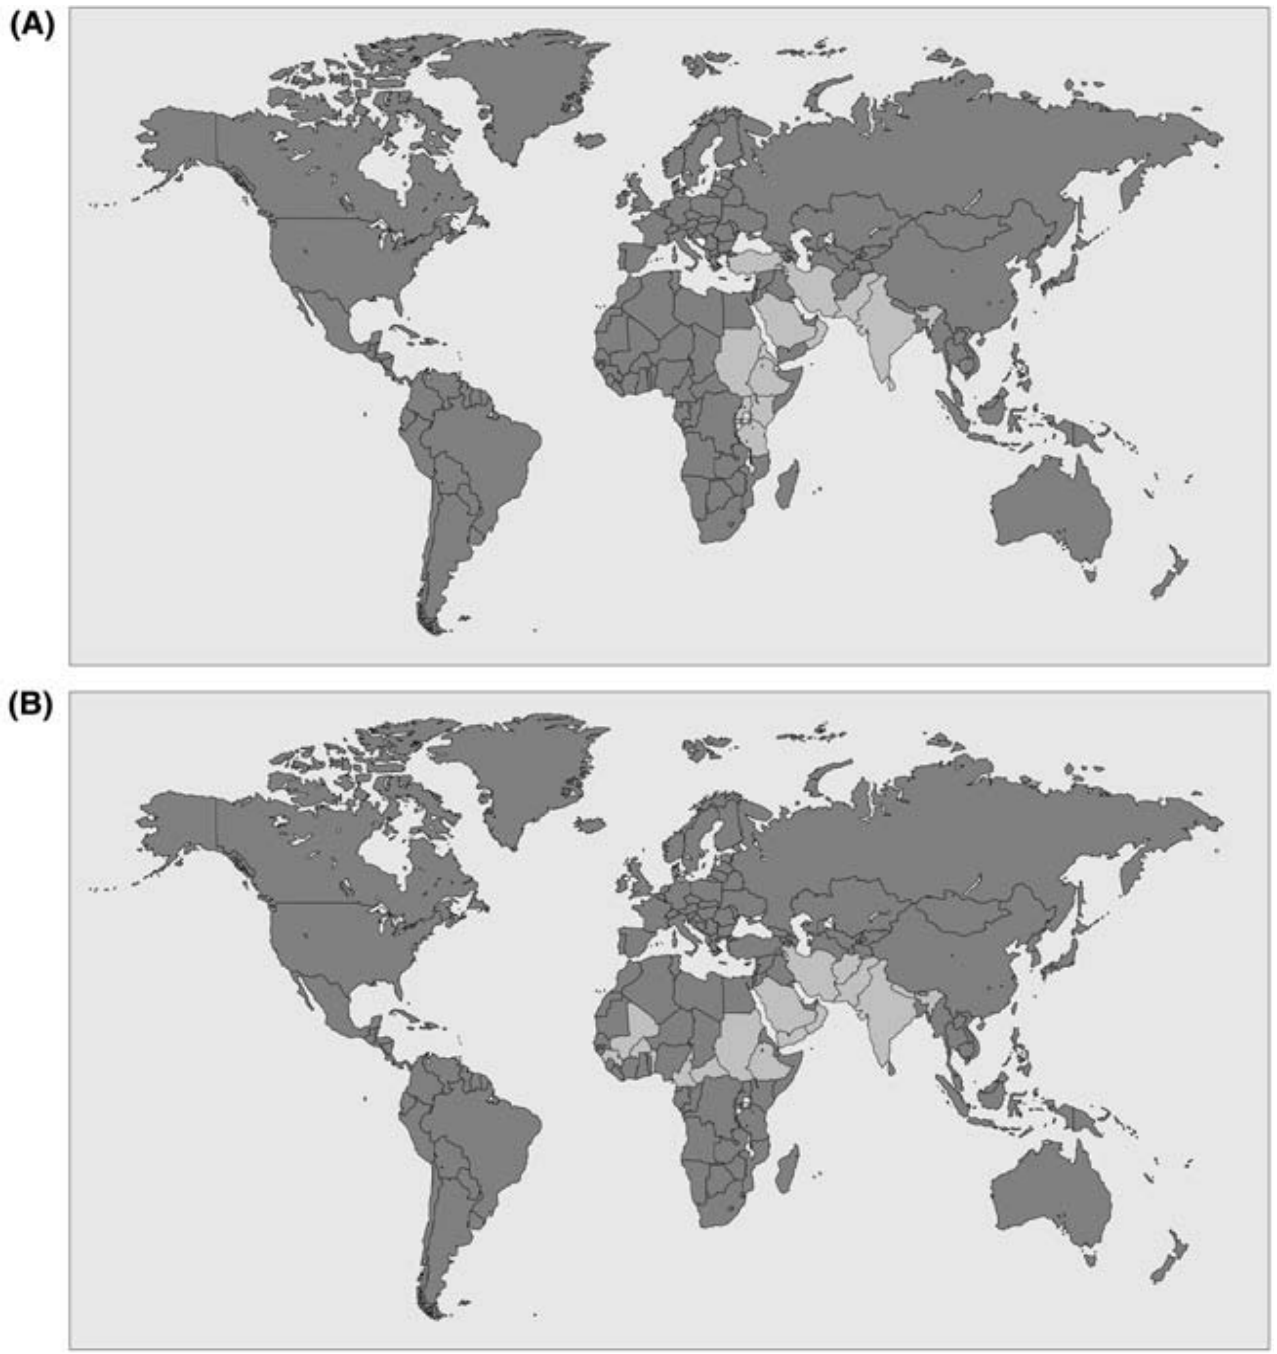

Figure 1 The present (1999) distribution of **(A)** rinderpest and **(B)** peste des petits ruminants viruses. Countries reporting disease since 1990 are in lighter shading.

Host Range and Virus Propagation

All species of the order *Artiodactyla* can be infected with rinderpest virus but some species are more susceptible to disease than others. In the case of cattle, Asian breeds are more resistant than European, while the opposite is the case in pigs. In the case of domestic ruminants, peste des petits ruminants virus only causes clinical disease in sheep and goats – goats being particularly susceptible. Peste des petits ruminants virus can also infect wild ruminants, as was illustrated by an outbreak of peste des petits ruminants virus in a zoo in the United Arab Emirates, but its full host range is unknown. In that outbreak

gazelle (*Gazella dama*), ibex (*Capra ibex nubiana*) and gemsbok (*Oryx gazella*) were involved. Some large ruminants and pigs can be infected subclinically but they are dead-end hosts and do not transmit the disease.

Canine distemper causes disease in all *Canidae* (dog, wolf, fox), *Mustelidae* (ferret, weasle, mink), *Procyonidae* (racoon, panda) and collared peccaries (*Tayassu tajacu*). Canine distemper can probably infect all carnivore species but in certain cases, e.g. some *Felidae* (cats), the infection may be subclinical. Until recently it was thought that canine distemper could not cause disease in large cats such as tigers, lions and panthers; however, in 1991–1992 canine distemper was found to have been responsible for the deaths of large cats in several zoos in the USA. Shortly afterwards a distemper outbreak had a devastating effect on the population of lions in the Serengeti in Africa. The virus responsible for infection in large cats was most closely related to that circulating in local wild carnivores, e.g. racoons in the USA and hyaenas (*Hyaena crocuta*) in Africa, and not a new strain adapted specifically to felids. The outbreak of canine distemper virus in Siberian seals has extended its range to aquatic carnivores.

Phocid distemper virus is known to infect several species of seal, ranging from the harp seals and ringed seals (*Phoca hispida*) of the North Atlantic to the grey (*Halichoerus grypus*) and harbor seals which have a more southerly distribution. During the 1988 European epizootic, although few grey seals succumbed to the infection, many were found to have developed morbillivirus-specific antibodies. This indicated a difference in susceptibility to disease as harbor seals died in large numbers. Phocid distemper virus accidentally infected mink in Denmark during the 1988 epizootic and so it can also cause disease in terrestrial carnivores.

The morbilliviruses can be isolated in a variety of cell types. Primary bovine kidney cells are usually used to isolate field strains of rinderpest virus and primary lamb kidney cells for peste des petits ruminants virus. More recently a marmoset lymphoblastoid cell line (B95a) and a *Theileria parva*-transformed bovine lymphocyte cell line have been reported to be suitable for rinderpest virus isolation. Virus can be best isolated from tissues such as mucosal lesions, lymph nodes or by cocultivation of washed buffy coat with susceptible cells such as bovine kidney or B95a cells. Cytopathic effects are usually evident between 3 and 12 days after infection, whereas control cells treated with antirinderpest antiserum should remain healthy.

Canine distemper virus is usually isolated by cocultivation of lymphocytes from infected animals with mitogen-stimulated canine or ferret lymphocytes and can then be adapted to grow in MDCK or Vero cells. Lung tissue is also a good source of virus for canine distemper and phocid distemper virus isolation. Primary seal kidney cells were used initially to isolate phocid distemper virus but the virus can also be adapted to grow in Vero cells. Typical cytopathic effects such as cell elongation, cell rounding, the formation of stellate cells and syncytia can be observed between 3 and 12 days postinfection. Several blind passages may be necessary before cytopathic changes are observed in the cells.

Properties of the Virion and Genome

The rinderpest virus particle is made up of a lipid envelope derived from the host cell, six virus structural proteins and a genome consisting of a single strand of negative-sense RNA. Two other virus-specific proteins (C and V) found in infected cells, but not so far in virus particles, are termed nonstructural proteins. All morbilliviruses are identical in genetic configuration. In the case of rinderpest, the virion RNA consists of a short 3′ leader RNA (55 nucleotides) followed by the coding regions of the six structural protein genes and ending in a short 5′ trailer RNA (37 nucleotides). There are semiconserved start–stop sequence motifs at the start and end of each gene, and between these is a trinucleotide untranscribed intergenic sequence (usually GAA). Measles, rinderpest and canine distemper viruses have been completely sequenced; measles virion RNA is 15 894 nucleotides long, rinderpest 15 882 nucleotides long and and canine distemper virion RNA slightly shorter, at 15 690 nucleotides.

The two virus encoded glycoproteins, the haemagglutinin (H protein) and fusion proteins (F protein), are embedded in a lipid membrane which is derived from the host cell during budding and this forms the virus envelope. A nonglycosylated matrix protein (M protein) interacts both with the cytoplasmic domains of the envelope glycoproteins and with the nucleocapsids formed within the host cell during genome replication. The M protein is thought to be essential for virus morphogenesis and budding. The newly synthesized virion RNA is surrounded and protected in the cytoplasm by the nucleocapsid (N protein) protein which, in association with the virus polymerase (L protein) and phosphoprotein (P protein), forms the ribonucleoprotein complex (**Fig. 2**).

Replication

The two nonstructural proteins found in infected cells are derived from messenger RNAs transcribed from

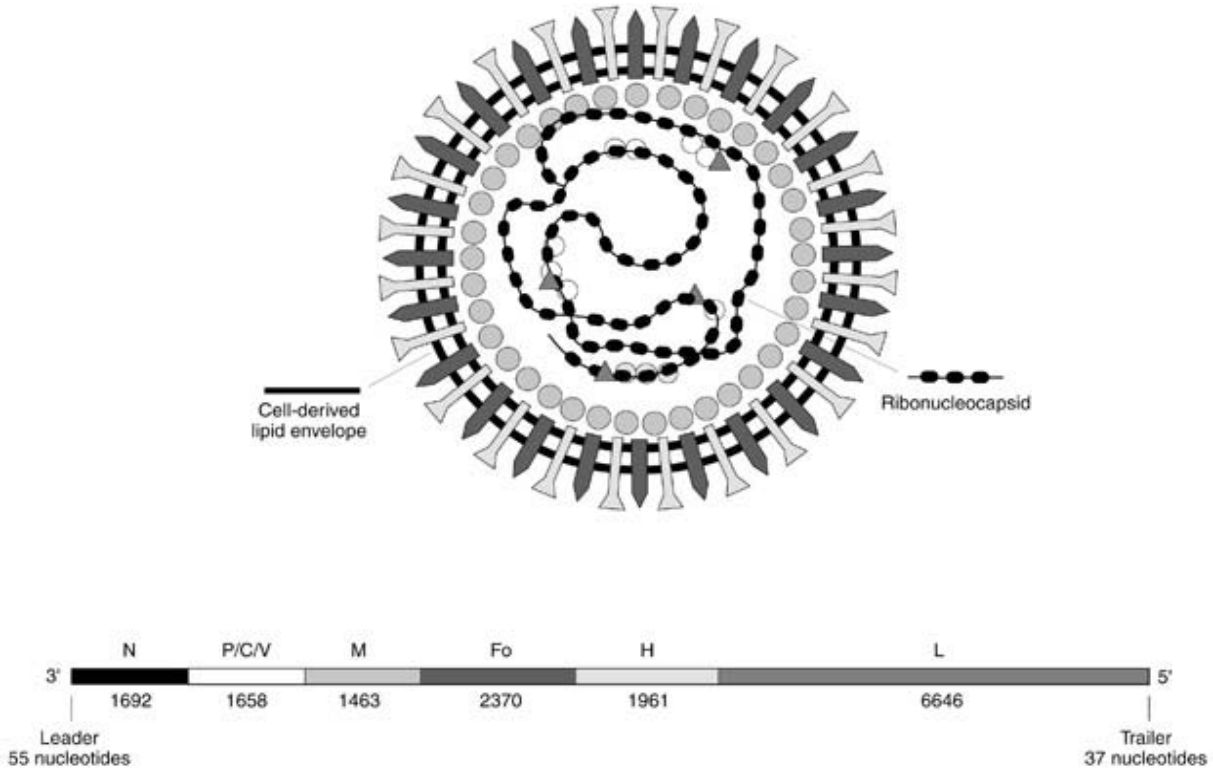

Figure 2 A typical morbillivirus showing the outer envelope with the two projecting surface glycoproteins and the inner helical nucleocapsid containing the virion RNA. The matrix protein is shown underneath the virus envelope. The arrangement of the genes along the virion RNA is shown below.

the P gene. The C nonstructural protein is translated from an alternate reading frame in the phosphoprotein mRNA beginning at the second AUG codon. The V protein is translated from an mRNA which is not an exact copy of the P gene sequence but from one which has an extra G residue inserted about halfway along the gene. This process is often referred to as 'editing' but is more correctly called alternative transcription and is a property of the virus polymerase, as it does not occur in other artificial systems. A conserved sequence motif is found in the region where the insertion occurs. Addition of an extra G occurs in about 50% of the mRNAs transcribed from the P gene in the case of measles and rinderpest viruses and there is evidence that it occurs in all other morbilliviruses. Translation of this mRNA produces a chimeric protein consisting of the N-terminus of the P protein with a new C-terminus, rich in cysteine residues, derived from RNA sequence in the third reading frame. This mRNA is also capable of translating the C protein as its coding region is located in front of the editing sequence position. The functions of these proteins are unknown but they most likely play a part in the control of transcription and replication of the genome RNA.

Evolution

Rinderpest virus

Monoclonal antibody and sequence analyses indicate that rinderpest virus is most closely related to measles virus, and phocid distemper virus to canine distemper virus. The nucleic acid homology between the N genes of phocid and canine distemper viruses is only about 77%. The two viruses are, therefore, almost as different as rinderpest and measles (70% homology) and must have had a long period during which they diverged from a common ancestor. The new dolphin and porpoise morbilliviruses are very closely related to each other, being different strains of the same virus, and are now often referred to as the cetacean morbillivirus. They are antigenically more related to rinderpest and peste des petits ruminants viruses than to phocid and canine distemper viruses but they fall into a distinct lineage group when their sequences are compared with other morbilliviruses (**Fig. 3**).

The exact evolutionary relationship between the different morbilliviruses is unknown but rinderpest has been proposed as the 'archevirus' of the group. Monoclonal antibody reactivities support this conclusion as rinderpest reacts with a broader range of

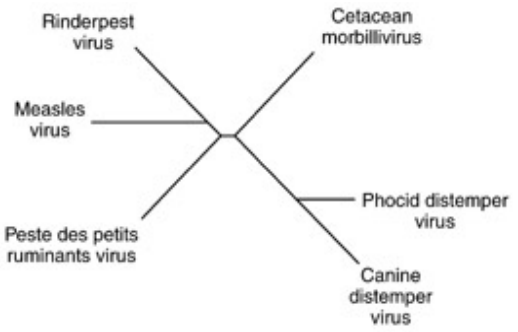

Figure 3 A computer-generated tree showing the phylogenetic relationships between the different morbilliviruses. The tree was generated using the PHYLIP programs to analyze the complete N gene coding region.

monoclonals produced against other morbilliviruses. The fragility of the virus particle and the lifelong immunity following infection (see Prevention and Control) dictate that morbilliviruses have a constant supply of susceptible hosts for their survival. Populations of 300 000 or more are required to maintain measles virus. Animal populations of the required size would most likely have been large herds of ruminants before humans formed sufficiently large settled groups. When cattle were domesticated they could have passed a morbillivirus infection to humans which eventually evolved into measles virus.

Canine distemper virus

Canine distemper virus infects a wide range of carnivores and is maintained by a virus reservoir in a large variety of wild carnivore species. This virus, unlike rinderpest virus, can in rare cases maintain a persistent infection from which the disease can reactivate as old dog distemper. It is conceivable, though less likely, that canine distemper is the progenitor of the group and that predators passed the disease to other nonpredator species, which then evolved into the distinct morbilliviruses. Little is known about the evolution of the morbilliviruses isolated from aquatic mammals. It is possible that seals contracted canine distemper from dogs or other carnivores with which they came into contact while hauling up on land or ice flows to breed. Their relatively close genetic relationship supports this suggestion. In the case of cetaceans the situation is much less clear. They do not come on land to breed and there are not many opportunities for contact with terrestrial mammals. This, and the great genetic distance between the cetacean and other morbilliviruses, indicates that the virus must have been present in cetaceans for a very long time. Pilot whales have been suggested as the most likely species in which the virus is naturally enzootic, as they are present in relatively large numbers and serological studies have shown a high prevalence of morbillivirus-specific antibodies in this species.

Serologic Relationships and Variability

All viruses in the group are antigenically related – the matrix, fusion and nucleocapsid proteins being the most highly conserved across the group. In fact, immunity induced to the F protein may be responsible for the strong crossprotection seen after vaccination with heterologous virus. Rinderpest vaccine is routinely used to vaccinate against peste des petits ruminants virus, and inactivated canine distemper virus vaccine has been shown to protect seals against infection with phocid distemper virus. It has also been shown experimentally that measles virus can protect dogs against distemper and cattle against rinderpest, and that distemper virus can protect humans against measles. This has no epidemiological significance as the viruses do not naturally crossinfect. The H protein, responsible for attachment to the host cell receptor, is the least conserved and least crossreactive morbillivirus protein. In immunoprecipitation reactions only the H protein fails to crossprecipitate with heterologous antisera, although some one-way precipitations are seen, e.g. measles antiserum will precipitate canine distemper H but not vice versa. Strain variations within each virus group can be readily demonstrated using monoclonal antibodies but these variations do not result in different serotypes for each virus.

Epizootiology

Rinderpest virus

Traditionally, rinderpest outbreaks follow wars and civil disturbance where there is unrestricted movement of people and troops with live food animals which can carry the virus. Recent outbreaks in Lebanon, the Middle East and Sri Lanka follow this pattern. The outbreak in Sri Lanka in 1987 was seen after a 40 year span free from the disease and the likely source was live goats brought from India with the troops and traded locally. More recently rinderpest reappeared in Turkey as a consequence of the Gulf war.

Rinderpest and peste des petits ruminants viruses are normally introduced into an area by importation of live infected animals from an enzootic area. Transmission by infected meat is very rare and considered to be a low risk. The most dangerous sources of virus are subclinically infected animals. Subclinically infected pigs act as a source of virus for

cattle. Sheep, goats and possibly other small ruminants can be infected with rinderpest virus and pass the infection to cattle. Experimentally this has been shown to occur with Asian strains of rinderpest virus which readily infect small ruminants. In contrast, African strains of rinderpest do not appear to productively infect sheep and goats. Another factor which may be important in the maintenance of rinderpest is the presence of strains which cause mild or subclinical infections in some enzootic areas. The incubation period for these viruses can be up to 15 days and this, along with their low transmission rates, means that they can persist unnoticed for many years in cattle populations. It is possible that the disease may flare up clinically when animals are put under stress, such as when they are moved to markets. In Africa the situation is also complicated by the presence of large numbers of susceptible wildlife species which can help spread the virus in an uncontrolled manner. Wild ruminants vary greatly in their response to rinderpest infection with species such as buffalo, kudu, eland and warthog (*Phacochoerus aethiopicus*) being highly susceptible, and others such as the hippopotamus (*Hippopotamus amphibius*) and Thompson's gazelle (*Gazella thomsoni*) highly resistant. The epizootiology of rinderpest virus on the two continents is therefore quite different. In Asia there is one known lineage of the virus, while in Africa two distinct virus lineages coexist (**Fig. 4**).

The role of wildlife species in maintaining the disease is unclear. There is no good evidence that wild ruminants act as a reservoir of infection for domestic animals but they may be important in helping to spread disease once an outbreak occurs. To date the evidence suggests that domestic animals are generally the source of infection for wildlife species. The virus was successfully eradicated from South Africa and Tanzania, despite the presence of considerable numbers of wild animals. In fact some highly susceptible wild animals may act as sentinels for the disease, as illustrated by the recent severe outbreak of rinderpest virus in lesser kudu, eland and buffalo in Kenya. The epizootiology of peste des petits ruminants virus and the role wildlife plays in its maintenance has not been studied in any detail.

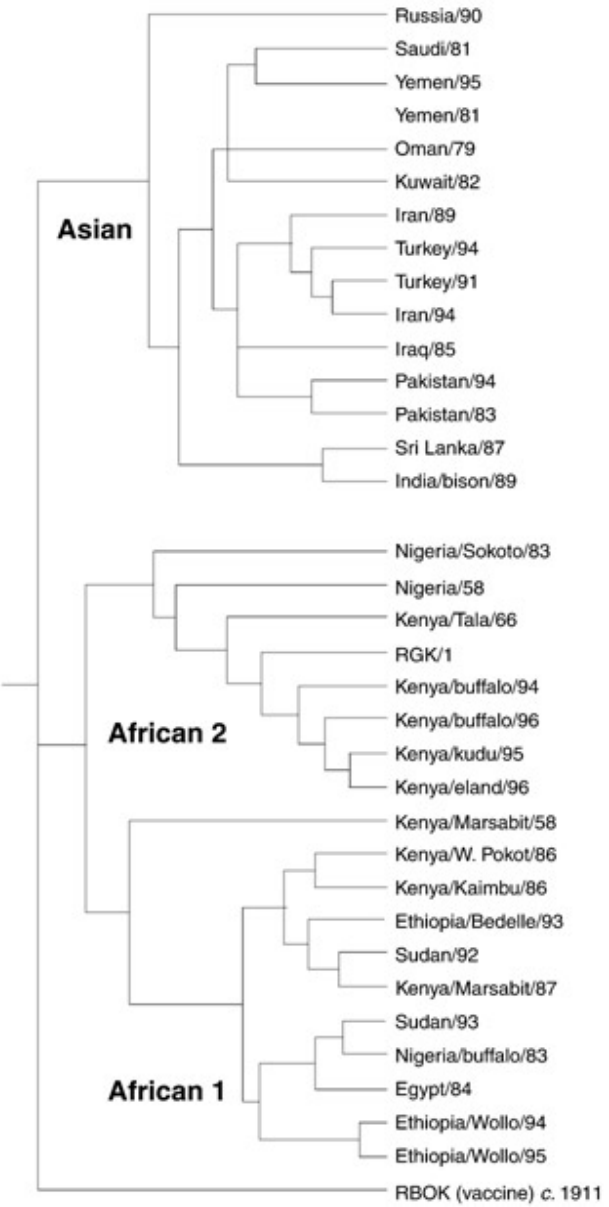

Figure 4 A computer-generated tree showing the relationship between African and Asian lineages of rinderpest virus. The tree was generated with the PHYLIP programs using partial sequence data from the F protein gene.

Canine distemper virus

Canine distemper virus is enzootic in wild carnivores and it remains a problem in poor urban areas where there are many stray dogs and vaccination is not carried out rigorously. The virus is also an important factor in the ecology of wild animal populations. The last free-living population of black-footed ferrets in Wyoming was almost wiped out by a canine distemper infection. The recent canine distemper outbreak in free-living lions in the Serengeti and in captive lions, tigers and panthers in zoos in the USA indicate that it must now be considered a threat to these species. As noted previously, canine distemper and a closely related phocid distemper virus have recently been isolated from several species of pinniped. Such a serious disease could have a devastating effect on small populations of rare sea mammals, such as that of the monk seals (*Monachus monachus*) in

the Mediterranean Sea and the Atlantic Ocean or in the Siberian seals in Lake Baikal. It is important to monitor these species for signs of infection and possibly vaccinate those taken into seal sanctuaries with safe subunit vaccines. The epizootiology of phocid distemper virus is poorly understood. Analysis of historic sera from Canadian harp seals and arctic ringed seals indicated that they were infected with a morbillivirus several years before the appearance of phocid distemper along the coasts of northern Europe. It has been suggested that climatic changes caused the harp seals to migrate further south, so passing the infection to other seal species which lacked herd immunity to the virus and as a result suffered a severe epizootic.

Transmission and Tissue Tropism

Morbillivirus transmission is by direct contact with secretions or excretions of infected animals. The morbilliviruses are highly contagious: all discharges can carry the virus. However, since the virus is extremely sensitive to environmental factors, such as heat, sunlight and chemical inactivation, it requires close contact with an infected animal for successful transmission. It is therefore relatively easy to control by regulating animal movements, in conjunction with a strict quarantine and slaughter policy where necessary. Even without the availability of vaccines rinderpest was successfully controlled and eliminated from Europe by these means.

The morbilliviruses are highly lymphotropic and cause a transient immunosuppression in infected animals. The more virulent strains of the virus also have a strong tropism for epithelial tissues and this helps the spread of the disease by contact, as high titres of virus are then excreted. Mild strains do not replicate so readily in epithelial surfaces and so are more difficult to transmit by contact. With the exception of rinderpest and peste des petits ruminants, morbilliviruses are known to infect brain cells, where they can set up persistent, eventually fatal, infections.

Pathogenicity

Although there is only one serotype of each virus, differences between isolates can be shown using monoclonal antibodies, and strains also vary in their ability to cause disease in infected animals. In the case of rinderpest, extreme variation in pathogenicity has been reported, ranging from the mild strains currently circulating in eastern Africa to highly virulent strains, such as those found in the Middle East, which can cause 90–100% mortality in susceptible hosts.

Variation in the severity of clinical disease and neurotropism have also been reported with different strains of canine distemper, which are known as 'biotypes'. Very little is known about the pathogenicity of the marine morbilliviruses. Different hosts are known to have different susceptibilities, as evidenced by the greater number of deaths in harbor seals relative to gray seals during the European seal epizootic in 1988. Likewise, pilot whales show a high level of seropositivity to cetacean morbillivirus but only dolphins and porpoises were severely affected during the epizootic in the Mediterranean Sea in 1990–1991. However, because of the immunosuppressive nature of morbilliviruses, secondary bacterial and concurrent parasitic infections can greatly influence the outcome of the disease and it is sometimes difficult to assess the contribution of virus infection. Nothing is yet known concerning the molecular basis of pathogenicity in morbilliviruses.

Clinical Features of Infection

Rinderpest virus

Typical rinderpest is an acute febrile disease, with mortality reaching close to 100% with some of the most virulent strains of rinderpest virus, such as the Saudi/81 strain. The course of the disease is divided into five stages: after a short (1) incubation period of 3–5 days, the (2) prodromal phase is seen in which there is a rapid rise in temperature. This is followed by the (3) mucosal phase in which severe mouth lesions are seen and there is a copious nasal and ocular mucopurulent discharge. The affected animals become depressed and anorexic and on postmortem examination many lesions are seen throughout the digestive and lymphatic system. This is followed by the (4) diarrheal phase where there is severe bloody diarrhea, the animal is prostrated and dies from dehydration and weakness. In nonfatal cases there follows the (5) convalescent phase which may take many weeks and during which pregnant animals may abort. Some strains, such as those prevalent in Eastern Africa, are generally mild and there may be no clinical signs in many cases, even though the animals seroconvert. With the mild strains the incubation period can extend up to 15 days.

Clinically peste des petits ruminants virus infection closely resembles rinderpest. There is an incubation period of 4–5 days, then a rise in temperature followed by nasal and ocular discharges, which can be very severe. Mucosal lesions and severe diarrhea then appear and the animals, in fatal cases, die of dehydration within 6 days of the onset of fever. Bronchopneumonia is a frequent complication.

Canine distemper virus

The incubation period for canine distemper virus is usually about 1 week. There are often two temperature peaks, the second corresponding with other signs such as nasal discharge, conjunctivitis and anorexia. As in the case of rinderpest, respiratory and gastrointestinal lesions follow and severe leukopenia is also seen. In some cases central nervous system (CNS) signs, such as convulsions and seizures, are seen as part of the clinical disease, or they may follow a subclinical infection. Recovered dogs frequently show persistent nervous 'ticks' or involuntary movements of one or more legs. Old dog encephalitis is a rare disease thought to be caused by canine distemper virus persistence in the brain and nervous tissue. Seals infected with phocid distemper virus show clinical signs, including CNS lesions, reminiscent of canine distemper infection in dogs, and this gave the first clue to the nature of the etiological agent.

Pathology and Histopathology

Severe morbillivirus infections are accompanied by a marked leukopenia, leading to a deficiency in the immune system. This often results in the activation of latent or other concurrent infections. In addition, secondary bacterial infections are common. These factors may complicate both the clinical and pathomorphological findings. In the case of rinderpest, leukopenia is most marked during the erosive mucosal phase. Histologically the virus shows a tropism for lymphoid and epithelial cells. All lymphoid organs are affected, with the greatest damage occurring in the mesenteric lymph nodes and gut-associated lymphoid tissue; severe destruction of the B and T cell areas is seen. Intracytoplasmic and intranuclear eosinophilic inclusion bodies are commonly found in the cells of morbillivirus infected animals.

Epithelial tissues of the upper respiratory, urogenital and alimentary tracts are also infected by the highly pathogenic, and highly contagious, strains of the virus. In acute rinderpest and peste des petits ruminants infections there is extensive erosive inflammation of mucosal surfaces of the digestive and upper respiratory tracts, with cellular necrosis and the formation of syncytia. Mild strains induce less extensive mucosal lesions and this may account for the reduced ability of these strains to transmit by contact. In the cecum, colon and rectum of animals infected with rinderpest and peste des petits ruminants viruses, so-called zebra or tiger stripes are commonly found. The stripes are caused by greatly distended capillaries packed with erythrocytes. Similar pathological changes are seen in infections with the other animal morbilliviruses. Dehydration in acute morbillivirus infections, the result of profuse diarrhea, causes changes in hematology and blood chemistry. There is an apparent increase in erythrocyte count and the packed cell volume increases by 40–65%. At death the blood is dark, thick and slow to coagulate. In acute canine distemper, phocid distemper and peste des petits ruminants virus infections a serous inflammation of intestinal and respiratory surfaces, associated with interstitial pneumonia, occurs. A nonsuppurative encephalitis is also seen.

Immune Response

There is a strong cell-mediated component in the response to morbillivirus infection. In the case of measles virus, individuals with a genetic defect leading to agammaglobulinemia can quite easily overcome measles infection but immunosuppressed individuals are at extreme risk from the disease. Animals with any detectable neutralizing antibody are considered immune to rinderpest and immunity following morbillivirus infection is lifelong. Either the F or H surface glycoprotein can confer immunity to disease, as poxvirus recombinant vaccines, expressing either the H or F proteins of rinderpest virus, are protective. Similar observations were made in animal model systems in the case of measles virus. In addition, it was found that vaccinia recombinants expressing the N protein could protect mice from lethal intracerebral challenge with measles virus, whereas a similar recombinant expressing the N gene of rinderpest virus gave no protection. In contrast, purified H and F antigens are not protective unless presented as immune stimulating complexes in association with Quil A (ISCOM vaccines). ISCOM vaccines are known to stimulate cytotoxic T cell responses in animals.

Prevention and Control

Morbilliviruses are extremely fragile; they are sensitive to sunlight, high temperature, low and high pH and chemicals which can destroy their outer lipid-containing envelope. Outbreaks of these viruses are therefore easily controlled by proper quarantine and hygienic measures. There is only one serotype of each virus and, once recovered from the infection, the animal is immune for life. As there is no evidence for a persistent or carrier state in the recovered animals, vaccination is a very effective means of controlling these diseases.

Diagnosis

Rapid and accurate differential diagnosis is the key to success in controlling a morbillivirus outbreak. Identification of the morbilliviruses is generally based on the species in which the disease is seen, e.g. measles in humans, rinderpest in cattle, canine distemper in dogs, etc. However, this is not always accurate as the viruses can sometimes infect unusual hosts and the diseases share clinical signs with other virus infections, so diagnosis can not be based solely on the host and clinical signs. For example, rinderpest and bovine virus diarrhea are often confused, and peste des petits ruminants virus can be mistaken for pasteurellosis or other microbial pleuropneumonias. Laboratory diagnosis, based on either virus isolation or specific antigen detection, is essential to confirm the presence of these diseases. A general morbillivirus-specific antigen detection test, the agar gel immunodiffusion (AGID) test, is currently used in field situations in Africa and Asia but it cannot distinguish between the viruses of rinderpest and peste des petits ruminants. Differential neutralization tests can be used to classify virus isolates but these are time consuming. However, rapid competitive ELISA systems using morbillivirus species-specific monoclonal antibodies, which can distinguish rinderpest and peste des petits ruminants viruses, have been developed for virus antigen and antibody detection. Rapid penside tests for the detection of rinderpest and peste des petits ruminants viruses have been developed based on latex bead technology and specific monoclonal antibodies. These new techniques are now being introduced into countries where these diseases are endemic. The most recent advance has been the introduction of the polymerase chain reaction for specific morbillivirus diagnosis (**Fig. 5**). This technique, in combination with sequence analysis of the DNA produce, has enabled a much more precise analysis of the epidemiology of these viruses in the field.

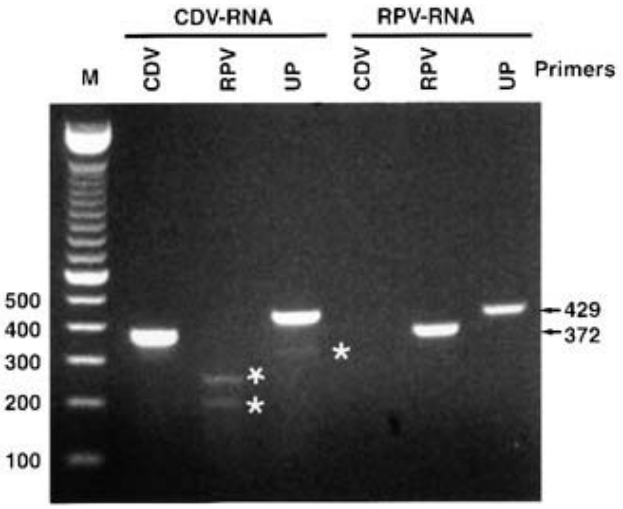

Figure 5 Example of a differential RT/PCR test to distinguish rinderpest (RPV) and canine distemper virus (CDV). Both a universal primer set (based on P gene sequences) and specific primer sets (based on F gene sequences) were used. Nonspecific amplification products are indicated by asterisks.

Vaccination

During the 1930s attenuated rinderpest vaccines were developed by passage of the virus in nonnatural hosts, e.g. rabbit and embryonated eggs (lapinized/avianized) or goats (caprinized). The Japanese lapinized/avianized vaccine was used extensively to control the disease in Asia. In India and Africa the caprinized virus was used; however, this virus was not completely attenuated and it may have been responsible for the circulation of rinderpest in small ruminants in India. In the early 1960s the Plowright tissue culture attenuated vaccine was introduced; it is safe and relatively easy to produce, with no clinical signs following vaccination in domestic animals. In addition, the virus does not replicate at epithelial surfaces and cannot be transmitted by contact. Immunity following vaccination is complete and lifelong. The vaccine is, however, very heat labile and establishment of an effective cold-chain and follow-up seromonitoring to determine the level of herd immunity are essential prerequisites for a successful vaccination campaign. Improvements in freeze-drying techniques have greatly increased the stability of the vaccine in the dry form but it is still very labile when reconstituted and must be used within a very short period.

In the 1960s an internationally funded rinderpest eradication campaign (Joint Programme 15 or JP 15) was carried out in Africa, using the tissue culture attenuated vaccine, and almost succeeded in clearing the disease from Africa. However, political instability, lack of funds to continue vaccination and disease surveillance and the existence of mild strains of the disease resulted in a resurgence in the 1980s. Quite often countries are reluctant to report cases of rinderpest or peste des petits ruminants virus infection because of the repercussions for trade in live animals and this makes the task of controlling outbreaks more difficult. An internationally funded vaccination campaign has been underway in Africa, the Pan African Rinderpest Campaign (PARC), since the mid-1980s and has successfully contained rinderpest virus to eastern Africa. Currently a Global Rinderpest Eradication Programme (GREP) has been established by the United Nations Food and Agricul-

tural Organization in an attempt to eradicate the disease early in the twenty-first century.

Generally rinderpest vaccine is used to control the spread of peste des petits ruminants virus but a homologous vaccine has now been developed and is being field tested in West Africa. The role that wildlife species play in maintaining rinderpest and peste des petits ruminants viruses needs to be more clearly understood before it will be possible to be certain that vaccination of domestic animals alone can eliminate these diseases.

Canine distemper vaccines are not attenuated for all species, and in some, such as the lesser panda (*Ailurus fulgens*), they cause quite severe disease. There are two widely used vaccines for canine distemper virus: the Onderstepoort strain was attenuated by growth in avian cells and the Rockborn strain in canine tissue culture cells. Immunity lasts for several years following vaccination with either vaccine. A less effective ISCOM subunit vaccine (see Immune Response) must be used for nondomestic species, particularly in the case of valuable zoo animals. Since there is a large wildlife reservoir of canine distemper virus and the vaccines are not attenuated for many wild animal species, it may be impossible to eradicate this virus disease.

Future Perspectives

Much research has gone into the development of poxvirus recombinants expressing morbillivirus antigens in an effort to obtain more heat-stable vaccines, which would make them easier to use in hot climates. They have proved to be effective vaccines in short-term protection studies; however, the duration of immunity and the level of protection these vaccines give in comparison with the conventional tissue culture vaccines needs to be established. The most exciting new development in the field of morbillivirus research has been the ability to rescue live virus from DNA copies of their genomes. This technology will enable us to study the molecular mechanisms that underlie pathogenic variation in the morbilliviruses. Identification of attenuating mutations will help in the design and production of safer vaccines. Another great advance will be the ability to introduce genetic markers into the viruses, which will enable vaccinated animals to be distinguished serologically from animals which have been naturally infected. A genetically marked vaccine will be a very valuable tool for GREP in its aim to eradicate rinderpest virus by the end of the first decade of the twenty-first century.

ROSS RIVER VIRUS AND BARMAH FOREST VIRUS (*TOGAVIRIDAE*)

Lynn Dalgarno and **Ian D Marshall**, Division of Biochemistry and Molecular Biology, School of Life Sciences, The Australian National University, Canberra, Australia

History

The first reports of a disease probably caused by Ross River virus (RRV) appeared in 1928, describing epidemics of transient arthritis and rash in two Murrumbidgee River towns on the semiarid inland plains of New South Wales (NSW), south-eastern Australia. During World War II, epidemics of arthritis with rash were described in troops serving in the tropical regions of Australia and on islands to the immediate north. Most of these outbreaks were differentially diagnosed against a background of endemic dengue fever, and published reports allowed the description of a syndrome adequate for clinical diagnosis of the disease, at least during epidemics. Several attempts failed to isolate or define the nature of the causative agent. These wartime reports provided the terms 'epidemic polyarthritis' and 'epidemic polyarthritis with rash' to characterize the disease; although these are still widely used, the noncommittal 'Ross River virus disease' is gaining currency. As fever is usually absent or unremarkable, 'Ross River fever' is inappropriate.

The first large, adequately documented community epidemic occurred in the Murray Valley of south-eastern Australia in 1956, but again two groups of investigators failed to isolate the causative agent. However, following consideration of the epidemiology and nature of the disease, and subsequent serological testing of convalescent sera, it was concluded that a mosquito-borne Group A arbovirus was the most likely candidate, and for several years the Malaysian alphavirus Bebaru was used as a surrogate diagnostic and survey antigen. Eventually, in 1963, the specific alphavirus was isolated from a pool of *Aedes vigilax* mosquitoes collected during dengue investigations near the Ross River at Townsville, coastal north Queensland. The first human isolate was in 1971 from the serum of a mildly febrile 7-year-old aboriginal boy, but, as is usual before puberty, characteristic signs and symptoms did not develop. The final incrimination of RRV did not occur until 1979, when the virus was introduced to Fiji, presumably by a viremic tourist from Australia; RRV was isolated in newborn mice inoculated with the acute stage serum of the indicator case. Numerous isolations were subsequently made during the ensuing series of virgin soil epidemics which, over the next 2 years, extended across the south Pacific from New Caledonia to the Cook Islands. RRV has since been isolated from patients in Australia but only from sera incidentally taken before onset of symptoms (see below).

Over recent years it has become apparent that a significant number of clinically well-defined cases of viral polyarthritis with rash are due to Barmah Forest virus (BFV), which was first isolated from mosquitoes in 1974 (see below). In 1988 BFV was shown to be the causative agent of a disease that is currently regarded as being clinically indistinguishable from that due to RRV infection. Although RRV and BFV are both alphaviruses, BFV has a number of features which are atypical. RRV and BFV are antigenically quite distinct. There have been several epidemics where both viruses circulated concurrently and the causative virus of individual cases was distinguished serologically.

Taxonomy and Classification

RRV and BFV are mosquito-borne arboviruses belonging to the genus *Alphavirus* of the *Togaviridae* family. RRV is a subtype of Getah virus in the Semliki Forest virus (SFV) serological complex. BFV is the sole member of a seventh alphavirus complex.

Properties of the Virion

Purified RRV virions have two glycosylated envelope proteins: E1, the hemagglutinin (molecular mass, 52 kDa) and E2, the neutralizing antigen (49 kDa). The nucleocapsid protein, C, is 32 kDa. RRV is sensitive to chloroform, ether, detergents, ultraviolet irradiation and low pH. The infectivity titre of wild-type RRV is virtually unaffected by incubation in cell growth medium at 50°C for 45 min. Under the same conditions, a mutant of RRV T48 with a deletion of seven amino acids (residues 55–61) in the E2 glycoprotein is thermolabile, showing a three log unit loss of infectivity.

Cryoelectron microscopy and image reconstruction have provided a detailed structural picture of RRV,

the first for an alphavirus. The nucleocapsid (approximately 40 nm in diameter) possesses icosahedral symmetry with a triangulation number (*T*) of 4 and is surrounded by a lipid bilayer (4.8 nm thick). The core structure, at a radius below 17 nm, is composed of both the genomic RNA and the basic, N-terminal domain of the nucleocapsid protein. The surface of the virion is largely protein. There are 240 heterodimers of E1 and E2 assembled into 80 trimeric spikes on the surface. The E1 protein forms the core of the trimeric spike and E2 is found largely on the outer surface. The trimers separate immediately above the lipid bilayer to form a propeller-like, tripartite head; at the end of each heterodimer E1 and E2 appear to separate. Fab fragments from neutralizing monoclonal antibodies directed against E2 determinants bind to one tip of the heterodimer. The spike has a hollow base which may have a role in fusion mediated by an E1 homotrimer. The heterodimers form one-to-one associations with nucleocapsid monomers across the lipid bilayer; this contact is due to the association of the 'cytoplasmic domain' of E2 and the ordered, C-terminal domain of the nucleocapsid protein.

Properties of Genome

The prototype RRV (T48) genome is a single-stranded, positive-sense RNA molecule of 11851 nucleotides excluding the poly(A) tail. The 5′ two-thirds of the RNA encodes the nonstructural proteins (NSPs); the 3′ one-third is expressed as a subgenomic (26S) mRNA which is transcribed from full length negative strands. In the genome, a 5′ noncoding region of 78 nucleotides is followed by an open reading frame (ORF) of 7440 nucleotides which is interrupted after 5586 nucleotides by a UGA termination codon. By analogy with Sindbis virus (SIN), the 5′ two-thirds of the genome encodes two polyproteins. One is NSP1-2-3 (1862 amino acids), and the second is produced by read-through of the 'leaky' UGA codon to generate NSP1-2-3-4. Four in-phase stop codons, three of which are in a region corresponding to the 5′ noncoding sequence of the 26S subgenomic RNA, ensure termination of NSP translation. The 3′ one-third of the genomic RNA has an ORF of 3762 nucleotides which encodes the polyprotein C-E3-E2-6K-E1. The length of the 3′ noncoding region can vary between isolates. For the prototype the length is 524 nucleotides; four closely related sequence blocks, 48–58 nucleotides in length, are found in the 3′ noncoding region of RRV (T48). Deletions, insertions, sequence rearrangements and single nucleotide substitutions are commonly observed in the 3′ noncoding region of different isolates of RRV.

The RRV genome has three regions which are strongly conserved between alphaviruses, including BFV. These are (1) a tract of 23 nucleotides next to the 3′ poly(A) tail; (2) 21 nucleotides at the 3′ terminus of the *NSP4* gene; and (3) 50 nucleotides near the 5′ end of the *NSP1* gene. The genome also contains a moderately conserved sequence element close to its 5′ end. All four sequence elements appear to have roles in the regulation of viral RNA replication. The 23 nucleotide tract is believed to be a promoter for negative strand synthesis; the complement of the 21 nucleotide element may be recognized, in the negative strand, by the 26S RNA transcriptase.

The prototype BFV (BH2193) genome is 11 488 nucleotides long, excluding the poly(A) tail. The 5′ and 3′ noncoding regions are 62 and 445 nucleotides in length respectively. The genome encodes an NSP of 2411 amino acids and a structural polyprotein of 1239 amino acids. The 3′ noncoding region has two unrelated sequence blocks of around 50 nucleotides which are each repeated once. One of these is unrelated to sequences in other sequenced alphaviruses; the other is closely similar to a repeat in the 3′ noncoding region of RRV and Getah RNAs. Thus recombination in the 3′ noncoding region of the RNA of common ancestor viruses may be part of the evolutionary history of these three alphaviruses. SIN, the fourth Australian alphavirus, shows no homology in its 3′ noncoding region with those of RRV/BFV/Getah.

Virus Proteins

Sequence data predict that for RRV, C, E3, E2, the '6K' protein and E1 are 270, 64, 422, 60 and 438 amino acid residues in length respectively, assuming no post-translational trimming. The RRV polyprotein is 75 and 48% homologous with the SFV and SIN polyproteins respectively. The capsid protein is highly basic in its N-terminal half, consistent with a role in interacting with genomic RNA. The N-terminal ten amino acids of E3 are hydrophobic and presumably form part of a signal sequence for the insertion of p61, the E2 precursor, into the host endoplasmic reticulum. Three neutralization epitopes on RRV E2, which together make up a significant antigenic site, have been mapped to residues 216 (epitope *a*), 232 and 234 (epitope *b1*) and 246, 248 and 251 (epitope *b2*). These epitopes are flanked in the primary sequence by asparagine-linked glycosylation sites at residues 200 and 262. This site is important in early virus-cell interactions and in virulence, as judged by biological studies on RRV mutants selected during epidemics (see below), selected during passage in cell culture or mice, or generated using infectious RNA derived from

cDNA clones. The existence of a '6K' protein has not been reported in RRV-infected cells. The hemagglutinin, E1, has an uncharged tract (residues 80–96) which is highly conserved between alphaviruses and may be involved in fusion with cell membranes during virus entry. Comparative sequence data predict that the genomic RNA encodes two polyproteins (NSP1-2-3, the major species; NSP1-2-3-4, a minor species) which are processed to four NSPs of 533, 798, 531 and 611 residues respectively.

Sequence data predict that for BFV (BH2193), C, E3, E2, 6K and E1 are 253, 68, 421, 58 and 439 residues in length. For the NSPs the corresponding figures are 533, 798, 470 and 610. BFV E2 appears to be unique among alphavirus proteins in its relatively low observed molecular mass (43 kDa) and in the absence of *N*-linked glycosylation sites; the molecular mass of BFV E1, which has two glycosylation sites, is high (56 kDa) relative to other alphaviruses.

Replication and Virus Assembly

In cultured vertebrate cells RRV infection is cytopathic. The latent period is 3–5 h; maximum extracellular virus titers (10^8 Vero PFU ml^{-1}) and levels of viral RNA synthesis are at 8–10 h, at which time the shutdown of host cell protein synthesis is virtually complete. Virus-specific RNAs formed in BHK and *Ae. albopictus* cells include RF, RI, 45S, 26S and small amounts of 38S and 33S RNA (conformational variants of 45S and 26S RNAs respectively). Seven major virus-specific polypeptides are detected in vertebrate cells: p127, p95, p61 (E2 precursor), p52 (E1), p49 (E2), p32 (capsid protein) and E3. In Vero cells RRV is commonly found in small cytoplasmic vesicles; 'type 1 cytopathic vacuoles' are observed. There is a pronounced accumulation of nucleocapsids, particularly late in infection. In vertebrate cells BFV replication appears to involve analogous steps to those seen for RRV and other alphaviruses.

In cultured *Ae. albopictus* cells at 28°C RRV generates a non-cytopathic, persistent infection with peak titers (2×10^7 Vero PFU ml^{-1}) at 2–3 days. At 12 and 48 h after infection, 85 and 5% of cells respectively assay as 'infective centres'. Viral protein synthesis is sustained over the period 10–24 h after infection but is quantitatively less than in vertebrate cells; no p95 is observed. There is no shutdown of host protein synthesis, and cell division rate is unaffected by infection. Virus matures within large electron-dense, cytoplasmic inclusions and at the cell membrane. Free nucleocapsids are infrequent. When titers decrease during the later stages of infection, inclusions are transformed into microvesiculated vacuoles which may result from fusion with lysosomal vesicles.

Geographic and Seasonal Distribution

An extensive serological survey of neutralizing antibodies in humans has established that before 1979 RRV occurred only in Australia, the islands of New Guinea, New Britain and the Solomons, with activity in these islands decreasing from west to east. Chikungunya virus was the predominant alphavirus west and north of New Guinea through to south-east Asia. No alphavirus activity was detected in island groups further to the east. Unfortunately the pathogenicity of BFV was not appreciated at that time, and evidence for BFV activity outside Australia has not been sought.

RRV and epidemic polyarthritis occur in every state of Australia. Limited surveys in New Guinea indicate that activity is confined to the lowlands and deep valleys of the central mountain ranges. The south Pacific island epidemics which started in 1979 petered out early in 1981, and there is no evidence that the virus has become enzootic in the region.

RRV infection occurs throughout the year in tropical and subtropical northern regions of Australia, with the highest incidence during the wet season, December to April. In temperate southern regions outbreaks occur mainly in late summer and autumn. Major RRV epidemics occasionally occur in years of flood in the Murray-Darling basin and persist from spring through to the fall. The epidemics are particularly severe in irrigation districts. Frequent localized outbreaks occur in coastal regions of eastern and southern Australia, including Tasmania. Cases have occurred on the fringes of most major cities during periods of increased coastal activity. Brisbane and Perth have experienced infrequent but significant suburban outbreaks.

The prototype BFV strain was isolated from *Cx annulirostris* mosquitoes trapped in February 1974 at Barmah Forest on the Murray River, north-eastern Victoria. It was independently isolated from mosquitoes collected at about the same time near Charleville, southern Queensland. In 1975 it was isolated from *Culicoides* spp collected near Darwin in the Northern Territory. BFV continued to be isolated sporadically in the eastern States, both inland and in coastal regions, but it was not until 1989 that it was recorded in Western Australia (in the far north). BFV distribution appears to coincide with that of RRV at least in eastern and northern Australia. In Western Australia more than 85% of the population is concentrated in the coastal districts of the south-west corner of the state. In and to the south of Perth, RRV is endemic in

the area, with an average of 154 cases annually. In the early spring and through the summer of 1992–1993 RRV appeared to be completely replaced by BFV; 18 BFV isolates were obtained from mosquito pools and there were 22 serologically confirmed BFV polyarthritis cases, the first indication of the virus in the region. The explanation for the apparent replacement of RRV by BFV during this episode is not known. No RRV was isolated from >70 000 mosquitoes tested during 1993, but since then, as in other States, both viruses have been active.

Host Range and Virus Propagation

In the primary cycle the vertebrate host range of RRV is effectively limited to placental and marsupial mammals. There is a lack of specificity in mosquito vector species; the virus has been recovered from 11 species encompassing five genera. Horses are commonly infected, sometimes resulting in lameness and constitutional or nervous disturbances of varying severity; RRV is suspected as a cause of equine death, but proof is lacking. No other domestic or native animal is known to show signs, but naturally acquired antibodies are found in most mammals, and virus has been recovered from macropods and from a horse. Antibodies are rarely found in birds, and, in the laboratory, viremia has been demonstrated only in recently-hatched chickens. It has been concluded that birds are not involved in the primary or amplification cycles for RRV. Viremia has been readily produced in a range of small and large adult marsupial species and in the small native rodent, *Pseudomys novaehollandiae*.

The host range of BFV is not known but limited serological investigations indicate that marsupials are more likely to be the primary hosts than are birds.

Newborn and weanling outbred mice have been the most commonly used experimental host. Many cell lines are susceptible to RRV and are used to prepare stocks, and in virus assay by plaque formation or induction of cytopathic effects. The C6/36 line of *Ae. albopictus* mosquito cells is the most sensitive available cell line, and is now the most common means of recovering RRV from patients and field material. Infection of mosquito cell monolayers cannot usually be visualized by cytopathic effect so they are commonly used together with immunofluorescent detection methods or in conjunction with Vero or BHK cells.

Genetics and Evolution

RRV genetic types and subtypes have been demonstrated from *Hae*III restriction digest profiles of cDNA to virion RNA and by sequencing genomic RNA. The examination of 14 isolates of RRV led to the identification of three genetic types with an estimated 1.5–5% nucleotide sequence divergence between types. RRV is not a bird virus and the relative immobility of mammalian hosts may allow the emergence of geographic variants adapted to local hosts. Based on pathogenicity for outbred infant mice there are a number of variants of RRV with degrees of mouse virulence. The prototype T48, from north Queensland, kills all infant mice in 5–6 days; a Nelson Bay (central coastal NSW) isolate kills 0–25% of infant mice in 10–12 days. There is no evidence for an association between a particular RRV genetic type and vector species.

Sequence studies on the genomes of RRV (T48) (genetic type I), and a strain from Nelson Bay (type III), showed 284 nucleotide differences, equivalent to 2.4% nucleotide sequence divergence. Most of the differences are 'silent'. There are 36 amino acid differences in the NSPs and 12 in the structural proteins, five of which are in E2. The distribution of these differences correlates with the location of nonconserved regions in the proteins of alphaviruses more generally.

Under conditions of natural selection in 'virgin soil' outbreaks the RRV genome is remarkably stable. During the first 10 months of the RRV epidemic in Pacific island communities (1979–1981), involving thousands of infections of humans, domestic animals and mosquitoes, changes in the E2 gene from the sequence seen in the earliest isolate obtained during the outbreak (the April 1979 Fijian strain) were confined to a single nucleotide which altered residue 219 (in the region of an antigenic site; see above). This mutation was first detected in a strain from an American Samoan patient infected in August 1979; there was no further change in the E2 gene in a strain from a Cook Islands patient infected in February 1980. No changes were observed in the 3′ noncoding region of the genome during the entire outbreak.

For BFV, the nucleotide sequence of the E2 gene from 12 isolates (1974–1995) differed by up to 1.7% in pairwise comparisons. The 3′ noncoding region can vary markedly between isolates, as is seen with RRV. BFV (BH2193) pathogenesis in infant mice is inconsistent even within a litter of day-old outbred mice; some will die within 24 h of peripheral inoculation, with high concentrations of virus generated in brain and muscle. Other mice will gradually develop signs and die 6–7 days after inoculation. No evidence has been obtained for differences in pathogenicity for infant mice between isolates.

In comparisons between the sequences of the BFV, RRV and SFV structural and nonstructural polypro-

teins, the percentage amino acid identity is relatively uniform along their lengths. There is therefore no evidence that BFV results from recombination between ancestral viruses in the coding region of the genome. Phylogenetic trees derived from sequence comparisons show that BFV, RRV and SFV arise from a separate evolutionary branch to that giving rise to SIN and the equine encephalitis viruses. RRV and SFV are more closely related to each other than either is to BFV.

Serological Relationships and Variability

RRV shares group- and genus-specific antigens with other alphaviruses. Based on antigenic relationships determined by hemagglutination inhibition (HAI), complement fixation tests and plaque reduction neutralization tests, RRV is in the SFV complex, and is a subtype of Getah virus. BFV shows little crossreaction in complement fixation tests or neutralization tests with RRV, SFV and other alphaviruses, although BFV is clearly related to RRV and SFV at the nucleotide and amino acid sequence levels.

Differences between the surface antigens of RRV geographic variants have been demonstrated with kinetic HAI and kinetic complement fixation tests. Homologous and heterologous virus/polyclonal antibody kinetic tests with RRV strains collected over a period of 13 years in north Queensland indicated antigenic identity. Similarly, strains collected over 3 years at Nelson Bay, NSW were antigenically identical by kinetic tests. However, heterologous kinetic tests between Queensland and Nelson Bay viruses and antibodies gave no crossreaction in HAI and significantly reduced crossreaction in complement fixation tests. The control crossreaction tests using standard incubation times suggested that all virus strains were antigenically identical.

Epidemiology

In Australia, the most important RRV vectors in coastal regions are brackish-water mosquitoes breeding in mangrove or melaleuca swamps. In these habitats *Ae. vigiliax* is the dominant vector in tropical and subtropical coastal regions, but in cooler southerly coastal regions such habitats are shared with or dominated by *Ae. camptorhynchus*. In the inland regions of Australia the major vector is the summer-breeding *Cx. annulirostris*. BFV has been isolated from a range of mosquito species similar to that for RRV in tropical and temperate ecosystems on the Australian mainland.

In Australia, RRV persists in a mammalian wildlife–mosquito primary cycle, probably augmented by a low-level transovarial cycle in *Aedes* mosquitoes. Year-round sporadic cases and the initiation of epidemics are presumably due to mosquitoes that have been infected in the primary cycle. It has now been demonstrated that there is a symptomless prelude of viremia prior to the onset of disease manifestations in Australian patients so that, as in the Pacific islands, a direct man–mosquito–man cycle can develop and accelerate into an epidemic.

Clinical Features and Infection

There are three major manifestations of RRV disease: rheumatic, rash and constitutional. Arthralgia usually develops very rapidly; the most common signs are pain on movement, tenderness and slight swelling. Wrists are most frequently involved, followed closely by knees, ankles and fingers. Elbows, toes and tarsal joints are also commonly affected. Pain is often more intense than indicated by observed signs. Rash occurs in about two-thirds of patients, but is rarely the sole manifestation of the disease. Most commonly it appears as erythematous macules and papules 1–5 mm across, distributed sparsely to thickly on trunk and limbs, and less frequently on face and scalp. Appearance on palms, soles and digital webs is characteristic, particularly when there is no rash elsewhere. Scattered purpura may be found, usually on the feet and lower legs. Except for hyperesthesia of the palms there is usually no discomfort due to the rash, and it resolves within 7–10 days. Pyrexia, one of the most common of the constitutional effects of other virus infections, is usually absent or slight. Myalgia is common, and carpal tunnel syndrome can be induced or exacerbated. Fatigue is the most consistently apparent constitutional effect and seems to be independent of other manifestations. Clinical signs and symptoms of RRV are rarely detected in infected prepubertal children but there is a normal antibody response.

Although diagnostic criteria of 'chronic fatigue syndrome' are difficult to define it seems that, in Australia, RRV infection might now be the most common precursor of the syndrome. In these cases fatigue is usually accompanied by persistent intermittent arthralgia. Such complications are uncommon in patients under the age of 30 years.

Although BFV causes disease in humans with a similar set of signs and symptoms to that caused by RRV, the possibility that BFV is responsible for milder symptoms than RRV has been suggested. Chronic fatigue has not been reported following BFV infections.

Pathogenicity

Differences in the pathogenicity of RRV strains involved in various outbreaks can be inferred from differences in the duration and severity of signs and symptoms, which can range from subclinical to a so-called chronic form. In reports of discrete epidemics there are differences in the incidence, severity and persistence of rash; in the presence or absence of muscle pain; in the average duration of incapacity; in the occurrence of relatively rare signs such as buccal and palatal enanthems; and in the correspondence of disease onset with viremia or antibody production.

By comparison with earlier unsuccessful attempts at virus isolation during outbreaks in Australia, virus isolation from humans was readily accomplished during the Pacific island outbreaks. In successfully isolating virus, investigators used mice, Vero or mosquito cell monolayers or *Toxorhynchites amboinensis* mosquitoes. Differences in the disease profile were also apparent. The incubation period (days from infection to onset of symptoms) was 2–3 days in the Pacific islands, compared with 9–11 days in Australia. The Pacific island patients were viremic for up to 7 days and HAI antibodies were usually detected by day 10; in some cases a brief remission of symptoms occurred after viremia, followed by relapse as antibodies developed. The onset of symptoms in Australian patients usually coincides with antibody production, so the level and duration of the symptomless viremia has not been determined.

Considering the apparent dearth of potential primary cycle mammals on these Pacific islands, it is probable that only an RRV strain which induces a relatively prolonged high level viremia in humans could sustain a 'virgin soil' epidemic for 2 years.

Studies on the molecular basis of RRV virulence for mice have demonstrated the involvement in virulence of a number of genetic determinants including E2, the NSPs and E1. The introduction of the E2 gene from the mouse-attenuated Nelson Bay RRV strain into a cDNA clone of RRV (T48) attenuates mouse virulence. Chimeric viruses have been constructed in which the 5′ and 3′ noncoding regions of the RRV and SIN genomes have been exchanged. Virus containing heterologous 5′ noncoding regions show host-dependent defects in replication; exchange of the 3′ noncoding regions gives rise to virus that grows surprisingly well.

Pathology and Histopathology

In the early stages of RRV infection in humans, cells in the synovial fluid and joint effusions are predominantly mononuclear and remarkable for the proportion of mitotic figures and highly vacuolated and phagocytic macrophages. In later effusions macrophages appear less activated and small lymphocytes predominate. RRV antigen has been detected by immunofluorescence on the surface of 20–30% of the larger cells in synovial fluid during the first few days after onset of symptoms, but attempts to isolate virus have failed. There is no erosion nor permanent damage to joints. In a minority of cases relapses occur over a year or more; these gradually decline in incidence and intensity.

The histology of the rash is variable. The dermis shows a chiefly perivascular mononuclear cell infiltrate, vasodilatation and varying degrees of edema. Diffuse to dense erythrocyte extravasation is quite common. Histologically detectable changes in the epidermis are present in about half the cases, although rarely recognized macroscopically. It is not clear whether rash is due to the direct action of virus or is the result of immunological processes.

Signs and symptoms of epidemic polyarthritis can be confused with those of rubella infection. There is no evidence that RRV is teratogenic, so, if termination is being considered in first trimester pregnant women, it is important to differentially diagnose cases of polyarthritis with rash.

The pathology and histopathology of BFV infection has not been explored.

Immune Response

The detection of RRV and BFV antibodies is now routinely performed by ELISA, although their first appearance can usually be detected several days earlier by standard alphavirus HAI tests. ELISA can also be used in antibody class capture assays to detect IgM, but precautions must be taken to avoid false positives due to the presence of rheumatoid factor, which is not causally present in epidemic polyarthritis. Specific IgM often persists for many months in RRV infection so is not a reliable indicator of recent infection; as with many other arbovirus infections, a rising titer of IgG antibodies from acute to convalescent stages is a more reliable diagnostic tool. Signs and symptoms can persist in the presence of antibodies. It is likely that infection bestows immunity to all genetic types of RRV.

In the laboratory, RRV titers in mice and in macrophage cultures are readily enhanced by low levels of specific antibody. Whether waning levels of antibody can exacerbate a second infection in humans is unknown but should be explored when considering the development of vaccines.

Prevention and Control

As with other zoonoses involving wildlife as vertebrate hosts, particularly those that are vectored by insects, there can be no prospect of eradicating RRV or BFV. A degree of control can be achieved by reducing the interaction of vectors and humans through education, and at the community level by carrying out mosquito abatement programmes appropriate to the district. At the personal level the avoidance of mosquito attack can be achieved by screening windows and doors, remaining indoors during periods of maximum vector mosquito activity, and by the use of efficient repellents.

Vaccination against a disease which is not life-threatening and is without permanent sequelae can only be administered on a request basis. RRV-infected children rarely express signs and symptoms, which, superficially, augurs well for the development of a live virus childhood vaccine. However, little is known about persistence or the nature of immunity after subclinical or frank RRV infection, nor whether the wide range of individual responses to infection, including long-term relapses, is related in any way to the prior immune status of the patient. Before developing candidate vaccines, prospective studies should be carried out to assess the duration of effective immunity following natural infection.

History

Diarrhea was long recognized worldwide as a leading cause of morbidity and mortality, but the search for important etiologic agents of human disease was not fruitful until the early 1970s. Rotavirus was known as a mouse diarrheal pathogen in the 1950s and as a simian and bovine pathogen in the 1960s, but it was not until 1972 that a virus was positively implicated as a cause of human gastroenteritis when Kapikian and coworkers used immune electron microscopy to identify Norwalk virus in diarrheal stools. The following year, investigators in several locations identified rotaviruses in intestinal biopsies and diarrheal stools of children. Rotaviruses are now identified as the leading cause of severe dehydrating gastroenteritis in infants and children. Efficient *in vitro* cultivation of many human rotavirus strains in the early 1980s, followed by the successful cloning of the rotavirus genome and expression of individual rotavirus proteins in recombinant systems, has provided a detailed knowledge of rotavirus structure and function, as well as many aspects of rotavirus serology, immunity and pathogenesis.

Classification

The family *Reoviridae* contains the *Rotavirus* genus and eight other genera. Rotaviruses share several common features that form the basis of the classification. Viral particles are approximately 102 nm in diameter (including surface spikes) and consist of two protein capsids surrounding a central protein core that contains the genome (designated as a 'triple-layered' particle). The extracellular icosahedral particles are not enveloped by a lipid membrane. Ten monocistronic and one bicistronic genomic segments form the organization of double-stranded RNA. The negatively stained electron microscopic appearance of the complete rotavirus particle is responsible for the name *rotavirus*, which derives from the Latin word *rota*, meaning wheel. The outer capsid appears as a sharply defined rim, to which spokes appear to radiate from a large central hub. Recent advance in cryo-electron microscopy with computer-enhanced reconstructed images has provided a more detailed view of rotavirus structure (**Fig. 1**). Notable features include the presence of spikes on the outer capsid that extend over 10 nm and pores that penetrate from the virion surface into the viral genome. These channels may permit importation of metabolites required for viral RNA transcription and export of the nascent RNA transcripts for subsequent viral replication processes.

Geographic and Seasonal Distribution

Rotaviruses are ubiquitous among humans and many animal species throughout the world, and are usually important causes of gastroenteritis wherever they occur. Human rotavirus illness predominantly occurs in the cooler months in developed countries, peaking in January and February, while it is an unusual cause of gastroenteritis in the summer months. Rotavirus infections in the USA occur in a wave, starting in the Southwest in November and spreading on to New England and the Canadian Maritime provinces in March. This seasonality does not occur in tropical climates (10° latitude from the equator) where rotavirus infections occur throughout the year.

Host Range and Virus Propagation

Rotaviruses are recovered from diarrheal stools shed by a multitude of animal species. As an indication of the breadth of the host range of group A rotaviruses, infection in species other than human occurs in simian, equine, porcine, canine, feline, lapine, murine, bovine, ovine and avian, although rotavirus is not an important cause of disease in all of these species. Among laboratory animals, group A rotaviruses do not infect guinea pigs or rats, although group B rotaviruses infect the latter. Animal strains, even those with serotypes indistinguishable from human strains, rarely infect humans. Recently, a few human rotavirus isolates have been described that are probably derived from feline, canine, bovine or porcine rotaviruses. The potential of animal rotavirus reservoirs as a source of genetic diversity for the evolution of new human strains is unknown.

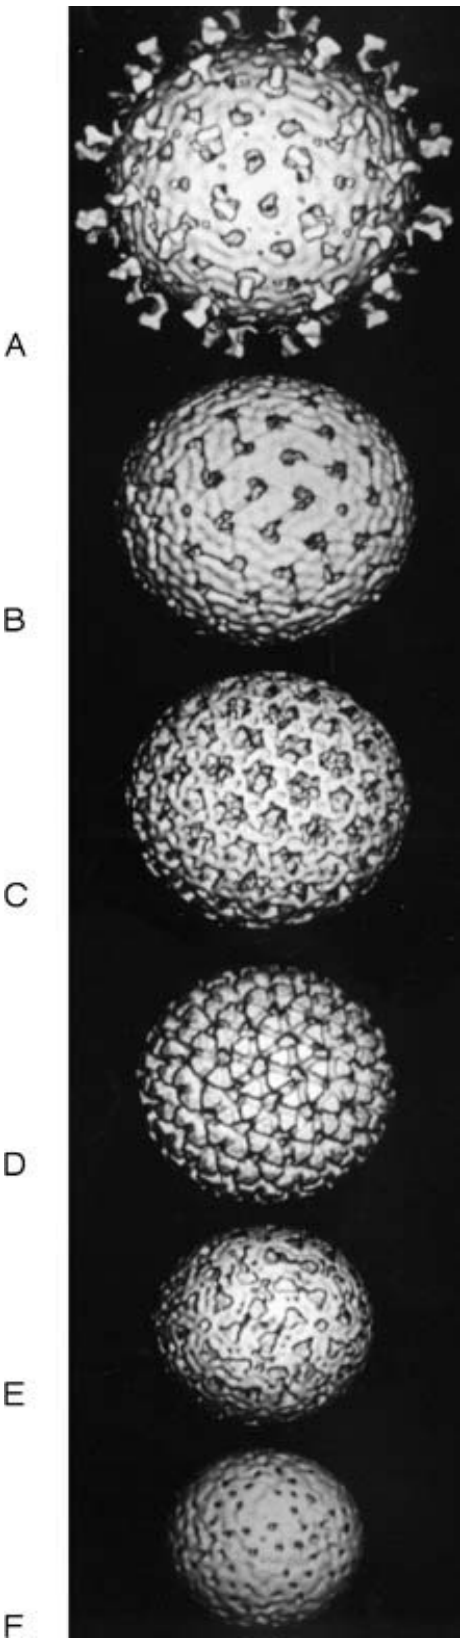
Rotaviruses were first propagated *in vitro* in 1963, when Mahlerbe and coworkers reported the isolation of simian SA11 from a vervet monkey kidney cell culture. Cultivation of human rotaviruses was not successful until the discovery that trypsin exposure, which cleaves amino acid bonds at three closely spaced sites of the VP4 protein, dramatically enhances virus infectivity in culture. Group B and C viruses are not generally cultivatable, with the exception of several porcine and bovine group C strains. Group A rotaviruses are usually cultivatable in simian kidney cell lines in the presence of trypsin. The most efficiently cultured animal rotaviruses typically yield 10^7–$10^{8.5}$ plaque-forming units (PFU) per milliliter in tissue culture systems. Human viruses tend to produce one to two orders of magnitude fewer PFU in tissue culture, although they are often shed in diarrheic stools in quantities of 10^9–10^{10} particles per milliliter.

Genetics

The double-stranded RNA (dsRNA) segments of the rotavirus genome have masses between 2×10^5 and 2.2×10^6 Da. The genes distribute by size into four classes that produce a characteristic pattern (the 'electropherotype') when separated by polyacrylamide gel electrophoresis. Electropherotype classification of rotaviruses was particularly important before *in vitro* cultivation of human rotaviruses. The wide variability of electropherotypes and the observation that serotypes and electropherotypes do not correlate well has decreased the importance of this technique in classification. However, some epidemiologic studies continue to use electropherotypes for detection and characterization of rotavirus, and it is still a useful technique for detection of non-group A rotaviruses.

Rotavirus RNA lacks 3′-terminal polyadenylated sequences and contains 5′-capped structures. Both ends of each segment contain short highly conserved regions of approximately eight nucleotides. These highly conserved sequences may be of importance in transcription, replication and assortment of the virus genome. These features are also characteristic of other *Reoviridae*.

The RNA itself is not infectious; rotaviruses contain within the double-layered particle an endogenous RNA-dependent RNA polymerase that tran-



scribes the gene segments into mRNA. Transcripts are full-length positive strands from which negative-strand synthesis occurs following the formation of replicase particles in the cytoplasm. RNA transcripts can be identified 3 h postinfection. The proteins and structural requirements of RNA replication are not fully understood. Reassortment of gene segments occurs at high frequency during mixed infection with two or more rotavirus strains, although, unlike influenza, there is no evidence that this is a mechanism for generation of serotypic diversity in nature.

Gene-coding assignments for group A rotavirus genes have been clearly established as follows. Genes 5, 7, 8, 10 and 11 code for nonstructural proteins, which were originally designated by the prefix 'NS' followed by the molecular mass, but are presently known as 'NSP' 1–5. The gene product of genes 5 (nonstructural protein NSP1) seems to have a role in the early stages of virus assembly. The gene 7 product (NSP3) has been detected in infected cells in association with complexes containing replicase activity and has specific RNA-binding function, but little else is known. The gene 8 product (NSP2) is associated with replicase activity but has a poorly defined function. NSP4, coded by gene segment 10, is a membrane-associated glycoprotein which plays an important role in viral assembly, in which the protein serves as a receptor for VP6 in the endoplasmic reticulum. In addition, NSP4 has been implicated in diarrheal pathogenesis (see below). NSP5, coded by gene segment 11 is a phosphoprotein of unknown function coded by gene segment 11. Genes 1–4, 6 and 9 code for structural proteins VP1–4, 6 and 7, respectively (in most group A viruses). VP4 and VP7 are the two

Figure 1 Three-dimensional structure of rhesus rotavirus by cryoelectron microscopy and icosahedral image reconstructure (Yeager *et al* (1990) *J. Cell Biol.* 110: 2133). The surface-shaped representations were obtained by truncating the three-dimensional maps with spherical envelopes to reveal the internal structure. The six structures from top to bottom with their corresponding diameters (in parenthesis) are as follows: (**A**) The virion outer capsid surface displays 60 spikes attributed to the VP4 hemagglutinin (102 nm). (**B**) The smoothly-rippled outer capsid surface attributed primarily to VP7, is perforated by 132 aqueous holes (79 nm). (**C**) The space between the outer and inner capsids forms an open aqueous network that may provide pathways for the diffusion of ions and small regulatory molecules as well as the extrusion of RNA (72 nm). (**D**) The inner capsid has a 'bristled' outer surface composed of 260 trimeric columns, attributed to VP6 trimers (66 nm). (**E**) The VP6 trimers merge with a smooth, inner capsid shell which is perforated by holes in register with those in the outer capsid (58 nm). (**F**) A third protein shell (referred to as the 'core') is thought to be formed by VP1, VP2 and VP3 and encapsidates the dsRNA segmented genome (53 nm).

surface proteins of the virion while VP6 is the major constituent of the double-layered particle.

The electropherotypes of non-group A rotaviruses differ from group A viruses primarily in gene segments 7, 8 and 9. The organization of the non-group A 7–9 genome segments lacks the tight triplet formation in polyacrylamide gel electrophoresis that characterizes the group A electropherotype. Non-group A rotaviruses are morphologically identical to group A strains but they are antigenically distinct and they do not crosshybridize in Northern blot analyses, even under conditions of low stringency. There appear to be at least five (B–F) non-group A rotavirus types. Groups B and C have been identified in humans as well as in animals. Sequence data are now available for several non-group A rotaviruses and this has allowed some gene coding assignments to be made. The development of serologic reagents from expressed viral proteins will extend the understanding of the epidemiology and importance of non-group A viruses.

Evolution

Little is known about the evolution of rotaviruses. While strong similarities in genomic sequences exist among some human and animal strains, there remains little evidence as to the origin of any particular strain. High rates of mutation exist in RNA genomes, and the capacity of the segmented genome to reassort during mixed infections provides theoretical opportunities for rotaviruses to mutate and evolve rapidly. However, during multiple passages in cell culture without the presence of obvious selection pressure, rotaviruses do not appear to change appreciably.

Serologic Relationships and Variability

Six of the viral proteins are structural, but only three have played important roles in the classification of group A rotaviruses by virtue of antigenic or functional properties. Non-group A rotaviruses have not been widely cultivated *in vitro* and far less is presently known about the structure and serologic classification of these viruses. VP6, the major structural protein of the group A secondary capsid, bears most of the common group antigens as well as the subgroup antigens. Rotaviruses that cause most human disease are classified as group A strains but occasionally group B and C also infect humans (see below, Epidemiology). Animal viruses have been classified into groups A–F. Human and animal group A rotaviruses are subdivided into subgroups (I and II) on the basis of serologic reactivity with subgroup-specific monoclonal antibodies directed at VP6. All group A rotaviruses share antigenic determinants on VP6, and some shared epitopes appear to be present on group C rotaviruses as well.

The glycoprotein VP7, the major neutralization protein of the outer capsid constituting 20% of the viral mass, induces serotype-specific neutralizing antibodies. VP4 is the other outer capsid protein, which is only 2% of the viral mass. It is the viral hemagglutinin, an important determinant of virulence, and is the cell attachment protein. VP4 is also responsible for inducing neutralizing antibodies. The contribution of VP4-specific neutralizing antibodies seems to be less important than VP7-specific neutralizing antibodies in hyperimmune sera used in determination of viral serotypes, but evidence delineating the relative roles of these antibodies in natural infections and following vaccination in many species is conflicting. A combined role of VP7- and VP4-specific immunity in the serologic classification of rotaviruses (such as the influenza binary system using hemagglutinin and neuraminidase antigens) has been adopted. In this system the VP7 serotype is classified as a G (glycoprotein) type and the VP4 type as a P (protease) type.

At least 14 group A G types have been identified, 10 of which have been isolated from humans (G1–4 are the major human pathogens worldwide; 8, 9 and 12 have been occasionally recovered from humans; and porcine G5 and bovine G6 and 10 have been recovered from children with diarrhea). Initially, serotyping required tissue culture growth of the viruses in the presence of defined serotype-specific sera, but serotype-specific monoclonal antibodies as well as serotype-specific nucleic acid probes are now readily available and have dramatically reduced the time and expense of the serotyping procedure. A total of 18 P types have been defined by amino acid sequence homologies, including seven in humans (P4, 6, 8, 9, 10, 11 and HCR3). The number of serotypes is steadily increasing as larger numbers of isolates are tested. In some studies, 70–80% of human isolates are either G1P8 or G2P4. Although it is assumed that the serotype classification of rotavirus strains is important in determining immunity to these viruses, the relationship of serotype to protective immunity is not entirely clear. For instance, VP6, the subgroup determinant, has recently been shown to elicit antibodies that mediate intracellular viral neutralization. A VP6 DNA vaccine has also resulted in protection from infection in a murine model, and particles containing only VP2 and VP6 have induced protective immunity in mice and rabbits.

Epidemiology

Group A rotaviruses are the principal cause of severe gastroenteritis in infants and young children through-

out the world, accounting for 12–71% (median 34%) of all diarrheal episodes requiring hospitalization in children under the age of 2 years. In developing countries, the annual toll includes roughly 18 million cases of severe diarrhea and nearly a million deaths. In the USA, over 60 000 children are hospitalized, and about 50 deaths are annually attributed to rotavirus infection.

Infants in the first 2–3 months of life seem to be relatively protected from severe rotavirus disease, probably because of residual maternal immunity mediated by transplacental antibodies. Severe disease is most common among children of 6 months to 2 years of age. Rotavirus infections occur beyond 3 years of age and into adult life but they are typically mild or asymptomatic. However, group A rotavirus may occasionally cause severe diarrhea in immunologically competent adults. Epidemics are known to occur in institutional settings, especially among the elderly in nursing homes, and occasional cases may be fatal.

The epidemiology of rotavirus infections and viral shedding can be monitored by serologic assays or by electrophoretic patterns of viral RNA (electropherotype) obtained from fecal specimens. Electropherotype studies have demonstrated that several genomic patterns may coexist within a community, but these patterns do not necessarily correlate with serotypic classifications. Several serotypes may also coexist within a community, but each season is usually dominated by a single serotype that may vary from year to year. Group A serotypes G1–4 cause most human disease and appear to be equally virulent. These serotypes have been identified in developed and underdeveloped settings and have been in circulation for at least 30 years.

Transmission and Tissue Tropism

Rotaviruses are transmitted by the fecal–oral route, as has been conclusively demonstrated by transmission of illness in human volunteers by oral inoculation of fecal filtrates. Transmission by the respiratory route has been considered but the evidence to support this route is weak. Rapid appearance of antibodies to rotaviruses is noted by 3 years of age in all areas of the world regardless of hygiene. Viral shedding is not always associated with symptoms, and asymptomatic infection occurs frequently in newborn nurseries and daycare centers. The virus is quite stable on environmental surfaces for prolonged periods. These factors complicate efforts to control hospital outbreaks, which are not always successful even if patients are carefully monitored for virus excretion and appropriate control measures are followed.

Rotaviruses replicate within and are primarily shed from mature small intestine epithelial cells located at the villous tips. Recent evidence of rotavirus infection of the liver in a small number of immunocompromised children has demonstrated that infection of other tissues is possible in some rare cases.

Pathogenicity

The genetic correlates of rotavirus pathogenicity have not yet been completely determined. Host range restrictions limit crossinfection between species in most cases. Animal strains have been used as human vaccine candidates as they possess antigenic similarity with human viruses but do not cause disease, except when given in very large doses. Animal rotavirus vaccine candidates appear to replicate in humans at a low level and stimulate local and systemic immunity. All serotypes of rotavirus seem to be equally virulent, although some neonatal strains have been associated with asymptomatic infection. Other studies, however, have indicated that it is the newborn host rather than the rotavirus strain that determines the avirulent phenotype in the newborn.

Clinical Features of Infection

Rotavirus gastroenteritis is seen most commonly in children between the ages of 3 months and 2 years. Asymptomatic infection is common in infants less than 2 months old or individuals older than 2 years, although episodic severe disease in adults may result from group A rotavirus infection. Group B rotavirus infection causes epidemics in older children and adults in China.

In some animal species, illness is strictly limited to the very young. Age-related restriction of rotavirus illness appears to be due, at least in part, to nonimmune mechanisms. The incubation period in humans and most animals appears to be 24–72 h. Malnutrition may increase the severity of the symptoms. In addition to the symptoms listed in **Table 1**, those related to severe volume depletion, such as lethargy, irritability, confusion, and eventually vascular collapse and death, can be seen.

Pathology and Histopathology

The pathologic lesion resulting from rotavirus infection varies somewhat depending on the species and age in question. For instance, porcine rotavirus causes a particularly large amount of cellular damage, whereas murine infection may be characterized by much more selective destruction. Infection of the very young of most species will characteristically produce more cell destruction than infection in adults. Blunt-

Table 1 Clinical features of rotavirus gastroenteritis

Symptom	*Frequency (%)*
Diarrhea	98
Diarrhea >10 times daily	28
Vomiting	87
Vomiting >5 times daily	51
Fever	84
Abdominal pain	18
Blood in stool	1
Hospitalization	39

ing of intestinal villi and vacuolation of enterocytes may be seen within hours after infection, prior to the presence of detectable viral antigen. Also seen are mononuclear cell infiltration of the lamina propria, distended endoplasmic reticulum, mitochondrial swelling and denuded microvilli. Viral particles may be seen within columnar epithelial cells, goblet cells, phagocytic cells and M cells in the small intestinal mucosa (the colon is generally spared). Production of viral antigen in the intestine peaks around 48–72 h postinfection in most species. Large amounts of viral proteins accumulate in the cytoplasm (viroplasm), which may appear swollen and vacuolated. However, some damaged cells may be seen without detectable viral antigen present. Intestinal cellular morphology returns to normal in about 7 days, although much of the damage is repaired as quickly as 3 days after infection.

The mechanism of virus-induced diarrhea is not clear. Lytic infection is not prominent in intestinal cell lines, nor is the histologic damage in the host clearly related to diarrhea. Toxin-like effects have been suggested, as exogenous administration of the rotavirus NSP4 protein has been reported to induce diarrhea in mice, and inactivated rotaviruses that do not cause tissue damage have also been demonstrated to cause diarrhea in mice. NSP4 has been reported to stimulate chloride secretion, but the role of this effect in disease is as yet unclear. Water absorption by the small intestine is impaired, but can be corrected by the administration of glucose–salt solutions. Abnormal motility may contribute to rotavirus-induced diarrhea. Also, carbohydrate malabsorption and secondary osmotic diarrhea may occur. An integrated understanding of the roles of these many factors in the pathogenesis of diarrhea has not yet been achieved.

Group B and C rotaviruses also cause small intestinal lesions in several animal species as well as in humans. Villous blunting is seen in various small intestinal regions. Syncytia including up to 20 enterocytes are seen during group B infection, a finding not observed in group A infections.

Immune Response

The antibody-based immune response to rotavirus infection has been studied in many animals as well as in humans. Serum and mucosal antibodies are detected, beginning several days after primary infection. Cytotoxic T cells have been identified in the intestinal mucosa of mice undergoing experimental rotavirus infection. The rapid resolution of rotavirus diarrhea during an acute infection occurs somewhat before the immune response is fully developed, so at least some of the factors responsible for resolution of the illness may be nonimmune. Immune factors are most likely to have substantial roles in the prevention of subsequent infections, although it is still unclear precisely which factors determine susceptibility to rotavirus infection.

Genetic studies using specific viral reassortants and passive transfer studies using monoclonal antibodies directed at specific rotavirus proteins have demonstrated that antibodies directed at either VP4 or VP7 (but not other rotavirus proteins) can neutralize virus and protect susceptible hosts. However, the bulk of antibodies elicited by rotavirus infection are directed at the major structural protein of the inner capsid VP6 (which constitutes 51% of the viral mass). While antibodies to VP6 may not neutralize virus in the intestinal lumen or in tissue cultures, VP6-specific IgA antibodies may prevent viral replication intracellularly during the process of transcytosis through intestinal epithelial cells. Protective efficacy against infection of IgG antibodies raised in mice following systemic vaccination (including adjuvant) with recombinant proteins assembled into virus-like particles has also been recently shown, despite the absence in the particle of VP4 or VP7. In addition, murine protection appears to be conferred by DNA vaccination with the gene that codes for VP6. Thus, several mechanisms and antigens appear to be capable of mediating protection from infection in animal models. The utility of these mechanisms in vaccine strategies or their role in response to natural infection remains to be determined.

The locations of the amino acid-defined regions of VP4 and VP7 that elicit neutralizing antibodies have been mapped. One large and complex conformationally determined neutralization domain exists on VP7, and at least two domains are found on VP4 (one on

each of the two fragments resulting from trypsin cleavage of VP4, which are referred to as VP5* and VP8*). Most neutralizing antibodies elicited by VP7 are serotype-specific, although at least one epitope is heterotypic and binds antibodies that are broadly crossreactive. VP4 serotypic diversity is still not well understood. There are at least two important neutralization regions on VP4, one on either side of the site of trypsin cleavage (cleavage of this site enhances growth in tissue culture; see above, Host Range and Virus Propagation). The N-terminal fragment, VP8*, contains neutralization sites that are limited to particular strains. The C-terminal fragment VP5* has a domain that is crossreactive among several human strains, and a similarly crossreactive region is shared among several animal strains.

Primary rotavirus infection induces neutralizing antibodies to VP7 and VP4. There is conflicting evidence, in various animal models and in humans, concerning the relative importance of these two groups of antibodies in the establishment of protection against subsequent infections. Prevailing opinion at the present time could be simplified to state that a primary human infection results in predominantly serotype-specific immunity, although heterotypic immunity is frequently detected at lower levels. Individuals gradually establish broader immunity with reinfections, although whether this is due to accumulated diversity of homotypic responses to serial VP7 exposures or a gradual increase in the immune response to the major heterotypic regions on VP4 or VP7, or even VP6, remains unknown.

The complexities of the intestinal immune environment have impaired the development of a complete understanding of the immune response to rotavirus infection and vaccination. The immunological environment of the intestinal mucosa is relatively difficult to monitor, either by serum or intestinal fluid measurements. Animal studies have confirmed that most of the specific antirotavirus antibodies generated in response to infection are IgA, which is secreted predominantly by lymphocytes in the small intestinal lamina propria. It has long been inferred from animal studies that replication of the virus in the intestinal tract was a prerequisite for the development of substantial local immunity. While infectious rotavirus administered directly into the intestinal tract has been demonstrated to be a powerful mucosal antigenic stimulus to specific antibody formation, it is not yet clear that replication is vital; or, if it is, the mechanism by which replication enhances the response is not determined. Furthermore, rotavirus-specific cytotoxic lymphocytes have been identified in the intestinal mucosa following parenteral administration of killed rotavirus. In immunodeficient murine model studies, passive transfer of immune cytotoxic T cells has been shown to prevent acute rotavirus infection and resolve ongoing rotavirus infection.

The mechanisms of rotavirus antigen processing and presentation in the mucosal immune compartment are largely unexplored. Rotaviruses, like many other particulate antigens, including reoviruses, are known to bind to and be internalized by M cells overlying intestinal lymphoid aggregates, at least in a porcine model. The importance of this route of contact with immune cells, as opposed to penetration of virus directly into the lamina propria or presentation of viral antigens by major histocompatibility complex (MHC) class I- or II-bearing enterocytes, is unknown.

Prevention and Control of Rotavirus

Two avenues leading to prevention and control of rotavirus disease are vaccination and oral rehydration therapy. Treatment with oral rehydration solutions containing glucose and electrolytes is highly effective for ameliorating the consequences of rotavirus infection, but there are serious logistical, cultural and educational difficulties limiting the distribution of this treatment resource into underdeveloped areas. Recent evaluations of this approach in the USA suggest that it is underutilized even in a developed setting.

Breast feeding has been advocated as an inexpensive and effective means of rotavirus disease suppression, as breast milk is effective in the reduction of morbidity and mortality caused by bacterial gastroenteritis. However, despite the presence of antirotavirus antibodies in breast milk, there is little evidence that breast feeding can protect against rotavirus infection or serious rotavirus disease.

Vaccination strategies that have been tested have utilized the host range restrictions of animal rotaviruses in a 'Jennerian' approach to disease prevention. For example, simian and bovine rotaviruses have been used as naturally attenuated vaccine strains in children. Field trials demonstrated these vaccines to be safe and immunogenic, and efficacy against severe disease was high in developed countries. Efficacy in underdeveloped countries has been more difficult to demonstrate, although at least one large study showed substantial efficacy. Animal rotaviruses have induced both homotypic and heterotypic protection in some studies, but in other circumstances these vaccines have failed to protect in both developed and less-developed settings. Overall, these findings have been considered encouraging by most authorities, and live attenuated 'Jennerian' vaccines with significant protection against severe disease may soon be

commercially available. However, further investigation may reveal an optimal vaccine strategy that will routinely provide reproducible protective efficacy in all parts of the world.

Future Perspectives

Vaccine strategies currently under consideration are varied. Both nonpathogenic neonatal rotavirus strains and multivalent collections of reassortant rotaviruses that contain human gene 4 segments are presently undergoing intensive testing. One example of the latter has now been approved by the FDA for use in the USA. Vaccines made from synthetic viral proteins or particles administered systemically or enterally are planned or under investigation, but the ability of these constructs to stimulate protective immunity in humans is unknown.

A better understanding of the mechanisms of viral antigen processing and presentation, the determinants of the magnitude and specificity of the antibody and cytotoxic T cell responses and a more precise determination of the mechanisms of naturally-occurring protective immunity may permit a more efficient and effective design for synthetic vaccine products that will elicit sufficiently broad protective immunity.

Properties of the Virion

Rotaviruses are members of the *Reoviridae* and are characterized by a genome of double-stranded (ds) RNA and a nonenveloped icosahedral structure (**Figure 1** also see Plate 31 for color). The rotaviruses were named (from the Latin *rota*, meaning wheel) based on the distinctive morphologic appearance of particles visualized by negative-stain electron microscopy. Virus particles resemble a wheel, with short spokes and a well-defined rim. The virion contains six structural proteins (VP1, VP2, VP3, VP4, VP6 and VP7) that make up a triple-layered protein shell. In the interior of particles, the genomic dsRNA is highly ordered, with about 25% of the genome making up a dodecahedral structure (**Figure 2**). Surrounding the genome is the innermost shell that is composed of VP2. VP2 shells also are called single-layered particles, and two internal proteins, VP1 and VP3, interact with the inner surface of VP2 at the fivefold axes where they are visualized as flower-shaped structures in three-dimensional reconstructions of virus-like particles containing proteins 1/2/3/6. VP1 is the viral transcriptase and VP3 is the guanylyltransferase. The addition of VP6 to single-layered particles results in structures called double-layered particles. These particles possess an active transcriptase activity and mRNAs are extruded from particles at the fivefold axes. The outer protein shell has a rippled surface composed of trimers of a glycoprotein, VP7; dimeric spikes composed of VP4 emanate through the VP7 surface and the base of the VP4 spikes interacts with the inner capsid protein VP6.

Three-dimensional reconstructions of rotavirus particles using images of particles embedded in vitreous ice have provided the most detailed description of particle structure (**Figures 1** and **2** see Plates 31 and 32 for color). The outer shell has a diameter of 76.5 nm, the second shell is 70.5 nm and the inner core shell is 50 nm in diameter. The two outer icosahedral layers have a $T = 13\,l$ symmetry, and the inner shell is composed of 120 molecules of VP2 arranged with a $T = 1$ symmetry. The most distinctive feature of the outer shell is the presence of 60 spikes, at least 10 nm

commercially available. However, further investigation may reveal an optimal vaccine strategy that will routinely provide reproducible protective efficacy in all parts of the world.

Future Perspectives

Properties of the Virion

Rotaviruses are members of the *Reoviridae* and are characterized by a genome of double-stranded (ds) RNA and a nonenveloped icosahedral structure (**Figure 1** also see Plate 31 for color). The rotaviruses were named (from the Latin *rota*, meaning wheel) based on the distinctive morphologic appearance of particles visualized by negative-stain electron microscopy. Virus particles resemble a wheel, with short spokes and a well-defined rim. The virion contains six structural proteins (VP1, VP2, VP3, VP4, VP6 and VP7) that make up a triple-layered protein shell. In the interior of particles, the genomic dsRNA is highly ordered, with about 25% of the genome making up a dodecahedral structure (**Figure 2**). Surrounding the genome is the innermost shell that is composed of VP2. VP2 shells also are called single-layered particles, and two internal proteins, VP1 and VP3, interact with the inner surface of VP2 at the fivefold axes where they are visualized as flower-shaped structures in three-dimensional reconstructions of virus-like particles containing proteins 1/2/3/6. VP1 is the viral transcriptase and VP3 is the guanylyltransferase. The addition of VP6 to single-layered particles results in structures called double-layered particles. These particles possess an active transcriptase activity and mRNAs are extruded from particles at the fivefold axes. The outer protein shell has a rippled surface composed of trimers of a glycoprotein, VP7; dimeric spikes composed of VP4 emanate through the VP7 surface and the base of the VP4 spikes interacts with the inner capsid protein VP6.

Three-dimensional reconstructions of rotavirus particles using images of particles embedded in vitreous ice have provided the most detailed description of particle structure (**Figures 1** and **2** see Plates 31 and 32 for color). The outer shell has a diameter of 76.5 nm, the second shell is 70.5 nm and the inner core shell is 50 nm in diameter. The two outer icosahedral layers have a $T = 13\,l$ symmetry, and the inner shell is composed of 120 molecules of VP2 arranged with a $T = 1$ symmetry. The most distinctive feature of the outer shell is the presence of 60 spikes, at least 10 nm

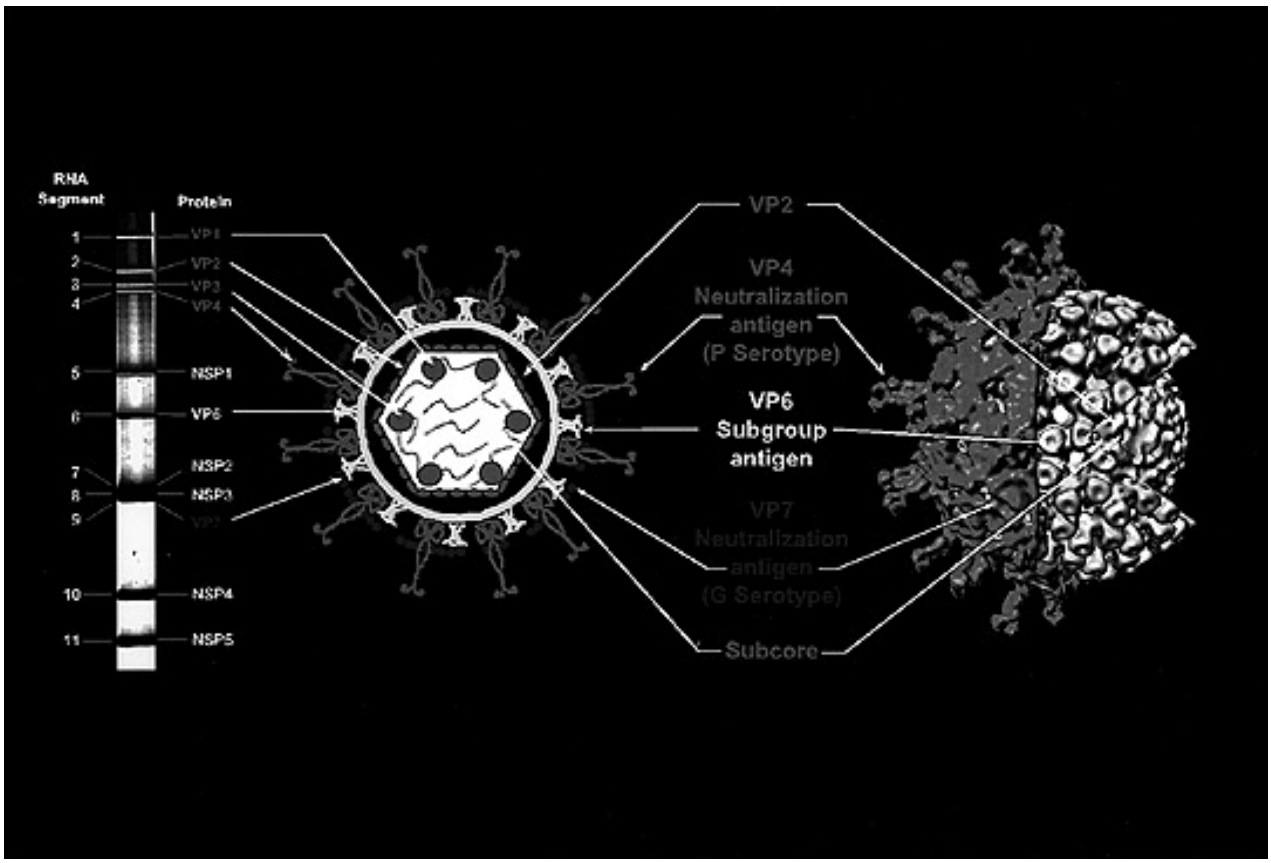

Figure 1 Rotavirus genes, proteins and structure. The left panel shows the RNA segments and the gene coding assignments for the simian rotavirus SA11. See **Table 1** for details on the genes and proteins. The location of the viral structural proteins in the different shells of the virus particles is shown in the schematic in the center. The major structural proteins that make up the outer shell of particles (VP4 and VP7), the intermediate shell (VP6), the inner shell (VP2) and the subcore region composed of ordered viral RNA are illustrated in the ~25 Å three-dimensional structure of particles shown in the right panel. (This reconstruction was kindly provided by B.V.V. Prasad.) **(For color references see Color Plate 28.)**

(100 Å) in length, that extend from the surface of particles. These spikes are made up of dimers of VP4, the protein product of genome segment 4. The spikes are situated at the edge of a subset of three types of 132 channels that lead from the viral surface to the center of the virion. The channels are involved in importing the metabolites for RNA transcription and exporting nascent RNA transcripts for subsequent virus replication processes. The channels at the fivefold axes are the conduits for the export of mRNA that first interacts with the enzyme complexes at the inner surface of these axes. Cleavage of VP4 is associated with enhanced viral infectivity. This proteolytic cleavage results in the appearance of two products, VP5* and VP8*, that both remain associated with virions. Cleavage of VP4 is thought to be important in viral penetration into cells. The VP6 shell has a bristle-like structure composed of trimers of VP6. These trimers have a central indentation and 132 channels lie in register with the channels in the outer capsid.

Properties of the Genome

The sequences of the genome of several rotaviruses (the simian rotavirus SA11, bovine rotavirus RF, and human rotavirus K8 strains) have been determined completely. The following summary of information about the genome is based on data known primarily for the group A rotaviruses, of which SA11 is the prototype strain. The viral genome consists of 11 RNA segments that range in size from 667 (segment 11) to 3302 (segment 1) base pairs, with the total genome containing 18 556 base pairs (**Table 1**). The RNA segments are thought to be encapsidated in association with protein molecules. Each RNA segment encodes one protein, with the exception of gene 11 which codes for two proteins.

Each genomic RNA segment contains a methylated cap 5′ sequence $m^7GpppG^{(m)}GPy$ followed by a 5′ nontranslated sequence, an open reading frame coding for the protein product, another set of noncoding sequences, and ending with a 3′-terminal

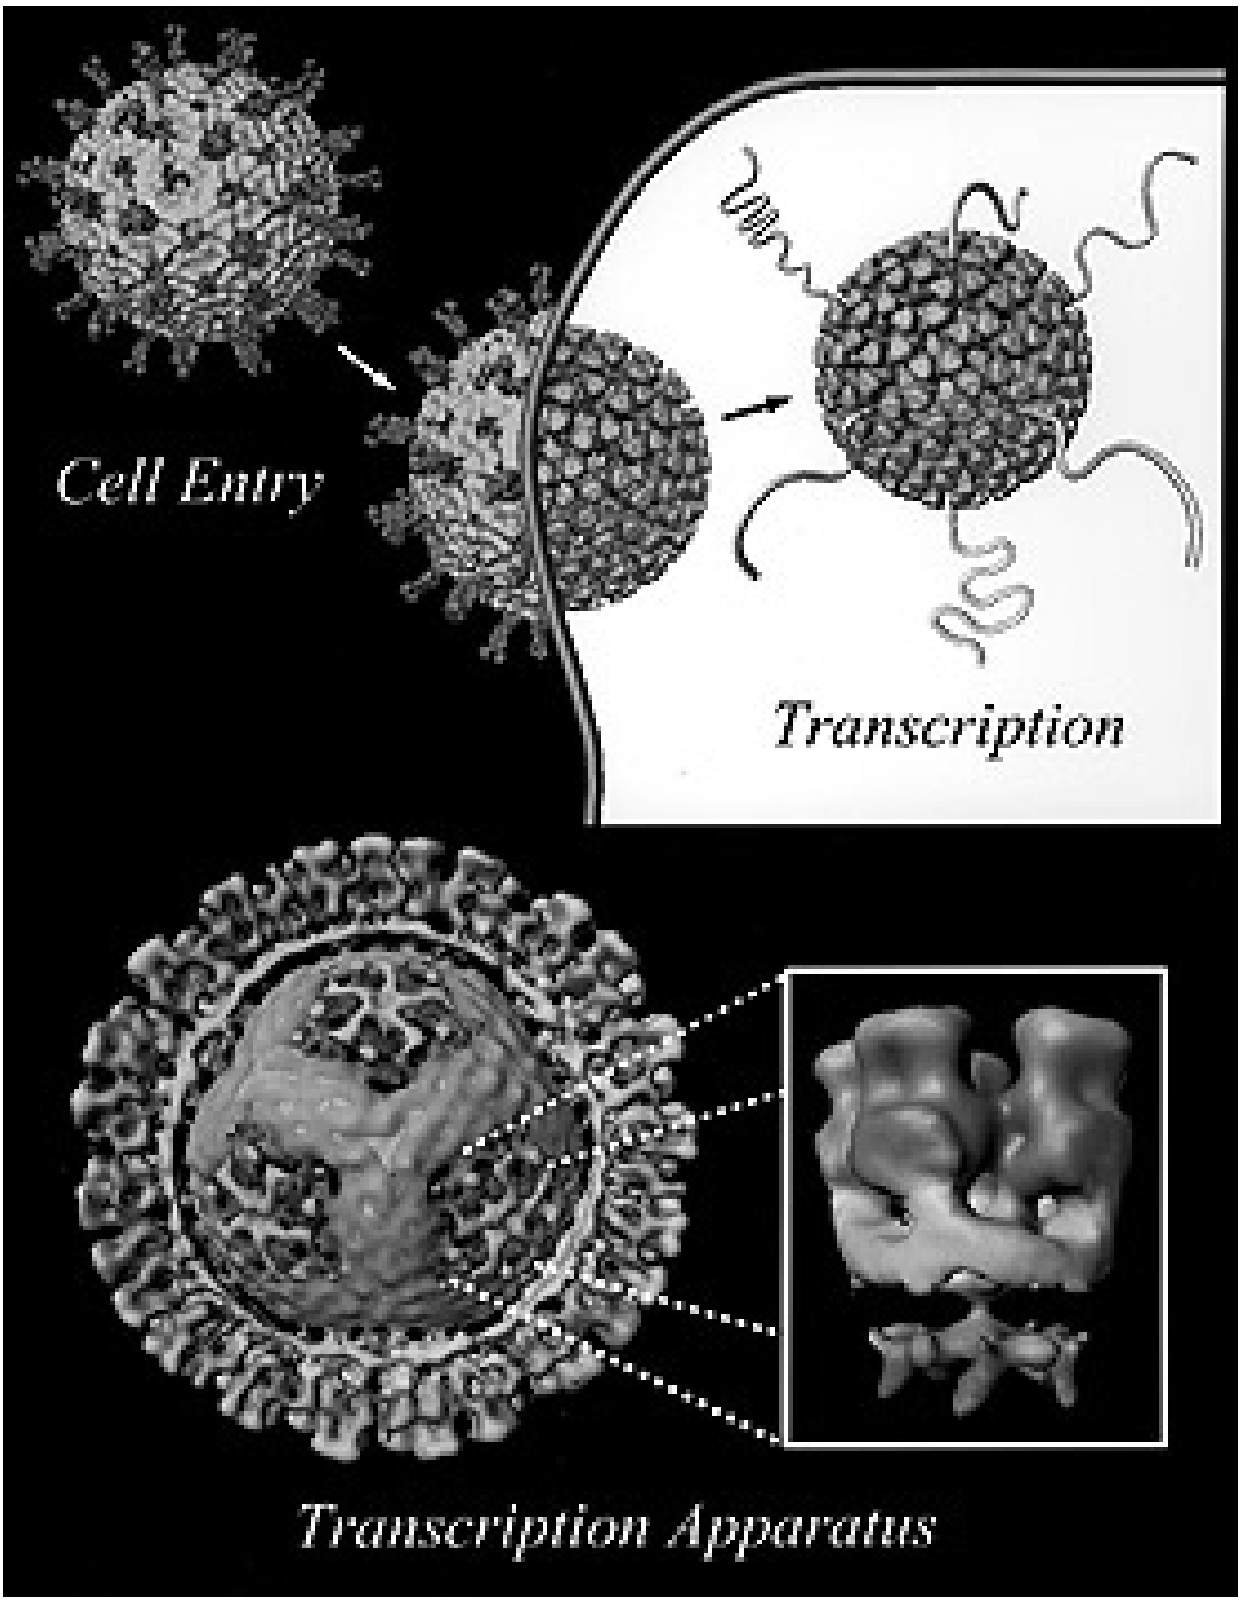

Figure 2 Rotavirus transcription. The top panel illustrates the early changes in rotavirus structure that lead to transcription and release of the mRNA molecules from the double-layered particles. The bottom panel shows the internal structure of rotavirus double-layered particles that are surrounded by trimers of the intermediate shell protein VP6 (blue). The double-stranded RNA genome is organized as a dodecahedral shell inside the particles and the minor internal proteins VP1 and VP3 are organized in a flower-shaped structure at the fivefold axes. The right-hand insert shows a side view of this structure highlighting VP6 (blue), VP2 (green) and the complex of VP1 and VP3 (orange). The newly made transcripts are extruded from these complexes at the fivefold axes (see top panel). (Figure kindly provided by J. Lawton.) (**For color references see Color Plate 29.**)

Table 1 Rotavirus genome RNA segments and protein products[a]

Segment	Number of base pairs	Number of noncoding sequences[b] 5′	3′	Protein product[c]	Nascent polypeptide mol.wt (no. of amino acids)[d]	Mature protein modified	No. molecules per virion[e]	ts mutant group[f]	Remarks
1	3302	18	17	VP1	125 005 (1088)		12	C	Core protein, slightly basic, polymerase

				NSP6	21 000	Phosphorylated		NA	Nonstructural phosphoprotein

[a] For the Group A/Si/SA11 strain. Modified from Estes (1996) and Mattion *et al.* (1994). [b] Number of 5′ noncoding sequences is up to the first AUG; number of 3′ noncoding sequences does not include the termination codon. [c] Determined by biochemical and genetic approaches. The size (in thousands) of the primary translation product is given for the nonstructural (NSP) proteins. [d] Molecular weights are calculated from the deduced amino acid sequences from nucleotide sequence data. The molecular weights are calculated from the largest potential open reading frame. [e] The calculated numbers of molecules of VP2, VP4, VP6 and VP7 are made from predicted structural analyses of individual particles using electron cryomicroscopy. [f] NA indicates none assigned. [g] There are two trypsin cleavage sites in SA11 4fM VP4 at amino acid 241 and 247. The indicated mature products are those based on use of only the preferred second cleavage site. [h] Mature cleaved VP7 contains 276 amino acids.

cytidine. A poly(A) tract is not found in the genomic RNAs and viral RNA transcripts are not polyadenylated. The 5′- and 3′ ends of each genome segment contain terminal consensus sequences of 7–10 nucleotides (nt). These consensus sequences are present in each RNA segment as part of the noncoding sequences. The 5′- and 3′-terminal consensus sequences are unrelated, implying they have functional differences. The terminal consensus sequences are assumed to be important *cis*-acting signals, which presumably include, at the 3′ ends, the viral promoters. The termini are also thought to contain sequences important in packaging and in the regulation of rotavirus gene expression at the levels of transcription, replication and translation. Both the 5′ and 3′ termini have been shown to be important for *in vitro* replication of the genome and they likely interact during translation of the viral mRNAs.

Properties of the Proteins

Descriptive properties of the six structural and six nonstructural proteins are quite well characterized (**Table 1**). Biochemical and antigenic information about the structural proteins is quite extensive, but molecular mechanisms of how these proteins function remain unknown. The two outer capsid proteins (VP4 and VP7) are the proteins studied in most detail because of their expected important roles in virus replication and in the induction of protective immunity. Indeed, VP4 and VP7 each have been shown to induce antibodies with neutralizing activity, and they function to mediate early events (attachment and penetration) in the replication cycle. Virus serotypes are defined based on antigenic properties of VP4 and VP7. VP7 serotypes (also called G for glycoprotein types) now are easily characterized and classified using monoclonal antibodies (MAbs). VP4 types (also called P for protease types) are still being characterized and VP4 typing MAbs are not yet available. VP4 and VP7 also interact with one another in still undefined ways, and these interactions can affect specific biologic and antigenic properties of virions. VP6 is the most immunogenic protein based on the ease of detection of antibodies to this protein following infection, and the most sensitive diagnostic assays are based on detection of this protein or antibodies to it. The minor subcore proteins, VP1 and VP3, are part of the RNA-dependent RNA polymerase activity associated with double-shelled particles. VP1 functions as the polymerase in association with VP3, which is the guanylyltransferase responsible for capping the newly made transcripts. VP2 is an RNA-binding protein that can self-assemble into single-layered particles. It is unclear if VP2 has an active role in the transcription process. VP2 is needed for replication of genomic RNA, and it may be one of the key proteins responsible for the packaging of the nascent RNA segments into newly forming particles in infected cells. VP6 is needed for transcriptase activity. However, it is not known whether VP6 simply functions as a structural component required to keep VP1, VP2, VP3 and the RNA segments in the proper conformation to permit transcription or if VP6 participates actively in the transcription process. Based on electron cryomicrograph studies, it is estimated that particles contain 120 molecules of VP2, 120 molecules of VP4, and 780 molecules of each VP6 and VP7.

The nonstructural proteins, found only in infected cells and not in mature virions, function in the steps of genome replication, mRNA translation and virion assembly. However, the precise role of only two of the nonstructural proteins (NSP3 and NSP4) in these processes is currently clear. Several of the nonstructural proteins involved in RNA replication may function as complexes. The nonstructural protein NSP3 binds specifically to four nucleotides at the 3′ end of viral RNAs and initially was suggested to be involved in RNA encapsidation. While this remains a possibility, recently NSP3 was found to interact with eIF4GI, a human eukaryotic initiation factor, and this interaction has been confirmed in rotavirus-infected cells by coimmunoprecipitation. In addition, the amount of poly(A) binding protein (PABP) present in eIF4F complexes decreases during rotavirus infection, and PABP is removed from eIF4F complexes after incubation with NSP3. These results indicate a physical link between the 5′ and the 3′ ends of mRNA is necessary for efficient translation of viral mRNAs and strongly support a closed loop model for the initiation of translation. These results also suggest that NSP3, by taking the place of PABP on EIF4GI, is responsible for the shut-off of cellular protein synthesis. Thus, NSP3 is involved in a new kind of viral mRNA translational regulation.

The nonstructural glycoprotein NSP4 is a unique protein that functions in the unusual rotavirus morphogenesis pathway that includes the transport of subviral particles across the membrane of the endoplasmic reticulum membrane, and acquisition and subsequent loss of a transient envelope on particles. This process culminates in the assembly of the outer capsid glycoprotein on to particles in the lumen of the ER. NSP4 has been found to have other properties including modulating intracellular calcium levels and chloride secretion. These activities relate to NSP4 functioning as an enterotoxin; NSP4 represents the first viral enterotoxin to be described.

Physical Properties of the Virions

The three forms of particles (triple-layered, double-layered and single-layered) are easily distinguished by electron microscopy and these also can be separated easily by centrifugation in gradients of cesium chloride (CsCl). The physical property of virions used most often to purify virus particles is virion density. In CsCl gradients, virions are relatively stable and viral infectivity is stable to extremes of pH (3.5–9.0). Virion stability is strain-dependent and some strains, particularly human virus strains, may be much less stable than viruses isolated from animals. Studies with reassortants suggest that virion stability during purification and storage at 4°C is determined by a particular gene 4 or its encoded protein VP4, and by specific interactions of VP4 with VP7. The outer capsid proteins can be removed by treatment of virions with chelating agents, such as 10 mM EDTA, or with ethanol, and this results in inactivation of infectivity. VP7 is a calcium-binding protein. In some cases, virus infectivity is less stable when virions contain cleaved VP4. In addition, the VP4 spikes can be removed by treatment of virions at pH 11.2 with ammonium hydroxide; removal of VP4 also may occur during other physical or chemical manipulations such as treatment with organic solvents. The ease of removing the VP4 spikes suggests that most virus preparations are quite heterogeneous and they probably contain many noninfectious particles (that lack a full complement of VP4 spikes). This heterogeneity of virus preparations may explain why early estimates of the approximate percent of each protein in particles determined by biochemical methods did not agree with the calculations made from electron cryomicrographs.

Replication

General features of the replication of rotaviruses are that infectious triple-shelled rotavirions bind to a host cell receptor and virions enter cells by still poorly characterized mechanisms. The outer shell of the virion apparently is disrupted or removed as part of the virus entry process and this allows activation of the RNA-dependent RNA polymerase (transcriptase) activity that is associated with the particles that contain VP1, VP2, VP3 and VP6. The virion-associated transcriptase synthesizes viral messenger RNAs (mRNAs) that are end-to-end transcripts of each of the 11 genome segments. These mRNAs are capped by the virion-associated capping enzyme. The mRNAs subsequently are translated, giving rise to all the viral proteins. The accumulation of viral proteins in the cytoplasm results in the formation of large perinuclear electron dense inclusions, termed viroplasms, that are thought to be the sites of genome replication and the assembly of progeny subviral particles. Subviral particles that contain a subset of newly made structural proteins (VP1, VP2, VP3, VP6) and of nonstructural proteins and mRNAs are apparently formed. Some subviral particles contain an associated RNA polymerase (replicase) activity that uses the mRNAs as templates for the synthesis of minus-strand RNA resulting in the formation of dsRNA. It has been proposed that the replicase particles mature into double-layered particles, and some of these nascent double-layered particles will function as transcriptase particles and synthesize additional mRNAs, thus leading to an amplification of the level of RNA replication in the cell. Other newly-formed double-layered particles associate with regions of the endoplasmic reticulum (ER) containing the nonstructural protein NSP4 and bud into the endoplasmic reticulum. During this process, the particles acquire a membrane that is subsequently lost, while VP4 and VP7 condense around the particles producing the outer shell of protein found on mature virus particles. VP4 probably associates with NSP4 and VP6 prior to the budding of particles into the ER.

Stages of the Replication Cycle

Adsorption, penetration and uncoating

The initial stages of virus replication have been examined by biochemical and morphologic (electron microscopic) procedures and they are not yet completely understood. Only triple-layered particles attach to cells when monitored by electron microscopy or by infectivity assays. Virus attachment is thought to occur via VP4 but VP7 may be involved in this process as well. Binding to cells does not require cleaved VP4 or glycosylated VP7.

The identity of the cellular receptor for rotaviruses appears to be different for different virus strains and cells. Some virus strains bind to cells in a sialic acid (SA)-dependent fashion. A study of the binding of radiolabeled simian rotavirus SA11 (a SA-dependent virus) to monkey kidney (MA104) cells found approximately 13 000 receptor units per cell. Binding is sodium-dependent, pH-insensitive between 5.5 and 8, and is dependent on sialic acid residues in the membrane. Virus binds but is not internalized at 4°C. The SA-dependent porcine rotavirus OSU has been shown to bind to ganglioside receptors NeuGcGM3 and NeuAcGM3 on porcine enterocytes. The SA-independent receptor has not yet been identified.

Many rotavirus strains contain a hemagglutinin, as demonstrated by their ability to bind to red blood cells. The hemagglutination activity has been mapped to VP8*, the N-terminal cleavage fragment of VP4. Studies of virus binding to red blood cells were the first to show that neuraminidase treatment reduces virus binding, indicating a role of SA in virus attachment. SA-containing compounds such as fetuin and mucin also inhibit virus binding to cells. These results add rotaviruses to an increasing number of viruses (such as reoviruses and influenza) that require SA for binding to cells. However, these studies have not determined whether virus binds directly to SA or whether SA maintains the configuration of the binding site without directly interacting with the virus. Binding to SA is not essential for rotavirus infectivity, as most human and animal rotaviruses infect cells in a SA-independent manner.

After binding to susceptible cells occurs, virus is internalized. Rotavirus infectivity is enhanced by proteolysis and this effect is not due to increased efficiency of virus attachment to host cells, but to facilitation of the virus internalization (penetration) step. Internalization will not take place at 0–4°C, indicating that this step requires active cellular processes. All virus is internalized by 60–90 min after binding. The mechanism of internalization (penetration) into cells remains unclear and controversial.

Both morphologic and biochemical approaches have been used to investigate the mode of entry of rotaviruses into cells. Current data indicate that trypsin-treated and nontrypsin-treated virus enter cells by different mechanisms. Nontrypsin-treated virus is thought to enter cells by receptor-mediated endocytosis, while trypsin-activated rotavirus is thought to enter cells more quickly by inducing permeability alterations in the plasma membrane which result in direct penetration of the cell membrane. Either pathway is essential for initiating penetration of the cell membrane but not for further steps in virus infectivity, as double-layered particles that lack the outer capsid proteins are infectious if they are delivered into the cytoplasm of cells by using a facilitator such as lipofectamine.

Other viruses that initiate infection by mechanisms involving receptor-mediated endocytosis often depend on the acidification of endosomes for partial uncoating or entry into the cell. The acidification of endosomes is not important for the entry of rotaviruses into cells. Unlike other viral systems, including reoviruses, lysosomotropic agents (ammonium chloride, chloroquine, methylamine, amantadine) or endocytosis inhibitors (dansylcadaverine and cytochalasin D or the vaculoar proton-ATPase inhibitor bafilomycin A1) have little inhibitory effect on rota virus replication as measured by RNA synthesis, polypeptide synthesis or virus yields. Energy inhibitors (sodium azide and dinitrophenol) have a minimal effect on rotavirus infection suggesting that rotaviruses do not use endocytosis to enter cells. However, it remains possible that these inhibitors (and the conditions tested) specifically affect the cell processes (if any) required for rotaviruses to enter cells.

It seems clear that the passage of rotaviruses from endocytic vesicles to the cytoplasm does not occur by a pH-dependent fusion mechanism, but this does not prove that rotaviruses are not taken up by endocytosis. The most direct support for the idea that rotaviruses enter the cell through direct penetration of the plasma membrane is the demonstration that trypsin-treated triple-layered rotavirus (but not nontrypsinized virus or double-layered particles) causes release of a fluorophore encapsulated within liposomes. A putative fusion region in VP5* has been identified that has sequence homology with Sindbis virus, and it has been suggested that this region might mediate virus penetration into cells. This remains to be demonstrated. It also remains to be determined if the interaction of cleaved VP4 with lipids occurs only at the plasma membrane or if this might occur in the endosome, or during virus morphogenesis (see below). It is possible that more than one mechanism, including endocytosis and direct passage, is operative for rotaviruses, as has been proposed for poliovirus and reoviruses. Recently, internalization of rotavirus or virus-like particles composed of proteins 2/4/6/7, but not of proteins 2/6/7 or 2/6, were shown to be able to induce a rapid and transient coentry of α-sarcin, a toxin that inhibits translation. Studies of the entry of this toxin may be useful to reveal the route used by rotaviruses to traverse the cell membrane and initiate productive infection.

Transcription and replication

The synthesis of viral transcripts is mediated by a viral RNA-dependent RNA polymerase (transcriptase) which has a number of enzymatic activities. The transcriptase is a component of the virion and properties of this enzyme (or enzyme complex) have been inferred by studying the characteristics of products from *in vitro* transcription reactions. Rotavirus particles presumably contain the same enzymatic activities found in reoviruses, including transcriptase, nucleotide phosphohydrolase, guanyltransferase and two methylases. These activities are inferred because rotavirus transcripts made *in vitro* in the presence of *S*-adenosyl methionine possess a methylated 5′-terminal cap structure, m^7GpppGm, and transcription is inhibited by pyrophosphate. Particles also

contain a poly(A) polymerase activity whose precise function remains unknown; it has been postulated to be responsible for the synthesis of oligo(A) molecules.

The virus-associated transcriptase is latent in triple-layered particles and can be activated *in vitro* by treatment with a chelating agent or by heat shock treatment. Such treatments result in removal of the outer capsid proteins with conversion of triple-layered particles to double-layered particles. In infected cells, triple-layered particles have been shown to be uncoated to double-layered particles, and transcription in cells occurs from such particles (**Figure 2**). Transcription is asymmetric and all transcripts are full-length (+) strands made off the (−) dsRNA strand. The intracellular site of transcription is unknown.

Activation of transcriptase activity is a process that is not well understood. 'Activation' may be a misnomer, since in reoviruses it has been suggested this process does not actually modify the enzyme complex but instead releases the templates from structural constraints, allowing them to move past the transcriptase catalytic site. Rotavirus transcription requires a hydrolyzable form of ATP and studies with analogues that inhibit transcription suggest that ATP is required in reactions other than polymerization. ATP may be used for initiation or elongation of RNA molecules, as has been described for vesicular stomatitis virus or vaccinia virus RNA polymerases. It remains unclear if distinct polypeptides in the transcriptively active particles perform distinct functions or if the inner core polypeptides function as an enzymatic complex, but the location of VP1 and VP3 as a structural complex at the fivefold axes favor the latter hypothesis. VP1 has been crosslinked with a photoreactable nucleotide analogue, indicating that VP1 is a component of the transcriptase. VP3 in virus particles and expressed alone in insect cells can bind GTP, suggesting this protein is the guanyltransferase. Whether VP3 also possesses transcriptase activity alone or in association with VP1 remains unclear. Similarly, the role of VP2 in the transcription process is unclear.

The synthesis of plus- and minus-strand RNA has been studied in SA11-infected cells and in a cell-free system. Optimization of an electrophoretic system that allows separation of the plus and minus strands of rotavirus RNAs based on the complementary strands migrating at different rates in acid urea agarose gels facilitated these studies. Analysis of the kinetics of RNA synthesis in infected cells showed that plus- and minus-strand RNAs are detected initially at 3 hours postinfection, in agreement with other studies that looked at the time of incorporation of [^{3}H]uridine into rotavirus RNA. After 3 hours, the level of transcription increases until 9–12 hours, at which time the levels of plus-strand RNAs are maximal. The ratio of plus- to minus-strand RNA synthesis changes during infection and the maximal level of minus-strand RNA synthesis is seen several hours prior to the peak of plus-strand RNA synthesis.

The delay in obtaining maximal plus-strand RNA synthesis has been hypothesized to be due to a requirement for the accumulation of stoichiometric amounts of a protein (e.g. VP6) necessary for the assembly of transcriptase particles. Both newly synthesized and pre-existing plus-strand RNA can act as templates for minus-strand RNA synthesis throughout infection, an unexpected result based on earlier studies with reoviruses. The observation that the level of RNA replication does not increase continually in conjunction with the increasing levels of plus-strand RNA suggests that RNA replication is regulated by factors other than the level of plus-strand RNAs in the infected cell.

The synthesis of dsRNA also has been analyzed using a cell-free system to study the replication of rotavirus RNA. The components of this system include: (1) open core particles prepared from purified double-layered particles or virus-like particles composed of VP1/2/3/6; (2) exogenously added viral mRNA or a synthetic transcript; and (3) salts and nucleoside triphosphates. The *in vitro* replication system does not require the nonstructural proteins and specifically replicates rotavirus templates. The synthesis of dsRNA *in vitro* is an asymmetrical process in which a nuclease-sensitive positive-strand RNA acts as template for the synthesis of negative-strand RNA. After its synthesis, dsRNA remains associated with subviral particles, suggesting free dsRNA is not found in cells.

This *in vitro* system supports the initiation of negative-strand RNA using exogenous viral positive-strand RNA as template. The conversion of exogenous mRNA to dsRNA by subviral particles provides a method of studying (1) the specificity of viral proteins in recognition and replication of rotavirus mRNAs, and (2) the effect of adding exogenous synthetic RNAs containing specific mutations on replication. Finally, the possibility exists that nascent replicated dsRNA can be assembled into these viral particles in this *in vitro* replication system. Unfortunately to date, the efficiency of the system has not been adequate to achieve this goal. Together these results suggest that a cell-free system to support rotavirus RNA replication, transcription and the assembly of subviral particles can be established. This system should be useful to help define the defects in rotavirus mutants and to study the RNA sequences and proteins involved in virus replication and assembly. The role

of individual proteins and specific protein complexes in RNA replication and viral morphogenesis will probably not be solved until they are studied *in vitro* with pure species of native rotavirus proteins and viral RNAs.

The sites and precise details of RNA replication remain unclear. However, electron-dense viroplasms are probably the sites of synthesis of the single-shelled particles that contain RNA. This conclusion is based on the localization of several of the viral proteins (VP2, NSP2, NSP5) to viroplasms and of VP4 and VP6 to the space between the periphery of the viroplasm and the outside of the ER, and on the observation that particles emerging from these viroplasms often seem to directly bud into the ER that contains VP7 and NSP4.

Assembly

The distinctive feature of rotavirus morphogenesis is that subviral particles, which assemble in cytoplasmic viroplasms, bud through the membrane of the ER and maturing particles are transiently enveloped. This is one of the more interesting aspects of rotavirus replication differing from virus members of other genera in the *Reoviridae* family. The envelope acquired in this process appears to be lost as particles move toward the interior of the ER, and it is replaced by a thin layer of protein which ultimately comprises the outer capsid of mature virions.

The sites of synthesis or localization of the viral proteins have been examined by ultrastructural immunocytochemistry using polyclonal monospecific or monoclonal antibodies and by studying the distribution of proteins by immunofluorescence or by subcellular fractionation. Taken together, the morphologic and biochemical data are consistent with rapidly assembling double-layered particles serving as an intermediate stage in the formation of triple-layered virions. Most of the rotavirus structural proteins and all of the nonstructural proteins are synthesized on the free ribosomes, although the nascent proteins on free ribosomes have not been analyzed. Instead, this conclusion has been drawn based on the absence of signal sequences that would indicate targeting to the ER and lack of protection to digestion in *in vitro* protease protection studies. In contrast, the glycoproteins VP7 and NSP4 are synthesized on ribosomes associated with the membrane of the ER and they are cotranslationally inserted into the ER membrane due to signal sequences at their N-termini. The glycoprotein NSP4 is a homotetramer oriented with the C-terminus on the cytoplasmic side of the ER membrane. This cytoplasmic domain of NSP4 acts as a receptor to bind to VP6 on the outer surface of nascent double-layered particles. This binding is thought to be the first step that initiates the membrane budding event.

VP7 is detected in the ER of SA11-infected cells in two pools. One pool is found only on intact particles and is detected only by a neutralizing monoclonal antibody. The second pool of VP7 is unassembled, it remains associated with the ER membrane, and it is detected by a polyclonal antibody made to denatured VP7. A kinetic study of the assembly of VP7 and of other structural proteins into particles has shown the incorporation of the inner capsid proteins into double-layered particles occurs rapidly, while VP4 and VP7 appear in mature triple-layered particles with a lag time of 10–15 minutes. Kinetic analyses of the processing of the oligosaccharides on the two pools of VP7 have shown the virus-associated VP7 oligosaccharides have a 15 minute lag compared with that of the membrane-associated form, suggesting that the latter is the precursor to virion VP7. This lag appears to represent the time required for virus budding and outer capsid assembly. NSP4, VP7 and VP4 also can form hetero-oligomers that are not associated with any known subviral particle; these hetero-oligomers are thought to be present at sites on the ER membrane where maturation to triple-layered particles begins. The proteins of the outer shell apparently are assembled on to the double-layered particles either during the budding process or once the particles reach the ER lumen.

Rotavirus maturation is a calcium-dependent process, based on the observation that virus yields are decreased when produced in cells maintained in calcium-depleted medium. Viruses produced in the absence of calcium were found to be exclusively double-layered, and budding of virus particles into the ER was not observed. Among the viral proteins, reduced levels of VP7 were observed, and subsequent studies showed that such reduced levels were due to the preferential degradation, and not to the impaired synthesis, of VP7. An interesting finding of these studies is that unglycosylated (but not mature) VP7 made in the presence of tunicamycin is relatively stable in a calcium-free environment. It is possible calcium stabilizes or modulates folding or compartmentalization of the newly glycosylated VP7 for subsequent assembly into particles. Alternatively, calcium deprivation may destabilize the ER or ER proteins required for the stable association of glycosylated VP7 with the membrane.

Virus release

Electron microscopy studies of infected tissue culture cells have shown the infectious cycle ends when

progeny virus is released by host cell lysis. Extensive cytolysis during infection and drastic alterations in the permeability of the plasma membrane of infected cells resulting in the release of cellular and viral proteins have been demonstrated. In spite of cell lysis, most double-layered and many triple-layered particles remain associated with the cellular debris, suggesting these particles interact with structures within cells. Interactions with cell membranes and the cell cytoskeleton have been suggested to occur and these may play a role in movement of the viral proteins or particles within the cell. Whether the cytoskeleton provides a means of transport of viral proteins and particles to discrete sites in the cell for assembly or acts as a stabilizing element at the assembly site and in the newly budded virions or if particles are simply trapped by the cytoskeleton remains to be determined. It also is possible that virus may not be released from infected enterocytes because of cytopathic effect and cell lysis. Instead, virus-infected enterocytes may merely be sloughed intact into the intestinal lumen. This possibility has been suggested by studies of rotavirus replication in polarized human intestinal epithelial cells. These cells are infected in a symmetric manner and cell functions are shut off before the development of cytopathic effect and extensive virus release. Recent studies in polarized epithelial cells have suggested that rotaviruses are released from cells by a novel vesicular transport that does not result in extensive cytopathic effects.

Future Perspectives

Future basic research is expected to define the functions of each of the nonstructural proteins in the replication cycle and to understand the mechanisms of RNA replication and genome packaging. This may lead to the ability to use reverse genetics to probe in great detail the functions of any gene and to construct virions with desired properties. Knowledge of the three-dimensional structure of these complex virions is awaited for further understanding of the interactions between the outer capsid proteins and between the proteins in each of the capsid shells.

RUBELLA VIRUS (*TOGAVIRIDAE*)

Teryl K Frey, Department of Biology, Georgia State University, Atlanta, Georgia, USA

Jerry S Wolinsky, Department of Neurology, The University of Texas Health Science, Center at Houston, Houston, Texas, USA

History

Acute rubella virus infection causes a generally benign disease known as rubella or German measles that is usually acquired during childhood. The virus is endemic worldwide and causes epidemics at irregular intervals. First described by German physicians in the eighteenth century as distinct from scarlet fever and

rubeola (measles), rubella only gained international acceptance as a unique disease in the late 1800s. Experimental transmission studies confirmed the viral nature of the disease in 1938. Three years later, Norman Gregg reported an epidemic of congenital cataracts often in association with cardiac malformations as a consequence of gestational rubella; this observation established rubella virus as a major teratogen. Rubella virus was not isolated in cell culture until 1962. The last major epidemic of rubella to impact the United States occurred two years later and the resulting load of 20 000 congenital rubella syndrome (CRS) cases led to rapid development of live-attenuated vaccines which were placed in use in vaccination programs in the US, Canada, Japan, and several European countries by 1969. These programs have been successful in greatly reducing the incidence of both rubella and CRS in these countries. However, since rubella virus is endemic in the rest of the world, it remains a challenge to countries in which vaccination programs are in place. Rubella virus is also of interest due to unique properties in its replication cycle that distinguish its closest relatives and its association with immune-mediated human disease.

Classification

Rubella virus is a member of the *Togaviridae* family and the only member of the genus *Rubivirus*. The other *Togavirus* genus, *Alphavirus*, contains 26 members all of which are arthropod-borne. In common with other togaviruses, the rubella virion consists of a single stranded, plus-sense genomic RNA contained within a quasispherical core or capsid which is surrounded by a lipid envelope. The capsid is composed of multiple copies of a single virus-specified protein, C, and embedded in the envelope are two types of glycoproteins, E1 and E2. Unlike other togaviruses, rubella virus has no invertebrate vector and the only known natural reservoir for rubella virus are humans. Further, rubella virus is serologically distinct from alphaviruses and shares no significant homology at either the nucleotide or amino acid level. Specific features of the genomic organization of rubella virus also distinguish it from the alphaviruses as discussed below.

Host Range and Virus Propagation

Rubella virus has no known natural host other than humans. It has been reported that nonhuman primates and a variety of laboratory animals can be infected with rubella virus, however the extent of viral replication is inconsistent among these reports and no reliable animal model exists for the study of rubella virus pathogenesis. Rubella virus replicates in a number of laboratory cell culture lines, however in most of these no cytopathic effect (CPE) is routinely observed. Primary African green monkey kidney cells (AGMK) were used for the initial isolation of rubella virus and subsequently were recommended as the standard cells for routine isolation of the virus from clinical specimens. Within several days, AGMK cells inoculated with positive clinical specimens exhibit interference with ECHO-11 virus. This interference assay is the classical standard assay for detection of rubella virus, however currently used detection assays generally employ immunofluorescence or polymerase chain reaction for detection of the virus. Continuous cell lines routinely used to propagate rubella virus include Vero (AGMK), RK-13 (rabbit kidney), and BHK-21 (baby hamster kidney). The highest yields of cell-free virus are obtained in Vero cells and these cells also exhibit CPE when infected with laboratory-adapted strains of the virus. In all cell lines in which rubella virus replicates, persistent infections are readily established and maintained. The noncytocidal nature of rubella virus predisposes it to persistent infection. Additionally, the virus persists in spite of the interferon response it induces in most of these cell lines. Finally, persistent rubella virus infection in cell culture cannot be cured by the inclusion of neutralizing antibodies in the culture medium because virus budding occurs at intracytoplasmic locations. Thus, rubella virus is highly adapted for persisting infection both at the cellular level and in the presence of a humoral response.

Properties of the Virion

In cross-section, rubella virions are 60–70 nm spherical particles composed of a 30 nm electron-dense core separated by an electron-lucent zone from the lipid envelope. In negative-stained preparations, virions exhibit a marked degree of pleomorphism. In the best preparations, a 6–8 nm fringe formed by glycoprotein spikes can be observed around the envelope surface, however more commonly protrusions from the enveloped surface are not observable. The virion has a density of 1.18–1.19 g ml^{-1} while isolated capsids have a density of 1.44 g ml^{-1}. The capsid is formed by multiple copies of the C protein (~34 kDa) which is present as disulfide-linked homodimers. Based on the alphavirus model, it is presumed that the rubella virus capsid has icosahedral symmetry, however its three-dimensional structure has never been solved.

The virion spikes are formed by two virion glycoproteins, E1 and E2. E1 has a molecular weight of 59 kDa whereas E2 is a heterogeneous species

ranging from 44 to 50 kDa due to differential glycosylation. Both E1 and E2 are class I membrane proteins with hydrophobic transmembrane sequences near the COOH-terminus and both contain covalently attached fatty acids. Both E1 and E2 contain N-linked glycans and E2 additionally contains O-linked glycans. In the virion, E1 and E2 appear to be primarily in the form of a heterodimer which is easily disrupted by routine preparation techniques. Disulfide-bonded E1–E2 heterodimers and E1–E1 homodimers are also detected. The higher order architecture of the virion spikes is entirely unclear. E1 is more exposed on the virion surface than is E2 and contains both the viral hemagglutinin and receptor site. E1 is also immunodominant in terms of the humoral response, although in most individuals antibodies are induced against all three of the virion proteins.

Rubella virions are stable at physiological pH values and can be frozen for years without loss of infectivity at temperatures below −20°C. Infectivity decays with a half-life of 5–20 min at 56°C, 1–2 h at 37°C, and more than a week at 4°C. The virus can be lyophilized and the vaccine is stored and distributed in lyophilized form. Rubella virions are susceptible to most commonly used inactivating agents, such as formaldehyde, UV light and lipid solvents.

Genomic Organization

The rubella virus genomic RNA is 9762 nucleotides in length and contains a 5′ terminal cap structure and a 3′ terminal poly(A) tract. A distinctive feature of the genomic RNA is that it contains 30% guanine residues and 39% cytosine residues, the highest G+C content of all RNA viruses. The genome contains two long, non-overlapping open-reading frames (ORFs) (**Fig. 1**). The 5′ proximal ORF encodes a 2116 amino acid product that is proteolytically cleaved into two products of 150 kDa (P150) and 90 kDa (P90), which are at the N- and C-termini of the ORF, respectively. The cleavage is mediated by a papain-like cysteine protease located at the C-terminus of P150. P150 and P90 function in virus RNA replication. By computer-assisted comparisons with other viruses, P150 contains a domain predicted to have methyltransferase activity whereas P90 contains both a helicase domain and an RNA-dependent RNA polymerase domain. The 3′ proximal ORF encodes a 1063 amino acid product that is proteolytically processed into the virion proteins by a cell protease, signal endopeptidase. The order of the virion protein genes within the ORF is 5′ C-E2-E1 3′. The SP-ORF is translated from a subgenomic RNA that is synthesized in infected cells. The start site for the subgenomic RNA is in between the ORFs and the subgenomic RNA contains the sequences from the start site through the 3′ end of the genome. An infectious clone for rubella virus has been developed. An infectious clone is a cDNA copy of the viral RNA contained in a plasmid in which it is placed adjacent to an RNA polymerase promoter. Since rubella virus has a plus-sense genome, *in vitro* transcripts from the plasmid will initiate virus replication following transfection into susceptible cells. The infectious clone allows for site-directed mutagenesis studies of the rubella virus genome.

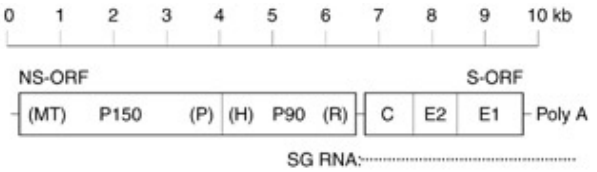

Figure 1 Coding strategy of the rubella virus genome. Shown is a schematic representation of the rubella virus genomic RNA with untranslated regions represented as solid black lines and coding regions (ORFs) as open boxes (NS-ORF, nonstructural protein ORF; S-ORF, structural protein ORF). Within each ORF, the coding sequences for the proteins processed from the translation product of the ORF are delineated and additionally within the NS-ORF, the locations of motifs associated with the following activities are indicated: methyl transferase (MT), protease (P), helicase (H) and replicase (R). The sequences encompassed by the subgenomic RNA (SG RNA) are also shown. The scale at the top of the diagram is in kilobases.

Intracellular Replication Cycle

The receptor for rubella virus on the surface of susceptible cells has not been identified. Following attachment to the receptor, the virus is taken into the cell by receptor-mediated endocytosis. Compared with other enveloped viruses, the time required for internalization following attachment is prolonged, taking as long as 8 h. In the reduced pH environment of the endocytic vesicle, fusion between viral envelope and the vesicular membrane occurs, releasing the capsid and genomic RNA into the cytoplasm of the cell. How release of the RNA from the capsid is accomplished is not known, however there is evidence to indicate that the capsid adheres to the membrane of the endocytic vesicle following fusion and subsequently dissociates.

The genomic RNA is translated to produce the nonstructural protein precursor which is cleaved into P150 and P90 (**Fig. 2**). These proteins then use the genomic RNA as a template for synthesis of a genome-length, minus-sense RNA. Host cell proteins may be involved in the replication process and it has been shown that a specific cell protein, calreticulin,

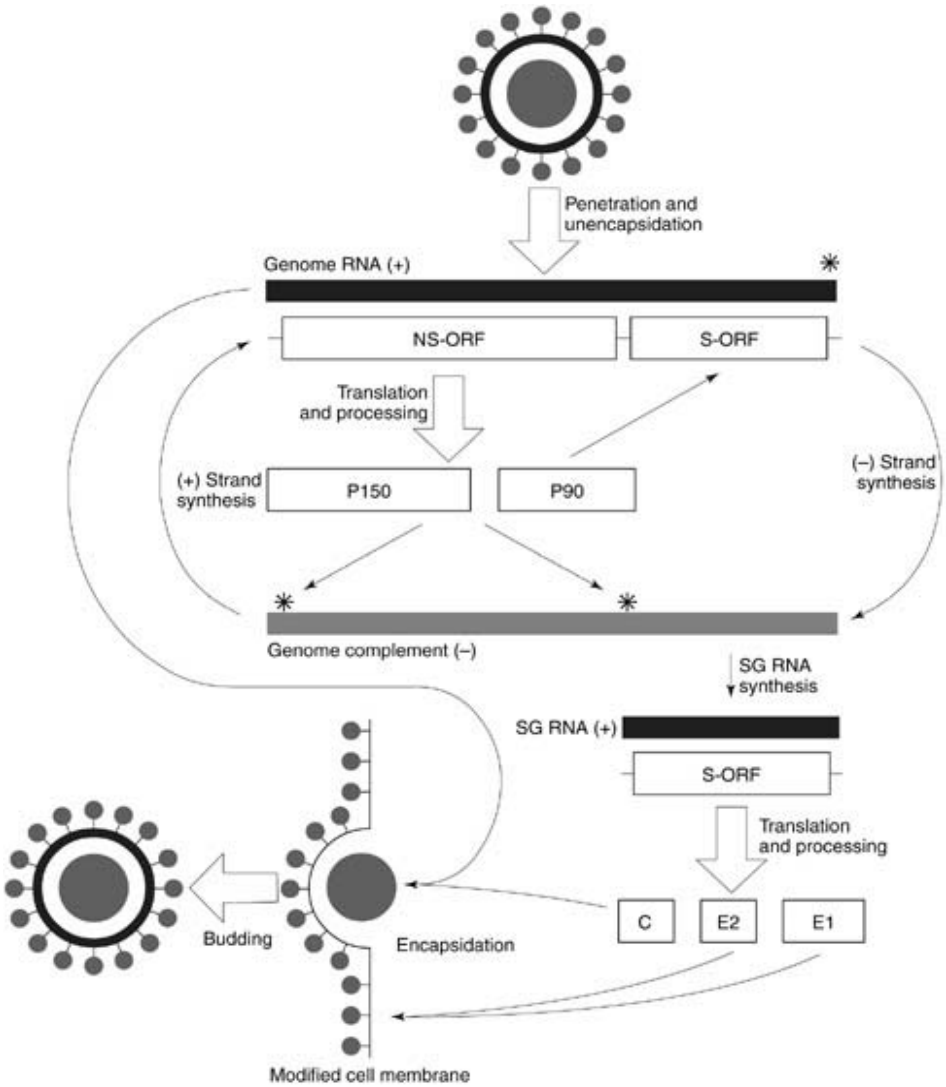

Figure 2 Replication strategy of rubella virus. The plus-sense genome and subgenomic RNA are represented by solid black lines; beneath each, the ORFs that they contain are shown as open boxes. The minus-sense genome RNA complement, represented as a hatched line, is used solely as a template for the two plus-sense RNA species. Putative *cis*-acting sequences on each RNA that are recognized by the virus replicase to initiate synthesis of complementary RNAs are marked with an asterisk. The general functions of the virus proteins are indicated by arrows (e.g. P150 and P90 functioning as the replicase by interacting with *cis*-acting sequences on the viral RNA species and synthesizing complementary strands).

binds to a stem-loop structure near the 3′ end of the genomic RNA. In so doing, it may facilitate recognition of the 3′ end by the virus replicase. The genome-length, minus-sense RNA is then used as the template for synthesis of both the genomic RNA and the subgenomic RNA. Synthesis of the subgenomic RNA is initiated by internal recognition of sequences on the genome-length, minus-sense RNA template. RNA synthesis is asymmetric in infected cells in that more of both of the plus-sense species than the minus-sense RNA is produced. In alphavirus-infected cells, the activity of the nonstructural (NS) protease (which cleaves the nonstructural precursor into four proteins rather than two proteins) is important in regulating plus- and minus-sense RNA synthesis. It has not been determined whether the rubella virus NS protease plays a similar role. Rubella virus RNA synthesis occurs in cytopathic vacuoles of lysosomal origin which occur in infected cells.

In the structural protein ORF, E2 and E1 are immediately preceded by hydrophobic signal sequences that function to direct translation of secreted and membrane-associated proteins into the lumen of the endoplasmic reticulum. Therefore, following translation of the C sequences within the ORF, the E2 signal sequence mediates association of the

translation complex with the ER. C-E2 cleavage is mediated by signal endopeptidase, or signalase, which functions in the lumen of the ER to remove signal sequences from secreted and membrane-associated proteins (unlike alphaviruses, rubella C protein does not have autocatalytic protease activity). Following cleavage, the E2 signal sequence remains associated with C. Similarly, the E1 signal sequence maintains the association of the translational complex with the ER, signalase mediates the E2–E1 cleavage, and the E1 signals sequence remains attached to E2. Heterodimerization of E2 and E1 occurs in the lumen of the endoplasmic reticulum soon after synthesis. The three-dimensional folding of E1 appears to be a complicated process that requires intramolecular disulfide-bond formation by all 20 Cys residues in the ectodomain of the protein. Both E1 and E2 acquire high-mannose glycans in the ER; E1 contains three potential glycosylation sites and E2 contains four and all appear to be occupied. The site of O-glycosylation of the E2 is not known. E1 appears to contain an ER retention signal that is only over-ridden once conformational folding is complete after which the E1–E2 heterodimer migrates to the Golgi. In the Golgi, the N-glycans of both E2 and E1 are modified to complex form, although modification is not complete and the extent of modification is heterogeneous on both proteins. Modifications of the O-glycans on E2 also occur and account for the size heterogeneity of E2. E2 contains a Golgi retention signal, indicating that the Golgi is the preferred site of viral budding in infected cells. However, late in infection E1 and E2 migrate to the cell surface and budding also occurs at this site.

Rubella virus capsid morphogenesis occurs in association with cell membranes. The association of rubella virus capsid protein with membranes is probably mediated by the E2 signal sequence which is retained at the COOH terminus of C. In fact, C may associate with the E2–E1 heterodimer and migrate as a passenger on the cytoplasmic side of vesicles transporting E2–E1 from the ER to the Golgi and among the Golgi stacks. Unlike the alphaviruses with which capsids accumulate in infected cells, rubella virus capsids only become visible in association with deformed, thickened membranes that appear to be in the early process of budding. A putative encapsidation signal has been localized near the 5′ terminus of the genomic RNA. Early in infection, the Golgi is the preferred site of viral budding, but late in infection budding occurs from the plasma membrane as well. Interestingly, in cells in which the complete SP-ORF is expressed in the absence of genomic RNA, virus-like particles form which have the same morphology and isopycnic density as do virions. It would be anticipated that these particles contain nonviral RNAs, however specific RNA contained within these particles have not been demonstrated.

Rubella virus replicates in the cytoplasm of the infected cell. Whether any of the virus proteins migrate to the nucleus during infection is under investigation; preliminary evidence indicates that P90 binds to the p105Rb tumor suppressor protein. Rubella virus infection does not appear to inhibit cell macromolecular synthesis in any grossly detectable manner, however perturbations of specific macromolecular products and induction of specific genes may occur. Microscopically, rubella virus-infected cells appear similar to uninfected cells, however rearrangements of cellular cytoskeletal elements and organelles such as mitochondria have been reported. Rubella virus inhibits growth in primary human cell cultures in part due to an inhibition of mitosis, however the virus has no reproducible effect on the growth of stable cell lines. In those cell lines which exhibit CPE (Vero and RK-13 cells), cell death is due to apoptosis.

Genetics and Evolution

The rubella virus genome appears to be relatively stable. Currently, the genomes of three independent strains of rubella virus have been sequenced in their entirety and all three are identical in terms of the size of the genome as well as the coding and noncoding regions within the genome. More extensive phylogenetic analysis has focused on the *E1* gene. Isolates from Europe, North America, and Japan vary by up to 4% and form a single genotype. A second genotype that varies from the first by 7–10% occurs in Asia. Although the natural variation at the nucleotide level is not as great as encountered with other RNA viruses, the evolution rate of rubella virus has been measured as 0.1% per year which is fairly typical of RNA viruses. A unique feature of rubella virus evolution is that changes to G and C are selected for, indicating an adaptive advantage of the high G+C content of the genome.

Since their are no known animal relatives of rubella virus, the origin of the virus prior to its introduction into the human population is unknown. Rubella virus and the alphaviruses share no nucleotide homology except for short stretches at the 5′ end of the genome and at the subgenomic promoter site. Thus these two genera are only distantly related. Rubella virus and the alphaviruses both belong to the 'alphavirus-like superfamily' of plus-sense RNA viruses which includes a large number of plant viruses as well as human hepatitis E virus, which is currently classified as a calicivirus. Within this superfamily, computer-assisted phylogenetic analysis of the nonstructural

proteins indicates that rubella virus is more closely related to HEV and beet necrotic yellow vein virus than to the alphaviruses. This dissimilarity is borne out by differences in order of motifs in the NS-ORF. Thus, it is hypothesized that the evolution of the genera of the *Togavirus* family may have been more complicated than simple divergence from a common ancestor and probably involved recombination between progenitors of the current alphaviruses, rubella virus, HEV and possibly plant viruses.

Serologic Relationships and Variability

Rubella virus is monotypic and immunological characterization of diverse strains has only revealed subtle antigenic differences. These reside on C and E2 as E1 has been found to be antigenically identical using a variety of assays. The recent discovery of the second Asian genotype raised the possibility of greater antigenic variation, however the two genotypes only vary by 1–3% in predicted amino acid sequence of E1 and none of the recognized monoclonal epitopes contain major changes. Additionally, immune human serum neutralizes viruses from both genotypes with similar kinetics. As might be anticipated by the lack of serologic crossreaction with the alphaviruses, there is no important homology between rubella virus and sequenced alphaviruses in the subgenomic region that specifies the structural polypeptides of the virion.

Epidemiology

Rubella virus is endemic worldwide. In temperate zones, seasonal peaks occur in the spring and before widespread vaccine use, rubella epidemics occurred at 5–9-year intervals. There is considerable geographic variation in rubella attack rates in different age groups. In developed, temperate zone countries, peak infection rates occur in 5–9-year-old children. However, in much of Africa, the highest infection rates occur in children under 5, and 80% of all children are immune by 10 years of age. In contrast, in island and rural tropical populations the incidence of rubella is low, with high percentages of susceptible women of childbearing age. Much of this regional variation is explained by population densities, socioeconomic factors, and levels of medical sophistication. An additional factor in rubella epidemiology is that rubella virus is not as transmissible as is measles virus and thus even during epidemics, susceptibles are missed. Thus, infection of adolescents and young adults in any population is not uncommon.

Needless to say, vaccination programs have considerably altered the epidemiology of rubella in countries in which they are employed. Vaccination strategies and their effect on the incidence of rubella are discussed below.

Transmission and Tissue Tropism

Rubella virus is transmitted between individuals by aerosolation. Congenitally infected infants shed virus for three to six months following birth and are a source of transmission. Although vaccine virus can be recovered from vaccinees, transmission of vaccine virus to susceptible individuals has not been observed.

The epithelium of the buccal mucosa provides the initial site for rubella virus replication after infection and the mucosa of the upper respiratory tract and nasopharyngeal lymphoid tissue serve as portals of virus entry. The virus is then spread by local lymphatics which seed regional lymph nodes where further virus replication occurs. After an incubation period of 7–9 days, virus appears in the blood. The secondary sites of replication which account for the maintenance of viremia have not been identified, however infection of mononuclear cells contributes. Viremia ceases with the onset of detectable rubella-specific antibody shortly after the rash appears 2–3 weeks postinfection. Through the viremia, virus is seeded into the nasopharynx where it is shed by aerosolation. Patients are most infectious immediately preceding and during the rash; virus generally disappears from nasopharyngeal secretions within four days of appearance of the rash.

Reinfection with rubella virus does occur and is more frequent among vaccinees than naturally infected individuals due to lower antibody levels. Reinfection usually proceeds without viremia, clinical illness or virus shedding, however, reinfection with clinical illness has been reported. There are a small number of cases in which rubella virus reinfection of pregnant women with well-documented immunity has resulted in CRS.

During pregnancy, placental tissues are very susceptible to infection. Placental infection results in scattered foci of necrotic syncytiotrophoblast and cytotrophoblast cells and damage to vascular endothelium. Following placental infection, virus can spread to the fetus but this does not always occur and rubella virus is more often recovered from placental tissue than from fetal products of conception. Once fetal infection occurs, virus spreads throughout the fetus and almost any organ may be infected. *In vitro* cell cultures derived from infected fetuses are persistently infected with rubella virus. Severe fetal damage is only associated with infection during the first trimester of pregnancy. This is due to a combination of an apparent decline in the efficiency of placental transfer after the first trimester and a reduction in the

ability of the virus to inflict fetal damage after this time of gestational development.

Clinical Features of Infection

Rubella acquired in childhood or early adulthood is usually mild, however symptoms in adults tend to be more severe than in children. It is estimated that up to 50% of rubella infections are clinically inapparent. Symptomatic rubella encompasses combinations of maculopapular rash, lymphadenopathy, low-grade fever, conjunctivitis, sore throat and arthralgia. The rash is the most prominent and earliest feature and appears following an incubation period of 16–20 days. The rash begins as distinct pink maculopapules on the face that then spread over the trunk and distally onto the extremities. The maculopapules coalesce and the rash rapidly fades over several days. An associated posterior cervical and suboccipital lymphadenopathy is also characteristic. Fever is typically low grade. The entire clinical syndrome usually resolves in a few days. Infrequently occurring complications include thrombocytopenia and post-infectious encephalitis. Acute polyarthralgia and arthritis following natural rubella virus infections of adults are common and occur more frequently and with greater severity in women than in men. Joint involvement is usually transient, resolving within one to several weeks, however chronic arthritis persisting or recurring over several years has been reported. The most common symptoms of rubella, lymphadenopathy, erythematous rash, and low-grade fever, are nonspecific and easily confused with similar illnesses caused by other common viral and nonviral pathogens or drug-induced eruptions. Therefore, a definitive diagnosis of rubella requires confirmation by virus isolation or, more commonly, by serology.

Fetal infection with rubella virus has dire consequences for fetal development. The rate of CRS following maternal infection is highest early in pregnancy; 50%, 25% and 10% during the first, second, and third months, respectively. CRS is rare following maternal infection after week 16 of gestation. The clinical manifestations of CRS apparent at birth vary widely, most frequently including thrombocytopenia purpura ('blueberry muffin syndrome'), intrauterine growth retardation, congenital heart disease (patent ductus arteriosus or pulmonary artery or valvular stenosis), psychomotor retardation, eye defects (cataract, glaucoma, retinopathy), suspected or confirmed hearing loss and hepatomegaly and/or splenomegaly. Less frequent features include adenopathy, bony radiolucencies, hepatitis usually with jaundice, and hemolytic anemia. Nearly 80% of CRS children show some type of neural involvement, particularly neurosensory hearing loss.

Most clinical manifestations of congenital rubella are evident at or shortly following birth and some are transient. However, recognition of retinopathy, hearing loss and mental retardation may be delayed for several years in some cases. Progressive consequences of congenital rubella have become increasingly appreciated as CRS children from the 1964 epidemic have been followed longitudinally. These predominantly involve endocrine dysfunction (diabetes mellitus, which ultimately affects 40% of CRS patients, and thyroid dysfunction). A rare, fatal neurodegenerative disease, progressive rubella panencephalitis (PRP), was also described in CRS patients that bears superficial resemblance to subacute sclerosing panencephalitis associated with measles virus. Subsequently, PRP cases were also reported in individuals who were infected postnatally.

Pathogenesis, Pathology and Histopathology

There is limited information on the pathogenesis of uncomplicated rubella because of the benign nature of the illness. With respect to the complications that can accompany acute rubella, the postinfectious encephalitis is thought to be autoimmune in nature since rubella virus cannot be isolated from cerebrospinal fluid or the brain at autopsy. Interestingly, however, extensive inflammation and demyelination are not observed. In a few cases of rubella arthritis, the presence of rubella virus in synovial fluid and/or cells has been demonstrated and therefore it is assumed that virus persistence is involved. However, considering the age and sex factors in the incidence of arthritis, it seems likely that immunopathological mechanisms also play a role. No predisposition for development of arthritis following rubella, immunological or otherwise, has been identified.

Following fetal infection, virus can be isolated from practically every organ of abortuses or infants who die soon after birth. However, only 1 in 10^3 to 1 in 10^5 cells are infected and it is not known how such a low infection rate leads to the profound birth defects exhibited in CRS. Affected organs are routinely small for gestational age and contain reduced numbers of cells. Considering the inhibitory effect of rubella virus on primary cells, it is thought that virus infection early in organogenesis inhibits cell division leading to both retardation and alteration in organ development. Virus persistence continues after birth as evidenced by shedding which generally ceases within six months of age. Whether virus persistence continues beyond cessation of shedding and plays a role

in the delayed and progressive manifestations of CRS is not known.

Histologically, affected organs from CRS show a limited number of well-recognized malformations with noninflammatory histopathology predominating. Particularly apparent are vascular lesions and focal destruction in tissue bordering these lesions. These lesions are likely to be due to virus replication in the vascular endothelium and the damage to neighboring tissue may play a role in the pathogenesis of CRS. The neuropathology of CRS is of interest not only because of the defects manifest shortly after birth, but also because some CRS patients develop schizophrenia-like symptoms later in life. CRS brains are generally free of gross morphological malformations with a common tendency towards microcephaly. Vascular damage, leptomeningitis, decreased numbers of oligodendroglial cells, and alteration of white matter are observed. Recently, magnetic resonance imaging of a group of CRS adults with schizophrenia-like symptoms revealed specifically reduced cortical gray matter and enlargement of the ventricles, which were not previously observed aspects of CRS-induced neuropathology. Interestingly, the comparative finding that non-CRS schizophrenia patients exhibit a pattern of brain dysmorphy similar to CRS patients with schizophrenia-like symptoms supports the hypothesis that the pathogenesis of schizophrenia is developmental in nature (there is some evidence for a viral trigger to schizophrenia).

Immune Response

The earliest detectable serological response to rubella virus infection is the presence of immunoglobulin (Ig)M antibodies at the time of onset of the rash. Since these antibodies generally wane within a month or two, serodiagnostic testing for the presence of IgM is the primary means for diagnosis of acute rubella virus infection currently employed. In the succeeding weeks, antirubella virus antibodies appear in all immunoglobulin classes. The dominant early and persistent IgG response is in the IgG_1 subclass and antibodies of this class persist indefinitely after natural infection in healthy individuals. Immunoprecipitation studies disclose that the majority of the antibody response is directed to the E1 glycoprotein, with proportionally lesser amounts of the response directed at E2 or C. Although neutralizing and complement fixing antibodies are induced as well, the classical assay for the presence of antirubella virus antibodies was hemagglutination inhibition (HAI) and the current standard titer recognized for immunity of 10 IU ml^{-1} is based on a reciprocal HAI titer of roughly 1:8. Because of the importance of serodiagnostic testing for rubella, a worldwide commercial market for rubella tests exists and a number of companies offer such kits, most of which are based on latex agglutination or enyzme immunoassay.

Rubella virus-specific cellular immune responses are measurable within one to two weeks of onset of rubella. These decline over several years but persist at low levels indefinitely following natural rubella. MHC-restricted CD4+ epitopes have been mapped to all three of the virus structural proteins, however CD8+ epitopes have thus far only been mapped to the C protein.

Following fetal infection, the fetus produces IgM antibody, detectable at 18–20 weeks of gestation, and maternal IgG antibody crosses the placenta. Both types of antibody exhibit virus neutralizing activity *in vitro*, however neither is sufficient to resolve virus infection during gestation. As discussed above, the intracellular maturation of virus probably shields it from antibody. After birth, the presence of IgM or a lack of decline of IgG titer are both considered diagnostic of fetal infection. CRS infants exhibit impairment in the cellular immune response to rubella virus to varying degrees and it is thus a deficiency in this arm of the immune response that allows the virus to persist. Considering this deficiency in CRS infants, it is curious that detectable virus persistence ends relatively shortly after birth. The means by which virus persistence is cleared under these conditions is not understood.

Prevention and Control of Rubella

As discussed above, live attenuated vaccines were developed and placed in use by 1970. The vaccine used in most countries, with two exceptions, is the RA 27/3 vaccine. This vaccine was developed by multiple passaging of a virus isolate from an explant culture of a fetal human kidney in WI-38 human fetal diploid lung cells. Several of the passages were done at 30°C and limiting dilutions were used at some of the passages. Production of the vaccine is done in both WI-38 and MRC-5 diploid human cell cultures. In Japan, five attenuated vaccine strains were developed and are currently in use. Additionally, at least one Chinese vaccine strain is currently in use in China.

Rubella attenuated vaccines cause subclinical infection with transient viremia in susceptible recipients. However, transmission of vaccine virus has not been reported. The RA27/3 vaccine strain produces seroconversion in greater than 95% of recipients. Vaccine-induced titers are lower than those induced by natural infection but appear to last indefinitely. The rubella vaccine is generally administered to children in trivalent form with the measles and

mumps attenuated vaccines. Additional testing has shown that the recently licensed varicella vaccine can be combined with these vaccines in a tetravalent vaccines with no detectable interference between the component vaccine viruses.

In general, the rubella vaccines have been among the most successful in terms of induction of immunity with an absence of side effects. However, two issues have arisen concerning rubella vaccination. The first is that the vaccine virus can cross the placenta and infect the fetus. However, in a registry kept in the US between 1971 and 1988 of over 300 deliveries to women inadvertently vaccinated within three months of conception or during the first trimester of pregnancy, no congenital abnormalities were reported. Nevertheless, vaccination during pregnancy is contraindicated and is deferred until post-partum. Second, is the occurrence of arthralgia and arthritis following vaccination. Joint complications are nonexistent in children with the currently used rubella vaccines, however transient arthralgia and arthritis is reasonably common among adult female vaccinees. There have also been reports of chronic arthritis and related neurological involvement following vaccination of adult women. Although these complications are consistent with complications that can accompany natural rubella in adult females, recent studies have shown that the incidence of such vaccine-related complications is rare and cannot be statistically differentiated from the incidence of similar symptoms in control, unvaccinated populations.

Since the inception of rubella vaccination, the US has employed a strategy of universal vaccination at 15 months of age augmented with vaccination of seronegative 'at-risk' individuals (women planning pregnancy, health care workers) which was successful in bringing the incidence of rubella and CRS to record low levels by 1988. However, a resurgence occurred between 1989 and 1991 among foci of unvaccinated individuals concentrated primarily on college campuses, among Amish communities in the Northeast, and among the Hispanic population in the Southwest. Since most of the infected individuals were of adolescent age or older, the ratio CRS to rubella cases was higher than in unvaccinated populations and over 50 CRS cases occurred despite the fact that only 3000 rubella cases were reported. Since the resurgence, a second vaccine at age 5–10 has been included in the vaccination program as well as more strict enforcement of vaccine requirements for school admission. The incidence of rubella and CRS has subsequently dropped to minuscule levels. Most of these cases are thought to be imported and no rubella was reported during a two month period in 1996, possibly indicating a break in endemic transmission.

In Japan and Europe, a strategy of vaccination of adolescent girls was initially adopted since it was felt that natural immunity was more robust than vaccine-induced immunity and thus it was considered desirable that as many individuals as possible should contract natural rubella. Predictably, rubella virus continued to circulate and thus postadolescent women who managed to break through without a rubella titer were infected and CRS was not eliminated. Therefore, most of these countries adopted the universal strategy in the late 1980s. Aggressive implementation of the universal policy in the UK and Scandinavia has brought rubella down to very low levels; however, in many countries with rubella vaccination programs, vaccination is not comprehensively pursued and thus both rubella and CRS still occur.

Rubella vaccination is practiced in only a few countries outside of the US, Canada, Europe and Japan. In underdeveloped countries, this is primarily because of the expense of the vaccine, the nature of national public health infrastructures, and the general mildness of the disease in comparison to those caused by life-threatening pathogens. However, rubella exacts a societal load in every country in which it is endemic. Because rubella virus is exclusively a human virus and excellent vaccines for use against it exist, it is potentially eradicable and recently attention has been focused on the possibility of elimination or eradication efforts for two major reasons. First, because the rubella and measles vaccines are administered together in most childhood vaccination programs, it would be efficient to include the rubella vaccine in currently ongoing worldwide measles elimination efforts. In addition to controlling two diseases with one effort, measles surveillance requires diagnosis of rubella because of the similarity of symptomology and thus inclusion of rubella vaccine would also concomitantly reduce surveillance costs by reducing rubella cases. Secondly, rubella elimination is potentially of great benefit to the countries which maintain expensive comprehensive vaccination and control programs. In these countries, most rubella outbreaks are due to importation and thus a substantial reduction or elimination of rubella would allow easing of control efforts as well as eventual discontinuation of vaccination. Therefore, a concerted worldwide effort on rubella control appears to be forthcoming.

Future

Because of its association with a diverse group of clinical diseases, rubella virus will remain a fascinating pathogen. As an example, the incidence of diabetes in CRS patients is the best statistically direct

association between a specific human virus and a specific autoimmune disease. The mechanism of viral involvement in each of these diseases is not fully understood. Unfortunately, our present understanding of disease mechanisms in the rubella virus-related syndromes is hindered by the current lack of a suitable animal model system that fully mimics the infection seen in humans and development of an animal model is a research priority. Virologically, rubella virus is taxonomically unique and appears to have evolved as a recombinational hybrid of other distantly related viruses. Thus, investigation of its molecular biology will likely reveal novel replication strategies and yield insight into virus evolution. The biggest challenge concerning rubella virus, however, will be potential forthcoming elimination efforts which could well consume the next quarter to half century.

SALMONELLA PHAGE P22 (*PODOVIRIDAE*)

Anthony R Poteete, Department of Molecular Genetics and Microbiology, University of Massachusetts Medical Center, Worcester, Massachusetts, USA

Introduction

P22 is a temperate bacteriophage that mediates generalized transduction of its host, *Salmonella typhimurium*. This capability forms the basis of the first claim of P22 to distinction: the discovery of transduction described by Zinder and Lederberg in 1952 involved the transfer of *Salmonella* genes by P22. P22 continues to the present day to be an indispensable tool of *Salmonella* genetics. It is an unassigned species in the family *Podoviridae*.

The molecular genetics of P22 itself have been studied intensively. Research with P22 has contributed to our understanding of a number of biological processes, including replication, recombination, and regulation; protein folding and assembly; and viral morphogenesis and evolution.

Virion Structure

The P22 virion can be described as an icosahedral head, with a diameter of approximately 570 Å, attached at one vertex to a short tail/baseplate structure, from which a single, slender fiber extends (radially with respect to the head) (**Fig. 1**). The virion is roughly half protein and half DNA by weight.

P22 virions contain nine protein species. The major one is the coat protein, which is present in about 400 copies arranged in an icosahedral ($T = 7$ laevo) shell. One minor structural polypeptide, the portal protein, forms a ring-shaped dodecamer around the place in the head where the tail/baseplate attaches. Another, described as the tailspike protein, forms trimers (**Fig. 2**); six trimers attach to the tail to form the baseplate. The remaining six proteins of the capsid have structurally undefined roles in forming the tail and in DNA injection.

The single P22 chromosome is a linear double-stranded DNA molecule of approximately 43 400 bp. Its precise structure varies from one virion to another, due to the nature of the viral assembly process. P22 DNA is packaged from a large DNA molecule, called a concatemer, consisting of multiple tandem repetitions of the phage genome. Packaging into a preformed head structure, called a prohead, starts at a specific sequence, *pac*, and proceeds unidirectionally until a headful of DNA has been taken up. At that point, wherever it occurs in the phage DNA sequence, packaging into the first prohead terminates, and packaging into a second prohead initiates. This sequential packaging can continue for many headfuls. The process, in the case of wild-type P22, results in

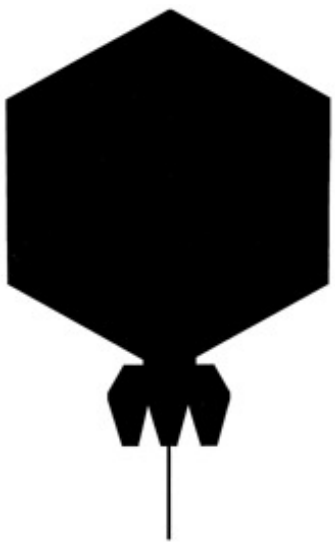

Figure 1 Schematic drawing representing the appearance of P22 virions in electron micrographs of negatively stained preparations. The capsid is icosahedral, but can appear hexagonal in outline. The baseplate is hexagonally symmetric. Adapted from Casjens S and Hendrix R (1988) Control Mechanisms is dsDNA backeriophage assembly. In: Calendar R (ed.) *The Bacteriophages*, vol. 2. New York: Plenum

from P_{ant}, encodes antirepressor, which induces lytic growth of any P22-related prophage that happens to be resident in the infected cell.

The P22 genes that are expressed as a result of gene *24* protein action include ones that promote homologous recombination, DNA replication, and late transcriptional regulation. The late transcriptional regulatory gene, *23*, encodes a protein that antiterminates transcription from the promoter P_{LATE}. The late transcript thus extended is over 20 000 bp in length, and includes all of the genes required for phage assembly and host cell lysis.

Replication of P22 DNA requires the action of two phage-encoded proteins, whose function is to recruit host replisomes to the phage replication origin. The key product of replication is the linear concatemer that serves as a substrate for sequential headful DNA packaging. This concatemer is generated from a circular P22 chromosome by a rolling circle mechanism. The circular form of the P22 chromosome is formed by homologous recombination between the repetitious ends of the linear DNA molecule injected by the phage.

Assembly of P22 virions proceeds by an ordered pathway that starts with the formation of proheads. Coat protein aggregates into a roughly spherical shell around a core of scaffolding protein. Four minor proteins, including the portal protein, also participate in this process. Proheads of normal appearance in electron micrographs can assemble in the absence of any of these minor proteins; however, they cannot mature into infectious phage. During the DNA packaging process, the scaffolding protein is ejected intact; it subsequently participates, catalytically, in the formation of new proheads. The coat protein shell also expands and rearranges. Addition of three minor proteins is required for the formation of a stable head with a short tail, to which trimers of the tailspike protein attach as a final step.

Packaging of DNA by the prohead requires the action of two proteins which are not incorporated into the final structure, one to bring the prohead to the pac site, and the other to pump DNA inside. P22 mutants, called HT, direct the synthesis of altered versions of the first of these, and reduce the specificity of *pac* recognition. HT mutants exhibit elevated frequencies of transduction of bacterial genes, and are especially useful for *Salmonella* genetics.

Lysis of the infected cell results from the action of two proteins. One of the proteins, called a holin, inserts into the cytoplasmic membrane, creating channels that permit the passage of small proteins. The second protein, a lysozyme, thereby gains access to the cell wall peptidoglycan, which it hydrolyzes to effect disruption of the host cell.

Lysogeny

Like other temperate phages, P22 can follow either of two pathways following infection of a sensitive host cell: it can grow lytically, or form a lysogen. Which of these pathways is favored depends on a variety of factors, including the multiplicity of infection and the nutritional status of the cell. The key element in the choice between pathways is a transcriptional regulatory protein, the product of gene *c1*, which is transcribed as a result of antitermination by gene *24* protein. Regulation of c1 protein synthesis and stability is complex and only partially understood. When present at sufficient levels, c1 protein stimulates transcription from the promoter P_{RE}. The c2 protein, encoded in the P_{RE} transcript, is then synthesized, and acts by binding to operators overlapping P_L and P_R, repressing transcription; at the same time, it turns on its own transcription from the otherwise silent promoter P_{RM}. An additional transcriptional repressor, the product of the *mnt* gene, is required for maintenance of the lysogenic state; the function of this protein is to turn off transcription of antirepressor.

Establishment of stable lysogeny requires, in addition to transcriptional repression, integration of the phage DNA into the bacterial chromosome to form a prophage. This function is carried out by integrase, a protein that promotes reciprocal recombination between specific sequences called attachment sites in the circular phage and bacterial chromosomes.

In the lysogenic state, a number of P22 genes are expressed. In addition to the c2 and Mnt repressors, these include *sieA*, *sieB* and *a1*. The functions of the latter genes all involve keeping out infecting phages: the product of *sieA* interferes with DNA injection by P22 and related phages; *sieB* causes the lytic cycle of certain other *Salmonella* phages (not P22 itself) to abort at an early stage; and *a1* alters the structure of the lysogen's O-antigen, interfering with adsorption by P22 and related phages.

The lysogenic state is homeostatic. The c2 protein turns on its own gene, and turns off most of the other phage genes; spontaneous induction is a rare event. On the other hand, treatment of lysogens with agents that damage DNA results in efficient induction. The mechanism of this induction is based on the host cell's normal reaction to such agents. A signal, perhaps single-stranded DNA, generated as a consequence of DNA damage, activates RecA protein, which in turn promotes proteolysis of LexA protein, a cellular repressor that controls transcription of the global SOS regulon. Some phage repressors, including c2 protein, are homologues of LexA protein; they are similarly cleaved in response to activated RecA

protein. With repressor thus rendered inactive, transcription from P_L and P_R initiates. The resulting lytic growth requires the reversal of integration–excision, promoted by the combined action of the phage-encoded integrase and excisionase, but is otherwise similar to lytic growth following infection.

Research Directions

Current research with P22 is focused on the molecular mechanisms of selected aspects of the phage's biology. Some of this research is comparative. For example, P22 frequently serves as a system in which particular mechanisms of λ gene regulation can be tested for generality. P22 has also found use as a component of certain specialized cloning systems. In addition, a few P22-encoded proteins serve as model systems for the study of protein folding and stability, of DNA binding, and of transcriptional regulation.

Antirepressor

P22 departs from the familiar pattern of lambdoid phage transcriptional regulation by possession of an antirepressor (the protein product of gene *ant*). Embedded in the late operon of P22, *ant* is subject to regulation by its own set of three repressors: two proteins, the products of genes *arc* and *mnt*, and one antisense RNA, the *sar* transcript. All of these have been extensively characterized.

The *ant* operon has been employed in the construction of a specialized cloning system. In it, a DNA sequence thought to function in gene regulation is installed in P22 in place of the operator that normally controls *ant* expression. The resulting hybrid phage will invariably kill a bacterium that can not control its synthesis of antirepressor; it can be used to select among bacterial clones for those which express a protein that can bind specifically to the DNA site in question. A closely related P22 strain provides a direct selection for bacteria expressing a protein that can bind specifically to a site in RNA. The phage is constructed so that the RNA site question overlaps the *ant* ribosome binding site.

DNA packaging

The molecular basis of the limited sequence specificity of one of the DNA packaging proteins (the product of gene *3*) has been the subject of recent investigation. This research has led to understanding of the sequence determinants of *pac* activity, as well as a picture of what constitutes a *pac*-like site. The DNA packaging apparatus of P22 has been used in a cloning system in which it is combined with the ends of the transposon-phage Mu. The resulting replicon, when inserted into the host cell's chromosome (essentially anywhere), becomes a locked-in prophage, unable to excise. However, upon induction, it packages the host chromosome, one headful at a time; sequences located near and to one side of the insertion are packaged with particularly high efficiency.

Homologous recombination

P22 depends on genetic recombination to circularize its chromosome following infection. This recombination must take place at high efficiency within the 1600 bp sequence repeated at the ends of the linear DNA injected by the phage. The recombination system of the bacterial host is inefficient in this process. P22 encodes proteins that work in conjunction with the host system to increase its efficiency. One of these proteins, Abc, binds to the host cell's RecBCD nuclease/helicase and modulates its nuclease activity. Another, Erf, is a single-stranded DNA-binding protein that accelerates association of complementary strands. A third protein, Arf, is a general recombination enhancer of unknown mechanism. Though the phage and host proteins work together, the combined system contains functional redundancies, and can operate at nearly normal efficiency in the absence of any of the known host functions.

Like P22, phage λ encodes a homologous recombination system, called Red, that can function in the absence of the known host recombination proteins, but that works most efficiently in their presence. Both phages encode strand exchange-promoting proteins (Erf and Redβ, respectively) analogous to RecA. However, the two phages use different strategies for interactions with RecBCD. Whereas P22 modifies RecBCD and uses it in promoting phage recombination, λ completely nullifies RecBCD and elaborates its own exonuclease. The two phage recombination systems share no apparent sequence homology, but are functionally interchangeable. The functional significance of such an efficient recombination system for λ is not obvious, as it is in the case of P22, as the λ chromosome circularizes by an entirely different mechanism. The explanation may reside in the idea of the lambdoid phages as mosaics of interchangeable genetic modules; efficient recombination systems are required to retain the capability of headful packaging in the group.

Tailspike

The P22 tailspike protein has proven to be an interesting object for studies of protein structure, folding and assembly, and aggregation. The mature form of the protein is a trimer of identical 666 amino acid residue subunits. The most prominent feature of the monomer is a large β-helix, consisting of 13

helical turns of parallel β strands. In the trimer, the helical coils pack into a parallel bundle. Distally, the three polypeptides intertwine to create an extremely stable bundle of β sheets.

Folding and assembly of the tailspike occur in concert: monomers partially fold, assemble into a structure called a protrimer, then complete folding together. Folding and trimerization of the tailspike polypeptide are slow *in vivo* under certain physiological conditions, and the various forms of the tailspike exhibit different solubilities and electrophoretic mobilities. It has thus been possible to dissect the tailspike folding and assembly pathway *in vivo* as well as *in vitro*.

The mature tailspike trimer is an unusually stable protein. However, its folding/assembly process is unusually temperature sensitive. At 40°C, most of the subunits fail to fold correctly, and end up in insoluble aggregates. Investigators have characterized mutant proteins that exhibit increased and decreased tendencies to aggregate.

P22 in novel settings

P22 does not form plaques on *Escherichia coli*, but only because it cannot adsorb. If *E. coli* is given the capability of synthesizing the *S. typhimurium* O-antigen, it will support lytic growth, lysogeny and generalized transduction by P22. Plasmid-borne *rfb* and *rfc* genes from *S. typhimurium* are sufficient for this purpose. This observation suggests the possibility of using P22 as a generalized transducing phage in other, less genetically characterized Gram-negative bacteria.

Early in this century, a key aim of bacteriophage researchers was to use these viruses as antibacterial therapeutic agents. This line of investigation was discontinued due to technical difficulties and the advent of antibiotics. However, the recent proliferation of antibiotic resistant strains has revived interest in this area. Recently, investigators have described the isolation of mutants of phages λ and P22 that have extended lifetimes in the murine circulatory system, and can abort experimental infections.

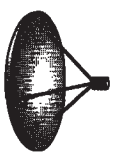
SATELLITE RNAs AND SATELLITE VIRUSES



ME Taliansky and **PF Palukaitis**, Virology Department, Scottish Crop Research Institute, Invergowrie, Dundee, UK

Introduction

Satellites are a heterologous collection of subviral agents which comprise nucleic acid molecules that depend for their productive multiplication (replication) on a helper virus, but which contain sequences substantially distinct from those of the genomes of either their helper virus or their hosts. Satellites are thus distinct from either defective (D) or defective interfering (DI) RNAs, because the latter are wholly derived from their helper virus genomes. However, there are some hybrid RNAs between satellites and parts of the viral genome, such as the chimeric molecules formed from part of a satellite RNA associated with turnip crinkle virus (TCV) and part of a DI RNA formed from the virus genome. Satellites may encode their own coat protein (CP) (satellite viruses), or they may rely on the helper virus for encapsidation as well as replication (the satellite RNAs or satellite DNA). Satellites are not needed

helical turns of parallel β strands. In the trimer, the helical coils pack into a parallel bundle. Distally, the three polypeptides intertwine to create an extremely stable bundle of β sheets.

Folding and assembly of the tailspike occur in concert: monomers partially fold, assemble into a structure called a protrimer, then complete folding together. Folding and trimerization of the tailspike polypeptide are slow *in vivo* under certain physiological conditions, and the various forms of the tailspike exhibit different solubilities and electrophoretic mobilities. It has thus been possible to dissect the tailspike folding and assembly pathway *in vivo* as well as *in vitro*.

The mature tailspike trimer is an unusually stable protein. However, its folding/assembly process is unusually temperature sensitive. At 40°C, most of the subunits fail to fold correctly, and end up in insoluble aggregates. Investigators have characterized mutant proteins that exhibit increased and decreased tendencies to aggregate.

P22 in novel settings

P22 does not form plaques on *Escherichia coli*, but only because it cannot adsorb. If *E. coli* is given the capability of synthesizing the *S. typhimurium* O-antigen, it will support lytic growth, lysogeny and generalized transduction by P22. Plasmid-borne *rfb* and *rfc* genes from *S. typhimurium* are sufficient for this purpose. This observation suggests the possibility of using P22 as a generalized transducing phage in other, less genetically characterized Gram-negative bacteria.

Early in this century, a key aim of bacteriophage researchers was to use these viruses as antibacterial therapeutic agents. This line of investigation was discontinued due to technical difficulties and the advent of antibiotics. However, the recent proliferation of antibiotic resistant strains has revived interest in this area. Recently, investigators have described the isolation of mutants of phages λ and P22 that have extended lifetimes in the murine circulatory system, and can abort experimental infections.

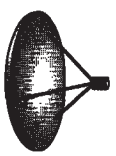
SATELLITE RNAs AND SATELLITE VIRUSES



ME Taliansky and **PF Palukaitis**, Virology Department, Scottish Crop Research Institute, Invergowrie, Dundee, UK

Introduction

Satellites are a heterologous collection of subviral agents which comprise nucleic acid molecules that depend for their productive multiplication (replication) on a helper virus, but which contain sequences substantially distinct from those of the genomes of either their helper virus or their hosts. Satellites are thus distinct from either defective (D) or defective interfering (DI) RNAs, because the latter are wholly derived from their helper virus genomes. However, there are some hybrid RNAs between satellites and parts of the viral genome, such as the chimeric molecules formed from part of a satellite RNA associated with turnip crinkle virus (TCV) and part of a DI RNA formed from the virus genome. Satellites may encode their own coat protein (CP) (satellite viruses), or they may rely on the helper virus for encapsidation as well as replication (the satellite RNAs or satellite DNA). Satellites are not needed

by helper viruses for their accumulation. However, some RNA molecules which are not required by the helper virus for experimental infection, appear to be essential for the natural life cycle of the virus, by contributing to vector transmissibility. Such examples are the RNAs associated with groundnut rosette virus (GRV) and beet necrotic yellow vein virus (BNYVV), which have been described and are referred to as satellite-like RNAs. A related group of subviral agents is that containing RNAs that resemble satellites but which depend on a helper virus only for encapsidation rather than for replication [e.g. hepatitis delta virus (HDV) and beet western yellows virus (BWYV) ST9-associated RNA].

History

The term satellite virus was adopted by Kassanis to describe the small 17 nm diameter particles associated with tobacco necrosis virus (TNV), in 1962. It was serologically unrelated to TNV and hence encoded its own CP. In 1969, a satellite was found associated with tobacco ringspot virus (TRSV), which was encapsidated by the helper virus, and the term 'satellite' was broadened to include satellite RNAs. In recent years, a large number of other satellite viruses and satellite nucleic acids associated with different groups of viruses have been described. Most known satellites consist of single-stranded (ss) RNA, with ssRNA plant viruses as helpers. However, satellite ssDNAs and double-stranded (ds) RNAs have also been described.

Classification

Satellites do not constitute a homogeneous taxonomic group. They represent quite different disparate groups of subviral agents associated with plant, animal, protozoan and fungal viruses containing different types of genetic material such as ssRNA, dsRNA or ssDNA. It seems very unlikely that such different groups of satellites might be evolutionarily related. There are also no taxonomic correlations between the viruses that support satellites. Satellitism would appear to have arisen independently a number of times during the evolution of viruses. Thus, classification of satellites is based largely on features of the genetic material of the satellites. The nature of the helper virus and helper virus host range are important secondary characters. All known satellites appear to be included into the following categories.

Satellite viruses

- Subgroup I. Satellite tobacco necrosis virus (STNV)
- Subgroup II. Chronic bee paralysis associated satellite virus (CPVA)

Satellite nucleic acids

- ss satellite DNA
- ds satellite RNA
- ss satellite RNA
  - Subgroup I. Large ss satellite RNA with messenger properties
  - Subgroup II. Small linear ss satellite RNA
  - Subgroup III. Circular ss satellite RNA

As mentioned above, satellite-like RNAs and subviral agents dependent on a helper virus only for encapsidation may also be regarded as satellite-related agents. A complete list of satellites and satellite-related agents is presented in **Tables 1–3**.

Table 2 Satellite nucleic acids

Helper virus/satellite nucleic acid	*Size of satellite nucleic acid (encoded protein MW)*

General Properties of Satellites and their Effects on Helper Virus and Host Plants

The satellite viruses

Satellite viruses occur as nucleoprotein particles that are morphologically and serologically distinct from their helper viruses. No serological relationships were found between different satellite viruses except between satellite panicum mosaic virus (SPMV) and satellite St Augustine decline virus (SSADV), the helper viruses of which, PMV and SADV, respectively, are closely related. All known satellite viruses including CPVA contain ssRNAs between 800 and 1200 nucleotides (nt). Particles of all known satellite viruses are isometric and are 17 nm in diameter. Whereas helper viruses of most satellite viruses also have isometric particles, the helper virus of satellite tobacco mosaic virus (STMV) has rod-shaped particles.

Subgroup I The most studied of satellite viruses are plant virus satellites belonging to subgroup I. The three-dimensional structures of STNV, STMV and SPMV have been determined at high resolution by x-ray crystallography. The shell of all these satellite viruses is composed of 60 protein subunits. Most satellite virus RNAs are presumably monocistronic. The CP is the sole product of *in vitro* translation of the STNV, satellite maize white line mosaic virus (SMWLMV) and SPMV RNAs, although the last contains several additional open reading frames (ORFs) which are untranslatable *in vitro*. However, in the case of STMV, in addition to the CP, another product of about 6.8 kDa is produced during *in vitro* translation, although it remains unclear if this product is functionally active.

Although the STNV CP is not related to that of the helper virus, TNV, both particles bind specifically to the surface of zoospores of the fungal vector *Olpidium brassicae*. The replication of STNV inhibits that of TNV and the extent of the inhibition depends on the particular combination of strains of STNV and TNV. A second satellite RNA of about 620 nt has been detected in STNV particles. It is distinct from STNV RNA, in that it has no messenger RNA activity, but still depends on TNV for replication. Therefore this RNA may be considered as a satellite of TNV for replication, and a satellite of STNV for encapsidation (**Table 1**).

The effect of the multiplication of SPMV on the accumulation of its helper, PMV, is unknown, but it is known that the presence of SPMV alters the mild mosaic symptoms induced by PMV in maize to severe mosaic and necrosis. On the other hand, no differences in symptomatology have been observed between isolates of MWLMV or TMV containing or lacking satellite viruses.

Subgroup II Less is known about satellite viruses belonging to the subgroup II (**Table 1**). RNA of CPVA satellite virus consists of three species, each about 1.1 kb, which are distinct from CPV helper RNA, although some T1 oligonucleotides appear in common between CPV and CPVA RNA. The satellite virus interferes with CPV replication.

Satellite nucleic acids

ss Satellite DNAs This category comprises tomato leaf curl virus (TLCV) satellite DNA with a circular ssDNA genome, which does not encode a satellite CP (**Table 2**). The 682 nt DNA contains no ORFs and shows little sequence similarity to the helper virus genome, limited to two short motifs present in two separate stem–loop structures. One of these motifs is universal for all geminiviruses, and the other motif is identical to a replication-associated protein binding site in TLCV. The satellite DNA is strictly dependent on the helper virus replication-associated protein and is encapsidated by TLCV CP. Replication of TLCV satellite DNA is also supported by other taxonomically distinct geminiviruses, including African cassava mosaic virus and beet curly top virus.

ds Satellite RNAs These RNAs have been found in association with viruses of the family *Totiviridae*. The dsRNA range from 0.5 kb to 1.8 kb and are encapsidated by the helper virus CP. These particles often also contain a positive-sense ssRNA copy of the dsRNA. The presence of satellites in helper virus cultures can affect markedly the virulence of the helper virus infection. This category comprises the M satellites of L-A dsRNA virus of *Saccharomyces cerevisiae* and satellites of *Trichomonas vaginalis* virus (TVV) (**Table 2**).

Some strains of *S. cerevisiae* secrete a protein toxin that is lethal to other strains, but not to the toxin-secreting strain, which is said to be immune or resistant. The protein responsible both for the killer phenotype and for immunity to the toxin (in the form of the prototoxin) is encoded by M_1, a dsRNA satellite of the major yeast dsRNA virus L-A. Several other satellite dsRNAs of L-A, each encoding a toxin-immunity system, have been described and are called M_2, M_3, M_{28}, etc. The family of these satellites comprises dsRNAs, varying from ca. 1.0 kb to 1.8 kb. These RNAs completely depend on the helper virus (L-A) encoded proteins Gag and Gag-Pol for encapsidation and replication. In addition, a strict dependence of M_1 satellite multiplication on host chromosomal genes has also been described. M_1 needs 30 so-called *MAK* (maintenance of killer) genes, of which only three are required by the helper virus L-A. The M_1 satellite represses the copy number of the L-A helper virus.

Another series of dsRNA satellites is associated with a virus infected with a sexually transmitted protozoan, *T. vaginalis* (TVV). Three different dsRNA satellites of TVV have been found, containing approximately 500 bp, 700 bp and 1700 bp. All these RNAs are synthesized conditionally and are present in only some *T. vaginalis* isolates harboring the virus, which seems to replicate and encapsidate them.

ss Satellite RNAs This is the most numerous group of known satellites. The ss satellite RNAs range in size from just under 200 nt to approximately 1500 nt. The larger satellite RNAs appear to contain functional ORFs, although as yet no precise function has been assigned to any of their gene products. Small ss satellite RNAs do not appear to encode any functional ORFs, but tend to be highly structured. Small ss satellite RNAs may be either linear or circular. Despite their small size and the usual absence of any potential products, these ss satellite RNAs may have a dramatic effect on the symptoms induced by their helper virus, ranging from amelioration to severe exacerbation. These symptom effects vary with the helper virus, host plant, and satellite.

Subgroup I: Large ss Satellite RNAs with Messenger RNA Properties The most studied of this type of satellite RNAs is that of the nepoviruses (**Table 2**). These satellite RNAs, ranging in size from approximately 1100 to 1500 nt, resemble the genomic RNA of their helper viruses in that they have a 3′-terminal poly(A) sequence and a 5′-terminal genome-linked protein (VPg). The VPgs of satellite RNAs of tomato black ring virus (TBRV), arabis mosaic virus (ArMV) and grapevine fanleaf virus (GFLV) are indistinguishable from those attached to the helper virus genome RNA and therefore must be encoded by the helper virus genome. These satellites encode a nonstructural protein with M_r ranging from 36 to 48 kDa, which at least in some cases, such as in TBRV, GFLV and ArMV satellites, has been shown to be essential for satellite RNA replication. Comparison of amino acid sequences of proteins encoded by different satellite RNAs of nepoviruses revealed several domains: the terminal regions are strongly basic, most notably the N-terminal region, and the central region contains both basic and acidic residues. The satellite-encoded proteins are also relatively rich in cysteine and histidine residues, mostly in the 3′-terminal halves. It has been suggested that these proteins may be involved in adapting the helper virus replicase to the satellite RNA. The most characteristic biological property of these RNAs is that the symptoms induced by infection with the helper virus are only slightly or not at all affected by the presence of the satellite RNA. TBRV, strawberry latent ringspot virus (SLRV), chicory yellow mottle virus (CYMV) and GFLV satellite RNAs induce no changes in the symptoms induced by the helper virus. However, in the case of the large ArMV satellite RNA, the satellite RNA was found to exacerbate symptoms in three

species and ameliorate symptoms in ten species out of 42 plant species tested. The large satellite RNAs of nepoviruses have little or no effect on the accumulation of their helper viruses, even in plants in which satellite RNA enhanced or ameliorated the symptoms of ArMV infection.

Another large ssRNA satellite which may be included in this category is associated with the potexvirus bamboo mosaic virus (BaMV). This RNA is a linear molecule of 836 nt [excluding the poly(A) tail] and like other satellite RNAs is encapsidated by the CP of its helper virus. However, it differs from all other known satellites in that the RNA is encapsidated into rod-shaped particles. The BaMV satellite RNA contains an ORF for a protein of 183 amino acids (20 kDa). This protein shares 46% sequence identity with the CP amino acid sequence of SPMV (see above). The ORF for the BaMV satellite RNA appears to be translated *in vitro* and *in vivo*. However, the encoded protein is not essential for satellite RNA replication. The presence of the BaMV satellite RNA caused a reduction of BaMV genomic RNA accumulation, in the range 65–85%.

Subgroup II: small linear ssRNAs This subgroup comprises the satellites with genomes less than 0.8 kb (**Table 2**). No circular molecules are present in infected cells. Some of these satellites contain potential ORFs, but the evidence indicates that there are no *in vivo* functions for these ORFs. Although small satellite RNAs of some cucumber mosaic virus (CMV) strains have been shown to direct the synthesis of protein products *in vitro*, these ORFs are not conserved among different isolates. Moreover, neither mutagenesis of the 5′-proximal initiation codon in a biologically active cDNA clone nor a frameshift mutation of the ORFs altered the biological activity of CMV satellite RNAs. Other small, linear, ssRNA satellites also do not appear to encode functional proteins, and hence the biological functions of these satellite RNAs must rely on the nucleotide sequence and the corresponding secondary structure. The small satellite RNAs have highly ordered secondary structures. The small size and high degree of secondary structure are probably responsible for the high stability and survivability of satellites both *in vitro* and *in vivo*. The latter may in turn account for the highly infectious nature of many satellite RNAs.

Small RNA satellites can dramatically alter the symptoms induced by the helper virus. The alterations can be either an attenuation or an exacerbation of the virus-induced symptoms. Some satellite RNAs of CMV can ameliorate the symptoms induced by the helper virus on one host and intensify them on another host. The symptom modulation can also be affected by the particular strain of helper virus. Thus, a three-factor interaction involving the particular satellite, the strain of helper virus, and the species of host determines the type of host response. In most cases, satellites attenuate the symptoms. Exacerbation of symptoms is much rarer. Attenuation of symptoms is usually accompanied by a reduction in the virus titer. This has led to the suggestion that the competition for the replicase between the satellite and helper virus genomes results in a reduction in the concentration of the helper virus elicitor of host pathogenesis. However, it has also been shown that the chimeric satellite RNA of TCV may inhibit movement of the virus helper (rather than replication), thus reducing its accumulation and symptom expression; the CP of TCV is involved in this type of interaction. However, in some other satellite virus: helper combinations [for example CMV satellite RNA and the helper tomato aspermy virus (TAV)], a reduction in pathogenicity was not accompanied by a reduction in the titer of the helper virus. Thus, more than one mechanism may be responsible for satellite RNA-mediated symptom attenuation.

A few satellites exacerbate the symptoms induced by the helper virus. Of these, the best characterized are the satellite RNAs of CMV. Examples of symptom intensification include chlorosis on tobacco (and pepper), chlorosis on tomato, and necrosis on tomato. As in the case of satellite-mediated symptom attenuation, there might be different mechanisms for symptom intensification. One of them may be based on the interaction of the satellite RNA with a helper virus-encoded product. Chlorosis and some forms of necrosis involve interaction between specific regions (pathogenicity domains) of CMV satellite RNA and a factor(s) derived from CMV RNA 2, i.e. either the encoded 2a or 2b proteins or RNA 2 itself. In addition, whereas interactions between certain satellite RNAs and either RNA 2 or the 2a protein induce severe pathogenic responses in some host species, on other plant species the same combinations attenuate symptoms. The host component(s) involved in the above interactions is (are) clearly a crucial factor. Another possible mechanism of symptom exacerbation seems to involve direct interaction between the pathogenicity domain in the negative strand of the CMV satellite RNA with some helper component(s) without essential contribution from a helper virus.

Subgroup III: small circular ss satellite RNAs This subgroup comprises satellites with genomes that contain about 350 nt and occur as circular as well as linear molecules (**Table 2**). Replication of some has been shown to involve self-cleavage of linear, multi-

meric, progeny molecules by an RNA-catalyzed reaction. The helper viruses of these satellite RNAs come from three different genera. The sobemoviruses specifically encapsidate the circular satellites (these satellites have been referred to as virusoids in some of the literature because of their structural resemblance to viroids and the erroneous, premature conclusion that they were essential for the replication of the helper virus). Members of the other two virus genera (*Nepovirus* and *Polerovirus*) encapsidate the linear form of the satellite RNA. However, the circular forms, which are essential for rolling circle replication (see below), can be found in infected tissues. As with small, linear satellite RNAs, circular satellites do not display messenger RNA activity, although some short ORFs are detected in the genomes of some of these circular satellites. The effect on symptoms induced by helper viruses may vary from attenuation to exacerbation, as in the case of small, linear, satellite RNAs. Satellite RNAs of TRSV generally reduce the titer of the helper virus as well as the severity of TRSV-induced symptoms. The satellite RNA of barley yellow dwarf virus (BYDV)-RPV (Rho-palosiphum padi virus) also reduces the accumulation of the helper virus and attenuates symptoms. By contrast, circular satellite RNAs of sobemoviruses, such as velvet tobacco mottle virus (VTMoV) sat-RNA, greatly enhance the severity of symptoms induced by the helper virus.

Satellite related agents

Satellite-like ssRNAs Two examples have been reported of RNA molecules which have many similarities to satellites and are not required for mechanical transmission/infection of the helper virus; however, in contrast to the true satellites these RNAs are required for the natural infection of the helper virus (**Table 3**). One of these, GRV (an umbravirus) ss satellite-like RNA, contains 895–903 nt. This RNA relies on GRV for its replication, but it is needed in addition to groundnut rosette assistor virus (a luteovirus) for aphid transmission of GRV. Therefore, it is essential for the survival of GRV in nature and is thus regarded as a satellite-like RNA. This RNA shares no significant sequence similarity with the GRV genomic RNA and does not code any functional proteins. It is the satellite-like RNA that is largely responsible for the symptoms of groundnut rosette. The GRV satellite contains two nontranslatable elements involved in symptom induction. Symptoms produced by different GRV satellites are independent of the helper GRV isolate, and indeed indistinguishable symptoms are produced when a different virus, pea enation mosaic virus (PEMV) is substituted for GRV as a helper virus. Thus it seems that this RNA may induce symptoms itself without an essential contribution from the GRV helper. Normally, satellite-like RNA isolates of GRV do not affect the accumulation of GRV genomic and subgenomic RNAs in infected plants, but a few, so-called mild GRV satellites have been identified that drastically diminish the replication of the helper GRV in infected or transgenic plants. Sequence alignment revealed striking similarities between GRV satellite-like RNAs and a true satellite RNA of PEMV, belonging to the subgroup II of small, ss, linear, satellite RNAs.

Although beet necrotic yellow vein virus (BNYVV) (a benyvirus) has a bipartite RNA genome, field isolates of BNYVV have two or three additional satellite-like RNAs of which RNA 3 (1774 nt) and RNA 4 (1467 nt) are essential for spread in root tissues and transmission by the fungal vector of the virus, respectively (**Table 3**). However RNA 5 (1342–1347 nt) of BNYVV may be a true satellite RNA, since it is not essential for spread of the virus in nature. The satellite-like RNA 3 has been also implicated in symptom expression (rhizomania). The 25 kDa protein encoded by the longest ORF of the RNA 3 is probably needed for symptom production. Another ORF, ORF N, which is translationally silent on full-length RNA 3 but is translationally activated by a long, internal deletion, may also contribute to symptom production in some hosts. RNA 4 also contains a long ORF encoding a potential 31 kDa protein, although it is not clear if it is essential for the functional activity of RNA 4. RNA 5 can intensify the severity of symptoms induced by BNYVV, and a 26 kDa protein encoded by this RNA may be important for the expression of symptoms.

Other satellite related agents *Hepatitis Delta Virus (HDV)* HDV is a subviral, human pathogen that propagates only in the presence of its helper. With this helper, HDV can replicate most efficiently in hepatocytes and can greatly increase the severity of liver damage caused by a hepatitis B virus (HBV) infection. The replication of HDV genome takes place in the nuclei of infected cells. The host RNA polymerase II (that usually directs DNA-dependent RNA synthesis) is probably responsible for this RNA-directed transcriptional event in infected cells, which is independent of the hepadnavirus helper. Therefore, by definition, HDV is not a satellite. However, HDV is dependent on the envelope proteins of the helper virus required for the assembly and release of infectious virions. The HDV genome is a single-stranded, circular, 1679 nt RNA that folds into an unbranched rod-like structure in which 70% of its

nucleotides are paired. This genomic RNA exists both within virions and in infected nuclei as a ribonucleoprotein (RNP), which contains the only protein encoded by HDV, the delta antigen. Two forms of this antigen are observed during infection. The small delta antigen (δAg-S), a 22 kDa nuclear phosphoprotein, is synthesized early and is required for replication to occur. Later in infection, a specific RNA-editing event leads to the mutation of the δAg-S termination codon and the synthesis of the large antigen, δAg-L, which contains an additional 19 amino acids at its C-terminus. δAg-L acts as a potent inhibitor of HDV genome replication and in combination with δAg-S promotes the assembly of the HDV RNP into HBV envelope particles.

Beet western yellows virus (BWYV)-associated RNA The ST9 strain of BWYV encapsidates not only the 5.6 kb genomic RNA that is typical of luteoviruses, but also a ss, linear 2843 nt-associated RNA (ST9aRNA), which has a distinct nucleotide sequence. The ST9aRNA was postulated to be a satellite RNA. However, this RNA has been shown to be able to replicate without a helper virus. Thus, ST9aRNA is an infectious, subviral agent of plants which depends on its associated virus, BWYV (ST9 strain), for encapsidation but not for replication. Plants infected with BWYV containing the ST9aRNA exhibit a more severe symptom phenotype and contain ~10-fold more virions than do plants infected with BWYV containing no ST9aRNA. The ST9aRNA contains three large ORFs, which, at least *in vitro*, can be translated to yield several products, the largest of which is ~85 kDa, derived from various combinations of readthrough of the three ORFs. The deduced amino acid sequence of two regions of an 85 kDa protein contain significant homology with the RNA-dependent RNA polymerase of carmoviruses.

Structure and Replication of Satellite RNA

Information on secondary structure and replication mechanisms has been obtained mostly for ss satellite RNAs. These small satellite RNAs have highly ordered secondary structures with base pairing up to 73%. The small size and high degree of secondary structure are probably responsible for the high stability, survivability and infectivity of many satellites. As mentioned above, small satellite RNAs may strongly modify symptoms induced by their helper viruses. The sequences involved in pathogenicity are located in discrete small domains. For example, in the case of the CMV satellite RNAs, distinct RNA elements, present in the positive or negative strands, may program chlorosis induction in tobacco and tomato or necrosis in tomato.

RNAs of some satellites can form a tRNA-like domain similar to some plant virus RNAs. For example, the 3′ end of the STMV RNA folds into a tRNA-like structure similar to that in TMV RNA. Accordingly, functional assays have shown that STMV RNA can be aminoacylated *in vitro* with histidine as is the case for TMV. The biological implications of these observations remains unknown.

Satellites are dependent on their helper viruses for replication. The helper virus in turn is dependent on the host plant to supply some components necessary for replication, and thus a complex three-way interaction between satellite, helper virus and plant host is required for satellite replication. The specificity of satellite replication occurs at the level of both the helper virus and the host plant species. With the satellite RNAs of TRSV and CMV, the apparent level of satellite replication varies widely with the strain of helper virus. In addition, related viruses may or may not replicate the same satellite RNAs. For example, most satellite RNA isolates of CMV are replicated efficiently by the related cucumovirus, TAV, but not by another cucumovirus, peanut stunt virus (PSV). Moreover, PSV satellite RNA replication is not supported by CMV. In addition to the helper virus specificity, the host plant often plays a significant role in the efficiency of satellite replication. The small satellite RNA of ArMV replicates very efficiently in *Chenopodium quinoa*. By contrast, the large satellite RNA of another nepovirus, TBRV, replicates poorly in *C. quinoa*, but replicates very efficiently in *Nicotiana clevelandii*. Replication of satellite RNAs has been presumed to occur using the replicase of the helper virus. However, satellite RNA replication does not always involve the same mechanism as replication of the viral RNAs, and it seems likely that other factors which are specific for satellite replication are involved. For large satellite RNAs associated with nepoviruses, the satellite RNA-encoded proteins may function as such factors interacting and modifying the helper virus replication complex. In the case of noncoding, linear, satellite RNAs like the CMV or TRSV satellites, such factor(s) might be host component(s).

Circular, ss, RNA satellites are replicated by a rolling circle mechanism. The replication cycle involves the copying of the encapsidated circular plus (+) strand by an RNA-dependent RNA polymerase to yield a longer than unit length minus (−) strand, which in most cases can self-cleave to yield monomeric products. (For satellite RNAs present in virions as linear molecules this stage is preceded by a ligation

of (+) linear molecules to yield a circular (+) strand.) Then, these (−) RNA monomers are circularized and copied to produce a multimeric, linear (+) strand, which self-cleaves to form linear (+) monomers, which then self-ligate to form circular satellite RNAs. For those multimeric (−) RNAs which are not processed (e.g. satellites of some sobemoviruses), the multimeric (−) RNA is copied to give a multimeric (+) strand which then undergoes cleavage to monomers. The (+) RNA monomers are either circularized and then encapsidated in the circular form (as in the case of sobemovirus satellite RNAs), or packaged as a linear form [as in the case of the BYDV-RPV satellite RNA (a luteovirus), and the small nepovirus satellite RNAs]. Replication of HDV RNA also occurs via a rolling circle mechanism and self-cleaving reactions. HDV is the only animal pathogenic RNA which replicates via a rolling circle mechanism.

There are two types of ribozyme structure found in satellite RNAs possessing self-cleavage activity: the hammerhead and the hairpin ribozymes. Hammerhead structures have been identified in both (+) and (−) RNA strands of lucerne transient streak virus (LTSV) (a sobemovirus) and BYDV-RPV (a luteovirus), as well as in the (+) strands of small satellite RNAs of nepoviruses. Hairpin structures have been found in (−) strands of small nepoviruses. The HDV RNA also contains self-cleaving sequences. However, these appear different from hammerhead and hairpin ribozymes.

Sequence Variation, Evolution, Origins

Some sequence variants of plant satellite viruses (in particular STMV, STNV and SSADV) as well as plant satellite RNAs (predominantly satellite RNAs of CMV and TRSV) have been described. The STNV and CMV satellite RNAs exhibit differences in biological properties, often in a particular host. The large number of CMV satellite RNA isolates sequenced has been used to establish the evolutionary relationships between different groups of CMV satellite RNAs and to demonstrate the presence of structural constraints on satellite RNA evolution. In the case of CMV satellite RNAs, the actual evolution of satellite RNAs in the greenhouse as well as in the field has been observed, as a function of passage with different helper virus strain.

Nothing is known about the origin of satellite RNAs. Limited sequence similarity was observed between one satellite RNA of CMV and chloroplast RNA sequences, and between a satellite RNA of CMV and the potato spindle tuber viroid.

Strategies for Virus Control

The ability of satellite to attenuate the disease symptoms induced by their helper viruses has led to the suggestion that satellite may be useful as biological control agents of pathogenic molecules. Two approaches to test the viral control potential of satellite have been used. In the first approach, the application of mild strains of CMV containing satellite RNA to greenhouse and field crops has been evaluated. In several cases, CMV containing satellite RNA are able to protect plants to various extents against infection by more virulent strains. In the second approach, transgenic plants expressing CMV satellite RNA, TRSV satellite RNA, or GRV satellite-like RNA sequences were found to be either resistant or tolerant to virus infection. Moreover, plants expressing CMV satellite RNA sequences are also resistant to potato spindle tuber viroid, with which CMV satellite RNA shares some similarity.

SENDAI VIRUS (*PARAMYXOVIRIDAE*)

Morio Homma, Department of Home Economics, Kobe Women's University, Kobe, Japan

Masato Tashiro, Department of Viral Diseases and Vaccine Control, National Institute of Infectious Diseases, Tokyo, Japan

History

Sendai virus was first discovered in 1952 by Kuroya, Ishida and Shiratori at Tohoku University Hospital, Sendai, Japan, during an epidemic of fatal pneumonitis among newborn babies. A new virus with hemagglutinating activity antigenically different from known influenza viruses was recovered from mice inoculated with the autopsied lung tissues. The virus was originally named newborn pneumonitis virus, type Sendai. However, the question soon arose as to the causative agent of human disease because this virus was reported to be widely spread among laboratory rodents and pigs in Japan at that time. Since then, Sendai virus has been shown to prevail worldwide and to cause enzootic or epizootic infections in mice and rats. Sendai virus was designated hemagglutinating virus of Japan (HVJ) in 1955 by the Society of Japanese Virologists. Later, Sendai virus was shown to be related to human parainfluenza virus type 1, isolated by Chanock in 1955 and named hemadsorption virus type 2 (HA2). As Sendai virus causes a respiratory infection in mice, this virus–animal system has been widely investigated in pathogenesis and immunology as a suitable model of respiratory viral infections. Okada's finding of cell fusion by Sendai virus in 1958 has developed a new field of cell biology, e.g. the production of hybrid cells such as heterokaryons and hybridomas. Proteolytic activation of the fusion glycoprotein was first described for Sendai virus by Homma and Ohuchi in 1973. Additionally, most of the information on the molecular biology of paramyxoviruses has been obtained from studies on Sendai virus, the prototype of the family *Paramyxoviridae*. Recently, a reverse genetics technology to recover infectious viral particles from a cDNA copy of the Sendai virus genome was developed by Kato, by which any mutant viruses could be obtained.

Taxonomy and Classification

Sendai virus belongs to the genus *Respirovirus* in the subfamily *Paramyxovirinae* of the family *Paramyxoviridae* of RNA viruses. Based on serological relationships, Sendai virus is assigned to a murine subtype of human parainfluenza virus type 1, the classification being supported by phylogenetical analyses of the genome nucleotide sequences among paramyxoviruses.

Properties of Virion and Genome

The virions are pleomorphic in size and shape. They are roughly spherical and 150–250 nm in diameter but larger particles are common. The particles consist of a nucleocapsid with helical symmetry (18 nm in width, 1 μm in length), which is enclosed by a lipid envelope derived from host cell plasma membrane. The nucleocapsid is composed of a nonsegmented, linear, negative-stranded genomic RNA (15 384 nucleotides) containing six genes, covalently linked in tandem, and associated proteins NP, P and L (**Fig. 1**). The envelope contains protein M beneath the inner layer, and two spike-like projections, composed of tetramers of glycoprotein HN and trimers of glycoprotein F, respectively. They penetrate the lipid bilayer beyond the outer surface to make the fuzzy appearance of the envelope surface when viewed by electron microscopy. The NP protein (58 kDa), bound directly to the genomic RNA, is the major structural component of the nucleocapsid. Proteins P (72 kDa) and L (255 kDa) act in concert as RNA polymerase complexes with transcriptase and replicase activities. The P–NP complex functions to encapsidate the RNA genome. The C and V proteins, nonstructural proteins and possible minor virion components encoded by overlapping reading frames within the P gene region, are not essential for viral replication but

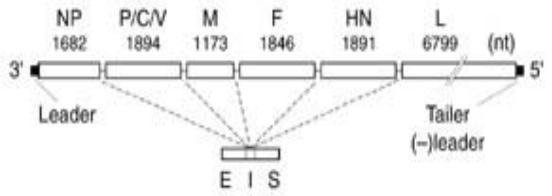

Figure 1 Sendai virus genome RNA. The extragenetic 3′-terminal leader and the complementary 5′-tailer regions are shown by bold lines. The conserved transcription regulatory sequences (E, end; I, intergenic; S, start) are located at the gene boundaries.

appear to regulate mRNA transcription and genome replication. The M protein (40 kDa) has a dual affinity for the NP protein and the cytoplasmic domain of the glycoproteins and plays an important role in the virus assembly process. The larger glycoprotein HN (68 kDa) has receptor binding, hemagglutinating and neuraminidase activities, while the smaller glycoprotein F (63 kDa), when proteolytically cleaved into disulfide-linked F_1 and F_2 subunits, has membrane fusing and hemolytic activities and mediates virus entry through envelope fusion.

Replication

In common with other paramyxoviruses, virus replication takes place exclusively in the cytoplasm and does not require DNA synthesis of host cells. A one-step replication cycle takes about 12–15 h and one infected cell usually yields thousands of progeny viral particles.

Virus Entry

The HN glycoprotein mediates attachment of viral particle to the sialic acid-containing receptors on the carbohydrate side chains of the glycoproteins or glycolipids of host cell surface. After adsorption, the F (F_1 + F_2) glycoprotein mediates, at neutral pH, an envelope fusion between the viral envelope and the plasma membrane, by which the nucleocapsid is introduced into the cytoplasm to initiate the primary transcription catalyzed by the virion-associated RNA polymerase complexes.

Characterization of Transcription

Transcription of the genome RNA to synthesize mRNA occurs in the cytoplasm, for which host factors, e.g. tubulin, are required. The genomic RNA consists of the leader sequence at the 3′ end and the related tailer sequence at the 5′ end. There is a tandem set of six genes ordered NP, P/C/V, M, F, HN and L, and bound by the consensus transcriptional regulatory sequences for the poly(A) initiation site (E), intergenic (I) and a gene start sequence (S). The P–L polymerase complexes associated with the nucleocapsid catalyze the primary transcription to synthesize monocistronic mRNA species, with adding poly(A) tail at the 3′ end, corresponding to each polypeptide. Several polycistronic mRNAs may also be synthesized by reading through the stop signals at the intergenic sequence. The P/C/V gene encodes the P mRNA of the complementary copy of the genomic RNA, from which the P protein is translated. The C protein, a small basic protein, is also translated from a (+1) open reading frame in the 5′ end region of the P mRNA by internal translational initiation at another site. In addition to the P gene transcript, a second mRNA species is synthesized by RNA editing, with insertion of an additional G residue not coded by the genome at the specific editing site, resulting in a frameshift downwards. The second mRNA encodes the V protein, a hybrid protein with the N-terminus half of the P protein and a new reading frame downwards for a cysteine-rich C-terminus region. The secondary transcription is catalyzed by the RNA polymerase complexes of the viral proteins newly synthesized in infected cells.

Characterization of Translation

Each monocystronic mRNA translates a corresponding polypeptide. With the P mRNA, however, four nonstructural proteins (C, C′, Y_1, and Y_2) are synthesized from reading frames overlapping the P gene using different initiation codons by ribosomal scanning. The glycoproteins HN and F are synthesized on membrane-bound polysomes and subjected to post-translational processing.

Post-translational Processing

The F protein, a type I membrane protein, is translated and inserted into the membrane of the rough endoplasmic reticulum by the signal peptide at the N-terminus, which is removed after insertion. On the other hand, the HN is a type II membrane protein anchored to the lipid bilayer at a hydrophobic region in the N-terminus. Both proteins are glycosylated and during transport to the smooth endoplasmic reticulum the carbohydrate side-chains are processed to mature forms. The HN polypeptide forms homotetramers, a pair of disulfide-linked dimers, while the F polypeptide forms homotrimers by noncovalent bonds.

This precursor form of F glycoprotein is biologically inactive, and gains the fusion activity by proteolytic cleavage into the disulfide-linked subunits, F_1 and F_2 (**Fig. 2**). The cleavage site of the F protein,

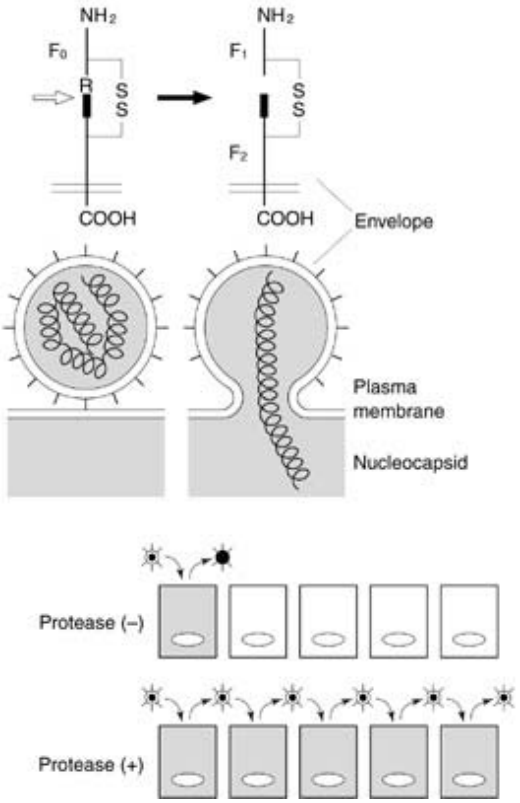

Figure 2 Proteolytic activation of Sendai virus F glycoprotein and infectivity. Upper panel: Sendai virus infects target cells through envelope fusion between viral envelope and plasma membrane. Sendai virus possessing the precursor F_0 is noninfectious. Proteolytic cleavage of F_0 by an activating protease at residue 116-arginine (indicated by open arrow) into disulfide-linked subunits, F_1 and F_2, results in the exposure of hydrophobic fusion-inducing domain (shown by bold lines), which is required for membrane fusion activity and infectivity. Lower panel: Sendai virus can undergo multiple cycles of replication and show pathogenicity in tissues where suitable activating protease(s) is present. Open circles indicate activated (infectious) virus particles and closed circle indicates nonactive (noninfectious) particle.

consisting of a single arginine residue, is not cleavable by ubiquitous cellular proteases present in the trans-Golgi region that cleave preferentially dibasic or multibasic motifs. Accordingly, Sendai virus produced in most tissue culture cells possesses uncleaved F protein and remains nonactive, lacking cell fusion and hemolytic activities and infectivity. These activities are restored by *in vitro* treatment of the virus with trypsin, blood clotting factor Xa in the chorioallantoic fluid of chicken eggs, and tryptase Clara, a serine protease secreted by Clara cells of rat bronchial epithelia. By contrast, progeny virus is recovered in the activated form in several host cells or tissues, such as the chorioallantoic membrane of chick embryos, primary monkey kidney cells and mouse lungs. In these cases, the cleavage of F protein takes place extracellularly by secreted host proteases which cleave the single arginine residue of the F protein.

Strategy of RNA Replication

Replication of the genome RNA is mediated by polymerase complexes composed of the gene products of the primary transcripts, P, L and probably some of the nonstructural proteins. The NP proteins assembled with the genomic RNA also interact with the replication complexes. The leader sequence at the 3′ end and the tailer sequence at the 5′ end of the genomic RNA are required for genome replication. The C protein appears to regulate the switch between mRNA transcription and genome replication. Genome replication provides templates for secondary transcription and for further amplification of the genome, and finally supplies the mature progeny genome for incorporation into virus particles. The entire nucleotide sequence of the negative-stranded genomic RNA is copied complementarily to the antigenomic positive-stranded RNA that serves as an intermediate template for the synthesis of progeny genome RNA. Subgenomic RNA species are frequently synthesized and incorporated into viral particles producing defective-interfering (DI) particles.

Assembly and Release

The progeny genome RNA is combined with the NP protein to form a helical structure to which the P and L proteins are incorporated to form the assembled nucleocapsid. The glycoproteins F and HN are transported through the Golgi apparatus to the cytoplasmic membrane, where they replace host membrane proteins. In polarized epithelial cells, the glycoproteins are transported to the apical membrane domain, where virus assembly occurs. The M protein accumulates beneath the cytoplasmic domain of the glycoproteins and binds the glycoprotein tails with the nucleocapsid. Viral particles are then assembled by budding with incorporation of the lipid bilayer of the host plasma membrane to form the viral envelope. Cellular actin, which is incorporated into the envelope, plays a role in the budding process. The neuraminidase residing on the HN glycoprotein facilitates the release of viral particles from infected cells by destroying cellular receptors.

Cytopathology

Sendai virus usually produces a lytic-type cytopathic effect, which is associated with disruption of the cytoskeletal systems likely caused by the M protein. Apoptotic cytolysis is also reported with Sendai virus-

infected cells. Since the F protein is not activated in ordinary tissue culture cells, syncytial formation mediated by 'fusion from within' is not observed, unless trypsin is added to the culture medium. Inhibition of cellular RNA or protein synthesis is not remarkable. Sendai virus can set up a variety of persistent infections in tissue culture cells without killing infected cells.

Cell Fusion

Sendai virus causes cell fusion and produces multinuclear giant cells. The F protein is directly responsible for the fusion activity for which proteolytic activation is required. Coincidence of the HN glycoprotein is specifically required for inducing cell fusion. Cell fusion falls into two categories: 'fusion from without (FFWO)' and 'fusion from within (FFWI)'. FFWO occurs in cells within a few hours after infection at high multiplicity of virus infection and does not require virus replication. FFWO has been used for producing hybrid cells, such as heterokaryons and hybridomas, and for introducing macromolecules into cells. On the other hand, FFWI occurs late in the replication cycle and is mediated by, in concert with the HN glycoprotein, the F protein synthesized in infected cells and expressed at the cell surface in the activated form.

Geographic Distribution

Retrospective serological surveillance revealed that Sendai virus initially appeared in Japan in the early 1950s and became prevalent worldwide by 1970 as a most common contaminant in laboratory rodent colonies under conventional conditions.

Host Range and Virus Propagation

Mice and rats are natural hosts of Sendai virus, while other rodents, including hamsters, guinea pigs and rabbits, and also pigs can be infected. Suckling and weanling mice are highly susceptible to the respiratory infections. Susceptibility to experimental infections varies considerably among mouse strains, probably due to differences in immunological responses. Sendai virus can grow efficiently in the chorioallantoic cavity of embryonated chicken eggs and replicates productively in a broad spectrum of tissue culture cell lines as well. However, exogenous trypsin is usually needed for proteolytic activation of the F glycoprotein to support multiple cycles of replication in tissue culture cells. Primary monkey kidney cells support multiplication of the virus without exogenous proteases. Sendai virus isolated from mice and passaged only in mouse lungs or monkey kidney cells retains original pathogenicity in mice, whereas it becomes less pathogenic, due to a mutation in the C gene, when passaged in chick embryos. Sendai virus replication is detected by hemagglutination of chicken erythrocytes and the virus is identified by the hemagglutination inhibition test.

Serological Relationship and Variability

The Sendai virus core soluble (S) antigen, mainly composed of the NP protein, exhibits a serological relationship to, but distinguishable from, human parainfluenza virus type 1. Envelope components, HN, F and M proteins, share antigenicity with their human counterparts among the members of the *Paramyxoviridae*, as determined by analyses of the genome nucleotide sequences. Sendai virus is antigenically homogeneous, i.e. there are no subtypes.

Epidemiology

Sendai virus is a most frequent contaminant maintained persistently in conventional colonies of laboratory mice and rats, while no evidence for the infection in wild rodents has been obtained. Both acute enzootic and epizootic infections occur in laboratory rodents.

Curiously, in the 1950s, Sendai virus was prevalent nationwide among pigs in Japan, but by 1961 the virus had disappeared from pigs. Infection of Sendai virus in pigs has not been reported in other countries.

Transmission and Tissue Tropism

Virus replication in the respiratory tract of mice reaches a peak 4–6 days after infection, declines gradually, and virus shedding terminates within 2 weeks. However, the virus may be recovered for up to 6 weeks after infection. In suckling mice, the virus persists longer. Virus transmission occurs either by direct contact with infected mice or by airborne route. Vertical transmission is suggested to occur from pregnant mice to fetus, resulting in stillbirths or a variety of malformations in offspring.

Sendai virus is exclusively pneumotropic in weanling and adult mice, the target tissues being restricted to the epithelial cells of the upper respiratory tract, trachea, bronchi and bronchioles. Neither subepithelial invasion from the surface mucosa nor spread to systemic organs via viremia occurs. Alveolar cells are not infected under usual conditions. Infection of alveolar and peritoneal macrophages results in abortive infections. In newborn and suckling mice, the virus may spread from the nasal epithelium to the brain via the olfactory route. Intracranial inoculation

of the mice causes infections in the ependyma and meninges.

Pathogenicity

Pneumotropism of Sendai virus in mice cannot be explained by cellular receptors in the lungs, as receptors for the virus are also present in other organs not permissive for Sendai virus infection. Instead, pneumotropism has been shown to be primarily determined by host protease-mediated activation of the F glycoprotein. Activated virus with the cleaved F ($F_1 + F_2$) protein will infect the respiratory mucosa and replicate in multiple cycles, as the F protein of progeny virus undergoes cleavage activation in the bronchial lumen by tryptase Clara, an arginine-specific serine protease secreted by Clara cells of the bronchial epithelium. Upon Sendai virus infection, secretion of tryptase Clara is stimulated, whereas that of pulmonary surfactant, an inhibitor of the protease also secreted by Clara cells, is reduced, thereby producing a condition in the bronchial lumen preferable for activation of progeny virus. As a result, infected cells are increased in number and lung lesions are extended. In contrast, infection by a protease-activation mutant, whose F protein is not cleavable by trypsin and tryptase Clara but by chymotrypsin, terminates after a single cycle of replication in the lung, because the progeny virus remains noninfectious. Various organs of mice other than lungs, which lack the protease(s) required for the activation of wild-type F protein, have a potential capacity to support replication of wild-type virus but only for a single cycle. On the other hand, a pantropic mutant, whose F protein is cleavable by ubiquitous host proteases distributed in various organs, causes a systemic infection in mice. These results, together with similar observations on the virulence of Newcastle disease virus and avian influenza viruses, indicate that organ tropism and pathogenicity of Sendai virus are primarily determined by the presence of activating proteases for the F protein in target tissues.

The mode of virus budding at the primary target of infection is considered an additional determinant for organ tropism. The budding site of wild-type Sendai virus in the bronchial epithelial cells is restricted to the apical membrane domain, whereas the pantropic mutant buds bidirectionally at the apical and basolateral domains, due to amino acid exchanges in the M protein. This may explain why infection by wild-type virus remains localized in the surface epithelium of the respiratory tract, whereas the pantropic mutant readily invades subepithelial tissues to gain access to the spread to distant organs via viremia.

A deletion mutant in the V protein replicates less efficiently in mouse lungs, causing a slighter lung lesion, although it is highly cytopathic in tissue culture cells. The results suggest a regulatory role of the V protein in the pulmonary pathogenicity.

Clinical Features of Infection

With enzootic infections the virus usually produces a subclinical infection in mice and rats. Experimental infections as well as epizootic infections cause symptoms characteristic of acute respiratory infection. Moderate fever, ruffled furs and nasal discharge are common signs of the upper respiratory infection, appearing 2–3 days after exposure. Dyspnea, cough, anorexia and loss of body weight, which usually appear on the sixth or seventh day after infection, will indicate progression to bronchopneumonia. With weanling mice, retardation of body weight gain reflects the severity of the disease. In the second week of infection, infected animals die of bronchopneumonia or begin to recover from the infection. In newborn or 1- to 2-day-old suckling mice, intracranial inoculation causes meningitis and ependymitis, resulting in hydrocephalus.

Pathology and Histopathology

Major pathology of Sendai virus infection in mice is mild rhinitis, moderate tracheitis and severe bronchopneumonia. Immunohistological studies reveal that target tissue of the virus is confined to the epithelial mucosa of the upper respiratory tract, trachea, bronchi and bronchioles. Subepithelial tissues, alveolar epithelium and infiltrating cells are not usually involved. Macroscopically the lungs become swollen and hyperemic in a few days after intranasal infection, and lung consolidation, looking like the liver or spleen, begins to appear around day 7. Light microscopic studies reveal infected epithelial cells to be swollen and pyknotic with destruction of cilia within day 1. Submucosal edema and hyperemia occur with a peribronchial infiltration by neutrophils and mononuclear cells. For several days such infected cells increase progressively in number, meanwhile becoming necrotic and desquamated. The cellular infiltration progresses for 2 weeks, with massive edema and bleeding in the interstitium and alveolar spaces. Resolution of the lesion, if it occurs, begins about day 10 and proceeds rapidly, but complete resolution takes more than a month. When 1- to 2-day-old mice are infected intracranially, meninges, ependyma, choroid plexus and labyrinth are involved with respective inflammations.

Immune Response

Recovery from Sendai virus infections involves both humoral and cellular immunities. Envelope glycoproteins, HN and F, are mainly responsible for the humoral response and internal proteins, NP and M, are also of importance as target antigens for the cellular responses. Virus is cleared mainly by CD8+ cytotoxic T lymphocytes (CTLs) in a class I-restricted manner, and therefore, in nude mice, virus infection persists for more than 2 months. CTL response in mice depends on the *H-2* haplotype. Macrophages, natural killer cells and interferons contribute to the virus clearance in concert with the T lymphocytes. Lung consolidation is mainly caused by CD4+ T cells primed by the internal proteins.

Mucosal IgA antibodies to the HN are primarily responsible for resistance to infection. Serum IgG antibodies are less effective for preventing replication of initially infecting virus, but can minimize further replications and lung lesions. The role of cellular immunity in protection is controversial.

The HN molecule contains at least four antigenic epitopes. Antibodies against HN inhibit hemagglutinating and neuraminidase activities, and neutralize infectivity. Antibodies to the F protein, with at least four antigenic sites, inhibit fusion and hemolytic activities, and can also prevent infection, specifically cell-to-cell infection. When mice are infected, considerable titers of serum antibodies become detectable. Since the HN, F, NP and M proteins share antigenic determinants with other members of paramyxoviruses, most closely to human parainfluenza virus type 1, heterotypic antibody responses may occur when Sendai virus-primed animals are immunized or boosted with a related virus, or vice versa.

Sendai virus is a strong inducer of interferons in tissue culture cells and in mice.

Prevention and Control

Control of Sendai virus infection is practically important for breeding and maintenance of laboratory animals and for the performance of animal experiments. Contamination with the virus will interfere with experimental data, specifically in immune responses and lung histology, and often interrupts animal experimentation by causing epizootic acute infections, with or without devastating animal death. A drop in breeding efficiency as a result of infection can be critical for maintenance of animal strains.

Virus-free animals are produced by cesarean birth and can be maintained under specific pathogen-free conditions isolated from conventional colonies. Once Sendai virus-free colonies are established, frequent serological surveillance and quarantine of contaminated colonies are needed for maintenance of laboratory animals.

Inactive vaccines prepared from egg-grown virus are commercially available, but are presently far from being in general use. Experimental live vaccines of protease-activation mutants, temperature-sensitive mutants or defective-interfering particles with considerable efficacy have been developed. Recombinant vaccinia viruses with genes encoding Sendai virus proteins or oligopeptides corresponding to the epitopes responsible for immune protection have been shown to induce protection in mice.

SEQUIVIRUSES (*SEQUIVIRIDAE*)

MA Mayo and **AF Murant**, Scottish Crop Research Institute, Invergowrie, Dundee, UK

History

The genus name *Sequivirus* was adopted in 1995 for the former 'parsnip yellow fleck virus group'. The eponymous member (PYFV) was first described in 1968 and two serotypes have been recognized, both infecting plants in the family Umbelliferae: parsnip serotype, found in parsnip, celery and *Heracleum sphondylium*; and anthriscus serotype, found in carrot and *Anthriscus sylvestris*. Both serotypes depend on a helper virus, anthriscus yellows virus (a tentative member of the genus *Waikavirus* of the family *Sequiviridae*) for transmission by aphids in a semipersistent manner. The only other species in the genus *Sequivirus* is dandelion yellow mosaic virus (DYMV) which was first isolated from diseased *Taraxacum officinale* (Compositae), but causes a severe necrotic disease in lettuce (*Lactuca sativa:* Compositae). DYMV has been relatively little studied but it is aphid-transmitted and the limited data available suggest a semipersistent mode of transmission. There is no evidence to show if a helper virus is involved.

Taxonomy and Classification

Viruses in the genus *Sequivirus* have isometric particles of *c.* 30 nm diameter and monopartite, positive-sense, single-stranded (ss) RNA genomes of about 10 kb. The RNA-dependent RNA polymerase encoded by PYFV RNA is 'picorna-like'. The genus is classified, together with the genus *Waikavirus* (type member, rice tungro spherical virus), in the family *Sequiviridae*. Viruses in both genera have genomes that encode a large polyprotein from which the mature virus proteins are cleaved by protease action. The viruses possess three coat proteins whose genes are located near the 5′ ends of the genomes, properties which are shared with picornaviruses. Sequiviruses have sometimes been referred to as 'plant picornaviruses'.

Properties of the Virion

Although PYFV may have an infectivity dilution end-point of up to 10^{-5} in sap of *Spinacia oleracea* (spinach), the virus concentration is often very low in extracts of glasshouse-grown plants. Best virus yields have been obtained by growing infected *S. oleracea* plants at 15°C with light at 10 000 lux for 8 h per day, and collecting systemically infected leaves 19 days after inoculation of the plants. Yields of about 5–20 mg of viral nucleoprotein per kilogram of leaf material are obtained by clarifying leaf extracts with diethyl ether or butan-1-ol followed by differential centrifugation.

Particle preparations of PYFV contain 30 nm diameter isometric particles which sediment either as 'top component' (apparently empty protein shells) or 'bottom component' (infective nucleoprotein particles). The top component particles are relatively fragile. Top and bottom components of an isolate of the parsnip serotype, separated by sedimentation in sucrose density gradients or by isopyknic banding in CsCl or Cs_2SO_4 solutions, respectively had sedimentation coefficients ($s_{20,w}$) of 60 S and 152 S, buoyant densities in CsCl of 1.29 and 1.49 g ml^{-1}, and A_{260}:A_{280} ratios of 0.8 and 1.7. Top and bottom component particles of PYFV contain three major protein species of M_r ($\times 10^{-3}$) 31, 26 and 22.5 (parsnip serotype) or 31, 26 and 24 (anthriscus serotype). Bottom component particles of PYFV each contain one ssRNA molecule of *c.* 10 kb.

The infectivity dilution end-point of DYMV in sap of *Chenopodium amaranticolor* or *C. quinoa* may be up to 10^{-5}. Purification involves clarification of phosphate-buffered extracts of leaf by adding butan-1-ol to a concentration of 8% (v/v), followed by differential centrifugation; however, the yields are low. The nucleoprotein particles are isometric, *c.* 30 nm in diameter, and have an $s_{20,w}$ of 159 S, A_{260}:A_{280} of 1.67 and a buoyant density in Cs_2SO_4 of 1.42 g ml^{-1}. DYMV particles have three protein species, of M_r ($\times 10^{-3}$) 32, 29.5 and 27, and one ssRNA molecule of *c.* 10 kb.

Properties of the Genome

Most of the 9871 nucleotide ssRNA genome of PYFV comprises one large open reading frame that encodes a polyprotein of 3027 amino acids. Mature coat proteins, such as the virion proteins, are produced from the primary polyprotein translation product by proteolysis. **Figure 1** illustrates the position of this open reading frame in PYFV RNA. The genome RNA does not have a 3′-terminal poly(A) sequence and is thought to have a 5′-terminal genome-linked protein.

Figure 1 also shows the polyprotein translation product of the PYFV genome RNA and indicates

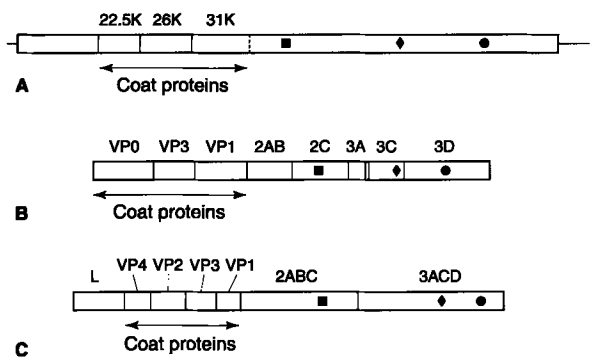

Figure 1 Genome organization of (**A**) PYFV, and comparison of the PYFV polyprotein with those of (**B**) poliovirus 1 and (**C**) foot-and-mouth disease virus. The locations of conserved domains are shown as filled squares (NTP-binding), filled diamonds (protease) or filled circles (polymerase).

where coat proteins have been mapped in the polyprotein. Other cleavage sites are unknown. However, some sequences in the polyprotein have striking similarities to those of domains in other virus proteins that are thought to have NTP-binding, protease or RNA-dependent RNA polymerase functions. The positions are shown on the diagram. Viruses in several families of plant viruses have genomes that are expressed by the cleavage of a large polyprotein. However, the genomes most resembling those of sequiviruses (and of waikaviruses which form the other genus in the family *Sequiviridae*) are those of viruses in the family *Picornaviridae*. Two examples of the polyproteins of such viruses are shown for comparison in **Fig. 1**. In some, the coat proteins are N-terminal; in others there is a protein to the N-terminal side of the coat proteins. The relative positions of the three domains with putative functions in the PYFV polyprotein are the same as in the picornavirus polyproteins (**Fig. 1**).

Sequence Comparisons

Some small regions of the structural and nonstructural proteins of PYFV seem to resemble sequences in picornaviral structural proteins. But there is little overall percent identity much in excess of that between unrelated proteins. This is also true in comparisons between PYFV nonstructural proteins and corresponding proteins of viruses in the genus *Waikavirus*, or of viruses such as comoviruses and nepoviruses (family *Comoviridae*). **Table 1** shows the only values of percent identity between pairs of proteins that were above the background level in comparisons of PYFV proteins and corresponding proteins of other 'plant picornaviruses' (family *Comoviridae*) and viruses in the genera *Enterovirus* and *Hepatovirus* (family *Picornaviridae*).

Evolution

The similarity between the genome expression strategies of sequiviruses and picornaviruses has prompted speculation about common ancestry of these groups. Some picornaviruses have insect hosts, and sequiviruses and waikaviruses are transmitted by insects (see below), albeit in a nonpropagative fashion. This has prompted further speculation about a common origin from an insect virus ancestor. As in most such speculation, there is no evidence to support or to counter these ideas.

Serology

PYFV and DYMV are moderately to highly immunogenic. The virus concentrations in plant extracts are usually too low for reactions to be obtained in gel diffusion tests but satisfactory results can be obtained in other kinds of test, including ELISA and immunosorbent electron microscopy (ISEM). The parsnip and anthriscus serotypes differ by a serological differentiation index of 4–5. Results of ISEM tests suggest the possibility of an extremely distant serological relationship between PYFV and DYMV.

Geographic Distribution

PYFV is reported only from the UK, The Netherlands

Table 1 Comparison of parsnip yellow fleck virus proteins with those of other viruses

	% identity with corresponding polypeptides of PYFV		
Virus	*NTP-binding*	*Polymerase*	*Classification*
Rice tungro spherical	41	49	*Sequiviridae*
Tomato black ring	29	33	*Comoviridae*
Cowpea mosaic	30	40	*Comoviridae*
Poliovirus 1	33	31	*Picornaviridae*
Hepatitis A	30	30	*Picornaviridae*

and Germany. DYMV is reported from these countries and also from Czechoslovakia, Scandinavia and China.

Host Range and Virus Propagation

Both PYFV and DYMV have restricted natural and experimental host ranges. In nature, PYFV is reported only from a few species of Umbelliferae: the parsnip serotype from parsnip (*Pastinaca sativa*), celery (*Apium graveolens*) and hogweed (*Heracleum sphondylium*); the anthriscus serotype from cow parsley (*Anthriscus sylvestris*), carrot (*Daucus carota*) and dill (*Anethum graveolens*). Experimentally, isolates of both PYFV serotypes can infect a few other species of Umbelliferae, notably chervil (*Anthriscus cerefolium*) and coriander (*Coriandrum sativum*), and a few plants in the families Amaranthaceae, Chenopodiaceae, Portulacaceae and Solanaceae. *Chenopodium amaranticolor* and *C. quinoa* are good local lesion assay hosts. *Spinacia oleracea* (spinach) and *Nicotiana clevelandii* (for the parsnip serotype only) are good systemic hosts for maintenance and propagation. *N. benthamiana* is a very sensitive indicator host, developing a lethal systemic wilt and necrosis in 4–7 days.

DYMV has been found naturally only in two species of Compositae (dandelion and lettuce). Experimentally, it has been transmitted to a few species in each of the families Amaranthaceae, Chenopodiaceae, Compositae and Solanaceae. *Chenopodium amaranticolor* and *C. quinoa* are useful both for local lesion assay and as systemic hosts for propagating the virus for purification.

Transmission and Tissue Tropism

Sequiviruses are mechanically transmissible, although mechanical transmission of DYMV to lettuce or dandelion is difficult. The natural vectors of sequiviruses are aphids: *Cavariella aegopodii* for PYFV and *Aulacorthum solani, Myzus ascalonicus, M. ornatus* and *M. persicae* for DYMV. Detailed information on aphid transmission of DYMV is lacking, but PYFV is transmitted only by aphids that also transmit a so-called helper virus (anthriscus yellows virus; AYV). The helper virus must be acquired either before or at the same time as PYFV. The AYV– PYFV complex is transmitted in a semipersistent manner. The minimum acquisition access time (AAT) is about 10–15 min and the minimum inoculation access time (IAT) is 2 min. The transmission efficacy of aphids increased with increasing AAT and IAT of up to 24 h. Adult aphids retain the ability to transmit for up to 4 days after the end of the AAT, but nymphs cease to transmit after molting. Aphids did not transmit virus after injection into the hemocele with purified preparations of PYFV or with extracts of aphids carrying PYFV and AYV. Electron microscopic examination of viruliferous aphids suggested that the virus is carried in the aphid foregut.

Sequiviruses are thought to infect cells in all host tissues. Virus can be acquired by aphids when they feed on mesophyll cells. Sequiviruses are not seed-transmitted.

Pathogenicity

The symptoms in parsnip plants of infection with the parsnip serotype range from yellow flecking to yellow and green mosaic with some stunting. Symptoms can be more severe in infected celery plants. The symptoms of infection of carrot plants with the anthriscus serotype range from mild mottling to severe necrosis, wilting and death.

Available evidence indicates that *Anthriscus sylvestris* is the main wild host of the anthriscus serotype, which infects carrot, and that *Heracleum sphondylium* is the main wild host of the parsnip serotype, which also infects celery. Both these wild hosts are infected symptomlessly. Carrot, celery and parsnip are immune to the helper virus, AYV, so that all the infections observed in these crops are primary and there is no secondary spread within the crop. Nevertheless, PYFV is common in parsnips in the UK. In celery, plants infected with PYFV are usually confined to the edges of fields. In The Netherlands, infection by the anthriscus serotype is uncommon in ware crops of carrot but common in carrot seed crops, in which infection results in 'early-season dieback', which in some years causes severe losses in seed production.

DYMV was so called because it was isolated from dandelion plants showing a bright yellow mosaic with rings and oak leaf patterns. It has also been isolated from lettuce showing a severe necrotic disease: veinal chlorosis and necrosis, thickening and curling of the leaves, severe stunting and prevention of heading. The virus was transmissible from diseased dandelion and lettuce plants to lettuce both by aphids and by manual inoculation. However, evidence that the virus that causes the necrosis in lettuce is the cause of the yellow mosaic in dandelion is either lacking or negative; the appropriateness of the name dandelion yellow mosaic virus for this virus is therefore in some doubt.

Prevention and Control

The diseases caused by PYFV in celery and parsnip, and in ware crops of carrot, do not seem to be

sufficiently serious to warrant specific control measures, although insecticides applied for the control of aphids or carrot fly (*Psila rosae*) may serve to decrease the incidence of PYFV. The disease caused by PYFV in carrot seed crops in The Netherlands is economically important but spraying with systemic biological control insecticide seems of only limited usefulness in preventing infection.

The restricted host range of the AYV helper virus suggests possible control measures by eliminating overwintering weed hosts in the vicinity of susceptible crops.

Little is known about the epidemiology or importance of DYMV. Most outbreaks of necrosis disease in field crops of lettuce occurred in the vicinity of yellow mosaic-diseased dandelion, which suggested that dandelion is an important overwintering host. There is no information about resistance genes.

SHRIMP VIRUSES

Philip C Loh, Department of Microbiology, University of Hawaii, Honolulu, Hawaii, USA

Introduction

Since the first shrimp virus *Baculovirus penaei* (BP) was isolated from wild penaeid shrimp (*Penaeus duorarum*) in the early 1970s, a number of penaeid shrimp viruses have assumed great importance because of the severe effect on the growth and sustenance of the penaeid shrimp aquaculture industry. Several of these viruses have been associated with large epizootics and massive mortalities in shrimp farms and hatcheries. The number of penaeid shrimp viruses reported at present belong to six families (**Table 1**). This number, however, is expected to increase and additional studies of viral diseases of penaeid shrimp result in more being isolated and characterized. Many of the penaeid shrimp viruses have only been observed through electron microscopy and have not been extensively characterized in regard to their biological, immunological, biochemical and physical properties.

The Host Animal

Depending on the geographic location, the following penaeid shrimp species have been commercialized on a large scale: *Penaeus monodon* (giant tiger shrimp); *P. vannamei* (whiteleg shrimp); *P. stylirostris* (blue shrimp); *P. japonicus* (kuruma shrimp); *P. chinensis* (orientalis) (fleshy prawn); *P. duorarum* (northern pink shrimp); *P. merguiensis* (banana shrimp); *P. indicus* (Indian white prawn); and *P. setiferus* (northern white shrimp).

The Virus: General Features

Host range

The penaeid shrimp viruses implicated in epizootics and associated with massive mortality in cultured shrimp belong to four groups: *Baculoviridae, Rhabdoviridae, Parvoviridae, Picornaviridae* (**Table 1**).

SHRIMP VIRUSES

Philip C Loh, Department of Microbiology, University of Hawaii, Honolulu, Hawaii, USA

Introduction

Since the first shrimp virus *Baculovirus penaei* (BP) was isolated from wild penaeid shrimp (*Penaeus duorarum*) in the early 1970s, a number of penaeid shrimp viruses have assumed great importance because of the severe effect on the growth and sustenance of the penaeid shrimp aquaculture industry. Several of these viruses have been associated with large epizootics and massive mortalities in shrimp farms and hatcheries. The number of penaeid shrimp viruses reported at present belong to six families (**Table 1**). This number, however, is expected to increase and additional studies of viral diseases of penaeid shrimp result in more being isolated and characterized. Many of the penaeid shrimp viruses have only been observed through electron microscopy and have not been extensively characterized in regard to their biological, immunological, biochemical and physical properties.

The Host Animal

Depending on the geographic location, the following penaeid shrimp species have been commercialized on a large scale: *Penaeus monodon* (giant tiger shrimp); *P. vannamei* (whiteleg shrimp); *P. stylirostris* (blue shrimp); *P. japonicus* (kuruma shrimp); *P. chinensis* (orientalis) (fleshy prawn); *P. duorarum* (northern pink shrimp); *P. merguiensis* (banana shrimp); *P. indicus* (Indian white prawn); and *P. setiferus* (northern white shrimp).

The Virus: General Features

Host range

The penaeid shrimp viruses implicated in epizootics and associated with massive mortality in cultured shrimp belong to four groups: *Baculoviridae, Rhabdoviridae, Parvoviridae, Picornaviridae* (**Table 1**).

Table 1 Penaeid shrimp viruses

Family	*Name/acronym*	*Shape/size (nm)*	*Nucleic acid/sense*	*Envelope*	*Growth in cell culture*
Rhabdoviridae	Rhabdovirus of penaeid shrimp/RPS	Bullet, 70 × 125	ssRNA (−)	+	+
	Yellowhead virus/YHV	Bacilliform, 45 × 160	ssRNA (−)	+	+
Picornaviridae	Taura syndrome virus/TSV	Icosahedron, 31–32	ssRNA (+)	−	−
Reoviridae	Type III reolike virus/REO-III	Icosahedron, 50–70	dsRNA (segmented)	−	−
	Type IV reolike virus/REO-IV				
Togaviridae	Lymphoid organ vacuolization virus/LOVV	?, 55	?	+	−
Parvoviridae	Infectious hypodermal and hematopoietic necrosis virus/IHHNV	Icosahedron, 22–25	ssDNA	−	−
	Hepatopancreatic parvovirus/HPV	Icosahedron, 22–24	ssDNA	−	−
	Lymphoidal parvo-like virus/LPV	Icosahedron, 25–30	?	−	−
Baculoviridae					
Occluded Type A					
	Baculovirus penaei/BP	Rod, 75 × 228	dsDNA	+	−
	Monodon baculovirus/MBV	Rod, 69 × 275	dsDNA	+	+
Nonoccluded Type C					
	Baculoviral midgut necrosis/BMN	Rod, 72 × 310	dsDNA	+	−
	Bacilliform virus/BV	Rod, 83 × 275	dsDNA	+	−
	Chinese baculovirus/CBV	Rod, 120 × 265	dsDNA	+	+
	Systemic ectodermal mesodermal baculovirus/SEMBV	Rod, 121 × 276	dsDNA	+	+
	Whitespot baculovirus/WSBV	Rod, 87 × 330	dsDNA	+	+
	penaeid rod-shaped DNA virus/PRDV	Ovoid, 84 × 226	dsDNA	+	+

The susceptibility of the different species of cultured penaeid shrimp to these viruses varies from infection of only a few to infection of a large number of species. Although the range of these viruses in feral or wild shrimp has not been fully documented, a member of the non-occluded group of baculoviruses, the white spot baculovirus (WSBV), has not only been detected in several species of wild penaeid shrimp but also in other wild decapods. Wild shrimp populations have also been reported to carry the parvovirus, infectious hypodermal and hematopoietic necrosis virus (IHHNV).

Infection and severity

The mortality and morbidity of the penaeid shrimp to several of these pathogenic viruses are affected by age. The older shrimp are generally less susceptible to infection than younger ones. The viruses can infect the penaeid shrimp at various stages of its development, from protozoea to adult, with the highest mortality occurring at the early postlarval stage. Depending on the virus and the species of penaeid shrimp, infected animals exhibit gross physical changes and histopathological aberrations of their organs and tissues. Primary organ and tissue targets may vary with the viral pathogen.

Transmission

There is very little information available on the natural routes of transmission of these viruses. Transmission via the oral route has been demonstrated through feeding of either contaminated foods or infected carcasses and appears to be a dominant route of natural infections. Transmission by way of the gills is another possible route. Although asymptomatic infections have been reported, little is known concerning the mechanism of latent or persistent viral infections in the penaeid host.

Control and prevention

Currently the most effective means of controlling the viral disease problem is to destroy the infected animals, decontaminate the ponds, and start again with virus-free stocks. Although specific-pathogen-free (SPF) shrimp has been developed as a way to control the disease problem, it represents a partial

solution since the animals were tested for only a limited number of viral pathogens. Such SPF animals have been found to be equally susceptible as wild stock to other shrimp viral pathogens.

Growth and assay

Until recently penaeid shrimp viruses were grown only in a sensitive indicator shrimp bioassay system. Primary shrimp cell cultures such as primary lymphoid cell lines are currently used to isolate, grow and assay some of the shrimp viruses. Such primary cell lines have been used in limited studies on the synthesis of viral proteins, viral pathogenesis, of antiviral chemicals, and the development of virus detection/diagnosis protocols. A stable continuous cell line has been prepared by transforming primary shrimp lymphoid cells with the viral oncogene, SV40-large T-antigen. Although the transformed shrimp lymphoid cells exhibited many of the properties of stable, continuous transformed cell lines, they were found to be non-permissive to some of the shrimp viruses. The transformed cells exhibited antiviral activities.

Detection and diagnosis

At present the detection/diagnosis of shrimp viral diseases is still dependent on the clinical history and light and/or electron microscopical examination of affected tissues showing characteristic cytopathology obtained from infected shrimp. Asymptomatic and latent infections can be detected only through the use of either enhancement or bioassay techniques in sensitive indicator shrimp. However, these traditional methodologies have limited sensitivity, require time (days to weeks), specialized equipment, highly trained personnel and high cost. A number of molecular and immunologically based technologies have been recently developed which have facilitated the rapid, specific, sensitive and cost-effective detection/diagnosis of shrimp viral infections. Various methods, such as the nitrocellulose-enzyme immunoassay (NC-EIA), the Western blot and various modifications of the nucleic acid probe (NAP) and polymerase chain reaction (PCR) procedures have been effectively employed.

Basic Properties of Some Penaeid Shrimp Viruses

In this section, the discussion is limited to those shrimp viruses on which there is adequate information concerning their basic properties.

RNA viruses

Rhabdoviridae There are two viruses belonging to this family: the rhabdovirus of penaeid shrimp (RPS) and the yellowhead virus (YHV). The YHV is provisionally grouped in this family.

Rhabdovirus of penaeid shrimp The RPS is the first rhabdovirus to be isolated from penaeid shrimp and also to uniquely infect a continuous fish cell heteroploid line, epithelioma papulosum cyprini (EPS). It was originally isolated from infectious hypodermal and hematopoietic necrosis (IHHN)-diseased and healthy *P. stylirostris* and *P. vannamei* obtained from shrimp farms in Hawaii and Ecuador. However, experimental infections of juvenile penaeids (5–6 g) did not induce histopathological changes characteristically associated with IHHNV infection, nor were clinical or gross manifestations of disease observed. In such animals no mortality occurred and virus replication was demonstrated only in the lymphoid (Oka) organs by plaque assay and immunofluorescence. The affected lymphoid organs, which showed gross cellular changes, were significantly larger in size (6–7 times) than the corresponding organs from uninfected animals and appeared to be the primary target organ of RPS infection. Mortality was observed in younger postlarval (PL) shrimp (0.2 g) experimentally infected by three routes of infection: water-borne (12%), oral feeding (21%) and intramuscular injection (43–50%). The water-borne and oral feeding routes may represent the natural routes of transmission.

Thin-section electron microscopic studies indicated that RPS replicates in the cytoplasm of infected cells and appears to bud from both cytoplasmic vesicles and the plasma membrane. Both thin sections and negative staining studies showed bullet-shaped particles which are enveloped (typical of animal rhabdoviruses). Emanating from the envelope are regularly shaped projections with a knob-like structure at the distal end. Complete virions measured 115–138 × 65–77 nm.

In virus susceptibility studies of several fish cell lines, the heteroploid EPC cell line was determined to be the most susceptible to RPS and had the highest yield of virus. The EPC was found to be especially useful for the primary isolation of RPS. Although several of the other fish cell lines were susceptible, their yields of infectious RPS were much lower (<10%). Single-cycle growth studies of RPS in EPC cells showed an eclipse period of 3 h, followed by a period of exponential growth which was completed by 48 h postinfection (p.i.). Since the virus uniquely replicates in a fish cell line (EPC) causing distinct cytopathic changes, this has enabled the development of a quantitative plaque assay protocol which has greatly facilitated the study of RPS. The efficiency of

plating (EOP) of RPS in EPC was determined to be 30 virus particles per infectious unit. The virus was found to be highly fragile, being sensitive to 20% ethyl ether, low pH, repeated freezing and thawing (3 times), to 37°C (12 h), and storage at −10°C (4 weeks) but was stable at −70°C for several weeks. The buoyant density of RPS in sucrose gradients is 1.19 g cm^{-1}.

The molecular weight of the single RNA species of the RPS genome was determined to be 3.6×10^6 Da (~10.4 kb). The viral RNA has a negative polarity and is sensitive to ribonuclease. Since the replication of RPS in EPC was not inhibited by the DNA antagonist 5-bromo-2′ deoxyuridine (20 μg ml^{-1}), this confirms the RNA genome of the virus.

Analysis by sodium dodecylsulfate–polyacrylamide gel electrophoresis (SDS–PAGE) of RPS proteins revealed the presence of at least four major structural proteins with the following molecular weights (kDa): 165, 65.7, 45.1 and 27.8. The number of structural proteins and the electrophoretic profile of RPS are very similar to those of the prototype rhabdovirus, vesicular stomatitis virus (VSV), and of the fish rhabdovirus carpio (RC) (also named spring viremia of carp virus, SVCV), both of which belong to the genus *Vesiculovirus*. In number of structural proteins and electrophoretic profile, they are different from the lyssatype fish rhabdoviruses, infectious hypodermal necrosis virus (IHNV) and viral hemorrhagic septicemia virus (VHSV). The lyssa variety is easily distinguished from the vesiculo group in that the matrix proteins are composed of two structural polypeptides, M1 and M2, versus a single polypeptide, M, in the vesiculo group. Western blot analysis of the electrophoretically separated RPS structural proteins with anti-RPS polyclonal serum revealed, in addition to the four major proteins, an extra viral protein with a molecular weight of 38 kDa. Based on its molecular weight, this polypeptide was presumed to be nonstructural protein which is present in the vesiculo group of rhabdoviruses. The Western blot technique further revealed that the RPS is partly related to VSV, IHNV and VHSV. The anti-RPS serum identified the G protein of both IHNV and VHSV and the M protein of VSV. Although the anti-RPS serum cross-reacted with the structural proteins of RC, suggesting a close evolutionary relation of these two viruses, the intensity of reaction to RC was much weaker than that observed with RPS. Serologically, RPS is unrelated to IHNV and VHSV and is closely related to but distinguishable from RC when the plaque reduction and neutralization techniques are used.

A solid-phase enzyme-immunoassay protocol, nitrocellulose-enzyme immunoassay/streptavidin–biotin (NC-EIA/SAB), employing a rabbit polyclonal anti-RPS IgG, was developed for the diagnosis and detection of RPS. The NC-EIA/SAB was reported to detect as few as 10 plaque-forming units (PFU) or 300 viral particles (400 pg of viral protein) in experimentally infected shrimp. The protocol has successfully detected natural RPS infections in apparently healthy animals at different stages of development in shrimp farms in Hawaii.

Yellowhead virus The yellowhead virus was named after the disease it caused in the black tiger shrimp, *P. monodon*. Diseased animals showed a characteristic yellow color of the cephalothorax and gills and a pale or bleached appearance. The infection generally resulted in a cumulative mortality of 100% within 3–5 days after the onset of the disease. The etiological agent was initially identified as a baculo-like virus but subsequently was reported to contain RNA and to possess properties not characteristically associated with baculoviruses.

In addition to the original host *P. monodon,* two other penaeid species, *P. stylirostris* and *P. vannamei,* were reported to be highly susceptible to YHV. Intramuscular inoculation of a 10%, w/v, cephalothorax filtrate prepared from naturally infected *P. monodon* Fabricius into subadult (3–10 g) *P. stylirostris* (Stimpson) and *P. vannamei* (Boone) resulted in 100% cumulative mortality within 5–7 days p.i. In such experimentally infected animals, the characteristic light yellowing of the hepatopancreas and gills observed in naturally infected *P. monodon* was not seen. Histopathological examination of naturally and experimentally infected shrimp revealed widespread cellular necrosis in the gills, connective tissues, hemocytes, hematopoietic organs, and lymphoid organ, and strongly indicated a preferential infection of the cells of ectodermal and mesodermal origins.

Primary cultures of shrimp lymphoid cells have been used for the quantitative titration of infectious YHV. This has permitted study of the pathogenesis of YHV in the infected shrimp. The primary targets for infection were the lymphoid organ, gill and head soft tissues, all of which contained 10- to 800-fold higher titers of infectious virus than found in the other tissues and organs tested. Four fish cell lines (fathead minnow or FHM, EPC, chinook salmon embryo or CHSE-214 and brown bullhead or BB) and two insect cell lines (SF9 from *Spodoptera frugiperda* and CRL 1963 from *Drosophila*) were found not susceptible to YHV.

Electron microscopic examination of ultrathin sections of gills and lymphoid tissues from infected animals revealed the presence of numerous enveloped virus particles with bacilliform morphology, measuring 150–200 × 40–50 nm in the cytoplasm of infected

cells. Virions budding out through the cytoplasmic membrane were frequently observed. Cross-sections of the complete virions showed an electron-dense nuclear core which measured 20–30 nm in diameter, surrounded by a trilaminar envelope.

To prepare purified virus the hemolymph was found to yield the cleanest preparation and the largest number of virus particles. Attempts to purify YHV from the gill and head soft tissue met with difficulty because of contaminating vesicles and other membranous cellular materials which banded nonspecifically with the virus in sucrose gradients. The buoyant density of purified YHV ranged from 1.18 to 1.20 g ml^{-1}. This is comparable to the buoyant densities of known rhabdoviruses.

Electron microscopic examination of uranyl acetate-stained, purified YHV revealed peplomer-containing, enveloped, rod-shaped particles measuring 190–200 × 50–60 nm and resembling the plant rhabdoviruses. As with plant rhabdoviruses, the virus particle is fragile and flexible, often assuming pleomorphic forms. The nucleocapsid is arranged in an orderly helical fashion. The helix consists of a coiled tubular structure layered in a regular fashion at right angles to the long axis of the complete virus particle. YHV does not exhibit the bullet-shaped morphology typical of rhabdoviruses infecting vertebrates. However, it closely resembles the bacilliform (with rounded ends) rhabdo-like viruses infecting the blue crab, *Callinectes sapidus*, and the helical, rod-shaped plant rhabdoviruses. In terms of their dimensions and ultrastructure, these rhabdoviruses are very much alike.

Genome analysis of YHV by agarose gel electrophoresis showed a single band of RNA of mol. wt. 8×10^6 Da (~22 kb). The size of the RNA genome is approximately twice that of the rhabdoviruses. The viral RNA is susceptible to ribonuclease (RNase) and is therefore a single-stranded structure. The failure of YHV RNA to be translated in an *in vitro* rabbit reticulocyte translation system strongly indicates that the viral genome possesses a negative polarity.

Structural protein analysis of purified YHV preparations by SDS-PAGE revealed four major bands with the following estimated molecular sizes (kDa): 170, 135, 67 and 22. These bands probably correspond to the large (L), glycoprotein (G), nucleocapsid (N) and matrix (M) proteins of rhabdoviruses. The putative G protein of YHV was determined to be glycosylated.

Western blot analysis of the protein bands using rabbit polyclonal anti-YHV immunoglobulin G (IgG) showed strong reactivity by the antibody with the putative G protein. The proteins of VSV, RPS, and control shrimp tissues did not crossreact with the same antibody preparation. Although the structural protein profile of YHV is similar to that of RPS and other members of the family *Rhabdoviridae*, the molecular sizes of YHV proteins are different. The G protein of YHV is larger (135 kDa versus 90 kDa) and probably accounts for the very prominent peplomers. Furthermore, YHV has a smaller M protein (22 kDa versus 30 kDa), which may account for the high flexibility and fragility of the virus.

In hemagglutination studies, both YHV and VSV were found to agglutinate chicken red blood cells with endpoints of 1:256 and 1:64, respectively. Neither virus was eluted even after 24 h incubation at room temperature, suggesting the formation of a stable complex which lacked receptor-destroying enzymes.

A number of *in vitro* methodologies are available for the detection/diagnosis of YHV infection. An indirect NC-EIA method employing a rabbit polyclonal anti-YHV IgG has been used for the rapid, specific diagnosis and detection of acute and asymptomatic YHV infection of the penaeid shrimp. The solid-phase enzyme immunoassay procedure was capable of detecting as few as 100 $TCID_{50}$ units of virus or an equivalent of 0.4 ng of viral protein. Although gill tissues and lymphoid organs were highly satisfactory sources of YHV antigen for the NC-EIA test, the sampling of the hemolymph which was found to contain a considerable amount of virus, was found to be a more convenient and a less invasive way of monitoring YHV infection in cultured shrimp, particularly invaluable broodstock animals.

Recently a Western blot protocol has been successfully used for the detection of YHV infection in field samples of cultured shrimp from Southeast Asia and the USA. A reverse transcriptase–polymerase chain reaction (RT-PRC) protocol has been used with limited success.

Two of 45 recombinant clones which gave positive hybridization with YHV RNA were negative with the DNA of *P. monodon* and that of the white spot baculovirus. The problem with the probes is that we do not know from which regions of the viral genome they originate. Also, the family of genes making up the YHV genome has not been identified.

Picornaviridae The only member provisionally assigned to this family is the Taura syndrome virus (TSV) which causes a highly infectious disease named Taura syndrome (TS) among the whiteleg shrimp, *P. vannamei*. Epizootics of TS have resulted in extensive economic losses to the shrimp farming industry in the Americas. Several penaeid species have been found to be susceptible to TSV: *P. chinensis, P. aztecus and P. duorarum*. In contrast *P. stylirostris* and *P. setiferus*

were found to be resistant after experimental challenge with TSV.

Taura syndrome generally occurs in juvenile (0.1–5 g) *P. vannamei,* and its clinical effect is mortality (>90%). As a rule, older animals are more resistant.

There is scant information available concerning the presence or distribution of TSV in feral shrimp populations. Several attempts to demonstrate TSV in captured wild broodstock, spawned eggs or naupli have not been successful.

Little is known concerning the natural transmission routes of TSV. Experimental transmission studies have provided strong evidence that the waterborne-oral feeding route may represent the natural route of transmission. Some evidence has been presented to suggest the role of seagulls as the probable transport vector of TSV among shrimp farms.

The buoyant density of TSV in CsCl gradients is 1.338 g ml^{-1}. The virus is a nonenveloped icosahedron with a diameter of 30–32 nm. It has a single-stranded RNA genome which is polyadenylated at the 3′ end. Viral RNA has a positive sense and is approximately 9 kb in length. The viral capsid is made up of three major (55, 40 and 24 kDa) and one minor (58 kDa) structural proteins.

Shrimp with acute natural and experimentally induced TSV infections show a distinct histopathology that consists of multifocal areas of necrosis in the cuticular epithelium and often in the subcuticular connective tissue. Present in these tissues are numerous variably sized eosinophilic to basophilic cytoplasmic inclusion bodies that give TS lesions a 'buckshot' pattern of necrosis which is typical of the disease. These characteristic changes are used as a means of diagnosis of TS. An *in situ* hybridization method using a complementary DNA (cDNA) probe has been developed as a diagnostic tool for the detection of TSV in fixed tissue preparations.

DNA viruses

Occluded baculoviruses The two occluded baculoviruses that have caused serious disease and economic losses in shrimp farms are: Baculovirus penaei (BP) occluded type A also known as *Penaeus vannamei* single nuclear polyhedrosis virus (PVSNPV) and *Penaeus monodon* baculovirus (MBV) occluded type A also known as *Penaeus monodon* single nuclear polyhedrosis virus (PMSNPV).

Baculovirus penaei BP was first described by light and electron microscopy in naturally infected *P. duorarum* (pink shrimp). Since then the virus has been found in several wild and cultured penaeid species: *P. aztecus, P. setiferus, P. vannamei, P. stylirostris, P. penicillatus, P. schmitti, P. paulensis, P. subtilis* and several others. Thus far the virus has been limited in its distribution to the Western hemisphere and Hawaii.

Epizootics of BP can result in high mortality of larval and early postlarval shrimp, particularly in intensive culture systems which facilitate the development and transmission of the disease. However, in larval or late postlarval penaeid shrimp, the effects of BP infection are minimal. Age appears to play a role in susceptibility of the penaeid shrimp to BP.

In the infected animal, BP affects primarily cells of the hepatopancreatic and midgut epithelium. In the hypertrophied nuclei of infected cells in these affected tissues, the newly synthesized progeny may be either free or occluded, with characteristic tetrahedral crystalloid bodies termed occlusion bodies (OBs). The polyhedra are easily seen by light microscopy and may be as large as 17 μm. From one to several polyhedra may occupy a nucleus. The OBs, which are composed primarily of the protein polyhedrin, are used as a diagnostic feature of patent BP infections.

Little is known concerning persistent BP infections in the natural environment. Attempts to demonstrate this phenomenon experimentally in the larvae and postlarvae of *P. vannamei* have not been successful.

A mixed infection involving BP and a reo-like agent has been described. Each shrimp with a reo-like infection also had a BP infection, but the reverse was not always true. Both viruses were observed in the same tissue and occasionally in the same cell.

There is sparse information concerning the biochemical and cellular events involved in the infection cycle of BP. Based on electron microscopical studies the BP virion, presumably after attachment and viropexis or fusion, uncoats or injects its DNA into the host cell nucleus at the nuclear pore. After integration of the virion into the host cell genome, a series of morphologically recognizable sequences of events occur, leading to the eventual production of mature BP and tetrahedral OBs. A distinct intracellular morphological change observed is the appearance of extensive membranous labyrinths (ML) adjacent to the endoplasmic reticulum. The ML appeared to originate from dilated Golgi and endoplasmic reticulum vesicles and from the outer nuclear envelope.

The BP virion is a rod-shaped nucleocapsid surrounded by a trilaminar envelope. Unlike some nuclear polyhedrosis viruses with multiple nucleocapsids per envelope, BP has only one per envelope. The intact, enveloped virions, when banded in CsCl gradient, exhibit a buoyant density of 1.265 g ml^{-1}. On the basis of negative staining, the enveloped virion is 312–320 × 75–87 nm and the nucleocapsid is

approximately 306–312 × 62–68 nm. The complete enveloped virions appear to possess appendage-like structures at both extremities that are assumed to be loose envelope extensions. Similar structures have also been seen among other shrimp baculoviruses, such as the nonoccluded virions. Thin section measurements of the virion reveal a smaller particle of approximately 270–296 × 54–59 nm with nucleocapsid dimensions of 260 × 44.2 nm.

Sucrose-banded OBs, when analyzed by SDS-PAGE using 12% polyacrylamide gels, revealed one major polypeptide with a molecular weight of 52 kDa. Nothing is known about the structural proteins and glycoproteins that compose the complete enveloped virus.

The BP genome is a double-stranded, circular DNA with a molecular weight of 75×10^6 Da. Analysis by electrophoresis in a 1% agarose gel of extracted BP DNA digested with the restriction endonuclease *Bam*HI revealed seven bands with estimated sizes: ≥23, 11.7, 8.2, 4.8, 4.0, 2.9 and 1.1 kb. The largest band probably contained two or more high-molecular-weight bands.

The BP virion is sensitive to a number of physical and chemical conditions. It is completely inactivated under the following conditions: within 30 min at pH 3 but not at pH 11; after 10 min at 60–90°C; after ultraviolet (UV) inactivation for 40 min at a wavelength of 254 nm; and after desiccation for 48 h. On the other hand, it survives 32 parts per thousand sea water at 22°C for 7 days and at 5°C for at least 14 days.

Diagnosis of BP infections has been accomplished in a number of ways: (1) by light microscopic observation of characteristic tetrahedral OBs in wet mount squash preparations of the hepatopancreas, midgut or feces or on histological sections and (2) by the use of the recently developed gene probes that detect BP nucleic acid in infected cells by *in situ* hybridization assay. The latter procedure, which was found to be specific, can also detect BP infections even before the appearance of OBs in wet mount squashes. The probes can detect BP in various species of shrimp from different geographical areas.

More recently, a PCR-based detection procedure was developed for BP. However, this procedure still has, among several caveats, the potential problem of the presence of compounds in shrimp tissues that inhibit the DNA polymerase used in the PCR procedure. It should be added that these recently developed molecular procedures have not been comprehensively evaluated in field studies.

Penaeus monodon baculovirus Since its initial isolation, MBV has been found in a wide variety of both cultured and wild penaeid shrimp species from Asia, Australia, Africa, southern Europe and the Middle East. Reports indicate its presence in shrimp stock in the Americas, but the animals were originally imported from Asia. The virus has been linked to serious diseases and major economic losses in shrimp farms in Southeast Asia and Asia.

A similar agent was found in cultured *P. plebejus* in Australia and was called *Plebejus* baculovirus (PBV). However, on the basis of virus-induced host cell cytopathology and virus morphology, PBV is believed to be a strain of MBV type of viruses rather than a distinct virus type.

MBV is a highly infectious virus that spreads very quickly and causes high larval and juvenile mortality. In adult shrimp the infection is less severe, with the animals showing no significant external signs of disease. In the Indo-Pacific region, MBV has been reported to be a ubiquitous pathogen of cultured *P. monodon*. However, despite its high prevalence and wide distribution, the virion does not appear to be a highly virulent pathogen for *P. monodon*. In disease epizootics, the penaeid shrimp has been frequently found to have mixed infections of MBV and other pathogens. Transmission of MBV is believed to be primarily oral, e.g. from cannibalism. However, other routes of horizontal transmission may occur, such as through contamination of spawned eggs with virus-contaminated feces.

As with all occluded baculoviruses, a principal histopathological and diagnostic feature of MBV infections is the presence of single and multiple, generally spherical OBs, in the hepatopancreas and less often in midgut epithelial cells. The OBs, which have diameters in the range 0.1–20 μm, may be demonstrated in squash preparations of hepatopancreas, midgut, or feces by phase or bright-field microscopy. Different kinds of stains, such as 0.05% aqueous Malachite Green, Acridine Orange, or Phloxine, can be used to enhance visualization of MBV occlusions.

Very little information is available concerning the replication of MBV. A limited ultrastructural study on the morphogenesis of the virions in hepatopancreatic cells revealed certain cytopathic alterations occurring late in the infection, such as nuclear hypertropy, chromatin diminution, loss of nucleolus, formation of virogenic stromata, appearance of many enveloped virions, and appearance and formation of OBs. Another distinct change was the appearance of ML membranes, as was observed in BP infection. Again, the ML was postulated to play two roles in the virion replication cycle: first, as a conduit or transport system for viral structural precursors from the cytoplasm to the nucleoplasm, and second, after this

function is completed, as a mechanism for release of virus and OBs.

Primary shrimp lymphoid cell cultures have been used to support MBV replication. As the result of viral replication, cytopathogenic effects occurred as early as 2–3 days p.i. and became more extensive as the infection progressed. The virus was successfully passaged in primary lymphoid cell cultures at least six times. Unfortunately, no further studies were done until the recent report on the use of primary shrimp lymphoid cells for the growth and assay of YHV and the Chinese baculovirus (or white spot baculovirus).

Electron microscopic examination of uranyl acetate-stained MBV revealed enveloped, rod-shaped particles measuring 265–282 × 68–77 nm and nucleocapsids measuring 250–269 × 62–68 nm. The envelope surface appeared to consist of small, uniformly sized granular structures interspersed with small spikes which were more apparent at the vertices. At the extremities of the envelope were appendage-like structures which were believed to be envelope extensions. Each extremity of the nucleocapsid was enclosed with a double-layered structure, or cap, 16–18 nm thick.

When banded in 30–50% CsCl, complete MBV has a buoyant density of 1.28–1.29 g ml^{-1}, and the OBs have a buoyant density of 1.32–1.33 g ml^{-1}.

The polyhedrin subunits of the spherical MBV polydedron were icosahedral-like structures measuring 22–23 nm in diameter. Analysis of purified MBV OBs by SDS-PAGE and Western blot protocols revealed a single protein band of 62 kDa. The molecular size of the MBV polyhedrin appears to be slightly larger than that of BP (53 kDa), the other occluded baculovirus of penaeid shrimp.

Visualization of MBV DNA by electron microscopy revealed large, supercoiled molecules which were not sufficiently relaxed to allow measurement of the total molecular weight of the genome. However, the viral DNA, after digestion with *Bam*HI endonuclease and electrophoresis in 1% agarose gel, yielded five bands with the following estimated sizes: ≥21, 9, 6.5, 3.5 and 2.8 kb. From these studies, the mol. wt. of the MBV DNA was estimated to be 58–110 × 10^6 kDa (80–160 kb), which falls within the DNA size range of insect baculoviruses. In another study, the molecular size of MBV DNA based on *Eco*RI-cleaved fragments was estimated to be 100–200 kb.

Traditional diagnosis/detection of MBV infection is accomplished by histological examination for the presence of characteristic spherical OBs in hypertrophied nuclei of the hepatopancreas and anterior midgut of the infected animal. Still another source of OBs is shrimp feces. However, these methods do not detect MBV infection at early stages, nor are they adequately sensitive.

Molecular-based methods for the early and specific detection and diagnosis of MBV infections have been developed. The PCR procedure and either *in situ* or dot-blot hybridization techniques employing DNA probes can be used for accurate and early diagnosis or detection of MBV infection.

Non-occluded baculoviruses There are several members belonging to this non-occluded baculovirus group; the classification of all of them has not been officially accepted by the International Committee on Taxonomy of Viruses (ICTV). All of these viruses have caused major epizootics and significant economic losses to the shrimp aquaculture industry.

Baculoviral midgut gland necrosis virus (BMNV) nonoccluded type C also named Penaeus japonicus *nonoccluded baculovirus (PJNOB)* The BMNV is a nonoccluded, gut-infecting virus first isolated in *kuruma* shrimp, *P. japonicus*, larvae. It is highly pathogenic in the early life stages of the shrimp, causing heavy mortality in larval production. Although *P. japonicus* is the natural host for BMNV, other penaeid species, such as *P. monodon*, *P. chinensis*, and *P. semisulcatus*, were found to be experimentally susceptible. Whereas *P. monodon* was found to be highly susceptible, both *P. chinensis* and *P. semisulcatus* showed great resistance to the virus. As with the other shrimp viral pathogens, the waterborne-oral feeding route may represent the natural route of transmission.

Histological examinations of BMNV-infected animals indicate that the midgut and the intestine are the target organs. Infected cells show characteristic nuclear hypertropy and chromatolysis, as well as the absence of OBs which characterize infections by Type A baculoviruses.

Thin-section electron micrographs of the infected nuclei and the midgut lumen reveal numerous rod-shaped, enveloped viral particles, many of which have outer and inner envelopes. The average dimension of the virion was 310 × 72 nm. Purified inner rod-like nucleocapsid structures had capped ends and measured approximately 260 × 50 nm.

No information is available concerning the replication of BMNV at the cellular level.

Viral DNA extracted from purified nucleocapsids was sensitive to digestion with restriction endonucleases *Bam*HI and *Sau*3AI, but not with *Eco*RI, *Pst*I, *Xho*I and *Sal*I. Electrophoretic analysis in agarose gels of the enzyme-digested viral DNA revealed 13 fragments with relative molecular sizes in the range

2.2–27.0 kb. From these results, the mol. wt of viral DNA was estimated to be 85.1×10^6 Da.

Structural protein analysis of nucleocapsid preparation by SDS-PAGE revealed two major proteins with molecular weights of 35 and 14 kDa and three minor bands (mol. wt = 72, 65 and 12 kDa).

Several methods are available for the diagnosis of BMNV infections. Both stained preparations and dark-field microscopic diagnostic methods are used to detect infected, hypertrophied nuclei in squashed preparations of affected tissues such as midgut and intestine. The dark-field microscopic method, because of its simplicity, rapidity, precision and low cost, is the method of choice in shrimp hatcheries in Japan. An immunofluorescent antibody (IFA) procedure has been successfully used to detect BMN-specific virus antigen in smears or sectioned preparations of affected tissues, such as midgut epithelial cells.

White spot baculovirus (WSBV) nonoccluded type C also called systemic ectodermal and mesodermal baculovirus (SEMBV), bacilliform virus (BV), rod-shaped nuclear virus of Penaeus japonicus *(RV-PJ), penaeid rod-shaped DNA virus (PRDV), penaeid hemocytic rod-shaped virus (PHRV) and Chinese baculovirus (CBV)* All these names have been given to the viral isolates obtained from different species of cultured penaeid shrimp from different geographical areas. Until further characterizations of their serological, biochemical and genomic properties are made, the isolates may be considered to be either related strains of the same virus or identical. Although *in situ* hybridization studies have suggested that these nonoccluded baculovirus isolates may be closely related, a recent report has presented evidence to show that they can be distinguished by RFLP (restriction fragment length polymorphism) analyses of the viral genomes. All of these isolates cause epizootics and mass mortality in cultured penaeid shrimp. Diseased shrimp show a characteristically abnormal reddish color together with white spots primarily on the inside surface of the carapace. However, with two experimentally infected penaeid species, *P. stylirostris* and *P. vannamei*, the characteristic white spots were not seen and the reddish color was seen only in the extremities of the appendages. These gross distinctive changes have been used in the diagnosis of WSBV infection. At the cellular level, infected cells showed markedly hypertrophied nuclei. In certain cases, histopathological examination of infected gill tissues may show Cowdry type A nuclear inclusions in hypertrophied nuclei. The natural route of transmission for these virions appears to be the waterborne-oral feeding routes.

Electron microscopical examination of thin sections of affected tissues revealed the presence of large numbers of rod-shaped baculo-like viral particles located primarily in the markedly enlarged nuclei which also showed a loss of integrity of the marginated chromatin material. Viral particles had a multilaminar outer envelope which had a mean size of 265 ± 20 nm in length and 120 ± 10 nm in diameter. The size of the electron-dense nucleocapsid of the virus was 205 ± 12 nm in length and 78 ± 5 nm in diameter. A large number of viruses had double envelopes.

When banded isopycnically in CsCl, the complete virus had a buoyant density of 1.23 g ml^{-1} and the nucleocapsid particle 1.31 g ml^{-1}.

Negatively stained purified CBV particles measured 322–378 nm in length and 130–159 nm in diameter. The inner nucleoprotein core exhibited a unique striated structure and measured 316–350 nm in length and 65–66 nm in diameter. The striations appeared to be the result of the stacking of ring-like structures. These rings consisted of two rows of 12–14 globular units, each measuring 10 nm in diameter.

Genomic analysis of purified CBV revealed a nonsegmented, double-stranded DNA molecule. The reported sizes of the viral DNA genome ranged from 150 kbp to 200 kbp.

Analysis of the structural proteins of purified CBV by SDS-PAGE showed among several, four prominent protein bands with approximate molecular weights of 19, 23.5, 27.5 and 75 kDa. The structural viral proteins were substantiated by Western blot analysis. The 19, 27.5 and 75 kDa structural proteins were found to be nonglycosylated components associated with the viral envelope. The 23.5 kDa protein, also nonglycosylated, was identified with the capsid structure.

For the rapid, sensitive and specific detection/diagnosis of CBV (WSBV) infections both diagnostic probes for *in situ* hybridization and primers for detection by PCR technology have been successfully used. Such studies have also indicated that the gut and the gills of the penaeid shrimp were the primary routes of viral entry and that the lymphoid organ and gills were primary targets for viral replication.

A combined SDS-PAGE/Western blot/EIA protocol has been successfully used for the early detection of CBV in the hemolymph of infected animals. This combination technology has several advantages for the monitoring and surveillance of shrimp populations for virus infections. The sampling of hemolymph is relatively simple and less invasive, particularly for the monitoring of invaluable shrimp broodstocks.

Primary shrimp lymphoid cell cultures have been used in an *in vitro* quantal assay ($TCID_{50}$) for CBV.

Despite limitations associated with primary cell cultures, this assay provides a simple, convenient, reliable and quantitative method for the study of shrimp viruses.

Four fish cell lines (epithelioma papulosum cyprini [EPC]), chinook salmon embryo (CHSE-214), fathead minnow (FHM), and sockeye salmon embryo (SSE-5) and an insect cell line (CRL1963, a *Drosophila* cell line) were resistant to CBV.

A second group of DNA-containing penaeid shrimp viruses causing epizootics are two members of the parvovirus family.

Infectious hypodermal and hematopoietic necrosis virus (IHHNV) The IHHNV is widely distributed, causing severe epizootics and massive mortality in cultured penaeid shrimp, particularly the juveniles of *P. stylirostris*. In other penaeid species, the disease is somewhat less severe. With certain cultured penaeid species, such as *P. vannamei*, a 'runt-deformity syndrome' (RPS) may be the consequence. The affected animals characteristically exhibit greatly reduced growth rates and a variety of cuticular deformities, all of which lessen their market value.

Natural infections by IHHNV have been reported in a number of penaeid species, such as *P. stylirostris*, *P. semisulcatus* and *P. japonicus*. As with the other shrimp viral pathogens, the waterborne-oral feeding route may represent the natural route of transmission. Survivors of IHHN epizootics apparently harbor the virion for life and transmit it to their progeny by vertical and horizontal routes.

Gross clinical symptoms of acute IHHNV infections are not specific. In the infected animal, certain distinguishable histopathological changes occur. Present in affected cells are intranuclear Cowdry type A inclusion bodies (CAI) contained in hypertrophied nuclei in tissues of ectodermal (epidermis, hypodermal epithelium of foregut and hindgut, nerve cord, and nerve ganglia) and mesodermal (hematopoietic organ, antennal gland, gonads, lymphoid organ, connective tissues, and striated muscle) origin.

Purified IHHNV has been prepared from infected penaeid shrimp and banded in CsCl gradients at a buoyant density of $1.40\,g\,ml^{-1}$. Negatively stained, purified virions are nonenveloped icosahedrons with a diameter of 20–22 nm. The virions possess a linear, single-stranded DNA genome of either negative or positive polarity with an estimated size of 4.1 kb. The purified virion is made up of at least four structural polypeptides, VP1 to VP4, with molecular weights of 74, 47, 39 and 37.5 kDa.

To date no cell lines exist which will support the growth of IHHNV. No information is available regarding viral replication at either the cellular or molecular levels.

Several methods are available for the diagnosis of IHHNV infections. The histopathological examination of affected tissues for the presence or absence of intranuclear CAI has provided a fairly reliable diagnosis. However, the formation of CAI may be induced by rather general types of cell injury not involving viruses. Under certain conditions, both DNA- and RNA-containing viruses have been reported to cause CAI. Another method involves enhancement procedures in which the suspected animals are kept under stressful conditions for 2–3 weeks prior to sampling for histologic examination.

For the detection of asymptomatic IHHNV infections, susceptible small juveniles of *P. stylirostris* have been used as indicator shrimp for the presence or absence of the virus.

Gene probes have been developed for the detection/diagnosis of IHHNV infection. The probes have been used in dot-blot and *in situ* hybridization studies and are currently available commercially as a kit.

Hepatopancreatic parvo-like virus (HPV) The HPV is another parvo-like virus that infects a number of cultured and wild *Penaeus* species (*P. chinensis*, *P. merguiensis*, *P. semisulcatus*, *P. monodon*, *P. indicus*, *P. penicillatus*, *P. esculentus*). It has a wide geographic distribution, including the Indo-Pacific area and the Americas. The relationship between all of these reported HPV-type viruses is not known since identification of these virions was based solely on microscopic or histopathological examinations.

Although HPV has been circumstantially implicated in the cause of major disease epizootics, its role as a serious pathogen remains to be clearly defined. This is because of the relative difficulty of diagnosing HPV infections and also because these infections are often accompanied by other viral pathogens which may obscure its importance. Little is known concerning the natural mode of transmission of HPV, although the waterborne-oral route is the most likely. No cell lines are currently available which support the replication of HPV.

In the infected animal, the principal lesion of the disease is characterized by the necrosis and atrophy of the hepatopancreas, which is common to all the penaeid species. Large, prominent, basophilic, Feulgen-positive intranuclear inclusion bodies were often observed in hypertrophied nuclei of hepatopancreatic tubule epithelial cells. These histological changes were used in the diagnosis of HPV infections.

The HPV and the IHHNV are both parvoviruses, but in the permissive host animal they infect different

target tissues: the hepatopancreatic epithelial cells for HPV and all nonenteric tissues for IHHNV.

Electron microscopic analysis of thin sections of HPV-infected cells revealed intranuclear inclusion bodies containing granular virogenic stroma and viral particles 22–24 nm in diameter.

Purified HPV prepared from infected penaeid shrimp and banded in CsCl gradient had a buoyant density of 1.41 g ml^{-1}. Negatively stained, purified virions were nonenveloped, icosahedral particles with a diameter of 22 nm. The virions contained a linear, single-stranded DNA genome of either negative or positive polarity with an estimated molecular size of 5 kb, which, surprisingly, encoded a single protein of 54 kDa.

Gene probes have been used with limited success in *in situ* hybridization assays for the diagnosis of HPV infections. Since the probe did not react positively in the tissues of HPV-infected penaeids from the Indo-Pacific region and the Americas, it is strongly indicated that there are probably several different strains of HPV. The HPV probe did not crossreact with the other shrimp parvovirus, IHHNV. The probe is commercially available as a kit for the diagnosis of HPV.

The following penaeid shrimp viruses have been reported. Most of them remain to be isolated and their relevant properties characterized:

Lymphoidal parvo-like virus (LOV)
Penaeid hemocyte-infecting, nonoccluded baculovirus (PHRV)
Shrimp iridovirus (IRIDO)
Type III reo-like virus (REO-III)
Type-IV reo-like virus (REO-IV)
Lymphoid organ vacuolization virus (LOVV)
Naked star-shaped virus (NSV).

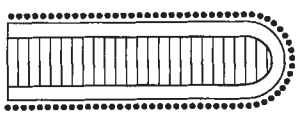
SIGMA RHABDOVIRUSES (*RHABDOVIRIDAE*)



Danielle Teninges, Centre National de la Recherche Scientifique, Institut de Génétique humaine, Montpellier, France

History

The sigma virus of *Drosophila* is a harmless virus of a harmless insect and probably would never have attracted any attention were it not for the fact that geneticists use carbon dioxide (CO_2) as a mild narcotic for the flies they handle. This gas is generally not noxious and flies recover from narcosis within a few minutes after return to a normal atmosphere. Those infected by the sigma virus, in contrast, remain irreversibly paralyzed and die. CO_2 sensitivity in some *Drosophila* strains was first reported in 1937 by L'Heritier and Tessier as a hereditary trait which was not chromosome-linked. The viral etiology was not suspected at first owing to the complete absence of horizontal transmission of CO_2 sensitivity in natural conditions. Later, L'Heritier observed that inoculation of acellular extracts from CO_2-sensitive flies into resistant flies produced the symptom after an incubation period which increased with the dilution of the inoculum. The size of the agent was deduced from the target size to x-ray inactivation. Studies by electron

target tissues: the hepatopancreatic epithelial cells for HPV and all nonenteric tissues for IHHNV.

Electron microscopic analysis of thin sections of HPV-infected cells revealed intranuclear inclusion bodies containing granular virogenic stroma and viral particles 22–24 nm in diameter.

Purified HPV prepared from infected penaeid shrimp and banded in CsCl gradient had a buoyant density of 1.41 g ml^{-1}. Negatively stained, purified virions were nonenveloped, icosahedral particles with a diameter of 22 nm. The virions contained a linear, single-stranded DNA genome of either negative or positive polarity with an estimated molecular size of 5 kb, which, surprisingly, encoded a single protein of 54 kDa.

Gene probes have been used with limited success in *in situ* hybridization assays for the diagnosis of HPV infections. Since the probe did not react positively in the tissues of HPV-infected penaeids from the Indo-Pacific region and the Americas, it is strongly indicated that there are probably several different strains of HPV. The HPV probe did not crossreact with the other shrimp parvovirus, IHHNV. The probe is commercially available as a kit for the diagnosis of HPV.

The following penaeid shrimp viruses have been reported. Most of them remain to be isolated and their relevant properties characterized:

Lymphoidal parvo-like virus (LOV)
Penaeid hemocyte-infecting, nonoccluded baculovirus (PHRV)

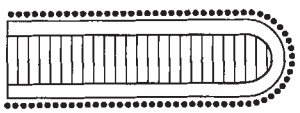
SIGMA RHABDOVIRUSES (*RHABDOVIRIDAE*)



Danielle Teninges, Centre National de la Recherche Scientifique, Institut de Génétique humaine, Montpellier, France

History

The sigma virus of *Drosophila* is a harmless virus of a harmless insect and probably would never have attracted any attention were it not for the fact that geneticists use carbon dioxide (CO_2) as a mild narcotic for the flies they handle. This gas is generally not noxious and flies recover from narcosis within a few minutes after return to a normal atmosphere. Those infected by the sigma virus, in contrast, remain irreversibly paralyzed and die. CO_2 sensitivity in some *Drosophila* strains was first reported in 1937 by L'Heritier and Tessier as a hereditary trait which was not chromosome-linked. The viral etiology was not suspected at first owing to the complete absence of horizontal transmission of CO_2 sensitivity in natural conditions. Later, L'Heritier observed that inoculation of acellular extracts from CO_2-sensitive flies into resistant flies produced the symptom after an incubation period which increased with the dilution of the inoculum. The size of the agent was deduced from the target size to x-ray inactivation. Studies by electron

microscopy confirmed this information and identified sigma virus as a member of the rhabdovirus family. It has not been assigned to a genus. With its genetic background, *Drosophila melanogaster* was an ideal host to allow genetic analyses of the host factors involved in a virus–insect association and most efforts have been centered on research of this kind.

Pathology

The CO_2 sensitivity symptom is the only sign of disease observed in infected flies. It affects larvae as well as adults and persists throughout their lives. The range of CO_2 concentrations that are lethal to the flies is not frequently met in nature and this cannot account for any counterselection of infected flies. Among inoculated flies the expression of CO_2 sensitivity is correlated to the appearance of infectious material in the central nervous system. Immunocytochemistry reveals the presence of granular inclusions of viral material in the cortex of the cephalic and thoracic ganglia. In hereditarily infected flies, such inclusion bodies are present in all tissues, except muscle. Wild sigma virus-infected flies have been compared to uninfected flies for egg viability, male and female fertility, female longevity and sexual selection. Sigma virus infection only reduced egg viability; other parameters did not show any systematic or significant variation. Survival of adults under winter conditions in France was also studied and showed that the fitness of infected flies to overwintering was slightly lower. Wild sigma virus clones show a very low multiplication rate, which may account for their relative innocuousness. Laboratory strains selected for high multiplication rates generally affect fertility and egg viability in such proportions that when they appear in natural populations they are probably severely counterselected.

In *Drosophila* cells cultivated *in vitro,* sigma virus multiplies without any evidence of a cytopathic effect and a persistent infection is maintained throughout cell transfers.

Since a number of other rhabdoviruses and a bunyavirus (but no flaviviruses) were shown to induce CO_2 sensitivity after inoculation to *Drosophila* flies or to mosquitoes, exposure to CO_2 was proposed as a fast means of screening infected insects in nature.

Virion and Genome Structure

Sigma virus particles exhibit all the structural details of typical rhabdoviruses: a bullet shape, a coiled nucleocapsid, and an envelope derived from the host cell and covered with surface projections. The diameter is 75 nm and the length 200 nm. The presence of shorter particles has also been recorded. The genome structure of a strain selected for high yields in *Drosophila* cell cultures *in vitro* has been studied. It consists of a single segment of approximately 13 000 nucleotides. It encodes six proteins mapped in the following order on the genome strand: 3′-N-P-X-M-G-L-5′ where N is the nucleoprotein and P a phosphoprotein which is the equivalent of the polymerase-associated protein in vesicular stomatitis virus (VSV); gene 3 (X) encodes a protein of unknown function with many potential phosphorylation sites and showing similarities to some of the retroviral reverse transcriptase motifs; M is the matrix protein, G is the glycoprotein and L is the polymerase. The respective lengths predicted for the polypeptides are 450 amino acids for N, 322 for P, 296 for X, 207 for M, and 499 for G. The exact length of L is still unknown but its electrophoretic mobility corresponds to a protein of 250 kDa. The consensus gene-start and gene-end sequences are respectively, CAACANC and $CAUG(A)_7$ in the mRNA sense and thus conform to the consensus AACA and $AUG(A)_7$ observed in all the rhabdoviruses previously analyzed.

Intergenic sequences are thought to intervene in transcriptional control. Some rhabdoviruses like VSV have constant intergenes, whereas others, such as rabies virus, show variation. Sigma virus belongs to the second category and has 36 untranscribed nucleotides which separate N and P, six which separate P and X and four which separate X and M; then G overlaps M, starting 26 nucleotides upstream of the end of the M gene, so the polymerase has to read through the end sequence of the M gene to transcribe the G gene. In spite of this overlap, the transcription results in the regular synthesis of monocistronic M and G mRNAs. The start signal of the L gene is immediately adjacent to the end signal of the G gene. As deduced from UV target size analyses, the transcription of unsegmented negative-strand viruses proceeds sequentially from the 3′ extracistronic region of the genome to the 5′ end. A gene overlap implies that sites of initiation other than the most 3′ proximal one can be used by newly entered polymerases. Gene overlap could be a means of reducing the expression of the two most distal genes from the 3′ end.

Serology and Taxonomy

Fifty animal rhabdoviruses of diverse origins were screened for antigenic crossreactivity. Most of them could be classified in the two large subgroups – the lyssaviruses and the vesiculoviruses. In this study, sigma virus was shown to crossreact with Tupaia, a vesiculovirus isolated from a shrew, and with

Tibrogargan, Humpty Doo and Parry Creek, three lyssaviruses isolated from mosquitoes; it was thus proposed to bridge the gap between the two subgroups. Considering other criteria, such as the scores of similarity between predicted protein sequences, sigma virus appears almost equally distant from the prototypes of both subgroups. The progress of molecular data on other rhabdoviruses may raise the necessity for the definition of new subgroups more closely related to sigma virus.

Virus–Host Interactions

Hereditary transmission is a very efficient means of propagation but its efficiency varies according to the virus genotype and to the sex and genotype of flies. The so called 'stabilized' females transmit the virus to all their descendants with few exceptions. They issue from oocytes that were infected very early, and in which the virus was able to multiply enough to invade all the germline cells from the outset. Their male progeny may also transmit the virus but with a lower efficiency (infection via a spermatozoid is an efficient means of cloning virus particles). The pattern of virus transmission from flies hatched from spermatozoid-infected eggs is different from that of stabilized females: males do not transmit the virus and females may transmit it but only to a small proportion of their descendants. This is an effect of the low concentration of virus genomes in the spermatozoid-infected eggs: cell differentiation and organogenesis probably result in barriers against the penetration of the virus into some tissues. There could be a race during embryogenesis between the virus invasion and the building up of these barriers. Male germ cells which are not infected at the very early stages of embryogenesis (before segmentation) are not invaded at a later stage of development. Female germ cells may be invaded at any stage, including adults, provided that the virus genotype is g^+ (g^- mutants are normally perpetuated in stabilized maternal lines and virions are infectious to somatic cells but they cannot invade the germinal cysts, once isolated by organogenesis). Some stabilized maternal lines (the ultra-rho lines) perpetuate defective viruses which are not infectious and which do not induce CO_2 sensitivity; the only sign of their presence is an immunity to superinfection by homologous virus – immunity which shows exactly the same inheritance pattern as nondefective viruses.

In other stabilized lines, the rho lines, the same phenotype was observed but a still unexplained genetic instability of the viral genomes infecting these lines resulted in the occasional production of fully infectious virions. Some stabilized maternal lines, infected with temperature-sensitive mutants for maturation functions, express exactly the same phenotype as the ultra-rho lines when bred for several generations at nonpermissive temperature, but the CO_2 sensitivity symptom is restored upon return to the permissive temperature. The persistent infection of germ cells through generations by viruses which are defective (or temperature restricted) proves that only the maturation functions are affected in these mutants, not the genome replication. It also proves that viral information may be transmitted by cellular continuity without a necessity for infectious virus production.

Natural populations of *D. melanogaster* are often polymorphic for alleles of genes that confer resistance to sigma virus infection. These restrictive alleles map to six different loci: *ref(1)H*, *ref(2)M*, *ref(2)P*, *ref(3)O*, *ref(3)V* and *ref(3)D* (the number in parentheses represents the *Drosophila* chromosome carrying the gene, the capital letter is the particular name of the gene, and specific alleles of those genes are indicated by an exponent). The refractory loci (*ref*) do not represent a general antiviral system: not only do they not affect other insect viruses but none of them confers resistance to all strains of sigma virus (with a possible exception for *ref(3)V*; see later).

Restrictive effects have been assessed for several parameters of viral infection, such as the mean incubation time required for the expression of CO_2 sensitivity, the probability of initiating infection, the kinetics of virus production (either in flies or in cells cultivated *in vitro*) and the efficiency of virus transmission either by females or by males. A distinction can be made between restriction during either virus maturation or earlier stages of virus production (i.e. genome replication): since hereditary transmission in stabilized maternal lines does not require the production of infective virus, those alleles restricting this transmission necessarily affect the genome replication steps. The four alleles $ref(1)H^h$, $ref(2)M^m$, $ref(2)P^P$ and $ref(3)D^d$ reduce the probability of initiating infection and increase the incubation time for the manifestation of the CO_2 sensitivity symptom. The transmission through the maternal gametes is also reduced very strongly by $ref(1)H^h$ and $ref(2)P^P$, whereas $ref(2)M^m$ and $ref(3)D^d$ exert a weaker action. This implies that the products of these four genes intervene in the replication of the viral genomes. $Ref(3)O^e$ does not affect the hereditary transmission but increases the incubation time of the viral clones sensitive to its action. The allele $ref(1)H^h$ is the only fully dominant allele; flies heterozygous at all other loci express intermediate phenotypes. The $ref(3)V^P$ restrictive allele does not affect the virus multiplication in somatic cells nor in female germ cells and its unique effect is to prevent transmission by

spermatozoa. The specificity of this interaction with sigma virus is still unknown, as to date no viral strains have been found to be resistant. In contrast, the major effects described for the restrictive alleles at other loci apply only to sensitive viral strains.

Flies that are homozygous for either permissive or restrictive alleles are indistinguishable except for the difference in their capacity to permit the multiplication of sigma virus. The most extensively studied refractory gene is *ref(2)P*. Loss of function alleles ($ref(2)P^{null}$) were induced by mutagenesis of a permissive $ref(2)P^{o}$ allele. Homozygous flies for the $ref(2)P^{null}$ alleles are all viable and display no phenotype other than male sterility in particular genetic backgrounds. Some alleles of a gene located on the third chromosome suppress the male sterility of $ref(2)P^{null}$ homozygotes. Such alleles are present in approximately one-third of the flies in natural populations, which means that *ref(2)P* is essential to male fertility in two-thirds of the flies. The mutation exclusively affects the structure of the spermatozoa in which the organization of the mitochondrion and axonema is perturbed. Nevertheless, *ref(2)P* is expressed in a wide variety of tissues: it is expressed in female germ cells as seen from the strong inhibition of the virus transovarian transmission by restrictive alleles; however females are normally fertile, thus the gene is not essential at the cellular level. It is also expressed in somatic cells, as seen, for instance, from the effects on virus yields and CO_2 sensitivity. This expression is autonomous: in organs transplanted into individuals bearing permissive or restrictive alleles, the action of *ref(2)P* on the virus conforms to the organ genotype.

The effect of restrictive alleles is also observed at the single cell level in permanent *in vitro* cell lines. Homozygotes $ref(2)P^{null}$ are permissive to sigma virus infection, thus the *ref(2)P* gene product serves no indispensable function in the virus cycle and hence could be considered as a defense gene. The expression is ubiquitous. All the transcripts found in different tissues result from the same splicing pattern of three exons but different initiation sites are used. As a consequence, the 5′ untranslated region varies in length according to the cell type. The size distribution of the transcripts and their abundance varies according to the tissue, suggesting a tissue-specific regulation of the gene expression at the transcriptional and possibly at the translational level.

The gene encodes a single protein of about 600 amino acids containing a cysteine-rich region resembling a zinc-finger motif. The amino acid sequence is very variable and there is a length polymorphism in the coding region. Restrictive and permissive alleles are codominant, and *ref(2)P* proteins of both types form complexes with the viral P protein. The *ref(2)P* protein crossreacts with antibodies directed against the viral N protein, due to the presence of a common conformation-dependent epitope. The *hap* viral mutants are mutants which escape the restrictive effect of $ref(2)P^{P}$. In the *hap7* mutant, this epitope is not present and the N protein differs from that of the original virus by a single amino acid substitution.

These data could suggest that the *ref(2)P* protein competes with the N protein by means of this epitope to complex the P protein in a form which is unsuitable for its function in the viral transcriptional complex (which requires the N, P and L proteins). However, the restriction mechanism is certainly more complicated, as a transgene containing only the 91 N-terminal amino acids of a restrictive allele, but not the epitope, is sufficient to confer a restrictive phenotype to transformed *Drosophila* lines in the conditions of artificial inoculation, and not in the hereditary transmission process.

Interestingly, a simultaneous adaptation or disadaptation of a number of *hap* mutants to other *ref* genes, such as $ref(1)H^{b}$, $ref(3)O^{e}$ or $ref(2)M^{m}$, was observed. This covariation suggests that the same viral protein interacts with the cellular proteins encoded by these other *ref* genes.

The variability of natural alleles of the *ref(2)P* gene is high and there is a high rate of amino acid replacement to synonymous codon changes. The most recent alleles are the restrictive ones. A possible explanation is that when a restrictive mutant appears and reaches sufficient frequency in a population, the virus evolves rapidly in response to this new allele, which becomes permissive to the adapted virotype; then a new restrictive mutant may arise and be transiently selected.

The time between inoculation and the first detection of virus progeny is about 30 h at 20°C. All the present knowledge about the viral replication process results from the physiological study of temperature-sensitive and host-range mutants. These mutants identify four steps in the growth cycle of the sigma virus. At 20°C, after a rapid phase of adsorption-penetration (1 h), there is a phase lasting about 8 h which corresponds to the temperature-sensitive period of the mutant *hap7*. The next stage, from 4 to 15 h postinfection, is defined by the mutant *ts4*. The mutants *hap7* and *ts4* have been designated early mutants. *Ts4* is defective in hereditary transmission at the restrictive temperature (28°C); *hap7* is not, even at 30°C. The function affected in *hap7* is indispensable before genome replication, and facultative once genome replication has started.

The next stage is defined by mutants such as *ts9*, in which germinal transmission is not temperature sensitive. In such mutants, designated late mutants,

the genome replication functions are not affected and their temperature-sensitive period corresponds to a phase of virus assembly and budding. The functions necessary to initiate infection are not affected in *ts*9 (as deduced from analyses of infectious center decay) but the virions are thermolabile. The *ts* mutations have not yet been assigned to any gene. In analogy to the molecular biology of other rhabdoviruses, some predictions can be made. In VSV only the three proteins of the viral nucleocapsid (N, P and L) are required for the synthesis of monocistronic capped and polyadenylated mRNAs and, in the next step, of full genome length RNAs.

The matrix protein M is required for the transport of newly synthesized nucleocapsids toward the membrane patches in which the glycoprotein G is inserted and for the budding of progeny virions. The sigma virus counterparts of these proteins are likely to play the same roles. If so, the proteins modified in early mutants may be N, P or L, while late mutants may bear temperature-sensitive M or G proteins. We have no clues which could permit the prediction of the phenotypes of mutants affected in the additional protein X. Nevertheless, the absence of cytopathogenicity of the virus, even in the most permissive host genotype, and even in the most sensitive stages of host development, strongly suggests that the sigma virus multiplication rate is self-restricted. It is tempting to speculate that the protein of yet unknown function, or the gene overlap, or both, could account for this feature. According to the first hypothesis, mutants with disfunctioning X protein would produce higher virus yields. Paradoxically, clones with temperature-sensitive mutations of X would be more invasive to the host and thus have enhanced temperature resistance. Viral strains with such a phenotype exist. High yield and high-temperature resistance in sigma virus clones are always correlated with a pathogenic effect on the germline and the loss of hereditary transmission. Such characteristics are shared by the vesiculoviruses (which do not have an X gene) when inoculated into *Drosophila*.

Ecology

The specific CO_2 sensitivity symptom makes the identification of infected flies very easy and has allowed significant exploration of *Drosophila* natural populations. CO_2-sensitive flies were found among several *Drosophila* species throughout the world. The viruses carried by the different fruit fly populations share the major characteristics of sigma virus (hereditary transmission, symptom, etc.) but they may be distinct. The data indicate that such viruses are endemic in all the populations of *Drosophila,* the infected flies being the minority (10–20% in French natural populations). The high proportion of uninfected flies does not correspond to a virus-resistant fraction of the populations, as they and their offspring may become infected experimentally in the laboratory.

The genetic approach to the study of an insect–virus relationship performed with sigma virus underlines the complexity of the interactions and the difficulties involved in the control of all the relevant parameters.

SIMIAN IMMUNODEFICIENCY VIRUSES (*RETROVIRIDAE*)

Vito G Sasseville and **Ronald C Desrosiers**, Harvard Medical School, New England Regional Primate Research Center, Southborough, Massachusetts, USA

Hillary G Morrison, Marine Biological Laboratory, Woods Hole, Massachusetts, USA

History

Simian immunodeficiency virus (SIV) was first isolated in 1984 from immunodeficient captive rhesus macaques (*Macaca mulatta*) at the New England Regional Primate Research Center (NERPRC). This virus was originally called STLV-III because of its similar morphology, growth characteristics and antigenic properties to the newly described immunosuppressive virus in humans termed HTLV-III, LAV or ARV. When HTLV-III was renamed human immunodeficiency virus (HIV), STLV-III was appropriately changed to SIV. Retrospective studies show that SIV was introduced to the NERPRC via a group of rhesus monkeys with immunosuppressive disease delivered from another primate center 15 years prior to the initial isolation of SIV in 1985. This original cohort of animals was most likely inadvertently infected with SIV from wild-caught sooty mangabey monkeys housed at the same location. Following this initial isolation of SIV from rhesus macaques, SIV was isolated from other captive macaque species (*M. fascicularis, M. nemestrina, M. arctoides*) dying of diseases associated with immunosuppression and from feral asymptomatic African nonhuman primates, including African green monkeys (SIVagm), mandrills (SIVmnd), sooty mangabey monkeys (SIVsmm), red-capped mangabeys (SIVrcm), Sykes' monkeys (SIVsyk) and chimpanzees (SIVcpz).

Taxonomy and Classification

SIVs belong to the *Lentivirus* genus of the *Retroviridae* family. This genus includes the classic ungulate lentiviruses (visna virus of sheep, caprine arthritis encephalitis virus and equine infectious anemia virus) and the immunodeficiency viruses of humans (HIV), monkeys (SIV), cats (FIV) and cattle (BIV). The retroviruses can be subclassified by morphologic and morphogenic criteria. Lentivirus particles are approximately 80–110 nm in size and consist of an RNA genome and viral enzymes enclosed in a core of viral proteins that is encased by a cell-derived membrane spiked with viral envelope glycoproteins. Lentiviruses can be distinguished from other subgroups of retroviruses by the presence of a cylindrical or rod-shaped nucleoid in mature particles. In lymphocytes, lentivirus particles bud from the plasmalemma into the extracellular space, but in macrophages particles often bud from the plasma membrane into cytoplasmic vacuoles where they can accumulate. Lentiviruses also share a similarity in certain biological properties and the organization of their genomes. Unlike many of the other retroviruses, they are not oncogenic. Instead, they produce long-term, persistent infections which eventually lead to chronic debilitating disease. All lentiviruses studied to date replicate and persist in cells of the monocyte/macrophage lineage. In addition to the standard *gag*, *pol* and *env* genes that all retroviruses have, lentiviruses possess a number of additional genes not found in other retroviruses.

The SIVs are named according to the primate species of origin, e.g. SIVmac from macaques or SIVsmm from sooty mangabey monkeys. Based on genetic sequence analysis, five discrete groups of primate lentiviruses have been identified (**Fig. 1**, **Table 1** and see later). These are HIV-1/SIVcpz, HIV-2/SIVsmm/SIVmac, SIVagm, SIVmnd and SIVsyk.

Geographic and Seasonal Distribution

African green monkeys (*Cercopithecus aethiops*), Sykes' monkeys (*Cercopithecus mitis*), sooty mangabey monkeys (*Cercocebus torquatus atys*), red-capped mangabey monkeys (*Cercocebus torquatus torquatus*) and mandrills (*Papio sphinx*) have been shown to be infected with SIV in their natural habitats. Serological evidence suggests that SIV infection of African green monkeys is widely distributed in Africa. Between 20 and 50% of African green monkeys in Kenya, Ethiopia, South Africa and Senegal have antibodies to SIV. However, green monkeys which became established in the Caribbean since the seventeenth century are seronegative. Recent data also indicate that sooty mangabey monkeys in their native habitat in the coastal forests of western Africa are infected with their own highly divergent SIVs. These SIVsmm isolates, which differ markedly from

one another, are closely related to HIV-2 subtypes D and E from humans in the same areas. These findings suggest that different HIV-2 subtypes may have originated from multiple cross-species transmissions of divergent SIVsmm strains from sooty mangabeys to humans. Macaque monkeys do not harbor SIV in their native Asian habitat, but became infected presumably via contact with SIV-infected sooty mangabeys while in captivity at Regional Primate Research Centers in the United States. Thus, African nonhuman primates and not Asian macaques are the natural hosts of SIV.

Host Range and Virus Propagation

African green and Sykes' monkeys, sooty and red-capped mangabey monkeys and mandrills appear to be natural hosts for their own discrete SIVs. Other species that are susceptible to infection are restricted to primates including humans (SIVhu) on rare occasions. However, immunosuppressive disease appears to be largely restricted to SIV-infected macaque monkeys. The natural routes of transmission for SIV are in general not known, but most evidence suggests horizontal spread via fighting and biting among group-housed macaques. Experimentally, macaques have been infected via intravenous and intramuscular inoculation and by exposure of the genital mucosa. Some SIVs clearly have the capacity for crossing species barriers. For example, SIVsmm is readily able to infect macaque monkeys. In contrast, numerous attempts to infect macaques and other Old World primates with HIV-1 have met with limited success. Baboons (*Papio cynocephalus*), rhesus and cyno-

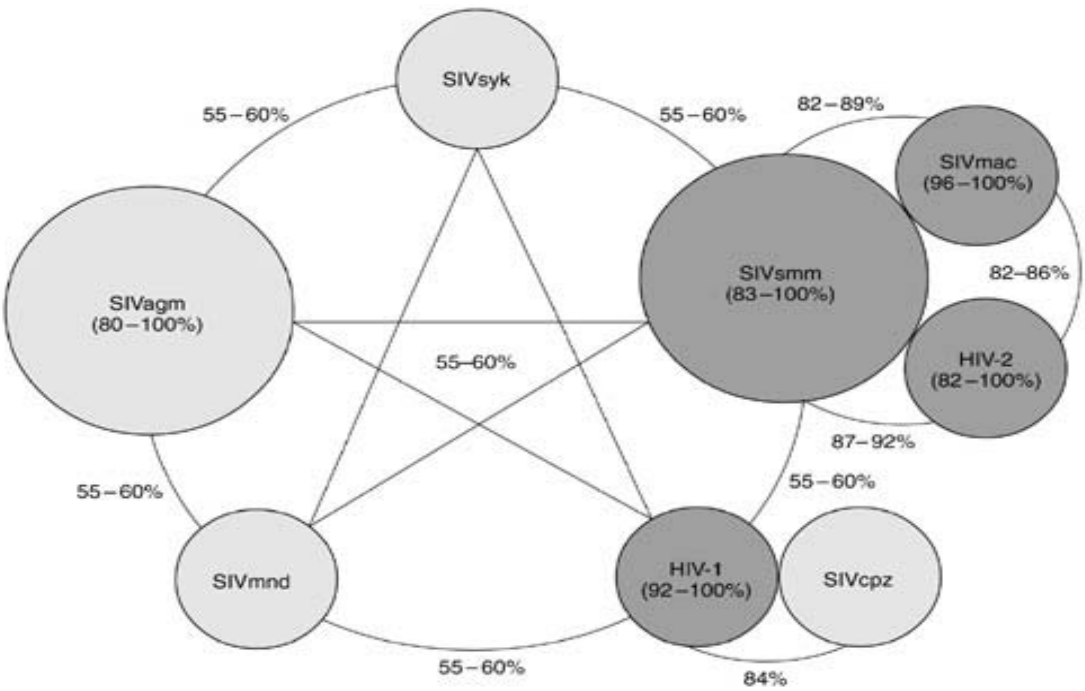

Figure 1 Five groups of primate lentiviruses.

molgus monkeys could not be infected with HIV-1. However, it was discovered that chimpanzees (*Pan troglodytes*) are susceptible to HIV-1 infection, but with the exception of one animal infected for greater than ten years, they have not developed AIDS-like disease. Likewise, pig-tailed macaques (*M. nemestrina*) have been reported to be infected with HIV-1, albeit transiently, but also fail to develop immunosuppression and disease. Although both of these models are important in investigating the interaction of HIV-1 with the host, the lack of clinical disease in most of these animals as well as the expense and endangered species status of chimpanzees limits their usefulness as animal models for AIDS.

SIVs can be propagated in mitogen-stimulated primary peripheral blood mononuclear cells (PBMC), in monocytes/macrophages from primates, and in many cultured cell lines, primarily tumor-derived CD4+ T lymphocytes and monocytes. The acutely pathogenic strains SIVsmmPbj14, SIVmac239YEnef and SIVmac239/R17Y are unusual in their ability to replicate in lymphocytes of resting PBMC cultures without prior lymphocyte activation. In PBMC cultures and many of the cell lines, viral infection results in the fusion of cellular membranes producing large syncytial cells. Syncytium formation, which is mediated by *env*, allows the virus to spread directly from cell to cell. Persistently infected virus-producing cell lines can be established from the cells surviving initial infection. Some isolates also grow well in cultured macrophages derived from lung, blood or bone marrow. As with HIV-1, infection with SIV is predominantly a CD4-mediated event, but CD4 alone is not sufficient to mediate viral entry. Certain chemokine receptors have been shown to be important coreceptors for both SIV and HIV infection. Nonsyncytium-inducing (macrophage tropic) HIV-1 strains predominantly use CCR5, whereas CXCR4 (LESTR/fusin) is utilized primarily by syncytium-inducing (T cell tropic) strains. CCR3, CCR2b, BOB (GPR15) and Bonzo (STRL33) are also utilized by some HIV strains. Similarly, SIV strains have so far been found to utilize CCR5, BOB and Bonzo. As with CD4 interactions with HIV/SIV, coreceptor use is also controlled by *env*. In rare instances, HIV-1 and SIV infection of CD4− cells *in vitro* has been reported. Infection of CD4− cells may be through these or other novel chemokine receptors.

Genetics

Retroviruses contain an RNA genome that replicates via a DNA intermediate. The viral particle contains a diploid genome of single-stranded RNA, linked noncovalently near the 5′ ends of the molecules. The 5′ end of the viral RNA is capped, and the 3′ end is polyadenylated. DNA synthesis by the viral-encoded reverse transcriptase is primed by host tRNA that is base-paired to the viral RNA. The double-stranded (ds) DNA provirus is integrated into the host cell chromosome by a viral-encoded integrase and further events in transcription, translation and assembly are host cell dependent. Particles assemble and bud through the plasma membrane.

All retroviruses possess certain basic features in their genomic organization. Regulatory sequences controlling DNA synthesis, integration, transcription and other functions are located in the long terminal repeat (LTR) at each end of the provirus. LTRs are common to the broader group of eucaryotic transposable elements (retrotransposons) that include the retroviruses. The open reading frames encoding the major structural proteins lie between the LTRs. Genes may be encoded in any of the three possible open reading frames, and overlaps between open reading frames are common. All retroviruses contain genes called *gag* (group-specific antigen) encoding the core proteins, *pol* (polymerase) encoding the viral reverse transcriptase, protease and integrase, and *env* encoding the envelope glycoproteins.

The SIVs similarly contain *gag*, *pol* and *env* genes and use a replication strategy similar to all retroviruses. However, SIVs, HIVs and other lentiviruses contain a number of genes not found in other genera of retroviruses. The SIV genome is approximately 9.6 kb from the 5′ cap to the 3′ polyadenylation site. The sequences of several cloned SIVs have been reported (SIVmac251, SIVmac142, SIVmac239, SIVsmmH4, SIVsmmPBj14, SIVmmGB1, SIVagmTYO1 and SIVcpz). The envelope gene, encoding gp120 and gp41, often contains a premature translation termination signal, resulting in a truncated transmembrane protein. In addition to the major open reading frames *gag*, *pol* and *env*, the human and simian immunodeficiency viruses contain open reading frames for *tat* (transactivator protein), *rev* (regulator of gene expression), *vif* (viral infectivity protein) and *nef* (originally termed negative factor). The *vpu* open reading frame found in HIV-1 and SIVcpz is not present in HIV-2 nor in any of the SIVs. HIV-1/SIVcpz, SIVsmm/HIV-2/SIVmac and SIVmnd contain an open reading frame called *vpr*, which is not found in SIVagm. SIVagm and SIVsmm/HIV-2/SIVmac contain a gene called *vpx* not found in SIVmnd and HIV-1/SIVcpz. Genes *vpx* and *vpr* share sequence similarity and one probably arose from the other via a gene duplication event. The presence of these additional open reading frames in the five discrete groups of primate lentiviruses is summarized in **Table 1**. Several of these additional genes (speci-

fically *vpx*, *vpr* and *nef*) can be deleted without abrogating the ability of the virus to replicate in tissue culture cells, but they certainly must contribute to the virus life cycle *in vivo*. Nef has been found to play an important role in maintaining high virus loads *in vivo* and for disease development. These observations have led to the development of molecular clones of SIV with specific deletions in *vpx*, *vpr* and *nef*, which have been successfully utilized as modified live-virus vaccines in rhesus monkeys.

SIV proteins are translated from a complex population of unspliced, singly spliced and multiply spliced mRNA molecules. The amount of each protein is regulated at least in part by the extent of splicing. The mechanisms that regulate splicing continue to be unraveled, but the interaction of the Rev protein (encoded by fully spliced transcripts) with a region of RNA called the rev-responsive element (RRE) is known to result in the accumulation of full-length transcripts that are translated into the major structural proteins.

SIVs, like other lentiviruses, accumulate genetic changes rapidly *in vivo*, presumably because of errors introduced by the error-prone reverse transcriptase and because of the selective pressures of the host. Lentiviruses may differ from other retroviruses in being able to tolerate greater variation in their envelope glycoproteins and this may contribute to their ability to persist. In one report, the rate of fixation of mutations in the gp120 portion of the envelope gene of SIVmac239 was found to be 8.5×10^{-3} changes per site per year. Mutations in the envelope gene result in antigenic variations that may enable the virus to evade ongoing host immune responses and contribute to its ability to establish persistent infection. Other mutations in the *env* gene appear to affect cell and tissue tropism, for example, by altering the ability of the virus to replicate in macrophages vs lymphocytes. Moreover, recent evidence suggests that env-mediated chemokine receptor usage by HIV changes with time allowing the virus to infect additional populations of leukocytes. Another mechanism that may generate genetic diversity is the production of heterozygous dimer genomes or pseudotype particles in cells that are infected by more than one virus. Endogenous SIV sequences have not been detected in the germ line and gene conversion/recombination events have not been documented.

Evolution

Comparisons of genetic sequences among human and simian immunodeficiency viruses suggest that there are at least five discrete groups of primate lentiviruses in existence (**Figs 1** and **2**): HIV-1 and the closely related SIVcpz; SIVmnd; SIVagm; SIVsmm/SIVmac/HIV-2; and SIVsyk. The evolutionary origin of each of these groups may never be known. It is possible that HIV-1 and HIV-2 evolved from simian viruses and entered the human population by cross-species transmission relatively recently in history. Cross-species transmission between primates in nature or in captivity may have resulted in the generation of new pathogenic variants, with SIVmac infection of macaques possibly being analogous to HIV-2 in humans. However, it is also possible that some of the primate immunodeficiency viruses may have always been present in the corresponding host population but not have been recognized until recently. The SIVs and HIVs are more closely related to one another than to any of the nonprimate lentiviruses. This suggests that the HIVs and SIVs are inherently primate viruses and that they were not derived from rodents, cats, ungulates or other nonprimates via cross-species transmission.

Serologic Relationships and Variability

The *gag* and *pol* genes are the most highly conserved among related primate lentiviruses; sequence comparison of these regions are often used to estimate relatedness rather than serologic tests. Antiserum to the Gag protein is generally crossreactive among different isolates within a group, whereas antiserum to the envelope protein can be used to distinguish between them. Serologic crossreactivity between a member of one group to one in another group is usually weak even to Gag proteins.

Epidemiology

SIV has been found in many species of African nonhuman primates throughout sub-Saharan Africa, but infection does not cause AIDS-like disease. In contrast, SIV infection of Asian macaque monkeys in captivity induces AIDS-like disease similar to that observed in HIV-infected humans. SIV-associated disease has not been seen outside these settings.

Transmission and Tissue Tropism

The routes of transmission of SIV in the wild are not known, but, as with HIV-1, transmission through contact with infected blood seems likely. In nonhuman primates, bite and scratch wounds may be more significant than sexual contact. Macaques can be experimentally infected via intravenous or intramuscular inoculation, or by exposure of the genital mucosa. Like HIV, SIV is tropic for CD4+ cells; both viruses grow preferentially in CD4+ cells, and soluble CD4 or monoclonal antibodies specific to the CD4

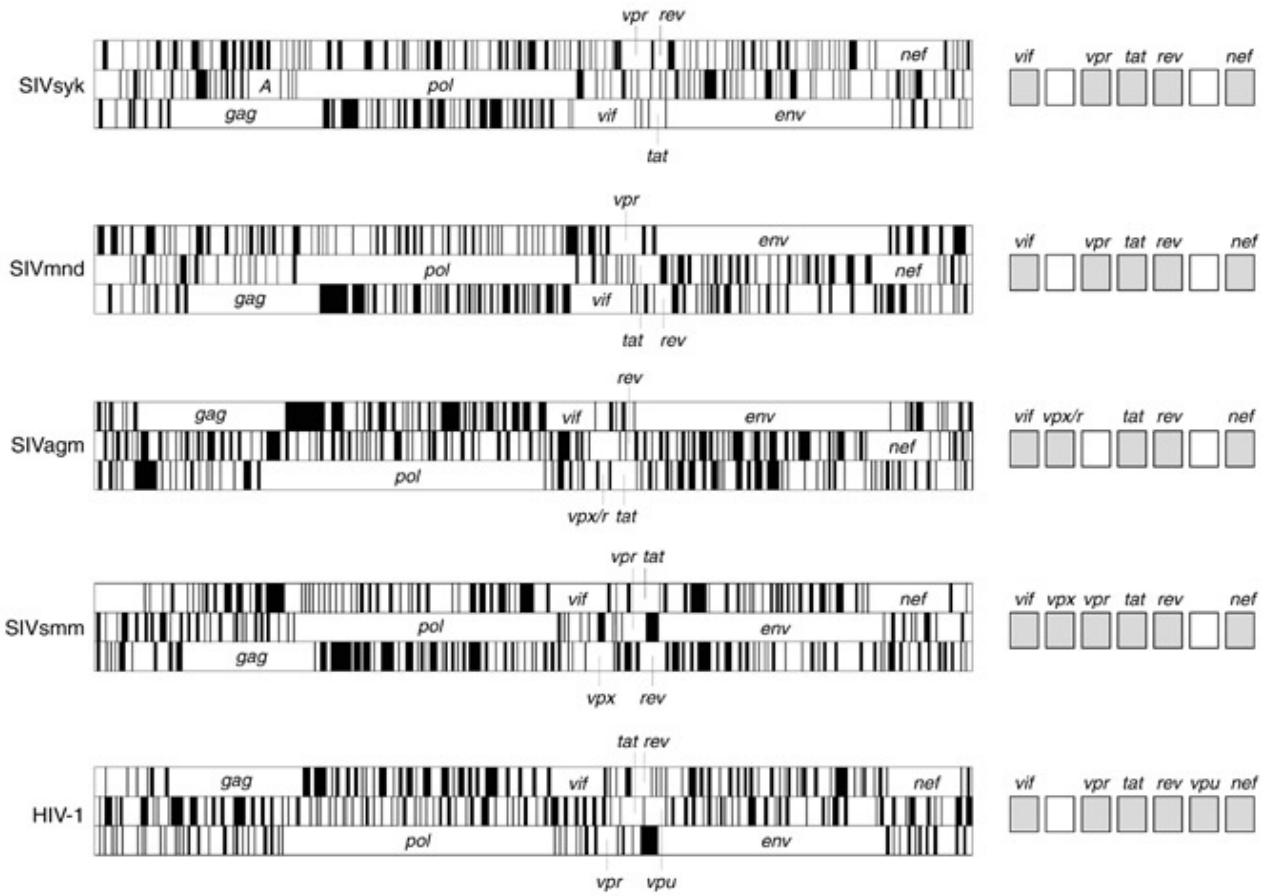

Figure 2 Organization of open reading frames in the five groups of primate lentiviruses. Reproduced from Hirsch VM, Dapolito GA, Goldstein S *et al* (1993) *Journal of Virology*, 67: 1517. Permission granted by American Society for Microbiology.

antigen can block viral infection. Recently, it has been shown that several coreceptors are required for *env*-mediated cell fusion and entry of HIV and SIV into CD4+ cells. These coreceptors are all members of the seven-transmembrane G-protein-coupled receptor family; many serving as chemokine receptors. Of the chemokine receptors used by HIV (CCR5, CCR2b, CCR3, CXCR4, BOB and Bonzo), SIV has so far been found to utilize CCR5, BOB and Bonzo. The primary targets for infection in the macaque are CD4+ helper/inducer T lymphocytes, mononuclear phagocytes, Langerhans cells and dendritic cells of lymphoid organs. Thus, lymphoid tissues (thymus, spleen, lymph nodes, gut-associated lymphoid tissue) are the principal targets of virus infection and replication. Cells of the monocyte/macrophage lineage are also major cell types replicating virus in the infected host. Infection of CD4− cells, such as endothelium, neurons, astrocytes, various epithelial cells and CD34 bone marrow progenitors, has been reported *in vitro*, but infection *in vivo* is controversial.

Pathogenicity

Natural infection of African green and Sykes' monkeys, red-capped and sooty mangabeys and mandrills with their own SIV appears to be non-pathogenic. SIVmac and SIVsmm can be pathogenic in rhesus, cynomolgus, stump-tail (*M. arctoides*) and other macaques. Disease course is dependent on the viral strain used for infection and host immune response to the virus. Acutely pathogenic strains (SIVsmmPBj14, SIVmac239YEnef and SIVmac239/R17Y) can cause death from severe enterocolitis within seven to ten days postinfection. Other strains containing gene deletions (specifically *vpx*, *vpr* and *nef*) are able to replicate *in vitro* and *in vivo*, but are markedly attenuated and rarely cause mortality. However, these clinical outcomes are the exception and most animals infected with a variety of other SIV strains generally succumb within 1–3 years postinfection with immunosuppressive disease. The induction of AIDS-like disease in macaques following infection

with SIVmac is currently used as a model for human AIDS to investigate mechanisms of pathogenesis and to evaluate potential vaccines and therapies.

Clinical Features of Infection

Infection of rhesus macaques with SIV induces both acute and chronic disease syndromes similar to that of HIV-infected humans. Within the first few weeks of infecting macaque monkeys with most strains of SIV, animals develop antigenemia and often have lymphadenopathy of the axillary and inguinal lymph nodes and an erythematous maculopapular rash. A CD8+ T cell lymphocytosis and rise in SIV-specific antibodies correlate with decreased antigenemia. Following the onset of an effective immune response (cell-mediated and humoral), animals enter an asymptomatic period of variable duration. During this time, immune abnormalities include gradual declines in the absolute CD4+ lymphocyte count, CD4/CD8 ratio, and responses to mitogens. Animals can also exhibit chronic diarrhea and wasting, with losses of up to 60% of original body weight. Lymphoid changes are profound and include thymic atrophy and hyperplasia or atrophy of lymphoid tissue (lymph nodes, spleen, gut-associated lymphoid tissue) depending on the stage of the disease. End-stage of SIV infection is characterized by a spectrum of diseases that can be divided into four broad categories: SIV-related inflammatory diseases; opportunistic infections associated with immunosuppression; neoplastic diseases; diseases of unknown pathogenesis. Tropism of SIV strains for monocyte/macrophages correlates with pronounced inflammatory and degenerative changes in the central nervous system (CNS), lung, digestive tract, and other organs independent from pathology associated with opportunistic pathogens. The incidence and characteristics of these lentivirus-induced inflammatory lesions in SIV-infected macaque monkeys closely mimics those observed in HIV-infected patients. CNS involvement (SIV encephalitis) is frequent, with the likelihood of brain lesions appearing to depend on the strain of SIV. At necropsy, 30–50% of SIVmac-infected macaques have a characteristic multinucleate giant cell encephalitis similar to that described for HIV encephalitis. Likewise, the opportunistic pathogens observed in SIV-infected macaques are similar to those observed in HIV-infected patients and include *Mycobacterium avium* complex, cytomegalovirus, rhesus Epstein–Barr virus (rhesus lymphocryptovirus), papovavirus (SV40), adenovirus, *Pneumocystis carinii, Cryptosporidia* sp. and *Toxoplasma gondii*. Neoplastic diseases in SIV-infected macaques are primarily limited to lymphomas, the occurrence of which varies among the different Primate Research Centers. Epizootics of lymphoma in SIV-infected macaques have been associated with co-infection with rhesus Epstein–Barr virus. Diseases of unknown pathogenesis include a nonneoplastic proliferation of lymphoid tissue (lymphoproliferative syndrome), arteritis and arteriopathy.

The course of disease in pigtailed macaques infected with SIVsmmPBj14 virus and rhesus macaques infected with SIVmac239YEnef and SIVmac239/R17Y is extremely rapid in comparison to most other strains of SIV. Macaques infected with these strains usually develop marked lymphoid proliferation, maculopapular rash and profuse, hemorrhagic diarrhea within one week of infection, and can die from severe fluid and electrolyte loss.

Pathology and Histopathology

Pathologic findings in macaques are varied and depend on the clinical course of disease. Within a few weeks of infecting macaque monkeys with most strains of SIV, an erythematous maculopapular eruption can occur, which is histologically identical to that described in primary HIV-1 infection. Vessels of the superficial dermis are congested and contain perivascular infiltrates of lymphocytes and macrophages. SIV nucleic acid and protein have been observed only in biopsies obtained from rhesus macaques infected with the acutely pathogenic strains SIVmac239YEnef and SIVmac239/R17Y, which induce a rash of greater severity and earlier onset than that observed with other strains of SIV.

Lymphoid tissues are the principal targets for SIV and a range of histologic changes are observed including follicular hyperplasia and dysplasia, follicular involution and hyperplasia of the T cell-dependent areas, and lymphoid depletion. These histologic changes represent successive stages in the reaction of lymphoid tissue to persistent SIV infection. In addition, some animals develop a generalized lymphoproliferative syndrome in which lymphoid tissues throughout the body become enlarged due to a nonneoplastic proliferation of lymphocytes. Multiple nodular aggregates of similar cells frequently are found in other organs and tissues of affected animals, including the salivary gland, kidney, lung, liver, bone marrow, skin and thymus.

Approximately 50% of infected animals develop primary lentiviral-induced meningoencephalitis, which is characterized by perivascular infiltrates of macrophages and multinucleated giant cells localized primarily in the white matter. These perivascular macrophages and multinucleated giant cells contain abundant viral nucleic acid and protein and contain

mature lentiviral particles within cytoplasmic vacuoles. These findings are similar to reports on HIV-infected patients with HIV encephalitis. Other SIV-induced lesions in macaques are multinucleate giant cell infiltrates in the lymph nodes, spleen, lung, gastrointestinal tract and other organs.

Other inflammatory lesions, which are histologically distinct from those directly related to SIV, are usually secondary to opportunistic infections. In the CNS, these include SV40-induced progressive multifocal leukoencephalopathy and cytomegalovirus- and *T. gondii*-induced necrosuppurative meningoencephalitis. Rarely, in the absence of a significant inflammatory response to opportunistic infections, the presence of the abnormally large numbers of organisms can cause morbidity and mortality. For instance, *P. carinii* commonly proliferates unabated to the point of filling most alveoli within lung lobes; eventually killing the host.

In SIV-infected macaques, diarrhea can apparently be caused directly by SIV. In these cases, nonspecific enteropathy consisting of blunting of the small intestinal villi, shortening of the crypts of Lieberkuhn, a predominantly mononuclear inflammatory infiltrate within the lamina propria, and attenuation or immaturity of the epithelium is seen. However, diarrhea is most frequently associated with overgrowth of commensal and pathogenic protozoa (i.e. *Cryptosporidia* sp., *Giardia* sp, *Balantidium coli, Trichomonas* sp.) and bacteria (*Mycobacterium avium*). *Cryptosporidia* sp. also infects the tracheal, pancreatic and biliary epithelium. Unexplained arterial lesions have been seen in SIV-infected macaques. These most frequently involve medium- to large-sized pulmonary vessels and include a spectrum of histologic patterns from transmural lymphocytic infiltrates to complete occlusion of the lumen secondary to intimal proliferation and thrombosis. Other organs, such as heart and kidney, may also have SIV-induced abnormalities, but these have not been well characterized.

Immune Response

Depending on viral isolate and host immune response, the disease course in SIV-infected macaque monkeys can be quite variable, as in HIV-infected patients. Experimentally infected animals generally fall into two classes: those that develop a high, persistent humoral and cellular immune response, and those with little or no response. Although the early immune response does limit viral replication, it does not control it. In both HIV-infected people and SIV-infected macaque monkeys, viremia is persistent and sustained by continuous rounds of viral replication throughout the course of infection. Animals in the first group remain persistently infected, develop a protracted disease course similar to AIDS in humans, and generally die one year or longer after infection. Viral load in the blood is variable with higher loads being predictive of rapid disease progression. Approximately 25% of animals do not mount a significant immune response to SIV and viral loads in the blood remain high throughout the course of infection. Generally, these animals die within 3–5 months and are termed rapid progressors. In addition to virus factors, unique host factors may also be important for disease susceptibility and progression.

Prevention and Control

Extensive testing programs have essentially eliminated SIV from captive macaque colonies. However, continued vigilance is needed to maintain breeding colonies free from accidental exposure to the virus. Animals can be conveniently tested serologically for evidence of infection. As rare human cases of SIV infection have been documented, SIV is handled with the same precautions as for work with HIV-1. Disposable surgical gloves and gowns are used, all work with live virus is carried out in a biosafety cabinet, procedures creating aerosols are avoided and use of glass and needles is minimized.

Future Perspectives

The most important role of SIV will be its use in basic research relevant to AIDS. The induction of AIDS in macaques by infectious molecular clones of SIV represents the best existing animal model for AIDS in humans. SIVs are the closest known relatives of the HIVs and the disease induced in macaques is remarkably similar to AIDS in humans. Rhesus and other macaque species are not endangered, can be purchased at a reasonable cost and breed well in captivity. This system can be used to dissect the molecular determinants of AIDS pathogenesis; to define the role of the so-called nonessential genes; to map functional regions of the structural genes such as the envelope; and to evaluate the potential of new treatment and vaccine strategies. Finally, the ongoing investigation of 'new' isolates and their genetic relatedness to existing SIV and HIV isolates may shed light on the origins and evolution of the primate immunodeficiency viruses.

SIMIAN VIRUS 40 (*PAPOVAVIRIDAE*)

Janet S Butel, Division of Molecular Virology, Baylor College of Medicine, Houston, USA

History

Simian virus 40 (SV40) was discovered in 1960 as a contaminant of poliovaccines. Hundreds of millions of people worldwide were inadvertently exposed to SV40 in the late 1950s and early 1960s when they were administered contaminated virus vaccines prepared in rhesus macaque kidney cells. Infectious SV40 had unknowingly contaminated batches of both the inactivated and live attenuated forms of the poliovaccine, as well as preparations of some other viral vaccines. Although primary cultures of monkey cells were known to be commonly contaminated with indigenous viruses and safety testing was carried out, SV40 had escaped detection because it failed to induce cytopathic effects in rhesus cells. However, when it was inoculated into African green monkey kidney cells, a prominent cytoplasmic vacuolization developed. Originally christened as 'vacuolating virus', the name was later changed to SV40 to conform with a numerical system of designating simian virus isolates.

Concern about the vaccine contaminations heightened considerably when it was found in 1962 that SV40 was tumorigenic in newborn hamsters and could transform many types of cells in culture. Because of the potential risk to public health posed by the previous distribution of contaminated poliovaccines, SV40 became the focus of intensive investigation. Fortunately, the individuals exposed to SV40-contaminated vaccines appear not to be at higher risk of developing cancer than those who received SV40-free vaccines. However, SV40 DNA is sometimes found in tumors arising in persons too young to have been exposed to the contaminated vaccines. For scientists, SV40 has turned out to be an invaluable tool for dissecting molecular details of eukaryotic cell processes. Numerous techniques now commonly used in molecular biology were pioneered in the SV40 system. It continues to serve as a leading model for basic studies of viral carcinogenesis.

Taxonomy and Classification

SV40 is classified as a member of the *Polyomavirus* genus in the *Papovaviridae* family (**Table 1**). The other well-studied member of the genus is polyoma virus of mice. The group also includes the human polyomaviruses, BKV and JCV, as well as isolates from other species, including hamsters, rabbits, cattle, birds and baboons. The papillomaviruses are classified in the other genus, *Papillomavirus*, in the family. The human and animal polyomaviruses are antigenically distinct, and there is only one recognized serotype for each virus.

The polyomaviruses are small and simple and share certain physical and chemical properties. These include an icosahedral capsid about 45 nm in diameter that contains three viral proteins, the lack of an envelope and a double-stranded (ds) circular covalently closed DNA genome about 5 kbp in size. The outstanding biological characteristics of the polyomaviruses are that they establish persistent infections in natural hosts, stimulate cellular DNA synthesis in infected cells, and are tumorigenic in the appropriate hosts.

Properties of the Virion

SV40 particles are small and spherical, with a diameter of approximately 45 nm. Infectious virions

Properties of the Virion

SV40 particles are small and spherical, with a diameter of approximately 45 nm. Infectious virions

Table 1 Properties of SV40

Classification	Family *Papovaviridae*, genus *Polyomavirus*
Strain variation	Genetically stable; one serotype, multiple strains
Virion	Icosahedral, 45 nm in diameter, no envelope
Genome	Circular covalently closed dsDNA, 5200 bp
Proteins	Three structural proteins, VP1, VP2, VP3; cellular histones condense DNA in virion; nonstructural replication protein, T-antigen, is potent oncoprotein
Replication	In certain primate kidney cells; nucleus; stimulate cell DNA synthesis; long growth cycle
Natural host	Asian macaques, especially the rhesus monkey
Diseases	Asymptomatic persistent infections in natural hosts; neurological disease in immunocompromised hosts; tumors in experimentally infected rodents
Historical note	Contaminant in early poliovaccines administered to millions of people

have a sedimentation coefficient of 240S in sucrose and band at a density of 1.34 g ml^{-1} in CsCl; empty capsids have a density of 1.29 g ml^{-1}. The molecular mass of the SV40 virion has been estimated at 270 kDa. The DNA content is 12.5% (w/w). The major capsid protein (VP1) accounts for 75% of the total virion protein. VP2 and VP3 are minor capsid proteins. Cellular histones (H2A, H2B, H3, H4) are used to condense the viral DNA for packaging and are present in the core of the particle. There is no lipid envelope. SV40 does not agglutinate erythrocytes.

SV40 particles exhibit icosahedral symmetry. The virion is composed of 72 pentameric capsomeres composed of the VP1 protein arranged on a $T = 7d$ icosahedral surface lattice. This puzzling structure (that the hexavalent capsomeres have pentameric substructure) demands nonequivalent contacts between pentamers. This seems to be accomplished by the C-termini of the VP1 polypeptides, which extend as arms from one pentamer and fit into binding sites on adjacent pentamers. The arms can go in different directions, providing the necessary flexibility to build a capsid. The N-terminal arm of VP1 is completely internal in the virus particle. Minor capsid proteins VP2 and VP3 are predominantly internal as well and do not contribute to the basic structure of the virus outer shell.

The virus particles are very resistant to heat inactivation but are relatively labile when heated in the presence of divalent cations. Whereas SV40 is stable at 50°C for hours, incubation in the presence of 1 M $MgCl_2$ at 50°C for 1 h will inactivate the virus. At a higher temperature (60°C), ~99% of infectious virus is inactivated within 30 min in the absence of divalent cations. Purified virions can be disrupted by strong alkaline conditions (pH 10.5), by lower pH (9.2) plus a reducing agent, or by detergent treatment. Intact virus particles are not affected by nucleases, but in the presence of a reducing agent nuclease can enter the virion and cleave the viral DNA. SV40 is efficiently inactivated by UV light irradiation, following single-hit kinetics.

Properties of the Viral Genome

The SV40 genome is a circular covalently closed dsDNA molecule (**Fig. 1**). The native DNA assumes a superhelical configuration (form I) that sediments at 21S in a neutral sucrose gradient. A single-stranded (ss) nick generates relaxed circular dsDNA molecules (form II) that sediment at 16S, whereas a ds break produces linear dsDNA (form III, 14S). Alkaline denaturation of form I DNA produces dense cyclic coils that sediment at 53S. Form II DNA is converted into ss circular (18S) and ss linear (16S) molecules by denaturation. The supercoiled (form I) molecules can be separated from relaxed circular and linear forms by centrifugation of a DNA preparation in CsCl gradients with ethidium bromide. The form I molecules will band in a lower position in the gradient. The DNA forms also separate during electrophoresis in a neutral agarose gel; the supercoiled molecules migrate the fastest, the linear forms move at an intermediate speed, and the relaxed circles migrate the slowest.

The viral DNA both in virions and in infected cells is associated with cellular histones H2A, H2B, H3 and H4. The histones are assembled in 24–26 nucleosomes on the viral DNA. The nucleosome structure and histone composition of the viral minichromosome mimic the chromatin structure of cellular DNA.

SV40 DNA was the first eukaryotic viral genome to be physically mapped by restriction endonuclease analysis (1971) and to be completely sequenced (1978). The DNA of reference strain 776 contains 5243 bp for a calculated molecular weight of 3.5×10^6. The genome is numbered in a clockwise direction from 1 to 5243, the center nucleotide of the unique *BglI* recognition site being assigned as 0/5243. Numbering continues through the late region in the

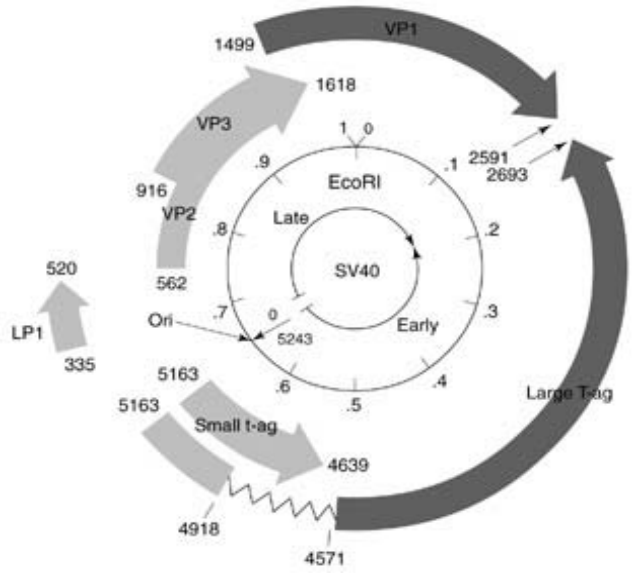

Figure 1 Genetic map of SV40. The thick circle represents the circular SV40 DNA genome. The unique *Eco*RI site is shown at map unit 0/1. Nucleotide numbers begin and end at the origin (*Ori*) of viral DNA replication (0/5243). Boxed arrows indicate the open reading frames that encode the viral proteins. Arrowheads point in the direction of transcription; the beginning and end of each open reading frame is indicated by nucleotide numbers. Various shadings depict different reading frames used for different viral polypeptides. Note that T-ag is coded by two noncontiguous segments on the genome. The genome is divided into 'early' and 'late' regions that are expressed before and after the onset of viral DNA replication, respectively. Only the early region is expressed in transformed cells. (Reproduced with permission from Brooks GF, Butel JS and Ornston LN (1998) *Jawetz, Melnick & Adelberg's Medical Microbiology*, 21st edn. Norwalk, CT: Appleton & Lange.)

sense orientation and the early region in the antisense orientation. The numbering system begins and ends (0/5243) in the middle of the functional origin of DNA replication. The unique *Eco*RI site at nucleotide 1782 was arbitrarily chosen as a point of reference and assigned a value of 0/1.0 on the circular map. Laboratory-adapted strains of SV40 contain a duplication of the 72 bp element in the enhancer region, whereas most natural isolates do not.

SV40 makes maximal use of a limited amount of genetic information, including having compact regulatory sequences and overlapping genes. The genome contains a single origin of replication (core *Ori* = 64 bp in size) embedded within a nontranslated regulatory region. These elements control transcription and replication and span about 400 bp. The SV40 genetic map is divided into two halves, corresponding to regions that are expressed during the early and late stages of infection. These regions represent the 'early' nonstructural genes and the 'late' structural genes, respectively, and are transcribed off opposite strands of the viral DNA.

There is a variable domain at the C terminus of the *T-ag* gene, encompassing about 270 bp. Nucleotide changes within this region can be used to distinguish strains of SV40.

Properties of Viral Proteins

SV40 encodes six gene products: two 'early' nonstructural proteins [large T antigen (T-ag), small t antigen (t-ag)], three 'late' structural proteins (VP1, VP2, VP3) and a maturation protein (LP1 or agnoprotein).

The nonstructural proteins are expressed early in infection, before the onset of viral DNA synthesis. The coding regions of the two T-ags overlap; alternative splicing of viral transcripts determines each protein sequence. Large T-ag of strain 776 (**Table 2**) contains 708 amino acids (~90 kDa), and small t-ag contains 174 residues (~20 kDa). The large and small T-ags share 82 N-terminal amino acids, whereas the remainder of each protein is unique. The T-ag/t-ag common exon contains a 'J domain,' believed to modulate hsc70 activity in the assembly and disassembly of multiprotein complexes.

Large T-ag is an essential replication protein required for initiation of viral DNA synthesis. It stimulates host cells to enter S phase and undergo DNA synthesis and is the SV40 transforming protein. Large T-ag contains a nuclear transport signal (Pro126-Lys-Lys-Lys-Arg-Lys-Val132) that targets the protein into the nucleus. However, about 10% of the T-ag in the cell is found in the cytoplasm and the plasma membrane. The biology of small t-ag is enigmatic. It is a cytoplasmic protein that is not essential for viral replication in cultured cells. It associates with the regulatory and catalytic subunits (36 kDa and 63 kDa) of protein phosphatase 2A and is believed to cause cellular growth stimulation. Perhaps it is required during natural infections by SV40 in host primates.

Large T-ag is a multifunctional protein that is chemically modified in several ways (**Fig. 2**). Its functions in SV40 DNA replication are regulated by phosphorylation. The sites of phosphorylation are clustered near the ends of the molecule, one region lying between residues 106 and 124 and the other between residues 639 and 701. The majority of the phosphorylated residues are serines, although two threonine residues also become phosphorylated. Unlike many oncoproteins, T-ag is not phosphorylated at tyrosine residues.

T-ag is a DNA-binding protein that recognizes multiple copies of the sequence GAGGC in three T-

Table 2 Properties and functions of SV40 T-ag

Structural properties

1. Size:
   - 708 amino acids
   - 82 N-terminal residues shared with t-ag
   - 81 632 Da
   - M_r 90 000–100 000
2. Modifications:
   - Phosphorylation
   - N-terminal acetylation
   - *O*-glycosylation
   - Poly-ADP-ribosylation
   - Palmitylation
   - Adenylation
3. Supramolecular structure
   - Zinc finger
   - Nuclear localization signal
   - J domain
   - Monomers, dimers, higher homooligomers
   - Heterooligomers with transcriptional coactivators (CBP, p300, p400)
   - Heterooligomers with DNA polymerase α; hsc70; cdc-2, cyclin, and tubulin
   - Heterooligomers with tumor suppressor proteins (p53, pRB, p107, p130)

Subcellular distribution

1. Nuclear:
   - Nucleoplasmic
   - Chromatin bound
   - Nuclear matrix associated
2. Plasma membrane:
   - Nonidet P-40 soluble
   - Nonidet P-40 insoluble (plasma membrane lamina)
   - Butanol soluble

Functions

1. Specific DNA binding (viral origin of replication)
2. Initiation of viral DNA replication
3. Autoregulation of viral early transcription
4. Induction of viral late transcription
5. Determination of host range
6. ATPase activity
7. Helicase activity
8. Complex formation with CBP, p300, p400

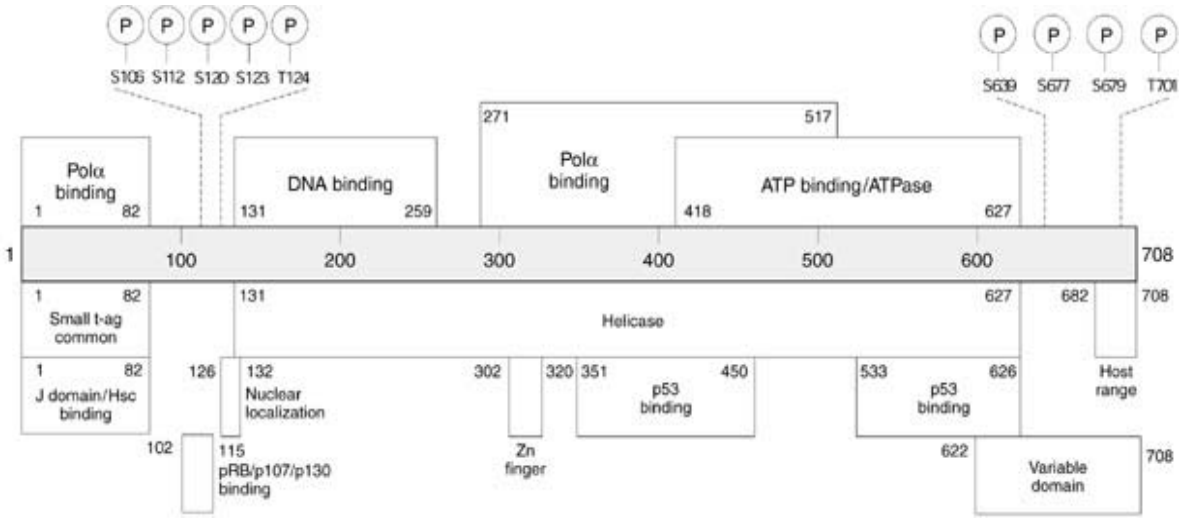

Figure 2 Functional domains of SV40 large T-ag. The numbers given are the amino acid residues using the numbering system for SV40-776. Regions are indicated as follows. Small t-ag common: region of large T-ag encoded in the first exon. The amino acid sequence in this region is common to both large T-ag and small t-ag. Polα binding: regions required for binding to polymerase α-primase. J domain/Hsc binding: region required for binding the heat shock protein hsc70. pRB/p107/p130 binding: region required for binding of the RB tumor suppressor protein, and the RB-related proteins p107 and p130. Nuclear localization: contains the nuclear localization signal. DNA binding: minimal region required for binding to SV40 *Ori* DNA. Helicase: region required for full helicase activity. Zn finger: region which binds zinc ions. p53 binding: regions required for binding the p53 tumor suppressor protein. ATP binding/ATPase: region containing the ATP binding site and ATPase catalytic activity. Host range: region defined as containing the host range and Ad helper functions. Variable domain: region containing amino acid differences among viral strains. The circles containing a P indicate sites of phosphorylation found on large T-ag expressed in mammalian cells. S indicates a serine and T indicates a threonine residue. (Reproduced with permission from Stewart AR, Lednicky JA, Benzick US, Tevethia MJ and Butal JS (1996) Identification of a variable region at the carboxy terminus of SV40 large T-antigen. *Virology* 221: 355.)

ag-binding sites in the viral *Ori*. The phosphorylation of one amino acid, Thr124, is crucial for T-ag to be able to bind to site II and to initiate viral DNA replication. The minimal origin-specific DNA-binding domain of T-ag lies between residues 131 and 259. T-ag is predicted to have a zinc finger motif, typical of DNA-binding proteins, between amino acids 302 and 320. T-ag-specific ATPase and helicase activities are required in addition to DNA-binding activity in order for T-ag to function in initiation of DNA replication. The ATP-binding domain of T-ag is similar in structure to other ATP-binding proteins and is located between residues 418 and 627.

Large T-ag forms complexes with several cellular proteins. Such interactions are involved in T-ag functions in viral DNA replication and induction of cellular DNA synthesis. Target cellular proteins found in heterooligomeric structures with T-ag include transcriptional coactivators (CBP, p300, p400), tumor suppressor proteins (p53, pRB, p107, p130), DNA polymerase α, the molecular chaperone heat-shock protein hsc70, cell-cycle regulatory proteins cdc-2 and cyclin and tubulin. The indicated cellular proteins are not all found in the same T-ag-associated complex; many subpopulations of T-ag exist in a cell.

The variable domain at the C terminus of T-ag encompasses the host range-adenovirus helper function exhibited by SV40 (and mapped to T-ag) in some monkey kidney cell lines. The significance of the variable domain to natural infections by the virus is unknown.

The structural (capsid) proteins are expressed late in infection, after the onset of DNA replication. They are synthesized in much greater abundance than the early proteins. The major capsid protein, VP1, contains 362 amino acids (~45 kDa). The minor structural proteins are VP2 (352 residues, ~38 kDa) and VP3 (234 residues, ~27 kDa). The coding regions for VP2 and VP3 overlap, and they are translated in the same reading frame, so the sequence of VP3 is identical to the C-terminal two-thirds of VP2. VP3 is synthesized by independent initiation of translation via a leaky scanning mechanism. It is not a proteolytic cleavage product of VP2. The N-terminal portion of VP1 is derived from sequences that encode the C-termini of VP2 and VP3. However, VP1 is translated in a different reading frame from a different spliced transcript, so it shares no sequences with VP2 and VP3. VP1 is modified by phosphorylation and acetylation.

The late proteins are required only for the assembly

of progeny virions during lytic infection. They are not involved in the early phases of viral replication. They are synthesized in the cytoplasm and move into the nucleus where particle morphogenesis occurs. The minor capsid proteins contain nuclear transport signals. The VP2/3 signal is Gly-Pro-Asn-Lys-Lys-Lys-Arg-Lys-Leu (VP2, residues 316–324; VP3, residues 198–206). For VP1, two clusters of basic residues within the N-terminal 19 residues are independently important for nuclear targeting. Mutations in VP1 affect capsid assembly and/or virion stability. Mutations in VP2 and VP3 affect the uncoating process, when virions penetrate new host cells.

The agnoprotein LP1 is synthesized late in infection but is not found in virus particles. It is a small (62 residue, ~8 kDa) basic protein involved in particle assembly. It is believed that LP1 interacts with VP1 molecules to inhibit self-polymerization until they interact with viral minichromosomes in the nucleus to form virions.

Replication

Overview of SV40 replication cycle

The SV40 replication cycle is cleanly divided into early and late events, with the onset of viral DNA replication being the dividing landmark. SV40 virions attach to receptors on the cell surface, become internalized, and are transported to the cell nucleus where the viral DNA is uncoated. After uncoating, the half of the genome that contains the early region is transcribed ('early' mRNAs). Viral early proteins (T-ags) are synthesized, cellular genes are expressed, and the cells enter S phase. Viral DNA replication then begins. 'Late' mRNAs are transcribed from the other half of the viral genome (the opposite strand), and viral structural proteins are synthesized. Virus particles are assembled. The majority of progeny virions stay associated with the cell until cell lysis occurs following cell death. The SV40 multiplication cycle is slow, taking 48–72 h. The time course of the virus growth cycle is dependent on the viral multiplicity of infection and the growth state of the host cell at the time of infection.

Strategy of replication of nucleic acid

SV40 DNA is replicated in the cell nucleus as a free unintegrated minichromosome. The only viral components required are the viral origin of replication on the DNA and the T-ag protein; all other factors are provided by the host cell replication machinery. T-ag is required for the initiation of DNA replication. The specific T-ag functions required are its DNA-binding ability and its ATPase/helicase activities. The relative simplicity of the SV40 system has allowed the development of cell-free replication systems and the identification of factors involved in mammalian DNA replication.

T-ag binds to the viral *Ori*, a 64 bp segment that contains binding site II for T-ag. In an ATP-dependent process, T-ag causes localized unwinding of the *Ori* region; cellular single-stranded binding protein is required to stabilize the unwound single strands. The cellular DNA polymerase α–primase complex initiates DNA replication, and replication proceeds bidirectionally, with the two forks advancing at equal rates. The strand growing in the 5′ to 3′ direction is synthesized in a continuous fashion, whereas the strand growing in the 3′ to 5′ direction is synthesized as small pieces (Okazaki fragments). Elongation involves DNA polymerase α, DNA polymerase δ and proliferating cell nuclear antigen. Termination occurs 180° away from the viral *Ori;* topoisomerase II segregates the newly synthesized daughter molecules. Cellular histones are added to the new strands during the process of DNA replication.

Only certain monkey and human cells support SV40 DNA replication. This cell permissiveness seems to depend on the nature of the DNA polymerase α–primase complex.

The onset of viral DNA replication is carefully coordinated with the host cell cycle by the phosphorylation of a specific site on T-ag. The T-ag synthesized soon after viral infection drives the cell to enter S phase. The binding of p53 and pRB cellular proteins is presumably important in this process. A cell cycle-dependent kinase becomes activated and phosphorylates T-ag at Thr124. Only then can T-ag bind to site II in the viral *Ori* and initiate viral DNA replication. This regulation assures that viral DNA does not become unwound for replication until the host cell has entered S phase and the necessary cell replication factors are in place.

Characterization of transcription

Transcription of the viral DNA is carried out by the cellular RNA polymerase II. In the noncoding region of SV40 DNA near the origin of replication are early and late promoter structures and enhancer elements. Early transcription begins at about nucleotide 5237, proceeds in the counterclockwise direction, and ends at the polyadenylation site at nucleotide 2694. The early promoter contains a TATA box about 30 bp upstream of the early RNA initiation site. (This start site is about 70 nucleotides upstream of the initiation codon shared by the early proteins.) There are three G+C-rich regions, the '21 bp repeats,' located 40–103 nucleotides upstream that are binding sites for the Sp1

cellular factor. Even farther upstream are the SV40 enhancer elements, the 72 bp elements, which contain binding sites for other cellular factors that regulate transcription. The primary early transcripts are differentially spliced to generate the mRNAs that code for large T-ag and small t-ag.

There is no requirement for virus-encoded proteins, but early transcription is regulated by T-ag. As the concentration of T-ag increases in the cell, it binds first to site I and then to sites II and III on the viral DNA. Early transcription is repressed when site II is occupied, because the presence of T-ag blocks the binding of RNA polymerase. Therefore, T-ag regulates its own synthesis.

Late transcription begins after viral DNA synthesis is underway. The abundance of late transcripts is much greater than the early transcripts because progeny DNA molecules are utilized as templates. A heterogeneous collection of late mRNAs is made, with late transcription beginning at multiple sites between nucleotides 120 and 482 and proceeding in the clockwise direction, ending at a polyadenylation site at nucleotide 2674. Both the 21 bp repeats and the 72 bp elements have positive effects on late transcription. T-ag *trans*-activates late transcription by an unknown mechanism that does not involve DNA binding. The late transcripts are alternatively spliced into two size classes (19S, 16S). VP1 is synthesized from 16S RNA and both VP2 and VP3 are translated from the 19S species. The agnoprotein is synthesized predominantly from the most abundant species of 16S RNA.

Characterization of translation

Early gene products (T-ag, t-ag) are synthesized from differentially spliced early transcripts. Likewise, the structural proteins (VP1, VP2, VP3) are produced from differentially spliced late transcripts. VP3 is a truncated version of VP2, due to initiation of translation at an internal site on the same species of transcripts. The agnoprotein LP1 is translated from the leader region of late transcripts. The late gene products are produced in much greater abundance than the early proteins, reflecting the relative concentrations of the transcripts.

Post-translational processing

No post-translational cleavages are involved in the production of SV40 proteins. As noted above, T-ag and VP1 are modified in various ways, including phosphorylation.

Uptake and release of virions

SV40 particles attach to receptors on the cell surface. The receptors recognized by virus particles are believed to be the major histocompatibility complex class I molecules.

Attached particles are internalized by endocytosis. Conformational changes are thought to occur that expose the nuclear localization signals on capsid proteins and allow the virions to squeeze through the nuclear pore complex. The capsid disassembles in the nucleus, releasing the viral DNA.

Maturation of progeny virions occurs in the nucleus, where the viral nucleic acid is replicated. Viral proteins are synthesized in the cytoplasm off viral transcripts exported from the nucleus, and the proteins are then transported back into the nucleus. The structural proteins condense around the viral minichromosomes. There is a packaging signal on SV40 DNA that includes the *Ori* and part of the enhancer element. During the maturation process, the agnoprotein is released and is not retained as a component of mature virions. Assembly intermediates that sediment more slowly than extracellular virions have been detected. Certain SV40 T-ag mutants are defective in the assembly of virus particles, but the mechanism is obscure. There are size constraints for packaging DNA; molecules ranging from 3.5 kbp to 5.7 kbp can be encapsidated into SV40 particles.

Some progeny virus is released from the cell by an unknown mechanism, but the majority stays associated with the cell until lysis caused by cell death. Host cells are killed as the result of a variety of effects, including the release of lysosomal enzymes into the cytoplasm and damage to the cell mitochondria. Late in infection, monkey kidney cells develop a characteristic cytopathic effect, cytoplasmic vacuolization. Between 10^4 and 10^5 virus particles are produced by each infected cell.

Geographic and Seasonal Distribution

The geographic distribution of SV40 can only be inferred, as no comprehensive surveys have been conducted. Its distribution in the wild presumably reflects its narrow host range. As far as is known, SV40 is found naturally in wild populations of certain Asian macaque species. Many captive primates can be infected if they have been in contact with an infected macaque. Infections in humans are probably more widespread geographically, as contaminated polio-vaccines were broadly distributed. Nothing is known about seasonal effects on natural infections by SV40.

Host Range and Virus Propagation

Papovaviruses, in general, have a narrow host range,

Table 3 Origin of SV40 strains

Virus strain	*Year isolated*	*Source*
SV40-776	1960	Adenovirus type 1 seed stock prepared in monkey kidney cells
Baylor	1961	Type 2 Sabin poliovaccine prepared in 1956 in monkey kidney cells
VA45-54	1960	Uninoculated green monkey kidney cells
Rh911	ca. 1960	Uninoculated rhesus monkey kidney cells
A2895	ca. 1961	Tumor from hamster injected with rhesus monkey kidney cells
D-128	1962	Uninoculated rhesus monkey kidney cells (Russia)
SVPML-1	1970	Cultured human brain cells from patient with progressive multifocal leukoencephalopathy
SVMEN*	1984	Human meningioma (cloned directly)
SVCPC*	1995	Human choroid plexus carcinoma
SV40-K661	1997	Brain from rhesus monkey coinfected with simian immunodeficiency virus

Data taken from Stewart AR, Lednicky JA and Butel JS (*J. Neurovirol.* 1998; 4: 182) and from Lednicky JA, Arrington AS, Stewart AR *et al* (*J. Virol.* 1998; 72: 3980).
*SVMEN and SVCPC are identical.

with each virus infecting only one or a few closely related species. Based on antibody surveys of wild populations of primates, the natural hosts for SV40 appear to be a few species of Asian macaque monkeys, especially the rhesus (*Macacca mulatta*). In captivity, several related species are easily infected, including the cynomolgus macaque (*M. fascicularis*) and the African green monkey which belongs to the same family as macaques (Cercopithecidae). The virus grows poorly in more distantly related primates. SV40 can infect humans.

SV40 is propagated in tissue culture in established cell lines derived from kidneys of African green monkeys. Characteristic vacuolated cells appear in response to viral replication. The virus grows in rhesus kidney cell lines in which it establishes a persistent infection but produces no cytopathic effects. The SV40 growth cycle is long, compared with those of other virus families.

SV40 does not cause tumors in its natural hosts. To demonstrate its tumorigenic potential, the virus must be inoculated into experimental animals (newborn hamsters are most susceptible). Many types of cells can be transformed in culture, especially those of rodent origin. Primate cells can be transformed, but only if experimental conditions are manipulated to prevent viral replication.

Genetics

SV40 is genetically stable. Sequence variation exists at the C-terminus of the *T-ag* gene among different isolates. Many point mutations, deletions and substitutions have been introduced into the SV40 genome in the course of experimental studies designed to examine mechanisms of gene regulation, viral replication and cell transformation. Adaptation of natural isolates to tissue culture involves the selection of viruses with duplications or rearrangements in the viral regulatory region. The origins of the most well-characterized SV40 strains are listed in **Table 3.** Serial undiluted passage of virus in cultured cells often results in the accumulation of defective-interfering particles containing DNA with extensive deletions and rearrangements. To produce high-titer stocks of virus, serial passage of undiluted preparations should be avoided.

Evolution

Different strains of SV40 can be distinguished on the basis of nucleotide differences in the regulatory region and in the variable domain of the *T-ag* gene. During natural infections, viruses with heterogeneous regulatory regions but a common *T-ag* gene may be generated. During adaptation to tissue culture, a virus with a duplication in the enhancer will usually be selected. The evolutionary origin of SV40 is obscure. Sequence comparisons have revealed short regions of similarity between portions of SV40-encoded gene products and cellular proteins. It may be that the viral proteins are composites of functional domains pirated from cellular progenitors. Because of size constraints imposed on the SV40 genome by capsid architecture, the bulk of the coding sequence for a cellular protein would have to be jettisoned, making identification of origins difficult. Among the polyomaviruses, SV40 is most closely related to BKV by base sequence homology. When all the polyomaviruses are compared, the lowest homologies are found in the noncoding regulatory sequences.

Serologic Relationships and Variability

Only one serotype of SV40 is known. The virus does not undergo noticeable antigenic variation. Perhaps restrictions imposed by the symmetry of the capsid permit only minimal deviation in amino acid sequence of the structural proteins, making most changes lethal for the virus.

There is a genus-specific antigenic determinant on the major capsid protein, VP1, that is shared by all animal and human polyomaviruses. It is internal in the virion, but antibodies are elicited against it by immunization with disrupted capsids or with purified VP1 protein. The determinant is expressed in infected cells. Antibodies against the shared determinant are not neutralizing, as the site is not exposed on the surface of virus particles. Although the structural proteins of SV40 and the two human polyomaviruses are antigenically distinct (with the exception of the genus-specific determinant on VP1), the T-ags of SV40, BKV and JCV show extensive antigenic cross-reactivity.

Epidemiology

Most adults of the Asian macaque species believed to be natural hosts for SV40 have neutralizing antibodies to the virus. Few of the juvenile animals of those species, in the wild, have antibodies. However, in captivity the young animals are readily infected if they have contact with a virus-positive animal.

Serologic surveys have detected SV40-neutralizing antibodies in humans not exposed to contaminated vaccines, with prevalences of 2–10%. Possible cross-reactivity with BKV and JCV does not explain the presence of such antibodies. This suggests that SV40, or an unknown SV40-like agent, is circulating in the human population.

Transmission and Tissue Tropism

SV40 establishes persistent infections in the kidneys of susceptible hosts. The level of virus present may be very low. Modes of transmission are not known, but transmission probably occurs due to virus shed in the urine. Experiments have established that susceptible animals can be infected by the oral, respiratory or subcutaneous routes. Both viremia and viruria occur in infected animals. SV40 may cause neurologic disease in immunocompromised hosts.

The major known source of human exposure to SV40 was via the administration of contaminated viral vaccines before SV40 was recognized. That risk no longer exists. Human exposure could occur by contact with infected monkeys, a situation limited to small numbers of animal handlers. It is presumed that patterns of tissue tropism and transmission similar to those described in monkeys would be observed in humans infected by SV40.

Pathogenicity and Pathology

SV40 infections in normal monkeys appear to be asymptomatic and harmless. However, SV40 has been associated with a fatal case of pulmonary and renal disease, as well as with cases of progressive multifocal leukoencephalopathy, in unhealthy rhesus monkeys. SV40 can cause widespread infections in monkeys suffering from simian AIDS. No tumors have been found in the natural hosts. Transgenic mice carrying wild-type SV40 DNA develop choroid plexus papillomas and die rapidly because of the physiological importance of the tumor site. When foreign tissue-specific regulatory sequences are substituted for the native promoter-enhancer of the virus, SV40 expression can be directed to other tissues in transgenic animals. Tumors usually appear in the targeted tissue and are lethal. In conventional animals, tumors induced by virus injection tend to stay localized and do not invade or metastasize, but rodents bearing such tumors usually succumb due to the tumor load. SV40-induced tumors are usually classified as undifferentiated carcinomas or sarcomas. Intravenous inoculation of SV40 into weanling hamsters induced leukemia, reticulum cell sarcoma and osteogenic sarcoma. SV40 DNA has been detected in several types of human cancers, including brain tumors (especially those from children in the first decade of life), mesotheliomas, osteosarcomas and kidney tumors. The role SV40 may have played in the induction of those tumors is unknown.

Immune Response

SV40, like other members of the *Polyomavirus* genus, induces an asymptomatic, persistent infection in natural hosts. An antibody response to capsid antigen is elicited that can be detected in neutralization assays. It is well documented with the human viruses BKV and JCV that impaired cell-mediated immunity is associated with virus re-activation, showing that viral replication is under the control of the immune system of the host; the same presumably applies to SV40.

Little is known about the immune response of humans to infection by SV40. Small numbers of individuals exposed to contaminated vaccines were analyzed for neutralizing antibody responses to SV40. Humoral responses were variable and dependent on the size of inoculum and route of inoculation. Recent serological surveys have detected SV40 neutralizing

antibody in 2–10% of persons not exposed to SV40-contaminated viral vaccines. Antibodies to SV40 were most often detected in people with some type of immune suppression.

Experimental studies have shown that animals with active infections by SV40 may produce humoral antibodies against the replication oncoprotein, T-ag. The responses were variable and probably reflected the extent of viral replication. It should be noted that a T-ag antibody response could not be used to monitor SV40 infections in humans because of the crossreactivity among the T-ags of SV40 and the human viruses BKV and JCV.

SV40 tumor-bearing animals develop a strong immune response to T-ag. Both humoral and cell-mediated responses occur. No antibodies are produced against capsid antigens, as the structural proteins are not expressed in tumor cells in rodents. Cytotoxic T cells directed against T-ag determinants at the cell membrane help render the animals resistant to the growth of SV40 tumor cells. This system has been an important experimental model for helping to understand the immune response to neoplastic cells in humans.

Interferon is induced only weakly by the polyomaviruses and is not thought to be an important component of the host response to SV40.

Prevention and Control

No control measures are available to prevent SV40 infections.

Future Perspectives

The reports of antibodies to SV40 in humans and the infrequent association of SV40 markers with human tumors suggest that SV40 may be present in the population. If its presence is substantiated, it will be important to determine the natural history of SV40 in humans, including modes of transmission and factors affecting susceptibility to infection. If tumors are produced in humans following exposure to SV40, it will be necessary to develop appropriate control measures to prevent such infections. Because of its small genetic content and dependence on host cell functions, SV40 will continue to be a useful model system for discerning mechanisms of cellular processes, such as mammalian cell DNA replication, cell cycle progression and growth control processes altered in neoplasia.

SINDBIS AND SEMLIKI FOREST VIRUSES (*TOGAVIRIDAE*)

Milton J Schlesinger, Department of Molecular Microbiology, Washington University School of Medicine, St Louis, USA

History

Sindbis (SIN) virus was first isolated in 1952 from a group of *Culex univittatus* mosquitoes captured in a light trap in the Sindbis health district 30 km north of Cairo, Egypt. Isolation was by inoculation of triturated mosquitoes into 3-day-old mice. The diameter of the virus was estimated to be 40–48 nm and, based

on its pathogenesis in neonatal but not adult mice, it was initially classified as a coxsackie-type virus. Additional studies showed it to be distinct from these viruses and it was placed into a separate class.

Semliki Forest virus (SFV) was first isolated in Uganda in 1942 from *Aedes (Aedimorphus) abnormalis*. Its diameter was estimated to be 20–67 nm.

Taxonomy and Classification

SIN and SFV are members of the *Alphavirus* genus of the *Togaviridae* family. Based on sequences of the viral genomes, SIN and SFV are grouped separately and both are distinct from another group that includes Eastern equine and Venezualen equine encephalitis viruses. In the SFV group are ten other alphaviruses; in the SIN group are four other alphaviruses plus Western equine encephalitis virus, which is a genetic recombinant with glycoproteins derived from SIN-like sequences and the balance of the genome from Eastern equine encephalitis virus. SIN and SFV are serologically related to Eastern, Western and Venezualan equine encephalitis viruses. They have also been classified as members of the RNA virus superfamily 1.

Geographic and Seasonal Distribution

SIN strains have been isolated worldwide. Two geographical subgroups exist: European–African and Asian–Australian. Sindbis virus has been isolated in the Near East, Africa, Southeast Asia, India, Borneo, Australia, the former USSR and Czechoslovakia. Viruses closely related to SIN have been isolated in Scandinavia, New Zealand, Brazil and Argentina. SFV and closely related viruses have been isolated from Africa, the former USSR, Australia, Japan, Malaysia and South America. As mosquito-borne viruses, they are more prevalent in tropical regions and their presence is amplified during summer months and during periods of precipitation in tropical areas.

Host Range and Propagation

The natural vectors of SIN include *Culex univittatus, C. antennatus, C. annulirostris, C. pseudovishnue, C. tritaeniorhynchus, C. bitaeniorhynchus* and *Mansonia fuscopennata*. SIN has been isolated also from mites and ticks. Migratory birds are an important host and probably account for the global distribution of these viruses. SIN transmission between birds is from bites of *Ae. albopictus, Ae. aegypti* and *C. pipiens*. SFV is propagated by *Ae. abnormalis* and *Aedes* spp. Transovarial transmission occurs in *Aedes* spp. Both viruses exist in an enzootic cycle involving small wild animals, birds, subhuman primates and mosquitoes. They are arthropod-borne viruses.

Virion Structure

SIN and SFV virions are spherical, 70–80 nm in diameter, with icosahedral symmetry and a $T = 4$ lattice. The internal nucleocapsid or core is spherical, 40 nm in diameter, with icosahedral symmetry and a $T = 4$ lattice. The virus particle (molecular mass of 52 MDa) is composed of 30% lipid, 57% protein, 6% carbohydrate and 7% RNA. The sedimentation coefficient is 280 S and the density is 1.22 g ml^{-1} in sucrose-D_2O. The core's sedimentation coefficient is 140 S. Virions of SFV and SIN are stable to storage at 4°C and to repeated freeze–thawing. Infectious particles rapidly lose activity at 56°C (−1 log/10 min, but varies with a particular strain) and are labile to organic solvents, detergents and thiol reducing agents. The RNA in isolated cores is susceptible to RNase.

The external spikes are arranged as 80 trimers, each consisting of stable heterodimers composed of two glycosylated transmembranal proteins. The spikes are embedded in a lipid bilayer which is derived from the plasma membrane of the infected host cell. Curvature of the membrane is such that the outer area is about 40% greater than the inner leaflet. Cryo-electron micrographs of Sindbis virus are presented in **Fig. 1:** a cross-sectional view has been constructed to show the internal core and the lipid bilayer, which appears nonuniform with an average thickness of 4.8 nm. The spike arrangement indicates a cup-like structure for the trimers which form at their base a protein shell around the lipid bilayer with exposed areas of the latter on the virion surface. An atomic structure of the capsid protein has been determined from x-ray diffraction data to a resolution of 0.3 nm and amino acids from 114 to 264 are folded in a manner closely resembling mammalian serine proteases with the catalytic triad of serine, histidine and aspartate surrounding a hydrophobic pocket occupied by tryptophan.

The genome consists of a nonsegmented, single-stranded RNA with a sedimentation coefficient of 49 S. The RNA is capped at its 5′ end with m^7G and is polyadenylated at its 3′ terminus with average length of 70 A's. Genomic RNA is of the positive orientation and isolated RNA is infectious. The complete sequences of about 12 kb from two strains of SIN and one of the SFV genome have been determined and plasmids containing these sequences in the form of cDNA can be transcribed *in vitro* to yield infectious RNA. The cDNA under control of a eukaryotic promoter is also infectious.

The genome encodes four nonstructural and four

(**B**) Cross-sectional view shows spikes (S), lipid envelope (M), nucleocapsid protein (C) and RNA genome (R). Below, surface of the nucleocapsid with 5, 3 and 2-fold axes of symmetry. (Reproduced with permission from V. Prasad. In: Fields BN *et al* (eds) (1996).) *Fields Virology* 3rd edn, p. 76. Philadelphia: Lippincott-Raven.)

structural proteins. Their sizes and functions are listed in **Table 1.** Four regions in the genome contain *cis*-acting sequences critical to expression and replication of the genome. These include 44 nucleotides at the 5′ terminus, 21 nucleotides at the junction between nonstructural and structural genes, 19 nucleotides at the 3′ terminus and a sequence of 132 nucleotides near the 5′ terminus of the SIN RNA (nt 948) which forms a structure that functions as a packaging signal and selectively binds to the virus capsid. Different sequences in the NSP2 gene appear to serve this function for SFV.

Replication and Molecular Biology

Infection initiates with virus binding to host cell receptors. Attachment is sensitive to ionic conditions and host range mutants can differ in net surface charge of the virion. SIN binds to a highly conserved laminin receptor on mammalian and possibly also on insect cell surfaces. Chicken cells have a high-affinity receptor distinct from laminin and accounting for half of potential receptor sites. Mouse neuronal cells may have two other surface receptors. The virus protein most important for binding to cell receptors is E2, although changes in E1 can affect binding. The E2 sequence between amino acids 170 and 220 is particularly critical. A single amino acid change in SIN at position 55 of E2 from glutamine to histidine confers neurotropism and neurovirulence in rodents. In most cells, the major route for uptake is via clathrin-coated pits and acidified endosomes. Delivery of virus cores into the cell cytoplasm occurs after fusion of the virus membrane with the cell's endosomal membrane, which is mediated by the E1 glycoprotein. At a pH <6, this protein dissociates from the heterodimer to form a homotrimer with a conformation distinct from that on the virion surface. A hydrophobic sequence of amino acids at positions 78–96 has been designated as a fusion domain that is exposed at the lower pH and may initiate formation of a coiled-coiled structure required for fusogenesis. Cholesterol and sphingolipid are essential components in the host cell membrane for virus binding and fusion. Bio-

Table 1 Sizes and functions of SIN and SFV proteins

Protein	*SIN*	*SFV*	*Properties and function(s)*
NSP1	540	537	Methyl and guanyl transferase; 5′ capping activity; specifically required for initiation of (−)RNA transcription; modulation of NSP2 proteinase; membrane associated; palmitylated and mutants lacking fatty acyl groups show different cell membrane distribution
NSP2	807	798	Cysteine protease in the C-terminal half of the protein which functions in *cis* and *trans* cleavages of the NSP polyprotein; nucleoside triphosphatase and RNA helicase motifs in the N-terminal half of the protein; RNA binding activity; specifically required for 26S RNA transcription; accumulates in the nucleolus of infected (or transfected) cells; single site mutations decrease the virus-induced shutoff of host cell protein synthesis
NSP3	556	482	Phosphoprotein (threonine/serine are phosphorylated); variable length in the C-terminus
NSP4	610	614	RNA polymerase; unstable and degraded by the ubiquitin pathway; concentration is tightly regulated
Capsid	264	267	Forms nucleocapsid; folds during synthesis to a serine-like protease that autocatalytically cleaves the capsid from the polyprotein; contains hairpin RNA structure near the N-terminus that enhances translation of virus encoded structural proteins in infected cells; positively-charged N-terminus binds genomic RNA
p62	487	488	Precursor to E2; type 1 transmembrane glycoprotein; palmitylated and glycosylated; cleaved in a *trans*-Golgi vesicle by a furin-type protease; rarely incorporated into virus particles
E3	64	66	N-terminal part of p62 containing the signal sequence; glycosylated; retained on SFV but not on SIN virions
E2	423	422	Component of the heterodimeric virus spike; contains sites for binding to cell receptors and epitopes for neutralizing antibodies; type 1 transmembrane protein with 33 amino acids at its C-terminus in the cytoplasm which forms a motif that binds to the capsid during assembly; glycosylated, palmitylated and, possibly, phosphorylated; amino acid changes in the ecto-domain affect virus assembly, stability, virulence and tropism
6K	55	60	Membrane associated; palmitylated; C-terminus is the signal sequence for E1; small amounts in virions; enhancer for virus assembly and budding
E1	439	438	Component of the heterodimeric virus spike; glycosylated and palmitylated; contains sequences which function in low-pH activated membrane fusion; type 1 transmembrane protein with 2 positively-charged amino acids in the cytoplasm

Values are the number of amino acids in the protein. Note that the p62 protein does not normally appear as a structural protein of the infectious virion.

chemical mechanisms for nucleocapsid uncoating to release RNA are unknown. Within 0.5–1 h postinfection, cells are resistant to superinfection by homologous viruses.

Biosynthetic activities that lead to progeny virions consist of the following steps.

1. Genomic RNA is partially translated to form a polyprotein composed of the four nonstructural proteins, nsP1–4 (**Fig. 2A**). For SIN, most of the polyprotein terminates at the end of the NSP3 gene at an opal stop codon; however, suppression of this codon allows for 20% of the polyprotein to include nsP4. For SFV, the entire nsP1–4 polyprotein is formed. Several stop codons located about two-thirds of the length of the genomic RNA insure that termination of translations stops at the end of the NSP4 gene for both SIN and SFV.
2. A complex consisting of the nsP1–3 polyprotein and nsP4, which has been proteolytically cleaved from nsP1–4 by a *cis*-acting protease encoded in the nsP2 C-terminus, interacts with a 19 nucleotide sequence at the 3′ end of genomic RNA to initiate replication that produces a full length (−)RNA template (**Fig. 2B**). Host cell proteins are also involved in this activity. The replication complex is associated with cellular membranes. Transcription from (−) to (+) RNAs requires modification of the nsP123 complex by the nsP2 protease acting in *trans* to give individual subunits with altered structures (**Fig. 2B**). Proteolytic cleavage of the nsP1–3 complex shuts off (−)RNA synthesis. (−)RNA templates are transcribed into full length (+)RNAs and into a subgenomic species with sequences identical to the 3′ one-third of the virus genomic RNA and a sedimentation coefficient of 26 S (**Fig. 2A**). The minimal promoter for 26S RNA transcription consists of 19 nucleotides upstream and five nucleotides downstream from the transcriptional start site on the (−) RNA. Full-length genome

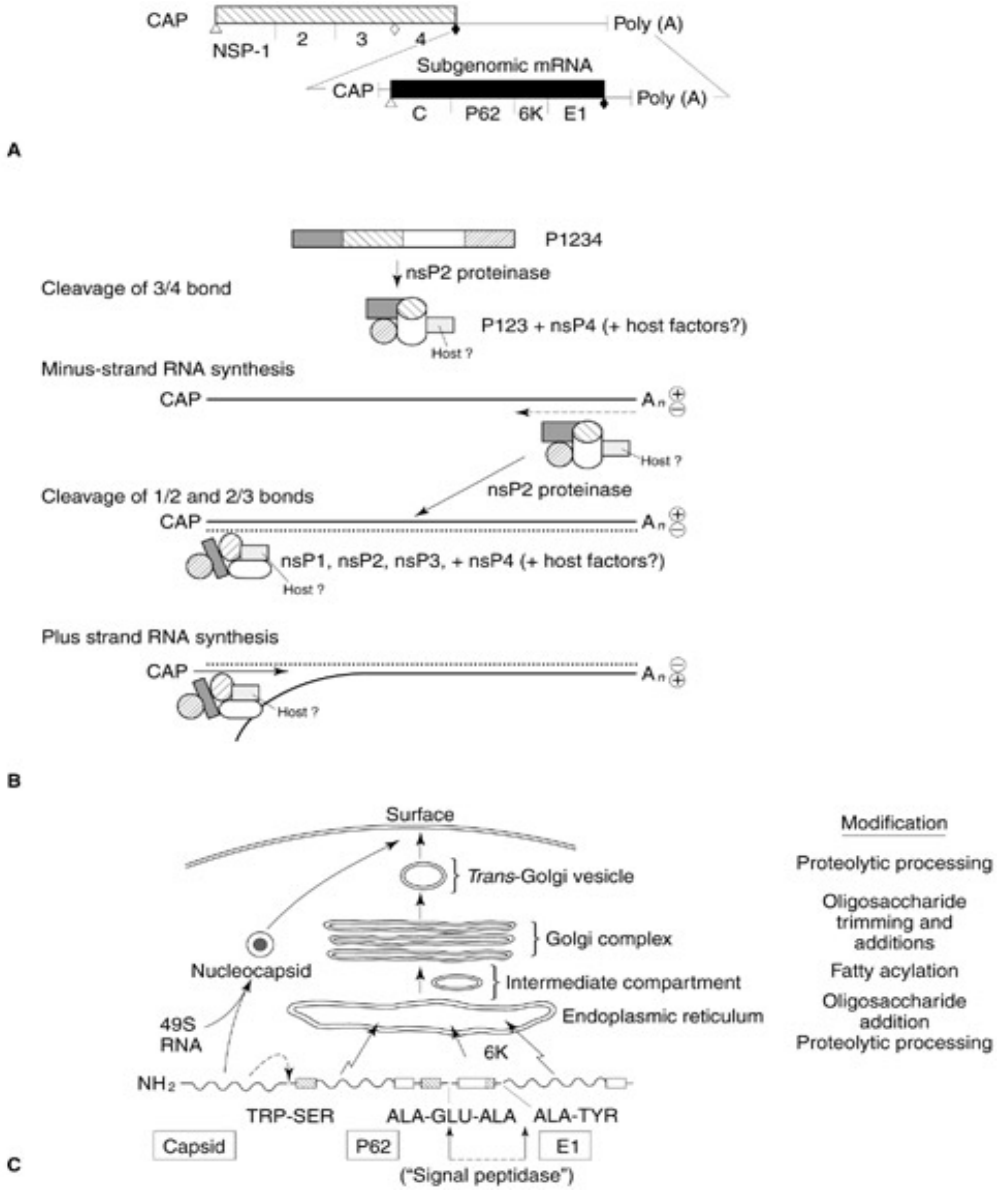

Figure 2 Organization and expression of SIN and SFV genome. (**A**) Order of genes and the sites of initiation (△) and termination (◆) of translation for the genomic and subgenomic mRNAs. In SIN, and opal codon (◇) terminates translation to produce the polyprotein P123. (**B**) Two stages of processing by the nsP2 proteinase of the P1234 polyprotein translated from the genomic mRNA and the function of the different complexes in viral RNA transcription and replication. (**C**) Formation, maturation and transport through intracellular membrane vesicles of the viral structural proteins translated from the subgenomic 26S mRNA. Signal sequences for insertion into the membrane are noted by the cross-hatched boxes. (Reproduced with permission from Schlesinger and Schlesinger (1996).)

(+) RNA is packaged with capsid subunits and subgenomic 26S mRNA becomes the predominant RNA translated in the infected cell.

3. 26S RNA encodes the capsid, p62 (E3 + E2), 6K and E1 virus structural proteins and translation initiates at a single site near its 5′ capped end. The first gene translated codes for the capsid protein which folds to form a serine-like protease that autoproteolytically releases capsid protein from the growing nascent polypeptide. A stem–loop structure in the mRNA near the N-terminus of the capsid functions as a translational enhancer in virus-infected cells, yielding very high levels of the virus structural gene products. A transmembranal signal sequence encoded at the N-terminus of the second gene initiates insertion of its protein

product, p62, into the lumen of the endoplasmic reticulum (**Fig. 2C**). Stop-transfer signals followed by additional signal and stop-transfer signals lead to insertion of the C-termini of p62, 6K and E1 and the N-terminus of the 6K into the ER membrane. Host cell signalases cleave at p62–6K and 6K–E1 sites in the ER lumen to give the separate p62, 6K and E1 polypeptides. These three proteins move as a cohort through the intracellular transport vesicles of the host cell where several post-translational modifications occur. The latter include attachment of glycosyl groups to p62 and E1 immediately upon entry into the lumen of the endoplasmic reticulum; a reorientation of the C-terminus of p62 from a transmembranal to a cytoplasmic location, covalent attachment of palmityl groups to cytoplasmically oriented cysteines of p62, 6K and E1 during transport to the Golgi and proteolytic cleavage of the p62 to the E2 glycoprotein in a *trans*-Golgi vesicle by a furin-like protease.

4. Assembly of progeny virus requires two stages: there is the self-association of capsid subunits in the cell cytoplasm to form substructures that bind to specific regions of genomic RNA (nucleotides 945–1076 of SIN and 2737–2993 plus others for SFV) to form nucleocapsids. Capsids can, however, assemble to nucleocapsid-like particles in the absence of RNA. Preformed nucleocapsids bind to arrays of E1–E2 trimers localized to the plasma membrane to initiate the budding process. A motif composed of hydrophobic amino acids in the 33 amino acid cytoplasmic domain of E2 acts as a ligand to bind to a hydrophobic pocket receptor on the surface of capsid subunits. There are 240 such interactions which lead to envelopment of the nucleocapsid by the host cell plasma membrane. Lateral interactions among the glycoproteins are important in the assembly process. The host cell can also influence this assembly; i.e. hyperglycosylated E2 is inhibitory for growth in vertebrate cells but has little effect in assembly in insect cells, and deletion of the 6K protein is relatively nondefective in insect cells but blocks virus assembly in avian cells grown at 40°C. Fusion of the virus lipid bilayer allows for release of progeny virions from the cells. Assembly and budding require cholesterol in the membrane. The process described can occur within 3 h in permissive cells such as chicken embryo fibroblasts and produces thousands of progeny virus which are secreted into the extracellular fluid. Replication is slower in cultured insect cells, with peak production of virus occurring some 15–20 h postinfection.

Pathology and Histopathology

Neither SIN nor SFV are serious pathogens for adult vertebrates unless virus is injected directly into the brain. In rare infections in humans, SIN and SFV produce arthralgia, rash and fever. Human polyarthritis can result from infection by some SIN strains.

SIN is highly pathogenic to embryonated hens' eggs. Within the host organism, the infected cells include neuron and glial cells, striate and smooth muscle cells, cells of lymphoid origin, synovial cells and brown fat cells. Neonatal rodents develop severe neurocytopathology when virus is given intracerebrally or intraperitoneally. In the CNS, focal cystic degeneration, vascular dilatation and neurolysis occur. Strains of SIN that lead to fatal encephalitis after infection of neonatal mice show lesions associated with a severe stress response – including high levels of interferon α/β and toxic cytokines such as tumor necrosis factor α and little evidence of encephalitis. Less virulent strains produce a more classical encephalitis. Adult mice are susceptible to some SIN strains and neuroinvasiveness is attributed to a change in amino acid 55 of the E2 glycoprotein from glutamine to histidine. Other single-site amino acid changes in E2 alter neurovirulence and cytopathology of SIN. Additional changes in the 5′ noncoding region of the genome and at position 190 of the E2 glycoprotein can confer neuroinvasiveness on other isolates. Attenuation of these strains by mutations produces encephalitis but low levels of mortality and low levels of interferon α/β. Comparison of neurological damage in B6 versus SJL mice infected with SFV show more acute encephalomyelitis in the former, which could be correlated with lower levels of several cytokines and higher virus titers early after infection. Cytopathic effects and neurovirulence are dependent also on strains of SFV. Subacute demyelinating disease, chronic benign infection and teratogenesis in pregnant mice have been detected in SFV-infected mice and high mortality for some strains is attributed to replication in the spleen, lymph nodes and liver. Replication in skeletal muscle leads to atrophy, focal necrosis and viremia.

In vertebrate tissue culture, SIN and SFV have a broad host range and are highly cytopathic, inducing apoptosis in many cells. Host cell macromolecular synthesis (protein, DNA and RNA) is shut off early after infection as a result of expression of virus nonstructural genes and high levels of virus RNA. Mutations in the NSP2 gene of SIN can lead to a persistent infection in BHK cells. Blocks in Na^+/K^+-ATPase activity in membranes from SIN-infected cells alters internal ion concentrations and contributes to

cell cytolysis. Virus structural protein synthesis and intracellular vesicle transport are associated with cytopathology.

In the mosquito, replication occurs in epithelial cells of the midgut, in the salivary glands, thoracic muscle and respiratory tissue. Persistent infection occurs in the insect hemolymph, hindgut and tracheole-associated cells, as well as in cultured insect cells. An antiviral hydrophobic peptide is induced by virus infection of cultured insect cells and limits infection but leads to persistent virus replication. Infection of the mosquito also leads to persistent infection.

Genetics

The frequency of mutation is about 10^{-4}–10^{-5}, which is similar to other RNA viruses. Specific nucleotide mutations, however, have been noted in which the frequency is much lower, in the range of 10^{-7}–10^{-8}. Low rates of divergence have been found and attributed to the natural infection and growth of the virus in both insects and vertebrate cells with varying temperatures and host cell metabolic activities. Temperature-sensitive and host-range mutants have been isolated and placed into seven complementation groups. A large number of site-directed and deletion mutations in virtually every gene of these viruses have been prepared and analyzed utilizing the infectious cDNA clones of SIN and SFV. Close to 50% of the amino acids in the structural proteins of SFV are identical to SIN, and 64% are identical between the nonstructural proteins of the two viruses. A chimeric virus with SFV capsid gene and SIN glycoprotein genes is infectious but the reciprocal construct is not.

Defective interfering (DI) particles are generated within six to nine passages in tissue culture cells at high multiplicities of infection. Genomes of DI particles are about one-third the size of wild-type genome and contain scrambled and repeated portions of the genome. Three regions of the wild-type virus genome are conserved in the DI particle: the 5′ domain, a packaging site near the 5′ end of the RNA and 19 bases at the 3′ terminus of the genome RNA.

SIN and SFV undergo recombination; homologous, nonhomologous and aberrant homologous crossovers occur.

SIN and SFV vectors have been developed to express a foreign gene inserted in the subgenomic region and expressed from the 26S mRNA. They contain conserved *cis*-acting sequences and are self-replicating. Helper viruses containing virus structural genes but lacking nonstructural genes and packaging signals are used to package replicon RNA. These virus-like particles can be used to deliver the foreign genes into a susceptible host cell in place of cDNA or RNA.

Evolution

Evolutionary trees have been constructed based on sequences of eight alphaviruses and they show SIN and SFV occupying different subgroupings. SIN-like viruses that were isolated from different geological areas but are related serologically diverge up to 20% in amino acid identity. Western equine encephalitis virus is a recombinant that contains glycoprotein genes derived from a SIN-like virus and the rest of its genome from an Eastern equine encephalitis virus parent. Domains in the SIN nonstructural proteins, nsP1 (methyltransferase), 2 (helicase) and 4 (core RNA polymerase), are homologous to similar domains in tobacco mosaic virus and several other RNA plant viruses in the bromo and tobamo groups. Furthermore, the plant viruses transcribe one or more subgenomic mRNAs, one of which encodes the capsid, in a manner identical to SIN and SFV. There is the suggestion that alphaviruses evolved from recombination with the tobamo group of plant viruses.

Immunological Response

SIN and SFV are highly antigenic and produce high titers of neutralizing antibodies. Humans with antibodies to SIN and SFV have been found worldwide. Cell-mediated immunity and cytokine response also play important roles in clearing virus infections. Benign persistent infections result from infection of *scid* mice, which lack both humoral and cell-mediated immunity.

Two domains of E2 have epitopes to which monoclonal antibodies will bind and block infection (neutralizing). One epitope of E1 generated a monoclonal antibody that is neutralizing and this overlaps with an E2 epitope. Most monoclonal antibodies to E1 are sensitive to the protein's conformation but this is not so with E2, as monoclonal antibodies can react with fragments and denatured protein. Antibodies to some of the latter peptides injected into mice protected them against virus infection.

SINGLE-STRANDED RNA PHAGES (*LEVIVIRIDAE*)

J van Duin, Gorlaeus Laboratories, Leiden University, Leiden, The Netherlands

Introduction

Since their discovery in 1961 by Loeb and Zinder, the RNA phages have served as a model system to explore a variety of problems in molecular biology. As a source of homogeneous and readily obtainable messenger RNA, they have been particularly helpful in solving questions on regulation of gene expression at the level of translation. The concepts of translational polarity and translational control by repressor proteins resulted from early studies on bacteriophage RNA.

The RNA phages have also provided us with the best defined RNA replication system, which is currently used to study template recognition, *in vitro* RNA recombination and replication.

Available infectious clones have opened the possibility to explore the compromise between the need to fold in a specific way and the need to encode proteins.

Taxonomy and Classification

The RNA coliphages form the family *Leviviridae*. Within this family two genera can be distinguished, *Levivirus* and *Allolevivirus*. The leviviruses, also known as supergroup A, are subdivided into group I and II, whereas the alloleviviruses (supergroup B) consist of the groups III and IV (**Fig. 1**).

The best characterized phage in group I is MS2. Close relatives are R17, f2, M12 and JP501. Somewhat more distant but still in group I is fr, isolated by Hoffmann-Berling from a dung hill. The genomes of MS2, M12, JP501 and fr are completely sequenced and from the others partial sequences are known. In group II, GA and KU1 have been fully sequenced. Other members of this group are JP34, TH1 and BZ13. The prototype of group III is Qβ which, together with M11 and MX1, has been sequenced. Other members include VK and TW18. In group IV SP and NL95 are sequenced representatives. Other strains belonging to group IV are FI, TW19 and TW28. Most of the phages mentioned here are part of the Watanabe Collection at the Keio University, Japan.

Classification into the four groups (**Fig. 1**) was initially based on serological and physicochemical properties, but is presently being replaced by hybridization with group-specific DNA probes. This test recognizes the nucleic acid sequence as the primary criterion for classification. Serotyping is sometimes ambiguous since a few amino acid substitutions in the major coat protein can change the immunological properties dramatically.

Most research has centered around groups I (MS2) and III (Qβ) but it is assumed that features found for group I also hold for group II. Likewise, properties of group III should also exist in group IV.

Virion Structure

In addition to one molecule of positive-strand RNA, each virion contains 180 copies of the coat protein and one copy of the maturation, or A, protein. The group III phages contain in addition about 12 copies of the read-through protein in their capsid. For this reason, the protein shell of the single-stranded (ss) RNA phages is not isomeric like other icosahedral viruses such as poliovirus or satellite tobacco necrosis virus. The diameter of the phage is 26 nm, and the protein shell is about 2 nm wide (**Fig. 2**). The icosahedral shell has a $T = 3$ surface lattice. Crystals of phage MS2, GA, fr and Qβ have been obtained. The coat protein structure of MS2 has been solved to 2.7 Å resolution by x-ray diffraction. Unfortunately, the RNA and the A protein are not seen in the electron

density map. These molecules are apparently not ordered in the crystal.

The Infection Process

The RNA gains access to the interior of the cell via long, filamentous structures called pili. These can be of various origins and serotypes. In *Escherichia coli*, the sex (or F) pili are employed as vehicle but in *Pseudomonas* and *Caulobacter* polar pili are used for this purpose. Transfer of RNA via pili is not essential for infection, however. Cells that lack pili can be infected if they are converted to spheroplasts.

The attachment of the phage to the sides of the pili proceeds via the maturation (A) protein (**Fig. 3**). The coat protein is dispensable for this process; bacteria can be infected with a binary complex of A protein attached to phage RNA. In group III phages the minimal infection set requires the additional presence of the readthrough (A1) protein.

Contact of the phage with the pilus results in cleavage of the A protein into a 15 kDa and a 24 kDa fragment. This cleavage probably triggers the ordered ejection of the tightly packed RNA from the virus shell. The binding sites of the MS2 A protein on the RNA have been determined at nucleotide regions 400 and 3500, respectively. When cleavage of the A protein occurs between the two RNA binding domains of the protein this would potentially lead to the liberation of the two ends. Conceivably, the 5′ end of the RNA begins to move along the pilus towards the cell. This stage of infection corresponds to the RNase-sensitive step. The two A protein fragments remain associated with the RNA during penetration of the cell envelope. However, it is unlikely that these protein fragments play any further role, since the naked RNA is fully able to generate infectious progeny in spheroplasts. For example, transformation of *E. coli* with phage cDNA containing plasmids leads to productive infection.

Host Range and RNA Phages of Other Genera

RNA phages have also been found in other Gram-negative bacteria. In *Pseudomonas aeruginosa* PP7 and 7S have been characterized and ϕCb5, ϕCb12r, ϕCb8r and ϕCb23r were found in different *Caulobacter* strains. Lately, an *Acinetobacter* RNA phage was identified. As judged by several criteria, these phages must be very similar to the coliphages. They have the same morphology, diameter, and molecular weight range. Sequence comparison shows PP7 to be a member of supergroup A.

Pseudomonas and *Caulobacter* phages enter the cell via polar pili. The dependence of RNA phages on pili

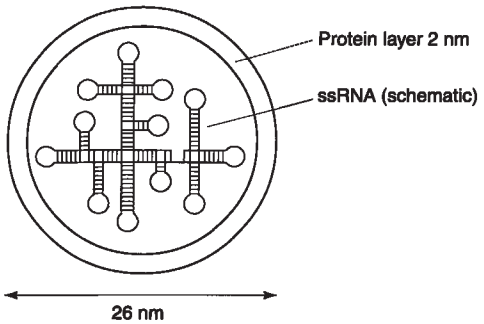

Figure 2 Schematic view of an RNA bacteriophage. The RNA is shown as a highly ordered structure.

as an entry to the bacterial cytoplasm is also reflected in the existence of the ssRNA phage PRR1 that will infect many genera such as *Pseudomonas, E. coli, Salmonella typhimurium,* and *Vibrio cholerae,* provided the host expresses the pili encoded in the drug resistance factor RP (P compatibility group, e.g. RP1, RP4, or R1822). In this connection, it should be mentioned that some members of the *Enterobacteriaceae* have been artificially converted to coliphage sensitivity by introducing the F factor of *E. coli* into *Shigella, Proteus* or *Salmonella.*

Ecology

Furuse has examined and reviewed the geographical distribution of the ssRNA phages as well as their present-day habitat. They are most frequently encountered in sewage and feces of mammals, and their titers in sewage samples may be as high as 10^7 PFU/ml. RNA phages may constitute up to 90% of total coliphages present in these samples, but the number can vary substantially.

The geographical distribution of groups II and III shows a strong bias. In northern Japan, there is a relative abundance of group II over group III (6:1) per sampling site. Moving southward, this ratio drops dramatically until in Southeast Asia group II becomes rare. Furuse has suggested that the north–south gradient is related to differences in climate. Group III (and also groups I and IV) propagates well at 40°C but not at 20°C, whereas for group II the situation is reversed. A problem with this hypothesis is that group II is rare in, for example, The Netherlands where the average temperature is below 20°C.

Although the natural host for ssRNA phages is not known with certainty, it is clear that they survive passing through the gastrointestinal tract of gnotobiotic mice and propagate stably in the intestines if *E. coli* is present as host. Thus *E. coli* can sustain the life cycle of the phage under 'natural' circumstances. In Japan and The Netherlands attempts have been made to determine whether certain phage groups are preferentially associated with certain animal species or with humans. So far, these studies have not been conclusive.

Index Organism

The RNA coliphages and enteroviruses share the same habitat. In addition, because of their structural similarity RNA phages show approximately the same inactivation characteristics as enteroviruses in sewage water treatment processes. For this reason RNA phages can be and are used as index organisms for the possible occurrence of pathogenic enteroviruses.

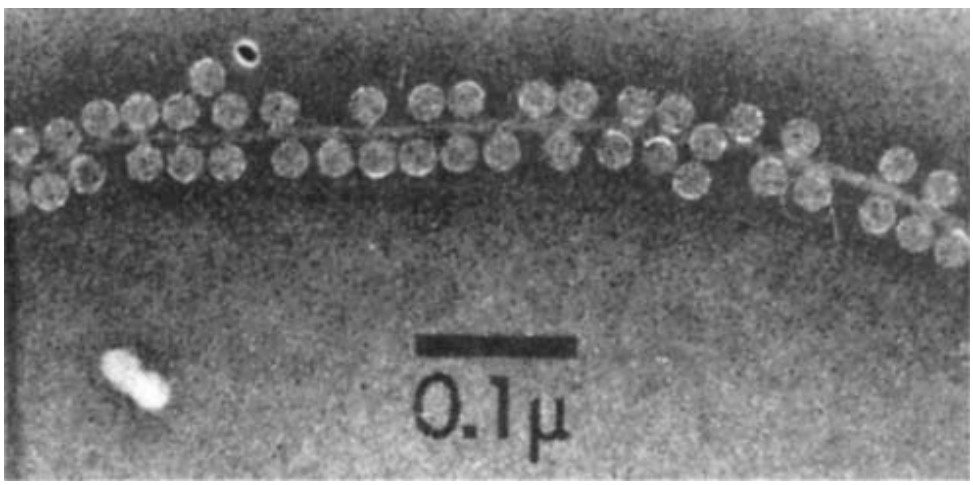

Figure 3 RNA phages attached to the F pilus of *E. coli.* Bar = 0.1 μg. (Reproduced with permission from Zinder ND (1975) Attachment, ejection and penetration stages of the RNA phage infectious process. In: Zinder ND (ed.) *RNA Phages,* p. 89. Cold Spring Harbor: Cold Spring Harbor Laboratory Press.)

RNA phages can be positively identified by specific DNA hybridization probes (see above).

The Genetic Map

A map of the four groups is shown in **Fig. 1**. The conspicuous difference between supergroups A and B is the presence of a readthrough protein in group B. Here, the major coat protein gene ends in a leaky UGA stop codon that is read as tryptophan with a probability of about 5%. This leads to a C-terminally extended coat protein that is incorporated in the capsid and required for infectivity. The other major divergence is the presence of a separate lysis gene in group A. This out-of-frame overlapping gene encodes a hydrophobic peptide about 70 amino acids long, that short-circuits the cytoplasmic membrane of the bacterium. Somehow, loss of membrane potential distorts the balance between components of the bacterial enzyme ensemble that cleaves and extends the peptidoglycan network. This leads to cell lysis.

Genetic differences within the genera are more subtle. In supergroup A the most pronounced one is a 60-nucleotide insertion in the 3′ untranslated leader of group I. A 90-nucleotide insertion in the A2 protein gene of group IV represents the major difference with group III in supergroup B.

The Lysing Protein of Group B Phages

The strong similarity in gene arrangement and control of gene expression between the ssRNA phages is fully lost in the way the phages organize their escape from the wasted host. Bacteria that overproduce the Qβ maturation protein lyse. Qβ mutants carrying an amber mutation in the maturation protein gene do not cause bacteriolysis. Thus it is now thought that the maturation protein of supergroup B has a dual function; it is a constituent of the virion and it triggers cell lysis.

Control of Gene Expression

The appearance of the phage-coded proteins in the infected cell is carefully controlled in timing and amount. For instance, replicase is a minor early product, and the amount of coat protein exceeds by far that of the other proteins. Since no DNA intermediates occur in the life cycle of the phage, control is predominantly exerted at the translational level: it is the RNA secondary structure that regulates access of ribosomes to initiation regions.

The maturation protein is needed at only one copy per virion, and its translation is accordingly kept at a low level. In MS2 the maturation gene can only be translated from a growing strand. Its ribosomal binding site is only accessible during a short period when the growing RNA has not yet reached its equilibrium folding. In the equilibrium structure the RNA is inaccessible. For Qβ the mechanism awaits clarification.

In group A, both replicase (R) and lysis (L) gene are under translational control of the coat gene as witnessed by the observation that early nonsense mutations in the coat gene inhibit expression of the R and L genes. For the replicase the underlying mechanism is base-pairing between the start of the R gene and a coding region of the coat gene. Coat protein-synthesizing ribosomes pass through this region, destroy the pairing and temporarily liberate the R start. Coupling of the lysis gene arises by a local hairpin burying the L start. Exposure is brought about by a ribosome that has arrived at the coat gene terminator codon. After releasing the synthesized coat protein this ribosome can, with a low efficiency, reach the L start site by random movements along the RNA.

The real down regulator of replicase is the coat protein. Once present in sufficient concentration, dimers bind to a hairpin structure that contains the R-start, thereby preventing any ribosome binding. The complex between the hairpin and the coat protein dimer has been modeled by x-ray analysis.

Translational coupling of L and R genes, and the temporary expression of the A gene are not only simple ways to cut down on the product levels, but the designs also serve a more sophisticated purpose. On full-sized RNA the only site independently accessible to ribosomes is the start of the coat gene. As discussed below replicase binding also involves this start site. The resulting competition between ribosome and replicase effectuates that the RNA is either used for replication or for translation.

Apart from the occasional competition by the replicase, the coat protein is not negatively regulated.

Replication

Most of our knowledge on replication has been obtained in the Qβ system, but it is assumed that the principles also apply to the other groups. The replicase holoenzyme contains four different proteins called subunits I to IV, or subunits α, β, γ and δ. Subunit I was identified as ribosomal protein S1, and subunits III and IV are the translation elongation factors EF-Tu and EF-Ts. Thus, three proteins that normally function in the synthesis of proteins are recruited by the phage to assist in RNA synthesis. Subunit II is encoded in the viral genome, and these four subunits all occur in the enzyme complex in not more than one copy. Replication proceeds via the synthesis of a free negative strand. Annealed positive

and negative strands are not a substrate for the replicase enzyme.

The requirements for copying the positive and the negative strand are different. To copy the negative strand, only subunits II, III and IV are required, whereas positive strand replication also needs subunit I. In addition, copying the positive strand is greatly dependent on the product of the bacterial *hfq* gene, called Host Factor. In the uninfected cell one function of this protein seems to be to promote the accessibility of highly structured messengers. In replication its role may be similar, since replication in the absence of Host Factor proceeds only if the base-pairing occluding the 3′ terminus of Qβ RNA is destabilized by substitutions that introduce mismatches. Supergroup A uses a different host factor for copying the positive strand.

Replicase binds to two internal Qβ RNA sequences, called the S and M site. The interaction with the S site provides for the necessary competition with the ribosome, but it is not required for replication itself. Interaction with the M site is essential. It is supposed that in this binary complex the folding of the RNA places the 3′ terminus in the active site of the enzyme. In this concept then, the specificity of the enzyme is derived from RNA structure and not from sequences. From this point of view it is easy to see that Qβ replicase can multiply group IV RNAs as the RNA foldings in groups III and IV are very similar.

Replication of the negative strand depends on structure elements at both the 5′ and 3′ termini and is thus basically different from positive strand copying.

6S RNA and Qβ RNA Variants

Infection of *E. coli* by Qβ leads, apart from phage multiplication, to the accumulation of what has been termed '6S' RNA. This is a nonhomogeneous collection of RNA molecules that vary in size from about 50 to 200 nucleotides and that together with their negative strands serve as templates for Qβ replicase. They do not code for any protein nor do they contribute to the infection process. These molecules arise either by continuous deletion of Qβ RNA sequences or by RNA recombination events using the plethora of RNA fragments present in each cell. Some show homology with Qβ RNA but others do not. All are characterized by a high degree of secondary structure and like all phage RNA have at least three consecutive Cs at their 3′ ends. 6S RNA is also generated on transformation of *E. coli* with the cDNA for Qβ replicase or by the *in vitro* incubation of Qβ replicase with the four nucleotide triphosphates in the absence of added template. The last experiment showed that Qβ replicase is able to perform uninstructed RNA synthesis.

From an evolutionary point of view, it is interesting that these molecules that are not constrained by a coding sequence quickly respond to selective pressure. It is easy to obtain mutants of 6S RNA that are adapted to *in vitro* replication under adverse conditions, such as the presence of ethidium bromide, T1 ribonuclease or limiting amounts of the building blocks. Abbreviated Qβ RNA variants can be prepared *in vitro* by gradually reducing the time allowed for Qβ replication. After some 70 replication rounds the length of Qβ was reduced to about 12%. There seems no basic difference between such truncated Qβ RNA and the RNA present in the defective interfering (DI) virus particles that accompany, for instance, influenza infection. Also here, the abridged molecules once created by replication errors can survive as long as they are templates for the replicase, and their multiplication does not endanger the survival of the virus population as a whole.
