PREFACE

The *Encyclopedia of Virology*, now in its second edition, continues to assemble the basic and practical aspects of virology in a concise form, providing a rapidly accessible synopsis of each subject for the use of both professional and interested lay readers. The number of subjects (including animal, insect, plant, and bacterial viruses) and the number of illustrations have been significantly increased, and the contents have been revised and updated. Although it is not possible to cover all members of taxonomic families or genera, important examples of each are discussed by acknowledged experts in those fields. Articles that address general subjects related to specific viruses or viral diseases help to synthesize the relevant biomedical and economic issues. Thus, the encyclopedia addresses a large number of topics that are of interest to experimentalists, clinical virologists, and students, as well as to scientists and educators in related fields. The format of the book readily lends itself both to casual reading of articles on general subjects and to use as a primary reference source. As the Foreword to this edition, we are pleased to present two articles that describe 100 years of research on Tobacco Mosaic Virus and Foot and Mouth Disease Virus. Studies of these two viruses have contributed many conceptual and practical advances to the field of virology.

Although the report of the Seventh International Committee on Taxonomy of Viruses (ICTV) will not be published until the summer of 1999, we were provided preliminary information about prospective revisions of the scheme of virus classification. The editing and production deadlines prevented the comprehensive incorporation of these changes into the encyclopedia and we include a table listing the changes in taxa which follows the Table of Contents. This information was provided by Claude M. Fauquet who is the author of the *Taxonomy, Classification and Nomenclature of Viruses* entry and is also a member of our Advisory and ICTV Committees.

To accommodate the anticipated broad readership of the encyclopedia, we have provided a comprehensive Table of Contents that allows readers to locate any topic quickly. First, all entries are listed alphabetically by title. In the titles, common virus names are followed by the taxonomic family of the virus or viruses addressed. When viruses have not been assigned to a family, the genus is specified in the text. After the list of titles is an alphabetized list of general topics, followed by a list of all virus entries alphabetized by taxa.

The encyclopedia is presented in three volumes. Volume 1 covers *Adenoviruses* to *Hepatitis E Virus*, Volume 2 covers *Herpes Simplex Viruses* to *Polyomaviruses*, and Volume 3 covers *Pomoviruses* to *Zoonoses*. A complete Table of Contents appears at the beginning of each volume. When multiple viruses or subjects are addressed in a single entry, each is listed in the Table of Contents. Our aim is to allow the reader to locate quickly any topic that does not have its own separate entry by referring to the Table of Contents or the Index. The Guide to Use of the encyclopedia provides detailed information about locating subjects of interest. We have also included, as an Appendix, the complete list of all virus names from the Seventh ICTV meeting report, kindly provided by Claude M. Fauquet.

The individual articles are written by researchers who are widely acknowledged as experts in their fields. Because each entry is complete in itself, some overlap is inevitable. Redundancy has been minimized where possible, but some repetition is needed to ensure that readers can locate information without repeated reference to the index. Because the size of entries had to be limited, the information supplied is not exhaustive. Our aim was to provide the most relevant information in as concise a manner as possible. Readers should consider each entry an introduction to the specific topic addressed; the updated reading list at the end of each provides ample direction for more detailed study. Further, each entry contains a 'See Also' list that directs readers to related sections in the encyclopedia.

New developments will obviously continue to emerge in the rapidly advancing field of virology, but we expect the fundamental information offered by the encyclopedia to remain valid. Contributors were asked to

project their fields into the future and to anticipate progress that can be expected at the beginning of the new millenium. Our colleagues in the subspecialties of virology have consistently found the *Encyclopedia of Virology* a valuable source of quick information and a useful teaching aid. Our goal has been to maintain and to improve that usefulness.

Allan Granoff
Robert G. Webster

ACKNOWLEDGMENTS

Like the first edition, the second edition of the *Encyclopedia of Virology* represents the work of many people. Its success rests most significantly on the expertise of the individual contributors, who are preeminent in their fields. We thank each of them for their willingness to take part in this endeavor and for the quality of their contributions. Our task as editors was eased enormously by the help of our outstanding editorial advisory board, which identified potential contributors and provided advice, especially in the areas of the insect, plant, and bacterial viruses, as the project progressed. We are pleased to acknowledge Ms. Valerie Audino at St. Jude Children's Research Hospital who provided expert editorial assistance in the production stage of publication. Special thanks are also due to Dr. Martha Howe, who was particularly helpful in identifying prospective authors for the bacteriophage sections and to Dr. Milton Zaitlin for his help in identifying appropriate authors for plant virus entries. We greatly appreciate Dr. Claude M. Fauquet's extensive contribution to the updated taxonomic organization of viruses and to his providing the ICTV's virion icons for use in the book. We also wish to acknowledge Lorraine Parry's contributions in bringing the second edition of the *Encyclopedia of Virology* to completion. As associate editor at Academic Press, she had the considerable task of seeing that this work was published on schedule.

FOREWORD: ONE HUNDRED YEARS OF FOOT-AND-MOUTH DISEASE

Foot-and-mouth disease (FMD) is a highly contagious disease of cattle, goats, pigs and sheep which often leads to great losses in productivity. Consequently, as an understanding of infectious diseases began to emerge during the last two decades of the nineteenth century, stemming from the pioneering work of Pasteur and Koch, FMD became the subject of intensive study in Germany because of the many outbreaks that were occurring there. The problem was so great that it led to the offer in 1893 by the Prussian Ministry of Agriculture of a prize of 3000 Reichmarks for the person who "identified and, if possible, isolated the contagious matter causing foot-and-mouth disease and demonstrated its effectiveness by means of decisive experiments on animals". Ten applicants worked unsuccessfully on the problem until 1895. A year later a motion was submitted to the Reichstag "to request the Imperial Chancellor to take account of the need for the immediate establishment of experimental institutions for the thorough investigation of FMD on behalf of the Empire and in the individual Federal States". This led to the allotment of 55,000 Reichmarks and to the establishment of a commission for research into the disease. Loeffler, who was Professor in the Institute of Hygiene at the University of Greifswald, started experiments on the disease in 1897, working with Frösch in Berlin, and in their third Report to the Prussian Minister of Culture in 1898 they described their landmark studies which established the causal agent as a virus. This was an historic event because it was the first demonstration that an animal disease could be caused by a virus and, remarkably, was made in the same year as Beijerink's description of the nature of tobacco mosaic virus. Loeffler continued the work at Greifswald but the highly contagious nature of the disease resulted in pressure from farmers in the area to stop the studies until they could be done in a safe place. This led eventually to the move in 1909 to Insel Riems, a small island in the Baltic Sea just north of Greifswald.

Clearly vaccination against the disease was the major target and methods to provide effective vaccines dominated research for the first 60 years of this century. One of the problems was the expense and difficulties associated with working with the natural hosts and led to the search for a susceptible laboratory animal. This search did not succeed until 1920 when Waldmann and Pape produced the disease in guinea pigs. This animal has been particularly useful in assessing the potency of experimental vaccines because the immunized animal can be challenged for its ability to resist infection. It was not until Skinner's work in 1951 that the suckling baby mouse was added to the repertoire of experimental animals that could be used for FMD research. The baby mouse was used extensively for the titration of the virus in the days before tissue culture cells became generally available. Moreover, it was the species used extensively by Skinner in attempts to produce strains of the virus which would be useful as attenuated vaccines.

A major step in the study of the disease and its control by vaccination took place in the early 1920s when Vallée and Carré in France and Waldmann in Germany showed that the virus occurs as multiple serotypes. The two groups discovered three serotypes now known as O, A and C. The nomenclature caused some confusion until it was resolved by discussion at the Office International des Epizooties in Paris. Vallée and Carré had first recognized the occurrence of two serotypes and named them after their place of origin, O for the Department of Oise in France and A for Allemagne. Their observation was confirmed by Waldmann and Trautwein in Germany who called them A and B. The latter group then discovered a third serotype which they called C. It was eventually decided to name them Vallée O, Vallée A and Waldmann C, which have now been reduced to O, A and C. The antigenic differences were such that an animal that had been infected with a virus of one serotype was still susceptible to the other serotypes. Clearly this was to have considerable importance in the control of the disease by vaccination and the problem was exacerbated by the demonstration of sub-types

within the major serotypes in the late 1920s, a problem which can cause havoc in the control of the disease because antigenic variants continue to emerge.

To add to the problem, four further serotypes were identified later by the Pirbright triumvirate of Galloway, Brooksby and Henderson, three in the Southern African Territories (SAT1, SAT2 and SAT3) in the 1940s and Asia 1 in 1954. Interestingly, no other major serotypes have been identified in the past 45 years. Nevertheless the wide antigenic spectrum within each serotype and the new variants which are constantly emerging means that vaccines have to correspond closely to these emerging variants if they are to be effective in controlling outbreaks. Many devastating outbreaks in vaccinated animals provide evidence of the importance of this issue.

Consequently the composition of vaccines remains important in FMD. The first experimental vaccines were prepared in 1925, using formaldehyde-inactivated vesicular fluid from infected calves. However, large-scale field trials did not take place until 1948 when Rosenbusch and his colleagues successfully vaccinated more than two million cattle in Argentina. It was clear, however, that the necessary large-scale production of the virus would require its *in vitro* cultivation. Work in the early 1930s by Hecke in Germany and the Maitlands in England had shown that this could be achieved. It was Frenkel who showed in 1947 that *in vitro* cultivation of the virus on a large scale could be achieved by using surviving bovine tongue epithelial fragments. This was a major step in the provision of vaccines for the control of the disease and it was Holland, where Frenkel worked, which introduced the first comprehensive vaccination programme. Germany and France soon followed and these vaccination programmes have led to the eradication of the disease from Western Europe.

There have been minor hiccups on the way. One of the problems was the uncertainty surrounding the use of formaldehyde as the inactivant. This reagent had been used by Glenny and Ramon to detoxify diphtheria and tetanus toxins and it was probably the influence of Ramon on the French workers Vallée, Carré and Rinjard which persuaded them to use formaldehyde in their experimental vaccine studies in 1925. However, the suspicion that formaldehyde-inactivated vaccines were not innocuous, first expressed by Moosbrugger, led to studies with alternative reagents. From these studies, first N-acetylethyleneimine and then ethyleneimine were introduced and the latter compound is now used exclusively for the preparation of FMD vaccines.

The comprehensive vaccination programmes introduced have gradually led to the control of the disease and its elimination from many countries. Western Europe and several countries in South America which formerly had tens of thousands of outbreaks each year are now free from the disease.

The development of molecular techniques during the past 50 years has enabled us to study the virus and its nucleic acid and proteins in great detail. The structure of the virus at a resolution of 2.8 Å has been described and its mode of replication is known in the most intimate detail. From these fundamental studies have emerged two important practical issues. The first is the demonstration that protective immunity can be achieved by the inoculation of a 20-mer peptide corresponding to the highly immunogenic epitope located on the surface of the virus particle. Moreover, the important antigenic variation of the virus is almost certainly related to the amino acid sequence in the surface epitope. The second practical issue is the ability to identify animals that have been infected with the virus. Many of these animals become persistently infected for as long as three years and are consequently potential sources of further outbreaks of the disease. These animals can be identified by the presence in their sera of antibodies against non-structural proteins which are not present in naive or vaccinated animals. This information has emerged from the finding that certain of the non-structural proteins are not secreted from the cells in which the virus is grown and are consequently not included in the medium from which the vaccine is prepared.

Consequently, eradication of the disease could be accomplished worldwide because the scientific knowledge and means are available. It would be an appropriate ending to a century of FMD research if this goal were placed high on the agenda of the Food and Agricultural Organisation.

FOREWORD: TMV – 100 YEARS OF CONTRIBUTIONS TO VIROLOGY

Tobacco mosaic virus (TMV) has played a prominent role in the development of the concept of viruses as pathological agents and in unraveling the composition and structure of these unique agents. It also is the virus with which many concepts and phenomena unique to plant virology have been discovered. The mosaic disease which afflicted tobacco was known in Europe since tobacco was introduced there in the 17th century. It causes light and dark green areas on infected plants, accompanied by considerable stunting and loss of yield. The first person to transmit it experimentally was Adolph Mayer who in 1886 reported that when he took juice from diseased plants, it was infectious to healthy plants; he also gave the disease its name. The capacity to transmit the disease experimentally facilitated the studies which ultimately resulted in depicting the new class of infectious agents, the viruses.

Attribution for the discovery of the virus concept is in dispute, ascribed by some to Dmitrii Ivanowski in 1892, but by others, to Martinus Beijerinck in 1898. The basis for the dispute lies in the interpretation of the results both workers obtained when tobacco sap was passed through a porcelain, bacteria-retaining filter; the agent had retained its infectivity. Ivanowski found it difficult to accept that the agent was something new, even after he was aware of Beijerinck's conclusions. Ivanowski was concerned that the filter might have had a crack, or that some small spore of the bacterial causal organism had passed through. Beijerinck, on the other hand (1898) concluded that he had a unique pathogen, which he termed a *'contagium vivum fluidum'* – a contagious living fluid. Animal virologists will also argue that early work on foot-and-mouth disease also should be considered for attribution for the virus concept (see foreword by Fred Brown in this volume).

In the years before the agent was purified and characterized, several findings were made using TMV that had important ramifications for plant virology. In 1929, McKinney discovered the phenomenon of 'cross protection', i.e., that infection of a plant with a mild strain of a virus would protect the plant from disease when inoculated subsequently with a severe form of that virus, but would not protect it against unrelated viruses. This phenomenon was used for many years to determine virus relationships, and in a few cases it was used to protect crops against disease. Additionally, in 1929 Holmes developed a quantitative bioassay for the virus using host plants that developed necrotic local lesions in response to infection, thereby potentiating experiments where virus quantification was important.

Prior to the ultimate isolation of the infectious agent in the 1930s, a number of studies gave clues to its nature and pointed the direction for its isolation. By injecting sap from infected plants into rabbits, Purdy (1929) demonstrated that the agent was immunogenic; others found that the infectious agent could be precipitated from tobacco sap with protein precipitants, both findings hinting at a proteinaceous agent. Further, birefringence experiments suggested it was elongate. Purification was being actively pursued in the United States by several groups, and by scientists in Australia and England. Wendell Stanley, then at the Rockefeller Institute in Princeton, New Jersey, was the first to publish that he had purified the virus (1935), and he received the principal recognition, most notably the Nobel Prize in 1946. However, he incorrectly thought the virus to be composed of only protein, missing the fact that it contained both phosphorus and carbohydrate. Bawden and Pirie, who were one step behind Stanley in the purification, set the record straight in 1936, by showing that the virus contained RNA.

TMV was the first virus seen in the electron microscope (1939) and in 1941 it was the first to have its structure revealed by X-ray crystallographic analysis. Further investigations in the 1950s revealed the position of the RNA in the particle, and defined its structure.

The 1950s saw an intense rivalry between workers in Tübingen, Germany (Schramm, Melchers, Gierer, Wittmann and others) and the group in Berkeley directed by Fraenkel-Conrat at the Virus Laboratory established by Wendell Stanley. Many of the findings outlined here were made almost simultaneously in both laboratories, although partisans might not agree with such attribution. The work was greatly facilitated because TMV, unlike any other virus known at the time, was easy to purify, and because of the large quantities which could be obtained. (In my own laboratory we isolated 60 grams of highly purified virus for one of our studies.) Also, TMV – at least the common 'strain' – is very stable, and will maintain its infectivity for decades at refrigerated temperatures if a little chloroform is added to inhibit growth of microorganisms.

In the 1950s both groups discovered that the RNA of the virus was infectious, that the virus could be reconstituted from isolated coat protein and RNA, determined the sequence of amino acids in the coat protein, and found that chemical agents could mutate the virus. The latter studies were particularly meaningful in the confirmation of the universality of the genetic code, in that directed mutational changes induced in the RNA led to predictable changes in the viral coat protein. Additionally, mixed reconstitution experiments, utilizing proteins from one strain and RNA from another, demonstrated conclusively that the RNA was indeed the genetic material of the virus, as some had questioned that the infectivity of 'naked' RNA was really a reflection of a small amount of a protein contaminant. These studies demonstrated conclusively that the coat protein was coded for by the RNA component of the mixed reconstituted virus.

In 1969 Takebe and Otsuki published a paper which revolutionized plant virology when they demonstrated that cell wall-free protoplasts isolated from tobacco leaves could be infected by TMV and that TMV would replicate in those cells. Thus, plant virologists now had a system to enable single cycle analysis of virus replication, previously not possible in inoculated leaf tissues involving only a few initial infections, followed by subsequent sequential replication in surrounding layers of cells.

In 1970 my colleague V. Hari and I ascertained that TMV-infected tissues contained at least four viral proteins. Subsequent events showed these to be the 126-kDa and 183-kDa proteins of the replicase complex, the 30-kDa movement protein, and the 17.6-kDa coat protein. There is also an open reading frame for a 54-kDa protein within the read-through portion of the 126-kDa replicase protein, coincident with sequences in the 183-kDa protein. This protein has not been detected in diseased tissues, however.

Plant viruses are now known to potentiate their passage from cell-to-cell in their hosts. The 30-kDa protein of TMV was shown to be involved in this process, deduced from studies with a temperature sensitive mutant of the related tomato mosaic virus, which was defective in cell-to-cell movement. In 1987 the movement protein was shown to modify the size exclusion limit of plant plasmodesmata to allow for cell-to-cell movement, by some elegant microinjection studies from the laboratories of William Lucas and Roger Beachy. Movement proteins have now been found in most plant viruses in which they have been sought, and have been shown to have RNA binding properties.

The concept that translation of some proteins in many RNA viruses is controlled by the production of subgenomic mRNAs was first demonstrated with TMV. Virus-infected tissues were shown to contain small, virus related RNAs, and *in vitro* translation demonstrated their mRNA capacities.

Other phenomena of particular significance to plant virology were the detailed analysis of how the virus assembles *in vivo*, and the phenomenon of co-translational disassembly in which it was demonstrated that cytoplasmic ribosomes remove the coat protein from the virion, thus exposing the RNA, which is also being translated during the process to synthesize the replicase subunits. TMV was the first plant virus to be completely sequenced (1982), and was the first virus to be shown to have at least one ubiquitinated subunit in the virion. In 1996, Barbara Baker reported the first isolation of a plant gene conferring resistance to a virus. This was the *N gene*, utilized in the aforementioned bioassay developed by Holmes in 1929.

The important discoveries in which transformation of plants with viral sequences to induce resistance or tolerance to disease were all pioneered with TMV. The widely-adopted coat protein-mediated protection concept was developed in 1983–84 in the laboratory of Roger Beachy, then at Washington University, in collaboration with scientists at the Monsanto Company who had developed technology for plant transformation. They found that the gene for the TMV coat protein, when transformed into tobacco plants gave significant delay of symptom development, and in some cases led to complete resistance. This concept has now been widely applied to at least 30 different viruses, representing at least 15 genera. Squash plants have been marketed which are resistant to several viruses, and currently there are plantings of papaya trees in Hawaii resistant to the devastating papaya ringspot virus.

The use of replicase genes for resistance was also first shown with TMV in my laboratory in work started in 1988. We found that a portion of the 183-kDa replicase gene gave near immunity to TMV disease. This

phenomenon, known as 'replicase-mediated resistance' has also found application with a number of other viruses in other genera. Potato plants with the replicase gene of potato leaf roll virus are in commercial production.

TMV movement protein was also the first to be used in plant transformation experiments, seeking resistance. The laboratories of Beachy, Allan Dodds, and Josef Atabekov were pioneers in this technology. Interestingly, transformation with a defective movement protein from TMV was able to provide some measure of resistance to TMV, other tobamoviruses, and to several unrelated viruses.

A recently-published anthology on TMV contains reprints of the original papers with commentaries on the discoveries described above (Scholthof, K-B.G., Shaw, J.G., and M. Zaitlin (1999) *Tobacco Mosaic Virus: One Hundred Years of Contributions to Virology*. American Phytopathological Society Press, St. Paul, Minnesota, USA).

Notes on the Subject Index

Entries

1. Bacteriophages are listed after the main index entry 'Bacteriophage', unless there are cross-references to other locations. ϕ is alphabetized as 'phi'. ψ is alphabetized as 'psi'.
2. Readers are advised to seek not only the genus, but also the group name e.g. *Baculovirus* and *Baculoviruses*.
3. US spelling is used.

Abbreviations

Abbreviations used in index subentries are as follows:

CMV	Cytomegalovirus
EBV	Epstein-Barr virus
FIV	Feline immunodeficiency virus
HBV	Hepatitis B virus
HCV	Hepatitis C virus
HIV	Human immunodeficiency virus
HPV	Human papillomavirus
HSV	Herpes simplex virus
IRES	Internal ribosome entry site
LCMV	Lymphocytic choriomeningitis virus
LDV	Lactate dehydrogenase-elevating virus
ORF	Open reading frame
RSV	Respiratory syncytial virus
SIV	Simian immunodeficiency virus
VSV	Vesicular stomatitis virus
VZV	Varicella zoster virus

sion over more than 40 weeks. It was demonstrated that, following liver gene transfer, transcriptional initiation was only from the liver-specific promoter, and that splicing of the primary transcript and processing of RNA and protein were normal. Gene transfer with increasing doses of this vector resulted in very high and stable α_1-antitrypsin serum levels that so far are unparalleled by gene transfer with any other tested combination of strong viral promoters and the α_1-antitrypsin cDNA. Significantly, the high serum α_1-antitrypsin levels that would be considered supraphysiological in humans were not accompanied by any significant hepatotoxicity. Gene transfer with the same dose of a first-generation vector carrying an α_1-antitrypsin expression cassette led to hepatic damage that was morphologically characterized by liver cell necroses and infiltration by granulocytes and was accompanied by significantly elevated liver enzymes in the serum. Improved expression and decreased toxicity with high-capacity adenoviral vectors were confirmed with another vector that carried the murine leptin cDNA under the control of a viral promoter. Taken together, these results indicate that high-capacity adenoviral vectors will be useful for functional studies on gene transfer and likely also for somatic gene therapy because of their improved safety and expression profiles. Their increased capacity for foreign DNA is a significant advantage over first and second generation adenoviral vectors.

Mária Benkö, Veterinary Medical Research Institute, Hungarian Academy of Sciences, Budapest, Hungary

History

Members of the adenovirus family (*Adenoviridae*) can be recognized in virtually every class of vertebrate animals (**Table 1**). However, not all of the family members contain the same common antigen and initially two genera have been established each of them being characterized by a common (or group) antigen. The genus *Mastadenovirus* comprises viruses isolated from mammals (humans, monkey, cattle, pig, sheep, horse, dog, goat, tree shrew, deer, whale, mouse, etc.) whereas the *Aviadenovirus* genus contains viruses isolated from avian species (chicken, turkey, goose, pheasant, duck, etc.). The organization of the genome, though normally rather conserved within a genus, differs considerably between the two genera. Recently, strong evidence (based on genomic organization and phylogenetic analysis; **Fig. 1**) supported the establishment of a third genus incorporating several bovine adenoviruses (BAVs), the ovine adenovirus isolate 287 (OAV287) and the egg drop syndrome (EDS) virus which (lacking the genus-specific common antigens) had been recorded as 'atypical' members of the *Mastadenovirus* or *Aviadenovirus* genera. The proposed name of this possible third genus is *Atadenovirus* (referring to the characteristic AT-rich genome rather than the host animal taxon). The candidate BAV serotypes (4 to 8) of this proposed genus do not fit clearly into the *Mastadenovirus* genus and are presently separated as subgroup 2 from the subgroup 1 BAVs which obviously belong to the mastadenoviruses. A number of adenoviruses isolated from (or only detected in) lower vertebrate hosts (fish, frog, snake, chameleon, crocodile, etc.)

have as yet no genus attribution – mainly because of the lack of comparative data.

Properties of the Virion

The virion has an icosahedral capsid of diameter 75–90 nm and a core containing the viral DNA and basic proteins. The capsid has 252 capsomers; 240 of them are at the faces and on the edges of the icosahedral capsid, surrounded by six others and hence called hexons. The remaining 12 capsomers are located at the apices and, being on the axes of fivefold symmetry, are surrounded by five hexons and termed pentons. The proximal hexons are further defined as peripentonal hexons. These peripentonal hexons and pentons can be detached from the remainder of the capsid by a variety of treatments and it appears that the remaining 180 hexons are cemented together in 20 groups of nine via another structural component, polypeptide IX in mastadenoviruses. However, in the aviadenoviruses and in the members of the proposed third genus, protein IX is missing. The pentons are characteristic of the *Adenoviridae* and have a dumbbell shape with a (penton) base and a protruding knobbed fiber. The fiber is of variable length, the largest so far described being visualized on an equine adenovirus of length 50 nm. Several bovine adenoviruses also have considerably longer fibers than human adenoviruses and sometimes these are bent. Most of the aviadenoviruses have two fibers normally of very different sizes (varying from 8.5 to 47 nm) attached to the same penton base. High-resolution x-ray crystallography of the hexon and image reconstruction from cryoelectron micrographs of human adenoviruses have provided a detailed understanding of virion structure and all studies of animal adenovirus so far completed have indicated that they will in general conform to these same structural parameters. Thus it has been demonstrated that avian adenoviruses possess a terminal protein covalently linked to the 5′ termini of the virus DNA and that animal virus hexons possess a similar spectrum of type, subgroup and group specificity already noted in the human viruses. In the studied members of the *Aviadenovirus* and the proposed third genus, however, besides the above-mentioned protein IX, a structural component protein V is also missing. Moreover, in the OAV287 and in the EDS virus (candidate members of the third

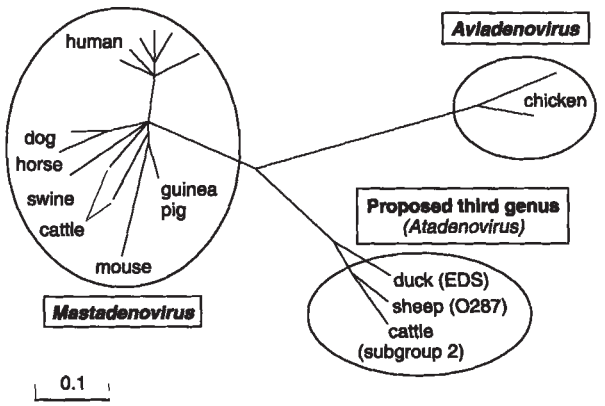

Figure 1 Genetic distance between adenoviruses isolated from different animal species resulting from the phylogenetic analysis of 23 known hexon gene amino acid sequences. The unrooted phylogenetic tree was generated by distance matrix analysis: PROTDIST and FITCH of the PHYLIP v3.5c program package of J. Felsenstein (*http://evolution.genetics.washington.edu/phylip.html*). The length of the branches indicates the phylogenetic distance between the different viruses, the scale bar represents 10% mutations. The virus types composing the two existing and third (proposed) genera are circled. The original sequence alignment and the alignment edited for the calculations are available at *http://www.vmri.hu/~harrach*. From the hexon gene of the guinea-pig adenovirus only a short sequence was available and therefore only preliminary conclusions could be drawn for this virus type. The tree was visualized using the TreeView program of R. Page (*http://taxonomy.zoology.gla.ac.uk/rod/treeview.html*) and the Windows Metafile was edited in Microsoft Word 7.0 for demonstrating the discussed new (three cluster) grouping of the adenoviruses of different hosts. Similar clustering was obtained by the analysis of protease gene (either amino acid or nucleic acid) sequences.

genus), the occurrence of new, homologous open reading frames (ORFs) encoding putative structural proteins termed 28K or 24K, respectively, were observed. In OAV287, the presence of the 28K protein in the virion was confirmed by sodium dodecyl sulfate–polyacrylamide gel electrophoresis (SDS-PAGE).

Properties of the Genome

Adenoviruses have a linear double-stranded DNA genome with inverted terminal repeats (ITRs) of varying length and all animal adenoviruses studied have conserved this feature. Aviadenoviruses appear to have about 17% of their total weight as DNA and a molecular weight of $28–30 \times 10^6$ which is slightly greater than that of human adenoviruses. Compared to the long genome of aviadenoviruses exceeding 44 kb, mastadenoviruses have a genome length of 31–36 kb, and the DNA of the members of the proposed third genus is shorter in the range 28–33 kb. There is very limited base homology between the genomes of viruses of the different genera. Within a genus however, as a rule, more significant base homologies have been detected among the DNAs of different serotypes of the same host species. Cattle, sheep and chicken seem to be exceptions in this respect, since these animal species can apparently be infected with unrelated adenoviruses from different genera (no DNA homology could be detected by DNA hybridization between bovine adenoviruses belonging to the *Mastadenovirus* genus or to the proposed new genus).

Besides the four entirely sequenced human adenoviruses (types 2, 5, 12 and 40), there are five animal adenoviruses with completely sequenced genomes: canine adenovirus types 1 and 2 (mastadenoviruses), fowl adenovirus 1 (aviadenovirus), and OAV287 and EDS virus (proposed third genus). Many further partial sequences are available (or to be published soon) from different hosts, such as ovine adenovirus type 3, porcine adenovirus types 1 to 5, BAV-1, 2, 3 and 10, mouse adenovirus type 1, equine adenovirus types 1 and 2, tree shrew (tupaia) adenovirus, fowl adenovirus types 8 and 10, turkey hemorrhagic enteritis virus, and BAV-4, 6, 7 (candidate members of the proposed new genus) etc. (see **Table 1**).

The data in hand in relation to regulatory events and the sequence data available for the animal adenoviruses suggest that genome organization of the mastadenoviruses should be generally similar to that already discerned for the human adenoviruses. The only real differences between the members of the *Mastadenovirus* genus can be seen in the content of the E3 region, which has a different number and entity of genes even in the different types of human adenoviruses. To date, the shortest E3 region was found in the murine adenovirus (MAV) type 1 and BAV-10 (only one but a different gene in each), whereas the longest was described in the subgenus B human adenoviruses (eight E3 genes in type 35, and possibly nine in type 3). The aviadenoviruses and the members of the proposed new genus, however, have strikingly different genomic organization especially at the two ends of their genomes mainly concerning the early regions. Although the genes of the structural proteins (apart from the missing proteins V and IX) and their location and organization in the middle part of the genome is very similar to that of the mastadenoviruses, apparently there is no recognizable E1A region in the aviadenoviruses and in the candidate members of the proposed genus. Similarly, the region contained between the pVIII and fiber genes (at the conventional location of the E3 region) has no similarity to the E3 of mastadenoviruses. Furthermore, in the aviadenoviruses, no E1B region has been identified. The corresponding region in the members

of the candidate new genus is also very divergent from the mastadenoviruses and needs further characterization. There are several additional ORFs found on the right hand end of the genome, which are homologous only among the members of the aviadenoviruses or proposed new genus, respectively.

Apparently, most human and chimpanzee adenoviruses encode two RNA polymerase III-transcribed low-molecular-weight 'virus-associated' (VA) RNAs which are important in efficient translation of late virus mRNAs. In the twelve monkey adenoviruses which have been examined, however, there is only one VA RNA. The avian adenoviruses also code for a single VA RNA but this is much shorter (90 compared to 160 nucleotides (nt)) and does not exhibit sequence homology with the human VA RNA species; nevertheless, its predicted secondary structure is similar. The location of the VA RNA in aviadenoviruses (CELO) at the far right hand part of the genome is also different from that in mastadenoviruses. In the EDS virus a VA RNA similar to that of CELO virus and located at the far right end of the genome has been described.

Properties of Virus Proteins

Most of the proteins encoded by human adenovirus prototype strains have been well-characterized and, as mentioned, the animal adenoviruses of the *Mastadenovirus* genus seem to be similar. The aviadenoviruses and the proposed new genus show differences in the number of the structural proteins: the lack of protein V and IX, and the existence of several new, yet uncharacterized proteins (28K in OAV287, or 24K in EDS virus). Most avian adenoviruses also have an additional fiber protein (see earlier) coded by a second gene, but a similar phenomenon also occurs in human adenovirus types 40 and 41. The most distinctive feature of the CELO virus polypeptide composition appears to be the increase in the amount of core polypeptides present and it has been suggested that these may be needed to neutralize the negative charge of the DNA which is 30% larger than human adenovirus DNA.

Physical Properties

Virions have a molecular weight of $\sim 170 \times 10^6$–185×10^6, sedimentation value ~560S and a density in CsCl of 1.32–1.35 g/cm^{-3}. As noted earlier, aviadenoviruses appear to have larger genomes and this is reflected in the physical properties of the virions. Virus infectivity is resistant to lipid solvents and is relatively acid stable.

Replication

In the animal adenoviruses (so far examined) and which belong to the *Mastadenovirus* genus the genome organization appears to be broadly similar to that of the human adenoviruses. The early regions E1A and E1B are similarly located at the left hand end of the genome and E3 at around 80 map units. All three of these transcription units are transcribed in the rightward direction and a region corresponding to E4 transcribed (as in the human viruses) in the leftward direction has also been detected. In the avian adenoviruses and the members of the new proposed genus, however, an E1A region could not be identified. Moreover, in OAV287, BAV-6 and EDS a supposedly nonessential region tentatively called 'E3' (because it was proven to be deletable in OAV287) is located after the E4 region and is transcribed in the leftward direction. The role of this region in the replication is not known and neither is the role of the unidentified open reading frames of the aviadenoviruses at the right-hand end of their genome. Analogous findings to human adenoviruses with respect to the mechanisms of virus DNA replication have been established with a number of animal virus systems (e.g. avian and murine adenoviruses). Thus all the sequences of the ITRs from animal adenoviruses contain sequences at nucleotides 8–15, consistent with the termini being the origins of DNA replication. Other aspects of the molecular biology of the animal mastadenoviruses have so far indicated that they appear to conform with that already established in much more detail for the human adenoviruses, while the lack of the E1A region in the avian and candidate third genus adenoviruses raises interesting questions about the early events in their replication.

Host Range and Virus Propagation

Animal adenoviruses generally can be readily propagated in a range of epithelial cells derived from tissues of their own species, although some adenoviruses can also replicate in other tissue cell lines. There is a wide variation in their ability to replicate in cells from other species, e.g. ovine adenoviruses can be propagated in bovine and porcine cells as well as ovine, but murine adenoviruses are more restricted to mouse cells, preferably mouse embryo cells. Aviadenoviruses can only replicate in avian cells, doing best in cells from the homologous species. Although the animal adenoviruses appear to be specific to their original host, there are some reports on isolation of bovine adenoviruses from sheep, buffalo, and deer. On the other hand, restriction enzyme fragmentation, DNA hybridization and limited sequencing suggested that

BAV-9 clearly belongs to subgenus C of human adenoviruses. These observations leave open the possibility that the isolation of BAV-9 could be an artifact (laboratory contamination). On the other hand group C human adenoviruses can perhaps establish infection in cattle. Nevertheless, HAV-5 is also capable of replication in bovine cell cultures or even in cell lines with similar efficiency as in human cells. Similarly to human adenovirus types 40 and 41, the hemorrhagic enteritis virus of turkey can be propagated in live animals or in transformed cell lines only. BAV serotypes 4 to 8 and 10 are also restricted to primary or low-passage number bovine testicular or endothelial cells.

Genetics and Evolution

Complete sequence data are available from five animal adenovirus genomes, and numerous partial sequences have been determined recently (**Table 1**). Sequence data along with restriction enzyme patterns have been used in some cases (e.g. bovine and avian adenoviruses) for the confirmation of groupings based on serological results. More importantly, however, these sequence data also make possible the examination of the phylogenetic relationships among adenoviruses. Initially, the ITRs present at the termini of the virus DNA were used for comparisons, whereas nowadays the DNA and predicted amino acid sequences of selected viral proteins available from many different adenovirus types provide useful data for comparative taxonomy. For example, on the basis of serological crossreactivity and similarities in restriction enzyme cleavage patterns, several simian adenoviruses could previously be allocated into four (A, B, C, E) out of the six known human subgenera. Comparison and phylogenetic analysis of the VA RNAs of human and simian adenoviruses further defined their close relationship and possible common origin. Phylogenetic analyses based on reasonably large data sets comprising those possibly most restricted to their host species (sequences of the hexon or the protease genes are most appropriate) consistently resulted in the obvious separation of three clusters corresponding to the two accepted, and the third proposed genera (**Fig. 1**). The subgenus classification of HAVs, and the general similarity of adenoviruses isolated from the same host was also confirmed.

Several interesting aberrations could be observed among adenoviruses isolated from cattle or sheep. BAVs apparently belong to two different genera and the isolate OAV287 is definitely more closely related to subgroup 2 BAVs (the proposed new genus) than to OAV-3. On the other hand, OAV-3 and BAV-2 are clustered together, whereas other subgroup 1 BAVs (BAV-1 and -3) are further from BAV-2. Although as its name indicates, BAV-2 was first isolated from cattle, it has in fact also been isolated from sheep with an equal or higher frequency, and might therefore genuinely be an ovine adenovirus. Another questionable virus concerning its host and evolutionary origin is BAV-10 which was originally described as a member of subgroup 2 BAVs. Its genome analysis and the phylogenetic calculation clarified however that BAV-10 is a typical mastadenovirus, although distantly related to subgroup 1 BAVs.

An interesting example of the use of sequencing and phylogenetic calculations is a guinea-pig adenovirus which has never been isolated, yet partial amplification of its genome by polymerase chain reaction (PCR) was successful. The amplified partial hexon sequence could then be included into phylogenetic calculations, and the obtained distance (branch length) data confirmed that the virus is not closely related to any other known adenoviruses and will likely be a new type (**Fig. 1**).

Serologic Relationships and Variability

Typing of mammalian animal adenoviruses on the basis of neutralization has recognized at least 57 different types distributed as follows: simian (27), bovine (10), ovine (6), swine (5), equine (2), canine (2), caprine (1), murine (2), tree shrew (2). All are mastadenoviruses with the exception of BAV types 4 to 8 and OAV287 (showing one-way crossneutralization with BAV-7). Among the 21 avian adenoviruses there are fowl (12), turkey (3), goose (3), pheasant (1) and duck (2) serotypes (duck adenovirus type 1 being the EDS virus belonging to the proposed new genus). In addition to these type-specific antigens, there are group-specific antigens characteristic of the three genera as well as a variety of subgroup antigens which indicate more diverse antigenic relationships between the types. Panels of monoclonal antibodies have been produced which can further define these antigenic relationships, e.g. between the fowl serotypes. Most of these different antigenic sites appear to be associated with hexons, although some have also been ascribed to the fiber components (see earlier). Hemagglutination with rodent and monkey erythrocytes has proved to be a useful laboratory tool to establish serological groupings and inhibition and enhancement of hemagglutination can be used to make further serological refinements.

Epizootiology, Transmission and Tissue Tropism

The animal adenoviruses appear to be widely dispersed in their respective host species mostly in an

asymptomatic manner. Similarly to human adenoviruses, persistent infection might be established and the virus can be excreted to the environment from the respiratory and gastrointestinal tracts. Vertical (transplacental) spreading in cattle and swine, as well as egg transmission in poultry have also been described. There are several reports on fulminating diseases attributed to adenovirus infection (over a thousand Californian mule deer died of a disseminated hemorrhagic disease). In other cases of fatal hemorrhagic enteritis in cattle or epizootic lethal pneumonia in guinea pigs, low contagiousness and morbidity, but acute course and very high mortality (up to 100%) were observed. A very wide spectrum of tissue tropism among the animal adenoviruses is evident, e.g. porcine adenovirus type 3 shows a tropism for columnar epithelial cells whereas bovine adenoviruses prefer capillary endothelial cells; however, it is not clear how far tissue tropism relates to pathogenesis and disease. Nevertheless, it is known that for example canine adenovirus types 1 and 2 cause distinct pathology. The two murine adenovirus serotypes (MAV-1 and -2) also have very divergent pathogenic effects. Moreover, recent studies demonstrated that different inbred or outbred, but fully immunocompetent, murine strains show different susceptibility to MAV-1 and according to the presence of genetically determined cellular receptors the infection also has different manifestations.

There is some evidence that an adenovirus which is asymptomatic in its natural host can produce disease in another species. Thus epidemics of reduced laying and soft-shell or shell-less eggs in some flocks of chickens could be attributed to a duck adenovirus (EDS). Aviadenoviruses appear to require avian cells to replicate although they can abortively infect mammalian cells and under the appropriate conditions can transform them.

Pathogenicity and Clinical Features of Infection

Most adenoviruses can be isolated from tissues obtained from healthy animals, but isolations have been associated with respiratory, gastrointestinal and conjunctival diseases, particularly in intensively reared herds and flocks. There is also some evidence for disease etiology in natural infections in the wild. In the case of canine adenoviruses (CAV) the two serotypes, CAV-1 and CAV-2 do seem to have differing tropisms associated with disease patterns. Thus CAV-1 is the agent responsible for infectious canine hepatitis (Rubarth's disease) and along with CAV-2 contributes some of the viruses constituting the 'kennel cough' syndrome. CAV-1 also appears to induce transient corneal opacity and may also cause encephalopathy. Epizootic infections with CAV-1 in foxes, bears, wolves, coyotes and skunks have also been reported. CAV-2 on the other hand appears to be confined to infections of the canine respiratory tract. Recently, an adenovirus was isolated in connection with the deaths of over a thousand mule deer in California. The virus seemed to be a subgroup 2 BAV. It is also notable that every isolate of BAV-10 has so far originated from diseased and subsequently dead animals showing intestinal hemorrhages. Retrospective *in situ* DNA hybridization of tissue sections from similar cases suggested that not only BAV-10 but the subgroup 2 BAVs may also be responsible for economic losses.

There is evidence that, as in humans, pre-existing adenovirus infection in animals can also develop into generalized disease in immunocompromised hosts. Disseminated adenovirus infection affecting the vascular endothelium was detected by electron microscopy in a cat that had a concomitant feline leukemia virus infection. The origin of the adenovirus infection has not been determined. Clinical manifestation of adenovirus infection was also described in horses with combined immunodeficiency syndrome and in a simian immunodeficiency virus (SIV)-infected rhesus monkey.

Avian adenoviruses have been associated with a wide range of disease patterns, e.g. haemorrhagic enteritis in turkey, bronchitis in quail, 'marble spleen' disease in pheasant, inclusion body hepatitis, pulmonary congestion and edema. Recent pathogenesis studies on turkey's hemorrhagic enteritis suggested that HEV has a tropism for the B lymphocytes and macrophages and that intestinal lesions are not induced by local cytopathic viral replication, but rather are immune mediated.

Several animal models have been used for the study of human adenovirus pathogenicity. Cotton rats, rabbits and chinchilla could successfully be infected with HAV-5 or HAV-1, and reproducible pneumonia, ocular infection and otitis media could be established, respectively.

Pathology and Histopathology

Animal adenoviruses infect susceptible cells and elaborate similar gross pathology to that seen with human adenoviruses, e.g. early rounding of cells and aggregation followed by the later appearance of characteristic basophilic nuclear inclusions. Examination by electron microscopy can also reveal crystalline assays of virus particles in the case of aviadenoviruses. 'Marble spleen disease' of chickens and pheasants induced by avian adenoviruses can be accompanied by

gross lesions including pulmonary congestion, splenomegaly, hepatomegaly and congestion of egg follicles. Microscopic lesions include multifocal pneumonia and edema and reticuloendothelial cell hyperplasia of the spleen with concurrent white-pulp neurosis and lymphocyte depletion. Many of the hyperplastic cells contain the basic intranuclear inclusions characteristic of adenovirus infection. However, there are conflicting reports on the nature of the etiological agents relating to pathologies seen in avian species and it has been suggested that concurrent infections with other microorganisms may play a synergistic role in tandem with adenovirus infection.

Immune Response, Prevention and Disease Control

Serological analyses of animal species have indicated that there is widespread natural infection demonstrated by the presence of antibody against the group antigens. In studies with murine adenoviruses a protective role for T cells was demonstrated but in other systems there have been very few definitive investigations of the nature of the immune responses to infection. On the other hand, vaccination programs have been successfully developed with bovine, ovine, canine, equine and avian adenoviruses. Live attenuated, inactivated and *ts* viruses have all been used in these programs. Inactivated combined bovine adenovirus vaccines exist consisting of one subgroup 1 and one subgroup 2 serotype, thereby conferring immunity to BAVs belonging to two different genera. Recently, there has been great interest in using animal adenoviruses themselves as viral vectors to express and deliver foreign antigens in cattle, sheep, swine, dog, poultry, etc. For the insertion of foreign genes, generally the E3 region is replaced. This region has been or is now being characterized in a number of animal mastadenoviruses (BAV-2, BAV-3, etc.). In addition a nonessential, deletable, putative E3 region has been identified in the OAV287 (a member of the proposed new genus) and a gene expression vector has already been developed from it and also from BAV-3.

Malignant Transformation and Oncology

Margaret P. Quinlan, Department of Microbiology and Immunology, University of Tennessee, Memphis, Tennessee, USA

Introduction

Adenoviruses (Ad) are double-stranded DNA viruses that cause a number of acute respiratory infections, in addition to some other types of infections, depending upon the cell type infected. They came to prominence in 1962 because they were shown to cause tumors in rodents. From this, they were considered DNA tumor viruses. The various serotypes have been classified into subgroups, which exhibit different degrees of oncogenic potential in rodent systems (**Table 1**). Subsequently, it was determined that induction of tumors is an alternative path followed when a productive lytic cycle cannot be completed. Adenovirus transformation has not been reported for humans, which are permissive for the genus Mastadenovirus of the adenoviridae family. Ad normally infects quiescent epithelial cells, but requires the host DNA synthetic machinery for its own replication, thus the virus has evolved mechanisms to reactivate quiescent cells into the cell cycle. It has been through the identification of these viral genes, which are

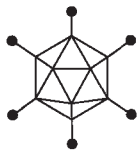
ADENOVIRUSES (*ADENOVIRIDAE*)



Contents

General Features

Göran Wadell, University of Umeå, Umeå, Sweden

History

Characteristic outbreaks of epidemic keratoconjunctivitis occurred among factory workers in Germany during the nineteenth century. In 1953, Wallace Rowe and colleagues explanted surgically removed adenoids from 53 children in Washington DC in order to evaluate different tissues for growth of polio viruses. After 4 weeks, 33 of the cultures showed a slowly progressive cytopathic effect. The agents isolated from these cultures were named the adenoid-degenerating (AD) agent. In 1980, it was demonstrated that the enteric adenoviruses that were associated with infantile diarrhea differed from all other human adenovirus by being fastidious and could be assigned to a separate subgenus designated F.

The observation by Trentin (1962) that adenovirus 12 (Ad12) of subgenus A induced sarcomas in all inoculated newborn hamsters introduced human adenoviruses as a model of viral oncogenesis. It was subsequently demonstrated that only the early (E1) gene of the adenovirus genome was required for *in vitro* transformation of normal human cells. Furthermore, the E1a region could cooperate with the *Ras* oncogene in the transformation process. Mukai demonstrated (1980) that Ad12 could induce retinoblastomas in newborn baboons. On the molecular level, Harlow (1988) found that E1a gene products interacted with the retinoblastoma protein. Furthermore the E1b gene products interacted with the p53 protein thus providing a means for inactivation of these oncogene suppressor proteins.

Taxonomy and Classification

Adenoviruses have been isolated from every species of the placental mammals, marsupials, birds and amphibians studied. The adenovirus family has two genera: *Mastadenovirus* and *Aviadenovirus*. There is no shared family-specific antigen. The mastadenoviruses share a genus-specific antigen (bovine adenovirus serotypes 4–8 are an exception). However, there is no common antigen among the aviadenoviruses.

The classification of adenoviruses has evolved from schemes based on biological properties to a reproducible and discriminating system based on genomic differences. Human adenoviruses were originally classified into four groups based on different hemagglutination properties with rat and rhesus monkey erythrocytes. In 1967, it was suggested that human adenoviruses should be divided into subgenera on the basis of high, weak and no oncogenesis in newborn hamsters.

The polypeptides of the virion represent a major portion of the products of the viral genome. The structural internal polypeptides were expected to be conserved and offered a means of classifying human adenoviruses. The 47 human adenovirus serotypes are divided into six subgenera by sodium dodecyl sulfate–polyacrylamide gel electrophoresis (SDS–PAGE) of polypeptides. This method was compatible with the previous method. Furthermore, Ad4 and enteric adenoviruses, Ad40 and Ad41, were recognized as two newly identified subgenera E and F, respectively (**Table 1**).

The conclusive classification of viruses should be based on nucleotide sequence differences between the

Modified from Wadell (1984).

[a] The restricted DNA fragments were analyzed on 0.8–1.2% agarose slab gels. DNA fragments smaller than 400 bp were not resolved.

[b] I, Complete agglutination of monkey erythrocytes; II, complete agglutination of rat erythrocytes; III, partial agglutination of rat erythrocytes (fewer receptors); IV, agglutination of rat erythrocytes discernible only after addition of heterotypic antisera.

[c] Polypeptide V of Ad31 was a single band of 48 kD.

[d] Members of subgenus B are divided into two clusters of DNA homology based on pronounced differences in DNA restriction sites.

[e] Only polypeptide analysis and/or DNA restriction analysis has been performed with Ad32–Ad39 and Ad42–Ad47.

[f] Polypeptides V and VI of Ad8 showed apparent molecular mass of 45 and 22 kD, respectively. Polypeptide V of Ad30 showed an apparent molecular mass of 48.5 kD.

genomes of the different viruses. The DNA homology of adenoviruses has been studied by hybridization techniques, DNA restriction analysis and nucleotide sequencing. These techniques confirm the assignment of the 47 human adenovirus serotypes into six subgenera.

Members belonging to the genus *Mastadenovirus* share common epitopes on the hexons. Subgenus is defined by the DNA homology of more than 50% between members within a subgenus and less than 20% between members of different subgenera.

The serotype is defined by quantitative neutralization with hyperimmune sera. The ratio of homologous to heterologous neutralization titer must be greater than 16. The designation recombinant should be used only when the two parent genomes have been identified. An evolutionary variant is one in which genetic alteration was generated via insertion or intragenomic recombination in progeny of the same strain. A genomic cluster is a group of genome types that are significantly more closely related to each other than to any other genome type. The genome type denotes a distinct viral entity within a genomic cluster identified by DNA restriction analysis. Strain corresponds to the progeny of each wild-type isolate.

Geographic and Seasonal Distribution

Ad8 causing epidemic keratoconjunctivitis is common in East Asia and rare in Europe and the United States. Respiratory infections show two peaks in mid-winter and late summer. The first predominantly among small children and the latter among school children. Newly enlisted military recruits are infected by the end of the third week after their recruitment. Enteric adenoviruses causing infantile diarrhea show no seasonality. Keratoconjunctivitis in Japan is presented as epidemic outbreaks during late summer and early fall. Eye infections are particularly prone to appear in hot and dry climates or in densely populated areas. Within each serotype certain genome types show an appearance characteristic for regions and continents.

Host Range and Virus Propagation

Adenoviruses are highly species specific. Human adenoviruses may infect chimpanzee. The adenoviruses belonging to subgenus C can cause symptoms after infection of rodents. Ad2 and Ad5 produce pneumonia in cotton rats or hamsters. Ad5 can cause hepatitis in mice. Several animal adenovirus infections may serve as models for human adenoviruses.

Genetics

Changes occur by accumulation of point mutations in the adenovirus DNA. There is no evidence that the mutation rate of adenoviruses differs from that of the host chromosome. The subgenera serve as recombination barriers. Experimentally, recombinants can only be created within each subgenus.

Evolution

As adenoviruses are detected in all host species studied, they are considered to be phylogenetically old. Members of the six subgenera of the human adenoviruses display characteristically different tropisms, i.e. they will replicate in different organs. They have also evolved so far from each other that subgenera serve as recombination barriers. That adenoviruses display an unusually high host species specificity speaks in favor of the notion that adenoviruses have evolved with their host species. It should therefore be possible to find correlates of different subgenera of human adenoviruses also among adenoviruses of other host species.

Serological Relationships and Variability

The single capsid is composed of 240 hexon capsomers and 12 vertex capsomers. From the latter 12 fibers project. Genus-specific epitopes reside in the basal part of the hexon. The serotype is defined by neutralization of infectious activity or by hemagglutination inhibition. The epitopes capable of inducing type-specific antibodies are localized on the external portion on the hexons and on the most distal knob of the fiber. Furthermore, the hexon carries epitopes which are the structural correlates of a diverse cross-reactivity. The vertex capsomer contains intrasubgenus-specific epitopes and subgenus-specific epitopes. The fibers contain subgenus-specific, intrasubgenus-specific and type-specific epitopes. Serological intermediates are found with neutralizing hexon epitopes of one serotype, and hemagglutination-inhibiting epitopes of the fiber of other serotypes. Monoclonal antibodies or extensively absorbed hyperimmune sera have to be used to obtain type-specific reagents to be used for typing of adenoviruses by enzyme-linked immunosorbent assay (ELISA) techniques.

The serological cross-reactivity of Ad4, the only member of subgenus E may have evolutionary implications. Hexons of Ad4 cross-neutralize hexons of Ad16 (subgenus B); the fibers of Ad4 share epitopes of fibers of subgenus C members; hexons of Ad4 share external epitopes with the hexons of Ad40 (subgenus F); and the early antigens of Ad4 share epitopes with

subgenera of all other adenoviruses to an extent that is not noted for other human adenoviruses.

Epidemiology

Among the isolates reported to the World Health Organization (WHO) register during a 10-year period, adenovirus accounted for 13% of the reported isolations providing evidence that adenovirus infection is second only to influenza A which accounts for 28% of the reported isolates. The human adenoviruses represent different organ tropisms leading to different diseases and are therefore presented according to subgenus.

Subgenus A

Ad12, Ad18 and Ad31 are rarely isolated because they are difficult to cultivate. However, infections are relatively common. The prevalence of neutralizing antibodies demonstrated that Ad31 and Ad18 were second to members of subgenus C. The majority of the isolates were obtained from infants and 60% of these children had gastrointestinal disease. It is still difficult to evaluate their role as a cause of diarrhea.

Subgenus B:1

Ad3 and Ad7 account for 13 and 20% of all adenovirus isolates reported to WHO. Both Ad3 and Ad7 show epidemic appearance with 4–5 years intervals. Three different epidemic patterns of Ad7 infection have been identified. The first pattern represents outbreaks mainly during the winter season among infants and infections can be severe. The second pattern consists of epidemic outbreaks of respiratory disease among school children. Moderate to severe infections with fever for 7 days are usually seen but fatal outcome is rare. Outbreaks among newly enlisted military recruits constitute the third epidemic pattern. These are caused by Ad4, Ad7, Ad14 and Ad21. The etiology of the syndrome may be sought in the fact of gathering of young men with lowered immunity sleeping in crowded quarters after hard exercise. The frequency of reported Ad7 isolated in Japan and the antibody prevalence were highly discordant. Adenovirus-specific antibodies were detected in 50% of the adult sera with only 2% of adenovirus strains isolated in Japan typed as Ad7. By contrast, 52% of isolates were typed as Ad3. In other parts of the world, Ad7 is the predominant adenovirus respiratory pathogen. DNA restriction analysis has revealed the occurrence of different genome types within each serotype. In Europe a shift from genome type Ad7c to Ad7b occurred in 1969 and the analogous shift took place in Australia 1975. Ad7b dominates in the United States whereas Ad7c now dominates in Africa. Ad7d is the predominating genome type in China. Ad7e is unique to Brazil and Ad7h responsible for a recently recognized severe outbreak of respiratory illness among small children in Argentina, Chile and Uruguay. Ad21 has been isolated from military recruits at the major basic training centers in the US army as a cause of severe respiratory disease.

Subgenus B:2

Ad14 causes outbreaks among military recruits. Ad11, Ad34 and Ad35 cause persistent infections of kidneys and are the most common adenoviruses isolated from the urine of AIDS patients or bone marrow transplant recipients.

Subgenus C

The members Ad1, Ad2 and Ad5 are regarded as endemic. Infants are infected by older siblings shedding the virus after recrudescent infections for up to 2 years. By the age of 4 years at least 50% of the children have antibodies against Ad1 or Ad2. By the end of the grammar school years all children will have had several adenovirus infections. Subgenus C members account for 50% of all adenovirus strains reported to the WHO.

Subgenus D

Contains 28 serotypes, i.e. more than half of all recognized human adenoviruses, Ad8, Ad19 and Ad37 are causes of epidemic keratoconjunctivitis in particular in dry climates or in densely populated areas.

Subgenus E

Ad4 is rarely isolated from children in Europe or the US. Two distinct genome types, Ad4 and Ad4a, have been identified. Ad4 is responsible for epidemic outbreaks of respiratory disease among military recruits and the Ad4a genome type is second only to Ad8 as a cause of adenovirus-associated eye disease in Japan.

Subgenus F

The enteric adenoviruses Ad40 and Ad41 are the only members of subgenus F. They are second only to rotaviruses as a cause of infantile diarrhea and in contrast to rotaviruses they cause diarrhea in children throughout the year. Enteric adenoviruses cannot be found in stools of healthy controls using the polymerase chain reaction (PCR) technique. Ad40 or Ad41 have been isolated in stool specimens from Africa, Asia, Europe, Latin America and North America. Fifty percent of 6–8 year old children in Asia and Europe have neutralizing antibodies to Ad41. At the

end of the 1970s Ad40 dominated in Europe. Ad41 is the predominant type for 1992.

Transmission and Tissue Tropism

Adenoviruses of humans can be spread by aerosols. Transmission is particularly effective when the population density of sensitive individuals is high such as several young children of the same age group or newly enlisted recruits that sleep in the same dormitory. During early childhood, infection by the oral route, as the consequence of shedding into stools after recrudescence, also occurs. Similarly, transmission by this route may result in the characteristic swimming pool outbreaks of Ad3 and Ad7. Infections of the eye can be transmitted through direct contact as revealed by outbreaks from ophthalmologists' office via tonometers as the common source of infection.

Airborne transmission has been experimentally demonstrated with the avian FAV1 virus. Among fowl, vertical transmission may also occur.

Tissue tropism varies with the subgenera. Subgenus A cause cryptic infections of the gut where the host cell has not yet been identified. Subgenus B viruses cause respiratory infections or infections of the urinary tract. Members of subgenus C cause respiratory infections but have also been demonstrated to replicate in lymphocytes. The subgenus D viruses can infect the conjunctiva and cornea of the eye. Subgenus E virus can infect both the eye and respiratory tract whereas subgenus F viruses infect enterocytes. This information might indicate that different adenoviruses utilize different host cell receptors. These have not been identified.

Pathogenicity

Among the 47 adenovirus serotypes, several differ in pathogenicity. Ad7 is the most severe cause of respiratory infections. Among the 28 serotypes of subgenus D that have predilection for the eye only one serotype, Ad8, is responsible for most severe outbreaks of keratoconjunctivitis. Even within a particular serotype, there are differences. The Ad19 prototype has rarely been isolated during the last three decades whereas genome type Ad19a has been responsible for numerous outbreaks of keratoconjunctivitis since 1973. Even after infection with the same genome type, it is obvious that infants or young animals display more severe or fatal symptoms that are not apparent after infection of older individuals. Infections with mouse adenovirus will kill suckling mice, whereas adult mice display viruria for 24 months. Canine Ad1 displays 80% mortality in experimentally infected fox pups that are less than 6 months old. The adenoviral genes responsible for the pathogenicity have not been identified. However, it is obvious that deletion of the entire E3 region can effect pathogenicity.

Clinical Features of Infection

Respiratory disease in children

Serotypes 1, 2 and 5 are endemic whereas serotypes 3 and 7 cause epidemic outbreaks of adenopharyngoconjunctival fever. The pharyngeal conjunctival fever appears after a mean incubation period of 6 days. The initial conjunctivitis is followed by high fever and sore throat. One half of the susceptible population shows asymptomatic infection. Vomiting, diarrhea and meningeal signs are found and temperature returns to normal after 7–8 days. Symptoms are usually more severe in children but sequelae are rare.

Lower respiratory tract infections with symptoms as bronchiolitis and pneumonia appear after an incubation of 8 days. Symptoms appear as cough, dyspnea, inspiratory and expiratory wheezing with fever of 7–8 days. Among hospitalized patients after infection with Ad3, Ad4, Ad7 and Ad21, significant chronic lung damage as impaired lung function or bronchiectasis occur. Unusually severe forms are seen among children below the age of 2 years, in particular amongst North American Indians, Polynesians and children in Latin America.

Epidemic keratoconjunctivitis (EKC)

After 1–7 days incubation, symptoms in the form of pain, photofobia, lacrimation and corneal erosion and edema appear. The duration is characteristically 4–6 weeks and may result in scarring caused by Ad8, Ad19 and Ad37 transmitted via contact in particular to eyes damaged by foreign bodies or extensive sunlight exposure. Ad37 can also be sexually transmitted.

Diarrhea

After an incubation period of 8 days, infection with enteric adenoviruses, Ad40 and Ad41, results in diarrhea, vomiting, moderately elevated temperature and dehydration in less than one-fifth of patients. The diarrhea is not as acute as rotavirus-induced diarrhea but the duration is significantly longer, 9–12 days. Appearance of sequelae has not been sufficiently evaluated.

Other symptoms

Acute hemorrhagic cystitis among young boys, caused by Ad11 and Ad21, is common in Japan but not so frequent in Western countries. Intussusception, meningoencephalitis, pericarditis, rhabdomyolysis,

polyarthritis and Steven Johnson like exanthemas may be seen after adenovirus infection.

In immunocompromised hosts, hepatitis may be seen after transplantation and acute hemorrhagic cystitis after kidney transplantation; in severe combined immunodeficiency, hepatitis and pneumonia usually with a poor prognosis can be caused by Ad5 or Ad31.

Pathology and Histopathology

The property of adenoviruses to shut off the expression of the host mRNA and the unregulated synthesis of viral proteins is incompatible with normal cell function. The structural proteins form characteristic intranuclear inclusions that are the pathological hallmarks of adenovirus infection. In the upper respiratory tract, ciliar abnormalities and microtubular aberrations may cause a defective mucociliar clearance. In adenovirus pneumonia, a necrotizing destruction of the broncheal epithelium occurs with damage of the broncheal gland. The intranuclear inclusion bodies are refractile like ground glass. Adenoviruses of subgenera B and C produce large amounts of free vertex capsomers with an associated toxin-like activity, but the viral gene products that are responsible for the adenovirus-induced symptoms in the host are not defined. Some of the infrequent symptoms of adenovirus infection seen in man mirror adenoviral disease in animals. Diarrhea as a function of infection of endothelial cells in the gut is seen in bullocks. Hemorrhagic enteritis is also seen in turkeys. Encephalitis resulting from infection of endothelial cells with perivascular cuffing is seen in foxes. Hepatitis is seen in dogs, sheep, Nile crocodiles, boa constrictors and domestic fowl. Cauda equina nervitis is seen in immunodeficient foals. Porcine adenoviruses can also infect nervous tissue.

Immune Response

Human antibodies directed against epitopes on the external towers of the hexons and the knobs of the fiber may induce neutralizing antibodies. Antigenic extinction experiments have revealed that 1 ng hexon and 100 ng fibers or 10^7 virions are needed to elicit a primary immune response. A cell mediated immune response is required for resolution of adenovirus infections. Adenovirus infections are seen in individuals devoid of adequate cellular immunity such as neonates or children with congenital cell disorders. Some bone marrow transplantation recipients experience severe or even fatal adenovirus infections. Mouse Ad1 causes duodenal lesions in adult nude mice but heterozygotes are not susceptible. The immune response against adenoviruses is modulated by gene products of the E1a and E3 region. The E1b/19K protein prevents lysis of human cells by tumor necrosis factors (TNFs) whereas the E3/14.7K protein protects transfected cells from TNF-induced cytolysis. On the other hand, E1A products render infected cells sensitive to lysis by TNF. The E3/gp19K protein downregulates MHC1 antigens. The promoter of E3/gp19K is driven by NF Kβ factor. This consequently provides a molecular mechanism for the observed evasion of the immune elimination of adenovirus infected lymphocytes.

E1a-induced tumors can be eradicated by E1a-specific cytotoxic T lymphocytes. Expression of Ad2E3/19K protein inhibits lysis of the cytotoxic T lymphocytes by blocking the cell surface expression of MHC1 that consequently also inhibits the expression of the immunogenic E1A antigen. Five additional gene products are expressed from the E3 region with unknown function.

Prevention and Control

No antivirals have been conclusively demonstrated to have a clinical effect on adenovirus infections. In epidemic keratoconjunctivitis topical steroids may delay the appearance of corneal filtrates and also delay the final corneal healing. Their use is consequently not justified.

Enteric coated vaccines for oral administration protect against respiratory illness caused by Ad4, Ad7 and Ad21. So far these vaccines are widely but exclusively used in military populations. The extent of the attenuation of these vaccine strains has not been documented and they have been demonstrated to spread to household contacts. It is consequently not recommended to extend their use to young children.

Adenoviruses can serve as vaccine vectors. Foreign genes have been introduced to the E1 region. In this case, complementation by an immortalized host cell transfected by the E1 region is mandatory. Alternatively, foreign genes are inserted in the E3 region which is dispensible for growth *in vivo*. However, the effect of the elimination of the immunomodulating gene products of this region is incompletely known. Several vaccines against adenovirus infection among animals have been applied. Live attenuated canine Ad2 can be used for protection against the hepatitis caused by canine Ad1. There is also a vaccine against hemorrhagic enteric virus in turkeys and an inactivated vaccine protecting against equine adenoviruses.

Future Perspectives

The increasing awareness of the impact of adenovirus infection among children living in crowded conditions

urges an evaluation of the possibility to develop protective vaccines that are effective also in young children. The extended application of bone marrow, liver and kidney transplantation and improved care of immune-compromised patients demands introduction of rapid methods for the detection and typing of adenovirus infections. Subsequently development of immunoprofylaxis in the form of safer vaccines to be used before transplantation may become justified. Epidemiological surveillance is required to detect re-emerging and previously unrecognized genome types as has been observed with Ad7, Ad19, Ad21 and Ad41.

Introduction

For a long time, adenoviruses have served as excellent tools for detailed studies on basic molecular mechanisms in mammalian cells, on the mechanism of viral oncogenesis and on gene transfer in mammalian organisms. In this brief article, it will not be possible to cover all of the recent progress accomplished in adenovirus research in a sensible way. We have therefore chosen to summarize current research on the following topics:

- The fate of viral DNA in mammalian cells.
- The abortive infection of hamster cells with human adenovirus type 12 (Ad12).
- Viral DNA integration and oncogenesis.
- A third generation adenovirus gene transfer vector.

References to more comprehensive surveys on ongoing adenovirus research have been listed under Further Reading.

Fate of Viral DNA in Mammalian Cells

The fate of foreign DNA in mammalian cells is of general biological interest. Foreign DNA can integrate into the genomes of mammalian cells, and this process plays major roles in viral oncogenesis and in the generation of transgenic organisms and will be important in evolving regimens for human somatic gene therapy. At least in cell culture, foreign DNA can be taken up by mammalian cells under appropriate conditions or in a stabilized conformation, e.g. in a complex with basic proteins.

Human adenovirus type 12 (Ad12) infects human cells productively and leads to viral DNA replication, whereas infection of Syrian hamster cells remains abortive with total blocks in viral DNA replication and late viral gene transcription. In abortively Ad12-infected BHK21 cells, the viral DNA can be integrated into the cellular genome early after infection. Viral oncogenesis by Ad12 has been demonstrated in

gross lesions including pulmonary congestion, splenomegaly, hepatomegaly and congestion of egg follicles. Microscopic lesions include multifocal pneumonia and edema and reticuloendothelial cell hyperplasia of the spleen with concurrent white-pulp neurosis and lymphocyte depletion. Many of the hyperplastic cells contain the basic intranuclear inclusions characteristic of adenovirus infection. However, there are conflicting reports on the nature of the etiological agents relating to pathologies seen in avian species and it has been suggested that concurrent infections with other microorganisms may play a synergistic role in tandem with adenovirus infection.

Immune Response, Prevention and Disease Control

Serological analyses of animal species have indicated that there is widespread natural infection demonstrated by the presence of antibody against the group antigens. In studies with murine adenoviruses a protective role for T cells was demonstrated but in other systems there have been very few definitive investigations of the nature of the immune responses to infection. On the other hand, vaccination programs have been successfully developed with bovine, ovine, canine, equine and avian adenoviruses. Live attenuated, inactivated and *ts* viruses have all been used in these programs. Inactivated combined bovine adenovirus vaccines exist consisting of one subgroup 1 and one subgroup 2 serotype, thereby conferring immunity to BAVs belonging to two different genera. Recently, there has been great interest in using animal adenoviruses themselves as viral vectors to express and deliver foreign antigens in cattle, sheep, swine, dog, poultry, etc. For the insertion of foreign genes, generally the E3 region is replaced. This region has been or is now being characterized in a number of animal mastadenoviruses (BAV-2, BAV-3, etc.). In addition a nonessential, deletable, putative E3 region has been identified in the OAV287 (a member of the proposed new genus) and a gene expression vector has already been developed from it and also from BAV-3.

Malignant Transformation and Oncology

Margaret P. Quinlan, Department of Microbiology and Immunology, University of Tennessee, Memphis, Tennessee, USA

Introduction

Adenoviruses (Ad) are double-stranded DNA viruses that cause a number of acute respiratory infections, in addition to some other types of infections, depending upon the cell type infected. They came to prominence in 1962 because they were shown to cause tumors in rodents. From this, they were considered DNA tumor viruses. The various serotypes have been classified into subgroups, which exhibit different degrees of oncogenic potential in rodent systems (**Table 1**). Subsequently, it was determined that induction of tumors is an alternative path followed when a productive lytic cycle cannot be completed. Adenovirus transformation has not been reported for humans, which are permissive for the genus Mastadenovirus of the adenoviridae family. Ad normally infects quiescent epithelial cells, but requires the host DNA synthetic machinery for its own replication, thus the virus has evolved mechanisms to reactivate quiescent cells into the cell cycle. It has been through the identification of these viral genes, which are

Table 1 Tumorigenic potential of adenovirus serotypes

Subgroup	Serotype	Oncogenic potential Tumors in animals	Transformation in vitro
A	12, 18, 31	High	+
B	3, 7, 11, 14, 16, 21, 34, 35	Moderate	+
C	1, 2, 5, 6	Low to none	+
D	8–10, 13, 15, 17, 19, 20, 22–30, 32, 33, 36–39	Low to none	+
E	4	Low to none	+
F	40, 41	Unknown	?

referred to as viral oncogenes, and the mechanisms by which their gene products accomplish this essential goal that several mammalian cell cycle regulators have been identified and characterized and contributed to our understanding of them and tumor suppressors (especially pRB and p53), which are often the targets of Ad, and other DNA tumor virus oncoproteins. These viral genes, in the absence of the rest of the viral genome, are able to effect growth stimulation and transformation of a variety of primary and established cells. These are properties that Ad oncoproteins share with other DNA tumor virus transforming proteins. The major oncogenes encoded by Ads are E1A and E1B, each of which encodes multiple mRNAs. However, recently, additional viral genes that exhibit transforming potential have been identified in Ad9 (subgroup D). These are *E4ORF1* and *E4ORF6*. Interestingly, Ad has two proteins, E1B55K and E4ORF6, that bind to the p53 tumor suppressor and promote transformation by modulating its transcription functions.

E4

The E4 region of Ad9, of subgroup D, exclusively elicits estrogen-dependent mammary tumors, predominantly fibroadenomas, in rats, but also transforms CREF cells in culture. E4 from Ad subgroups A (Ad12) or C (Ad5) does not. E4 encodes several transcripts, two of which have been implicated in tumorigenic transformation. Open reading frame (ORF) 1 encodes a novel, cytoplasmic transforming protein, three regions of which are required. The C-terminus contains a PDZ domain and interacts with the PDZ domain of hDlg/SAP97, a mammalian homologue of the Drosophila discs large tumor suppressor, which also binds APC, another tumor suppressor. E4ORF6 encodes a protein with similarities to Ad E1B (see below). It interacts with the C-terminus of p53 and prevents p53 binding to $TAF_{II}31$, a component of TFIID of the basal transcription complex (BTC), thus blocking p53 transcriptional activation and repression activities. E4ORF6 also blocks the induction of p53-mediated apoptosis. The levels of p53 protein are also diminished. ORF6 promotes focus formation in cooperation with E1A and E1B and accelerates *in vivo* tumor formation of E1A + E1B transformed cells.

E1B

E1B cannot transform primary cells on its own, but cooperates with E1A, an immortalizing oncogene, to do so. E1B encodes two oncoproteins, 55K and 19K. E1B19K is functionally similar to the proto-oncogene *bcl*-2, which was originally isolated from a follicular lymphoma. There is little similarity in the primary sequence, but there are three short regions of homology in the central region of the protein. This same region is necessary to cotransform with E1A and for its antiapoptosis activity. 19K contributes to oncogenesis by preventing p53-mediated apoptosis, similar to *bcl*-2 and *bcl*-xL. It interacts with bax, bak and bik, *bcl*-2 family members which promote apoptosis. E1B19K alleviates p53 repression, but does not affect p53 activation. E1B19K also negatively interferes with the activation of NFkB.

E1B55K extends the lifespan of normal mammalian cells in culture. It associates with E4ORF6. 55K binds p53 without displacing it from DNA, and thus serves as a direct repressor targeted to p53-responsive genes. Transcriptional repression is regulated by phosphorylation at the C-terminus. E1B55K mutants defective in p53 binding are unable to cooperate with E1A.

E1A

E1A encodes two nuclear, multifunctional phosphoproteins, of 289 and 243 amino acids, derived from 13S and 12S transcripts, respectively, that can affect the proliferative state of cells. Either polypeptide can

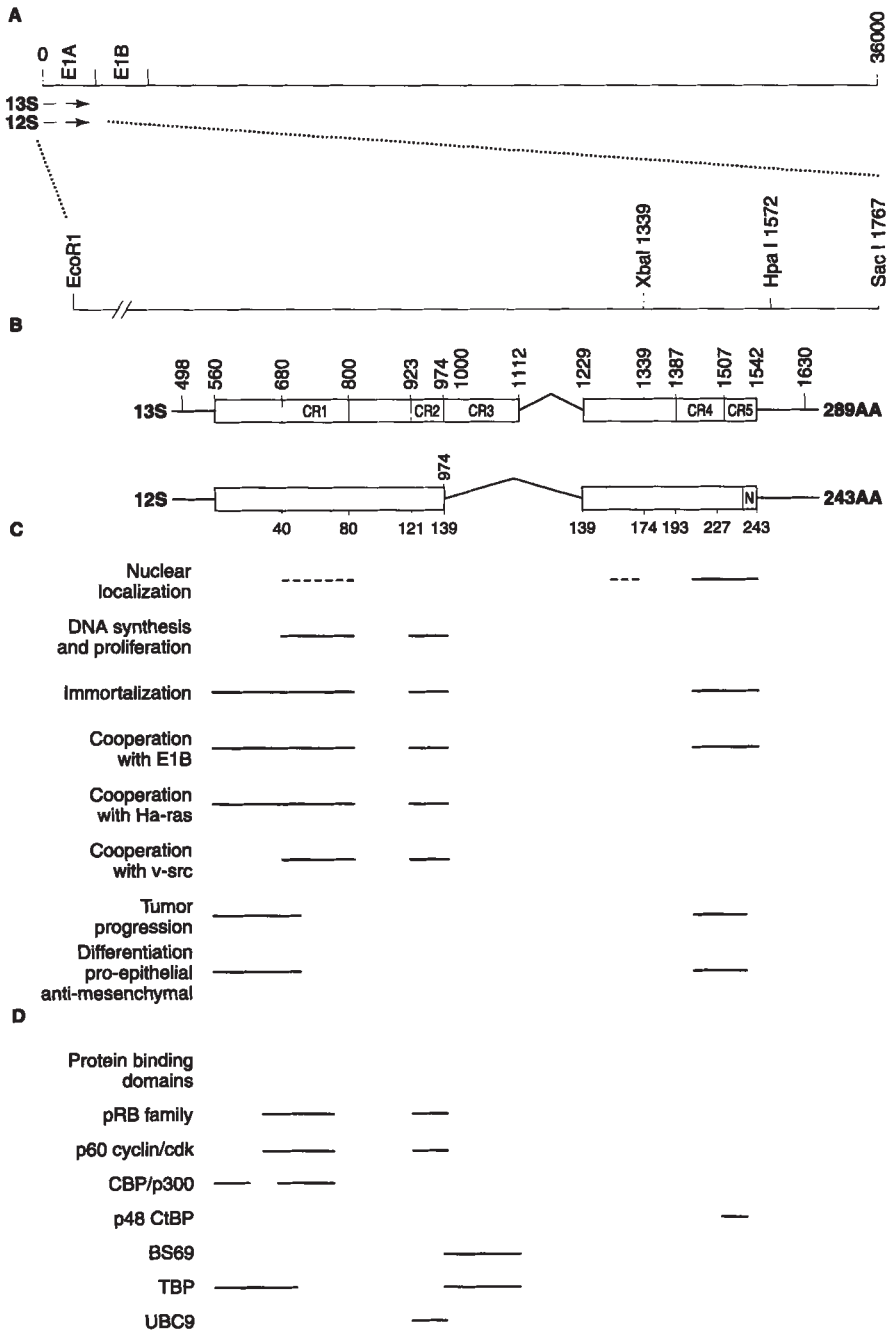

Figure 1 Structures and functional regions of the major adenovirus type 5 E1A gene products. (**A**) Localization of the E1 transforming region in the adenovirus genome. (**B**) Expanded view of the E1A region. The numbers above refer to nucleotide numbers. The top line indicates salient restriction enzyme cleavage sites. Below are the 13S and 12S transcripts. The numbers below the 12S transcript indicate amino acid positions in the 243 aa protein. The boxes represent exons, the solid lines represent non-coding regions and the carets indicate the introns. CR1, CR2, CR3, CR4, CR5 indicate the regions conserved among the different serotypes. (**C**) Functional regions of E1A. The functions or phenotypes are indicated on the left. The region of the protein required for that function is delineated with a solid line. (**D**) Cellular polypeptide binding regions of E1A are indicated by a solid line at the right of the name of each protein.

immortalize on its own, or cooperate with other viral and cellular oncogenes to transform cells. The E1A 12S gene product is much more efficient at this function(s). E1A functions are mediated, at least in part, through its binding to families of growth inhibitory and/or gene regulatory proteins. The E1A proteins contain five regions that are highly conserved among the various serotypes (**Fig. 1**). Three of these

(CR1-CR3) are located in the first exon and two (CR4, CR5) are located in the second exon. One of these, CR3, is unique to the 13S gene product and is necessary for the transcriptional transactivation of the viral early promoters to effect a lytic infection. CR3 is dispensable for the transforming functions of E1A, but can contribute to them. Thus, the E1A12S protein is fully competent at immortalization and cotransformation. These conserved regions seem to correspond to functions or activities carried by the E1A proteins. These, in turn, seem to be due to the interactions of the peptides encoded by these regions with cell cycle and/or transcriptional regulatory proteins in the host cell. In addition to the conserved regions, a non-conserved, N-terminal region (NTR) turns out to have several roles in regulating gene expression and to be important in immortalization and transformation with some, but not all, cytoplasmic oncogenes. The regions and interactions of the first exon are better characterized than those of the second exon, at this time. However, several functions have been assigned to the C-terminus of the protein and are under investigation. E1A may function at various control points during the cell cycle, which may be regulated by its phosphorylation status. The E1A proteins have many phosphorylation sites (serines and threonines) that can be phosphorylated by cyclin-dependent kinases, such as cdc2, cdk2 and cdk4, at true phosphorylation sites.

The 12S oncoprotein positively and negatively regulates the expression of cellular genes. It can thus redirect the metabolism of the host cell to bring about the transformed state. There are no data demonstrating that E1A proteins can directly interact with regulatory sequences in promoters of E1A-sensitive genes. The overall mechanism by which E1A affects both viral and cellular gene expression is by various regions or peptides in the E1A protein making contact with general transcription factors and/or gene-specific factors. In fact, in some cases, an E1A peptide serves as a bridge between these two classes of transcriptional regulatory proteins. E1A-sensitive sites include activating transcription factor (ATF) and TATAA sites in promoters and E2F and AP-1 enhancer sites.

Protein Complexes and Gene Expression

Several polypeptides have been shown to complex with E1A proteins, directly or indirectly (**Fig. 1**, **Tables 2** and **3**). Those most consistently and readily found include proteins with molecular masses of 400, 300, 130, 107, 105, 60 and 33 kDa (referred to as p400 etc.) and associate with peptides encoded by exon 1, which encodes the N-terminal 'half' of E1A. The identity of many of them has been made. More sensitive methods have led to the identification of additional protein interactions, including the first identification of a protein partner for the C-terminus, p48 CtBP, which interacts with CR5. CtBP has homology to NAD-dependent dehydrogenases. E1A immortalizing and co-transforming abilities are determined primarily by binding to cell cycle or transcriptional regulatory proteins and interfering with their functions. Mutants that are defective for binding to these cellular proteins are also defective for immortalization and cotransformation with E1B. The cell cycle regulatory proteins bind CR1 and CR2 and include the tumor suppressor pRB (p105; retinoblastoma gene product) and its family (nuclear pocket protein family) members p107 and p130, cyclins (p60 cyclin A and E; cdk regulatory proteins) and a cyclin-dependent kinase (cdk2, p33). The cyclins and cdks form complexes with E1A and p107 or p130.

Table 2 Cell cycle regulators affected by E1A

Positively	*Negatively*
E2F-DP1	p53
cyclinA	pRB family
cyclinE	cyclinD1
cdk2	cdk inhibitors
cdc25A phosphatase	p16 INK
p70S6kinase	p21 WAF/CIP/SDI
UBC9	p27 KIP
fos	TGFβ

The importance of pRB in immortalization/co-transformation is further underscored by the fact that it has not been possible to produce an E1A mutant that is defective for pRB binding while maintaining this phenotype intact. The importance of pRB and the other proteins in E1A-mediated immortalization and cotransformation is also supported by the observation that proteins of other DNA tumor viruses, namely the large T-antigens of SV40 and polyomavirus, and the E7 of human papilloma virus (HPV), also bind to pRB, p107 and p130 and all of these viral gene products are able to bring about immortalization and transformation of primary cells. Kinase activity has been detected in E1A complexes and probably derives from p60 cyclinA/E linked p33 cdk2, associated with p107 and p130, but not pRB. Phosphorylation of E1A and the other members of the complex may contribute to their functions in cell cycle regulation. In fact, phosphorylation of pRB also inactivates its tumor suppressor function. Thus, E1A has two means by

which to inactivate pRB function. pRB regulates transcription during the cell cycle, by its underphosphorylated form binding to transcription factors, especially E2F/DP1 factors (**Fig. 2**). E2F1/DP1 are cell cycle regulating transcription factors. They activate genes whose products are required for S phase progression. During most of G_1, E2F/DP1 is repressed by pRB, which complexes with the activation domain and prevents E2F transactivation. Phosphorylation of pRB and/or its sequestration by E1A, releases E2F and enables it to bind to its cognate sequence in the promoters of the E2F-sensitive genes. E2F is also affected by other cell cycle regulators, such as p53, cdk2, cdk4 and some cyclins. Overexpression of E2F, itself, can be transforming, presumably by constitutively activating S-phase genes. E1A also competes for binding with pRB with RIZ, a 250 kDa nuclear, Zn finger, pRB binding protein with structural and antigenic homology to the E1A region concerned with RB binding and the C-terminus, which are juxtaposed in RIZ. UBC9, which has homology to ubiquitin-conjugating enzymes interacts with CR2 in both AD5 and 12 E1A proteins. It complements a cell cycle defect in the UBC9 gene in yeast and therefore may play a role in cell cycle regulation that can be usurped by E1A.

The extreme N-terminal 80 amino acids, the nonconserved NTR, also binds several proteins that are involved in regulating transcription, positively and negatively. The N-terminus is also involved in immortalizing/transforming functions. p400, p300 and CBP (CREB binding protein) directly bind the N-terminus and part of CR1 of E1A from both Ad5 and Ad12. p300 and CBP are homologous transcriptional adapters or co-activators and histone acetyltransferases, which are thought to enable passage of

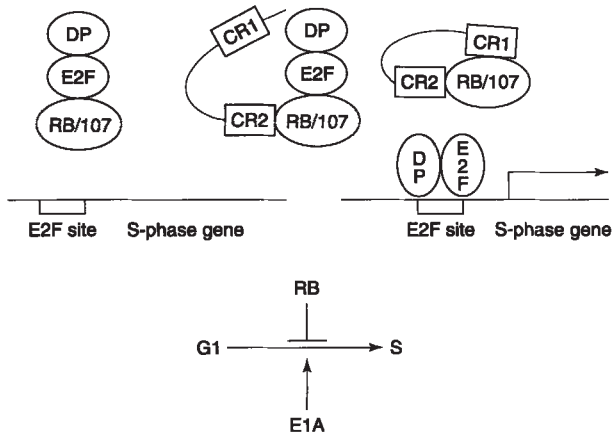

Figure 2 Model of the pRB pathway of gene activation by E1A 12S. CR1 and CR2, indicate the regions of E1A involved in making contact with the pocket protein family members. For details see text.

the BTC through chromatin. They participate in cell cycle arrest, mesenchymal cell differentiation, transactivation and co-activation of CREB [cAMP response element (CRE) binding protein]. p300 is a common mediator protein by which E1A can access multiple transcriptional regulatory pathways, including sequence specific transcription factors, such as YY1 (a transcriptional repressor), CREB/ATF (activating transcription factor) and the jun proteins of the AP-1 transcriptional complexes. p300 also bridges E1A with components of the basal transcriptional machinery (BTC), such as TFIIB. p300 and CBP form *in vivo* complexes with TBP (TATA binding protein) (**Fig. 3**). They interfere with cellular processes controlling cell cycle progression, which is needed for viral DNA replication. The E2F1 activation domain has sequence similarity with the N-terminal domains of 12S, which contains the CBP binding site and pRB binding site. CBP also interacts with E2F activation domain. The E1A NTR eliminates CBP-induced activation of E2F/DP1, thus CBP is a coactivator for E2F. The convergence of RB and CBP on E2F regulation helps explain the cooperativity of these proteins in carrying out E1A functions.

The TBP, which is part of TFIID of the BTC is also targeted by N-terminus of E1A, directly, resulting in transcriptional repression by blocking the interaction between TBP and the TATA box. This can be overcome by excess TFIIB. Thus, TBP interacts with E1A in two regions: CR3 transactivator and the N-terminal 35 amino acids. CR3 has two subdomains that interact with several transcription factors involved in activation of gene expression required for the lytic cycle of the virus and may contribute to the immortalizing/transforming functions of E1A (**Table 3**). The N-terminal region of CR3 interacts with TBP and the C-terminal domain interacts with ATF/CREB transcription factors. E1A complexes with the retinoic acid receptor (RAR), but not RXR, resulting in activation of the RARβ promoter in the presence of RA. This is mediated by CR3, which acts as a cofactor stabilizing the preinitiation complex with RAR and TBP. BS69 is a novel protein that binds to CR3 and inhibits its transactivation ability.

CtBP is a cellular phosphoprotein that complexes with six amino acids of CR 5 in the C-terminus of 12S, just upstream from the C-terminal NLS. This region is required for immortalization, cotransformation with E1B and negatively regulates ras transformation. Deletion of CR5 (and CR4) results in the metastasis of E1A+ras transformed cells. CR5 seems to control CR1-dependent activation. Thus, the C-terminus may down-modulate CR1 transcriptional regulation, via p48 binding. Perhaps CtBP regulates E1A immortalization/cotransformation by affecting CR1-regulated transcription. However, no differences in cell cycle activation or complex formation with E1A N-terminus binding partners are observed with CR4 or CR5 deletions. There is, however, a loss of maintenance of the proliferative response and consequently, the loss of immortalization in CR4 and CR5 deletions.

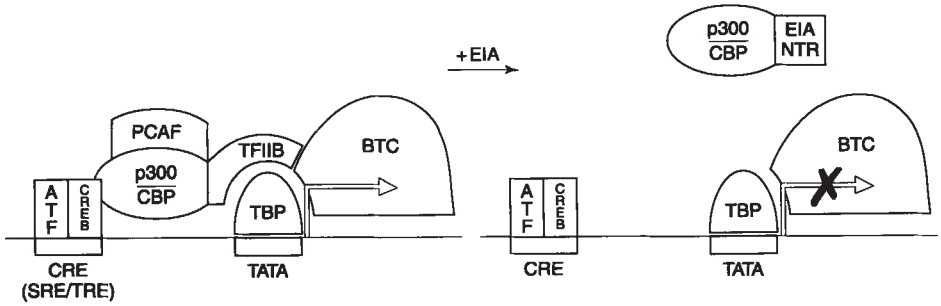

Figure 3 Model of the p300 pathway of repression of gene expression by E1A. E1ANTR indicates the region of E1A involved in contacting p300/CBP. For details, see text.

The bZIP proteins are transcription factors that contain a basic domain that interacts with DNA and a leucine zipper that dimerizes with other ZIP proteins. They regulate many different target genes with a broad range of consequences for the cell. Two of the subfamilies, AP-1 (activating protein)/ATF (activating transcription factor) and ATF/CREB are affected by E1A. The AP-1 family includes AP-1, jun and fos. The ATF/CREB family contains ATF1-4, CREB and CREM. These two subfamilies bind similar consensus DNA response elements [CRE (cAMP), S(serum)RE, T(TPA)RE)] and they can heterodimerize among themselves. There are altered repertoires of the transcription factors in E1A-expressing cells, which can generate novel transcription potentials. E1A affects c-jun, junB, c-fos, ATF-2, ATFa and ATF3. The expression of c-jun, junB and ATF3 is upregulated. A novel dimer between ATF3 and c-jun has been observed. E1A can activate or inhibit c-jun containing dimers depending on the dimeric partner. CR1 activates ATF-2 promoters that have jun1 and jun2 sites. c-jun can also associate with CBP, which can then be repressed by the E1A NTR and CR1. p300 interferes with c-jun/c-jun and c-jun/c-fos dimers. E1A 12S binds to AP-2 via a p300-independent region of the N-terminus. The relationship of all these transcriptional effects and immortalization and cotransformation has not been elucidated.

Cell Cycle Activation and Proliferation

E1A is able to overcome many growth inhibitory conditions. Ad normally infects quiescent cells and E1A, being an immediate early viral gene product, encodes functions to activate cells into the cell cycle, even in the absence of serum. These are accomplished by CR1, CR2 and the NTR in the first exon. These same regions are required for immortalization and cotransformation. E1A inhibits the breakdown of the E2F transcription factors that regulate cell cycle as well as releasing pocket protein (pRb)-E2F complexes (see above). The binding of CR2 to p107, but not to p300 or pRB, counteracts the p107-mediated repression required to activate transcription of cyclin A. This contributes to E1A being able to override negative growth controls. E1A CR1 enhances the expression and activity of the mitogen-inducible p70 S6 kinase (p70s6k), which is essential for G_1 progression.

Proliferating nuclear antigen (PCNA) is an E1A12S-inducible factor linked to DNA replication and cell cycle progression. Its promoter contains a 12S-sensitive, *cis*-acting element (PERE) that confers 12S inducibility. PERE binding proteins include ATF-1 (activating transcription factor) and CREB, which form heterodimers. CBP binds to CREB. Thus, 12S transactivates the PCNA promoter via the CBP-CREB-PERE pathway.

TGFβ is a regulator of proliferation and differentiation. It is a growth inhibitor for epithelial, endothelial, lymphoid and myeloid cells. E1A, especially the 12S protein, can overcome the growth inhibitory effects of TGFβ. This is due to the sequestration of pRB that blocks induction of cdk inhibitors such as p15/INK4, p21/WAF/CIP/SDI and p27KIP1 by TGFβ and provides another mechanism by which to override negative regulation of cell cycle progression. E1A also blocks transcriptional activation by TGFβ and this is dependent on the p300 interaction. E1A also binds to KIP and blocks its inhibitory effect, thereby restoring the activity of cyclin-cdk2 kinase and -cdk4 in TGFβ-treated cells. junB induction by TGFβ is reduced. E1A induces transcriptional downregulation of the TGFβ type II receptor due to decreased expression of transcription factor complexes that interact in the promoter at PRE1 and PRE2 sites.

The p53 tumor suppressor induces cell cycle arrest or apoptosis, depending on other conditions. Overcoming p53 and apoptosis are essential to the transformation pathway. E1A represses p53 transcriptional activation and abolishes p53 effects, including p53-mediated transactivation of the cdk inhibitor, p21/WAF/CIP/SDI, MDM2 or bax, a pro-apoptotic member of the bcl-2 family (*see also* **Apoptosis and virus infection**). This probably contributes to the ability of E1A to overcome apoptosis and effect immortalization/transformation. Repression of p53 effects requires the p300/CBP binding domain in the NTR.

Different cell types (neurons, skeletal and heart myocytes, adipocytes and keratinocytes) undergo terminal differentiation, which requires definitive withdrawal from the cell cycle. This is probably due to the induction of p21 WAF/CIP/SDI. Terminally differentiated cells are postmitotic and cannot be growth factor-stimulated. In addition to inducing the proliferation of reversibly growth arrested (quiescent) established or primary cells, 12S can induce full reentry into the cell cycle, including DNA synthesis, mitosis, cytokinesis and extended proliferation in otherwise permanently non-mitotic cells. p300 activates p21 expression and E1A binding to p300 represses it co-activator function, which enables E1A to overcome the block to cell cycle progression.

Immortalization

Normal primary cells exhibit a limited life span in culture and eventually undergo senescence. Immortal-

ization of cells, whereby the cells escape from senescence and apoptosis and acquire unlimited proliferative potential, has been considered an important and an early event in multistep tumorigenesis. Several studies indicate that immortalization itself is a multistep process. E1A 12S has been shown to be able to immortalize a variety of cell types (epithelial, endothelial and neuronal). These cells maintain many of their structural and ultrastructural and differentiated characteristics. Continuous expression of E1A is required for these cells to survive. E1A immortalized cells do not grow in soft agar or induce tumors in even nude mice or syngeneic animals. The various functions required for immortalization have been mapped to five regions, located in both exons of the 12S gene. Regions CR1 and CR2 in the first exon are necessary to activate quiescent cells into the cell cycle and increase the number of population doublings, however, they are insufficient to maintain the cells in a proliferative mode. The extreme N-terminus is also required, and its absence results in an earlier loss of proliferation, but the mechanism remains unclear. It most probably involves p300/CBP interactions and inhibition of p53 suppression of proliferation. Coexistence of strong E1A stimulation of the cell cycle and a conflicting growth suppressive signal can lead to apoptosis. Expression of the first exon (NTR + CR1 + CR2) enables primary cells to escape the M_1 phase of mortality, but not the M_2 phase and thus cannot extend their lifespan. The NTR, CR1 and CR2 are also required for cotransformation with E1B and *ras*. Expression of CR4 and CR5, in the second exon of 12S, is required to enable the cells to also overcome the M_2 mortality block and thus escape from senescence and become immortalized. The second exon seems to be required for performing a late crucial, function in immortalization, involving the reactivation of the cell cycle. Immortalization-competent 12S gene products induce the expression of a novel 110 kDa protein, p110, that forms a stable complex with rasGAP. Failure to induce the p110-rasGAP complex results in the concomitant loss of ability of 12S to immortalize primary epithelial cells. p110 induction is independent of the ability of 12S to activate the cell cycle and of the presence of adenovirus E1B and is not observed in the presence of the large T antigen of SV40. Thus, it is not a general response to proliferation or tumorigenic transformation, but rather seems to be specific to the immortalization function(s) of E1A 12S. The only identified protein to interact with the C-terminus is CtBP, which interacts with six amino acids in CR5. Efficient nuclear localization is required for immortalization and cotransformation with E1B, but not cotransformation with Ha-ras or v-src. A five amino acid nuclear localization signal (NLS) is found at the very C-terminus, and is part of CR5. Regions upstream of the NLS are also required for efficient nuclear targeting. Cooperation with E1B requires all the same E1A regions as immortalization by E1A, which is not surprising since the two genes have co-evolved.

Cotransformation

Expression of E1A on its own cannot bring about tumorigenic transformation, but rather enables the unlimited growth potential of cells, or immortalization. This is consistent with its function as a stimulator of the cell cycle in the virus lytic cycle. Coexpression of E1A with some viral or cellular oncogenes that cannot bring about transformation of primary cells on their own can result in transformed cells that can now grow in soft agar and form tumors in nude mice or syngeneic animals. These include AdE1B, Polyoma middle T, v-src and Ha-ras, but not v-raf, v-mos, V12rac, or V12cdc42. The eukaryotic translation initiation factor EIF-4E, which regulates the efficiency of translation, can transform in the presence of E1A or v-myc. Expression of antisense E1A in these transformed cells results in their apoptosis, thus they are continuously dependent on E1A for their viability. Individual oncogenes require different functions of E1A for cotransformation. E1B requires all the same regions and functions as immortalization does. Ha-ras only requires CR1, CR2 and the NTR and v-src only requires CR1 and CR2.

Oncogenicity

The highly oncogenic Ad serotypes of subgroups A (Ad12) and B (Ad3) are tumorigenic in immunocompetent animals, whereas the other serotypes are not. Ad12E1A suppresses multiple genes important for antigen processing and presentation. There is suppression in the transport and surface expression of all MHC class I antigens. There is a reduction in the TAP1 and TAP2 peptide transporters and proteasome associated gene expression. In addition, β_2-microglobulin is retained in the cell free of class 1 antigen, further subverting the major histocompatability complex. This enables the immunoescape of the Ad12-infected cells from CTL recognition and their development into tumors. Ad12-infected cells are also resistant to NK lysis. Ad12 E1A has a unique peptide segment that is contiguous with and separates CR2 and CR3. This unique peptide is also in the highly oncogenic simian adenovirus 7 E1A, but is not present in E1A from the non-oncogenic Ad5. This spacer region is an oncogenic determinant because it targets the MHC class I transcriptional enhancer and down-

regulates it. This enables immunoescape and, consequently, *in vivo* tumor formation. There is repression of MHC due to the loss of binding of the activator NFkB (p50/p65) to the region I enhancer (R1 element, H2TF1) and increased binding of COUP-TF (an orphan hormone receptor protein and a repressor) to region II (R2 element, CREII, class I-regulatory element II). There are not decreased levels of NFkB. Ad5 E1A has no such effects. In addition, CTL epitopes are encoded by Ad5, but not Ad12 E1A, further assisting immunoescape by Ad12 E1A expressing cells.

Differentiation

E1A has been shown to have two very different effects on cellular differentiation and these involve different regions of the gene. E1A12S can immortalize a variety of cell types (epithelial, endothelial and neuronal) that maintain their structural and differentiated phenotypes. E1A promotes epithelial characteristics in some tumor cell types, thereby partially reversing/suppressing the transformed phenotype, or at least diminishing the more aggressive growth characteristics and this has been attributed to CR4 and CR5. Mutations in the C-terminus result in the aberrant localization and loss of function of several cell–cell junctional complexes, including adherens junctions, which are cell–cell adhesion complexes that are hallmarks of epithelial differentiation. Loss of adherens junction function contributes to the progression of tumors to a more malignant phenotype. Introduction of an intact 12S gene suppresses this phenotype, without altering the proliferative potential of the cells. Similar results have been obtained with retinoic acid, a known inducer of differentiation, but this is accompanied by a slowing of cellular proliferation. E1A has been shown to induce differentiation of F9 teratocarcinoma and P19 embryonal carcinoma (EC) cells. An E1A-like activity in EC cells is required for differentiation by retinoids. c-jun is upregulated in response to RA or E1A during differentiation of F9 cells.

E1A inhibits terminal differentiation of skeletal and cardiac myoblasts and can reactivate the cell cycle in terminally differentiated skeletal muscle cells and suppress myocyte-specific expression. Expression of the myogenic, basic helix-loop-helix transcription factors, myogenin and MyoD also maintain cell cycle arrest. These transcription factors are repressed by E1A, but Myf5 is not. B-lymphocyte differentiation can also be inhibited by E1A. These cell types, whose differentiation can be inhibited by E1A, are of mesenchymal and not epithelial origin. This E1A phenotype has, in general, been attributed to the p300/CBP binding domain of the N-terminus. A role for CR1 has also been reported. It is also possible that the powerful stimulation of proliferation by the E1A N-terminus (NTR + CR1 + CR2) is antagonistic to such terminal differentiation and that this contributes to the loss of terminal differentiation in these cell types. Epithelial cells are more likely to be quiescent and able to be stimulated to proliferate without losing their differentiated properties. It is also possible that the presence of an intact C-terminus, which seems to be involved in maintaining epithelial characteristics, could participate in the 'epithelialization' or the prevention of a non-epithelial phenotype. The effect of C-terminal mutations on the inhibition of differentiation of mesenchymal cells has not been investigated.

Modulation of Transformation: Tumor and Metastasis Suppression

E1A is an immortalizing oncogene. Paradoxically, E1A has been shown to suppress transformation, *in vivo* tumorigenicity and metastasis, and consequently has also been considered an anti-oncogene or tumor suppressor. Cells transformed with a wild-type E1A give rise to cells that are transformed, but are equivalent to benignly transformed cells. They do not metastasize in immunocompromised rodents. The highly metastatic human melanoma cell line, BLM, is suppressed by E1A, along with the coordinate repression of a series of progression markers. Reduced oncogenicity in nude mice is also observed. Matrix metalloproteinases are important in the invasion and metastasis of tumor cells. E1A inhibits expression of matrix-degrading proteases, which are needed for cells to degrade the ECM and metastasize. This occurs through interfering with the DNA-binding capacity of cjun/cjun and cjun/cfos dimers. This requires CR1 and CR3. WT E1A suppresses ras and neu transformation. Neu (c-erbB, HER2) commonly occurs in human cancer and enhances tumor metastasis and chemoresistance. This can be suppressed by E1A and requires the NTR and CR1, but does not require CR2. This region of E1A represses neu overexpression by repressing promoter activity. E1A 12S reduced the anchorage-independent and tumorigenic growth of a variety of tumor cell types, but not their normal culture growth properties. E1A represses expression of the CD44 adhesion protein, which has been shown to confer metastatic potential. E1A can induce NM23, a nucleoside diphosphate kinase and a marker of low metastatic ability. E1A also promotes epithelial characteristics in some tumor cell types, thereby partially reversing/suppressing the transformed phenotype or at least diminishing the more

aggressive growth characteristics and this has been attributed to the C-terminus. Mutants that fail to bind to CtBP also give rise to metastases with an activated ras, whereas WT12S does not. It would appear that the region of E1A required for induction/maintenance of epithelialization and suppression of transformation progression, at least with ras, are the same. It is possible that the C-terminus could also contribute to the inhibition of non-epithelial differentiation pathways. The C-terminus of E1A 12S could be regulating epithelial–mesenchymal transitions (EMT) and deletions in this region result in EMT, contributing to tumor progression. EMT has been attributed to tumor progression.

Conclusions

E1A is a complex, multifunctional protein. It can affect a broad range of processes in cells. Analysis of E1A and its mechanisms of controling the cell has provided a vast amount of insight into the workings of the cell, from cell cycle to transcriptional regulation. It has led to the identification of many cellular proteins involved in these processes and to an understanding of how they function. E1A has provided and continues to provide a very fruitful model system to dissect proliferation, immortalization, tumorigenic transformation, metastasis, differentiation and transcriptional regulation. At times it seems as if E1A elicits contradictory behaviors. Some of these paradoxes may be a reflection of the multitude of different experimental systems in which it is used. But in all these cases, insights into the workings of cells, normal and otherwise, have been obtained. Underlying all the observed functions must be a unifying theme: to facilitate viral reproduction, since that is the function of any and all viral genes. It is important to keep this in mind when we interpret experimental results.

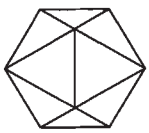
AFRICAN SWINE FEVER VIRUS (*ASFARVIRIDAE*)



María L Salas, Centro de Biología Molecular 'Severo Ochoa' (CSIC-UAM), Universidad Autónoma de Madrid, Madrid, Spain

History and Geographic Distribution

In 1921 Montgomery described African swine fever (ASF) as a peracute disease of domestic pigs caused by a virus. The disease was first recognized after the introduction of domestic pigs to Kenya in 1910. Montgomery established the likely transmission of ASF from wild swine and reported the lack of protection by passive immunization.

In 1957 the disease appeared for the first time outside Africa, in Portugal, and in 1960 spread to Spain. In the 1960s and 1970s the virus was found in France, Italy, Sardinia and Malta and, in America, in Cuba, Brazil, Dominican Republic and Haiti. In 1985 there was an ASF outbreak in Belgium and in 1986 in The Netherlands. Today, ASF is enzootic in sub-Saharan Africa and Sardinia.

Taxonomy and Classification

ASF virus (ASFV) is a deoxyvirus with an icosahedral morphology that multiplies in the cytoplasm of the infected cell. Because of these characteristics, the virus

urges an evaluation of the possibility to develop protective vaccines that are effective also in young children. The extended application of bone marrow, liver and kidney transplantation and improved care of immune-compromised patients demands introduction of rapid methods for the detection and typing of adenovirus infections. Subsequently development of immunoprofylaxis in the form of safer vaccines to be used before transplantation may become justified. Epidemiological surveillance is required to detect re-emerging and previously unrecognized genome types as has been observed with Ad7, Ad19, Ad21 and Ad41.

Introduction

For a long time, adenoviruses have served as excellent tools for detailed studies on basic molecular mechanisms in mammalian cells, on the mechanism of viral oncogenesis and on gene transfer in mammalian organisms. In this brief article, it will not be possible to cover all of the recent progress accomplished in adenovirus research in a sensible way. We have therefore chosen to summarize current research on the following topics:

- The fate of viral DNA in mammalian cells.
- The abortive infection of hamster cells with human adenovirus type 12 (Ad12).
- Viral DNA integration and oncogenesis.
- A third generation adenovirus gene transfer vector.

References to more comprehensive surveys on ongoing adenovirus research have been listed under Further Reading.

Fate of Viral DNA in Mammalian Cells

The fate of foreign DNA in mammalian cells is of general biological interest. Foreign DNA can integrate into the genomes of mammalian cells, and this process plays major roles in viral oncogenesis and in the generation of transgenic organisms and will be important in evolving regimens for human somatic gene therapy. At least in cell culture, foreign DNA can be taken up by mammalian cells under appropriate conditions or in a stabilized conformation, e.g. in a complex with basic proteins.

Human adenovirus type 12 (Ad12) infects human cells productively and leads to viral DNA replication, whereas infection of Syrian hamster cells remains abortive with total blocks in viral DNA replication and late viral gene transcription. In abortively Ad12-infected BHK21 cells, the viral DNA can be integrated into the cellular genome early after infection. Viral oncogenesis by Ad12 has been demonstrated in

newborn hamsters. In Ad12-transformed or Ad12-induced hamster tumor cells, the viral genome is found exclusively in a chromosomally integrated form.

The abortive infection of Syrian hamster cells with Ad12 facilitates monitoring the fate of viral DNA without interference by large amounts of newly synthesized Ad12 genomes. It is possible to introduce the viral DNA via different pathways. Cells can be naturally inoculated with the virus, the viral DNA can be transfected into the cell or, very gently, DNA can be directly added to the maintenance medium, either in protein complexes or as isolated DNA. The fate of Ad12 DNA at the single cell level can be followed by fluorescent *in situ* hybridization. This technique is sensitive enough to detect single copies or even fragments of an Ad12 genome per cell and to localize the foreign DNA in the nucleus and on cellular chromosomes.

Productive infection of human cells and abortive infection of hamster cells with Ad12

The inoculation of human or hamster cell lines with Ad12 leads to the transport of viral DNA into the nuclei of the cells and to the extensive association of viral DNA with the host cell chromosomes as early as 2 h postinfection (p.i.). Chromosomal association appears to be more efficient in productively infected permissive human cells (**Fig. 1C, E**) than in abortively infected nonpermissive hamster cells. Upon Ad12 superinfection, the Ad12-transformed Syrian hamster cell line T637, which carries multiple copies of integrated Ad12 DNA in a single chromosomal location (arrowhead in **Fig. 1B**), also exhibits extensive, apparently random chromosomal association of the superinfecting Ad12 genomes (**Fig. 1D**). The chromosomal association of adenoviral DNA remains stable even under conditions of high ionic strength or detergents and resists chromosomal stretching followed by mild fixation.

Transfection of human or Syrian hamster cells with Ad12 DNA

The application of the standard Ca^{2+}-phosphate precipitation method also leads to chromosomal association of the foreign DNA but seems to be less advantageous for cell survival and continuous growth.

Direct addition of Ad12 DNA to the maintenance medium

When Ad12 DNA is directly added to the growth medium of BHK21 hamster cells, an association of adenoviral DNA with the host cell chromosomes can also be documented (**Fig. 1H**), without any visible alteration of the thus treated cells. When plasmid DNA or bacteriophage M13 DNA are added, no significant chromosomal association can be observed. Chromosomal association of Ad12 DNA is markedly increased when Ad12 DNA still carrying the covalently linked terminal protein (Ad12-DNA-TP) is added to the medium. This finding raises the question of which function the terminal Ad12 protein might serve in the chromosomal association and integration of viral DNA.

Long-term studies on the chromosomal association of Ad12 DNA in abortively infected hamster cells reveal that the majority of the viral DNA will be eliminated from the cells after 90 h p.i. The loss of viral DNA may be due to a selective growth disadvantage of hamster cells carrying the foreign genome due to damages caused by the massive integration/association of foreign DNA and/or to an inherent instability of the chromosome-associated or integrated Ad12 DNA molecules. Stable integration of foreign DNA and concomitant survival of cells are probably rare events. The extensive association of Ad12 DNA with chromosomes of permissive human or nonpermissive hamster cells suggests a pathway for the interaction of foreign DNA with the chromatin of the target cells. In selected instances and at appropriately structured chromosomal sites, e.g., transcriptionally active regions, the association of foreign DNA may lead to its covalent linkage to the target cell genome.

Abortive Infection of Hamster Cells with Ad12

Upon the abortive infection of hamster cells with Ad12, defects in cell surface adsorption, entry and transport of Ad12 to the nucleus do not appear to account for the abortive infection in BHK21 cells. Ad12 virions enter the cells and viral DNA reaches the nucleus, where it can be integrated into the cellular genome. Early Ad12 mRNAs are synthesized in abortively infected hamster cells. *In vitro* translation studies have shown that most of the early Ad12 mRNAs isolated from BHK21 cells can be translated *in vitro* into viral proteins that are similar to the proteins translated *in vitro* from Ad12 mRNAs which have been isolated from productively Ad12-infected human cells. However, *in vitro* translation of Ad12 mRNAs isolated from Ad12-infected hamster cells reveals the lack of a 34 kDa protein, which is produced when mRNAs from productively infected human KB cells are translated. Moreover, in immunoprecipitation analyses of cellular extracts, Ad12 E1A-

specific proteins are detectable at 6 h p.i. in KB cell extracts, but not before 12 h p.i. in BHK21 cell extracts. The concentrations of Ad12 E1A and E1B proteins in abortively infected BHK21 cells are 6- to 20-fold lower than in productively infected KB cells. Although early genes of Ad12 are expressed in Ad12-infected BHK21 cells, the replication of Ad12 DNA is completely blocked.

Upon productive adenovirus infection, viral DNA replication is initiated within the inverted terminal repeats (ITRs) of the linear genome and proceeds by a strand displacement mechanism. Three viral gene products encoded in the E2 region of adenoviral DNA, the DNA-binding protein (DBP), the preterminal protein (pTP) and the adenoviral DNA polymerase (Ad pol), participate in adenoviral DNA replication. The initiation of adenoviral DNA replication is dependent on a protein-priming mechanism and requires pTP to be covalently bound to dCMP at the 5′-terminus. pTP must then interact with Ad pol. After this initiation reaction at either terminus, elongation proceeds from one or both termini to the opposite DNA end by the addition of nucleotides to the free 3′-OH group of the covalently bound dCMP. Elongation requires Ad pol and DBP. On the cellular side, nuclear factors I, II and III (NFI–NFIII) are essential for viral DNA replication. NFI and NFIII bind specifically to the origin of replication (ori) and form a stable preinitiation complex at the ori with the three viral proteins. NFII, which is related to topoisomerase I, is important for the elongation reaction. The activities of Ad pol and pTP for the initiation of DNA replication *in vitro* are equivalent in extracts from Ad12-infected BHK21 and KB cells. In contrast, the amount of Ad12 DBP is >100-fold lower in infected BHK21 cells than in infected KB cells. Thus, the reduced expression of the viral DBP may play a role in the mechanism of abortive infection of hamster cells by Ad12.

In BHK21 cells doubly infected by Ad2/5 and Ad12 or in Ad12-infected BHK297-C131 hamster cells, a cell line carrying and expressing the E1 region of Ad5, Ad12 DNA can replicate. On the other hand, the Ad12 early functions, although by themselves incapable of supporting the replication of Ad12 DNA in hamster cells, can substitute for the missing E1 functions in deletion mutants of Ad5 DNA, which are then capable of DNA replication and the completion of transcriptional and translational programs in permissive human cells. During complementation, the Ad2/5 E1 gene products may act directly on the Ad12 genome by substituting for the insufficient Ad12 E1 proteins in hamster cells. Ad12 recombinants in which the E1A and/or E1B regions are replaced with E1A and/or E1B of Ad5 are viable in human cells.

The levels of NFIII are markedly reduced in nuclear extracts prepared from mock-infected BHK21 cells as compared to complementing hamster BHK297-C131, or permissive human KB or HeLa cells. Upon the abortive infection of BHK21 cells with Ad12, nuclear extracts fail to show any change in the low NFIII levels. In contrast, Ad2 infection renders the levels of NFIII in BHK21 cells comparable to those in uninfected or Ad2-infected HeLa or BHK297-C131 cells. Another cellular factor which is required for efficient initiation of adenoviral DNA replication, NFI, does not appear to be limiting in the Ad12-BHK21 system. In productively Ad12-infected human cells, the structure of the promyelocytic leukemia (PML) protein arrays in the nuclei of infected human cells is markedly altered. Similar alterations have not been observed upon the abortive infection of hamster cells with Ad12. Since the redistribution of the PML protein is thought to be associated with adenoviral DNA replication in the nucleus, the absence of structural changes in the PML arrays may be related to the replication defect of Ad12 DNA in hamster cells.

The transcription of the late Ad12 genes and of the virus-associated (VA) RNA is also blocked in hamster cells. The major late promoter (MLP) of Ad12 does not function in Ad12-infected BHK21 hamster cells. The transcriptional defect of Ad12 DNA in hamster cells has thus been, at least partly, localized to the viral MLP. A 33 nt mitigator sequence, which is located in the downstream region of the Ad12 MLP, is responsible for the inactivity of the Ad12 MLP in hamster cells. Removal of this mitigator activates the Ad12 MLP in hamster cells and increases its activity in human cells. Because a similar negative regulator has not been found in the MLP of Ad2 DNA, the mitigator seems to be specific for the Ad12 MLP and might contribute to the abortive infection of Ad12 in hamster cells. The shutdown of major viral replicative functions may be a prerequisite for the malignant transformation of hamster cells by Ad12.

The late mRNAs of Ad12, which can be transcribed in the complemented system of Ad5-transformed BHK297-C131 cells, are polyadenylated, but are synthesized in reduced amounts as compared with the levels of Ad12 mRNAs in Ad12-infected human cells. The late Ad12 fiber gene-derived mRNA exhibits the authentic nucleotide sequence and carries the complete tripartite leader. Nevertheless, this RNA is not translated into fiber protein, even in the Ad5-complemented hamster cell system. It is therefore likely that cellular functions, either structural or enzymatic, which are required for the efficient translation of late Ad12 mRNAs, may also be missing in hamster cells. Thus, the abortive infection of

BHK21 cells with Ad12 is complex and related to the deficiency or altered activity of both viral and cellular functions.

Viral DNA Integration and Oncogenesis

The persistence of adenovirus DNA in an integrated state in hamster or other rodent cells is frequently associated with the transformed or oncogenic phenotype. In virus-transformed and virus-induced tumor cells, the integrated adenovirus genomes continue to be expressed. In general, early viral genes are transcribed and translated. Some of the early adenovirus proteins interact specifically with cellular proteins. The 289 amino acid protein encoded in the E1A region can bind to the gene product of the retinoblastoma (RB) gene, a tumor suppressor gene. Similarly, the 55 kDa protein encoded in the E1B region of the adenovirus genome has been shown to complex the p53 and similar cellular proteins. A strong case has been made for the notion that these specific interactions of certain adenovirus proteins with the products of cellular antioncogenes or tumor suppressor genes might interfere with the regulation of cell growth, in that the cells then override the apoptotic harnesses and are shifted on to a path of unlimited replication, possibly leading to tumor development. It remains to be proven that the sequestration of one or several tumor suppressor gene products in the cell would in fact suffice to transform a cell to the oncogenic phenotype. Cellular growth regulation seems to be subject to and safeguarded by several alternative pathways.

Viral DNA integration in Ad12-transformed or Ad12-induced tumor cells can have one or several of the following consequences for the cell whose genome has been targeted for foreign DNA insertion.

1. Insertion of foreign (viral) DNA leads to the stable and permanent genomic fixation of genes or DNA segments from sources outside the targeted cell or organism. Depending on the type of foreign genes inserted and its sequence environment at the site of insertion, the foreign DNA can be expressed, silenced, subjected to the cellular regulation or influence the regulation of neighboring cellular genes. Integrated foreign DNA in an established mammalian genome is in general *de novo* methylated extensively.
2. The cellular DNA sequences in the targeted cell that are directly affected by the insertion event could be silent or without an essential function. On the other hand, insertion might have a direct topical effect or, when a functional genetic center of the cellular genome is hit, the cell might not survive or alter its growth properties (insertional mutagenesis).
3. As a novel thought, we pursue the possibility that the insertion of foreign DNA into an established mammalian genome alters patterns of cellular DNA methylation, both at sequences close to and remote from the integrate. Such changes have been demonstrated in Ad12-transformed cells and in Ad12-induced tumor cells. Alterations of patterns in cellular DNA methylation have been shown to be associated with altered transcription patterns of the cellular genes affected. This model of the consequences of foreign DNA integration predicts *trans*-effects on regions of the cellular genome which might be located remote from the site of insertion. Alterations of the transcriptional program of the cell would amount to a novel type of functional insertional mutagenesis which would not be limited to genes at the site of integrated foreign DNA but might involve more extensive parts of the cellular genome.
4. The consequences of foreign DNA insertion on the overall chromatin structure of the targeted cell have not yet been investigated. Most frequently, foreign DNA molecules are inserted as multiple copies in pseudo-tandem arrays. With Ad12 as an example, up to 20, 30 or more copies of the viral DNA can thus be genomically fixed. With a genome length of 34 125 nucleotide pairs, 30 integrated copies of Ad12 DNA amount to the addition of >1 megabase of foreign DNA to the cell's highly organized genome. It is doubtful that perturbations of this magnitude can remain without functional sequelae for the cell.

Integrated Ad12 DNA can be lost from Ad12-transformed or Ad12-induced hamster tumor cells. At least in a few examples, the total or near-total loss of integrated foreign (Ad12) genomes has been shown to be still compatible with the maintenance of the oncogenic phenotype of the revertant cells. Detailed investigations on the presence of tiny segments of Ad12 DNA in some of the originally Ad12-induced hamster tumor cells by using the polymerase chain reaction method have revealed that different cells from this initially clonal population are losing the integrated Ad12 DNA at different rates. While some of the cells in the total cell population may have lost most or actually all traces of viral DNA integrates, others may still retain small Ad12 DNA segments. These results, which are based on the analyses of cell populations derived from clonal cells, argue in favor of a mechanism to eliminate the foreign DNA integrates that proceeds in a gradual, stepwise and clone-specific way. At present, it is unknown whether

these excisions are due to random events or the results of an active recognition and defense mechanism against foreign DNA in a mammalian genome. In this context, it is interesting to recall that in revertants of cell line T637, which have lost all but one or a few copies of the integrated Ad12 DNA, the remaining Ad12 DNA sequences are more heavily methylated than in the parent T637 cell line. This finding might imply that the levels of methylation in the integrated foreign DNA are somehow related to the ability of cellular defense mechanisms to recognize recently inserted DNA as foreign and lead to its elimination from the cellular genome.

In at least some of the Ad12-induced tumor cells, the continued persistence of integrated Ad12 DNA sequences is not a precondition for the maintenance of the oncogenic phenotype. A total population of between 10^2 and 10^7 revertant cells, which have lost almost all Ad12 DNA and are injected into hamsters to test for oncogenicity, is still sufficient to lead to tumor formation in the animals.

We have also demonstrated that the alterations in cellular DNA methylation patterns in the Ad12-transformed hamster cell line T637 persist in the revertant TR3, in which Ad12 DNA cannot be detected any longer by Southern transfer-hybridization experiments. It is thus likely that alterations in cellular methylation patterns and/or in cellular genome organization, which have been initially elicited by Ad12 DNA integration and viral genome products, are permanently imprinted onto the cellular genome.

Since cells originally transformed by Ad12 to tumor cells (like Ad12-induced hamster tumor cells) can maintain their oncogenic properties in spite of the loss of almost all of the integrated viral DNA from the cellular genome, the long-standing assumption that the human adenoviruses have no role in human oncogenesis has to be reconsidered. Obviously, failure to find adenoviral DNA sequences in human malignancies – even if it were confirmed with up-to-date technology – will not rule out a potential role of the virus or its genome, as it could have been lost from the human malignant cells.

A Third Generation Adenovirus Gene Transfer Vector

Somatic gene transfer has a considerable potential for the treatment of inherited or acquired diseases. Genetic diseases that are caused by loss-of-function mutations could be causally treated by introducing a functional copy of the defective gene into the appropriate tissue. Examples of genetic diseases that are good candidates for gene therapy are disorders like cystic fibrosis (CF), hemophilia A or B or hypercholesterolemia, disorders which are all caused by the absence or a low amount of a single functional gene product. In these diseases the pathogenesis has been characterized at the DNA level and the disease-causing mutations can be easily identified in each individual patient. Acquired diseases, like different types of cancer, are less well defined at the molecular level. Because of their frequency and their impact on public health, the interest in the development of gene therapy for these disorders is very high; hence, numerous clinical gene therapy trials have been conducted or have been approved. Nevertheless, so far there have been no unambiguous examples of the successful treatment of any human disease by gene transfer. Currently, one of the most significant reasons that prevent the broad application of gene transfer in the treatment of human diseases is the lack of safe and effective gene transfer technologies. Gene transfer encompasses the independent binding of the vector to the cell surface, its uptake through the cellular membrane, transport of the genetic material to the nucleus of the cell, and its expression. Several nonviral and viral gene transfer vectors have been tested *in vitro* and in different animal models of human diseases. What are the minimal requirements for the use of a viral or nonviral vector for gene transfer? The vector should be safe, nonpathogenic and stable and should be easily produced in large amounts. In addition, a vector should be able to transport and efficiently deliver foreign genes to different cell types. After gene transfer, the genes should be expressed at high levels, and these genes should preferably be regulated under tissue-specific control.

Adenoviruses have physical and genetic properties that fulfill most of these requirements. First-generation adenoviral vectors do not replicate in human cells under normal conditions because their early E1A and E1B functions have been deleted. These vectors are produced in a complementing cell line, usually in the 293 cell line, that provides the necessary E1 functions in *trans*. The results of clinical studies with first-generation adenoviral vectors have been instructive but disappointing and have led to the appreciation of several of their disadvantages.

1. Because in the 293 cell line only the E1A and E1B functions are expressed, all the other viral functions that are required for virus production need be expressed from the vector itself. Therefore, first-generation vectors still contain most of the adenoviral genes, which, if expressed in a tissue even at low levels, are believed to contribute to an antiviral immune response that

causes the clearance of transduced cells, resulting in only transient gene expression. Recent experimental data have shown that immune responses also against the transgene product are responsible for only short-term gene expression after gene transfer. For the permanent correction of a metabolic deficiency by gene transfer, however, the presence of numerous viral genes in the gene transfer vector is problematic.

2. Since the upper DNA packaging limit for adenoviruses is about 38 kb, the maximal size of foreign DNA that can be incorporated into these vector genomes is about 8 kb. Thus, the size constraints in the first-generation adenoviral vectors prevent or severely limit the use of this vector type in clinical applications. In order to decrease further the expression of late viral proteins, adenoviral vectors without the E2 and/or E4 functions, in addition to the deletion of the E1 region, have been generated. Presently, it is controversial whether these second-generation vectors have any significant advantages over the first-generation adenoviral vectors.

Recently, in an attempt to address several of the problems observed with first-generation adenoviral vectors, a new adenoviral vector has been developed that is predicted to be very useful for the functional analyses of genes *in vivo* and likely also for clinical applications. This vector, which has variably been called 'high-capacity adenoviral vector', 'gutless adenoviral vector' or 'helper-dependent (HD) adenoviral vector', has a capacity of more than 30 kb for the uptake of foreign DNA and at the same time does not contain adenoviral coding sequences. About two decades ago, several unusual types of adenoviruses were described that either had taken up large fragments of genomic cellular DNA after repeated passage of adenoviruses at high multiplicity of infection, that contained several copies of the SV40 genome, or expressed the large T-antigen of SV40. These recombinant viral genomes required for their replication the presence of functional wild-type adenovirus during productive infection of cultured cells. Interestingly, the recombinant adenoviral genomes always contained the adenoviral termini. Later it was demonstrated that the ITRs of the adenoviral genome are the adenoviral origins of replication. The only *cis*-element required for the packaging of DNA into adenoviral capsids, the packaging signal, resides between the left ITR and the E1 region. Thus, it was reasoned that it should be possible to rescue recombinant adenoviral vectors that contained large fragments of nonviral DNA and as the only adenoviral elements the left and right ITRs plus the packaging signal. The best-documented examples that demonstrate the validity of this concept concern the gene transfer of the murine dystrophin cDNA and of the human α_1-antitrypsin gene. The generation of vectors containing the 14 kb full-length dystrophin cDNA would not have been possible with first-generation adenoviral vectors. However, applying the helper virus concept, several groups could demonstrate that it was possible to rescue recombinant adenoviral vectors that did not contain any viral coding sequences. Initially, wild-type adenovirus was used as helper virus for production; later, replication-deficient adenoviruses served as helper virus. In one case the packaging signal of the helper virus was modified to impair packaging of the helper virus in order to package preferentially the recombinant vector DNA in viral capsids. It was possible to partially separate helper virus and vector by CsCl equilibrium centrifugation and thus purify the helper virus to approximately 99%. Gene transfer by intramuscular injection of the dystrophin vector into muscle of mdx mice, a genetic and biochemical model for Duchenne muscular dystrophy (DMD), resulted in the stable expression of the 400 kDa full-length dystrophin protein, correct localization of dystrophin to the sarcolemma membrane, redistribution of the dystrophin associated proteins (DAPs) to the muscle membrane and improvement of the histological phenotype. These were the first studies to demonstrate the usefulness of the new vector type for gene transfer *in vivo*. In a further development, the production system for the new vector was improved by taking advantage of the cre-lox recombination system of bacteriophage P1. In this production scheme, a helper virus is used that contains two lox-recognition sequences flanking the packaging signal. The vector is produced in 293 cells that express the cre-recombinase of bacteriophage P1. After infection of these cells by both helper virus and vector, the packaging signal of the helper virus is excised with relatively high efficiency. Thus, preferentially the vector is packaged. With this system, it is possible to facilitate production, reduce the contamination of vector with helper virus to less than 0.1% after CsCl equilibrium centrifugation, and also to increase vector yield. Using this improved production system a vector has been generated carrying the complete human α_1-antitrypsin gene locus as a 19 kb DNA fragment.

In vitro and *in vivo* gene transfer experiments with this vector were very instructive: gene transfer in mice with this genomic DNA fragment that contained the endogenous hepatocyte- and macrophage-specific promoters, all exons and introns and the endogenous polyadenylation signal of the α_1-antitrypsin gene resulted in tissue-specific and persistent gene expres-

sion over more than 40 weeks. It was demonstrated that, following liver gene transfer, transcriptional initiation was only from the liver-specific promoter, and that splicing of the primary transcript and processing of RNA and protein were normal. Gene transfer with increasing doses of this vector resulted in very high and stable α_1-antitrypsin serum levels that so far are unparalleled by gene transfer with any other tested combination of strong viral promoters and the α_1-antitrypsin cDNA. Significantly, the high serum α_1-antitrypsin levels that would be considered supraphysiological in humans were not accompanied by any significant hepatotoxicity. Gene transfer with the same dose of a first-generation vector carrying an α_1-antitrypsin expression cassette led to hepatic damage that was morphologically characterized by liver cell necroses and infiltration by granulocytes and was accompanied by significantly elevated liver enzymes in the serum. Improved expression and decreased toxicity with high-capacity adenoviral vectors were confirmed with another vector that carried the murine leptin cDNA under the control of a viral promoter. Taken together, these results indicate that high-capacity adenoviral vectors will be useful for functional studies on gene transfer and likely also for somatic gene therapy because of their improved safety and expression profiles. Their increased capacity for foreign DNA is a significant advantage over first and second generation adenoviral vectors.

Animal Viruses

William C Russell, School of Biomedical Sciences, University of St Andrews, St Andrews, Fife, Scotland

Mária Benkö, Veterinary Medical Research Institute, Hungarian Academy of Sciences, Budapest, Hungary

History

Members of the adenovirus family (*Adenoviridae*) can be recognized in virtually every class of vertebrate animals (**Table 1**). However, not all of the family members contain the same common antigen and initially two genera have been established each of them being characterized by a common (or group) antigen. The genus *Mastadenovirus* comprises viruses isolated from mammals (humans, monkey, cattle, pig, sheep, horse, dog, goat, tree shrew, deer, whale, mouse, etc.) whereas the *Aviadenovirus* genus contains viruses isolated from avian species (chicken, turkey, goose, pheasant, duck, etc.). The organization of the genome, though normally rather conserved within a genus, differs considerably between the two genera. Recently, strong evidence (based on genomic organization and phylogenetic analysis; **Fig. 1**) supported the establishment of a third genus incorporating several bovine adenoviruses (BAVs), the ovine adenovirus isolate 287 (OAV287) and the egg drop syndrome (EDS) virus which (lacking the genus-specific common antigens) had been recorded as 'atypical' members of the *Mastadenovirus* or *Aviadenovirus* genera. The proposed name of this possible third genus is *Atadenovirus* (referring to the characteristic AT-rich genome rather than the host animal taxon). The candidate BAV serotypes (4 to 8) of this proposed genus do not fit clearly into the *Mastadenovirus* genus and are presently separated as subgroup 2 from the subgroup 1 BAVs which obviously belong to the mastadenoviruses. A number of adenoviruses isolated from (or only detected in) lower vertebrate hosts (fish, frog, snake, chameleon, crocodile, etc.)

aggressive growth characteristics and this has been attributed to the C-terminus. Mutants that fail to bind to CtBP also give rise to metastases with an activated ras, whereas WT12S does not. It would appear that the region of E1A required for induction/maintenance of epithelialization and suppression of transformation progression, at least with ras, are the same. It is possible that the C-terminus could also contribute to the inhibition of non-epithelial differentiation pathways. The C-terminus of E1A 12S could be regulating epithelial–mesenchymal transitions (EMT) and deletions in this region result in EMT, contributing to tumor progression. EMT has been attributed to tumor progression.

Conclusions

E1A is a complex, multifunctional protein. It can affect a broad range of processes in cells. Analysis of E1A and its mechanisms of controling the cell has provided a vast amount of insight into the workings of the cell, from cell cycle to transcriptional regulation. It has led to the identification of many cellular proteins involved in these processes and to an understanding of how they function. E1A has provided and continues to provide a very fruitful model system to dissect proliferation, immortalization, tumorigenic transformation, metastasis, differentiation and transcriptional regulation. At times it seems as if E1A elicits contradictory behaviors. Some of these paradoxes may be a reflection of the multitude of different experimental systems in which it is used. But in all these cases, insights into the workings of cells, normal and otherwise, have been obtained. Underlying all the observed functions must be a unifying theme: to facilitate viral reproduction, since that is the function of any and all viral genes. It is important to keep this in mind when we interpret experimental results.

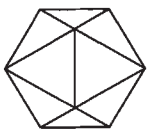
AFRICAN SWINE FEVER VIRUS (*ASFARVIRIDAE*)



María L Salas, Centro de Biología Molecular 'Severo Ochoa' (CSIC-UAM), Universidad Autónoma de Madrid, Madrid, Spain

History and Geographic Distribution

In 1921 Montgomery described African swine fever (ASF) as a peracute disease of domestic pigs caused by a virus. The disease was first recognized after the introduction of domestic pigs to Kenya in 1910. Montgomery established the likely transmission of ASF from wild swine and reported the lack of protection by passive immunization.

In 1957 the disease appeared for the first time outside Africa, in Portugal, and in 1960 spread to Spain. In the 1960s and 1970s the virus was found in France, Italy, Sardinia and Malta and, in America, in Cuba, Brazil, Dominican Republic and Haiti. In 1985 there was an ASF outbreak in Belgium and in 1986 in The Netherlands. Today, ASF is enzootic in sub-Saharan Africa and Sardinia.

Taxonomy and Classification

ASF virus (ASFV) is a deoxyvirus with an icosahedral morphology that multiplies in the cytoplasm of the infected cell. Because of these characteristics, the virus

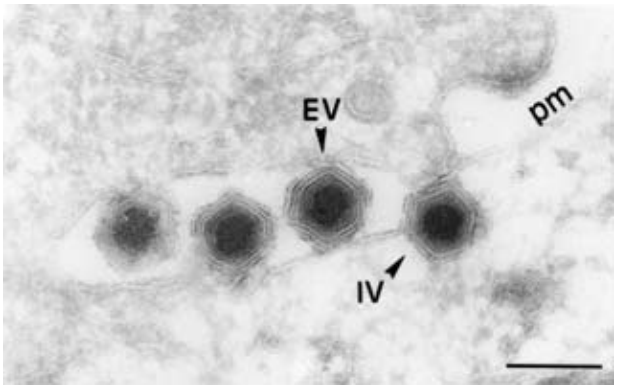


Figure 1 Electron micrograph of a cryosection of ASFV-infected Vero cells. The electron micrograph shows an intracellular virus particle (IV) and three extracellular virus particles (EV). pm, plasma membrane. Bar = 200 nm. (Courtesy of G. Andrés.)

has been classified for many years as an *Iridovirus*. However, several properties of ASFV are similar to those of poxvirus. The genome of ASFV resembles that of poxviruses in the presence of covalently closed ends and terminal inverted repetitions (see later). In contrast, the genomes of frog virus 3 and two other iridoviruses are both circularly permuted and terminally redundant. In addition, ASFV particles contain, like those of poxvirus, all the enzymatic machinery necessary for the synthesis and modification of early mRNA. Frog virus 3 particles do not contain RNA polymerase, and RNA synthesis in cells infected with frog virus 3 is sensitive to the host RNA polymerase II inhibitor α-amanitin, whereas transcription of the ASFV genome is resistant to this inhibitor.

ASFV has recently been assigned to a new family, *Asfarviridae*, as a member in the genus *Asfivirus*.

Virion Structure and Proteins

The ASFV particles have an icosahedral morphology and consist of a DNA-containing nucleoid of about 80 nm, a thick protein layer of about 30 nm, designated the core shell, a lipid envelope surrounding the core shell, the capsid, and, in the case of the extracellular virus, an outer membrane derived by budding through the plasma membrane (**Fig. 1**). The extracellular virions have a diameter of 200 nm. The capsid consists of a hexagonal arrangement of capsomers that appear as 13 nm long hexagonal prisms, each with a central hole. The intercapsomer distance is about 8 nm and the triangulation number is estimated to be between 189 and 217, corresponding to a number of capsomers between 1892 and 2172.

Two-dimensional gel electrophoresis analysis of purified virions has resolved 54 structural proteins with molecular weights ranging from 10000 to 150000. Some of these proteins have been localized in the virion by immunoelectron microscopy. The virus attachment protein p12 and protein p24 are present in the external region of extracellular virions, while proteins p150, p37, p34 and p14, products of polyprotein pp220, are found in the core shell. Protein p72, located in the surface of unenveloped intracellular virions, is the capsid protein.

ASFV particles contain a DNA-dependent RNA polymerase and other activities involved in the polyadenylation, methylation and capping of RNA. Other enzymes present in the virions are a protein kinase, two nucleoside triphosphate phosphohydrolases, an acid phosphatase, and a deoxyribonuclease active on single-stranded DNA.

The genes coding for 15 virion proteins have been identified and sequenced (**Fig. 3**). Two of these genes code for polyprotein precursors. Thus, gene *CP2475L* encodes a polyprotein of 220 kDa, which, after proteolytic cleavage, gives rise to four major structural proteins: p150, p37, p34 and p14; gene *CP530R* encodes polyprotein pp62, the precursor of proteins p35 and p15.

Properties of Genome

The genome of ASFV is a linear double-stranded DNA molecule with a size that oscillates between 170 and 190 kbp, depending on the virus isolate. The two DNA strands are covalently closed, at both ends, by a 37 nucleotide-long hairpin loop, composed, almost entirely, of incompletely paired A and T residues. The loops at each DNA end are present in two equimolar forms (fast and slow components) that, when compared in opposite polarities, are inverted and complementary (flip-flop), as in the case of poxvirus DNA (**Fig. 2A, B**). There is no homology between the hairpin loops of ASFV and vaccinia virus but, close to the hairpin loops, both viruses have a sequence 16 nucleotides long with a homology of about 80%. Following the hairpin loops there is a perfect terminal inverted repeat (TIR) with a length of 2134 nucleotides, which consists of unique sequences interspersed with five different sets of repeated sequences (**Fig. 2C**). The central region of the TIR contains 33 direct repeats in tandem of 34 nucleotides.

In addition to the TIRs, two types of internal repetitions have been described: short (10–50 bp) direct repeats in tandem at both intergenic and intragenic positions, and long (200 bp) tandemly repeated units found at the left end of the genome. The latter repeated sequences share similarities with eucaryotic scaffold-associated region (SAR)-like sequences.

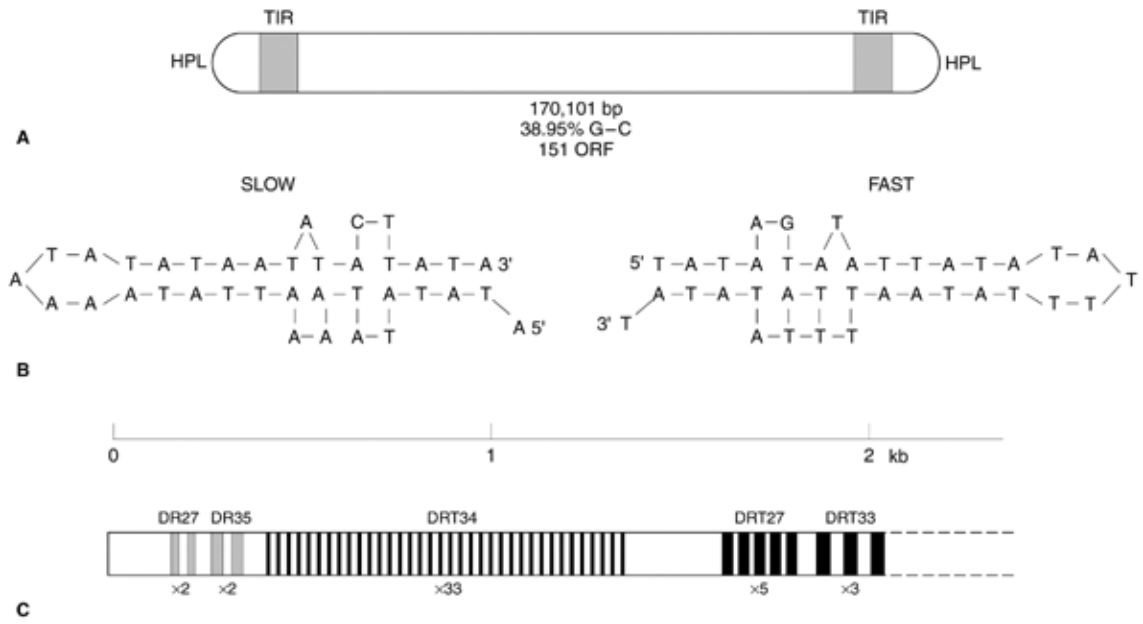

Figure 2 Structure of the ASFV genome. (**A**) ASFV DNA (BA71V strain). HPL, hairpin loop; TIR, terminal inverted repetition. (**B**) Predicted secondary structure of the 37 nucleotide-long fast and slow components in the HPLs. (**C**) Structure of the TIR. The TIR is 2134 nucleotides long and consists of unique sequences (in white) interspersed with two types of direct repeats (DR) and three sets of direct repeats in tandem (DRT).

The genome of ASFV strain BA71V has been completely sequenced and shown to contain 170101 bp, with a G-C content of 38.95%. Analysis of the DNA sequence has identified 151 major open reading frames (ORFs). A list of the ASFV genes encoding proteins for which there is functional information or significant homology is presented in Fig. 3.

Penetration

ASFV infection starts with the interaction of the virus with a cell receptor. Titration experiments have shown the existence in susceptible Vero cells and swine macrophages of a specific receptor for the Vero cell-adapted virus. Virus penetration takes place by a mechanism of adsorptive endocytosis that is sensitive to lysosomotropic drugs. Nonproducing L cells and rabbit macrophages lack specific binding sites, indicating that the presence of receptors is necessary for a productive infection.

Protein p12, encoded by ORF *O61R*, has been identified as the virus attachment protein. ORF *O61R* codes for a polypeptide of 61 amino acids with a putative transmembrane hydrophobic domain in the central region that may anchor the protein in the virus envelope. Three forms of the protein with molecular masses of 17, 12 and 10 kDa have been observed in SDS-polyacrylamide gel electrophoresis, depending on the presence of 2-mercaptoethanol and the alkylation with 4-vinyl-pyridine, indicating that disulfide bonds are responsible for the multimerization of the protein. This result is in agreement with the existence of a cysteine-rich domain in the C-terminal region of the predicted amino acid sequence. In ASFV-infected cells, protein p12 is synthesized at late times of infection. The comparison of the amino acid sequence of protein p12 in different field virus isolates, deduced from the nucleotide sequence of the gene, reveals a high degree of conservation. No mutations were found after adaptation to Vero cells. Protein p12 is synthesized in swine macrophages infected with all the isolates tested. These findings suggest an essential role of the protein in the virus replication cycle, and indicate that the variability of protein p12 is not a mechanism used by ASFV to evade the host immune response.

DNA Replication and Repair

The replication of ASFV DNA does not occur in enucleated cells. The results obtained by autoradiography of ASFV-infected macrophages in pulse-label and pulse-chase experiments, and by *in situ* hybridization of infected macrophages and Vero cells, suggest a mechanism for viral DNA replication with an initial stage in the nucleus followed by a cytoplasmic phase. The viral DNA in the nucleus is

Figure 3 ASFV genes with known functions or significant homology. An *Eco*RI restriction endonuclease map of the ASFV genome (BA71V isolate) is shown. Below are listed ORFs encoding proteins with known functions or significant homology to other proteins in the databases. Asterisks indicate ORFs encoding structural proteins. The ORFs are designated by the name of the *Eco*RI fragment where translation is started (the letter 'P' substituted for the prime apostrophe), followed by the number of amino acids encoded and a letter, L or R, indicating the direction of transcription (leftwards or rightwards).

localized as a single focus in proximity to the nuclear membrane. The replication of ASFV DNA is thus similar to that of the iridovirus frog virus 3 in the two-stage mechanism, even though the structure of the ASFV genome is different from that of frog virus DNA, and therefore the molecular mechanisms of DNA synthesis are probably also different. An analysis of ASFV replicating DNA molecules has shown the existence of head-to-head and tail-to-tail linked molecules that may be replicative intermediates formed by some of the mechanisms proposed for poxvirus DNA replication.

The synthesis of ASFV DNA requires a virus-induced DNA polymerase which is sensitive to phosphonoacetic acid, and is probably encoded by ORF *G1207R*, homologous to α-like DNA polymerases. Three other enzymes involved in DNA and nucleotide metabolism are induced in cells infected with ASFV: a thymidine kinase, a ribonucleotide reductase and a DNA ligase. The genes coding for these enzymes, as well as the genes encoding proteins homologous to thymidylate kinase and the proliferating cell nuclear antigen (PCNA), which is a processivity factor for DNA polymerase δ, have been identified and sequenced (**Fig. 3**).

ASFV also encodes several enzymes of a DNA repair system of the base excision repair type, including an apurinic/apirimidinic (AP) endonuclease and the product of gene *O174L*, which has been characterized as a pol β-type DNA polymerase.

Transcription of the ASFV Genome

ASFV particles contain all the enzymatic machinery necessary for the synthesis and modification of virus-specific RNA. *In vitro* transcription by ASF virions requires high concentrations of ATP and is inhibited by the topoisomerase II inhibitor coumermycin A1, suggesting that transcription of ASFV DNA requires a topoisomerase II. A gene (*P1192R*) coding for a topoisomerase II has been identified and sequenced. Six subunits of the virus RNA polymerase have been identified by sequence similarity, suggesting that the enzyme is a multisubunit protein (**Fig. 3**). A gene homologous to the eucaryotic transcription factor SII (ORF *I243L*) has also been identified, and the protein

product of gene *NP868R* has been shown to be a guanylyltransferase.

The RNAs synthesized *in vitro* by the virion-associated RNA polymerase have methylated CAP structures and poly(A) tails. These RNAs are complementary to the same DNA regions as those synthesized in ASFV-infected cells in the presence of cycloheximide or cytosine arabinoside, and the two RNAs give rise to the same polypeptides after hybridization-selection with DNA restriction fragments and translation *in vitro*, suggesting that, before DNA replication, the early viral RNAs are synthesized by the RNA polymerase present in the virus particles. A subclass of early genes, designated immediate early, whose transcription is silenced before the onset of DNA replication, and an intermediate class of mRNAs, with the characteristics of the poxvirus intermediate transcripts, have also been identified. Late genes are expressed after the initiation of DNA replication. The existence of early, intermediate and late mRNAs suggests a cascade model for the regulation of ASFV gene expression.

The mRNAs have short leader sequences before the translational start site and the 3′ ends of several early and late genes map within a conserved sequence motif formed by at least seven thymidylate residues (7T).

The host RNA polymerase II is not involved in the transcription of ASFV genes, as cells infected in the presence of α-amanitin or 5,6-dichloro-β-D-ribofuranosyl benzimidazole synthesize RNAs and proteins that are indistinguishable from those made in the absence of the drugs.

Proteins Induced in ASFV-infected Cells

Two-dimensional gel electrophoresis analysis of proteins synthesized in ASFV-infected Vero cells has identified 81 acid and 14 basic virus-induced polypeptides, with molecular masses ranging from 220 to 10 kDa. Three classes of ASFV-induced proteins can be defined: early proteins whose synthesis is switched-off after virus DNA replication; early proteins synthesized along the whole replication cycle; and late proteins which are not synthesized in the presence of cytosine arabinoside.

Post-translational Processing

Proteolytic processing

Polyprotein processing is an essential mechanism for the generation of major components of the virus particle. As mentioned above (Virion Structure and Proteins), six ASFV structural proteins are derived from polyprotein precursors by proteolytic cleavage at the consensus sequence G-G-X. This sequence, together with other physical properties of the protein, seems to be a recognition sequence for the processing of a variety of viral and cellular proteins.

Glycosylation

Partially purified intracellular ASFV particles, adapted to grow in monkey kidney (MS) cells, have three minor structural glycoproteins of molecular masses 89, 56, and 51 kDa. However, highly purified, extracellular ASFV particles lack major glycoproteins but contain several species of glycolipids, and two sugar-labeled components of apparent molecular masses 230 and 95 kDa, which could account for the virus agglutination with lectins. The nonprotein glycosylated components present in extracellular ASF virions have a cellular origin.

ASFV induces in Vero cells the synthesis of 19 glycosylated components of molecular masses ranging from 9 to 220 kDa. At least five of the induced glycosylated components are probably virus-coded glycoproteins. Most of these glycocomponents are synthesized at early times after infection.

Myristoylation

Polyprotein pp220 and several other proteins induced during infection of Vero cells with ASFV are covalently bound to myristic acid. Two myristoylated proteins of 28 and 13 kDa are incorporated into the virus particle.

Phosphorylation

The most highly phosphorylated protein in extracellular virus grown in Vero cells in the presence of [^{32}P]phosphate is the structural protein p17, with a molecular mass of 17 kDa. A second phosphoprotein of 35 kDa is found in ASF virions. The most abundant and immunogenic protein induced by ASFV at early times of infection, protein p32 encoded by ORF *CP204L*, is a phosphoprotein. Two-dimensional gel electrophoresis has revealed the existence of 15 ASFV-induced phosphoproteins in infected monkey cells.

Two virion proteins are preferentially phosphorylated *in vitro* by the protein kinase associated with ASF virions, the structural proteins p10 and p9, with molecular masses of 10 and 9 kDa, respectively.

Ubiquitination

ASFV gene *I215L* codes for a ubiquitin-conjugating protein, an enzyme involved in the conjugation of ubiquitin to proteins, a modification that generally targets the protein for proteolytic degradation. Three

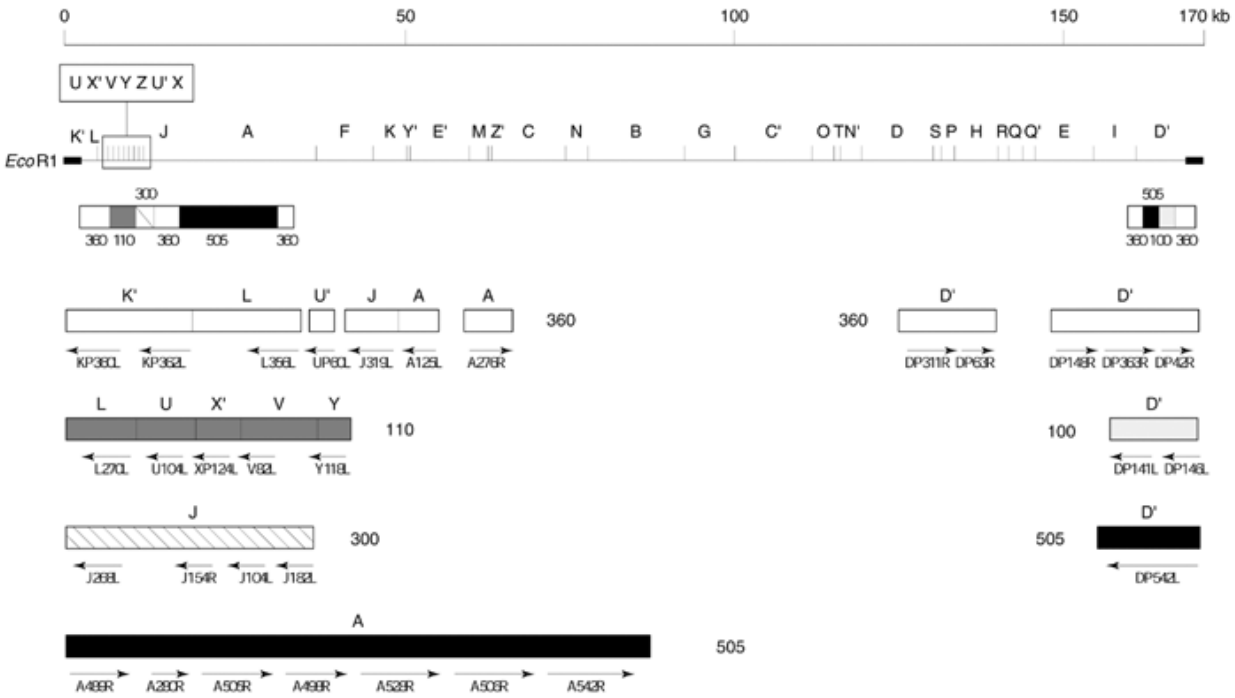

Figure 4 Multigene families in ASFV. Localization of multigene families 100, 110, 300, 360 and 505 in the *Eco*RI map of ASFV DNA (BA71V strain). The genes composing the different multigene families in the BA71V isolate are shown below. The arrows indicate the direction of transcription.

ubiquitinated proteins, with molecular masses of 5, 18 and 58 kDa, have been found in purified extracellular virions, the 18 kDa protein being externally located.

Morphogenesis

ASFV particles assemble from membranous structures present in discrete cytoplasmic areas termed viral factories. The viral membranes become polyhedral immature virions by the progressive formation of the capsid on their convex surface. Underneath the lipid envelope, two different domains are consecutively formed: first the core shell and then an electron-dense nucleoid, which is the DNA-containing domain (see above, Virion Structure and Proteins). The encapsidation of the viral genome is probably a late event in the ASFV assembly.

Host Range and Virus Propagation

ASFV infects domestic pigs and other members of the family Suidae. ASFV also propagates in ticks of the genus *Ornithodoros*, and is the only known arbovirus which contains DNA. In Spain the virus was isolated from the tick *O. erraticus* and in Africa from *O. moubata* collected from warthog burrows. ASFV may be primarily a virus of ticks. All efforts to infect other animal species with ASFV in an attempt to find a more adequate experimental model have been unsuccessful.

In pig tissues, viral antigens have been associated with macrophages and reticular cells, whereas in blood and bone marrow the main cells involved in the infection are monocytes, polymorphs and megakaryocytes.

ASFV replicates *in vitro* in pig monocytes and macrophages, a small fraction of polymorphs and in endothelial cells, but not in resting or mitogen-stimulated T or B lymphocytes. After adaptation, some ASFV isolates multiply in primary cell cultures or in established cell lines, such as pig kidney cells, Vero cells or other monkey kidney cells.

Genetic Variability

A comparison of restriction maps of different ASFV isolates has shown that the virus genome consists of a central, highly conserved region, with a constant length of about 125 kbp, and two variable regions close to the DNA ends, which show deletions or additions up to 8.6 kbp. Nucleotide sequence analysis of the variable regions has shown the existence of five multigene families, designated families 100, 110, 300, 360 and 505, of unknown function (**Fig. 4**). The deletions that occur in the variable regions result in

changes in the number of genes in the multigene families and may generate new members by recombination between homologous genes.

Twenty-three ASFV isolates (8 African, 11 European and 4 American) have been classified into five groups, according to the arrangement of *Sal*I sites in the central region. Four groups contain only African isolates, whereas all the European and American isolates belong to the same group. This distribution of isolates suggests that all non-African virus field isolates have a common origin.

A comparison of DNA sequences of ASFV strains BA71V, Malawi Lil 20/1 and LIS57 has shown that the proteins encoded are over 85% identical in the three virus isolates. The most variable proteins belong to the multigene families. In addition, the BA71V proteins EP402R (homologous to cellular CD2) and I177L are only 67.3 and 78.9% identical, respectively, to their counterparts in the Malawi strain. ASFV protein heterogeneity can also be generated by changes in the number of amino acid tandem repeats. These repeats have been found in 14 ASFV proteins, including the CD2 homologue, the α-like DNA polymerase, and the virion protein p54.

Evolution

The hairpin loop termini of ASFV DNA (see earlier) are very similar in structure, size and sequence to those found in linear plasmids of bacteria of the genus *Borrelia* (host-associated spirochetes that shuttle between arthropods and vertebrates). ASFV and *B. duttoni*, a relapsing fever species, share the same tick vector, *O. moubata*, in Africa. The similarities between these two DNA termini might indicate either a common ancestry or a horizontal genetic transfer.

The evolutionary relationships among the topoisomerase II sequences of ASFV, eucaryotes and procaryotes have been analyzed and a phylogenetic tree has been established. The tree indicates that the ASFV gene diverged from an ancestral cellular gene before the divergence of protozoa, yeasts and metazoa. The data support the hypothesis that an ancestor of ASFV was infecting a unicellular organism, possibly a lower eucaryote, and that the virus acquired the topoisomerase II gene at that time.

Serologic Relationships and Variability

A method of classifying different ASFV isolates is to compare different viruses and sera in a hemadsorption inhibition reaction. Animals surviving infection with ASFV or those infected with an attenuated virus develop hemadsorption-inhibiting antibodies, which seem to be virus-specific. Using this method, different virus isolates have been classified into three groups: A (Lisbon 57, Funchal 65 and Katanga 67), B (Lisbon 60, Madrid 60 and Angola 72) and C (Mozambique 64).

From stocks of hemadsorbing ASFV, nonhemadsorbing clones have been isolated by limiting dilution. Nonhemadsorbing viruses have also been isolated from nature. Hemadsorption of swine erythrocytes to ASFV-infected cells is a late function due to the virus protein EP402R, homologous to the cellular CD2.

A collection of monoclonal antibodies that recognize ten ASFV structural proteins have been used to determine the antigenic variability of ASFV passaged *in vitro* in either porcine macrophages or Vero cells, and to classify 23 field virus isolates from Africa, Europe and America into six antigenic homology groups, which indicates the existence of a complex variety of ASFV serotypes. No clear separation of virus isolates from different continents could be established, as virus isolates from Africa, Europe and America are present in the same antigenic homology group.

The African isolates differ among themselves more than the European or American isolates. This is probably because in Africa the virus has been circulating for a long time and has diverged extensively. The uniformity of the non-African isolates relative to the African ones might be due to the possibility that only one or few viruses entered Europe during 1957 to 1960.

Transmission and Tissue Tropism

Ticks can be infected with ASFV by feeding on viremic blood. The virus replicates in the insect's gut after ingestion, and then spreads to the sexual organs and salivary glands. ASFV can be transmitted between ticks transovarially and sexually. Natural transmission in wild African warthogs seems to occur by tick feeding. Once ASFV has been established in domestic pig populations, the disease can be readily transmitted by contact, as the virus is present in sufficient amounts in excretions and secretions. The virus is very stable in the blood and feces of infected animals. Airborne transmission over short distances can also occur.

Pathogenicity and Clinical Features of Infection

ASFV strains differ in pathogenicity. Highly virulent strains cause a fulminating disease in domestic pigs, with mortality rates of almost 100%. In these cases, pigs die within 1–3 days, before gross lesions can be detected. Since the introduction of ASFV in Europe in 1960, acute, subacute and chronic forms of the disease

Table 1 ASFV genes potentially involved in the regulation of immune response

Gene	*Homologous to*	*Proposed role*
EP402R	CD2-adhesion molecule of T lymphocytes and natural killer cells	Hemadsorption factor Prevents the interaction between infected cells and lymphocytes
A238L	IκB-inhibitor of NKκB transcription factors	Regulation of the host immune response
EP153R	C-type animal lectins	Control of the adhesion ability of infected cells
DP71L (*NL-S* gene of Malawi strain)	Neurovirulence gene *ICP34.5* of HSV	Virulence factor
A179L	Proto-oncogene *bcl-2*	Inhibition of apoptosis
A224L	Baculovirus *iap* gene	Inhibition of apoptosis

have evolved. Clinically, there is a longer incubation period, the course of the disease is slower and the lesions less severe. Chronic forms of the disease may develop in pigs that survive the subacute disease. Adult warthogs do not develop signs of disease, although ASFV has been found in their tissues. The clinical features of the infection are high fever, diarrhea accompanied by bleeding, generalized reddening of the skin and prostration. In some cases, nasal bleeding and swollen and hemorrhagic conjunctival membranes are observed.

The ASFV gene *NL-S* of the Malawi Lil 20/1 isolate, homologous to the herpes simplex virus neurovirulence gene *ICP34.5*, appears to be a viral virulence factor, as deletion of the gene converts the virulent Malawi strain into an attenuated form.

Pathology and Histopathology

After an initial replication of the virus in lymph organs, the spleen, liver and lungs are the main organs for secondary virus replication. Splenic enlargement has been observed and edema of the lungs has been frequently reported in pigs dying of acute ASF, while in chronic processes pneumonia is a common feature. Lesions in the liver consist of degeneration and necrosis of Kupffer cells and hepatocytes. Hemorrhage is the most severe symptom in ASF, and is often the cause of death in infected pigs. Hemorrhages are most consistently seen in lymph nodes, kidneys and heart. The development of disseminated intravascular coagulation seems to be responsible for the hemorrhagic syndrome.

Immune Response

The host immune response induced by ASFV is characterized by the lack of fully neutralizing antibodies, which has hampered the development of a vaccine to control the disease. Nevertheless, it has been reported that pigs infected with ASFV may recover and resist challenge exposure with virulent homologous, but not heterologous, virus. Partial protection by sera from ASF-resistant pigs or by several ASFV proteins has also been found. Although some antisera against whole ASFV or against several viral proteins exhibit high levels of virus inhibition *in vitro*, complete neutralization has not been achieved so far. Identification of the virus component(s) carrying the critical antigenic determinant(s) is one of the most important problems in ASF research.

The cellular immune system is not impaired by ASFV infection in pigs. Several studies have shown activity specific against ASFV of cytolytic T lymphocytes (CTLs) obtained from swine leukocyte antigen (SLA)-inbred minipigs surviving an experimental infection with ASFV. The CTL assays were performed using blood or alveolar macrophages as target cells. The specific lysis of these cells was mediated by purified CD8+ lymphocytes, and could be blocked by incubation with monoclonal antibodies against SLA class I proteins. The CD8+ population produced high levels of interferon γ (IFN-γ) this production being specific for the attenuated isolates of ASFV, suggesting that virulence could be related, at least in part, to isolate-specific IFN-γ production. CTL activity has been detected against cells infected with recombinant vaccinia virus expressing the ASFV p32 protein, an immediate early and one of the most immunogenic virus proteins.

The ASFV genome contains several genes coding for proteins potentially involved in mechanisms used by the virus to evade the host immune response (**Table 1**). One of these proteins, EP402R, homologous to the T cell adhesion molecule CD2, could prevent the interaction of CTLs with the infected

cells. Another ASFV protein (EP153R) that could be important in the control of the adhesion ability of infected cells is a homologue of C-type animal lectins. ASFV also codes for a protein homologous to the cellular IκB, an inhibitor of the transcription factors NFκB, which control the expression of genes involved in the inflammatory and immunological responses to viral infections. On the other hand, the proteins encoded by ASFV genes *A179L* and *A224L*, homologous to the cellular proto-oncogene *bcl*-2 and to the baculovirus gene *iap*, respectively, could prevent the death by apoptosis of the infected cell, thus allowing the development of a productive infection or, under certain conditions, the establishment of persistent infections.

Prevention and Control of ASF

ASFV is a menace to the pig population of the world because there is no vaccine. The control and eradication of ASF requires rapid diagnosis, drastic slaughter and quarantine. ASF diagnosis can be based on the demonstration of infectious virus, viral antigens and DNA or specific antibodies.

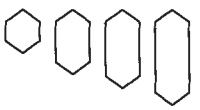
ALFAMOVIRUS AND ILARVIRUSES (*BROMOVIRIDAE*)



JF Bol, Leiden University, Leiden, The Netherlands

History

Alfalfa mosaic virus was identified in 1931 as the causal agent of an economically important disease in alfalfa. In the literature the name of the virus has been abbreviated as AMV and AlMV. In their sixth report of 1995 the ICTV assigned AMV to alfalfa mosaic virus as the type member of the genus *Alfamovirus*, and AIMV to the potyvirus alstroemeria mosaic virus. Consequently, alfalfa mosaic virus is denoted as AMV in this chapter. Many strains of AMV are known which are closely related by serology and nucleotide sequence similarity and which are all characterized by having virions with a unique bacilliform shape. In 1971 it became clear that coat protein has a critical role in the initiation of infection by AMV. A few years later it was found that the coat proteins of ilarviruses play a similar role in the initiation of infection. The observation that the coat proteins of AMV and ilarviruses were interchangeable in this early function suggested a close relationship between the *Alfamovirus* and *Ilarvirus* genera.

Taxonomy and Classification

The term *Ilarvirus* was originally coined from the words *i*sometric, *la*bile, *r*ingspotting. The viruses in this group have quasi-isometric particles varying in size around 30 nm. The following eight subgroups have been suggested: (1) tobacco streak virus (TSV, and its isolates black raspberry latent virus and asparagus stunt virus), *Hydrangea* mosaic virus (HdMV); (2) tulare apple mosaic virus (TAMV), citrus leaf rugose virus (CiLRV), citrus variegation virus (CVV), elm mottle virus (EMoV), asparagus virus 2 (AV-2), spinach latent virus (SPLV); (3) prunus necrotic ringspot virus (PNRSV) (cherry rugose mosaic virus, some rose mosaic virus isolates and hop virus C are synonyms to PNRSV), apple mosaic

cells. Another ASFV protein (EP153R) that could be important in the control of the adhesion ability of infected cells is a homologue of C-type animal lectins. ASFV also codes for a protein homologous to the cellular IκB, an inhibitor of the transcription factors NFκB, which control the expression of genes involved in the inflammatory and immunological responses to viral infections. On the other hand, the proteins encoded by ASFV genes *A179L* and *A224L*, homologous to the cellular proto-oncogene *bcl*-2 and to the baculovirus gene *iap*, respectively, could prevent the death by apoptosis of the infected cell, thus allowing the development of a productive infection or, under certain conditions, the establishment of persistent infections.

Prevention and Control of ASF

ASFV is a menace to the pig population of the world because there is no vaccine. The control and eradication of ASF requires rapid diagnosis, drastic slaughter and quarantine. ASF diagnosis can be based on the demonstration of infectious virus, viral antigens and DNA or specific antibodies.

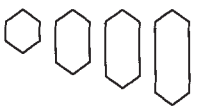
ALFAMOVIRUS AND ILARVIRUSES (*BROMOVIRIDAE*)



JF Bol, Leiden University, Leiden, The Netherlands

History

Alfalfa mosaic virus was identified in 1931 as the causal agent of an economically important disease in alfalfa. In the literature the name of the virus has been abbreviated as AMV and AlMV. In their sixth report of 1995 the ICTV assigned AMV to alfalfa mosaic virus as the type member of the genus *Alfamovirus*, and AIMV to the potyvirus alstroemeria mosaic virus. Consequently, alfalfa mosaic virus is denoted as AMV in this chapter. Many strains of AMV are known which are closely related by serology and nucleotide sequence similarity and which are all characterized by having virions with a unique bacilliform shape. In 1971 it became clear that coat protein has a critical role in the initiation of infection by AMV. A few years later it was found that the coat proteins of ilarviruses play a similar role in the initiation of infection. The observation that the coat proteins of AMV and ilarviruses were interchangeable in this early function suggested a close relationship between the *Alfamovirus* and *Ilarvirus* genera.

Taxonomy and Classification

The term *Ilarvirus* was originally coined from the words *i*sometric, *la*bile, *r*ingspotting. The viruses in this group have quasi-isometric particles varying in size around 30 nm. The following eight subgroups have been suggested: (1) tobacco streak virus (TSV, and its isolates black raspberry latent virus and asparagus stunt virus), *Hydrangea* mosaic virus (HdMV); (2) tulare apple mosaic virus (TAMV), citrus leaf rugose virus (CiLRV), citrus variegation virus (CVV), elm mottle virus (EMoV), asparagus virus 2 (AV-2), spinach latent virus (SPLV); (3) prunus necrotic ringspot virus (PNRSV) (cherry rugose mosaic virus, some rose mosaic virus isolates and hop virus C are synonyms to PNRSV), apple mosaic

virus (ApMV), (Danish plum line pattern virus, some rose mosaic virus isolates and hop virus A are synonyms to ApMV), blueberry shock virus (BlShV), *Humulus japonicus* virus (HJV); (4) prune dwarf virus (PDV); (5) American plum line pattern virus (APLPV); (6) lilac ring mottle virus (LRMV); (7) *Parietaria* mottle virus (PMoV); (8) *Fragaria chiloensis* virus (FClV). For viruses within one subgroup serological relationships have been reported. AMV strains that have been studied in most detail are the isolates AMV-L and AMV-M of strain 425 and strain AMV-S. The nucleotide sequence similarity between AMV strains is over 95%.

Together with the genera *Bromovirus, Cucumovirus* and *Oleavirus,* AMV and ilarviruses constitute the family of *Bromoviridae.* The tripartite RNA genomes of bromo- and cucumoviruses are infectious as such whereas the tripartite genomes of AMV and ilarviruses are not infectious unless a few molecules of coat protein or RNA4, the subgenomic messenger RNA for coat protein, are added to the inoculum. This phenomenon is called 'genome activation'. Moreover, bromovirus and cucumovirus RNAs contain a 3′-terminal tRNA-like structure that is absent in AMV and ilarvirus RNAs. The particles of AMV and ilarviruses have bacilliform and spheroidal morphology, respectively. However, in addition to spheroidal particles, the preparations of several ilarviruses contain AMV-like bacilliform particles, notably those of TAMV, PNRSV and PDV. On the other hand, spheroidal particles are found in AMV preparations.

To date, the complete nucleotide sequence is known of the three genomic RNAs of AMV isolate AMV-L and the ilarviruses CiLRV, SPLV, EMoV, TSV and PDV. In addition, the sequence has been determined of RNA3 of LRMV, AV-2, HdMV, PNRSV, ApMV and CVV. **Figure 1** shows a phylogenetic tree of AMV and ilarviruses based on sequence similarities between the RNA3-encoded movement protein. Two major clusters can be distinguished, one containing CiLRV, CVV, LRMV, AV-2 and TSV, and the other containing AMV, PNRSV, ApMV and PDV. A tree based on the RNA3-encoded coat protein yields a similar clustering. A comparison of the replicase proteins encoded by RNAs 1 and 2 yields one cluster containing CiLRV, TSV and SPLV, and another cluster containing AMV, ApMV and PDV. Within one cluster the sequence similarity of these proteins is 45% or more whereas the similarity between clusters is 35–40%. Based on these data it has been suggested that AMV should be incorporated into the genus *Ilarvirus.* Another feature separating the two clusters is the presence of an open reading frame (ORF) 2b, similar

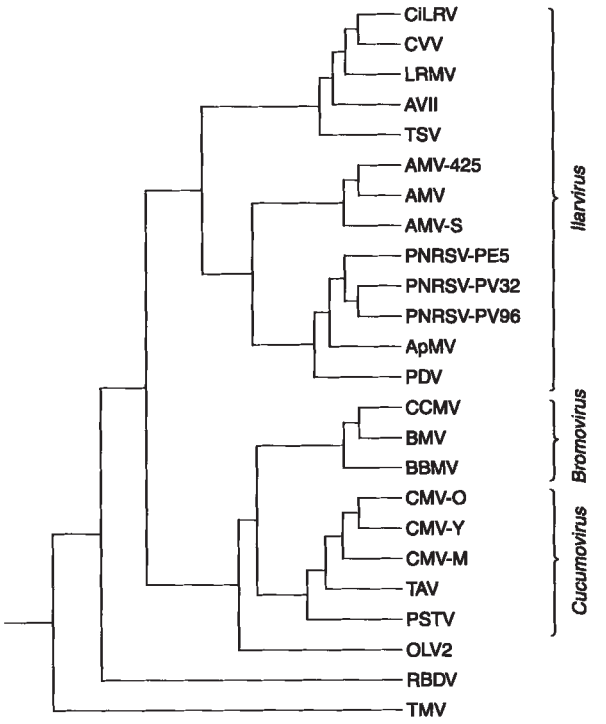


Figure 1 Phylogenetic tree obtained from the alignment of amino acid sequences of movement proteins encoded by RNA3 of viruses from the family *Bromoviridae.* In addition to the genera *Ilarvirus, Bromovirus* and *Cucumovirus,* the oleavirus OLV2, the idaeovirus RBDV and the tobamovirus TMV are included for comparison. (Reproduced with permission from Sánchez-Navarro and Pallás (1997) Evolutionary relationships in the ilarviruses: nucleotide sequence of prunus necrotic ringspot virus RNA3. *Arch. Virol.* 142: 749.)

to that found in RNA2 of several cucumoviruses. Such an ORF 2b is found in RNA2 of CiLRV, CVV, AV-2, TSV, SPLV and the related EMoV, but appears to be absent from RNA2 of AMV, ApMV and PDV. For comparison, **Fig. 1** shows the phylogenetic relationship of ilarviruses to bromo- and cucumoviruses, the idaeovirus RBDV, the oleavirus OLV2 and the tobamovirus TMV.

Host Range and Geographic Distribution

AMV occurs worldwide. Strains of this virus have been found in natural infections of about 150 plant species representing 22 families. The experimental and natural host ranges include over 600 species in 70 families. Although AMV infects mostly herbaceous plants, several woody hosts are included in its natural host range. Also, the host range of TSV is very wide, both experimentally and naturally, infecting many plant species in over 30 families. Both monocotyledonous and dicotyledonous hosts have been reported and both woody and herbaceous hosts. The original

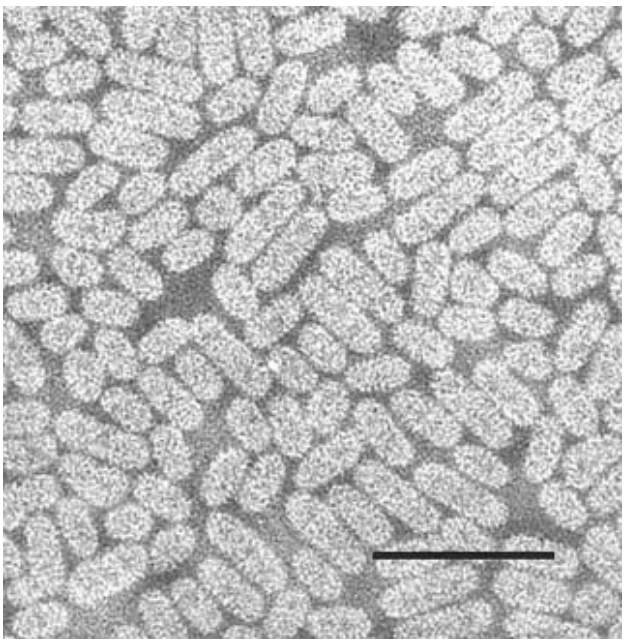

Figure 2 Electron micrograph of alfalfa mosaic virus. Scale bar = 100 nm.

description notes its occurrence near the edges of tobacco fields, suggesting that it spreads from perennial weeds. In contrast, TAMV was found in a single apple tree in California in 1955 and was discovered 20 years later in a hazelnut tree in France. Similarly, the *Citrus* species infected by CiLRV are restricted to one location in Florida. EMoV has been found in elm and lilac in Scotland and Germany. The distribution of PNRSV and PDV corresponds to those of their hosts as a result of their dissemination in vegetative propagating material as well as in seeds. Although some ilarviruses have a rather narrow natural host range they can all be transmitted experimentally to a wide range of herbaceous plants.

Structure and Composition

Preparations of AMV contain four major classes of particles called bottom component (B), middle component (M), top component b (Tb) and top component a (Ta) (**Fig. 2**). B, M and Tb are bacilliform and contain the genomic RNAs 1, 2 and 3, respectively. Ta contains two molecules of the subgenomic RNA4 and can be subdivided in bacilliform Ta-b and spheroidal Ta-t particles. The bacilliform particles are all 19 nm wide and have lengths of 56 nm (B), 43 nm (M), 35 nm (Tb) and 30 nm (Ta-b). The RNAs are encapsidated by a single type of coat protein which in the case of strain AMV -L has a length of 220 amino acids (mol. wt 24 280 Da). In solution, AMV coat protein occurs as dimers which under appropriate conditions of pH and ionic strength form a $T = 1$ icosahedral structure built from 30 dimers. This structure can be crystallized and has been studied by x-ray diffraction, cryoelectron microscopy and image reconstruction methods. The coat protein was found to have the canonical eight-stranded β-barrel fold with the N- and C-terminal arms as extended chains. Dimer formation in the $T = 1$ particle is based on the clamping of the C-terminal arms of the subunits. The dimer is further stabilized by interactions between the C-terminal arms and the icosahedral twofold axis.

From particle weight measurements and analysis of electron images it has been concluded that the number of coat protein monomers in the major virions is $60 + (n \times 18)$, n being 10 (B, 240 subunits), 7 (M, 186 subunits), 5 (Tb, 150 subunits) or 4 (Ta, 132 subunits). By gel electrophoresis at least 13 minor components have been resolved which probably represent other n values and are believed to contain monomers of genomic RNAs, multimers of genomic RNAs or RNA4 or specific degradation products of RNA3. Although details of the arrangement of the protein monomers have not been established, electron microscopical studies indicate that the cylindrical parts of the bacilliform particles have a hexagonal surface lattice with dimers of the coat protein associated with the twofold symmetry axes. The cylindrical part is believed to be capped by two halves of an icosahedron by changing the axes from sixfold symmetry in the cylinder into axes of fivefold symmetry. Neutron-scattering data suggested that the capsid structure of spheroidal Ta-t particles is represented by a deltahedron with 52-point group symmetry built from 120 subunits. The percentage of RNA in the virions decreases from 16.3 in B to 15.2 in Ta-b. The buoyant density in CsCl of the major components fixed with formaldehyde varies from 1.366 (Ta) to 1.372 (B) $g\,cm^{-3}$. The protein shell has an inner radius of 6.5 nm and an outside radius of 9.4 nm. The RNA is uniformly packed within the 6.5 nm radial limit, occupies about 20% of the interior volume available and slightly penetrates the protein shell. The particles are mainly stabilized by protein RNA interactions. The RNA is easily accessible to ribonucleases A and T1 through holes in the protein shell. At slightly alkaline pH the particles unfold reversibly. The structure of ilarviruses has been studied in little detail. By using sucrose gradient centrifugation virus preparations can be separated into four classes of spheroidal particles with diameters of 23 nm, 25–27 nm, 30–31 nm and 32–33 nm. The RNA content of all particles is about 16%. The capsids are built from one species of capsid protein with molecular weights between 23 635 Da (SPLV) and 26 346 Da (TSV). The

three largest particles of TSV contain the genomic RNAs and their capsids have been estimated to be built from 142, 179 and 225 subunits per particle. Like AMV RNAs, ilarvirus RNAs are degraded *in situ* by nucleases and the particles are readily disassembled into protein and RNA by high salt or low concentrations of sodium dodecyl sulfate (SDS).

Genome Structure

All four RNAs of AMV-L have been sequenced. RNA1 (3644 ribonucleotides) and RNA2 (2593 ribonucleotides) encode proteins of 126 and 90 kDa which are called P1 and P2, respectively. P1 and P2 are subunits of the purified AMV replicase. RNA3 (2142 ribonucleotides) contains a 5′-proximal reading frame for a 32 kDa protein called P3, and a 3′-proximal reading frame encoding the coat protein. P3 is required for cell-to-cell transport of the virus. Coat protein is translated from RNA4 which is identical in sequence to the 3′-terminal 881 ribonucleotides of RNA3. The length of the intercistronic region in RNA3 is 52 ribonucleotides including the leader sequence of RNA4 of 36 ribonucleotides. At the 5′-end, all four AMV RNAs are capped. The organization of the leader sequence of RNA3 varies between strains. For strains M, S, L and YSMV the length of this leader sequence is 240, 313, 345 and 391 ribonucleotides, respectively. The increased length of the last three strains is due to the presence of direct repeats of 56 (S), 75 (L) and 149 ribonucleotides (YSMV). At their 3′-termini the AMV RNAs do not contain a tRNA-like structure or poly(A) tail. There is about 80% sequence similarity between the 3′-terminal 145 ribonucleotides of the AMV genomic RNAs. The 3′-untranslated region (3′-UTR) of RNA3 is 182 ribonucleotides long and contains seven hairpins flanked by the single-stranded sequence AUGC. The 3′-UTR of AMV RNA3 contains at least two independent binding sites for coat protein, one being located in the region homologous to RNAs 1 and 2, and one in the region unique to RNA3. A minimal coat protein binding site is represented by the 3′-terminal 39 ribonucleotides containing two hairpins flanked by three AUGC-motifs. To initiate infection, each genome segment has to be complexed with a few dimers of the coat protein.

The genome organization of ilarviruses is very similar to that of AMV. Generally, the 5′-UTRs of RNAs 1 and 2 are relatively short (37–75 ribonucleotides) whereas those of RNA3 are longer (210–354 ribonucleotides). The 5′-UTR of SpLV RNA1 (73 ribonucleotides) and RNA2 (75 ribonucleotides) share a common 5′ sequence of 45 ribonucleotides; otherwise sequence similarity between the leaders is limited. The 3′-UTRs of SpLV and CiLRV vary in length from 174 to 418 ribonucleotides but the three genomic RNAs of the two viruses contain a highly conserved sequence of 190 ribonucleotides. In the 3′-UTRs of TSV (139–288 ribonucleotides) sequence similarity is limited to the 3′-45 ribonucleotides. Yet, the predicted secondary structure of the 3′-UTRs of ilarviruses is very similar to that of AMV and can be folded into a number of hairpins interspersed by AUGC motifs. These 3′-termini are fully equivalent in binding the homologous coat protein or heterologous coat proteins from other alfamo- or ilarviruses. The size of the ORF 2b protein that is encoded by RNA2 of several ilarviruses (SpLV, 21.1 kDa; TSV, 22.4 kDa) is twice the size of the corresponding cucumovirus 2b protein. The function of the 2b protein in ilarvirus replication is not known.

Replication

Replication of AMV can be initiated by inoculation of plants or protoplasts with a mixture of the viral particles B, M and Tb, with RNAs 1, 2, 3 and 4, or with RNAs 1, 2, 3 and coat protein. An infectious mixture is also obtained when purified B particles are added to a mixture of RNAs 1, 2 and 3. In this case the coat protein molecules of the B particle become readily distributed over the RNA molecules present in the inoculum. In protoplasts, RNA synthesis becomes detectable from 6 h after inoculation and levels off after 42 h. RNA3 is synthesized most rapidly whereas RNA4 accumulates rather late in the infection cycle. The accumulation of positive-strand RNAs is accompanied by the synthesis of three negative-strand molecules corresponding to RNAs 1, 2 and 3. In productively infected plants or protoplasts, massive amounts of coat protein are produced but the three nonstructural proteins are detectable only with specific antisera. On Western blots the P3 protein gives multiple bands suggesting a post-translational modification. RNAs 1 and 2 are able to replicate in protoplasts provided that some coat protein is added to the inoculum. However, in the absence of RNA3 or in the presence of RNA3 with a defective coat protein gene there is a strong reduction in positive-strand RNA accumulation. Apparently, the coat protein is required for (+)RNA accumulation *in vivo*. Infection of protoplasts with the complete genome or with RNAs 1 and 2 results in the accumulation of membrane-bound replication complexes. Replicase preparations purified from productively infected tobacco plants were found to contain P1, P2 and CP, and are able to transcribe plus-strand AMV RNAs into complementary minus-strands. Replicase can also be isolated from healthy transgenic tobacco

plants transformed with the P1 and P2 genes (P12 plants). Synthesis of RNA4 by this replicase on a (−)RNA3 template is strongly stimulated by coat protein *in vitro*. Available evidence indicates that all AMV components are synthesized and assembled in the cytoplasm.

Although the replication cycle of ilarviruses has been investigated in less detail, studies with purified particles, RNAs and coat protein of TSV, CiLRV, CVV, PNRSV and PDV demonstrated that for ilarviruses and AMV the requirements to initiate an infection are the same. As with AMV, the genomes of these viruses require coat protein or RNA4 in the inoculum to initiate infection. The coat proteins of AMV and these ilarviruses can reciprocally activate each other's genomes.

Genetics and Molecular Biology

Infectious cDNA clones of AMV RNAs 1, 2 and 3 have been used to map *cis*- and *trans*-acting functions in the genome by site-directed mutagenesis. The 3′-terminal sequence of 145 ribonucleotides that are homologous in the three AMV RNAs were found to be sufficient for a low level of minus-strand promoter activity *in vitro* and *in vivo*. Non-homologous upstream sequences from the 3′-UTRs of RNAs 1, 2 and 3 were required to enhance this promoter activity to wild-type levels. Coat protein is not required for minus-strand RNA synthesis *in vitro* or *in vivo*. Functions of the coat protein in genome activation, synthesis of plus-strand genomic RNA, synthesis of subgenomic RNA4, encapsidation and cell-to-cell movement could be mutated separately, suggesting that different domains of the protein may be involved in at least some of these functions. The P3 gene has no role in RNA replication but mutations affecting the expression of coat protein result in a 100-fold reduction of plus-strand RNA synthesis in protoplasts. When protoplasts are inoculated with wild-type RNAs 1 and 2 and a mixture of RNA3 mutants defective in the P3 gene or coat protein gene, the coat protein expressed by the P3 mutant permits asymmetric accumulation of RNA1, RNA2 and the RNA3 with the P3 mutation but does not stimulate plus-strand accumulation of RNA3 with the coat protein mutation. This indicates that coat protein is required in *cis* for replication of RNA3 and used in *trans* for replication of RNAs 1 and 2. Similarly, evidence has been obtained that P1 is required in *cis* for the replication of RNA1 whereas P2 is required in *cis* for the replication of RNA2. When plants rather than protoplasts are infected with a mixture of P3 and coat protein mutants, the mutant RNA3 molecules readily recombine to wild-type RNA3.

When the coat protein gene in AMV RNA3 was replaced by the coat protein genes of TSV or PNRSV, the ilarvirus coat proteins stimulated a relatively low level of plus-strand RNA accumulation in protoplasts and the PNRSV coat protein was able to encapsidate the AMV/PNRSV chimeric RNA. When both the P3 gene and the coat protein gene in AMV RNA3 were replaced by the corresponding genes of PNRSV, the mutant could hardly move in tobacco plants. This indicates that the RNA3-encoded proteins of AMV and PNRSV are not interchangeable in cell-to-cell movement.

Virus–Host Relationships

The fact that the AMV group is a large conglomerate of strains infecting a high number of susceptible hosts accounts for the tremendous range of symptoms displayed by AMV-infected plants. Mutations in the coat protein gene and 5′-UTR of RNA3 have been shown to affect symptom formation in tobacco. The ilarviruses mainly invade woody plants but also have a wide herbaceous host range. The symptoms of some of these viruses on their natural hosts are briefly listed here. TSV gives severe local and systemic necrosis in tobacco. TAMV induces mosaic in apple and hazelnut which can be followed by systemic necrosis. CiLRV is known for its rugosity and chlorotic flecks in species of *Citrus*. The symptoms of CVV in *Citrus* species range from patterns of chlorotic areas to severe distortion and variegation. EMoV causes ringspot and line patterns in elm, and white mosaic and chlorotic line patterns in lilac. The symptoms of PNRSV in *Prunus* species range from mild mottles to severe leaf necrosis, whereas chlorotic line patterns and rings are induced in roses. ApMV gives mosaic disease in apple and chlorotic lines in birch, plum and rose. PDV is responsible for thickened 'shoe-string' leaves on prune, chlorotic ringspot in sweet cherry and yellows in sour cherry.

In AMV-infected plants cytological modifications occur only in cells of organs showing symptoms. In these cells fragmentation of the ground cytoplasm and an increased accumulation of membrane-bound vesicles has been observed. Sometimes the lamellar system of chloroplasts is affected and invaginations of the nuclear membrane have been reported. The P3 protein has been localized in the middle lamellae of walls of those cells that had just been reached by the infection front and in which viral multiplication had just begun.

Virus particles are mainly found in the cytoplasm with a few records of particles in the nucleus. Depending on the strain, four types of intracellular aggregates of virus particles may occur. Also, ilar-

viruses induce only minor cytological changes in most of the virus–host combinations studied. These include an enhanced development of cytoplasmic membranes, production of vesicles and a slight degeneration of mitochondria. The virions of TSV are found in the cytoplasm, scattered randomly or packed in disordered or paracrystalline aggregates. In addition, tubular structures with single rows of virus particles are observed. The association of these structures with cell walls and plasmodesmata may suggest a function in cell-to-cell transport. Protoplasts infected with AMV produce tubular structures consisting of the P3 protein on their surface. These tubules appear to be filled with virus particles and are probably involved in cell-to-cell transport of the virus.

Transmission

AMV is easily transmissible manually. Field spread occurs predominantly by aphid transmission. At least 15 aphid species are known to transmit the virus in the stylet-borne or nonpersistent manner. Acquisition of the virus occurs within 10–30 s and is followed by immediate transmission without a latent period. The ability to continue transmission is lost by the aphid within 1 h. The variability of individual aphid species in their capacity to transmit different AMV strains suggests a specific virus–vector relationship which is probably governed by the structural properties of the coat protein. Seed transmission of AMV has been reported for alfalfa and seven other plant species with rates of transmission varying from 0.1 to 50%. Transmission of the virus between plants by parasitic dodder has been observed with five *Cuscuta* species.

Mechanical transmission of ilarviruses, particularly those of wood plants, frequently requires the addition of stabilizing compounds to the inoculum. Back transmission of these viruses from herbaceous plants to their woody hosts is generally difficult. In the field, transmission of ilarviruses occurs through seed and pollen. Seed transmission has been reported for AV-2, EMoV, LRMV, PDV, PNRSV and TSV. For EMoV, PDV, PNRSV and TSV transmission by pollen has also been observed. The effectiveness of pollen transmission is correlated with the activity of pollinating insects. For example, thrips have been shown to play a role in the spread of TSV-contaminated pollen.

Epidemiology and Control

Although there have been reports on resistance and tolerance of alfalfa to AMV, control of the virus in this crop can be done mainly by using virus-free seed and avoiding reservoir hosts of the virus. Because the virus occurs naturally in many different plant species this is practically impossible.

Ilarviruses are less widespread in nature, infecting many different plant families. Vegetative propagation of horticultural crops such as fruit trees, roses and berries is the most important factor in the dissemination of these viruses. Virus-free plantings should be used to prevent the rapid distribution of ilarviruses. Because of the seed transmission of these viruses the use of rootstocks grown from infected seeds is a particular risk. Transmission of the virus by pollen depends on the behavior of pollen-bearing insects. Honeybees, which are the most common visitors of flowers of fruit trees, tend to favor one flower species during pollen collection. Because bees forage only locally during a foraging trip, virus transmission by pollen in an orchard is most likely to occur between adjacent trees.

Tobacco plants transformed with the coat protein genes of AMV and TSV were found to be highly resistant to the homologous virus but not to the heterologous virus when infection was done by mechanical inoculation. Resistance to transmission of virus by aphids or pollen has not yet been tested.

Economic Significance

AMV is the causal agent of economically important diseases in alfalfa, clover, pea, potato, tobacco, pepper, tomato and celery. Ilarviruses of greatest economic importance are PNRSV, PDV, TSV and ApMV.

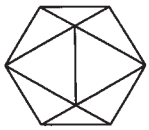
ALGAL VIRUSES (*PHYCODNAVIRIDAE*)



James L Van Etten, Department of Plant Pathology, University of Nebraska, Lincoln, Nebraska, USA

History

Since the early 1970s, viruses or virus-like particles (VLPs) have been reported in at least 44 taxa of eucaryotic algae, which include members in ten of the 14 classes of eucaryotic algae. However, most of these reports described isolated accounts of microscopic observations. The virus particles were not characterized because they were difficult to obtain in reasonable quantities. Several factors contributed to the low virus concentrations: (1) often only a few algal cells contained particles; (2) usually the cells only contained particles at one stage of the algal life cycle; (3) cells containing particles tended not to lyse; (4) in most cases the particles were not infectious; and (5) some hosts could not be easily cultured.

However, this situation began to change with the discovery of a family of large double-stranded (ds) DNA-containing viruses which infect and replicate in certain strains of unicellular, eucaryotic, chlorella-like green algae. The first of such 'chlorella viruses' was discovered in 1981 in chlorella symbiotic with the green coelenterate *Hydra viridis*, and subsequently in chlorella symbiotic with the protozoan *Paramecium bursaria*. The algae from *P. bursaria* can be grown free of the paramecium in culture, and these cultured, naturally endosymbiotic *Chlorella*, strains NC64A and Pbi or their equivalents, serve as hosts for many similar viruses (**Table 1**). These lytic viruses can be produced in large quantities and assayed by plaque formation using standard bacteriophage techniques. The prototype chlorella virus is PBCV-1, which stands for *Paramecium bursaria Chlorella* virus 1.

Large polyhedral, dsDNA-containing viruses which infect certain marine algae are also under active investigation. These include viruses that infect unicellular algae, *Micromonas pusilla* (MpV viruses) and *Chysochromulina* sp. (CbV viruses), as well as viruses that infect filamentous brown algae, including *Ecto-*

carpus sp. (EsV viruses) and *Feldmannia* sp. (FsV viruses) (**Table 1**). EsV and FsV viruses have a lysogenic phase in their life cycle and are only expressed as virus particles in sporangial cells of their host.

Taxonomy and Classification

The algal viruses are polyhedra (100–190 nm in diameter) with large dsDNA (160–380 kb) genomes. The 320–380 kb chlorella virus genomes are linear, nonpermuted molecules with crosslinked hairpin ends. In contrast, brown algal viruses have circular dsDNA genomes. Both MpV- and CbV-virus genomes are probably linear dsDNA molecules.

Despite the differences in genome structure, phylogenetic trees indicate that all the algal viruses are more closely related to each other than to other dsDNA viruses and that they form a distinct phyletic group, suggesting a common, albeit ancient, ancestor. The viruses fall into several clades, which correlate with their algal hosts. Based on DNA polymerase gene sequences, herpesviruses are the most closely related outgroup.

The algal viruses are morphologically similar to the iridoviruses, such as frog virus 3 (FV3). Other shared properties between the chlorella viruses and FV3 include: aquatic habitats, a large dsDNA genome, the presence of methylated bases in their genomic DNA, and an internal lipid component comprising 5–10% of the virus weight. However, the chlorella viruses differ in several ways from FV3. (1) FV3 is uncoated inside the host cell, whereas the chlorella viruses specifically attach to the host cell surface and release DNA into the host cell like bacteriophages. (2) FV3 cannot replicate in UV-inactivated host cells, whereas the chlorella viruses initiate and complete viral replication (albeit slowly and with a small burst size) in UV-inactivated host cells. (3) FV3 virons do not contain glycoproteins, whereas some of the chlorella virion proteins are glycosylated. (4) FV3 mRNAs are not polyadenylated, whereas the chlorella virus early, but probably not all late, mRNAs are polyadenylated. (5) The FV3 genome is a linear and circularly permuted molecule, whereas the chlorella virus genomes are linear and nonpermuted with covalently closed hairpin ends.

Chlorella virus genomes share two characteristics with the vaccinia virus (poxvirus) genome even though the virions are morphologically distinct. Like PBCV-1, vaccinia virus DNA contains covalently closed hairpin termini and inverted terminal repetition. However, the terminal repetitive region of vaccinia virus DNA is larger (*c.* 10 kb) than that of PBCV-1 DNA (2.2 kb), even though the PBCV-1 genome is about twice the size of the vaccinia virus genome.

African swine fever virus (ASFV) (presently unclassified) is the only other large polyhedral virus containing dsDNA with hairpin termini and inverted terminal repetition. However, PBCV-1 and ASFV differ in several ways. Most significantly: (1) these two viruses infect different hosts; (2) the PBCV-1 genome is about twice the size of the ASFV genome; (3) the PBCV-1 genome contains methylated bases, whereas the ASFV does not; and (4) no glycoproteins are present in ASFV particles, whereas at least three PBCV-1 virion proteins are glycoproteins.

The 330 kb PBCV-1 genome has recently been sequenced. Comparison of the deduced amino acid sequences of the putative PBCV-1 encoded proteins with those from procaryotes, eucaryotes and their viruses did not reveal a common ancestor for the chlorella viruses. That is, some PBCV-1 genes are most closely related to bacteria and their viruses, whereas other viral genes are obviously more closely related to eucaryotic organisms and their viruses. Consequently, the chlorella virus genomes contain an interesting mosaic of procaryotic- and eucaryotic-like genes.

The chlorella viruses have family status, with the name *Phycodnaviridae*. It has been proposed that the brown algal viruses and the MpV- and CbV-viruses be included in the *Phycodnaviridae* family and that the four groups be assigned to separate genera.

Structure and Composition

The chlorella virus PBCV-1 is a 175–190 nm in diameter polyhedron with a multilaminate capsid. Some electron micrographs indicate that PBCV-1 virions contain flexible hair-like appendages that extend from at least some of the vertices. One unique virion vertex may contain a 20–25 nm spike-like structure. PBCV-1 sediments at about 2300 S and has an estimated size of 1×10^3 MDa. Virus composition is about 64% protein, 21–25% dsDNA and 5–10% lipid. The virus contains at least 50 structural proteins, ranging in size from 10–200 kDa. Four proteins, including the major capsid protein (Vp54), are located on the virion surface.

Vp54 comprises about 40% of the total PBCV-1 protein and is one of three viral glycoproteins. The glycan portion of Vp54 is on the external surface of the virus and probably contributes to the protease resistance of PBCV-1. Four PBCV-1 proteins, including Vp54, are myristoylated and at least six PBCV-1 proteins are phosphoproteins. The PBCV-1 lipid component, which is located beneath the outer glycoprotein shell, is required for infectivity, as organic solvents inactivate the virus.

Genome Structure

The 330 740 bp PBCV-1 genome is linear and non-permuted with covalently closed hairpin ends. The termini consist of 35 nucleotide-long, incompletely base-paired, covalently closed hairpin loops that exist in one of two forms (flip and flop). Each hairpin loop is followed by an identical 2221 bp inverted repeat sequence, after which the sequence diverges. The PBCV-1 genome encodes 702 open reading frames (ORFs) that have 65 or more codons, as well as a cluster of ten tRNAs located in the middle of the genome. Of the 702 ORFs, 377 are believed to encode proteins; about 40% of these 377 ORFs resemble proteins in the databases (some ORFs are listed in **Fig. 1**). Certain PBCV-1 genes are interrupted by one of two different types of introns: a transcription factor-like gene contains a self-splicing type I intron, whereas the DNA polymerase gene contains a spliceosomal processed type of intron. In addition, one of the viral tRNA genes is predicted to have an intron. One unusual feature of the chlorella virus genomes is that they contain methylated bases (**Table 1**).

The EsV and FsV viruses that infect filamentous brown algae have circular dsDNA genomes. EsV has a 320 kb genome, whereas FsV contains two genome size-classes, 158 and 179 kb, which may be packaged in separate particles. The EsV dsDNA genome contains several single-stranded gaps. The FsV genomes have many 173 bp direct repeats located in specific regions of the DNAs. Unlike the lytic chlorella viruses, the FsV genomes, and probably the EsV genome, are integrated into the host chromosome(s) in certain stages of the algal life cycle. In this integrated state they are transmitted in a mendelian fashion.

Virus Replication

PBCV-1 attaches rapidly, specifically and irreversibly to cell walls, but not to protoplasts of host *Chlorella* NC64A. Following attachment, the host wall dissolves at the point of attachment and viral DNA enters the cell. An empty capsid remains on the cell surface. Since the virus also attaches to and digests wall fragments which have been boiled or extracted by harsh procedures, the virus carries the digestive enzyme(s). However, release of PBCV-1 DNA requires a host function, as attachment to wall fragments does not lead to empty capsids.

Presumably the infecting DNA, plus associated proteins, is rapidly transported to the host cell nucleus. Early PBCV-1 transcription is detected within 5–10 min postinfection. Three observations suggest that early virus transcription occurs in the nucleus. (1) PBCV-1 does not encode a recognizable RNA polymerase gene. (2) No RNA polymerase activity is detected in disrupted PBCV-1 virions. (3) The PBCV-1 DNA polymerase gene, which contains a spliceosomally processed intron, is an early gene product. Presumably the enzymatic machinery to process such an intron resides in the nucleus.

PBCV-1 translation occurs on cytoplasmic ribosomes and early PBCV-1 encoded proteins can be detected within 10–15 min postinfection. PBCV-1 DNA synthesis and late virus transcription begin about 1 h postinfection. Host nuclear and chloroplast DNAs are degraded beginning at about 1 h postinfection, even though the total DNA in the cell increases 4–10-fold by 4 h postinfection. Thus PBCV-1 DNA synthesis requires both energy and deoxyribonucleoside triphosphates from the host. While degraded host DNA may supply some intermediates, virus DNA replication requires 4–10-fold more deoxyribonucleoside triphosphates than recycling can provide.

At approximately 2 h postinfection host cells change cytologically. The nucleolus disintegrates and chromatin heterochromicity increases. The nucleus and cytoplasmic elements become appressed to the chloroplast, leaving one or more finely granulated electron-translucent areas in the cytoplasm (virus assembly centers). Membraneous material, which may function as templates for capsid assembly, appear in the virus assembly centers. This is followed by the accumulation of more dense material (presumably protein and/or glycoprotein) on the exterior membrane surface which gives rise to virus capsids at the periphery of the virus assembly centers. Apparent complete capsids are assembled prior to DNA packaging, which probably enters through an opening in the capsid. By 4–5 h postinfection, cells contain many filled virions which are distributed throughout the cytoplasm. PBCV-1 release, by cell lysis, begins at 4 h postinfection and is complete by 8–10 h postinfection. Mechanical disruption of cells releases infectious virus 30–50 min prior to spontaneous lysis. Consequently, PBCV-1 is completely assembled inside the host and does not acquire a membrane by budding through the host membrane.

The nuclear membrane and structurally intact mitochondria and chloroplasts are usually present at late stages of PBCV-1 infection. The role of organelles in virus replication is unknown. However, photosynthesis inhibitors do not prevent PBCV-1 replication; nor does PBCV-1 replication require host transcription, as PBCV-1 replicates in UV-irradiated cells. However, PBCV-1 replication is slow (latent period of 16–20 h versus 4–10 h) and the burst size is low (2–10 plaque-forming units (PFUs) per cell versus 200–350 PFUs per cell) in UV-treated cells; nor does

Figure 1 Some putative genes encoded by the 330 740 bp chlorella virus PBCV-1. The genes listed to the left of the genome are transcribed in a left to right orientation; the ones listed to the right of the genome are transcribed in a right to left orientation. The genes labeled with an asterisk have been overexpressed and shown to encode a functional enzyme. Symbols (E) and (L) refer to early and late transcripts.

PBCV-1 replication require labile host factors, as the virus replicates in UV-inactivated cells incubated in the dark for up to 8 h before infection.

Virus replication has not been detailed to any extent for any of the other algal viruses. However, like PBCV-1, all of the algal viruses appear to be assembled and DNA is packaged in virus assembly centers located in the cytoplasm.

Virus Transcription

Detailed studies on transcription are lacking for all of the algal viruses and only a few general statements can be made about PBCV-1 transcription. (1) PBCV-1 infection rapidly inhibits host RNA synthesis. (2) Viral transcription is programmed and early transcripts appear within 5–10 min postinfection. Late viral transcription first begins about 1 h postinfection (3) Some early viral transcripts are synthesized in the absence of *de novo* protein synthesis. As expected, the synthesis of later transcripts requires translation of early virus genes. (4) Early and late genes are dispersed in the PBCV-1 genome. (5) Early PBCV-1 transcripts, but only a few late transcripts, are polyadenylated. (6) PBCV-1 ORFs are tightly packed on both DNA strands and the coding regions of some of the genes overlap. The largest distance between PBCV-1 ORFs is a 1788 nucleotide stretch in the middle of the genome. However, this region contains ten tRNA-like genes. (7) Consensus promoter regions for early and late genes have not been identified, although the 50 nucleotides preceding the ATG start codon of most functional PBCV-1 genes are AT-rich. (8) Transcription of some PBCV-1 genes is complex. For example, some gene transcripts exist as multiple bands and these patterns change between early and late times in the virus life cycle. Furthermore, a single chitosanase gene can produce two different-sized proteins.

Additional *Chlorella* NC64A Viruses

Hundreds of large polyhedral, plaque-forming viruses that infect Chlorella NC64A have been isolated from the USA, South America, China, Japan, Israel and Australia. Over 50 of these viruses, called NC64A viruses, have been partially characterized. Like PBCV-1, each of these viruses contains many structural proteins, a large (>300 kb) dsDNA genome with about a 40% GC content, and they are chloroform sensitive. The DNAs of some of these viruses hybridize strongly with PBCV-1 DNA, while others hybridize poorly.

The NC64A viruses can be grouped into at least 16 classes by plaque size, antiserum sensitivity, DNA restriction patterns, sensitivity of the DNAs to restriction endonucleases and the nature and abundance of methylated bases. DNA from each of the viruses contains 5-methylcytosine (5mC) in amounts varying from 0.12 to 47.5% of the total cytosine (**Table 1**). In addition, many viral DNAs contain N^6-methyladenine (6mA) in amounts varying from 1.5 to 37% of the total adenine.

Other Chlorella Viruses

Plaque-forming viruses of *Chlorella* Pbi (called Pbi viruses) have been isolated from fresh water collected in Europe, Australia, Canada and certain parts of the USA. *Chlorella* Pbi, like *Chlorella* NC64A, is a former symbiont of the protozoan *Paramecium bursaria*. *Chlorella* NC64A and *Chlorella* Pbi were originally isolated from American and European isolates of *P. bursaria*, respectively. Pbi viruses, which are serologically distinct from the NC64A viruses, neither infect nor attach to *Chlorella* NC64A and vice versa. Pbi viruses have large dsDNA genomes and are structurally similar to NC64A viruses. The Pbi virus genomes also contain 5mC and 6mA (**Table 1**). DNAs from the Pbi viruses hybridize poorly with the NC64A virus DNAs and have higher GC contents (*c.* 46%) than the NC64A virus DNAs (*c.* 40%).

Viruses morphologically similar to the NC64A and Pbi viruses have also been isolated from chlorella symbiotic in the coelenterate *Hydra viridis*. However, these algae have not been cultured and their viruses do not infect either *Chlorella* NC64A or *Chlorella* Pbi.

Other Algal Viruses

Field isolates representing at least six genera of filamentous brown algae contain virus particles that are morphologically similar to EsV and FsV. Virus expression is variable; virions are rarely observed in vegetative cells but are common in unilocular sporangia (FsV) or both unilocular and plurilocular sporangia (EsV). EsV viruses only infect the free-swimming, zoospore stage of *Ectocarpus* sp. All natural isolates of *Feldmania* sp. are infected with virus and so infection studies cannot be conducted.

Viruses that infect *Micromonas pusilla* and *Chrysochromulina brevifilum* have been isolated from many marine environments. These viruses can be distinguished by DNA restriction patterns.

Viruses Encode DNA Site-Specific Endonuclease and DNA Methyltransferase Enzymes

Since the chlorella virus DNAs contain 5mC and 6mA and the methylated sequences differ from those in

host DNA, it is not surprising that the viruses encode multiple, sequence-specific, 5mC and 6mA DNA methyltransferases. However, unexpectedly, these viruses also code for DNA site-specific (restriction) endonucleases (**Table 2**). Thus algal viruses are a new source of DNA restriction endonuclease and DNA methyltransferase genes and the first source from a nonprocaryotic system. Some of the virus encoded site-specific endonucleases have the same recognition and cleavage specificities as bacterial restriction endonucleases (e.g. R.CviAI (/GATC) and R.CviBI (G/ANTC)); others are neoschizomers of bacterial endonucleases (e.g. R.CviAII(C/ATG) and R.CviQI (G/TAC)); and still others have novel recognition sites (e.g. R.CviJI (RG/CY) and R.CviRI (TG/CA)). Two of the site-specific endonucleases (NYs1-nickase (/CC) and NY2A-nickase (R/AG)) only cleave one strand of dsDNA, i.e. they are sequence-specific nicking enzymes.

The biological function(s) of the virus-encoded DNA site-specific endonucleases and DNA methyltransferases is unknown. However, the common occurrence of these genes in the viruses suggest that these enzymes have an important function in the natural history of the viruses. Bacterial restriction/methylation systems confer resistance to foreign DNAs and DNA viruses. In fact, the name 'restriction' refers to their role in excluding foreign DNA. Conversely, bacterial DNA methyltransferases serve to prevent self-digestion of bacterial DNA. We have considered two possible functions for the chlorella virus enzymes. (1) Chlorella virus endonucleases help degrade host DNA, providing deoxynucleotides that are recycled into virus DNA. Methylation of nascent DNA by the cognate methyltransferase would protect it from suicidal self-digestion. (2) Chlorella virus endonucleases prevent infection of a cell by a second virus. Experimental tests of these two hypotheses have yielded ambiguous results.

Although the genomes of most of the other algal viruses have not been characterized, preliminary studies indicate that methylated bases may be common in the genomes of these viruses.

Ecology

Eucaryotic algae are important components of both fresh water and marine environments; however, the

significance of viruses or VLPs in these systems is only beginning to be appreciated. The chlorella viruses are ubiquitous in fresh water collected throughout the world and titers as high as 40 000 infectious particles per ml have been reported in native waters. Typically the titer is 1–100 infectious particles per ml. The titers are seasonal with the highest titers in the spring. It is not known whether chlorella viruses replicate exclusively in algae symbiotic with paramecia or if the viruses have another host(s). In fact, it is not known if paramecium chlorellae exist free of their hosts in natural environments. It is known, however, that symbiosis protects paramecium chlorellae from infection and that the algae only become infected after they are released from the paramecium.

From an ecology standpoint, the MpV viruses that infect *Micromonas pusilla* have been the most extensively studied. Like the chlorella viruses, high titers of MpV viruses can be isolated from diverse marine environments. Detailed studies on the turnover of MpV viruses in nature indicate that these viruses probably play an important role in native populations of *M. pusilla*. Presumably similar viruses strongly influence populations of other marine algae.

Ectocarpus sp. and *Feldmania* sp. isolated from all over the world are infected with lysogenic EsV and FsV viruses, respectively. Lysogeny is consistent with the observation by many investigators that VLPs appear infrequently in eucaryotic algae and at certain stages of algal development. The apparent lack of infectivity by many of the previously observed VLPs in eucaryotic algae is also consistent with a lysogenic lifestyle. The VLPs might either infect the host and resume a lysogenic relationship or be excluded by preexisting lysogenic viruses.

Algae might also harbor viruses in a carrier-state relationship (also called pseudolysogeny), where at any one time a small population of algae are continually infected by virus. This type of relationship occurs with bacteriophages. A carrier-state-type relationship between PBCV-1 and *Chlorella* NC64A has been observed in the laboratory.

Future Perspectives

The algal viruses are similar in some respects to other large DNA viruses, in particular African swine fever virus, iridoviruses, poxviruses and herpesviruses. However, they also have some unique and interesting properties. (1) Algal virus genomes are the largest virus genomes characterized to date, more than one-half the size of the smallest free-living organism. (2) The chlorella viruses are a new source of DNA methyltransferase and site-specific endonuclease enzymes. (3) The chlorella viruses are the first viruses to encode many, if not all, of the enzymes involved in the glycosylation of their glycoproteins. (4) Chlorella virus PBCV-1 is the first virus to contain at least two different types of introns in its genome. (5) PBCV-1 is the first virus to code for enzymes such as aspartate transcarbamylase, translation elongation factor 3, hyaluronan synthase, UDP-glucose dehydrogenase, ornithine decarboxylase and histidine decarboxylase. (6) The brown algal viruses have a lysogenic phase as part of their normal life cycle, and convert to a lytic phase during the development of sporangia.

AMPHIBIAN HERPESVIRUSES (*HERPESVIRIDAE*)

Allan Granoff, St Jude Children's Research Hospital, Memphis, Tennessee, USA

History

In 1934, Baldwin Lucké, a pathologist at the University of Pennsylvania, discovered that kidney tumors (adenocarcinomas) of the common leopard frog, *Rana pipiens*, contained intranuclear acidophilic inclusion bodies typical of certain virus infections. On the basis of this observation and further study, Lucké concluded that the tumor was caused by a virus. More than 20 years later, electron microscopy revealed virus particles typical of herpesviruses in frog kidney tumor cells. Another decade passed before a causative relationship was established between the Lucké tumor herpesvirus (LTHV) and kidney adenocarcinoma in *R. pipiens*. Subsequent efforts to isolate and cultivate LTHV failed, but a second, distinct herpesvirus was isolated and grown in tissue culture. This virus (frog virus 4, FV4) was found not to be tumorigenic. To date, these remain the only two amphibian herpesviruses that have been identified. In contrast to the available information on the other animal herpesviruses, little is known of the properties of these viruses and their interactions with cells they infect.

Taxonomy and Classification

LTHV and FV4 are members of the family *Herpesviridae*. They have not been assigned to subfamily and genus.

Lucké Tumor Herpesvirus

Geographic distribution

The Lucké tumor and its associated LTHV has usually been limited to *R. pipiens* in north central and northeastern United States and adjacent southern Canada. For reasons that are unclear, the population of affected frogs in these regions has decreased drastically in recent years.

Properties of the virion

In size and structure, LTHV is similar to herpesviruses found in both higher vertebrates (humans) and lower vertebrates (fish). Virions in infected cell nuclei measure approximately 100 nm in diameter, with the size increasing after cellular membranes are acquired; extracellular virus increases to about 170 nm (**Fig. 1**).

The DNA of LTHV is a linear, double-stranded molecule with a base composition of 45–47% guanosine plus cytosine (G + C) and a molecular weight of 66×10^6, as determined by contour length measurement. If this value is confirmed by other methods of measurement, it is much lower than that of other herpesvirus DNAs.

Virus replication and gene expression

LTHV has not been cultured *in vitro*, a prerequisite for temporal studies of the kinetics of virus growth and molecular and biological events in the replication

cycle. This has not been from lack of effort; cells from a number of amphibian, piscine and mammalian species have been tested under various conditions.

There is a direct relationship of temperature to virus replication and expression of virus genes. At temperatures below 11.5°C, tumor cells *in vivo* or *in vitro* have typical intranuclear inclusions and virus particles, whereas the cells are free of virus at higher temperatures. This is true for tumor cells in the intact animal, in fragment cultures *in vitro*, and in fragments explanted to the anterior eye chamber of *R. pipiens*. Also, tumor cells can become virus-free or can be induced to produce virus by shifting the temperature of either the intact animal or the *in vitro* tumor fragment culture system.

The immune system does not appear to play a role in the failure of LTHV to replicate at higher temperature in the intact animal because explants of virus-containing tumor tissue cultured *in vitro* at higher temperature become virus-free in the absence of antibody. Thus, temperature is the controlling factor in replication of LTHV. Although virus particles have not been demonstrated in tumor cells at the higher temperatures, virus genetic information is expressed in the form of virus-specific RNA and virus-associated membrane antigens. Therefore, the LTHV genome resident in virus-free tumor cells at elevated temperature transcribes RNA, the translational product of which is probably expressed as a membrane-associated antigen.

Oncogenicity

Tumors can be induced at a high frequency in *R. pipiens* embryos and larvae inoculated with virus-containing cell fractions from Lucké tumors. Although Lucké tumors have been found in nature only in *R. pipiens*, typical renal tumors have been induced in embryos of *R. clamitans* and *R. palustris* and in hybrids of *R. palustris* and *R. pipiens*. In addition, LTHV that has been purified by rate zonal centrifugation of cytoplasmic fractions of virus-containing tumors is oncogenic when injected into developing frog embryos. Tumor-bearing frogs frequently have ascites and the ascitic fluid contains virus that induces tumors when inoculated into developing frog embryos.

Transmission

Data on the natural transmission of LTHV and factors that influence tumor formation in nature are lacking. However, two possible modes of natural transmission have been suggested: (1) contact with urine, which has been found to contain virus particles; (2) infection of oocytes in tumor-bearing female frogs. In the past, Lucké tumors were found in *R. pipiens* with high frequency (1–9%) suggesting ready transmission of the virus.

Frog Virus 4

During attempts to isolate the Lucké tumor herpesvirus from homogenates of Lucké tumors and urine of tumor-bearing frogs, a herpesvirus was isolated that had a cytopathic effect on frog embryo cells derived from *R. silvatica*. Subsequently, two *R. pipiens* embryo cell lines were also found to be susceptible to this virus. In size, morphology and site of synthesis, the virus – designated frog virus 4 (FV4) – is indistinguishable from LTHV and from other members of the herpesvirus family (**Fig. 2**).

Properties of the virion

Several properties, however, distinguish FV4 from LTHV. The DNA of FV4, extracted from purified

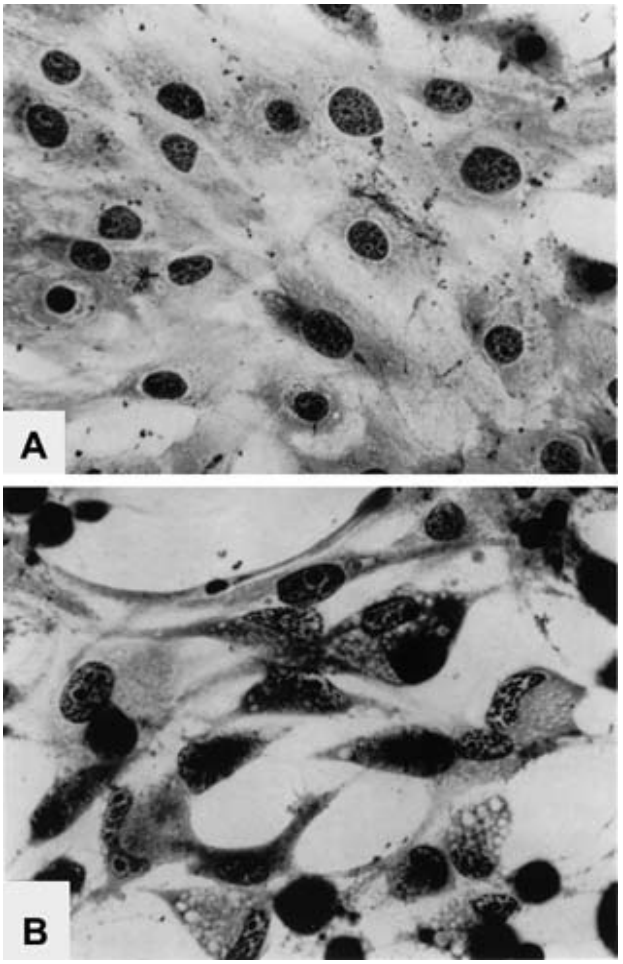

Figure 3 *R. pipiens* embryo cells infected with FV4 illustrating cytoplasmic vacuolization and intranuclear inclusions (**A**) uninfected, (**B**) FV4 infected (May–Gruenwald–Giemsa), ×356. (Reproduced from Merele Mizell (1969) *Recent Results in Cancer Research,* Special Supplement, *Biology of Amphibian Tumors,* p. 279. Springer-Verlag.)

virions, is a linear, double-stranded molecule. Its molecular weight, about 77×10^6, is comparable to the DNA of other herpesviruses that infect lower vertebrates, including channel catfish and trout, but significantly greater than that for LTHV. The base composition of FV4 also differs from that of LTHV, comprising 54–56% G+C. There is no sequence homology between FV4 and LTHV, as determined by DNA–DNA hybridization.

Virus replication

Unlike LTHV, FV4 can be readily cultured *in vitro*. The virus has a long growth cycle and produces a characteristic cytopathic effect in *R. pipiens* embryo and adult kidney cells at 25°C within 10–21 days after infection. This effect comprises rounding, vacuolization, enlargement of nuclei, polykaryon formation and intranuclear inclusions typical of the cytopathology of other herpesviruses (**Fig. 3**).

Transmission

Although FV4 infects *R. pipiens* embryos and larvae, animals that survive virus infection do not develop kidney tumors.

Future Perspectives

Further research on LTHV has been hampered by the lack of available virus-containing tumors and of a reproducible virus-susceptible cell culture system. The latter is an absolute requirement as a resource of substantive amounts of virus and for study of the various features of virus–cell interactions under controlled conditions. Initial information on FV4 suggests that this virus would be a useful model for furthering our understanding of comparative virology and the evolution of herpesviruses. However, research attention has focused on the more medically important herpesviruses and little additional work has been done on this potentially interesting one.

Introduction

Accomplishments in the discovery and development of antiviral drugs over the past few years have come at an ever increasing rate, so that the profile of available therapies today differs considerably from that described in the first edition of the *Encyclopedia of Virology*. In large part this has been driven by the increased emphasis on developing effective therapies for the treatment of human immunodeficiency virus (HIV) and diseases associated with immunosuppression, such as cytomegalovirus (CMV) retinitis and pneumonitis. But this progress has also been driven by the identification of novel targets (e.g. HIV and herpesvirus proteases) for antiviral therapy, and the considerable improvements in understanding the structure and functions of virus-encoded gene products. Just as new antiviral drugs emerge through improvements in understanding virus replication at the molecular level, so too is the improved understanding of virus gene function a result of new antiviral drug discovery and characterization of resistance mechanisms. Thus, the understanding of the mechanism of CMV-dependent phosphorylation of ganciclovir led to better definition of the CMV UL97 gene, and this occurred with the availability of ganciclovir-resistant mutants altered in the UL97 gene. Similarly, the discovery of the mechanisms of cytomegalovirus inhibition by the benzimidazole derivatives such as 1263W95 is helping to elucidate the mechanisms of DNA processing and virion maturation.

Another development that has driven advances in antiviral chemotherapy has been the realization that resistance to monodrug therapy accounts for considerable failure in the treatment of HIV. Thus the emphasis has shifted to drug combination therapy, with combinations of reverse transcriptase inhibitors and protease inhibitors getting most attention. An understanding of the dynamics of virus and host cell interaction and turnover and an appreciation of the importance of 'viral load' have led to these new strategies to inhibit the emergence of an array of virus mutants. As Dr Raymond Schinazi recently wrote 'Dead viruses don't mutate', recommending that 'we should learn rapidly from our experience with HIV and plan accordingly to hit the virus early with our best drugs' (Editorial (1997) *Int. Antiviral News* 5: 122). That philosophy is broadly applicable.

Here we have reviewed the newly approved antiviral drugs and drugs in clinical development, while trying to avoid redundancy with the first edition. Also, where applicable, we emphasize the strategies for overcoming treatment failure, including antiviral combination therapy. Only selected compounds will be mentioned in the text, so for ease as a quick and more complete reference, details of compounds and their development status are presented in **Table 1**.

Human Immunodeficiency Virus (HIV)

The emergence of HIV in the 1980s has had a devastating impact on the world's population. Although transmission in the USA is primarily through exchange of contaminated blood associated with male homosexual intercourse and illicit drug use, it is also increasingly transmitted by heterosexual intercourse, which is the primary mode of transmission in many parts of the world. Not only has the spread of HIV been a huge stimulus for new drug discovery and development, but also it has led to a revolution in the way clinical trials are conducted, including the use of surrogate markers, expedited Food and Drug Administration (FDA) review and expanded access to experimental agents outside of formal clinical trials. Numerous studies also now demonstrate that surrogate markers can be useful substitutes for the measurement of a drug's effect on disease progression and death. Changes in CD4 counts were initially, with some caveats, shown to be a reliable predictor for death. More recently, measurements of viral load appear to be more sensitive markers of therapeutic effect.

There are many stages of the viral replication cycle which can be targeted by anti-HIV therapeutics. These include: attachment and entry, uncoating, reverse transcription of genome RNA, DNA integration, transcription from the integrated genome, translation of viral proteins, and assembly and egress of progeny virions. To date, the approved drugs all act at the level of reverse transcription (reverse

Table 1 Approved and experimental antiviral drugs

Antiviral drug	*Chemical class*	*Probable mechanism of action*	*Potential virus/disease targets*	*Development status*
Human immunodeficiency virus				
Azidothymidine (AZT, Zidovudine, Retrovir)	Nucleoside analogue	RT inhibitor	First line Rx for adults and children 3–12 years; also to prevent transmission to newborns	Approved oral 1989; i.v. in 1990; transmission to newborns in 1994
Didanosine (ddI, Videx)	Same	Same	Adult and pediatric for advanced HIV refractory to AZT	Approved 1991
Hivid (ddC, Zalcitabine)	Same	Same	Combo with AZT	Approved 1992
			Monotherapy	Approved 1994
Stavudine (D4T, Zerit)	Same	Same	HIV unresponsive to other drugs	Approved 1994
			Full usage	Approved 1995
Lamivudine (3TC, Epivir)	Same	Same	Combo with AZT	Accelerated approval in 1995; full approval in 1997
Abacavir (GW 1592)	Same	Same	Combo therapy	Phase II/III
Lodenosine (F-ddA)	Same	Same	HIV	Phase I
Adefovir (PMEA, GS 393)	Nucleotide analogue	Same	HIV	Expanded access
Adefovir dipivoxil (GS 840, bisPOM-PMEA)	Adefovir prodrug	Same	HIV	Phase II/III
Delavirdine (Rescriptor, BHAP U-90152)	NNRTI		HIV combo therapy	Approved 1997
Nevirapine (BI-RG-587)	Dipyridodiazepinone	Same	HIV, in combo with nucleoside analogues	Approved 1996
Efavirenz (Sustiva, DMP-266)	Benzoxazin	Same	HIV, in combo with Indinavir	Phase III
HBY 097	Quinoxaline	Same	HIV	Phase II
Saquinavir (Inverase, Ro31-8959)	Peptide mimetic	Protease inhibitor	Combo with AZT for advanced HIV	Approved 1995
Fortovase	Gel formulation of saquinavir		Same	Approved 1997
Ritonavir (Norvir, ABT-538)	Same	Same	HIV, alone or in combo with nucleoside analogue RT inhibitor	Approved 1996 Pediatric approved 1997
Indinavir (Crixivan, MK 639, L-735,524)	Same	Same	Same	Approved 1996
Nelfinavir (Viracept, AG-1343)	Same	Same	HIV, adults and children	Approved 1997
Amprenavir (GW141W94, VX-478)	Carbamate derivative	Same	Combo with AZT & 3TC or NNRTI	Phase II/III
Zintevir (T30177)	Oligonucleotide	Virus binding and integrase inhibitor	HIV	Phase I/II
ISIS 5320	Same	Not well established	HIV	Studies on hold
GEM 92	Same	Same	HIV	Studies on hold
Herpesviruses				
Adenine arabinoside (Vira-A)	Nucleoside analogue	DNA Synthesis inhibitor	HSV-1, -2 VZV	Approved (i.v.) for herpes encephalitis, neonatal herpes
Acyclovir (Zovirax)	Same	Virus-activated DNA-synthesis inhibitor	HSV-1, -2 VZV	Approved, oral topical, i.v., ophthalmic

Table 1 Continued

Antiviral drug	*Chemical class*	*Probable mechanism of action*	*Potential virus/disease targets*	*Development status*
Valacyclovir (Valtrex)	Acyclovir prodrug	Same	HSV-1, -2 VZV	Approved(oral) for genital herpes, herpes zoster
Penciclovir	Nucleoside analogue	Same	HSV-1, -2 VZV	Topical for herpes labial
Famciclovir (Famvir)	Penciclovir prodrug	Same	HSV-1, -2 VZV, HBV	Approved (oral) for genital herpes, herpes zoster
Foscarnet (Foscovir)	Pyrophosphate analogue	DNA pol inhibitor	HSV-1, -2 VZV,HCMV	Approved (i.v.) CMV retinitis, resistant HSV
Docosanol (Lidakol)	Alkyl alcohol	Lipase inhibitor	Herpes labialis	Topical; phase III
348U87 +acyclovir	Combination	Ribonucleotide reductase inhibitor	HSV-1, -2	Phase II
Ro32-4397		Thymidine kinase inhibitor	HSV-1, -2	Experimental studies; orally active
HBPG	Nucleoside analogue	Thymidine kinase inhibitor	HSV-1	Experimental studies
BILS45BS	Thiazolyl phenyl-based	Helicase-primase inhibitor	HSV-1	Experimental studies; orally active
Ganciclovir (Cytovene)	Nucleoside analogue	Virus-activated DNA pol inhibitor	HCMV	Approved for HCMV retinitis; oral, injectable
Ganciclovir (Vitrosert)	Same	Same	HCMV	Approved vitreal implant for HCMV retinitis
Valgancyclovir	Valine ester prodrug of gancyclovir	Same	Same	Phase III
Cidofovir (Vistide)	Nucleotide analogue	DNA pol inhibitor	HCMV	Approved oral for HCMV retinitis
Lobucavir	Nucleoside analogue	DNA pol inhibitor	HCMV, HBV	Phase II oral for HCMV retinitis
1263W94	Benzimidazole analogue	DNA synthesis inhibitor	HCMV	Experimental studies
GW275175X	Same	DNA processing inhibitor	HCMV	Phase I
Unnamed	Same	DNA processing inhibitor	HCMV	Experimental studies
Bis-POMPMEA (Adepfovir dipivoxil, GS 840)	Nucleotide analogue	DNA pol inhibitor	HCMV	Phase III oral HCMV retinitis
Fomivirsen (Vitravene, ISIS 2922)	Oligonucleotide	Mechanism uncertain	HCMV	Approved 1998 for intravitreal HCMV retinitis
(ISIS 13312)		Same	Same	Phase I/II
GEM 132	Same	Antisense UL36/37 splicing inhibitor	HCMV	Phase I/II intravitreal HCMV retinitis Phase I/II i.v. for generalized HCMV
Myxoviruses				
Amantadine (Symmetrel)	Adamantane derivative	Inhibits viral M2 ion channel	Influenza A	Approved oral 1966
Rimantadine (Flumadine)	Same	Same	Same	Approved oral 1992
Zanamavir (GG167)	Sialic acid transition state analogue	Inhibits viral neuraminidase	Influenza A, B	Phase III
GS4104	Same	Same	Same	Phase III (oral)
2′-deoxy-2′-fluoroguanosine	Nucleoside analogue	Inhibits transcription	Same	Preclinical studies

Table 1 Continued

Antiviral drug	*Chemical class*	*Probable mechanism of action*	*Potential virus/disease targets*	*Development status*
Paramyxoviruses				
Ribavirin (Virazole)	Triazole nucleoside analogue	Inhibits RNA polymerases and transcription	RSV, PIV (also broad antiviral activities)	Aerosol approved for RSV in hospitalized infants Aerosol therapy of bone marrow transplant patients under evaluation
RespiGam	Immune globulin	Neutralizes viral infectivity	RSV	Prophylaxis in high-risk infants
Monoclonal antibodies	Same	Same	Same	Preclinical, early clinical, and phase III
Hepatitis viruses				
Interferons (INF) alpha/gamma (Intron A, Roferon)	Recombinant proteins	Immune modulator, direct antiviral	HBV, HCV	Approved i.m. injectable
Intron A/Rebetol, Rebetron (INF+ribavirin)			HCV	Approved 1998 for Intron A relapsed adults
INF+thymosin α_1		Immune modulators	HBV, HCV	Phase III
Famciclovir	See above	See above	HBV	Phase III
Lamivudine	See above	See above	HBV	Phase III
GS 840	See above	See above	HBV	Phase I
BMS-200475	Nucleoside analogue	DNA polymerase inhibitor	HBV	Phase I
Picornaviruses				
Pleconaril (VP-63843)	Isoxazole	Capsid binding, inhibits uncoating	Enteroviruses Common cold	Phase III, aseptic meningitis
Soluble ICAM (sICAM)	Peptide	Cell receptor decoy	Rhinoviruses	Phase II in prophylaxis in experimental rhinovirus infections
Papillomaviruses				
Interferon alpha (Intron, Aferon)	Protein	Immunomodulator direct antiviral	Intrawart injection	Approved 1996
Imiquimod (Aldera)	Quinoline	Immunomodulator	Topical for genital warts	Approved 1997
Condylox	Podophyllotoxin	Anti-mitotic	Same	Approved 1991
Cidofovir	Nucleotide analogue	Unknown	Topical/local genital warts, RRP	Phase III for genital warts
Ribavirin	See above	See above	Intravenous/oral laryngeal warts	Phase I/II clinical
5-fluorouracil (AccuSite)	Nucleoside analogue	Anti-mitotic	Intrawart injection	Approved in UK and Europe
Exotic Viruses (see text for discussion of antiviral agents)				

transcriptase inhibitors, or RTIs) or progeny assembly and egress (HIV protease inhibitors, or PIs); however, compounds addressing virtually every identified target are in stages of preclinical or clinical development.

For years it appeared that HIV replication smoldered between a burst at the time of primary infection and progressively higher chronic levels in the final stages of disease; however, it is now appreciated that replication is explosive throughout the disease course, with the early seeding of a large reservoir of latently-infected lymphocytes. Furthermore, host immune responses are continuously high in the desperate attempt to control viral replication and prevent the infection of new lymphocytes. If the assumption that pathogenesis is related to the rate of viral replication

is valid, then there is cause for optimism regarding the potential utility of antiviral therapeutics which can significantly reduce replication rates. This high level of virus replication also provides a rationale for the facility with which HIV develops resistance to monotherapies and underscores the urgency of the search for ever more potent aniviral drugs directed at novel gene targets for use in drug combinations.

The implementation of highly active antiretroviral therapy (HAART) has revolutionized the treatment of HIV infection. HAART has resulted in the restoration of immune function in patients with AIDS as well as a corresponding decrease in the incidence of opportunistic infections such as CMV retinitis. HAART generally involves the use of two RTIs in combination with a PI. It is important to change one or both RTIs at the time of addition of the PI, as resistance to the RTIs may have already developed. The stage of HIV disease also has an impact on the success of HAART, as patients with high viral loads ($>10^5$ RNA copies ml^{-1} blood) or low CD4 counts do not do as well as healthier patients. HAART increases the complexity of the dosing regimen as well as the number of pills, and strict patient compliance is also key to the success of HAART.

HAART has been so successful that it is the basis of the US Department of Health and Human Services (DHHS) treatment guidelines published in June 1997. These guidelines conclude that the damage to the immune system is the result of continued replication of HIV; and since replication of HIV is an error-prone process, the more replication, the likelier the selection of resistant mutants. Therefore the guidelines advise that the overriding goal of treatment is to decrease and maintain HIV replication below 10 000–20 000 copies of RNA ml^{-1}. Consequently, to reduce both the immune damage and mutant selection associated with viral replication, the guidelines recommend that initial treatment should consist of a combination of three anti-HIV agents with at least two others substituted at the same time if a patient's viral load increases. The current preferred form of HAART is two nucleoside RTIs combined with a PI. The guidelines also recommend that pregnant women receive azidothymidine (AZT) during pregnancy (at least from the 14th week) and intravenous AZT during labor and delivery, with the newborn receiving oral AZT for the first 6 weeks post partum.

Although HAART is dramatically effective in reducing or obliterating serum viral loads and preventing the emergence of drug-resistant virus, it has not been successful in eradicating virus from latently infected cells. The discovery that HIV remains dormant for years in a pool of latently infected lymphocytes led to the realization that HAART may not totally eliminate viral replication. Instead it may allow a replication level that is sufficient to establish new inducible latent infections, or the lifespan of the latently-infected cells may be sufficiently protracted to sustain infection. On an economic level, HAART is certainly financially beyond the reach of the vast majority of the world's HIV-infected population, emphasizing the need for prevention as well as treatment.

Approved agents

A. Nucleoside reverse transcriptase inhibitors (NRTIs)

Azidothymidine (AZT, retrovir), was the first drug to show clinical efficacy and receive FDA approval. Its licensure is for first-line therapy in early- and late-stage adults and in children over 3 months of age. The 1997 DHHS guidelines recommend its use with ddI, ddC or 3TC as the two nucleoside components of a three or more drug HAART regimen. AZT is a thymidine analogue in which the 3′OH is replaced by an azido group. AZT is phosphorylated in HIV-infected cells to AZT triphosphate and is preferentially incorporated instead of the natural thymidine triphosphate into replicating viral DNA by the HIV reverse transcriptase, resulting in chain termination. Thus, it inhibits reverse transcription at two levels, substrate specificity and elongation, with selectivity resulting from its low level of utilization by cellular DNA polymerase α. The first placebo-controlled study done with AZT in patients with advanced AIDS indicated that AZT therapy might prolong survival. Therapy has also been shown to reduce the number of opportunistic infections. The primary side effect is bone marrow toxicity, but it can also cause myopathy and gastrointestinal distress. Like the other nucleoside analogues, it is orally bioavailable and is excreted renally. AZT given during the last two trimesters of pregnancy and to the newborn after birth has been shown to prevent maternal to fetal transmission of HIV. The emergence of AZT-resistant virus is associated both with duration of therapy and stage of disease, and detailed characterization of HIV mutations is well documented. With the demonstration of the therapeutic potential of AZT, other dideoxynucleosides were also investigated for therapeutic potential and resulted in additional licensures.

ddC (Hivid, Zalcitabine): like AZT, ddC is converted to the active antiviral agent ddCTP by cellular kinases and incorporated by the HIV RT into proviral DNA as a chain terminator, in place of dCTP. Unfortunately, ddCTP is also a substrate for cellular polymerase β and mitochondrial polymerase γ. The

latter may be responsible for its primary toxicities, peripheral neuropathy occurring in about 25% of treated patients and pancreatitis in about 1% of treated patients. ddC is orally bioavailable and is excreted through the kidneys. Resistant mutants are often cross-resistant to ddI, d4T and 3TC. ddC is recommended in the 1997 DHHS Guidelines as a possible choice in combination with AZT for the two nucleosides in combination with a PI in HAART, but because of overlapping toxicities, ddC should not be used with ddI or d4T. The indication for which ddC was approved is as a combined therapy with AZT for patients with advanced AIDS.

ddI (Videx, didanosine): although extra steps are required for addition of the amino group to convert the inosine to adenosine, like the other nucleoside analogues ddI is processed by cellular kinases to produce the active antiviral agent, ddATP. The triphosphate competes with dATP for incorporation by the HIV RT into proviral DNA and results in chain termination. The intracellular half-life of ddATP is approximately 25 h, which is significantly longer than those of AZTTP and ddCTP. This suggests that it may be possible to decrease the number of daily doses needed from two to one. Didanosine is less orally bioavailable than the other nucleoside RTIs and must be taken on an empty stomach. Like ddC the principal toxicities are pancreatitis and peripheral neuropathy. The original approval was for adults who had already had long-term treatment with AZT and for treatment of adults or children who do not tolerate AZT or whose immune status deteriorated while on AZT. In the 1997 DHHS guidelines, ddI is recommended together with either AZT or d4T as a possible nucleoside combination to be used with a protease inhibitor as part of HAART.

d4T (Stavudine, Zerit) received approval for the treatment of patients who have failed to tolerate other approved therapies and for those who continue to decline on approved therapies. The 1997 guidelines list d4T, in combination with either ddI or ddC, as possible selection for the two nucleoside components of a triple drug regimen of HAART. Like the other nucleoside RTIs, d4T is phosphorylated to the active antiviral agent, stavudine triphosphate. Inhibition again is at two stages. First it competes with the correct RT substrate TTP and then further interferes by causing chain termination following incorporation. The three phosphorylation steps are all efficiently accomplished and there is not the accumulation of excess monophosphate with d4T that is seen with AZT. The primary toxicity is peripheral neuropathy.

3TC (Epivir, lamivudine, (−)-3′thiacytidine) received accelerated approval for use in combination with AZT on the basis of clinical trials using viral load and CD4 surrogate markers. Full approval was awarded in 1997 after improved survival was documented in an international study. Although 3TC is a potent inhibitor of both HIV and HBV RTs, resistant mutants are readily selected. Consequently it should always be used as part of a combination therapy. Its mechanism of action is similar to the other nucleoside analogues, e.g. phosphorylation to the triphosphate which is a competitive inhibitor of the HIV RT, with termination of growing proviral DNA chains. 3TC reacts less than the other nucleosides with the mitochondrial polymerase γ, a feature which is presumably responsible for its more attractive safety profile. The 1997 DHHS guidelines for HAART recommend its use as one of two nucleosides, preferably with AZT, combined with a PI.

B. Nonnucleoside reverse transcriptase inhibitors (NNRTIs)

The NNRTIs differ from the NRTIs in that they do not have a nucleoside structure and do not depend on phosphorylation for activity. They function as non-competitive substrate analogues and are selective inhibitors of HIV-1, with no activity against HIV-2 strains or even HIV-1 type O. Both approved NNRTIs have oral bioavailabilities greater than 60% and are highly protein bound. NNRTIs have been identified in multiple chemical classes, yet they all appear to bind the same region of the RT. This is separate from the binding region of the NRTIs, so the NNRTIs generally retain activity against AZT-resistant HIV variants. Although NNRTIs usually have potent antiretroviral activity, resistant mutants are readily selected and therefore these drugs are not recommended as monotherapy. The 1997 DHHS guidelines list the use of a combination of one NNRTI and two NRTIs as less preferred than a triple therapy of two NRTIs and a one PI.

Nevirapine (BI-RG-587, Viramune) in early clinical trials dramatically illustrated both the ease with which treatment with this class of compounds results in the selection of resistant mutants and the efficacy of combination therapy in preventing their appearance. One trial compared monotherapy with nevirapine to its use in combination with AZT. There was a quick drop in serum p24 levels in both groups, but the monotherapy arm returned to baseline levels within a few weeks. The combination group sustained the decreased p24 levels. Nevirapine is generally safe, but a pruritic rash, which can usually be managed by dose reduction, is potentially severe and may be life threatening.

Delavirdine (Rescriptor, U90152, a bis(heteroaryl)-piperazine) treated patients who received the drug as a monotherapy developed resistant virus within weeks of treatment. Accordingly, its approval is as part of a combination of antiretroviral agents and is based on surrogate markers rather than demonstrated clinical benefit. As with nevirapine, the primary toxicity is a rash which usually resolves, but can be serious.

C. Protease inhibitors (PIs)

The HIV protease is essential for the cleavage of the HIV polyprotein into the separate HIV proteins needed for virion assembly. The PIs are all highly potent enzyme inhibitors *in vitro*, and treatment with the first four PIs which were approved by the FDA have all resulted in improved CD4 cell counts and decreased viral loads. Improved clinical endpoints were also documented for the first three: *Indinavir, Ritonavir* and *Invirase*. Studies to determine the possibility of clinical benefit are underway for the fourth, *Nelfinavir*. These are the first drugs which attacked a viral target other than the RT and thus made highly potent combination therapies possible. In general, the pharmacokinetic properties of these drugs require strict observance of the dosing schedule to maintain efficacy and avoid the emergence of resistance. The PIs are principally metabolized by the liver cytochrome P_{450} oxidase system and consequently they can have serious interactions with other drugs in several classes. The PIs have been associated with a varied constellation of side effects which include the development of fatty masses, hyperglycemia and elevated triglycerides. New and exacerbated diabetes has also been reported during the postmarketing period, but it is not clear if this association is real or coincidental.

All four approved PIs are uncleaveable mimics of the HIV gag-pol polyproteins which occupy the active site of the protease. The inhibitors do not prevent the formation of progeny virions, but these virions are not mature and are noninfectious. Mutations which lead to resistance are usually (but not always) located in the drug-binding pocket and may require an accumulation of three or more for the development of significant resistance. Mutants resistant to one of these inhibitors often, but not always, show decreased sensitivity to other members of this class.

Inverase (saquinavir) has relatively poor oral bioavailability (about 5%) and has been formulated to maximize uptake and maintain plasma concentrations. It is metabolized by the liver P_{450} oxidase system, necessitating multiple dosing per day to maintain efficacy. Inverase's approval was based on both improvements in surrogate markers and a decline in disease progression and mortality in patients who received a combination of HIVID (ddC) and Inverase, as compared with patients who received either drug as a monotherapy. Safety for pediatric use has not been established. In 1997, *Fortovase*, a soft gel formulation of saquinavir which has significantly improved bioavailability, was approved.

Ritonavir (Norvir) is by contrast to Inverase much more readily orally bioavailable, requiring less frequent dosing. It is approved for use as a monotherapy or in combination with NRTIs on the basis of both improvements in surrogate markers of clinical progression as well as reductions in actual events of progression and mortality. Oral dosing is twice daily and a pediatric formulation is available for children aged 2 years or older. Interestingly, ritonavir enhances the plasma levels of saquinavir by up to 20-fold by blocking liver metabolism of the latter. This has the potential to provide a strategy to overcome the disadvantage of low bioavailability of saquinavir, but the predictability of the magnitude of this effect is not reliable and would necessitate extensive monitoring of patients receiving both drugs in combination.

Indinavir (Crixivan) obtained accelerated FDA approval with the demonstration of undetectable plasma virus load and increased CD4 cell levels when given in combination with two nucleoside analogue RTIs or as a monotherapy. It is not approved for pediatric use. To maintain adequate serum levels, Crixivan must be taken at 8 h intervals.

Nelfinavir (Viracept) is the most recently approved drug in this class and approval was based on changes in surrogate markers when it was administered either as a monotherapy or in combination with NRTIs. It is dosed orally three times a day and a pediatric formulation is available. A preliminary study suggested that some nelfinavir-resistant mutants may retain sensitivity to some other PIs, although nelfinavir was not always inhibitory to HIV mutants resistant to other PIs.

Experimental agents

New nucleoside (*Lodenosine*) and nucleotide (*Adefovir dipivoxil*) analogue RTIs and NNRTIs (*Efavirenz*) are in various stages of preclinical and clinical development, with the hope of achieving high plasma levels, overcoming resistance development, and also providing added benefit in combination with approved agents.

Also a new generation of protease inhibitors is in development, with the aim of providing greater efficacy in combination with PIs and RTIs (*Amprenavir, 141W94*), improved oral bioavailability (*DMP-*

450) and efficacy against virus resistant to other PIs through novel binding to the protease active site (*PNU140 690; BMS 232 632; PD 178 390*).

Numerous novel approaches against virtually every stage of the viral replication cycle are being pursued, and will just be mentioned in passing. These include the use of oligonucleotides (*GEM 92; Zintevir; ISIS 5320*) to inhibit by a combination of methods, potentially including antisense-mediated inhibition of RNA translation, blockade of virus adsorption and/or blockade of HIV provirus integration. A receptor-binding antagonist, RBC-CD4, uses the strategy of coating erythrocytes with surface CD4. These cells internalize free HIV, thereby preventing new infections, and also bind to gp120 on infected lymphocytes, resulting in phagocytosis of already infected cells. Peptide and/or nucleotide decoys which will interfere with the binding of the HIV TAT regulatory protein with the targeted TAR region of the HIV genome are also being investigated. Zinc fingers, which are highly conserved regions of HIV proteins that bind to the packaging region of the HIV genome RNA, are attractive targets as they are involved in multiple stages of the replication cycle including reverse transcription, genome integration, RNA packaging and protease function. Inhibition of multiple zinc finger functions make it theoretically likely that resistant viruses will not emerge. In addition, since they are part of the virus structure, drugs directed at zinc fingers may also be virucidal.

In addition to strictly antiviral approaches, several other strategies deserve mention. Multiple cellular functions have been targeted, including modulation of the immune system. The combination of HAART with *interleukin 2 (IL-2)*, to stimulate CD4 T cells and enhance resistance to secondary infections in AIDS, is in clinical evaluation. The therapeutic use of killed vaccines is also in clinical trials as a means of boosting residual immune function. Other cellularly targeted agents include *hydroxyurea (HU)*, which blocks cellular ribonucleotide reductase and depletes nucleotide pools for nucleic acid synthesis. The enhanced DNA incorporation of nucleotides derived from antiviral nucleosides is hypothesized to explain the potentiation of ddI's activity by HU when they are used in combination. Resistance is not a problem as the HU target is cellular.

Two approaches involving genetic alteration of the patient's stem cells are intriguing, although their practical utility remains to be demonstrated. The first, in phase I/II clinical trials, involves the transduction of HIV-targeted ribozymes into stem cells by means of retroviral vectors. Ribozymes are RNA enzymes which cleave at a specific HIV RNA nucleotide sequence following complementary base pairing. The second approach involves transfecting lymphocytes and stem cells *ex vivo* with genes encoding *intrakines* such as CDF, Rantes or MIP-1α. These serve to block the surface expression of both HIV coreceptors (CXCR4 and CCR5) and protect the intrakine-expressing cells from infection.

A possibly more feasible 'Trojan horse' strategy also is based on the use of cellular receptors for HIV. With this strategy, the envelope gene of vesicular stomatitis virus (VSV) is replaced with the genes encoding the T cell receptors (CD4 and CXCR4) for HIV. HIV-infected cells, displaying gp120 on their surface, now can fuse with the T cell decoy and are killed by the cytolytic virus. Similar decoy constructs are being developed to mimic macrophages. Although VSV is normally a mild pathogen for cows and pigs, and even milder for the accidentally infected humans, the decoy is noninfectious for these species owing to the loss of its envelope protein. The decoy can only infect and replicate in HIV-infected cells. The strategy has only been evaluated in tissue culture, but the clinical potential is exciting.

These myriad approaches underway inspire confidence that new therapeutic strategies will enable successful control of HIV, with the clear goal of providing drugs and strategies that will effect cures at costs that do not preclude their use.

Herpesviruses

Herpes simplex virus (HSV) and varicella virus (VZV) In spite of the awareness of the risks of sexually transmitted diseases during this era of the acquired immune deficiency syndrome (AIDS), the incidence of genital herpetic infection has continued to increase dramatically, so that today it is estimated that about 20% of the sexually active population of the USA may suffer from herpes genitalis. As with all herpesvirus infections, primary genital infection results in latency and periodic recurrences in the anal/genital area. The second major HSV-associated disease is generally the cosmetic nuisance resulting from HSV oral infection and resulting in herpes labialis (cold sores) in about 90 million people in the USA. Although experimental vaccines are being developed, none is approved, indicating the continuing need for effective antiviral therapy.

For VZV the situation is quite different. This ubiquitous virus is responsible for the systemic disease of chickenpox, usually in children, with possible recurrence from latency as herpes zoster (shingles) years later in a selected dermatome in the 'immune' adult. With the approval of an attenuated live VZV vaccine in 1995 in the USA, chickenpox is now a preventable disease. But the vaccine virus may

also establish latency, and the potential to recur as zoster or prevent wild-type infection over the long run is not yet resolved. Herpes zoster may be a very painful localized disease with postherpetic neuralgia. The recurrence incidence increases with advancing age, with an estimate that about one-third of the population may experience zoster by age 75. There is substantial incentive to develop effective antiviral drugs to halt reactivation and prevent postherpetic neuralgia.

Approved agents

The early success of *vidarabine* and the important discovery and success of *acyclovir (Zovirax)* in the clinical management of HSV genital and mucocutaneous infections has effectively pointed the way in antiviral drug researach. But acyclovir has limited oral bioavailability, requiring large multiple daily doses for the treatment of varicella zoster, since VZV is less sensitive to acyclovir than is HSU. Both its successes and its limitations have provided the incentive to develop new therapies. *Valacyclovir (Valtrex)* is the L-valyl ester prodrug of acyclovir and provides improved oral acyclovir availability. It is now approved in the USA for the oral therapy of varicella, and initial episodes or recurrences of genital herpes. *Penciclovir*, another acyclic nucleoside analogue, which is also selectively phosphorylated (like acyclovir) by HSV thymidine kinase (tk) and cellular kinases to the triphosphate inhibitor of viral DNA polymerase, has also been approved as a 1% cream for treatment of oral herpes. *Famciclovir (Famvir)*, a prodrug of penciclovir with enhanced oral bioavailability, has been approved for prophylactic suppression of recurring episodes of genital herpes.

In HSV-infected patients with normal immune responses, development of resistance to nucleoside analogues is not a significant problem. But in immunocompromised patients, infected neonates and in chronic skin infections acyclovir-resistant virus can be a clinical problem, presenting the need for alternative therapies. *Foscarnet (Foscovir)*, a DNA polymerase inhibitor, is considered a good alternative for treatment, although hospitalization is required for therapy and is associated with toxicity. Thus, there is a continuing need for new anti-HSV drugs with novel modes of action.

Experimental agents

The HSV ribonucleoside reductase inhibitor, *348U87* (from Glaxo Wellcome), has been used in combination with acyclovir in phase II clinical trials. Recently *lidakol* (10% *n*-docosanol cream), an inhibitor of enveloped viruses, has shown success in improving healing time as a topical treatment of herpes labialis and has moved into phase III clinical trials. HSV tk has long been recognized as a potential antiviral target because it is essential for virus reactivation and replication in neurons. A Roche Research Center team has identified an orally active tk inhibitor (*Ro 32-4397*) that is highly selective in inhibiting virus replication in dorsal root ganglia in mouse protection studies. Another tk inhibitor, HBPG, with *in vivo* efficacy is also under study at UMass Medical Center. Another exciting development is the identification of an inhibitor of HSV helicase/primase by a team at Boehringer Ingelheim and Bio-Mega. The lead thiazolyl phenyl-containing compound (*BIS45BS*) is orally active against both acyclovir-sensitive and -resistant viruses in animal protection studies, and further preclinical development seems warranted.

Human cytomegalovirus (HCMV) CMV is a common infection but an uncommon disease, associated with immunocompromised individuals such as late-stage AIDS patients, allograft recipients and the newborn. The rise in the incidence of CMV disease as an AIDS-opportunistic illness has been paralleled with the emergence of new products, primarily with the aim of halting the spread of CMV retinitis. Also the effect of HAART has resulted in a decrease in the incidence of CMV retinitis. But the needs go beyond AIDS, with life-threatening CMV still a problem for the bone marrow transplant patient. Furthermore, congenital CMV infection affects 1% of all American newborns and is the leading cause of hearing loss in children. Also emerging is an understanding that CMV infections may contribute to the development of atherosclerosis, and restenosis following angioplasty.

Approved agents

Ganciclovir (Cytovene, GCV) was initially approved for therapy in the treatment of CMV retinitis and later for the prevention of CMV disease in transplant recipients. Although GCV has poor oral bioavailability, an oral formulation has been approved as a prophylactic for the prevention of HIV- and solid organ transplant-related CMV disease, as well as an alternative to intravenous therapy for maintenance therapy for stable CMV retinitis in AIDS patients. However, the relatively poor oral bioavailability of GCV has been a significant deficiency, prompting the development of new drugs and new formulations. GCV has also been formulated, with approval in 1996, as an intravitreal implant (*Vitrasert*) for treatment of CMV retinitis. Furthermore, a valine prodrug of GCV (*Valganciclovir*) is in clinical evaluation for

the treatments of CMV. Unfortunately GCV lacks high anti-CMV potency for effective suppression of virus replication and the emergence of resistant mutants. Since CMV is a systemic infection, with localized sites of disease pathology such as retinitis in AIDS patients and pneumonitis in bone marrow transplant patients, it is important that effective therapy reduces the systemic virus load and reduces the chances of clinical resistance development. Prophylactic use of GCV results in emergence of resistant CMV strains in about 1% of patients; about 80% by mutation in the the *UL97* gene which is responsible for phosphorylation of GCV to GCV-monophosphate, and about 20% by mutations in the CMV DNA polymerase (DNA pol).

Unlike GCV, two drugs with antiviral potency not altered by the *UL97* mutation are *cidofovir (Vistide, HPMPC)*, which was approved in 1996 for intravenous treatment of AIDS-related CMV retinitis, and *foscarnet (Foscavir)*, which was approved for intravenous therapy of retinitis. Cidofovir is phosphorylated by cellular kinases and cidofovir diphosphate inhibits DNA pol. Foscarnet is a pyrophosphate analogue which inhibits CMV DNA synthesis. Both compounds are effective against GCV-resistant *UL97* mutants, but may not be effective against DNA polymerase mutants.

Experimental agents

Newer drugs now in different stages of clinical development have shown innovative approaches in the search for novel therapies. *Lobucavir*, a novel cyclobutyl nucleoside analogue, has been identified as active against the herpesviruses and hepatitis B virus, and is presently in phase I/II trials for oral therapy of CMV in AIDS patients, with the evaluation of CMV in semen. *Adefovir dipivoxil (GS 840, bis-pomPMEA)* a nucleoside phosphonate derivative, is in oral phase III clinical studies. Two benzimidazole derivatives which are in development have defined new targets for anti-CMV research. Glaxo Wellcome's *1263W94* inhibits CMV DNA synthesis but not by blocking DNA pol. Although mechanisms of inhibition are not fully elucidated, the compound is in phase I/II clinical trials. *GW275175X*, also from these labs, does not block CMV DNA synthesis but inhibits CMV *UL89* terminase, an apparently essential function for the processing and packaging of genomic CMV DNA into capsids. Lastly, three drugs have emerged from the antisense oligonucleotide approach to antiviral drug development. *Fomiversen (ISIS 2922)* (FDA approved 8/27/98), a phosphorothioate 21-mer oligonucleotide targeted to the *IE2* gene is presently in clinical phase III intravitreal injection studies for the treatment of CMV retinitis in AIDS patients. *ISIS 13312* is a chemically modified version of ISIS 2922 and has entered phase I/II trials. *GEM 132*, a 20-mer phosphorothioate RNA/DNA/RNA hybrid oligonucleotide targeted to the immediate early *UL36/37* splice site, is being evaluated in phase I/II studies by intravitreal injection in AIDS patients with CMV retinitis and also by intravenous injection in AIDS patients shedding CMV in the semen.

Perhaps the most exciting new potential targets for antiviral therapy of the herpesvirus group resulted from the identification of proteases of the HSV and CMV. This has stimulated the development of novel screens and structure/function studies in the anticipation that novel inhibitors will be developed to impact herpetic infections, just as the HIV protease inhibitors have proven useful in treating HIV. Although anti-herpesvirus proteases are in the preclinical development pipeline, the potential is exciting.

Myxoviruses

Influenza causes serious illness in most of the adults it infects and can result in death in vulnerable populations, such as the very young, the very old and those with underlying cardiac or pulmonary disease. On average in the USA alone, influenza epidemics kill approximately 30 000 people and cause 170 000 excess hospitalizations annually. Influenza has also been identified as a cause of fatal pneumonia in immunosuppressed bone marrow or stem cell transplant recipients. Typically, one or two influenza strains predominate in annual epidemics, requiring preparation of a customized killed vaccine as soon as these strains are identified. However, the vaccine successfully protects only 70–80% of recipients. Accordingly, both the magnitude of influenza morbidity and the vast numbers of its associated excessive mortality have made the identification of effective anti-influenza therapeutics a public health priority.

Approved agents

In 1966, the FDA for the first time approved a systemically administered anti-viral agent, the anti-influenza drug *amantadine (Symmetrel)*. A related drug, *rimantadine (Flumadine)*, was approved in 1993 and is equally effective but with a slightly better safety profile than amantadine. Both drugs are orally available and are excreted by the kidneys. The primary toxicities are gastrointestinal and central nervous system (CNS)-related, and can usually be controlled by dose reduction. Both drugs block the action of the influenza A M2 protein which normally establishes an ion channel in the viral membrane and

is essential both for the input virus uncoating and for progeny virus maturation.

The drugs are approved for prophylaxis in adults and children, and the treatment of adults. In addition, amantadine is approved for the treatment of influenza in children. The degree of protection afforded by prophylactic therapy is essentially complete, and the US Centers for Disease Control (CDC) have recommended rimantadine prophylaxis in residential settings with high-risk individuals, such as nursing homes, after an index case has been identified. A comprehensive nursing home study demonstrated that rimantadine prophylaxis provided significant benefits even when residents had been vaccinated.

Unfortunately, amantadine and rimantadine share three significant disadvantages: they are effective against only type A influenza; their therapeutic use yields only minimal clinical benefits; and therapeutic use results in the rapid emergence and shedding of resistant virus which is virulent and transmissable in approximately one-third of treated patients. To avoid the potential nightmare of epidemic-resistant virus, and because treatment benefits are only modest, investigators have recommended that infected close contacts of high-risk individuals forego the option of treatment in favor of the potentially more effective prophylaxis of the high-risk individuals.

Experimental agents

The influenza neuraminidase has been targeted by another class of antiviral compounds which are analogues of the neuraminidase's natural substrate, sialic acid. There are two candidate drugs in this class in clinical development (*Zanamavir* (or *GG167*) which is delivered by inhalation, and *GS4104* which is delivered orally), and at least one other in preclinical study. They share the significant advantage of activity against both types A and B influenza, and were designed using the known crystallographic structure of the influenza neuraminidase. Consequently, both are highly specific and selective, with no significant inhibitory activity against mammalian or bacterial neuraminidases. Inhibition of the influenza neuraminidase prevents the cleavage of terminal sialic acid residues from viral and cellular glycolipids and glycoproteins, preventing release of progeny virus from infected cells. In experimental phase II challenge studies, in which volunteers were inoculated with influenza virus, both drugs demonstrated good prophylactic and therapeutic activity, with drug resistance not an apparent serious problem.

Ribavirin has anti-influenza activity both *in vitro* and in animal models. Although it is approved as an aerosol for the treatment of respiratory syncytial virus (RSV) infections and has been used clinically either by aerosol or intravenous infusion for influenza, large controlled clinical efficacy studies have not been performed.

The influenza polymerase has also been identified as a possible target for the inhibition of influenza replication. The nucleoside *2'-deoxy-2-fluoroguanosine* interferes with transcriptional elongation, and inhibits types A and B *in vitro* and in mouse and ferret animal models by oral administration. The viral endonuclease which steals caps from cellular mRNAs provides another viral target for which potential antivirals (*2,4-dioxobutanoic acid derivatives*) are in the preclinical stages of development.

Paramyxoviruses

RSV is one of the common community-acquired respiratory infections that circulates in winter and early spring. It is the major cause of respiratory tract infections in infants and young children, infecting two-thirds in their first year of life. Children whose health is compromised by other conditions such as prematurity, bronchopulmonary dysplasia (BPD), cardiac problems or immune defects are at high risk for serious disease. RSV is estimated to result in 90 000 hospitalizations and 4500 deaths annually in the USA. Recently RSV, along with parainfluenza and influenza, was recognized as the cause of severe and often fatal pneumonia in immunosuppressed populations such as bone marrow transplant recipients and patients undergoing immunosuppressive treatments for leukemia and other cancers.

Approved agents

Aerosolized *ribavirin* (*Virazole*, a *triazole nucleoside*) was approved by the FDA in 1985 as a therapy for RSV infections in hospitalized infants. It has broad-spectrum antiviral activity and inhibits the replication of a wide variety of DNA and RNA viruses both in cell culture and in animal models. In the cotton rat model of RSV infection, the drug is effective both therapeutically and prophylactically when delivered orally or by aerosol. Ribavirin is believed to inhibit viral replication by several mechanisms, including ones which target host rather than viral activities. Consequently, it is not surprising that the emergence of ribavirin-resistant mutants has not been documented. The major mechanism probably involves inhibition of inosine-5'-monophosphate dehydrogenase activity by ribavirin monophosphate, leading to the depletion of intracellular pools of GTP. In addition inhibition of guanyl transferase by ribavirin triphosphate reduces mRNA capping. The triphosphate also appears to directly inhibit some viral polymerases.

Despite its well documented preclinical efficacy, the clinical use of ribavirin remains controversial. FDA approval of ribavirin and endorsement by the American Academy of Pediatrics (AAP) were based on several small placebo-controlled trials in nonventilated infants for whom treatment resulted in improved symptom scores and decreased RSV titers. However, some subsequent studies have failed to support benefit from ribavirin therapy in infants, and the AAP has now changed its recommendation from 'should be used' to 'should be considered'. The high cost of therapy as well as the need for careful environmental control due to the possibility of teratogenicity have also contributed to the lack of universal acceptance of ribavirin therapy for RSV in infants.

RespiGam, an intravenous immune globulin preparation enriched approximately sixfold for neutralizing antibodies to RSV (RSVIg) has recently been approved as a prophylactic use for infants in high-risk categories (BPD, prematurity), with the exception of underlying cardiac disease. Its prophylactic use every 30 days during the RSV season significantly reduced the incidence of hospitalization for RSV lower respiratory tract disease as well as the duration of the hospital stay. However, the use of RSVIg was not effective as a treatment for RSV in high-risk children hospitalized for RSV lower respiratory tract infection.

Because the mortality of RSV pneumonia in bone marrow transplant recipients is as high as 85%, a number of strategic approaches using drugs approved for other RSV indications have been tried. Although aerosolized ribavirin seems nonbeneficial once pneumonia is established, the results of an open label study suggested that the combination of aerosolized ribavirin with intravenous immunoglobulin reduced mortality below the expected rate, and may provide benefit as pre-emptive treatment. When symptoms of upper respiratory tract infection are observed and myxo- or paramyxovirus involvement is documented, then treatment with either ribavirin or rimantadine may be tried to prevent the progression of upper respiratory tract infection to lower respiratory tract disease.

Experimental agents

Monoclonal antibodies (MAbs) specific for the RSV F glycoprotein are under development, and in animal efficacy studies MAbs have been significantly more potent than RespiGam. Consequently, clinically effective levels of neutralizing antibody should be achievable from substantially smaller injection volumes than those required for the polyclonal product, and clinical evaluations of several potential MAb products are underway.

Parainfluenza virus (PIV) is also a common cause of respiratory infections, especially in children, in whom it is the classic cause of 'croup'. Ribavirin is effective against PIV in cell culture and in animal models, but no studies have been done to evaluate its clinical potential. In immunocompromised patients PIV, like RSV and influenza, can cause life-threatening lower respiratory tract disease. As with RSV infection, recent uncontrolled reports suggest that ribavirin might be useful for this indication.

Hepatitis Viruses

Hepatitis, or inflammation of the liver, can be caused by many different viruses and chemical substances. Viruses may cause acute infection (hepatitis A virus) or acute infection with the possibility for chronic liver infection leading to cirrhosis and hepatocellular carcinoma. Two major causative agents of acute and chronic disease are hepatitis B (HBV) and hepatitis C (HCV) viruses. The World Health Organization estimates the worldwide population of HBV carriers at about 350 million, with 75% of these living in the Far East. While less than 0.5% of the population of the USA and about 1% of that of Europe may carry HBV, 10 and 12% may be carriers in Southeast Asia and Africa, respectively. With the identification of HCV as the cause of most of the non-A, non-B hepatitis, and with the development of immunoassays for detection of antibody to HCV, it has become clear that HCV is a major worldwide problem. The CDC estimate that there are about 150 000 new cases in the USA each year, with 1.5% of the population antibody positive. In Japan there are about 2.5 million chronic HCV carriers, and infection is associated with high rates of hepatocellular carcinoma.

Approved agents

HBV is a preventable disease by immunization, with recombinant virus vaccines available worldwide and newer vaccines in development. Currently in the USA and in some countries of Europe, HBV immunization is recommended for all infants and adolescents. *Hepatitis B immune globulin (H-BIG)* preparations are also used as passive antibody prophylaxis in patients shortly after exposure to the virus to prevent transmission. Currently there are no approved HCV vaccines, but both vaccines and *HCV immune globulin (H-CIG)* are in preclinical development.

The only approved drugs for the treatment of hepatitis C virus (HCV) and hepatitis B virus infections in the USA are *interferons (IFNs)* α (*Intron* for HBV and HCV; *Roferon-A* for HCV), although

preparation of IFN-β and lymphoblastoid IFN are used elsewhere in the world. Interferons can be both direct inhibitors of virus replication and stimulators of specific and nonspecific immune responses. How they function to reduce hepatitis virus infection is uncertain, but they have been useful, as measured by virus DNA or RNA in the circulation. Unfortunately, only about 50% of chronic HCV or HBV patients treated with IFNs respond by virus suppression and half of these relapse back to elevated plasma virus levels. In addition, interferon therapy may also result in unwanted side effects, including depression, nausea, fever, fatigue, headaches and muscle aches. Recently a New Drug Application (NDA) for *Intron A/Rebetol (ribavarin) combination treatment* of chronic adult HCV patients who relapse following treatment with Intron was approved by the FDA.

Experimental agents

Since HCV and HBV are major causes of morbidity and mortality in the world, there are significant efforts to develop more effective therapies. IFNs are immunomodulators, and one approach in phase III studies is the combination of IFNs with thymosin α_1 (*Zadaxin*) for treatment of HCV and also for HBV. Although early in the drug discovery and development process, much research effort is now focused on the HCV protease/NPTase helicase as an antiviral target. The HCV serine protease is essential for virus replication and is associated with an NPTase domain which activates the protease, and a helicase domain that preferentialy unwinds double-stranded RNA. The three-dimensional structure has been determined and drug screening programs are underway in several laboratories to identify potent inhibitors.

A wider variety of therapies for HBV are now in development. Both *lamivudine (3TC)* and *famvir (famciclovir)* are in phase III studies, and are effectively demonstrating the capacity to reduce plasma HBV levels. However, resistance is also occurring in some patients after months of treatment. Newly emerging compounds with promise are *GS 840*, a phosphonate nucleotide analogue, and *BMS-200475*, a nucleoside analogue. Both are in early clinical studies.

It is important to note that antiviral drug development can be a risky venture. *Fialuridine (FIAU)* was a promising candidate for the treatment of HBV, and was in phase II clinical studies prior to the delayed emergence of severe toxicity resulting in deaths. This was not anticipated from the preclinical animal assessment studies. Thus, for the development of an antiviral agent that will be used for the repeated treatment of chronic disease, the potential for delayed or accumulative toxicity in the diseased patient must be appreciated and understood.

Picornaviruses

Although there is an abundance of human picornaviruses, including enteroviruses and the rhinoviruses, to date there are no approved antiviral agents. Yet there have been extensive studies on the structure of the virus capsids and also of the mechanisms of replication, providing attractive potential targets for antiviral intervention and resulting in the identification of novel experimental antiviral agents. The single-stranded picornavirus RNA genome is transcribed into a single polyprotein, which is cleaved by an essential protease into functional subunits, one of which is the RNA polymerase. *Enviroxime*, a benzimidazole derivative which inhibits rhinovirus polymerases and was promising in cell culture studies, was disappointing in the clinic against the common cold. However, studies are continuing with further modifications of enviroxime to increase oral bioavailability while retaining antirhinoviral potency and reduced toxicity.

The identification of promising isoxazole compounds that bind to a hydrophobic pocket within the capsid structure has led to extensive studies on the capsid structure and the inhibitors' capacity to prevent uncoating of the viral RNA. This similarity of structure/function of many enteroviruses and rhinoviruses has resulted in picornavirus inhibitors with a broad range of efficacy. *Pleconaril (ViroPharma VP-63843)* is an orally active low molecular weight pocket-binding compound that has been chosen for further development. Pleconaril reduces the duration and the severity of respiratory symptoms due to enterovirus infection, and is now in a multicenter phase II evaluations. Although laboratory studies have shown that resistance to pleconaril may occur due to mutations in the viral binding pocket, the significance of resistance in the clinic is not yet determined.

Ninety percent of rhinoviruses use ICAM-1 as their cell receptor, and *soluble ICAM-1 (sICAM)* acts as a decoy to inhibit effective virus–T cell binding and prevent infection. Recently sICAM has been successfully used as a prophylactic intranasal administration to prevent experimental rhinovirus infection in humans. The multiple treatments per day were well tolerated, indicating that this approach may be a promising novel preventative of the common cold.

Papillomaviruses (HPV)

Infections with HPV types are ubiquitous, with over 80 types that cause a variety of wart-associated

conditions. While most lesions are benign, some, especially those caused by HPV-16, -18 and other oncogenic HPV types, may progress to premalignant and malignant lesions. Papillomaviruses are causally associated with cervical cancer, which is diagnosed in 15 000 American women annually and causes approximately 4500 deaths. Types 6 and 11 are responsible for common genital infections and also for recurrent respiratory papillomatosis (RRP), a devastating but rare disease which may be acquired at birth as a result of vaginal delivery by an infected mother.

The HPV genome is small and encodes few enzymes. The virus consequently uses many host functions, such as DNA polymerase and other cellular replicative enzymes, for its own replication. This has made the goal of identifying safe and effective selective antiviral therapies especially challenging.

Approved agents

The currently approved therapies are not often satisfactory and generally involve physical ablation and/or antiproliferative or immunomodulatory agents as opposed to virus-specific strategies. These therapies include the crude ablative methods of surgery and electric cauterization, and the more precise laser vaporization. The primary disadvantage of these methods is high recurrence rates. Chemical ablative approaches include the use of trichloroacetic acid or podophyllotoxin and are no more successful than the physical methods.

Interferon α (Intron, Aferon) may provide a significant level of efficacy as intralesional therapy for condyloma acuminata (genital warts). Following a course of three times weekly intralesional injection, approximately 40% of IFN recipients achieved a complete response, as opposed to 20% of placebo recipients. As is the case with virtually all HPV therapies, approximately 25% of treated patients developed recurrences. The discomfort of intralesional injection has limited the wide use of this therapeutic strategy, and systemically delivered IFNs are not effective. Although IFN was discovered on the basis of its antiviral activity, it is also an immunomodulatory and antiproliferative agent. It is not known which of these properties is responsible for its anti-HPV effects.

Imiquimod (Aldara, R-837) is an immunomodulator which is approved as a topical therapy for genital warts. It is an interferon inducer and stimulates a natural immune response with the induction of several IFN-α subtypes and other cytokines associated with a Th1 immune response. These include tumor necrosis factor (TNF)α, IL-1α, IL-6 and IL-8. In clinical trials of a topically applied 5% cream, 40–55% of subjects experienced a complete clinical response following thrice-weekly use for 8–12 weeks. However, recurrences were observed in almost one-fifth of the complete responders.

Experimental agents

Both *ribavirin* and *cidofovir* were shown to be efficacious in a rabbit model of papillomavirus infection. On the basis of these studies, clinical trials for both agents have been undertaken. Ribavirin is being evaluated in phase I/II clinical studies as an oral therapy after laser ablation of laryngeal papillomas. In uncontrolled studies, cidofovir has been reported to have a dramatic degree of efficacy as an intralesionally administered agent for the treatment of RRP. Controlled studies are underway to determine whether these initial promising results can be confirmed. Cidofovir is also being evaluated as a topical therapy for genital warts in HIV-infected individuals. In a similar study of topical therapy for acyclovir-resistant genital herpes infections, the drug was not absorbed and no systemic toxicity was observed, suggesting the potential acceptability for this topical approach to therapy.

Another nonvirus-specific antimitotic agent, 5-fluorouracil, has been formulated for slow release in a collagen matrix gel and is designed to be injected intralesionally. Reponse rates with this product, *AccuSite*, were superior to those obtained with IFN. The product is approved in the UK and several European countries, although it has not been approved by the US FDA on the basis of toxicity concerns.

A number of virally targeted antipapillomavirus strategies are in very early stages of development. These include ribozymes directed at E6/7 mRNAs, peptides to interfere with the E7 transforming function, and agents designed to inhibit replicative activities of the viral E1 protein and transcriptional activities of the E2 protein. An antisense compound proceeded as far as early clinical evaluation but its development has since been terminated. Early-stage strategies targeting other than viral functions include the use of retinoids as inhibitors of angiogenesis and indole-3-carbinol, which downregulates estrogen activity and is being studied for possible prevention of cancer.

Exotic Viruses and Unmet Needs

At present there are no approved therapies for several types of 'exotic' viruses, those which are rare in the USA and Europe. However, several recent examples of emerging and life-threatening diseases due to Ebola

viruses and hantaviruses have made it clear that, with world travel requiring less time than many virus disease incubation periods, disease might spring up at any locale, and geographic containment alone is not realistic. There have been 15 outbreaks of Ebola virus infections reported since 1967, and the horrors of these infections have received considerable publicity. Hantaviruses have long been known to cause Korean hemorrhagic fever (KHF). More recently hantavirus pulmonary syndrome (HPS), with rapid disease course and mortality as high as 50% in less than a week, has occurred in regions of the USA. These examples have been part of the stimulus for investigations of immunotherapy, extended evaluation of available antiviral drugs, and new drug discovery to define effective strategies to treat and contain exotic virus outbreaks. Hyperimmune polyclonal equine antibody and MAb are being developed and tested to prevent acute Ebola disease and death in non-human primates. Furthermore, several inhibitors of *S*-adenosylhomocysteine hydrolase, including carocyclic 3′-deaza-adenosine, are also being evaluated in a mouse model of Ebola virus infection.

Ribavirin appears to effectively inhibit hantavirus infections, and is undergoing clinical evaluation in the intravenous treatment of HPS. Ribavirin also inhibits arenaviruses, which may cause hemorrhagic fever with CNS involvement, and the mosquito-borne bunyavirus, which causes La Crosse encephalitis. Controlled clinical evaluations of ribavirin for these indications are also in progress.

Cidofovir inhibits monkeypox virus, which can be spread from monkeys to and among humans. Monkeypox has been on the increase in Africa, perhaps as a consequence of the termination of smallpox vaccinations, which may have afforded a degree of crossprotection. Cidofovir has been effective in monkeypox animal protection studies and may be a candidate for clinical evaluation.

APOPTOSIS AND VIRUS INFECTION

Margaret P Quinlan, Department of Microbiology and Immunology, University of Tennessee, Memphis, Tennessee, USA

General Features

Maintenance of homeostasis between the cellular processes of proliferation and death is critical to a multicellular organism. Programmed cell death (PCD) is a genetically encoded and evolutionarily conserved, physiological process that induces a form of cellular suicide called apoptosis. Apoptosis is an important regulatory mechanism by which unwanted cells can be eliminated during normal development or because they are in excess or pose a threat to the organism, such as in the case of virus-infected cells. Thus, apoptosis protects the organism against cancer and viral infections and maintains homeostasis under a wide range of physiological and developmental stimuli. Defects in apoptosis can lead to diseases associated with increased cell types or numbers, such as autoimmunity or cancer, respectively. Increased apoptosis results in cell losses, such as found in immunocompromising or neurodegenerative diseases. The cell death program consists of the successive activation of unique apoptosis-specific genes and

viruses and hantaviruses have made it clear that, with world travel requiring less time than many virus disease incubation periods, disease might spring up at any locale, and geographic containment alone is not realistic. There have been 15 outbreaks of Ebola virus infections reported since 1967, and the horrors of these infections have received considerable publicity. Hantaviruses have long been known to cause Korean hemorrhagic fever (KHF). More recently hantavirus pulmonary syndrome (HPS), with rapid disease course and mortality as high as 50% in less than a week, has occurred in regions of the USA. These examples have been part of the stimulus for investigations of immunotherapy, extended evaluation of available antiviral drugs, and new drug discovery to define effective strategies to treat and contain exotic virus outbreaks. Hyperimmune polyclonal equine antibody and MAb are being developed and tested to prevent acute Ebola disease and death in non-human primates. Furthermore, several inhibitors of *S*-adenosylhomocysteine hydrolase, including carocyclic 3′-deaza-adenosine, are also being evaluated in a mouse model of Ebola virus infection.

Ribavirin appears to effectively inhibit hantavirus infections, and is undergoing clinical evaluation in the intravenous treatment of HPS. Ribavirin also inhibits arenaviruses, which may cause hemorrhagic fever with CNS involvement, and the mosquito-borne bunyavirus, which causes La Crosse encephalitis. Controlled clinical evaluations of ribavirin for these indications are also in progress.

Cidofovir inhibits monkeypox virus, which can be spread from monkeys to and among humans. Monkeypox has been on the increase in Africa, perhaps as a consequence of the termination of smallpox vaccinations, which may have afforded a degree of crossprotection. Cidofovir has been effective in monkeypox animal protection studies and may be a candidate for clinical evaluation.

APOPTOSIS AND VIRUS INFECTION

Margaret P Quinlan, Department of Microbiology and Immunology, University of Tennessee, Memphis, Tennessee, USA

General Features

Maintenance of homeostasis between the cellular processes of proliferation and death is critical to a multicellular organism. Programmed cell death (PCD) is a genetically encoded and evolutionarily conserved, physiological process that induces a form of cellular suicide called apoptosis. Apoptosis is an important regulatory mechanism by which unwanted cells can be eliminated during normal development or because they are in excess or pose a threat to the organism, such as in the case of virus-infected cells. Thus, apoptosis protects the organism against cancer and viral infections and maintains homeostasis under a wide range of physiological and developmental stimuli. Defects in apoptosis can lead to diseases associated with increased cell types or numbers, such as autoimmunity or cancer, respectively. Increased apoptosis results in cell losses, such as found in immunocompromising or neurodegenerative diseases. The cell death program consists of the successive activation of unique apoptosis-specific genes and

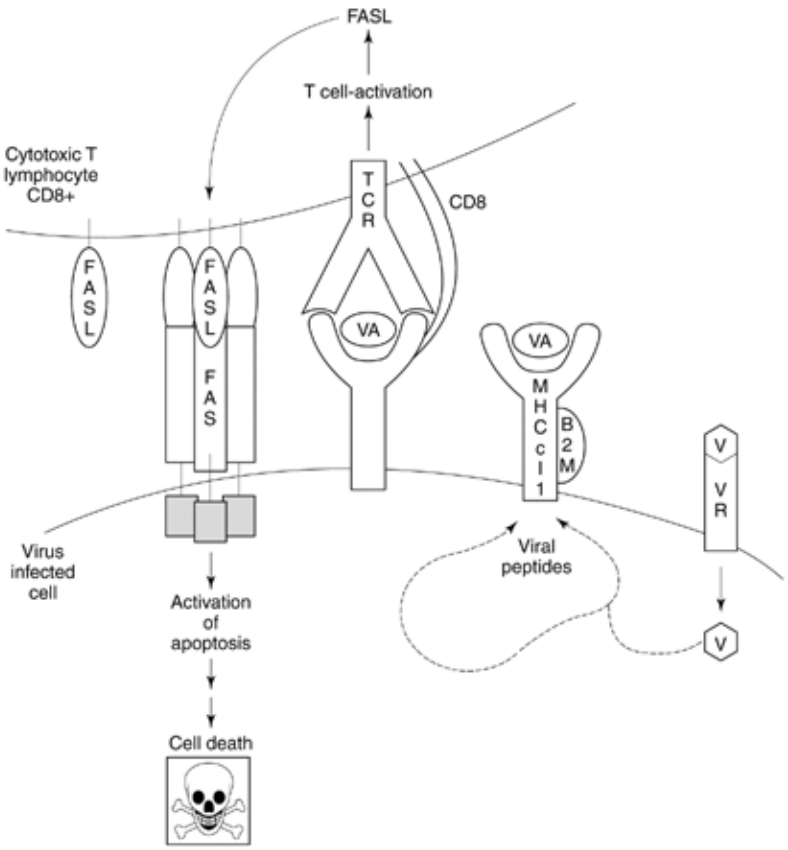

Figure 1 Immune mediated activation of apoptosis of virus infected cells. A virus (V) gains access to the inside of its target cell through a specific cell surface receptor (VR). Once inside, viral gene expression ensues. Viral peptides or antigens (VA) derived from the original virus (short dotted line) or newly synthesized by the cell (long dotted line) are presented by the class I MHC (MHC cl1)-β_2 microglobulin (B2M) complex on the surface of the infected cell. This is recognized as nonself by the T cell receptor (TCR) on the surface of a CD8+ cytotoxic T lymphocyte. The interaction between the viral peptide–MHC complex and the TCR activates the T cell to proliferate. This also results in the upregulation of FASL on the surface of the activated CTL. FASL interacts with FAS on the surface of the virus-infected cell and activates the apoptotic pathway in that cell leading to its death. ▤, death domain.

genes that are involved in the seemingly opposing functions of proliferation and development. Different cell types respond to different types of triggers, from inside and outside the cell, and possess different pathways to programmed cell death. The culmination in a death response is due to the extent, combination and timing of the collective set of genes activated. The changes observed in apoptotic cells include cell shrinkage, chromatin condensation, cytoplasmic blebbing, the generation of apoptotic bodies and internucleosomal fragmentation of the chromosomal DNA, an often used biochemical marker to identify apoptosis. Apoptotic cells or bodies are often phagocytosed by adjacent macrophages or parenchymal cells.

Rapid cell death of virus infected cells reduces virus spread. Apoptosis is used by the immune system to eliminate potentially dangerous cells, such as virus-infected ones. In fact, virus spread is limited by the immune response and apoptosis of infected cells. Killer lymphocytes are the primary immune effectors of virus and tumor immunity. Cytotoxic lymphocytes (CLs) play a pivotal role in the immune response to tumors, viruses etc. There are two effector populations with the ability to eliminate unwanted or harmful cells. These two cell types recognize the target cells in different ways. Cytotoxic T lymphocytes (CTLs) recognize target cell peptides, such as those derived from viral proteins, presented on the MHC class I glycoprotein at the cell surface (**Fig. 1**). This is accomplished by the recognition of the nonself antigen in the major histocompatability complex (MHC) by the T cell receptor (TCR) on the surface of the virus-immune T cell. The lymphocyte–target cell interaction activates the interacting T cell to proliferate and induce FASL expression. Natural killer (NK) cells mediate 'innate' immunity against virus-infected cells and do not require presensitiza-

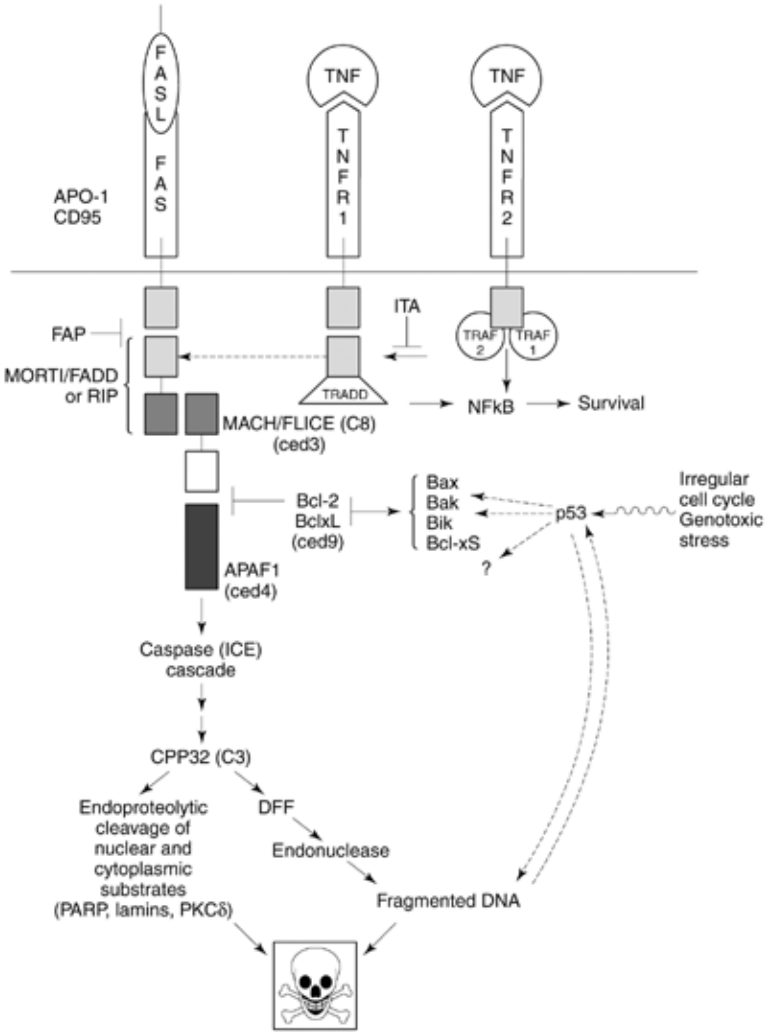

Figure 2 The apoptotic pathway. The apoptotic pathway can be initiated at the surface of a cell through the interactions of the tumor necrosis factor (TNF) with either of its receptors, TNFR1 or TNFR2 or FAS ligand (FASL) with its receptor FAS (APO-1, CD95). This initiates a series of intracellular, intermolecular events that are described in the text. ▒, death domains; ■ death effector domains. Solid lines indicate well-described events; dotted lines indicate less well described or hypothesized events.

tion. Target cells are killed through the induction of apoptosis by the secretory (perforin/granzyme) pathway or the nonsecretory pathway that involves triggering the cell surface death receptor, FAS (APO-1, CD95) by the membrane bound FASL (ligand) of the killer cell. These trigger an endogenous pathway of PCD resulting in the dissolution of the nuclear membrane, chromatin condensation and DNA fragmentation and ultimately, death of the virus-infected cell.

The expanded, activated CD8+ T cells arising in response to viral infection controls the virus, but can also be damaging to the host unless removed at the end of the immune response. This can be accomplished by the FAS-mediated apoptosis of the activated cells and is part of the regulation of the immune system.

The Apoptotic Pathway

The immune-mediated, apoptotic pathway (**Figs 1** and **2**) is initiated at the cell surface, with the interactions of the FAS (APO-1/CD95), which is ubiquitously expressed, or tumor necrosis factor (TNFR1, TNFR2) transmembrane receptors (death receptors) with their cognate, extracellular ligands, FAS ligand (FASL), which is predominantly expressed in activated T or NK cells, or TNF, respectively.

These death receptors are related. The death receptors contain 80 amino acid death domains, which are protein–protein interaction domains, in their intracellular, cytoplasmic, C-termini. The death domains are necessary for the receptor to trigger the cell death pathway. Once activated, the death domains of the death receptors interact with the death domains of cytoplasmic proteins. In the case of FAS, this is MORT1/FADD (FAS associated death domain protein) or RIP. The activation of FAS can be inhibited by FAP1 (FAS-associated phosphatase-1), which interacts with the C-terminal 15 amino acids of FAS. For the TNFR1, it is TRADD (TNFR associated-death protein). MORT1/FADD interacts with MACH (MORT1 associated CED-3/ICE homologue)/FLICE (FADD-like ICE), an ICE-(interleukin-1β converting enzyme) like enzyme. The ICE family members are now known as caspases. MACH/FLICE is also known as caspase 8. The ICEs or caspases are aspartate-specific, cysteine proteases that are the effectors or killer molecules (death proteases) of the apoptotic pathway. They are homologues to ced-3 in *Caenorhabditis elegans* and 10 have been identified in humans, thus far. This ced-3 homologue, MACH/FLICE binds to the ced-4 homologue, APAF1. This is the beginning of a caspase/ICE chain reaction, of which CPP32/caspase 3 is a part. CPP32 activates DFF (DNA fragmentation factor), which activates the endonuclease that results in DNA cleavage. CPP32 also brings about endoproteolytic cleavage of other cytoplasmic and nuclear proteins, such as PARP [poly(ADP-ribose) polymerase], lamins and protein kinase C (PKC)δ. In the TNFR1-TRADD path, TRADD is an adapter protein, which seems to link to the MORT1-MACH pathway, in an as yet unidentified manner. TNFR2 does not have a death domain, but interacts with two proteins, TRAF1 and TRAF2 (TNFR-associated factors). TRAF2 binds TRADD, which in turn connects to the FAS pathway, leading to the caspase/ICE cascade.

The ITA (inhibitor of T cell apoptosis) proteins, vertebrate homologues of the insect baculovirus IAP (inhibitor of apoptosis) form complexes with TRAFs, perhaps preventing TRADD from participating in the MORT1/FADD pathway. The bcl-2 family of ced-9 homologues are additional regulators of apoptosis. Presently, nine members are known and are related via their bcl-2 homology (BH) domains. Bcl-2 blocks a downstream step in the apoptotic pathway. It was originally discovered in B-cell lymphomas and contributes to neoplastic expansion by preventing programmed cell death or cellular turnover, disrupting homeostasis. Bcl-2 has subsequently been found in many other tumor types. The pro-death members of the bcl-2/ced-9 family include bad, bak, bax, bcl-xS and bik. The anti-death members are ced-9, bcl-2, bcl-w, bcl-xL, mcl-1, A1/Bfl-1 and Nr13. Their ability to form homo- and heterodimers with various members, and the ratio of inhibitors to activators regulates the final decision of life or death of the cell. Several viruses have evolved to encode BH domain-containing proteins that mimic bcl-2 to promote survival of infected cells (see **Table 1** and below).

Table 1 Viral gene products that inhibit apoptosis and their targets in the cell

Target	*Virus*	*Viral gene*
p53	Adenovirus	*E1B55K*
		E4ORF6
	Cytomegalovirus	*IE2*
	Epstein–Barr virus	*BZLF1*
		EBNA5
	Hepatitis B virus	*pX*
	Human papillomavirus	*E6*

	Herpes saimiri	*ORF16*
	Rous sarcoma virus	v-*src*
Caspase/ICE	Baculovirus	*p35*
	Cowpox virus	*crmA*
	Orthopoxvirus	*SPI1–3*
	Vaccinia virus	*B13R*
DED proteins	African swine fever virus	*A22L*
	Baculovirus	*IAP*
	Kaposi sarcoma herpesvirus	*E8*
	Molluscipoxvirus	*MC159*
Death receptor	Adenovirus	*E3 10.4/14.7K*
	Myxoma virus	*M-T2*

The apoptotic pathway can also be activated by the p53 tumor suppressor, in response to genotoxic stress; DNA damage due to irradiation or unregulated cell cycles due to the expression of viral or cellular oncogenes. The mechanism remains unresolved. p53 is a sequence-specific, transcriptional transactivator, with an acidic domain. One cellular target for p53 seems to be bax, a pro-death member of the bcl-2 family and a downstream regulator of apoptosis. Inhibition or functional inactivation of p53 is a common feature of many DNA tumor viruses, although it is accomplished in different ways by each (see **Table 1** and below).

Viruses and Apoptosis

Viruses coevolve with their hosts to circumvent detection and destruction by the host. They have also evolved to usurp or take advantage of the host proteins and processes to enable or enhance their own replication and spread. Viruses encode immunomodulators to affect antigen presentation, function as cytokines or cytokine inhibitors, interrupt the complement cascade and affect apoptosis. Many viral immunomodulators have host counterparts (**Tables 1** and **2**).

Induction of early death of the infected cell could severely limit the yield of virus and result in the reduction or elimination of the virus. Some viruses have evolved distinct strategies to evade or delay apoptosis to facilitate replication, spread, latency or persistence. Different mechanisms have been employed: direct inhibition of the death proteases, stimulation of antideath pathways or regulation of transcription factors monitoring cell survival. Some common themes include inactivation of p53, encoding bcl-2 homologues, encoding protease inhibitors to inhibit the ICE/caspase cascade or homologues to members of the FAS or TNFR signaling systems (**Table 1**).

Induction of apoptosis later in the virus life cycle could assist the release of the newly produced virus particles, especially nonenveloped nonlytic viruses, from the cell. The presence of virus in apoptotic bodies, which are phagocytosed by other cells, helps the virus evade the host immune surveillance system and spread. Virus-induced apoptosis also contributes to the clinical manifestations and cytotoxicity associated with virus infections. The viral gene products involved in activating PCD and their targets in the cell are only starting to be identified (**Table 2**).

Table 2 Viral gene products that effect apoptosis and their targets in the cell

Target	*Virus*	*Viral gene*
p53	Human papillomavirus	*E2*

Death receptors	Hepatitis B virus	(*pX*)
	Hepatitis C virus	*core*
	Human immunodeficiency virus	*Tat*

Viruses Associated with Inhibition or Suppression of Apoptosis

DNA viruses

Adenoviridae Adenovirus (Ad) encodes several immunomodulatory proteins that function to inhibit or promote apoptosis. E1A inhibits the transcriptional transactivation of p53. E1A12S enables cells to overcome growth factor withdrawal and transforming growth factor β (TGFβ)-induced apoptosis. E1A13S upregulates p53, which can bring about apoptosis, but this depends on whether inhibitors of proliferation are present simultaneously, giving rise to a conflict for the cell, which will then result in apoptosis. E1B55K binds the p53 transactivation domain, blocking activation of p53-responsive genes in some, but not all, serotypes, such as subgroup C. E4ORF6 also binds to p53, but to a different region, although its role in cell death has not yet been shown. E1B19K has functional similarity to bcl-2. The actual homology is low and is only in the BH domain, but it interacts with other members of the bcl-2 family, such as bax and bak, preventing them from forming homodimers that promote cell death. E1B19K does not interact with bad, thus Ad-infected cells are resistant to bad-mediated death. Both E1B19K and bcl-2 inhibit p53-dependent apoptosis, but the mechanism is unknown. E1B19K also suppresses TNFα and FASL activated death pathways (**Fig. 2**). The E3 10.4K and 10.4K/14.7K heterodimer proteins inhibit TNF- and FAS-mediated cell death. Although not completely understood, it seems to be by preventing signaling from the TNFR and by the clearing of FAS from the surface, respectively. This enhances infection by enabling cells to escape immune destruction via CTL killing of Ad-infected cells. E4ORF6 also binds to p53, blocks its ability to transactivate and blocks p53-mediated apoptosis. The avian Ad, CELO AD, GAM-1 gene product is a novel protein that functions like bcl-2, but has no homology. E3 gp 19K sequesters MHC class I proteins in the endoplasmic reticulum, which prevents viral antigen recognition by CTLs.

African swine fever virus The African swine fever virus (ASFV) encodes the gene *A179L* (*5-HL* gene), which is a viral homologue of *bcl*-2. It has all the same domains as *bcl*-2, including the conserved BH1 domain, which is required to inhibit apoptosis, similarly to *bcl*-2. Thus, *A179L* probably works by a similar mechanism. The ASFV *A22L* gene is a homologue of the IAP proteins. It is expressed late in virus life cycle. A virulent strain of ASFV has been shown to induce apoptosis.

Hepadnavirus Hepatitis B virus (HBV) encodes pX that interacts with p53, interfering with DNA binding and transcriptional activation. pX is also an HBV viral oncogene involved in HBV-induced hepatocellular carcinomas, perhaps by blocking p53-activated

apoptosis. Conflicting with this, it has been shown that pX on its own can induce apoptosis in some cell types.

Herpesviridae This family of viruses contains members that bring about many different responses and diseases in the host. These viruses encode many different genes that affect PCD of the infected cell. Normally, herpes simplex virus type 1 (HSV-1) does not induce apoptosis, however, if ICP4 is deleted, apoptosis ensues. Thus, ICP4 blocks apoptosis, perhaps allowing cells to become latent. The HSV US3 gene, which encodes a serine/threonine protein kinase, also protects against apoptosis. The late γ34.5 gene inhibits apoptosis in infected neurons and promotes neurovirulence and could underlie HSV-mediated encephalitis. HSV-2-inhibits FAS ligand expression on the surface. PCD of cells infected with these herpesviruses results in decreased virus production.

A lytic infection with Epstein–Barr virus (EBV) causes apoptosis. Expression of *BHRF1*, a homologue of *bcl-2*, early in infection prevents TNFα- and FAS-induced apoptotic pathways. This is a means to maximize viral particles. BHRF1 also enables infected epithelial cells to overcome apoptosis induced by γ-irradiation and chemotherapeutics. It also provides an alternative mechanism of becoming multidrug resistant during chemotherapy. The latent membrane protein 1 (LMP1), an EBV oncogene, downregulates *myc* and upregulates *bcl-2* and *A20* expression, cellular anti-apoptotic genes. This prevents p53-mediated apoptosis and is part of the mechanism of B cell transformation by EBV. LMP1 may also contribute to the establishment of latency. EBV also encodes two polypeptides that interact with p53, EBNA-5 and BZLF1. EBNA-5 may also be able to stimulate cell cycle progression. BZLF1 binds to a region of p53 similar to that by Ad E4ORF6 and suppresses p53 transcriptional transactivation. The specific function of BZLF1 seems to be to regulate the dominance of the lytic versus latent paths of the virus.

CMV encodes two transcription factors, IE1 and IE2, that have been demonstrated to induce apoptosis. IE2 interacts with pRB (the retinoblastoma tumor suppressor) and p53, similar to other DNA virus anti-apoptotic proteins.

In herpes saimiri, ORF 16, is also a bcl-2 homologue. Several gamma-herpesviruses, including Kaposi's sarcoma herpesvirus (KSHV, HHV-8), E8 protein is a v-FLIP, which is a death effector domain (DED)-containing protein that interferes with apoptosis signaled through the death receptors. It interacts with FADD, preventing the recruitment of FLICE (caspase 8) and with the prodomain of FLICE. Thus, it uses DED-mediated interactions to interfere with apoptotic signaling pathways.

Iridiviridae The baculovirus p35 of *Autographica californica* nuclear polyhedrosis virus (AcMNPV) binds to and inhibits CPP32 protease, a caspase of the ced 3 family of ICE proteases. p35 is homologous to crmA of cowpox and inhibits TNFα and irradiation-activated apoptosis. Its expression enhances infectivity *in vivo* and *in vitro*. Another class of baculovirus genes that prevent apoptosis is IAP (inhibitor of apoptosis) (the *Drosophila* homologue is th). The function of IAP is currently not known, however, the presence of a RING zinc finger motif suggests the possibility that it could be a transcription factor. Other viral and cellular proteins associated with death prevention have a conserved double repeat sequence referred to as the baculovirus IAP repeat (BIR). Both the RING zinc finger and the BIR domains are required to overcome apoptosis. The human homologues, ITAs, interact with the TRADD/TRAF2 signaling complex. Both p35 and IAP prevent apoptosis and enable productive virus replication.

Papovaviridae The human papillomavirus (HPV) E6 binds to p53 and prevents its DNA binding and transactivation and/or results in the ubiquitin-mediated degradation of p53. The latter occurs in highly oncogenic, high-risk serotypes, such as HPV16 and 18. In these cases, E6 serves to deliver p53 to E6-AP (E6 associated protein), an ubiquitin–protein ligase. This, of course, prevents p53-mediated apoptosis due to unregulated cell cycle progression in response to the HPV E7 protein. Simian virus 40 (SV40) large T antigen (LT) binds and inhibits p53, thus preventing apoptosis due to constitutive activation of the cell cycle by LT.

Poxviridae Many poxviruses encode numerous immunomodulatory proteins, including homologues of cytokine receptors. These receptor mimics, viroceptors, bind and sequester cytokines preventing their signaling cascade prior to receptor engagement. The myxoma virus (virulent rabbit leporipoxvirus) M-T2 gene encodes a TNFR homologue. M-T2 is secreted, binds TNFα and inhibits the cytolytic activity. M-T2 is also an intracellular apoptosis inhibitor, via a different domain of the protein. It is the first viral immunomodulatory protein that exhibits two distinct anti-immune properties. The myxoma virus encodes another gene that inhibits apoptosis, the M11L gene, whose product is a novel transmembrane protein. The closely related, benign leporivirus cannot inhibit apoptosis.

Poxviruses also encode members of the serine proteinase inhibitor (serpin) superfamily. Cowpox encodes crmA (cowpox virus cytokine response modifier), which is an ICE/caspase protease inhibitor of the serpin family. Infected cells die by necrosis. CrmA is effective on CTL, FAS and TNFR, but not irradiation-induced apoptosis. CrmA does not inhibit CPP32. Orthopoxviruses encode 3 serpins, SPI-1–3, and these are also required for viral replication. SPI-2 is similar to crmA of cowpox. The rabbit poxvirus (RPV) SPI-1 serpin gene is required for its replication and inhibits apoptosis of RPV-infected cells. Vaccinia virus (VV) encodes the B13R gene, which is homologous to crmA and SPI-2, and inhibits ICE. B and T lymphoblast cells infected with VV are refractory to FAS and TNFα-activated apoptosis. B13R may contribute to the higher pathogenicity of some strains.

dsRNA seems to trigger apoptosis. The VV E3L gene encodes a dsRNA binding protein which prevents activation of the dsRNA-dependent, interferon-induced protein kinase R (PKR), which induces apoptosis. Suppression of apoptosis correlates with functional binding of proteins to dsRNA. The tumorigenic molluscipoxvirus (molluscum contagiosum virus) MC159 protein is a v-FLIP, similar to that seen in gamma herpesviruses (E8 gene). The MC159 protein interacts with FADD, via DED, and prevents recruitment of FLICE. In poxvirus-infected cells, apoptosis results in very few virus particles produced.

RNA viruses

Flavivirus The hepatitis c virus (HCV) viral core protein, which seems to be a transcriptional regulator, suppresses apoptosis through the CPP32 cysteine protease, but the mechanism is not known. The core protein seems to be involved in the pathogenesis of HCV.

Retroviridae Several of the oncoviruses inhibit apoptosis. The bovine leukemia virus (BLV), which is homologous to HTLV-1, induces a chronic expansion of the B cells (persistent lymphocytosis) and the development of B cell leukemia/lymphosarcoma. It is able to protect peripheral mononuclear cells and B lymphocytes from apoptosis. The viral G4 and/or R3 genes, which can attenuate the viruses, are not responsible for either the persistent lymphocytosis or B cell leukemia/lymphosarcoma. Human T-cell leukemia virus type 1 (HTLV-1) is an etiological agent for adult T cell leukemia. The *Tax* gene plays a causative role in transformation. The *Tax* gene of HTLV-1 inhibits APO-1-mediated apoptosis. *Tax* has also been reported to mediate apoptosis, when cells are serum deprived. The E26 avian leukemia virus oncogene, v-*Myb*, a transcription factor, upregulates *bcl*-2 transcription. The bcl-2 promoter has myb binding sites, which are required for its transcription. It suppresses apoptosis in myeloid cells and could, therefore, be part of its transformation mechanism. The Rous sarcoma virus (RSV) oncogene pp60 (v-*src*) activates NR-13, a *bcl*-2 related gene that is a potent anti-apoptotic factor. Activation of *NR*-13 may be involved in RSV transformation. The Abelson murine leukemia virus oncogene v-*abl* causes pre-B cell leukemia and inhibits apoptosis, functions which are probably related.

Viruses that Promote Apoptosis

DNA viruses

Adenoviridae Adenoviruses encode proteins that promote apoptosis at later stages in the productive cycle. These are encoded in the E3 and E4 regions. The E3 11.6K, Ad death protein (ADP) is expressed at high levels late in infection and may bring on apoptosis, but this has not been demonstrated. It is required at very late stages for efficient cell lysis and virus release.

African swine fever virus Monocytes, macrophages and mononuclear cells infected with AFSV undergo apoptosis. This gives rise to lymphoid organ impairment in acute infections.

Circoviridae The VP3 gene of chicken anemia virus (CAV) encodes apoptin, which is localized in the nucleus and has to be to induce apoptosis. It is p53 independent. The resulting apoptotic bodies are endocytosed by surrounding epithelial cells.

Hepadnaviridae Hepatitis B virus (HBV)-infected cells undergo apoptosis, contributing to fulminant hepatitis. Expression of FAS is upregulated and correlates with viral hepatitis, but not directly with HBsAg expression. Some data suggest that it is due to the viral pX gene product, a multifunctional regulatory protein. pX has also been shown to prevent apoptosis and contribute to hepatocarcinoma development.

Herpesviridae Varicella zoster virus (VZV) induces apoptosis as part of the lytic cycle. Protection of cells from apoptosis may lead to latency, but cannot be accomplished by bcl-2. HSV-1 has been shown to induce apoptosis in activated, peripheral blood lymphocytes, especially CD4+, but not CD8+, lymphocytes. This may underlie the immunosuppres-

sion and lymphocytopenia accompanying HSV-1 infections. A similar result was observed with Marek's disease virus (MDV) in latently infected chickens. MDV also causes thymic atrophy during the acute phase of infection of chickens. Immature CD4+ and CD8+ thymocytes undergo apoptosis, probably the cause of the immunosuppression seen with MDV infections.

Papovaviridae The HPV E2 gene product activates p53 transcription and inhibits E6 (which degrades p53 transcription leading to an overall increase in p53) leading to apoptotic death. E7 primes cells for apoptosis in response to γ-irradiation, and this is p53-dependent.

Parvoviridae Human parvovirus B19 strain induces apoptosis of fetal erythroid precursors. It may be due to a nonstructural protein, NSP, localized to the nucleus and able to bind DNA. It is lethal when expressed in several cell types. However, the mechanism is unknown.

RNA viruses

Arteriviridae Porcine reproductive and respiratory syndrome (PRRS) virus p25 (ORF 5) is a membrane-associated glycoprotein, also present in virus particles. p25 induces apoptosis that cannot be inhibited by bcl-2.

Bunyaviridae La Crosse virus causes apoptosis of neuronal cells by an unknown mechanism.

Coronaviridae Infections with mouse hepatitis virus result in transient atrophy of the thymus. CD4+ and CD8+ lymphocytes are depleted and apoptosis of lymphocytes increases. The viral A59 (MHV-A59) gene is responsible, but its function or mechanism is presently not known.

Flavivirus The hepatitis C virus (HCV) core protein activates the FAS-mediated cell death pathway, by upregulating FAS. It can be prevented by inhibiting the CPP32 cysteine protease, but not ICE. Thus, the CPP32 protease is involved in the apoptosis effector pathway of HCV and may contribute to HCV immune-mediated liver damage. It has also been reported that HCV core protein can overcome some types of apoptotic death and thus contribute to transformation. Dengue (DEN) virus induces apoptosis late in the virus life cycle. This may be a key element in the pathophysiology of hepatic failure associated with DEN hemorrhagic fever/shock syndrome. Another major target cell type of DEN type 1 are neurons, which apoptose after accumulation of viral proteins in the endoplasmic reticulum, resulting in stress that brings about apoptosis.

Orthomyxoviridae In influenza virus-infected cells, neuraminidase activates latent TGFβ, which activates apoptosis. TGFβ levels increase in response to influenza. FAS-associated apoptosis may also be due to double-stranded (ds) RNA, which activates a dsRNA-protein kinase (PKR), which augments FAS expression. FAS gene activation is regulated by the PKR/interferon system.

Paramyxoviridae Newcastle disease virus (NDV) brings about apoptotic death in virus-infected macrophages. Measles virus (MV) induces apoptosis of thymocytes and thus contributes to a long-term alteration in immune responses. Apoptosis induction reflects the virulence of the virus: the more virulent, rapidly replicated strains induce cell death. Parainfluenza virus type 3 (PIV3)-induced PCD inhibits T cell function.

Picornaviridae Theiler's murine encephalomyelitis virus (TMEV) results in the apoptosis of infected neurons or nonpermissive cells, which could be responsible for the fatal outcomes and chronic demyelination associated with different strains.

Reoviridae Reovirus sigma 1 (S1), but not sigma1s (which determines viral serotype), and M2 genes, which encode proteins of the outer capsid, may be involved in viral entry and may trigger apoptosis that can be overcome by *bcl*-2 expression. There is no effect on virus growth. Some reports indicate that it correlates with the neural pathology associated with reovirus. Rotaviruses also cause apoptosis, but the mechanism is unknown. It may also be responsible for the pathogenesis of rotavirus-induced diarrheal disease.

Retroviridae The lentiviruses seem to be very competent at inducing apoptosis. Both human (HIV) and simian (SIV) immunodeficiency viruses cause T cell apoptosis. For SIV, both CD4+ and CD8+ cells apoptose. HIV infection effects apoptosis of CD4+ T cells, leading to T cell depletion and ultimately immunocompromised individuals. This plays a major role in HIV pathogenesis. It is FAS-mediated. HIV-infected cells may induce FASL and increase surface expression of FAS in monocytes, this can be inhibited by a cysteine protease inhibitor (E64d). It has also been shown that bcl-2 is cleaved by the viral protease. High levels of bcl-2 protect against apoptosis, but result in reduced viral yields. The HIV transcription

factor, Tat protein, upregulates the FAS receptor and downregulates bcl-2, and increases bax, leading to apoptosis of T and B lymphoid cells and monocytoid cells. The HIV *vpr* gene arrests cells in G_2, which is followed by apoptosis. The extent of arrest and apoptosis are directly correlated. The viral envelope glycoprotein–CD4 interactions are required for apoptosis of cell–cell transmitted virus. This does not require new virus replication. HIV and SIV also bring about dementia, which seems to be due to the apoptosis of neurons as a consequence of infected lymphoid cells accessing the CNS. SIV infections of the CNS with neurovirulent, neuroendotheliotropic strains results in the apoptosis of neurons, glial cells and endothelial cells of the CNS. Caprine arthritis–encephalitis virus (CAEV) is an ungulate lentivirus that results in PCD, but no gene or mechanism has been identified.

Rhabdoviridae Infections of neurons of intact mice with rabies virus results in an increase in bax protein and apoptosis that can be inhibited by overexpression of bcl-2. This suggests that apoptosis is important in the pathogenesis of this virus.

Togaviridae For bovine viral diarrhea virus (BVDV), virulent strains induce apoptosis, whereas noncytopathic strains do not. For Sindbis virus (an alphavirus), apoptosis directly correlates with cytopathic effect and neurovirulence and is dependent on viral replication. Sindbis virus-infected neurons of the CNS die by apoptosis. Bcl-2 shifts the infectious cycle from lytic to persistent. For Semliki Forest virus (SFV), apoptosis is also seen with neurovirulent strains, but not avirulent strains. It can be inhibited by bcl-2, which acts early in the virus life cycle to inhibit viral replication and results in reduced numbers of infected cells. This leads to the establishment of chronically infected cells.

Phylogenetic Background

Complete genome sequencing has confirmed the previous notion that the *Archaea* represent a novel domain of life, distinct from *Bacteria* and *Eucarya* (formerly known as Eukaryotes). Despite this fact, very little is known about their viruses. The *Archaea* themselves are divided phylogenetically into two kingdoms, *Crenarchaeota* and *Euryarchaeota*. The latter contains the methanogens, the extreme halophiles, the extremely thermophilic, sulfur-dependent *Thermococcales* and the highly acidophilic *Thermoplasmales*. Most of the known crenarchaeota are extremely thermophilic and sulfur-dependent organ-

factor, Tat protein, upregulates the FAS receptor and downregulates bcl-2, and increases bax, leading to apoptosis of T and B lymphoid cells and monocytoid cells. The HIV *vpr* gene arrests cells in G_2, which is followed by apoptosis. The extent of arrest and apoptosis are directly correlated. The viral envelope glycoprotein–CD4 interactions are required for apoptosis of cell–cell transmitted virus. This does not require new virus replication. HIV and SIV also bring about dementia, which seems to be due to the apoptosis of neurons as a consequence of infected lymphoid cells accessing the CNS. SIV infections of the CNS with neurovirulent, neuroendotheliotropic strains results in the apoptosis of neurons, glial cells and endothelial cells of the CNS. Caprine arthritis–encephalitis virus (CAEV) is an ungulate lentivirus that results in PCD, but no gene or mechanism has been identified.

Rhabdoviridae Infections of neurons of intact mice with rabies virus results in an increase in bax protein and apoptosis that can be inhibited by overexpression of bcl-2. This suggests that apoptosis is important in the pathogenesis of this virus.

Togaviridae For bovine viral diarrhea virus (BVDV), virulent strains induce apoptosis, whereas noncytopathic strains do not. ARCHAEAL PHAGES

Hans Peter Arnold, Kenneth M. Stedman and **Wolfram Zillig**, Max-Planck-Institute für Biochemie, Martinsried bei München, Germany

Phylogenetic Background

Complete genome sequencing has confirmed the previous notion that the *Archaea* represent a novel domain of life, distinct from *Bacteria* and *Eucarya* (formerly known as Eukaryotes). Despite this fact, very little is known about their viruses. The *Archaea* themselves are divided phylogenetically into two kingdoms, *Crenarchaeota* and *Euryarchaeota*. The latter contains the methanogens, the extreme halophiles, the extremely thermophilic, sulfur-dependent *Thermococcales* and the highly acidophilic *Thermoplasmales*. Most of the known crenarchaeota are extremely thermophilic and sulfur-dependent organ-

isms. Recent investigations have revealed that *Archaea* are not limited to extreme habitats like salterns or solfataras, but are ubiquitous.

This entry will focus on halophage ΦH and the virus SSV1. ΦH is the best characterized virus from euryarchaeota, SSV1 that of crenarchaeota. An overview of all other known viruses of the domain is also given and specific features of some will be discussed. Almost all known euryarchaeotal viruses resemble bacteriophages of the head and tail type, whereas the viruses of the *Crenarchaeota* exhibit novel morphologies (**Fig. 1**).

Viruses of Euryarchaeota

Halophages

All of the halophages isolated to date are head and tail phages similar to various coliphages (e.g. T phages and λ relatives). Halophages have isometric, icosahedral heads of widely differing sizes and tails, which in the case of ΦH, Hs1, HF1, HF2 and ΦCh1 are contractile. In the phages ΦH and ΦN tail fibers have been described, in the phages Hh3 and ΦCh1 collars. The DNA of halophages is double-stranded and varies between 30 and 60 kb in size, with the exception of Ja1 which carries an impressive 230 kb. Similar to their hosts, the guanine plus cytosine (G + C) content of the phage genomes is about 60–70%. Most of the halophages are inactivated in solutions of low ionic strength and are stable in solutions of high salt concentration, similar to their host's optimal growth conditions (typically 3–5 M). Their protein profiles in sodium dodecyl sulfate–polyacrylamide gel electrophoresis (SDS-PAGE) are relatively complex. Up to three major bands and a dozen or more minor bands are typical. Most halophages are stabilized by magnesium ions. These and other characteristics of halophages are listed in **Table 1.**

Halophage ΦH (*Myoviridae*) The best characterized of the halophages is ΦH. It is a temperate phage which causes lysis of the host cells when they enter the stationary growth phase. The phage persists in its host as prophage in the form of non-integrated, circular DNA, whereas the virion contains linear DNA. Several features of gene expression and genome organization have been elucidated. The structural and regulatory similarities to the coliphages are striking, despite the enormous evolutionary distance between these phage host systems.

Genome organization The phage particles contain linear double-stranded DNA with a length of 59 kb. This size differs from that of the viral episome, which is 57 kb. This difference is caused by the headful mode of packaging, leading to partial circular permutation and terminal redundancy of the phage genome. The terminal repetition comprises about 3% of the genome length. In comparison to bacterial phages the high rate of primary versus processive head filling is unusual; about 50% of all phage DNA molecules begin at the packaging start site of the genome (*pac* site). Because of the high genetic variability of *Halobacterium salinarum*, which is due to the high frequency of insertion elements, many variants of ΦH have been isolated (about 10% of any given phage population). This has facilitated the study of the genome organization and gene expression of the phage. All the changes are found in the so-called L region, a part of the genome which contains important regulatory elements and comprises the early genes and the insertion element ISH1.8 (in one or more copies). **Table 2** lists different host and phage variants.

The L region is flanked by the left and right arms of the viral genome. On the left arm are located the genes for the major structural proteins of ΦH: HP 20, HP 32 and HP 67 (9.3, 35.4 and 45.5 kDa respectively). The transcription of these late lytic genes proceeds across the terminal redundancy from the right to the left arm, which is possible because of the circularization of the viral genome upon its entry into the host cell. The most abundant phage variant, ΦH1, possesses the insertion element ISH1.8 at the left terminus of the L region (**Fig. 2**). In ΦH2 and ΦH5, which each carry two copies of ISH1.8 situated on both flanks, a genetic rearrangement can lead to inversion of the L region or to its looping out between the two copies of the IS element forming a plasmid, pΦHL, which harbors the L region. This plasmid can replicate autonomously and confers immunity to infection by ΦH, demonstrating the important role of the L region in the maintenance of the viral genome and in mediating immunity. The sequence of the L region has been determined. It contains two open reading frames (ORFs) which show similarity to bacterial and eucaryal genes encoding proteins that play a role in episome replication and maintenance.

Transcription of the L region and gene expression As mentioned above, ΦH can undergo a lytic cycle leading to host lysis or it can persist in a lysogenic state as a 'silent' episomal prophage. The decision between lytic cycle and lysogeny requires regulation of transcription in the L region (**Fig. 2**). The transcription of lytic phage genes is strictly time-dependent, with early gene products required for the expression of late genes. Three hours after infection

Table 2 Some features of *Halobacterium salinarium* strains and halophage ΦH variants

Strain/Variant	*Features*
H. salinarum	
R_1	*H. salinarum* strain which does not produce gas vacuoles
$R_1$24	R_1 lysogen harboring the complete circularized ΦH1 genome
R_1L	R_1 harboring the plasmid pΦHL which is derived from the L region of ΦH1, conferring immunity to ΦH1
Halophage	
ΦH1	Most abundant variant; >90% of the phage population, carrying a single copy of ISH1.8 at the right side of the L region
ΦH3, 4, 6	Like ΦH1, but differing by deletions or insertions outside the L region
ΦH 8	Like ΦH1, but carrying a single copy of ISH1.8 at the left side of L region
ΦH 7	Like ΦH 8, but with a deletion of 2.2 kb at the right border of the L region
ΦH2, 5	ΦH1 carrying one copy of ISH1.8 on both sides of the L region; capable of inverting the 12 kb L segment
pΦHL	Plasmid derived from ΦH1 consisting of the 12 kb L region, confers immunity to ΦH1 but not ΦHL1
ΦHL1	Variant in which an ISH23 element is inserted into the promotor of the transcript T4; this variant is able to overcome immunity of strain R_1L but not of strain $R_1$24
ΦHLA, B	Like ΦHL1, but carrying the L region in different orientation, variant A and B differ in carrying a flanking copy of ISH1.8 at one or the other end of the L region

the entire phage genome has been expressed, except for the left border of the L region and a small section in the right arm of the genome. Only these sections are expressed in lysogens and are thus most likely involved in lysogeny, including immunity to further phage infection. Another factor partially mediating immunity to superinfection is the *rep* gene product which can repress the formation of the major early lytic transcript T4. The promoters of the *rep* and T4 genes are situated back to back in a manner similar to that of *cI* and *cro* in bacteriophage λ. The region upstream of the T4 promoter contains two direct

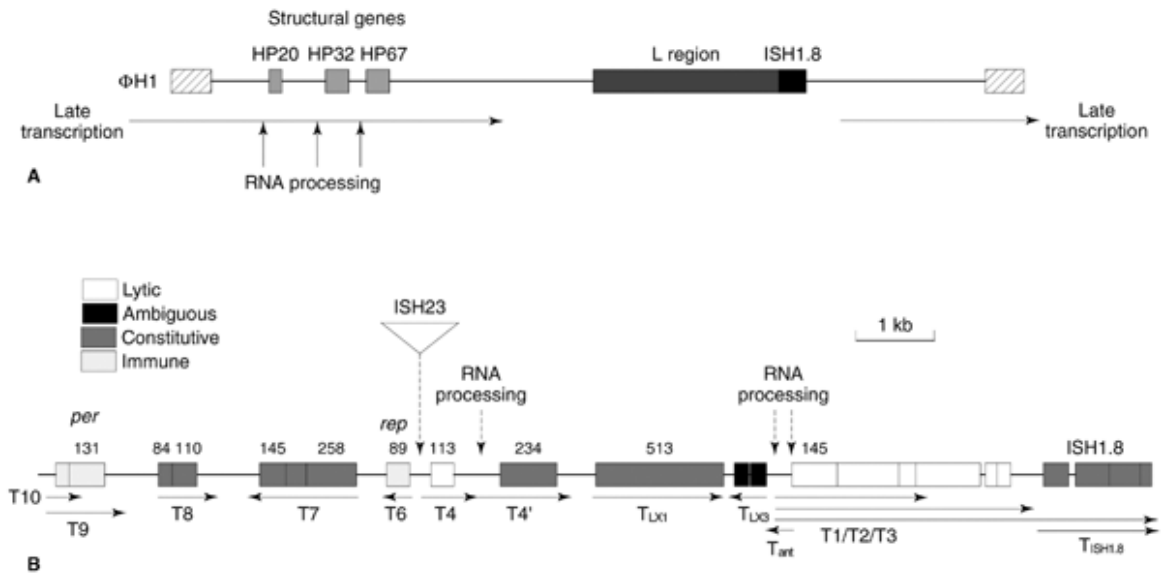

Figure 2 Map of the ΦH genome, showing genes and known transcription units. (**A**) Linear map of the phage variant ΦH1, which is the variant used in most studies on immunity and transcription. The hatched boxes at the ends of the DNA represent regions of terminal redundancy. The two arrows representing late transcription are parts of the same transcript, as the phage genome circularizes after entry into the cells. (**B**) Map of the L region. Boxes represent open reading frames. Transcripts denoted by a capital T followed by a designation are shown as arrows. The integration point of the IS element ISH23 in the phage variant ΦHL1 is indicated. The ISH1.8 insertion element shown is not part of the L region when present in plasmid pΦHL. (Reproduced with permission from Stolt P and Wolfram B (1994) Gene regulation in halophage ΦH; more than promoters. *Syst. Appl. Microbiol.* 16: 592.)

repeats with the sequence CTTCTCG separated by 15 bp. The repressor contains a helix-turn-helix motif and binds to this operator to repress transcription from the T4 promoter. The variant ΦHL1 can overcome the immunity of strain R_1L mediated by the plasmid pΦHL because of the insertion of element ISH23 into the promoter region of transcript T4 in ΦHL1. The insert functions as a spacer between repressor binding site (operator) and transcription start site, so that transcript T4 can be formed even in the presence of the repressor. Since ΦHL1 cannot overcome the immunity of *Halobacterium salinarum* carrying the wild-type prophage (strain $R_1$24), it is clear that immunity against ΦH is mediated by more than just the *rep* gene product. Transcription from the back to back promoters is mutually exclusive, with only the *rep* gene transcribed in the 'immune' (lysogenic) state and only transcript T4 produced during the lytic cycle. The product coded by transcript T4 has no effect on *rep* transcription but the transcription from the stronger promoter of the corresponding gene *per se* represses *rep* expression. These are the only two regulated promoters in the L region. All other L region promoters are transcribed constitutively.

Gene regulation also occurs at the level of RNA processing, particularly in the case of transcript T1. This lytic transcript is produced from a constitutive promoter 10 min after infection. In immune cells T1 is neutralized by the action of the antisense transcript T_{ant}. T_{ant} starts 151 bp downstream of the start site of T1 and is transcribed from a weak constitutive promoter in the opposite direction to T1. Consequently the first 151 nucleotides of T_{ant} and T1 form an RNA–RNA hybrid which is processed by an endonucleolytic RNase that removes the 3′ overhangs at the end of the RNA–RNA duplex but does not digest the double-stranded products. This leads to the removal of the 'Shine–Dalgarno' sequence (ribosome-binding site) of the lytic transcript T1 so that its RNA is not recognized by the translation apparatus. The RNase was shown to be host-encoded. Even though T_{ant} inactivates the early lytic transcript T1, its expression does not mediate immunity to phage infection but only a tenfold decreased production of phage particles. This is less than the immunity mediated by overexpression of the *rep* gene, which leads to a decrease in phage production by a factor 10^2, whereas pΦH1 mediates a 10^4-fold reduced phage production. Another example of the post-transcriptional modification of RNA in ΦH1 is 5′ processing of the large late lytic transcript on the left arm of the genome which encodes the three major structural proteins. Additionally, the transcripts T4 and T4′ are processed from a large common precursor RNA molecule by forming a loop structure and consecutive 3′ exonucleolytic removal of 40 nucleotides releasing both transcripts.

Halophages HF1 and HF2 (*Myoviridae*) *Morphology and hosts* Due to the genetic instability of *Halobacterium salinarum*, which is the only known host of the well-characterized halophage ΦH, investigators have also focused on viruses infecting members of the genus *Haloferax*, in particular *Haloferax volcanii*. Two novel viruses, HF1 and HF2, have been isolated from an Australian solar saltern. Both viruses are similar in their morphology, in their sensitivity to reduced ionic strength, their protein profiles, with one common major protein of 55 kDa and several minor proteins, and their linear, double-stranded DNA genomes of nearly the same size with similar restriction patterns (**Table 1**). DNA hybridization data also showed the two phages to be closely related. HF1 and HF2 are both lytic but differ in their host range. HF1 infects members of three halobacterial genera, including species of *Haloferax*, *Halobacterium salinarum* and *Haloferax volcanii*. In contrast to HF1 the host range of HF2 is confined to the closely related strains Ch2 and *Halobacterium saccharovorum*. HF2 also differs significantly from HF1 in plaque morphology.

Genome organization and replication strategy HF2 was chosen as a model for the study of the phage genome replication and the genome organization of the HF phages. The DNA of HF2 is not susceptible to cleavage by many type II restriction endonucleases, which is attributed to selection against palindromic restriction sites. The DNA termini of the linear HF2 genome exhibit homology to each other. Similar to bacteriophage T7, both ends are a 306 bp direct repeat, which contains five strings of C residues 3–6 bp in length separated by GT, TG or TGT motifs and two neighbouring sequences capable of forming stem–loop structures. The junction between the repeats and the rest of the HF2 genome contains two sequences which might be recognition sites for endonucleolytic cleavage. Similar sequences are flanking the cleavage sites of an endonuclease involved in replication in the genomes of the bacteriophages T3 and T7. This suggests a replication mode through concatameric intermediates also for HF2. As in the case of the bacteriophages T3 and T7, concatameric multimers of the genome have been observed in HF2-infected cells.

Other halophages *Phage ΦN of* Halobacterium salinarum (Siphoviridae) In contrast to all other known halobacterial phages, ΦN is not dependent on

high ionic strength or a high magnesium content in the medium to maintain infectivity. Curiously, in the genome of ΦN cytosine is completely replaced by 5-methylcytosine, a feature that has so far only been reported for the DNA of the bacteriophage XP12. Extensive C-methylation does not occur in the host and therefore a virus-encoded enzyme seems to be responsible for this modification.

Halobacterium salinarum *phage Hs1* (Myoviridae) The interaction of this phage with its host depends on the salt concentration of the medium. Lysis is retarded at higher salt concentrations, whereas the burst size remains unaffected. The rate of adsorption of the phage particles to their host cell is decreased at high salinity of the medium, whereas the growth rate of the host shows the opposite response. This is critical for the persistence of the phage in the host culture: at low salinity (17.5% NaCl) phage production exceeds archaeal growth, whereas at 25% NaCl the host can overgrow the phages via the segregation of cured, i.e. phage-free, cells. At concentrations between 25 and 30% NaCl a carrier state between Hs1 and its host is established. The frequency of lysis per cell and generation is 10^{-4} at 30% NaCl. Cells infected under low-salt conditions can be rescued by transfer to high-salt medium. This feature may be of selective advantage to the phage, as changes of the salt concentration in the natural habitat of the host often take place. The virus is lytic under conditions of low salinity, which are hazardous to its host. However, under conditions of optimal growth the phage propagates within its host in a stable carrier state.

Natronobacterium magadii *phage ΦCh1* (Myoviridae) The genera *Natronobacterium* and *Natronococcus* represent the alkalophilic group among the family of the *Halobacteriaceae*, with a pH optimum from 9 to 10. The phage ΦCh1 was detected via 'spontaneous' lysis of strains of *Natronobacterium magadii*. Morphologically ΦCh1 resembles other halophages. The tail has a collar at its end and an internal shaft which is visible after tail contraction. The host range of ΦCh1 is restricted to *Natronobacterium magadii*. The phage produces turbid plaques on lawns of *Natronobacterium magadii*, which is lysed by the phage in the stationary state. Incubation in medium of lower salinity than 2 M NaCl leads to the loss of the infectivity of the phage. But, as for most of the halophages, lower salt concentrations can be tolerated in the presence of magnesium. In addition to the partially methylated virus genome, host encoded RNA is found in the phage particles.

Viruses of methanogens

Although the methanogens represent the group of the *Archaea* with most known species and strains, knowledge of their viruses was, until recently, relatively sparse. In the past few years several new phages have been isolated and there is strong evidence that methanophages play an important role in lysis of methanogenic archaea in the rumen fluid. Almost all viruses of the methanogens are head and tail phages, except the virus-like particle (VLP) of *Methanococcus voltae*. Only two will be discussed here (see **Table 3** for more phages).

Phage ψM1 (*Siphoviridae*) ψM1 is the best characterized phage of the methanogenic archaea. It is an oxygen resistant phage of the thermophilic, strictly anaerobic, *Methanobacterium thermoautotrophicum* strain Marburg. The phage does not infect three other representatives of the genus *Methanobacterium* even though a defective prophage of ψM1 was found to be integrated into the chromosome of *Methanobacterium wolfei*. This methanogen is immune to infection by ψM1, but is not able to produce phage particles. In contrast to other species of *Methanobacterium*, *M. wolfei* lyses spontaneously upon energy starvation, a property possibly related to the possession of the integrated prophage. Only 85% of the DNA extracted from ψM1 phage particles is the phage genome, the rest are multimers of the cryptic plasmid pME2001 (4.5 kb) with the same size as the phage genome. The packaged pME2001 multimers are head to tail hexamers linked to an incomplete terminal copy of the plasmid. Despite lack of homology between the plasmid and phage DNA, the packaging appears to be the same for both and might be a headful mechanism. Similar plasmid encapsidation has been observed in mutant bacteriophage T4. Phage ψM1 also has the capacity to transduce a number of chromosomal markers at frequencies from 6×10^{-4} to 5×10^{-6} per PFU (plaque forming unit). Phage ψM1 thus appears to be a general transducing genetic element.

Virus-like particle from *Methanococcus voltae* A3 Electron-microscopic examination of the supernatant of *Methanococcus voltae* strain A3 revealed the presence of lemon-shaped particles, which morphologically resemble virus particles, particularly SSV1 (see below). Treatment of the particles with DNase showed that the DNA was protected from digestion until phenol extraction. However, neither infectivity nor inducibility of the virus-like particles could be demonstrated.

Table 3 Viruses and virus-like particles of methanogenic *Archaea*

Phage	*Host*	*Morphology*	*Size (nm)*	*Genome type and size (kb), DNA*	*Proteins*	*Propagation*	*Eclipse (h)*	*Latent period (h)*	*Burst size per cell*

TTV4	Stiff rod	30 × 500	linear, ds (17.0)	Lytic

ds, Double-stranded.

Viruses of *Crenarchaeota*

In contrast to the phages of euryarchaeota, which to date are almost all of the head and tail type, the few known viruses of *Crenarchaeota* (*Thermoproteales* and *Sulfolobales*) all have unique morphologies. The only known organisms, which serve as hosts for filamentous or rod-shaped viruses containing linear, double-stranded DNA, are crenarchaeota.

Viruses of *Thermoproteus tenax*

Thermoproteus tenax is an extremely thermophilic, strictly anaerobic and facultatively chemolithoautotrophic archaeon with a growth optimum at 88°C. In the chemolithoautotrophic mode of growth, energy is supplied by the formation of H_2S from S^0 and H_2. *T. tenax* is the host for four different viruses, termed TTV1, 2, 3 and 4. TTV1 is a flexible rod, TTV4 a stiff rod. TTV2 and TTV3 are flexible filaments. They differ in their protein composition and their morphology. No homology between their genomes has been observed in Southern hybridization analysis (**Fig. 1** and **Table 4**).

TTV1 (*Lipothrixviridae*) TTV1 is the best characterized of the four viruses. The virus is temperate. Lysis is induced when the sulfur in the host culture is consumed. TTV1 shows genetic variability confined to a specific part of its genome indicating an, as yet undefined, recombination mechanism. Some lysates of *T. tenax* cultures yield only one variant, while others contain simple virus mixtures. The variance mostly results from the regrouping of sequences with high homology to each other located between two nonadjacent reading frames. These sequences have an unusually high G + C content of about 58%, compared with 37% for the entire virus genome. On their left ends they carry the consensus sequence ACXCCTAC. The lengths of the relevant DNA sequences vary between 66 and 84 bp but are always in multiples of three, conserving ORFs on either integration or excision. Insertion of a fragment always leads to the introduction of a stretch of alternating proline–threonine sequences into the protein, termed TPX, which is expressed by the infected host cells. Two variants of this protein differing in the alternating proline–threonine stretches have been described. The function of the protein TPX and of these DNA arrangements remains unclear.

TTV1 consist of a core of linear, double-stranded DNA, to which equimolar amounts of the highly basic proteins P1 and P2 are bound. This core is covered by an inner envelope which is a helical array of a protein P3 that is formed by self-interaction of this protein. The envelope is closed by caps of protein P4. P3 is able to form hollow filaments in the absence of core. These are shortened and partially closed when protein P4 is present during aggregation. The inner envelope is covered by an asymmetric unit membrane assembled from the pool of host lipid components. The termini of the genomic DNA are covalently masked by hydrophobic ligands, which could not be removed by proteases. Therefore only about 85% of the sequence of the TTV1 genome has been determined.

TTV2, TTV3 (*Lipothrixviridae*) TTV2 and TTV3 resemble each other in their morphology. Both are long and flexible filaments. Both viruses are composed of a filamentous inner core consisting of linear DNA covered with protein and an outer envelope of unknown composition. TTV2 contains two basic major proteins of equal molecular weight. TTV2 is associated with its host in a lysogenic state. Virus particles are normally produced in small quantities, but occasionally a titer of 10^9–10^{10} ml^{-1} results from lysis. The lysis-inducing agent is unknown. Nothing is known about the relationship between TTV3 and *T. tenax*.

TTV4 (unknown affiliation) TTV4 resembles TTV1 in its shape, though it is stiff and its projections at both ends are long and thin (**Fig. 1C, E**). The virus is highly virulent and causes lysis of the host cells independent of the mode of host growth. It is extremely thermostable. One hour of autoclaving at 120°C leaves it infective and does not destroy its structure. One of the major proteins of TTV4,

apparently from the envelope, is highly hydrophobic and has an unusually high cysteine content. Under aerobic conditions these cysteine residues are oxidized, leading to extensive crosslinking. This might explain the extreme thermostability of the virus. In addition to the coat protein, a putative DNA-binding protein has been identified. In contrast to TTV1 no membrane lipids have been found.

Because the envelope of TTV4 had not been characterized, this virus was erroneously assigned to the envelope-less *Rudiviridae*. Since its envelope, in contrast to that of TTV1, does not contain host lipids, it should rather be classified as belonging to its own family Lipothrixvirus.

Sulfolobus viruses

Sulfolobus is one of the best characterized genera of the *Archaea*. It grows aerobically and either facultatively or obligately heterotrophically and can be easily cultivated in liquid media and on solid supports. Some *Sulfolobus* species, like *S. solfataricus*, have become model organisms of the *Crenarchaeota*. Thus, most of the extrachromosomal elements of the *Crenarchaeota* have been described in this genus. Besides conjugative and nonconjugative plasmids, a few viruses have also been found in the *Sulfolobales*.

***Sulfolobus shibatae* virus SSV1 (*Fuselloviridae*)** SSV1 is the best-characterized virus of the *Crenarchaeota*. It has been a very useful tool for investigation of promoter elements and gene expression in *Archaea*. At the moment it is one of the best candidates for the development of a transformation system for *Sulfolobus*.

Morphology and hosts The members of the genus *Sulfolobus* are all extremely thermophilic and acidophilic and often sulfur-dependent archaea with a growth optimum around 80–85°C. SSV1 was isolated from the species *S. shibatae* strain B12 from Japan and is infectious for some other *Sulfolobus* species (e.g. *S. solfataricus*), but not *S. acidocaldarius*. SSV1 is a spindle-shaped virus 60 × 100 nm in size with a very short tail and tail fibers at one pole. Its characteristic spindle form has no counterpart in any known bacteriophage. The coat of the virus is resistant to the conditions of the harsh environment of its host (thermostable up to 97°C and acid-resistant at least until pH 2.0). The DNA packaged into virus particles, however, is sensitive to these acidic conditions. Longer exposure to medium of the 'normal' pH of 3.5 leads to progressive nicking. If the pH is raised to 5.5, however, the virus maintains infectivity for a longer time. Under these conditions it is quite stable up to 85°C. The virus coat consists of two very similar hydrophobic proteins termed VP1 (73 amino acid residues) and VP3 (92 amino acid residues). Both coat proteins have an identical hydrophobic polypeptide stretch of 20 amino acid residues in their sequence, which is due to an identical DNA sequence of 61 bp in their genes. The extremely basic VP2 (74 amino acid residues) is a DNA-binding protein which can be isolated out of the virus particle along with small amounts of a mixture of at least two polypeptides, of which at least one is a host-encoded DNA-binding protein of 6 kDa. The virus is temperate. After infection its genome is integrated into the host chromosome. Nevertheless, a few virus particles are produced constitutively. SSV1 proliferation can be induced, e.g. via ultraviolet irradiation, leading to temporary growth inhibition of the host cells, but not to their lysis. Virus propagation starts 3–4 h after induction, with a maximum titer of 4×10^{10} ml^{-1} after about 16 h, when virus production reaches a plateau. At this time, virus production stops and the host cells return to their normal growth rate. SSV1 attaches with its short tail fibers to the host membrane but not to its S-layer. This reaction is so effective that plating efficiencies are apparently reduced to 10–50% compared to total counts by electron microscopy. This is due to the affinity of SSV1 particles to cell-derived membrane vesicles and to putative small (invisible) membrane fragments, in the former case forming the so-called 'sunflowers', and in the latter what have been termed 'virus-rosettes', in which the virus particles appear to be attached to each others tails (**Fig. 1F**).

Genome organization The genome of SSV1 is a 15.5 kb cccDNA, and the entire sequence has been determined. DNA isolated from virus particles is positively supercoiled, a feature not shown to occur in any other known extrachromosomal element. Reverse gyrase, a host-encoded topoisomerase first described in *Sulfolobus*, is responsible for generating this topology. The pool of episomal SSV1-DNA being replicated in the host cell after induction is, however, a mixture of both negatively and positively supercoiled DNA. The genome of SSV1 integrates at a specific attachment site into a chromosomal $tRNA^{Arg}$ gene of its host. The integration leaves this host gene intact, but the viral gene encoding the integrase is interrupted. This integrase was shown to perform recombination also *in vitro*. In some other bacterial systems tRNA genes are the target site for the integration of the genomes of bacteriophages (e.g. P2, P22, HP1c1). A viral gene encoding a putative excisionase has also been found. However, in contrast to bacteriophage λ, the integrase of SSV1 does not

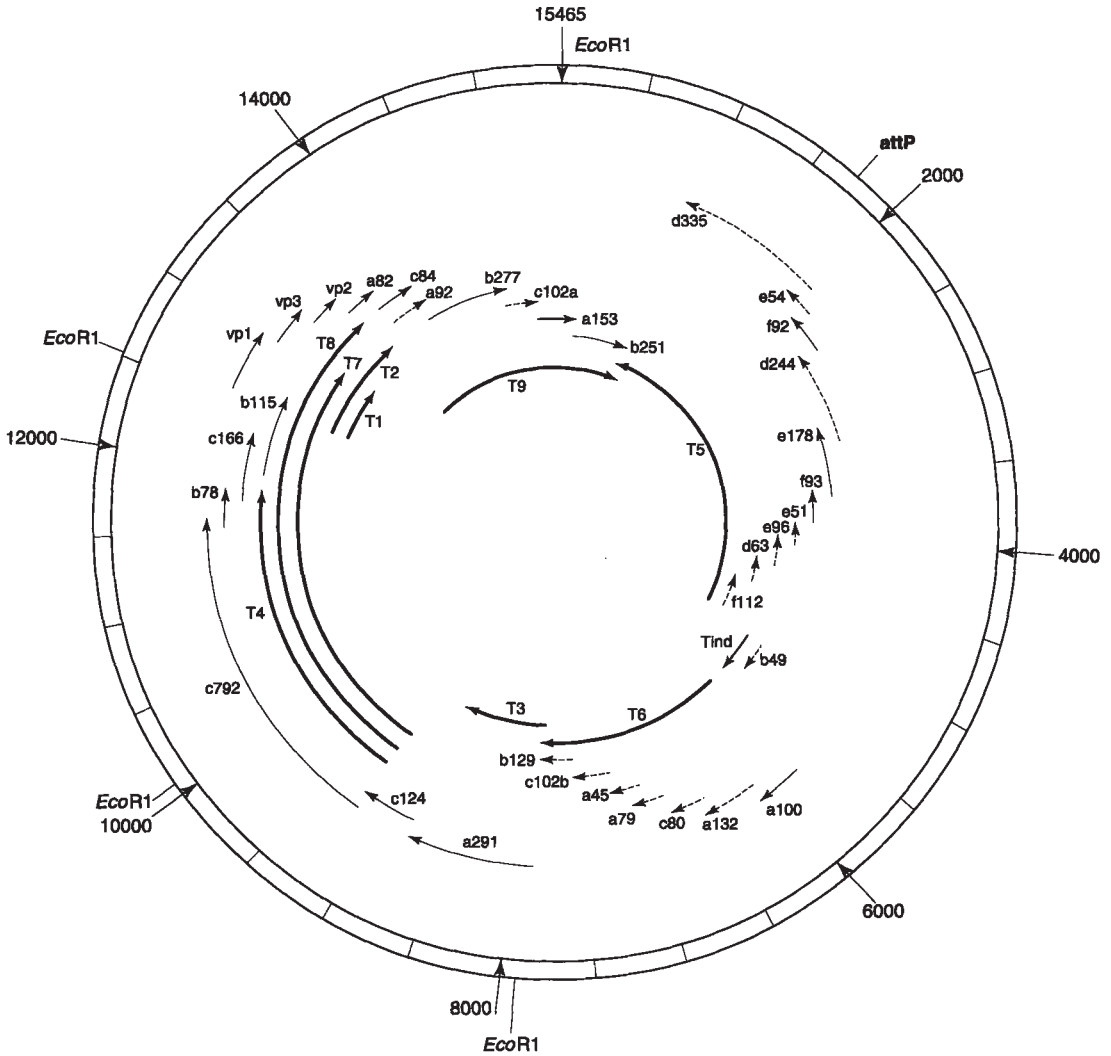

Figure 3 Map of the SSV1 genome, transcripts, proteins and open reading frames. Numbers refer to base pairs relative to the start of the largest *Eco*RI fragment. attP indicates the cleavage site for integration into the host genome. Bold arrows represent transcripts T1–T9 and T_{ind}; thin arrows are protein genes VP1–VP3 and all other open reading frames, without cysteine codons; dotted lines indicate open reading frames that contain cysteine codons. (From Palm *et al* (1991) *Virology* 185: 247.)

require accessory proteins like IHF and Xis for its *in vitro* activity.

Transcription All transcripts of the SSV1 genome have been identified (**Fig. 3**). In exponentially growing cells the major transcript is T1, although small but significant amounts of the transcripts T2, T3, T4, T7 and T8 are also detectable. Approaching stationary phase, the amount of the transcript T1 is amplified about twofold, whereas those of the transcripts T2, T3, T4, T7 and T8 are increased at least fivefold. The transcript T_{ind} appears as early as 2 h after ultraviolet irradiation, with a maximum between 3 and 4 h after induction, and has disappeared after 7 h. Transcripts T5 and T6 are also essentially absent in uninduced cells, but are transcribed 3 h after induction. They remain detectable longer than transcript T_{ind}. Although part of the amplification of the transcripts after ultraviolet induction could be due to an increase of gene dosage because of DNA replication, especially in the case of the transcripts T1 and T2, the transcripts T_{ind}, T5 and T6 are clearly induced.

Intriguingly, the promoter of the T_{ind} transcript lacks the typical, archaeal 'box A' motif about 26 bp upstream of the initiation site. The promoters of the transcripts T5 and T6, which are transcribed in opposite directions, are situated back to back. These transcripts start 5′ to the start and 3′ to the end of the T_{ind} gene, respectively, at the ends of long inverted repeat sequences. The entire length of the ultraviolet

inducible transcript T_{ind} maps between these two transcriptional start sites. The region between the promoters for the transcripts T5 and T6 contains stretches of DNA sequences exhibiting a complicated pattern of direct and inverted repeats. Regions of DNA containing such sequence repeats often constitute origins of replication, and it is likely that the region between the promoters of T5 and T6 is involved in the initiation of DNA replication. It has been claimed that this region allows a bacterial/archaeal shuttle vector to replicate autonomously in *Sulfolobus* and that the copy number of this vector is raised by ultraviolet irradiation (R. Cannio and M. Rossi, unpublished).

The constitutive transcripts T1 and T2 encode the three structural proteins of SSV1. Both transcripts share a common promoter. Transcript T2 is 1000 nucleotides long and encodes all of these proteins; T1 (500 nucleotides) terminates within the gene of VP3. Since the coat proteins VP1 and VP3 have been found to be integrated in the host membrane and since VP2, the DNA-binding protein, is also detectable in the cytoplasm during lysogeny, it appears that only DNA replication has to be induced for the maturation of virus particles. The newly synthesized DNA molecules then only need to be wrapped and packaged into their coat at 'virus membrane islands' in the host membrane. Virus particles have never been observed in the host cytoplasm. The transcript T_{ind} encodes only 49 amino acid residues and might serve as an RNA primer for DNA replication.

Other *Sulfolobales* viruses In contrast to SSV1 several other viruses from *Sulfolobus* isolates have not yet been extensively described (**Fig. 1G–I**). The rudivirus SIRV (*S. islandicus* rod shaped virus) was isolated from a *Sulfolobus* sp. strain from Iceland. It is a stiff rod and exhibits morphological similarity with the tobacco mosaic virus (TMV). A superhelix of the DNA with a DNA-binding protein forms a hollow tube which is terminally plugged and equipped with tail fibers at both ends. The virus appears to contain only one additional minor protein. There is no membrane or envelope coating the virus.

The lipothrixvirus DAFV (*D. ambivalens* filamentous virus) infects *Desulfurolobus ambivalens* (renamed *Acidianus ambivalens*), an obligately chemolithoautotrophic relative of *Sulfolobus*. It is filamentous, flexible and morphologically similar to TTV2 and TTV3 and contains linear double-stranded DNA of 56 kb.

Entirely different is SNDV (*S. newzealandicus* droplet-formed virus) which has not yet been classified. It looks like a droplet and is bearded with many fibres protruding around the pointed end. This virus is infectious for only a few strains from New Zealand and contains cccDNA of 20 kb.

Future Perspectives

Compared to the large number of characterized eucaryal viruses and bacteriophages, only a few viruses of archaea have been studied. Even so, the distribution of different morphological types within the two kingdoms of the *Archaea* is strikingly uneven. All known viruses of the *Crenarchaeota* are unique. Only in this group is found the combination of rod or filament shape and linear, double-stranded genomic DNA, whereas the phages of Euryarchaeota correspond to the head and tail morphology of many bacteriophages. However, the existence of head and tail phages in crenarchaeotes cannot be excluded. In electron micrographs of field samples, viruses with icosahedral heads have been observed attached via their tails to cells of *T. tenax* (length of the particles: 160 nm). The spindle-shaped SSV1 particle, which carries a short tail at one pole, could be regarded as a kind of head and tail virus, even though its head does not have the typical icosahedral form. Between SSV1 and the head and tail phages of Euryarchaeota and those of Bacteria exist additional similarities, particularly on the genetic level. This is an indication for the existence of head and tail viruses before the divergence of *Archaea* and Bacteria. A particularly striking argument is the similarity of the bacteriophage P1 and the halophage ϕH, which do not only resemble each other in their morphology but also both exist as episomal prophages in their lysogenic hosts. Moreover, both halophage ϕH and some λ related bacteriophages exert similar modes of control of transcriptional regulation of genes which are mutually transcribed from promoters situated back to back, with an operator for one or both of the genes in between. The genome of SSV1 is integrated into a tRNA gene in the host chromosome like that of some bacteriophages (e.g. P2, P22). Another similarity between SSV1 and lambdoid bacteriophages is the back to back arrangement of early genes and the switch from lysogeny to the lytic cycle after ultraviolet induction. These observations support the hypothesis that head and tail phages are derived of a common viral ancestor, already existing before the divergence of the three domains of life, even though the comparison of protein or DNA sequences between these viruses cannot yield direct evidence for this notion. After the divergence of the domains, the evolution of these phages could have been linked to that of their hosts, e.g. in the gene expression machinery and in coping with extreme environments. The extent of the differences between the modes of

gene expression in different domains and the divergent adaptation to the extreme living conditions make horizontal virus transfer between the domains after their divergence and stepwise adaptation of the phages to their novel hosts extremely unlikely.

Another incentive for research on archaeal viruses is the lack of a transformation system for *Sulfolobus*, which hinders progress of the molecular genetical investigation of the *Crenarchaeota*.

ARTERIVIRUSES (*ARTERIVIRIDAE*)

Margo A. Brinton, Georgia State University, Atlanta, Georgia, USA

History

Lactate dehydrogenase-elevating virus (LDV) was discovered by accident in 1960 during a study on the development of methods for early detection of tumors in mice. Inoculation of mice with Ehrlich carcinoma cells resulted in a 5 to 10-fold increase in lactate dehydrogenase (LDH) levels in the serum in 4 days. Because this early rise in LDH levels was also observed in mice inoculated with cell-free extracts or sera from tumor-bearing mice, the presence of an infectious agent was suspected. LDV is now known to produce an asymptomatic, persistent infection in mice characterized by a lifelong viremia and elevation of the levels of at least seven serum enzymes in addition to LDH.

Equine arteritis virus (EAV) was first isolated in 1957 in Bucyrus, Ohio from the lung tissues of an aborted fetus during an epidemic of abortions and arteritis in pregnant mares. However, equine disease consistent with that caused by EAV, was first observed in the late 1800s. At the time of its discovery EAV was distinguished from equine (abortion) influenza virus. Serological evidence has indicated that, although EAV is widespread in the horse population, it rarely causes clinical disease. EAV can produce persistent infections in seropositive horses.

Simian hemorrhagic fever virus (SHFV) was first isolated in 1964 during outbreaks of a fatal hemorrhagic fever in macaque colonies in the United States, Russia and Europe. A number of additional SHFV outbreaks in macaque colonies have occurred since the 1960s. The most 'famous' of these was the one in Reston, Virginia, which occurred in conjunction with a Reston Ebola virus outbreak. SHFV causes asymptomatic acute or persistent infections in several genera of African monkeys that are thought to be the natural hosts for this virus.

Porcine respiratory and reproductive syndrome was first detected in North America in 1987 and in Europe in 1990. This disease has also been referred to as porcine epidemic abortion and respiratory syndrome (PEARS), swine infertility and respiratory syndrome (SIRS) and mystery swine disease (MSD). The causative agent of this disease is now referred to as porcine respiratory and reproductive syndrome virus (PRRSV). The extent of the sequence divergence observed between American and European strains of

gene expression in different domains and the divergent adaptation to the extreme living conditions make horizontal virus transfer between the domains after their divergence and stepwise adaptation of the phages to their novel hosts extremely unlikely.

Another incentive for research on archaeal viruses is the lack of a transformation system for *Sulfolobus*, which hinders progress of the molecular genetical investigation of the *Crenarchaeota*.

ARTERIVIRUSES (*ARTERIVIRIDAE*)

Margo A. Brinton, Georgia State University, Atlanta, Georgia, USA

History

Lactate dehydrogenase-elevating virus (LDV) was discovered by accident in 1960 during a study on the development of methods for early detection of tumors in mice. Inoculation of mice with Ehrlich carcinoma cells resulted in a 5 to 10-fold increase in lactate dehydrogenase (LDH) levels in the serum in 4 days. Because this early rise in LDH levels was also observed in mice inoculated with cell-free extracts or sera from tumor-bearing mice, the presence of an infectious agent was suspected. LDV is now known to produce an asymptomatic, persistent infection in mice characterized by a lifelong viremia and elevation of the levels of at least seven serum enzymes in addition to LDH.

Equine arteritis virus (EAV) was first isolated in 1957 in Bucyrus, Ohio from the lung tissues of an aborted fetus during an epidemic of abortions and arteritis in pregnant mares. However, equine disease consistent with that caused by EAV, was first observed in the late 1800s. At the time of its discovery EAV was distinguished from equine (abortion) influenza virus. Serological evidence has indicated that, although EAV is widespread in the horse population, it rarely causes clinical disease. EAV can produce persistent infections in seropositive horses.

Simian hemorrhagic fever virus (SHFV) was first isolated in 1964 during outbreaks of a fatal hemorrhagic fever in macaque colonies in the United States, Russia and Europe. A number of additional SHFV outbreaks in macaque colonies have occurred since the 1960s. The most 'famous' of these was the one in Reston, Virginia, which occurred in conjunction with a Reston Ebola virus outbreak. SHFV causes asymptomatic acute or persistent infections in several genera of African monkeys that are thought to be the natural hosts for this virus.

Porcine respiratory and reproductive syndrome was first detected in North America in 1987 and in Europe in 1990. This disease has also been referred to as porcine epidemic abortion and respiratory syndrome (PEARS), swine infertility and respiratory syndrome (SIRS) and mystery swine disease (MSD). The causative agent of this disease is now referred to as porcine respiratory and reproductive syndrome virus (PRRSV). The extent of the sequence divergence observed between American and European strains of

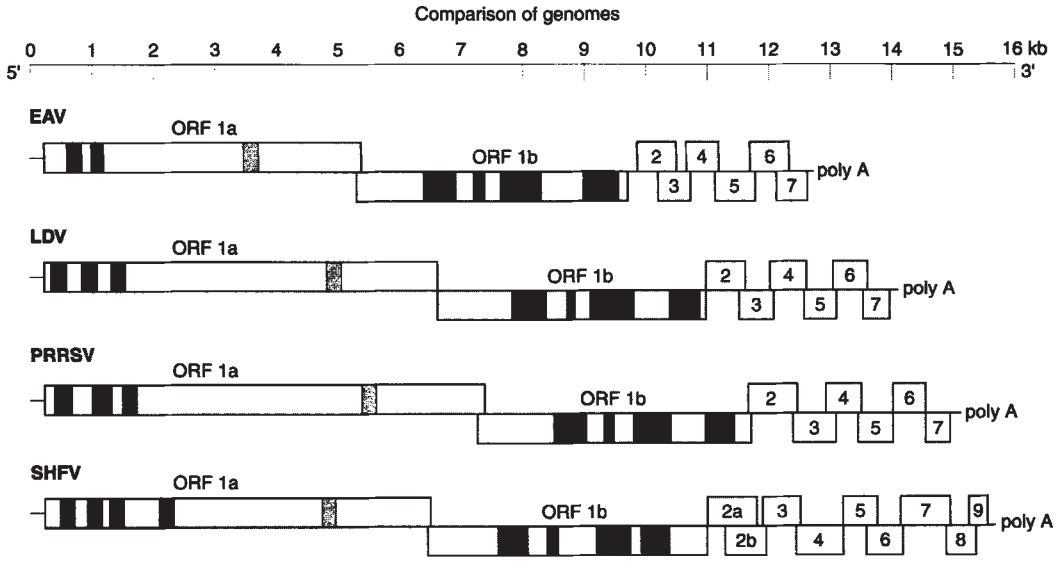

Figure 1 Organization of the genomes of LDV,EAV, PRRSV and SHFV. The nonstructural polyproteins are encoded by open reading frame (ORF) 1a/1b, which is located in the 5′ portion of the genome. ORF 1b is translated only when a −1 frameshift occurs. The conserved motifs in ORF 1a/1b are indicated by black boxes. From left to right these are: one to three papain-like cysteine proteases (stippled boxes), a cysteine protease, a serine protease, an RNA polymerase, a zinc finger, a helicase and a nidovirus-specific motif. The 3′ portion of the genome encodes the structural proteins. Adjacent 3′ ORFs are in different frames. (The genome sequences utilized are from: EAV, den Boon *et al* (1991) *J. Virol.* 65: 2910; PRRSV (Lelystad), Meulenberg *et al* (1993) *Virology* 192: 62; LDV, Godeny *et al* (1993) *Virology* 194: 585, Smith *et al* (1997) *Gene* 19: 205 and Brinton, unpublished data.)

PRRSV suggests that the ability to cause porcine disease emerged independently in these two virus populations.

Taxonomy and Classification

On the basis of the size and morphology of their virions as well as the infectious nature of their RNA genomes, LDV and EAV were originally classified within the *Togaviridae* family. After it was reported that EAV transcribed multiple subgenomic mRNAs, EAV was reclassified as the sole member of the *Togaviridae* genus *Arterivirus*. LDV was subsequently designated as a member of this genus. The genus *Arterivirus* was then designated as a 'floating genus'. SHFV was first classified as a togavirus and then as a flavivirus. In 1996, EAV, LDV, SHFV and PRRSV were designated as members of a new family, the *Arteriviridae*. At the same time, the family *Arteriviridae* was classified with the family *Coronaviridae* in the new Order *Nidovirales*.

The genomes of EAV, LDV, PRRSV and SHFV have been sequenced and their genome organization is similar to that of the coronaviruses (**Fig. 1**). Although the genomes of the four known arteriviruses contain the general features and conserved motifs characteristic of coronavirus genomes, they are only about half as long as coronavirus genomes. In addition, arterivirus particles are about half the size of coronavirus particles and differ from them morphologically; the surface of arterivirus envelopes is fairly smooth, and arteriviruses have icosahedral nucleocapsids.

Properties of the Virion

Virions are spherical, enveloped and 50–60 nm in diameter (**Fig. 2**). Unfixed virions undergo distortion and disintegration during standard negative staining procedures. The virion surface appears smooth and is thought to contain short, if any, spike-like projections. The virion capsid is icosahedral and about 30–35 nm in diameter. The general appearance of these viruses is similar to that of the alpha togaviruses and the flaviviruses and this morphological similarity resulted in some of the arteriviruses initially being classified as members of these virus families. Buoyant densities of 1.13–1.17 g cm^{-3} have been reported for arteriviruses in sucrose. The spherical capsid is composed of the nucleocapsid (N) protein. Virion envelopes contain the M protein, one major glycoprotein, and one to three minor glycoproteins. The major glycoprotein and the M protein are present as heterodimers in virions.

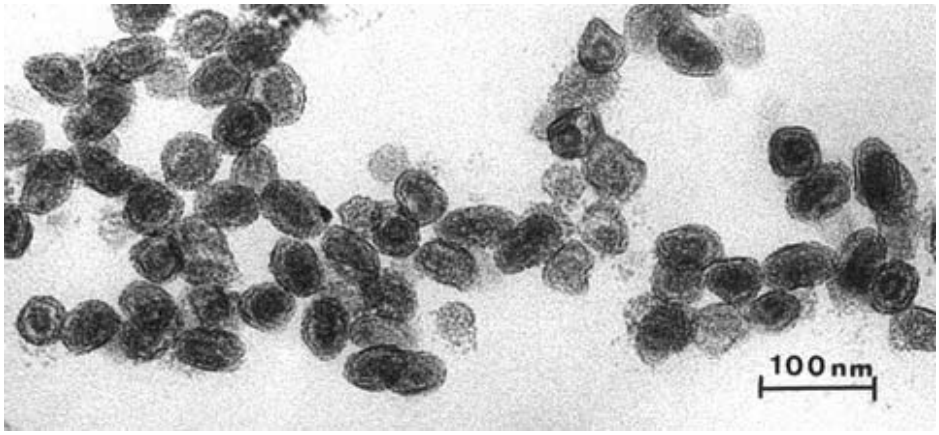

Figure 2 An electron micrograph of a positively stained thin section of gradient-purified LDV.

Properties of the Genome

The genomes of the arteriviruses are single-stranded RNAs of positive polarity. They contain a 3′ poly(A) tract of approximately 50 nucleotides in length and a 5′ type I cap. The length of the genome of EAV is 12.7 kb, that of LDV is 14.1 kb, that of PRRSV is 15.1 kb and that of SHFV is 15.7 kb (**Fig. 1**). The nonstructural polyproteins are encoded by ORFs 1a and 1b. The ORF 1b proteins are expressed only when a −1 frameshift occurs. The frameshift region is characterized by a slippery sequence upstream of a pseudoknot. Three different types of virion proteases are encoded in ORF 1a and these post-translationally cleave the ORF 1a and ORF 1a/1b polyproteins into 12 or more mature nonstructural proteins. There are six 3′ ORFs in the genomes of EAV, PRRSV and LDV, whereas SHFV encodes nine 3′ ORFs. Limited sequence homology suggests that the SHFV ORFs 2a, 2b and 3 may be duplications of the SHFV ORFs 4, 5, and 6, respectively (**Fig. 1**). Adjacent arterivirus 3′ ORFs are in different reading frames and in most cases overlap. Only the 5′ terminal ORF of most of the subgenomic mRNAs is translated. However, mRNA 2 of EAV, LDV, and PRRSV and mRNAs 2 and 4 of SHFV are bicistronic.

Properties of the Proteins

Two polyproteins are translated from the ORF 1a/1b region of the arterivirus genome. The ORF 1a polyprotein contains one or more papain-like cysteine proteases, a cysteine protease, and a serine protease. The serine protease cleaves at five sites within the ORF 1a polyprotein and eight sites within the ORF 1a/1b polyprotein. Three of the ORF 1a encoded proteins have hydrophobic domains which may be important for membrane association of the viral replication–transcription complexes. The ORF 1a/1b polyprotein is translated only after a −1 frameshift occurs. Motifs characteristic of a viral RNA polymerase, a zinc-finger, a helicase, and a conserved nidovirus-specific region are found in ORF 1b (**Fig. 1**). The capsid protein is encoded by ORF 7 (ORF 9 in SHFV), the nonglycosylated, triple-membrane spanning envelope M protein is encoded by ORF 6 (ORF 8 in SHFV), and the major virion glycoprotein is encoded by ORF 5 (ORF 7 in SHFV). The remaining 3′ ORFs each encode proteins of about 20 kDa in size that contain a number of putative N-linked glycosylation sites and may function as minor virion envelope glycoproteins. The ORF 2 (ORF 4 in SHFV) protein is a class I integral membrane protein. A soluble, non-virion-associated form of the ORF 3 protein is released from infected cells.

Physical Properties

Virions can be stored indefinitely at −70°C. At −20°C, samples of LDV lost half of their infectivity by 4 weeks. At 4°C, LDV in mouse plasma decreased in titer by about 3.5 logs in 32 days; at room temperature, plasma virus was stable for 24 h, whereas infectivity was completely inactivated by heating at 58°C for 1 h. LDV suspended in media supplemented with 10% serum was more heat labile than virus in plasma. Virions are fairly stable between pH 6 and pH 7.5, but are rapidly inactivated at high or low pH. Virus is efficiently inactivated by lipid solvents and is very sensitive to nonionic detergent treatment. A brief incubation with low concentrations (0.01%) of nonionic detergents, such as NP40 and Triton X-100, efficiently disrupts the virion envelope.

Replication

Viral replication occurs entirely in the cytoplasm. Infected cells contain full-length genome RNA,

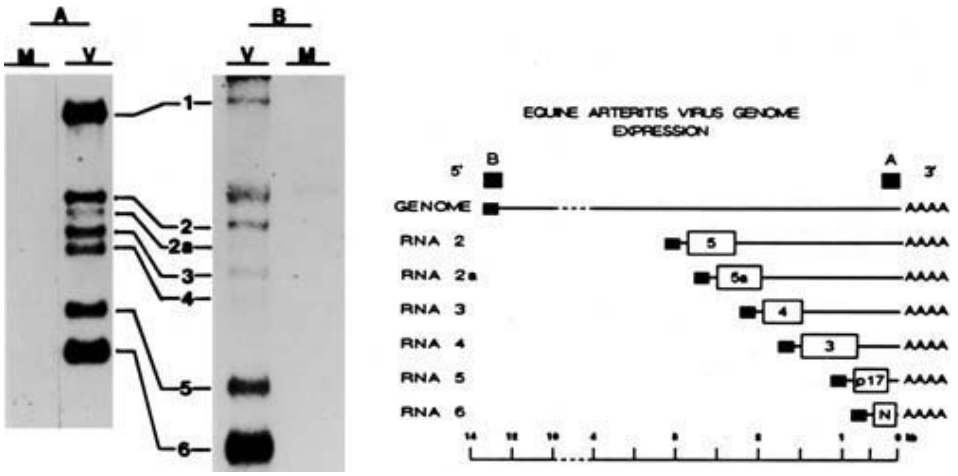

Figure 3 EAV proteins encoded at the 5′ end of the genome are translated from the genome RNA whereas proteins encoded at the 3′ end are translated from subgenomic mRNAs. The EAV genomic and subgenomic mRNAs are designated by numbers 1–6. The autoradiographs show Northern-blot hybridizations obtained with mock-infected (M) and EAV-infected (V) cell extracts reacted with either (**A**) a 3′ probe or (**B**) a 5′ probe. The open boxes represent ORFs, and the closed boxes represent the 5′ leader sequence. The bicistronic nature of mRNA2 is not indicated. (Reproduced with permission from Spaan *et al* (1989) In: Brinton MA and Heinz FX (eds) *New Aspects of Positive Strand Viruses*, p. 12. Washington: ASM Press.)

subgenomic viral mRNAs and full-length and subgenomic viral minus-strand RNAs. The subgenomic mRNAs form a 3′ coterminal nested set (**Fig. 3**) and are thought to be transcribed by an uncharacterized discontinuous mechanism which utilizes the conserved junction sequences that precede each 3′ ORF. Each subgenomic mRNA contains a common 5′ leader sequence which is identical to the 5′ terminal sequence of the genome RNA. Conserved RNA structures and cis-acting signals for plus-strand RNA replication have been identified in the 3′ noncoding region of the complementary full-length minus-strand RNA. The 3′(−)non-coding region has also been shown to bind specifically to four cellular proteins thought to be involved in viral RNA replication.

Assembly, Uptake and Cytopathology

Evidence for a specific saturable, but as yet unidentified receptor for LDV on a subpopulation of murine macrophages has been reported. LDV-immune complexes are infectious and apparently infect target cells via Fc receptors. Ventral motor neurons in susceptible mouse strains can be infected by 'free' LDV-C, but not by viral immune complexes. A heparin-like molecule on the surface of MARC-145 cells may serve as a receptor for PRRSV. PRRSV has been reported to enter cells via a low pH-dependent, endocytic pathway. Soon after infection, virus particles have been observed in small vesicles that appear to be clathrin-coated. Virus replication occurs in the perinuclear area of infected cells. Virions are observed to bud through endoplasmic reticular membranes into intracellular vesicles. Virions presumably move to the exterior of the cell via these vesicles. Assembled nucleocapsids have not been observed in the cytoplasm, except in association with budding virions. Infection of primary macrophages with EAV, SHFV, PRRSV and, probably, also LDV is cytocidal. The formation of double-membrane cytoplasmic vesicles is a characteristic of virus-infected cells. Laboratory strains of EAV, SHFV, and PRRSV cause obvious cytopathology in the continuous cell cultures which they infect. Cells become rounded and are released from the tissue culture flask. Apoptosis has been observed in PRRSV-infected porcine alveolar macrophages, MA-104 cells and testicular germ cells.

Geographic and Seasonal Distribution

Viruses with biological properties identical to those of LDV have been isolated from small groups of wild mice (*Mus musculus*) in Australia, Germany, the US and UK. EAV-infections and EAV-induced disease have been well documented in North America and Europe and antibodies to EAV have been detected in horse sera from Africa and South America indicating that EAV infection is geographically widespread. Natural PRRSV infections have been reported in North America and Europe. SHFV infection in captive patas monkeys has been documented and SHFV has been detected in the blood of wild patas monkeys, African green monkeys, and baboons

suggesting that these African primates are the natural hosts for SHFV.

Host Range and Virus Propagation

LDV replicates efficiently in all strains of laboratory mice and wild *Mus musculus* and somewhat less efficiently in the Asian mouse *Mus caroli*. Numerous attempts to infect other rodents such as rats, hamsters, guinea pigs, rabbits, deer mice (*Peromyscus maniculatus*) and dwarf hamsters (*Phodopus sungorus*) with LDV have not been successful. LDV grows very efficiently in mice reaching titers of 10^{11} ID_{50} ml^{-1} of plasma within the first day of infection. By a week after infection, viral titers have declined to a steady-state level of about 10^6 ID_{50} ml^{-1}. *In vitro*, LDV replicates only in an as yet uncharacterized subpopulation of primary murine macrophages. In peritoneal macrophage cultures obtained from 1–2-week-old mice, up to 70% of the cells are infectible. However, only 40% or less of the macrophages are virus susceptible when the cells are obtained from older mice. The highest number of infected cells was observed when peritoneal cell cultures were infected during the first 24 h plating. Thereafter, the number of infectible cells progressively declined, until by 7 days, the cultures were no longer infectible. However, incubation of fresh peritoneal macrophage cultures with colony-stimulating factor resulted in the continued differentiation of virus-susceptible cells from stem cells. Attempts to infect numerous continuous cell lines with LDV, including all attempts to infect murine macrophage cell lines, have been unsuccessful with one exception. A line of mouse macrophage–human hybrid cells was reported to be transiently permissive for LDV replication.

EAV infects horses and donkeys. Field isolates are rarely obtained and are difficult to propagate in cell culture. However, laboratory strains of EAV have been successfully grown in primary cultures of horse macrophages and kidney cells, rabbit kidney cells and hamster kidney cells and also in cell lines, such as BHK-21, RK-13, MA-104 and Vero.

Natural infections with PRRSV were thought to be restricted to pigs. However, a recent report suggested that chickens and mallard ducks may also be susceptible to infection with PRRSV. PRRSV replicates in primary cultures of porcine alveolar macrophages. Some, but not all, isolates of PRRSV can be adapted to replicate *in vitro* in MA-104 cells.

SHFV naturally infects several species of African primates, namely *Erythrocebus patas*, *Cercopithecus aethiops*, *Papio anuibus* and *Papio cynocephalus*. SHFV infection of members of the genus *Macaca* has occurred in a number of primate facilities. Some isolates of SHFV can replicate in primary cultures of rhesus aveolar lung macrophages and MA-104 cells.

Genetics

Evidence for the existence of virulence mutants of LDV, SHFV and EAV has been obtained. Virulent and avirulent mutants of EAV have been identified on the basis of the severity of the diseases they cause. A number of temperature-sensitive mutants of EAV have also been selected. One strain of LDV, designated LDV-C, was shown to induce neurologic disease in a few susceptible inbred mouse strains. SHFV isolates that produce acute infections and ones that cause persistent infections in patas monkeys have been reported. EAV and PRRSV infectious clones have recently been constructed.

Evolution

Comparison of the genomes of EAV, LDV, PRRSV and SHFV (**Fig. 1**) suggest that these genomes have evolved via both point mutations and copy choice RNA recombination mechanisms. Sequence comparisons of various field isolates of either PRRSV or EAV indicated that the sequences of the M and N proteins are more conserved than those of the glycoproteins. The extent of the divergence between the sequences of European and North American PRRSV isolates indicate that these two virus populations represent subspecies. Phylogenic analyses have shown that PRRSV is most closely related to LDV and that SHFV is more closely related to these two viruses than to EAV.

The organization of the genomes of LDV, EAV, SHFV and PRRSV is very similar to that of the coronaviruses (**Fig. 1**). Both types of viral genomes have the same set of conserved nonstructural protein motifs arranged in the same order within ORF 1a/b. Although there are significant differences in the structural protein regions of the arterivirus and the coronavirus genomes, both families of viruses encode their capsid protein as the terminal 3′ gene and a nonglycosylated envelope M protein as the penultimate 3′ gene. Coronaviruses have helical nucleocapsids, whereas LDV, SHFV, PRRSV and EAV have icosahedral nucleocapsids. The capsid protein of the coronaviruses is about twice as large as the one encoded by the arteriviruses. Coronavirus particles have large peplomer spikes on their surface, whereas LDV, SHFV, PRRSV and EAV particles have 'smooth' surfaces. The coronaviruses and the arteriviruses most likely evolved as two distinct lineages from a common progenitor. The prototype virus may originally have had an iscosahedral nucleocapsid, and

then via a copy choice recombinational event acquired a helical capsid gene from another virus. This change in the type of capsid utilized would have removed the packaging restrictions on the genome size. The additional genetic information found in the current coronavirus genomes could then have been gained during further evolution via recombination.

Serologic Relationships and Variability

All attempts to demonstrate antigenic crossreactivity between EAV, LDV, PRRSV and SHFV have been unsuccessful. Even though antiviral antibodies are detected in infected animals by a week after infection, all four viruses can cause persistent infections. The mechanism by which these viruses evade clearance by the immune system is not known. Neutralization escape virus variants have been reported to arise during persistent LDV infections. Antiserum obtained from animals chronically infected with LDV and PRRSV contains infectious viral immune complexes. Plasma from LDV-infected mice has a higher non-specific binding activity than plasma from uninfected mice; virus-specific binding measured by an ELISA usually cannot be detected until the plasma has been diluted at least 1:400.

Transmission

No insect vector has been associated with LDV or SHFV transmission in wild animal populations. In the laboratory, LDV infection is rarely transmitted between mice housed in the same cage, even though infected mice excrete virus in their feces, urine, milk and saliva, unless the cage mates are fighting males. Since LDV in mice and SHFV in patas monkeys is produced throughout the lifetime of an infected animal, the transfer of fluids or tissues from an infected animal to an uninfected one results in the inadvertent transfer of infection. Historically, the most frequent mode of transmission of LDV among laboratory mice and of SHFV from patas monkeys to macaques has been through experimental procedures such as the use of the same needle for sequential inoculation of several animals. Currently, the most frequent sources of LDV contamination are pools of other infectious agents or tumor cell lines that have been repeatedly passaged in mice, especially those first isolated in the 1950s. Such materials should be checked for the presence of LDV and, if found to be contaminated, can be 'cured' of LDV by repeated passage in culture. It has been suggested, but not proven, that SHFV can be transmitted between macaques via the respiratory route.

No evidence for transmission of EAV and PRRSV by insect vectors in domestic animal populations has been reported. Horizontal transmission of EAV and PRRSV can occur via the respiratory route as well as via the sexual route in semen. Vertical transmission of PRRSV *in utero* has been reported.

Tissue Tropism

The primary target cells of all four arteriviruses are macrophages. LDV replicates in an uncharacterized subpopulation of murine macrophages. Virus target cells are located in tissues as well as in the blood. Cells containing LDV-specific antigen have been identified in sections of liver and spleen by indirect immunofluorescence. In spleen, the virus-infected cells were nucleated and located in the red pulp. In liver, only Kupffer cells contained LDV-specific antigen. In C58 and AKR mice infected with a neurotropic strain of LDV, designated LDV-C, virus replication was demonstrated in ventral motor neurons. Measurement of the amount of virus in various tissues during natural EAV infections indicated that lung macrophages were the first host cells to be infected. Bronchial lymph nodes subsequently became infected and then the virus spread throughout the body via the circulatory system. In fatally infected horses, lesions are found in subcutaneous tissues, lymph nodes and viscera. PRRSV has been reported to replicate in testicular germ cells which could result in excretion of virus into the semen.

Pathogenicity and Clinical Features of Infection

Avirulent and virulent strains of EAV and PRRSV have been isolated. Attenuated vaccine strains of EAV and PRRSV have been selected and used as vaccines. Although these vaccines induce immunity against disease, immunized animals are not protected from reinfection. Horses infected with the virulent Bucyrus strain of EAV develop a high fever, lymphopenia and severe disease symptoms. LDV-C differs from other LDV isolates in its ability to infect ventral motor neurons in immunosuppressed C58 and AKR mice and induce poliomyelitis. Isolates of SHFV that induce persistent, asymptomatic infections and ones that cause acute, asymptomatic infections in patas monkeys have been reported. All SHFV isolates cause fatal hemorrhagic fever in macaque monkeys.

Mice infected with LDV usually display no overt symptoms of disease. A distinguishing feature of LDV infections is the chronically elevated levels of seven serum enzymes, LDH (8–10-fold), isocitrate dehydrogenase (5–8-fold), malate dehydrogenase (2–3-fold),

phosphoglucose isomerase (2–3-fold), glutathione reductase (2–3-fold), aspartate transaminase (2–3-fold) and glutamate–oxaloacetate transaminase (2–3-fold). The elevated LDH levels result primarily from a decreased rate of clearance of normal turnover enzyme from the blood. A permanent reduction in the population of Kupffer cells involved in receptor-mediated endocytosis of LDH has been shown to occur soon after infection of mice with LDV. A decrease in the humoral and cellular immune response to non-LDV antigens is observed during the first 2 weeks after LDV infection. Thereafter, the immune response to other antigens is normal. In immunosuppressed C58 and AKR mice, one isolate of LDV, LDV-C, can induce a sometimes fatal poliomyelitis. Immunosuppression is required to delay antibody production so that virus can reach the central neurons system (CNS) and infect the susceptible ventral motor neurons. LDV-infected neurons become the targets of an inflammatory response. In mice 6 months of age or older, paralysis of one or both hind limbs and sometimes a fore limb is observed. In younger C58 mice, poliomyelitis is usually subclinical.

Both EAV and PRRSV can cause either asymptomatic infections or induce various disease symptoms such as respiratory disease, fever, necrosis of small muscular arteries and abortion. The severity of disease caused by EAV and PRRSV depends on the strain of virus as well as the condition and age of the host animal. The most common symptoms of natural EAV infections in horses are anorexia, depression, fever, conjunctivitis, edema of the limbs and genitals, rhinitis, enteritis, colitis and necrosis of small arteries. If clinical symptoms occur, they are most severe in young animals and pregnant mares. Infections in pregnant mares are often inapparent, but can result in a high percentage (50%) of abortions. Young animals sometimes develop a fatal bronchopneumonia, but natural infections are usually not life-threatening. In contrast, about 40% of pregnant mares and foals experimentally inoculated with EAV die as a result of the infection.

SHFV causes asymptomatic acute or persistent infections in patas monkeys, but a fatal hemorrhagic fever in macaques. Infected macaques develop fever and mild edema followed by anorexia, dehydration, adipsia, proteinuria, cynosis, skin petechia, bloody diarrhea, nose bleeds and occasional hemorrhages in the skin. The pathological lesions consist of capillary-venous hemorrhages in the intestine, lung, nasal mucosa, dermis, spleen, perirenal and lumbar subperitoneum, adrenal glands, liver and periocular connective tissues. These signs and symptoms are not unique to SHFV-infected animals, since they are also observed after infection with other types of viruses that cause hemorrhagic fevers. Although the SHFV-induced lesions are widespread, the level of tissue damage is not severe. Even so, the mortality of SHFV infections in macaques approaches 100%.

Pathology and Histopathology

Although most LDV infections are inapparent in mice, some histopathogenic changes are observed in infected animals. As described above, the serum levels of seven enzymes are chronically elevated in LDV-infected mice. Normally, an increase in the serum levels of tissue enzymes is the result of tissue damage, but in LDV-infected animals little tissue damage is observed. Although there are five naturally occurring LDH isozymes in mouse plasma, only the level of isozyme LDH 5 is elevated. Studies have indicated that the increase in enzyme levels is primarily the result of a decreased rate of enzyme clearance. A recent report showed that a subpopulation of Kupffer cells involved in receptor-mediated endocytosis of LDH is severely diminished in mice by 24 h after LDV infection. It has been postulated that LDV replication in these cells causes their death and the depletion of these cells results in the slower turnover of LDH.

Splenomegaly, characterized by a greater than 30% increase in spleen weight, occurs in about 40% of the mice infected with LDV. The increase in spleen weight is observed by 24 h after infection and persists for up to a month. A marked necrosis of lymphocytes in thymic-dependent areas occurs during the first 4 days after LDV infection together with a transient decrease in the number of circulating T lymphocytes between 24 and 72 h after infection. A transient decrease in peritoneal macrophages is also observed between the first and 10th day of infection.

Despite the lifelong presence of circulating viral immune complexes and the demonstration of LDV antibody deposits in the kidneys of LDV-infected mice as early as 7 days after infection, infected animals do not develop kidney disease. It has been suggested that nephritis does not develop in chronically infected mice because of the inability of the majority of the LDV-antibody complexes to bind C1q. Low levels of C1q-binding activity can only be detected between days 10 and 18 after LDV infection.

The central nervous system lesions in LDV-C-infected C58 and AKR mice are located in the gray matter of the spinal cord and, occasionally, in the brainstem and consist of focal areas of inflammatory mononuclear cell infiltrate in the ventral horn. Virus-specific protein and nucleic acid have been detected and maturing virions have been observed in ventral motor neurons.

In horses experimentally or fatally infected with EAV, the most common gross lesions are edema, congestion and hemorrhage of subcutaneous tissues, lymph nodes and viscera. Microscopic investigation of tissues from chronically infected horses, which have mildly swollen lymph nodes and slightly increased volumes of pleural and peritoneal fluids, revealed extensive lesions consisting of generalized endothelial damage to blood vessels of all sizes and severe glomerulonephritis. Both types of lesions are thought to be caused by the deposition of viral immune complexes. Extensive capillary necrosis leads to a progressive increase in vascular permeability and volume, hemoconcentration and hypotension. During the terminal stages of the disease, lesions are also found in the adrenal cortex, and degenerative changes are observed in the bone marrow and liver. Virus infection causes focal myometritis which is thought to be the cause of deficiencies in the fetal and placental blood supply. The resulting anoxia is probably the cause of abortion.

Immune Response

The persistence of LDV infectivity in the plasma of infected mice and the failure of initial attempts to demonstrate the presence of neutralizing antibodies led investigators to postulate that LDV-specific antiviral antibodies were not produced. It was subsequently demonstrated that antiviral antibodies were efficiently produced in LDV-infected animals, but were complexed with virions. Whereas 99% of the infectivity in sera collected 24 h after infection could be neutralized with ether-extracted murine anti-LDV immunoglobulin, no neutralization of the LDV infectivity in sera from chronically infected mice could be demonstrated unless antibody to mouse immunoglobulin was also used. Anti-LDV antibody not complexed to virus can be detected by 15 days after infection, indicating that antibody is present in excess of virus in chronically infected mice. Studies with nude mice suggest that LDV is a T-independent antigen. LDV-infected mice display a polyclonal humoral response, but anti-LDV antibody apparently accounts for only a small portion of this polyclonal response. The mechanism by which LDV infection activates B cells polyclonally is currently not known, but mice immunized with inactivated virus do not develop a polyclonal response. Autoantibodies to a variety of cellular components (autoimmune antibodies) have been detected in mice chronically infected with LDV. LDV-infected animals develop cytotoxic T cells that can specifically lyse virus-infected macrophages after infection. However, the cytotoxic response does not clear the infection. A T cell response has also been detected in PRRSV-infected pigs.

Anti-EAV antibodies can be detected in horses 1 to 2 weeks after infection with virulent or avirulent strains of the virus by either serum-neutralization or complement-fixation assays. Virus neutralization is enhanced by the presence of fresh complement. Newborn foals with mothers that are immune receive protective antibodies in the colostrum. Complement-fixing, antiviral antibodies peak at 2–3 weeks after the initiation of infection and then decline. Neutralizing antibody levels peak between 2 and 4 months after infection. Often after 8 months, anti-EAV antibody can no longer be detected by complement-fixation or neutralization assays, but in some animals the virus persists and viral immune complexes may continue to circulate.

Neutralizing antibodies in sera obtained from EAV- and LDV-infected animals are ORF 5 protein-specific and the neutralizing epitope has been mapped to the ectodomain of this protein. The number of gylcosylation sites in the ectodomain of the ORF 5 protein varys in different LDV strains and it has been postulated that antibodies bind less efficiently to virions with extensive glycosylation in this region. The induction of neutralizing antibodies by the ORF 4 protein of PRRSV has also been reported. SHFV isolates that induce acute infections in patas monkeys induce high levels of neutralizing antibody, whereas SHFV isolates that induce persistent infections induce low titers of non-neutralizing antibody. Antibodies to virus that causes acute infection do not cross-neutralize virus that causes persistent infection.

Prevention and Control

The most effective means of prevention of LDV, SHFV, PRRSV and EAV infection is interruption of animal to animal transmission. Infected animals should be destroyed or isolated. However, the current lack of rapid diagnostic assays for the detection of LDV and SHFV in persistently infected animals means that it is still a time-consuming task to identify animals with inapparent infections. Materials obtained from animals that might be infected with an arterivirus should be checked for viral contamination before they are injected into a susceptible animal. Multiple animals should not be injected using the same needle.

Killed and attenuated live vaccines for EAV and PRRSV are commercially available. The live vaccines are more effective and induce a longer-lasting immunity than the killed vaccines. Although animals immunized with the live vaccines are protected from disease, they are not protected from reinfection and

can spread virus. Current serological assays can not distinguish field strains from vaccine strains.

Future Perspectives

Arteriviruses have so far been isolated from mice (LDV), horses (EAV), pigs (PRRSV) and monkeys (SHFV). It seems likely that other host species, including humans, may harbor additional members of this virus family. Such viruses will be especially difficult to find in natural hosts that develop asymptomatic infections. Because of the inapparent and persistent nature of infections caused by LDV, PRRSV, SHFV and EAV it is important to develop rapid and reliable diagnostic tests for these viruses to easily identify infected animals. The availability of complete genomic sequences for EAV, PRRSV, SHFV and LDV should facilitate the development of new diagnostic assays and vaccines and may also provide the means for detecting additional arteriviruses.

Introduction

Viruses are the causative agents of a wide variety of diseases, and occur in virtually all forms of life. Owing to their medical, veterinary and economic importance, the viruses that have been studied the most are those that cause important diseases of humans and their domesticated plants and animals. In contrast, viruses that attack insects have received relatively little study. The best-known insect viruses are those that attack honeybees or silkworms, or the viruses that attack crop-eating pests such as caterpillars. Studies of honeybee and silkworm viruses are aimed at controlling the viral diseases of these economically important insects, whereas the studies of caterpillar viral diseases emphasize development of the viruses that cause these diseases as microbial insecticides.

Though insect viruses have not been studied nearly as well as many of the vertebrate and plant viruses, they are no less interesting with respect to their general biology, pathology, biochemistry and molecular biology. Moreover, because insects are a remarkably diverse and evolutionarily successful group of organisms, with more species described – well over one million – than any other group of organisms, they represent a source of new and interesting viruses that can differ significantly in their biologies from known viruses. The ascoviruses are an example of just such a group. Initially discovered about two decades ago, these large, enveloped, double-stranded (ds) DNA viruses, known primarily from insects of the order Lepidoptera (butterflies and moths), are unique in their structure, pathology, and general biology. As a result, they take their place as a new family of enveloped, dsDNA viruses alongside

can spread virus. Current serological assays can not distinguish field strains from vaccine strains.

Future Perspectives

Arteriviruses have so far been isolated from mice (LDV), horses (EAV), pigs (PRRSV) and monkeys (SHFV). It seems likely that other host species, including humans, may harbor additional members of this virus family. Such viruses will be especially difficult to find in natural hosts that develop asymptomatic infections. ASCOVIRUSES (*ASCOVIRIDAE*)

Brian A Federici, Department of Entomology and Interdepartmental Graduate Program in Genetics, University of California, Riverside, California, USA

Introduction

Viruses are the causative agents of a wide variety of diseases, and occur in virtually all forms of life. Owing to their medical, veterinary and economic importance, the viruses that have been studied the most are those that cause important diseases of humans and their domesticated plants and animals. In contrast, viruses that attack insects have received relatively little study. The best-known insect viruses are those that attack honeybees or silkworms, or the viruses that attack crop-eating pests such as caterpillars. Studies of honeybee and silkworm viruses are aimed at controlling the viral diseases of these economically important insects, whereas the studies of caterpillar viral diseases emphasize development of the viruses that cause these diseases as microbial insecticides.

Though insect viruses have not been studied nearly as well as many of the vertebrate and plant viruses, they are no less interesting with respect to their general biology, pathology, biochemistry and molecular biology. Moreover, because insects are a remarkably diverse and evolutionarily successful group of organisms, with more species described – well over one million – than any other group of organisms, they represent a source of new and interesting viruses that can differ significantly in their biologies from known viruses. The ascoviruses are an example of just such a group. Initially discovered about two decades ago, these large, enveloped, double-stranded (ds) DNA viruses, known primarily from insects of the order Lepidoptera (butterflies and moths), are unique in their structure, pathology, and general biology. As a result, they take their place as a new family of enveloped, dsDNA viruses alongside

other viruses with similar structural and biochemical properties, namely the herpesviruses of vertebrates, poxviruses of vertebrates and invertebrates, baculoviruses of invertebrates, and plasmaviruses of bacteria.

History

The first ascoviruses were discovered during the late 1970s in southern California where they were found causing disease in larvae of moths belonging to the lepidopteran family Noctuidae. The diseased larvae where recognized by the presence of blood that was very white and opaque, in marked contrast to the blood of healthy larvae which is translucent and slightly green. The color and opacity of the blood in diseased larvae was shown to be due to the presence of high concentrations of vesicles that contained virions. The white blood and virion-containing vesicles are diagnostic for the disease, and the name for this group, *Ascovirus,* derived from the Greek 'asco' meaning 'sac,' was chosen on the basis of the latter characteristic. Since the discovery of the first ascovirus, ascoviruses have been isolated as the cause of disease in many species of noctuid larvae, and recently in France from larvae of the family Yponomeutidae.

Taxonomy and Classification

Because ascoviruses have been discovered only recently, little is known about their distribution, diversity or taxonomy. They are all placed in the *Ascovirus* genus of the *Ascoviridae* family. So far, four distinct types or species have been identified. These are the viruses isolated from, respectively, the noctuid species *Trichoplusia ni* (the cabbage looper), *Spodoptera frugiperda* (the fall armyworm) and *Autographa precationis* (which lacks a common name), and from the yponomeutid species, *Acrolepiopsis assectella* (the leek moth). The latter virus is unusual in that it is known to be vectored by the endoparastic wasp, *Diadromus pulchellus* (family Ichneumonidae), in which the viral genome is carried in wasp nuclei as an episome. Its unusual biology, discussed later, suggests it represents a second type of ascovirus.

For convenience, these four ascoviruses are referred to as *Trichoplusia* ascovirus, *Spodoptera* ascovirus, *Autographa* ascovirus and *Diadromus* ascovirus, with the last virus being named after its wasp vector. The primary characteristic used to establish these as different viral species is the failure of their DNAs to hybridize to each other under conditions of low stringency. In addition, as will be noted below, these viruses exhibit differences in G + C content, host range, tissue tropism and cytopathology, which further validate their being recognized as distinct species. Variants also exist, with the most notable being the *Helicoverpa* ascovirus, a variant of the *Trichoplusia* ascovirus isolated from *Helicoverpa zea* (= *Heliothis zea,* the corn earworm). The genome of this variant has a restriction enzyme fragment pattern distinct from that of the *Trichoplusia* ascovirus, and the virus differs from the latter virus in its histopathology. However, *Helicoverpa* and *Trichoplusia* ascovirus DNAs hybridize strongly even under conditions of high stringency, and thus *Helicoverpa* isolate is considered a variant of the *Trichoplusia* ascovirus.

Ascoviruses probably occur worldwide, but at present they are only known from the USA and France. Based on their likely worldwide distribution, it is probable that there are numerous species.

Virion and Genome Structure and Composition

Depending on the species, the virions of ascoviruses are either bacilliform, allantoid or ovoidal in shape, with complex symmetry, and are very large, measuring about 130 nm in diameter by 200–400 nm in length (**Fig. 1**). The virion consists of an inner particle surrounded by an outer envelope. The inner particle itself is complex, containing a DNA/protein core as well as an apparent internal lipid bilayer surrounded by a distinctive layer of protein subunits. Thus, the virion appears to contain two lipid membranes, one associated with the inner particle, the other forming the lipid component of the envelope. In negatively stained preparations, virions have a distinctive reticulate appearance, which is thought to be due to superimposition of subunits on the surface of the internal particle with those in the envelope.

As indicated by the size and complexity of the virions, the genome of ascoviruses is large, and consists of a single molecule of dsDNA, which, depending on the viral species, is either in the range of 116 kb in size (*Diadromus* ascovirus), 140 kb (*Spodoptera* ascovirus) or 180 kb (*Trichoplusia* ascovirus). The G + C content of the *Spodoptera* ascovirus is 60%, whereas for the *Trichoplusia* ascovirus it is 42%. Supercoiled circular DNA has not been detected in cesium chloride gradients, nor have circular forms been observed by electron microscopy. The DNA genome is therefore referred to as linear, though each terminus may consist of a short single-stranded loop connecting the stands, making the molecule circular, as occurs in herpes-

viruses. Recent studies of *Diadromus* ascovirus DNA indicate it is in the form of a relaxed circle.

Based on gel analyses, ascovirus virions contain at least 12 structural polypeptides, ranging in size from 12 to 200 kDa. In addition to proteins and the DNA genome, the presence of an envelope, as detected by electron microscopy as well as experiments with detergents and organic solvents, indicates that virions contain a substantial lipid component. And, as in other enveloped viruses of eucaryotes, it is likely that the virion also contains carbohydrate in the form of glycoproteins, though none have yet been identified.

Transmission and Ecology

One of the most interesting features of ascoviruses is that their transmission from host to host appears to be dependent on their virions being transmitted by female endoparasitic hymenoptera (wasps). Ascoviruses are extremely difficult to transmit *per os*, with typical infection rates averaging less than 15%, even when larvae are fed as many as 10^5 virion-containing vesicles in a single dose. In contrast to this, infection rates for caterpillars injected with as few as 10 virion-containing vesicles are typically greater than 90%. Moreover, experiments with parasitic wasps show that they can effectively transmit ascoviruses to their noctuid hosts. For example, when female wasps are allowed to lay eggs in ascovirus-infected noctuid caterpillars, thereby contaminating their ovipositor, and then allowed to lay eggs in healthy larvae, the majority of the latter contract ascovirus disease. Interestingly, though the parasite eggs hatch in their noctuid hosts, the parasite larvae die as the ascovirus disease develops in the caterpillar. Under field conditions, the prevalence of ascovirus disease in caterpillars is correlated with high rates of parasitization by endoparasitic hymenoptera. Thus, laboratory and field studies provide sound evidence that the primary mechanism for the transmission of ascoviruses attacking noctuid larvae is through being vectored mechanically by parasitic wasps. No evidence has been found in the lepidopteran hosts for transovum or transovarial transmission.

In the case of the *Diadromus* ascovirus, the association of the virus with its wasp and lepidopteran host is much more intimate. The ascovirus DNA is carried in wasp nuclei as an episome, and small numbers of virions are produced in the oviducts, but the virus does not cause noticeable pathology in the wasp host. The females lay eggs in the pupal stage of the lepidopteran host, introducing small numbers of ascovirus virions along with the wasp eggs. These virions invade lepidopteran host cells, replicate and initiate destruction of major host tissues. The wasp larva then emerges from the egg and feeds on the host tissues and ascovirus virions. The ascovirus genome is carried by both male and female wasps, where it is apparently transmitted from generation to generation transovarially.

These observations make ascoviruses the only known group of viruses pathogenic to insects primarily dependent on vectors for their transmission.

Now that the characteristics of the disease are known, field studies in southeastern USA and California are beginning to show that ascoviruses are probably the most common type of virus to occur during most of the year in populations of several important noctuid pests, including the cabbage looper, *T. ni*, fall armyworm, *S. frugiperda*, and the corn earworm, *H. zea*. Prevalence rates range from 10 to 25%, depending on the species and time of the year, with the highest rates of infection, as noted above, being correlated with high levels of parasitization.

Host Range and Virus Propagation

The experimental host range of ascoviruses varies with the viral species. The variants of the *Trichoplusia* ascovirus have a broad host range and are capable of replication in a variety of noctuid species, as well as in selected species belonging to other families of the order Lepidoptera. Alternatively, the experimental host range of the *Spodoptera* ascovirus is limited to other species of the genus *Spodoptera*. The *Diadromus* ascovirus can replicate in hymenopteran and lepidopteran hosts closely related to its natural host species. To propagate virus in the laboratory, all ascoviruses can be grown in their caterpillar hosts. To infect caterpillars, they are injected with virus in the fourth or early fifth instar, and virion-containing vesicles are harvested from the blood 5–7 days later.

Pathology and Pathogenesis

Gross pathology

The gross pathology of ascovirus disease is very indistinct, and probably accounts for the fact that ascoviruses were discovered only recently. The most obvious sign of disease is that, within 24 hours of infection, larvae cease to gain weight or progress in development. Healthy larvae, particularly in the early stages of development, will easily quadruple their weight and size in a period of 3–4 days, whereas ascovirus-infected larvae cease to grow and may actually lose weight. This is a characteristic that is virtually impossible to detect in the field, but which is easily noticed under laboratory conditions when infected and healthy larvae are reared side-by-side over a period of a few days. A second feature easily

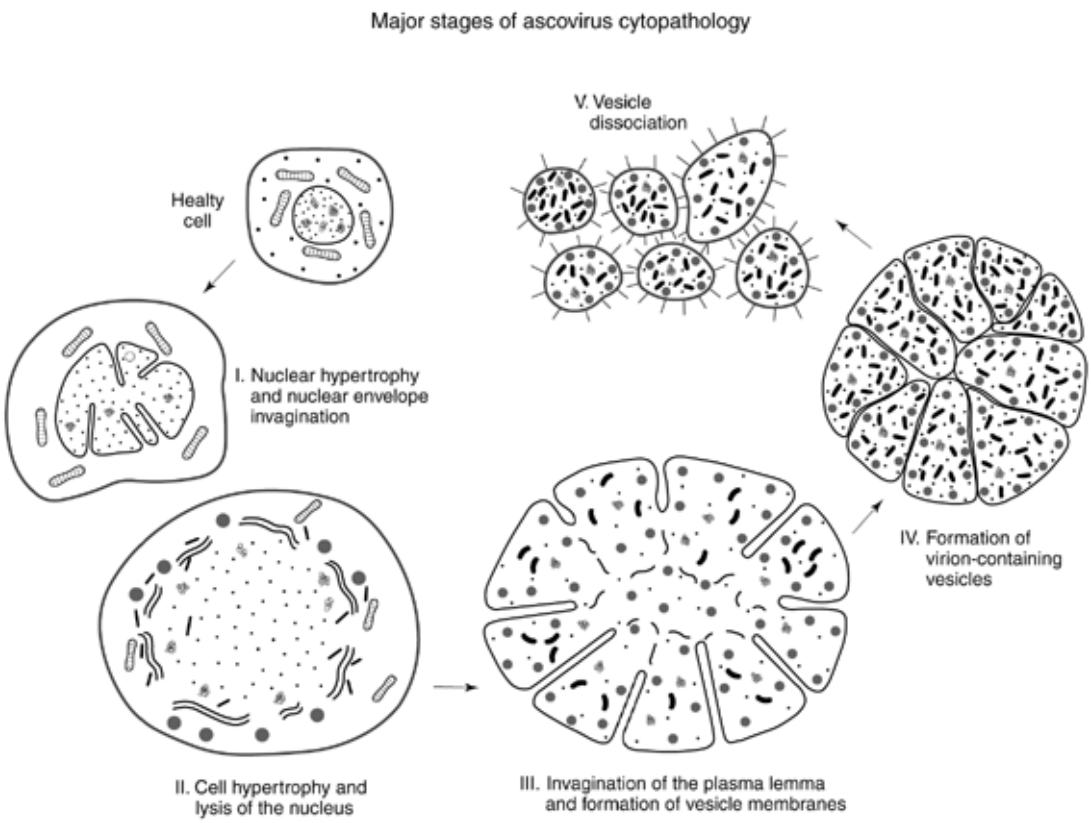

Figure 2 Major stages of cellular pathogenesis caused by a typical ascovirus. After infection, the nucleus enlarges and the nuclear membrane invaginates, and then lyses. Subsequently, the plasmalemma of the cell invaginates and coalesces with cytoplasmic membranes, apparently formed *de novo*, thereby dividing the cell into a cluster of virion-containing vesicles. These vesicles dissociate and are liberated into the blood as the basement membrane of infected tissues degenerates. Virion assembly becomes apparent as the nuclear membrane lyses, and continues throughout all subsequent stages of vesicle formation.

noted in the laboratory is that ascovirus diseases are chronic, though invariably fatal. When infected during early stages of development, ascovirus-diseased larvae often survive for 2–3 weeks beyond the time at which most healthy larvae have completed their development and pupated. Signs of disease other than these are minor, but include the inability to completely cast the molted cuticle, and an occasional white discoloration and hypertrophied appearance of the larval body at advanced stages of disease development.

Cytopathology

In comparison to all other known viruses, the most unique property of ascoviruses is the unusual cytopathology that leads to the formation of the virion-containing vesicles. At the cellular level, the disease begins with extraordinary hypertrophy of the nucleus followed by a corresponding enlargement of the cell (**Fig. 2**). Cells will typically grow from five- to tenfold the diameter of uninfected cells. As the nucleus enlarges, the nuclear envelope ruptures and disintegrates into fragments. At about this stage the cell plasmalemma begins to invaginate along 'planes' toward the now anucleate cell center. Concomitantly, sheets of membrane form closely adjacent to mitochondria that accumulate along the planes. As this process continues, the membrane sheets coalesce and join the invaginating plasmalemma, thereby cleaving the cell into a cluster of from 20 to more than 30 vesicles, ranging in size from 5 to 10 μm in diameter. The vesicles typically remain in the tissue until the basement membrane ruptures, though on occasion cell hypertrophy can be so great that the enlarging cell erupts out through the basement membrane of the infected tissue, releasing large fragments of the infected cell directly into the blood.

Despite the chronic nature of the disease caused by ascoviruses, virion-containing vesicles are present in

Table 1 Tissue tropism of four ascovirus species

	Major tissues infected[a]			
Viral species	*Epidermis*	*Tracheal matrix*	*Fat body*	*Midgut*
Trichoplusia AV	++	++	+	−
Heliothis AV[b]	+++	++	+	−
Spodoptera AV	−	−	+++	−
Autographa AV	−	−	+++	−
Diadromus AV	+++	++	+	+++

[a]The number of + signs indicates the degree of infection; +++ indicates the tissue is very heavily infected and almost completely destroyed by 5–7 days postinfection.

[b]Based on DNA hybridization data, the *Heliothis* ascovirus is a variant of the *Trichoplusia* ascovirus, i.e. a pathovar, not a distinct species.

the blood within 2–3 days of infection. Moreover, when the virus replicates in cells *in vitro*, the vesicles are formed within 12–16 h of infection.

Tissue tropism

Though the cytopathology of ascoviruses is consistent among different viral species, considerable variation occurs with respect to the tissues attacked, i.e. in which replication occurs (**Table 1**). The *Trichoplusia* ascovirus variants from *T. ni* and *H. zea* exhibit a relatively broad tissue tropism infecting the tracheal matrix, epidermis and connective tissue. Differences exist between these variants in that the variant from *H. zea* infects the epidermis much more extensively than the *T. ni* variant, whereas the *T. ni* variant can also replicate in fat body cells, but appears to only do this extensively when larvae are infected early in their development. Alternatively, the *Spodoptera* and *Autographa* ascoviruses have a very narrow tissue tropism, with the fat body being the primary site of infection. The *Diadromus* ascovirus occurs in the nuclei of all tissues of its wasp host, but appears to only produce progeny in ovarial tissues. In its pupal host, it attacks and replicates in a wide variety of tissues.

In all ascoviruses, the virion-containing vesicles are cleaved from cells as the disease progresses. Typically, the vesicles accumulate in the tissues where they are formed, but as these tissues degenerate during disease progression, the basement membrane of infected tissues deteriorates and ruptures, allowing the vesicles to spill out into the blood. There they accumulate, reaching concentrations as high as 10^8 vesicles ml^{-1} within 3–4 days of infection. There is some evidence that viral replication proceeds within the vesicles as they circulate in the blood, and thus this tissue must also be considered one of the tissues attacked by ascoviruses. If fact, because such high concentrations of viral vesicles are found in the blood, this tissue could be considered a major site of infection, particularly if it is eventually shown that these viruses continue to replicate in the vesicles as they circulate in the blood.

Replication and Morphogenesis

Though there have been no biochemical studies of viral DNA replication or protein synthesis, studies carried out with the *Trichoplusia* and *Spodoptera* ascoviruses *in vitro* in insect cell lines show that progeny virions first appear about 12 h after infection. Virion morphogenesis is initiated after the nucleus ruptures, and occurs before and during the cleavage of the cell into vesicles. The first recognizable structural component of the virion to form is the multilaminar layer of the inner particle. Based on its ultrastructure, this layer consists of a unit membrane and an exterior layer of protein subunits. As the multilaminar layer assembles, a dense nucleoprotein core aggregates on the interior surface. This process continues until the inner particle is complete. After formation, the inner particle is enveloped by membranes within the cell or vesicle. These membranes are apparently synthesized *de novo*. Thus, the assembly of the virions is reminiscent of that in other viruses with complex virions, such as the herpesviruses and poxviruses, where the virions differentiate after the association of the precursors of virion structural components.

After formation, the virions of the *Trichoplusia* ascovirus accumulate toward the periphery of the vesicle, where they often form inclusion bodies, i.e. aggregations of virions. In the *Spodoptera* ascovirus, occlusion bodies are formed in which the virions are actually occluded in a 'foamy' vesicular matrix that consists of a mixture of protein and minute spherical vesicles. When viewed with phase microscopy, these viral inclusion and occlusion bodies are phase bright,

and are largely responsible for the highly refractile appearance of the vesicles.

Evolution

The subject of viral evolution over millions of years has received little study due to the lack of a fossil record. Moreover, viruses are considered polyphyletic, with the more then 50 families of viruses thought to have originated independently. In this regard, the ascoviruses may provide a unique opportunity to obtain insight into virus evolution over long periods. The only ascovirus gene sequenced to date is gene encoding a DNA polymerase. Phylogenetic comparisons of this gene with other viral DNA polymerase genes confirm that the ascoviruses represent a unique and stand-alone virus family. However, ascovirus virions are structurally and morphologically similar to the particles formed by ichnoviruses of the family *Polydnaviridae*. As ichnovirus particles are produced in the reproductive tracts of endoparasitic wasps of the family Ichneumonidae, and the wasp host of the *Diadromus* ascovirus is a member of this family, there is a reasonable possibility that ascoviruses and ichnoviruses are related phylogenetically, and thus share a common ancestor. This possibility is currently under investigation, and should be resolved over the next few years through a comparative analysis of the molecular evolution of genes of ascoviruses and ichnoviruses after more of their genes have been cloned and sequenced. A major question to be addressed is whether the *Diadromus* ascovirus represents an intermediate evolutionary form of ascovirus between viruses such as those found in noctuids and the particles of ichnoviruses.

Economic Importance and Future Perspectives

At present, too little is known about ascoviruses to assess whether they are, or will turn out to be, of economic importance. Because of their poor infectivity *per os*, it is unlikely they hold promise for development as microbial insecticides. However, as more entomologists become familiar with the disease caused by ascoviruses, it may be shown that in habitats not treated with synthetic chemical pesticides, ascoviruses are responsible for significant levels of natural pest suppression, particularly where parasitic wasps are abundant. Such findings would encourage even greater emphasis on the development of biological control and other more environmentally sound methods of pest control. With respect to the cytopathology of the disease and viral molecular biology, ascoviruses provide interesting models for the study of novel replication strategies. The unusual process of cell cleavage by which the virion-containing vesicles form probably involves highly specific virus-directed mobilization of the cell cytoskeleton and mitochondria. In addition, it is possible that the virion-containing vesicles will provide a unique anucleate cellular system for studying the replication of a complex type of enveloped dsDNA virus *in vitro*.

ASTROVIRUSES (*ASTROVIRIDAE*)

Stephan S. Monroe, Centers for Disease Control and Prevention, Atlanta, Georgia, USA

History

Astroviruses were first described in 1975 by two independent research groups using electron microscopy (EM) to study viruses in stool samples from young children with gastroenteritis. The name astrovirus was coined by Madeley and Cosgrove and is derived from the characteristic five-or six-pointed star seen on the surface of some, but not all, particles (**Fig. 1**). Over the succeeding years, viruses with similar appearance were detected by EM in stool samples from a variety of young animals with gastroenteritis, including sheep, cows, deer, pigs, cats, mice, dogs, turkeys and ducks. A breakthrough in astrovirus research was the report by Lee and Kurtz in 1981 of the isolation of human astrovirus strains in primary human embryonic kidney (HEK) cells. Inclusion of trypsin in the growth medium was a strict requirement for both primary isolation and the subsequent adaptation of isolates to growth in LLCMK2 cells, a rhesus monkey kidney continuous cell line. The availability of a cell culture system allowed for the identification of virus serotypes, the development of immune reagents for virus detection and characterization, and ultimately, the molecular cloning and sequence analysis of the astrovirus genome.

Taxonomy and Classification

Astroviruses were recently classified by the International Committee on Taxonomy of Viruses in a distinct family of plus-sense, single-stranded (ss), RNA viruses, the *Astroviridae*. The family consists of a single genus, *Astrovirus,* with human astrovirus type 1 as the type strain. Virus species are identified by the host species of origin (e.g. human astrovirus [HAstV], bovine astrovirus [BAstV]), with serotypes identified by number (e.g. HAstV-1).

Properties of the Virion

As viewed by EM, astrovirus virions are non-enveloped particles, with icosahedral symmetry, approximately 28 nm in diameter, with a smooth outer edge and the characteristic star apparent on the surface of some particles. Particles with a rough edge containing spike projections are often seen in preparations of virus propagated in cell culture. The particles sediment with $s_{20,w}$ of approximately 160, and their buoyant density in CsCl is 1.36–1.39 g cm^{-3}. Virions are composed of a single copy of the genome RNA and multiple (presumably 60) copies of two to four capsid proteins. Different numbers and sizes of the capsid proteins have been reported, depending on the host species of origin of the virus and the conditions of virus purification and analysis. For instance, two capsid proteins with M_r 33 000 were reported for ovine astrovirus (OAstV), whereas two to four capsid proteins have been reported for human astrovirus. The consensus composition of human astrovirus strains is three capsid proteins with M_r of 26 000–36 000, which have been referred to as VP32, VP29 and VP26 (for HAstV-2), or, more generally, as P1, P2 and P3. The apparent size of the smallest protein, P3, varies as a function of virus serotype.

Properties of the Genome

The astrovirus genome is a single molecule of infectious, positive-sense, ssRNA, 6.8–7.9 kb in size. There is a poly(A) tract at the 3′ end, but the structure of the 5′ end has not been determined. Analysis of the complete sequence of two human astrovirus strains, HAstV-1 and HAstV-2, has shown that the genome contains three major open reading frames, ORF 1a, ORF 1b, and ORF 2 (**Fig. 2**). ORFs 1a and 1b are presumed to encode the proteins involved in viral replication, including a chymotrypsin-like protease (pro) and an RNA-dependent RNA polymerase (pol) identified by comparative sequence analysis. Between these two ORFs is a ribosomal

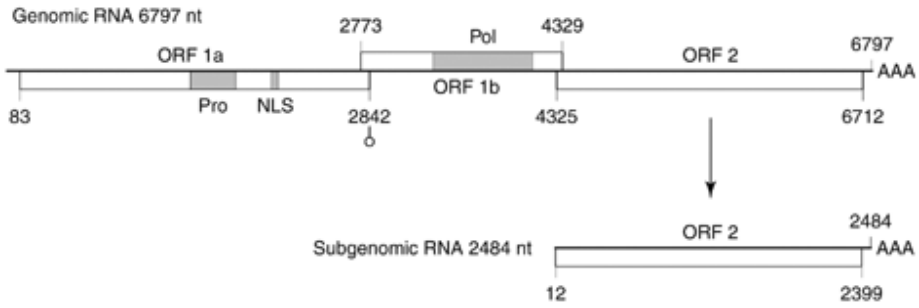

Figure 2 Genome organization of human astrovirus type 2. The arrangement of the three major open reading frames (ORFs) and locations of the motifs for the protease (Pro), polymerase (Pol) and ribosomal frameshifting site (δ) are indicated. The region corresponding to the subgenomic RNA detected in the cytoplasm of infected cells is also indicated. NLS, nuclear localization signal.

frameshifting signal that includes a heptanucleotide 'slippery sequence' and a predicted stem–loop structure. ORF 2, which overlaps ORF 1b by five nucleotides, encodes the capsid protein precursor. A conserved stem–loop structure is predicted at the 3′ end of the genomic RNA of human, ovine, porcine and turkey astroviruses.

Physical Properties

Astrovirus virions do not contain a lipid envelope and are resistant to treatment with organic solvents, such as chloroform, and to nonionic, anionic and zwitterionic detergents. The virus particles are relatively stable, being resistant to treatment at pH 3 and to incubation at 50°C for one hour.

Replication

The receptor by which astroviruses attach to and the mechanism by which they enter susceptible cells have not been determined. Purified astrovirus RNA is infectious; thus immediately following entry and uncoating of the virus particles, the first step in the virus life cycle is translation of the incoming genome RNA to generate the proteins involved in virus replication. For HAstV-2, ORF 1a encodes a 920-amino acid polyprotein with a predicted M_r of 103 000. The proteins encoded in ORF 1b are expressed as an ORF 1a–1b fusion protein (predicted M_r 161 000) generated via a −1 ribosomal frameshift, which occurs with an efficiency of approximately 25%. The heptanucleotide slippery sequence and the adjacent stem–loop structure are absolutely required for efficient frameshifting, but downstream sequences are dispensable, indicating that a pseudoknot structure is not involved. A chymotrypsin-like protease domain has been identified in ORF 1a, but the precise pattern and sequence of the proteolytic cleavages of the primary translation products of ORFs 1a and 1b have not yet been determined.

Approximately 12 h postinfection, two actinomycin D-resistant, virus-specific RNA species appear in the cytoplasm of infected cells. The larger RNA, ~7 kb, is progeny genome RNA, whereas the smaller species, ~2.7 kb, is a subgenomic mRNA encoding ORF 2, as indicated in **Fig. 2**. The subgenomic RNA is colinear with the 3′ end of the genome, and both species are polyadenylated. Concomitant with the appearance of the subgenomic RNA is the production of the viral structural protein precursor (M_r 88 000). This protein is processed to the mature capsid proteins through a cascade of proteolytic steps, for which the enzymes involved are not known. The amino termini of HAstV-2 proteins VP29 (P2) and VP26 (P3) have been mapped by microsequencing to residues 362 and 395, respectively, both adjacent to arginine residues, consistent with cleavage by trypsin.

Although most of the astrovirus replication takes place in the cytoplasm, at least one step in the replication cycle appears to involve the nucleus. There is a canonical nuclear localization signal in ORF 1a, and viral proteins have been detected in the nucleus of infected cells by using immunofluorescence. Assembly of viral particles occurs in the cytoplasm of the infected cell with the formation of paracrystalline arrays of particles seen late in infection by using thin-section EM. Release of progeny infectious virus is dependent on the presence of trypsin in the growth medium.

Geographic and Seasonal Distribution

Human astroviruses are distributed worldwide and have a distinct winter seasonality in temperate climates. Animal astroviruses are less well studied, but strains have been detected in all locations where serious efforts have been made to look for them.

Host Range and Virus Propagation

Astroviruses have been detected in a wide variety of mammals and some birds, with each host species supporting the replication of a unique virus species. The human astroviruses grow in a primate cell line, but direct infection of primates with human astrovirus strains has not been reported. In cases where it has been examined, serum from animals infected with a homologous virus does not react with heterologous virus from other species. The bovine and ovine astroviruses have been passaged in experimentally infected gnotobiotic animals, with symptomatic infection occurring only in the latter species. Human, bovine and porcine astroviruses have been adapted to growth in cell culture, in each case using a cell line derived from the host species and with the inclusion of trypsin in the growth medium. The human colon carcinoma cell line, Caco-2, is widely used for primary isolation and propagation of human astrovirus strains.

Genetics

The use of naturally occurring, or chemically induced, temperature-sensitive mutants, or other genetic approaches, has not been applied to the study of astrovirus gene expression. With the recent report of an infectious cDNA clone of HAstV-1, the potential exists for future studies to map gene functions by using site-directed mutagenesis.

Evolution

The genome organization of astroviruses and sequence comparisons of conserved protein motifs indicate that astroviruses are distinct from all other families of nonenveloped, plus-sense, ssRNA viruses. Astroviruses do, however, share several features with caliciviruses, including expression of the capsid protein(s) from a 3′-coterminal subgenomic RNA and sequence similarity in the putative chymotrypsin-like protease. In contrast, expression of the nonstructural proteins via ribosomal frameshifting, the absence of an RNA helicase motif, and similarity in the RNA-dependent RNA polymerase domain, are more typical of the plant luteoviruses.

One unusual feature of astroviruses is the marked difference among human serotypes in the degree of sequence similarity as a function of the coding region analyzed. Within a portion of ORF 1a, the pairwise nucleotide sequence distances between serotypes 1 through 5 range from 4.1% to 7.4%. In contrast, the corresponding range of values for a portion of ORF 2 is 19.3–22.7%. Moreover, when the recently identified serotypes, 6 and 7, are included in the analysis, they

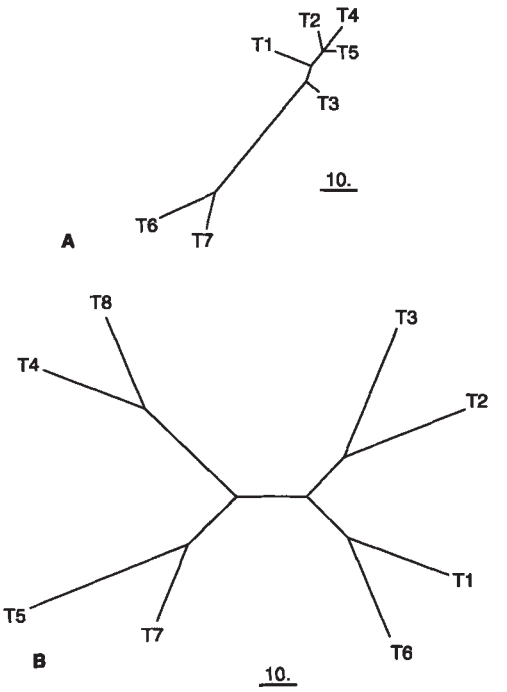

Figure 3 Phylogenetic analysis of human astrovirus nucleotide sequences. Unrooted trees were generated by maximum parsimony analysis with the PAUP program, using a 244-nucleotide region of ORF 1a (**A**) or a 348-nucleotide region of ORF 2 (**B**). Scale bars indicate number of nucleotide changes.

constitute a distinct clade in ORF 1a, as indicated in the phlyogram in **Fig. 3A**. This contrasts with the nearly equidistant arrangement of the sequences analyzed in ORF 2, as indicated in **Fig. 3B**. One possible explanation for this pattern is the occurrence of an RNA recombination event leading to discontinuous evolution in serotypes 6 and 7.

Serologic Relationships and Variability

Human astrovirus serotypes are defined on the basis of greater than 20-fold differences in two-way cross-reactivity as measured by immunofluorescence, immune EM, or neutralization using reference antisera raised in rabbits. Seven serotypes (HAstV-1 to HAstV-7) are currently recognized, with a possible eighth serotype not yet fully characterized. More recently, typing of human astroviruses has been done by using an enzyme immunoassay (EIA) or by phylogenetic analysis of nucleotide sequence information. Two serotypes of bovine astrovirus have been defined by crossneutralization, with a possible third serotype not yet fully characterized.

Several neutralizing monoclonal antibodies have been described, and the target epitopes have been mapped to proteins VP29 or VP26, or both. In

addition to type-specific epitopes, human astrovirus strains share one or more common epitopes recognized by group-reactive monoclonal antibodies.

Epidemiology

Our picture of the epidemiology of human astrovirus infection has changed as the methods to detect the virus have become increasingly more sensitive. On the basis of early studies, which relied on direct detection of virus particles in stool specimens by EM, astroviruses were thought to account for approximately 2% of the cases of gastroenteritis in young children. The development of specific EIAs for detection of astroviruses allowed for larger studies to be conducted using a simpler and more sensitive detection method. On the basis of several prospective studies, astroviruses are associated with 6–9% of the cases of gastroenteritis in children under 5 years of age, with most cases detected in children between 9 and 18 months of age. Most children will have an episode of astrovirus gastroenteritis by age 5 years.

The more recent use of reverse transcriptase–polymerase chain reaction (RT-PCR) assays for detection of astroviruses in stool samples from an outbreak in a daycare facility indicated that this assay is more sensitive than EIA for detecting prolonged shedding in symptomatic children and that asymptomatic infection was common in the older children. In addition to young children, the elderly are at increased risk for astrovirus infection, with outbreaks of illness occurring in nursing homes. Astrovirus infection was significantly associated with diarrhea in a cohort of persons infected with human immunodeficiency virus (HIV), indicating that immunocompromised persons are also at increased risk.

Serotype 1 is the predominant type of HAstV, accounting for approximately half of all infections. Serotypes 2–5 are associated with approximately 10% of the infections each, whereas types 6 and 7 are rarely identified. Additional insights into the frequency of astrovirus infection have been obtained by seroprevalence studies which have demonstrated that acquisition of antibodies commonly occurs in the first 5 years of life, and that 90–100% of adults have antibodies to one or more astrovirus serotypes.

Transmission and Tissue Tropism

Human astroviruses are most commonly spread by fecal–oral transmission, although increased levels of community sanitation appear not to have an impact, since the rates of infection in young children are similar for developing and developed countries. Person-to-person spread is the most likely mode of transmission in outbreaks in daycare centers and nursing homes. Infection may also occur via contaminated water or foods, particularly shellfish. Most human and animal astroviruses are associated with symptoms of gastroenteritis, and replication has been documented in the gastrointestinal tract. A noteworthy exception is duck hepatitis virus which has been detected by EM in the livers of animals with histologic evidence of hepatitis.

Pathogenicity

The pathogenic potential of astroviruses ranges from asymptomatic infection of calves with bovine astrovirus to severe hepatitis, with as high as 50% mortality in ducklings with duck hepatitis virus. The mortality rate of human astrovirus infection is extremely low, but deaths have been reported in young children and the elderly.

Clinical Features and Infection

Astrovirus infection of young children results in a mild, self-limiting gastroenteritis with an incubation period of 2–4 days and a duration of 2–3 days. Typical symptoms include watery diarrhea, vomiting, fever and abdominal pain. Experimental infection of adult volunteers with human astroviruses results in low levels of symptomatic infection, although seroconversions can be measured in a majority of the patients. This observation suggests that infection early in life may protect against symptomatic infection later in life.

Pathology and Histopathology

Little is know about the pathology of astrovirus infection in humans. A single report describes astrovirus particles in intestinal epithelial cells in two children who were shedding virus in their stools. Histologic changes have been well documented during experimental infection of gnotobiotic lambs with OAstV. Astrovirus particles were seen in columnar epithelial cells on the apical two-thirds of villi beginning 14 h postinfection (PI). By 23–38 h PI, there was sloughing of villus epithelial cells with release of virus particles, and by 120 h PI the villi had returned to normal. In contrast, experimental challenge of gnotobiotic calves with BAstV resulted in asymptomatic infection. Virus particles were detected in M cells overlying Peyer's patches in the small bowel.

Immune Response

Primary infection with human astroviruses results in the appearance of type-specific serum antibodies

detectable by immune EM, EIA or neutralization. The seroprevalence rates among 242 persons in the Netherlands as measured by neutralizing antibody to HAstV types 1 to 7 were 91, 31, 69, 56, 36, 16 and 10%, respectively. Antibody levels declined in the elderly, a finding that may account for the increased risk for symptomatic infection in this group.

Prevention and Control

Improvements in community sanitation are not likely to reduce the incidence of astrovirus infection since similar rates of disease have been reported in developing and developed countries. Strict adherence to standard enteric infection control practices may help to limit the spread of infection during outbreaks in daycare centers or nursing homes. Because primary infection with astrovirus appears to confer long-term immunity, as evidenced by the low rate of symptomatic infection in adults, there is good potential for the development of a protective vaccine.

Future

Much remains to be learned about the basic molecular virology of astroviruses. The number, size and genome location of the mature capsid proteins need to be precisely defined, as do the recognition sites and enzymes responsible for proteolytic processing. The putative replicative proteins encoded in ORFs 1a and 1b should be fully characterized. We have a relatively clear picture of the epidemiology of astrovirus infection, but the burden of disease in hospitalized children should be more carefully assessed as a step toward consideration of the development of a protective vaccine.

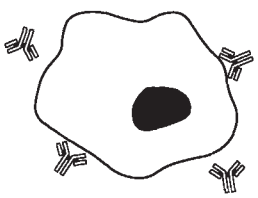
AUTOIMMUNITY



Robert S Fujinami, University of Utah, Salt Lake City, Utah, USA

Introduction

Several hypotheses have been proposed to explain the development of autoimmunity and subsequent disease in humans and animals. These include a viral etiology for the initiation of autoimmune disease. Potential mechanisms include: polyclonal activation of autoreactive T and B cells by virus infection; expression of altered self or neoantigens presented during infection; alterations in anti-idiotypic responses to self peptides generated by infection; infection of lymphoid and/or antigen-presenting cells (APCs) causing modulation of the ensuing immune antiviral response; and cross-reacting immune responses generated by the occurrence of common determinants between virus and self proteins, known as molecular mimicry.

Potential Mechanisms

Viruses can cause polyclonal activation of autoreactive T and B cells. This results in the production of activated self-reactive T cells and the production of autoantibodies. An example of this is the activation of self-reactive T cells by superantigens encoded by certain retroviruses. T cell activation normally takes place when the T cell receptor encounters a peptide in association with either major histocompatibility complex (MHC) class I or class II molecules on APCs (**Fig. 1**). In addition, the APCs provide auxiliary costimulatory signals that help drive the T cells to respond. The T cell receptor (TCR) provides the specificity in this interaction. Superantigens have the ability to bind to families of MHC class II molecules

detectable by immune EM, EIA or neutralization. The seroprevalence rates among 242 persons in the Netherlands as measured by neutralizing antibody to HAstV types 1 to 7 were 91, 31, 69, 56, 36, 16 and 10%, respectively. Antibody levels declined in the elderly, a finding that may account for the increased risk for symptomatic infection in this group.

Prevention and Control

Improvements in community sanitation are not likely to reduce the incidence of astrovirus infection since similar rates of disease have been reported in developing and developed countries. Strict adherence to standard enteric infection control practices may help to limit the spread of infection during outbreaks in daycare centers or nursing homes. Because primary infection with astrovirus appears to confer long-term immunity, as evidenced by the low rate of symptomatic infection in adults, there is good potential for the development of a protective vaccine.

Future

Much remains to be learned about the basic molecular virology of astroviruses. The number, size and genome location of the mature capsid proteins need to be precisely defined, as do the recognition sites and enzymes responsible for proteolytic processing. The putative replicative proteins encoded in ORFs 1a and 1b should be fully characterized. We have a relatively clear picture of the epidemiology of astrovirus infection, but the burden of disease in hospitalized children should be more carefully assessed as a step toward consideration of the development of a protective vaccine.

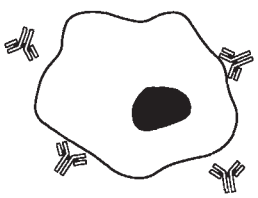
AUTOIMMUNITY



Robert S Fujinami, University of Utah, Salt Lake City, Utah, USA

Introduction

Several hypotheses have been proposed to explain the development of autoimmunity and subsequent disease in humans and animals. These include a viral etiology for the initiation of autoimmune disease. Potential mechanisms include: polyclonal activation of autoreactive T and B cells by virus infection; expression of altered self or neoantigens presented during infection; alterations in anti-idiotypic responses to self peptides generated by infection; infection of lymphoid and/or antigen-presenting cells (APCs) causing modulation of the ensuing immune antiviral response; and cross-reacting immune responses generated by the occurrence of common determinants between virus and self proteins, known as molecular mimicry.

Potential Mechanisms

Viruses can cause polyclonal activation of autoreactive T and B cells. This results in the production of activated self-reactive T cells and the production of autoantibodies. An example of this is the activation of self-reactive T cells by superantigens encoded by certain retroviruses. T cell activation normally takes place when the T cell receptor encounters a peptide in association with either major histocompatibility complex (MHC) class I or class II molecules on APCs (**Fig. 1**). In addition, the APCs provide auxiliary costimulatory signals that help drive the T cells to respond. The T cell receptor (TCR) provides the specificity in this interaction. Superantigens have the ability to bind to families of MHC class II molecules

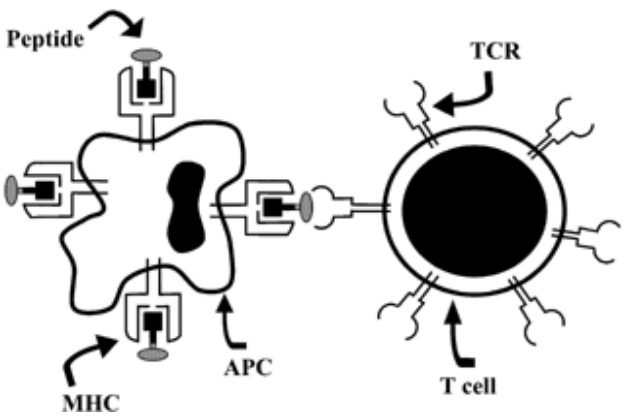


Figure 1 T cell–APC interaction. T cells recognize antigen, either foreign or self, on APCs. Recognition occurs by engagement of the TCR present on the surface of the T cells with the MHC molecule containing the self or foreign peptide on the surface APC. This interaction can lead to activation, anergy or unresponsiveness or deletion of the T cell, depending on the context in which the interaction takes place.

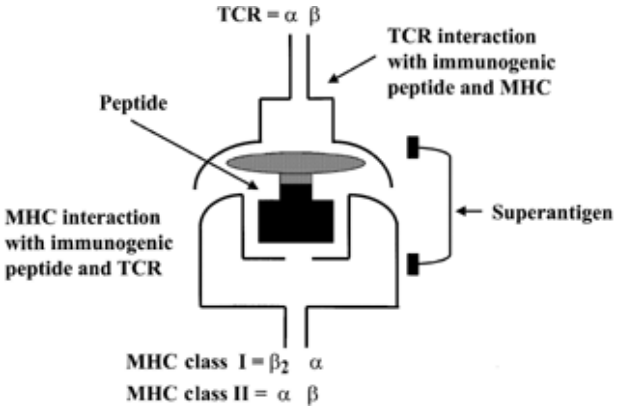

Figure 2 TCR–peptide–MHC interaction. TCRs are present on the surface of T cells and are heterodimers comprising an α and a β chain. The TCR interacts with the MHC class I or class II molecule on the surface of APCs or target cells. CD8+ T cells recognize peptide with class I molecules and CD4+ T cells recognize peptide with class II molecules. MHC class I molecules are heterodimers comprising β_2-microglobulin (β_2) and an α chain. Similarly, MHC class II molecules are heterodimers comprising an α and β chain. Superantigens can activate CD4+ T cells by linking the class II molecule and the TCR. This type of stimulation is thought to be involved in some forms of autoimmunity. The peptides can be either self or foreign peptides that are recognized.

and engage T cells recognizing the particular MHC class II families (**Fig. 2**). Thus, populations of T cells, some of which recognize self peptides, are activated and potentially could initiate autoimmunity. For B cells (production of autoantibodies), infection by Epstein–Barr virus (EBV) leads to the production of autoantibodies. B cells differentiate into plasma cells and secrete antibody of a single specificity. This can be antiviral or of antiself specificity. Normally, B cells require interleukin (IL)-2, IL-4, IL-5, IL-6 and interferon γ (IFN-γ) secreted by T cells for growth and differentiation into plasma cells. Infection of B cells with EBV drives these B cells to produce antibodies. Should the B cells (antibody) be specific for self protein, EBV-infected cells would produce antibodies reactive with self.

Neoantigens

Virus infection can cause the induction of neoantigens or self proteins not normally present in or on cells. For example, infection of cells with paramyxoviruses can lead to the expression of heat shock proteins not normally present in the uninfected cell. Self antigens expressed in cells can be presented in the context of MHC class I or class II pathways. Of potential concern is the scenario where peptides from heat shock proteins are presented to T cells in the context of class II molecules. If this were to occur in the environment of an inflammatory response where there are proinflammatory cytokines, the heat shock protein-reactive T cells could become activated and initiate a self-reactive immune response. In animal models, injection of heat shock protein in adjuvant can result in arthritis. The autoimmune disease can be transferred to naive animals with activated heat shock protein-reactive T cells taken from immunized animals. Therefore, a possible mechanism of autoimmunity is one where infection with the virus induces neoself antigens recognized by T cells which could cause disease. Even though the virus is cleared, an antiself response is generated owing to the continued presence of the self antigen. This is consistent with many chronic autoimmune diseases.

Anti-idiotypic response

Another mechanism to initiate autoimmunity by virus infection is the generation of anti-idiotypic responses. Viruses attach to cells due to specific regions or sites on the virus. This can be specific viral glycoproteins such as the influenza virus hemagglutinin or conformational sites made up of several viral capsid proteins such as the canyon for rhinoviruses. These virus proteins or sites bind to distinct receptor proteins on susceptible cells. Infection by a virus could generate antibodies, which react with those specific regions of the virus that bind to the host cell receptor. Hypothetically, these antibodies could induce the production of other idiotypic antibodies, which would bind to the combining site of the

original antibody and also to the receptor protein on the cell. Such anti-idiotypic antibodies that bind to the cells could initiate cell lysis or death due to the activation of the complement cascade. Similarly, lymphocytes are also thought to be regulated by idiotypic networks.

Infection of lymphoid cells

A third mechanism for virus-induced autoimmunity is infection of lymphoid cells and/or APCs. Different types of lymphoid cells can regulate the immune response. In addition, different viral proteins or epitopes comprising these proteins can help skew the immune response. Responses to self have to be more stringently regulated than antimicrobial responses, otherwise autoimmunity would be more pronounced. Negative selection eliminates many autoreactive cells (both T and B cells), but not all self-reactive cells are eliminated. Infection of lymphocytes can alter the cytokines produced by these cells. Different cytokines will favor a Th1 (delayed-type hypersensitivity, DTH) versus a Th2 response. CD4+ Th1 T cells (class II restricted) are the favored T cell type for autoimmune disease. Autoimmune disease can be transferred by Th1 autoreactive T cells in a variety of animal models of human autoimmune disease. Release of proinflammatory cytokines, for example IFN-γ, can push an immune response toward a Th1 type. Early clinical trials treating patients with multiple sclerosis (a proposed human autoimmune disease) with IFN-γ have led to exacerbation of clinical symptoms, suggesting enhancement of Th1 T cells increasing disease. Release of cytokines in areas of inflammation can also lead to upregulation of MHC class I and II antigens. These molecules can present additional self peptides to autoreactive T cells and could further diversify an autoimmune response through determinant spreading. This is the spreading of an immune response to other determinants or epitopes, not the first inciting epitope.

Molecular mimicry

Another potential mechanism by which viruses may incite autoimmune reactions is molecular mimicry. Viruses that have common determinants with self-antigens can induce crossreacting immune responses. These determinants (epitopes) can be recognized by B and T cells. Several predictions can be made for this type of mimicry/crossreaction. First, T and B cells reactive to the crossreacting determinant must not be eliminated by negative selection. Second, although crossreacting determinants are relatively common, the crossreacting epitope must be a disease-inducing determinant. For example, having an immune response to a nondisease-inducing epitope would result in the expansion of autoreactive T cells, but no disease or tissue injury would occur. Here, autoreactive T cells (Th2 cells) that downregulate the harmful autoaggressive T cells (Th1) could be generated. Third, it is probable that viruses, being facultative intracellular parasites, have acquired genes from the host cell encoding proteins necessary for replication and also to subvert the immune response, allowing the virus to replicate efficiently in the cell and persist in the host. Lastly, it is not unreasonable that viruses which look like self (mimicry) have a selective advantage over those that do not.

Models of Autoimmunity

Diabetes, particularly type I (insulin-dependent diabetes mellitus, IDDM) has been associated with viral infections. A potential mechanism described above is molecular mimicry. The principle here is that a virus encoding a crossreacting epitope is also present in the pancreas of the genetically susceptible individual. Infection with a virus having the crossreacting protein and/or epitope could initiate a crossreacting immune response. Here, the cell in the pancreas that contains the peptide in association with MHC molecules would be recognized by T cells and attacked. Two laboratories, those of Oldstone and Zinkernagle, have constructed transgenic mice to test this hypothesis. Lymphocytic choriomeningitis virus (LCMV) glycoprotein (GP) or nucleocapsid protein (NP) genes controlled by the insulin promoter were inserted into the germ line. Such transgenic mice expressed the viral GP or NP protein in the islet cells of the pancreas. These mice therefore consider the viral protein as self. Infection of the transgenic mice with LCMV led to the generation of NP- or GP-specific cytotoxic T lymphocytes (CTLs). These T cells migrate to the pancreas and kill the islet cells, leading to hyperglycemia and hypoinsulinemia. Two types of IDDM were observed in the Oldstone model: a fast onset and slow onset of IDDM after infection with LCMV. In the first instance, LCMV-infected mice developed IDDM within 1–2 weeks after infection. The slow onset progressed 1–2 months after infection. In both instances diabetes was dependent on the effector cell being a CD8+ T cell. The difference between the fast and slow onset is the number and affinity of the CD8+ T cells specific for the viral/self protein. In the fast-onset diabetes, the viral protein is not expressed in the thymus (where negative selection occurs) but only in the pancreas. The LCMV-specific T cells were not selected against in the thymus and frequency of CD8+ T cells was higher and affinity higher to peptide–MHC. In the slow-onset diabetes model,

transgenic mice express the viral protein in the thymus as well as the pancreas. Therefore, the high-affinity anti-LCMV-specific T cells are selected against and eliminated in the thymus. The numbers and affinity of LCMV-specific CD8+ T cells that enter the periphery are reduced. For disease to occur, CD4+ T cells are required to provide help for sufficient CD8+ T cell expansion. Depletion studies show that without the CD4+ T cell population, no expansion occurs and animals remain disease free. The CD4+ T cells are not cytotoxic for virus-infected cells. Therefore, a critical threshold is needed for disease to occur. CD8+ T cells can transfer disease to uninfected transgenic mice. Thus, this model reflects systems where class I effector T cells are important for elaboration of disease, and CD4+ T cells can regulate the CTL effector response. Myositis is an example of MHC class I restricted T cells playing a role in autoimmune disease.

Another model of viruses modulating autoimmune disease is an animal model for multiple sclerosis. This model is called experimental autoimmune encephalomyelitis (EAE). Here animals (mice) are injected with myelin proteins or disease-inducing peptides from these proteins in adjuvant. Mice develop clinical signs of ataxia and incontinence and inflammatory central nervous system (CNS) demyelinating disease. The mice have many of the clinical and pathological features of multiple sclerosis. CD4+ T cells obtained from immunized mice can transfer disease to naive mice.

The following experiments were initiated to determine whether virus encoding self proteins could modulate the outcome of autoimmune disease. A recombinant vaccinia virus was constructed to encode a disease-inducing region of myelin basic protein, MBP. Infection of PL/J mice with the recombinant virus encoding a portion of MBP did not induce EAE by itself. Antibody to MBP could be detected in the vaccinated mice. In contrast, PL/J mice injected with the recombinant virus encoding a portion of MBP and subsequently challenged with MBP or an encephalitogenic peptide (disease-inducing epitope AC 1–11) were protected from the development of EAE. PL/J mice vaccinated with a control recombinant vaccinia virus encoding β-galactosidase developed EAE. The protection is specific for MBP, as it does not extend to mice challenged with whole spinal cord. The major self-CNS antigen in whole spinal cord is proteolipid protein. The region of MBP encoded by the recombinant vaccinia virus encompasses the PL/J epitope and not the SJL/J strain. The disease-inducing region is specific for different mouse strains. For example, the first 9–11 amino acids (AC 1–11) of MBP represent the encephalitogenic peptide/epitope for the PL/J strain of mice. A different region (89–108 of MBP) is encephalitogenic for the SJL/J strain of mouse.

To further determine the specificity of the protection, SJL/J mice were vaccinated with the recombinant virus encoding the PL/J epitope (AC 1–11) and 5 weeks later were injected with the SJL/J encephalitogenic peptide (89–108). The SJL/J mice were not protected and developed EAE. Therefore, the protection was strain specific. These cells have the Th1 phenotype and this cell type is responsible for DTH reactions. In mice vaccinated with the recombinant vaccinia virus encoding AC 1–11 of MBP and not a control vaccinia virus, a decrease in DTH to MBP was observed. Thus, vaccination decreased the numbers of or anergized the MBP-specific Th1 T cells. As with many of these models of autoimmunity, disease can be transferred with self-reactive T cells. In the case of EAE, the disease can be transferred by the Th1 CD4+ MBP-specific T cells. Vaccinated mice infected with the recombinant virus encoding a portion of MBP and challenged with the encephalitogenic peptide from MBP do not develop EAE. T cells from these mice are unable to transfer EAE to other mice, whereas T cells from control virus vaccinated mice. T cells from mice injected with AC 1–11 of MBP (the encephalitogenic peptide) can transfer EAE to naive mice. These T cells were also able to transfer EAE to vaccinated mice, indicating that the block is at the activation stage. Once the effector cells are generated, vaccination cannot inhibit disease. In this system, depletion of CD8+ T cells does not alter the protection.

In a modification of the virus model for CD4+-mediated T cell disease, a recombinant vaccinia virus was constructed to encode the entire proteolipid protein (PLP) sequence. This is the major myelin protein found in the CNS. PLP or peptides derived from PLP can induce EAE in mice when injected with adjuvant. Infection of mice with the recombinant virus does not lead to autoimmune disease. However, it does prime mice for autoimmune disease. Mice vaccinated with this virus produce self-reactive antibody to three encephalitogenic epitopes (disease inducing) contained in PLP. When vaccinated mice are later challenged with encephalitogenic peptides from PLP, mice develop an enhanced acute disease which occurs much sooner and is more severe than mice vaccinated with a control virus or no virus. The extent of demyelination and inflammation in the CNS was enhanced in the mice vaccinated with the virus encoding the self protein. Interestingly, while mice vaccinated with the control virus or no virus went on to develop a relapsing and remitting clinical course of disease, mice vaccinated with the recombinant PLP virus had a much reduced clinical course with very few relapses.

In summary, virus infections can have negative or positive influences on the development of autoimmune disease.

Future Perspectives

Some of the initial studies on molecular mimicry and virus-induced autoimmunity indicated that viruses share common sequences with host components. It has been demonstrated that some viruses have acquired host genes and modified these to subvert the immune system. Herpesviruses encode MHC-like molecules, Fc receptors, IL-10-like factor and complement regulatory proteins, and poxviruses have incorporated into their genome, IL-1 receptor, tumor necrosis factor (TNF) receptor, IFN-γ receptors and complement control proteins. In addition, viral proteins need to perform specific functions in the cell to replicate its genome and assemble new virions. These functions use the existing cellular machinery and therefore mimic many of the host cells, which also perform similar tasks. The key question is still: how are these infections which are associated with autoimmune disease able to initiate the pathway leading to self-reactive immune responses?

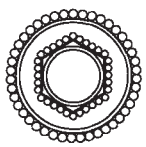
AVIAN TYPE C RETROVIRUSES (*RETROVIRIDAE*)



John M Coffin, Department of Molecular Biology and Microbiology, Tufts University, Boston, Massachusetts, USA

History

Avian leukosis virus (ALV) and related viruses are among the oldest retroviruses known. The first description (of a leukemia virus) was in 1907, but the continuing history of these viruses starts with the isolation of Rous sarcoma virus (RSV) by Peyton Rous in 1911. Numerous isolates of ALV, as well as transforming viruses which cause sarcomas as well as a variety of hematopoietic neoplasms, were reported in the decades that followed, but progress in understanding their nature was very slow until the development of cell culture assays in the late 1950s and the development of *in vitro* genetic and cell biological approaches to study replication and transformation. The discovery of reverse transcriptase in 1970 and of the origin and mechanism of action of viral oncogenes in the decade following led to an explosion of research activity, with results justifying the intensive study.

Taxonomy and Classification

The avian leukosis viruses comprise a single genus *Alpharetrovirus*, of the family *Retroviridae*. Although they share structural and biological characteristics with the mammalian C-type viruses (such as murine leukemia virus) these two groups are not closely related. All ALVs are closely related to one another sharing considerable sequence and antigenic identity. Isolates are differentiated by subgroup (i.e. receptor utilization) and the presence or absence of oncogenes.

In summary, virus infections can have negative or positive influences on the development of autoimmune disease.

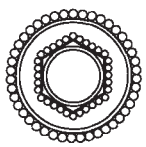
AVIAN TYPE C RETROVIRUSES (*RETROVIRIDAE*)



John M Coffin, Department of Molecular Biology and Microbiology, Tufts University, Boston, Massachusetts, USA

History

Avian leukosis virus (ALV) and related viruses are among the oldest retroviruses known. The first description (of a leukemia virus) was in 1907, but the continuing history of these viruses starts with the isolation of Rous sarcoma virus (RSV) by Peyton Rous in 1911. Numerous isolates of ALV, as well as transforming viruses which cause sarcomas as well as a variety of hematopoietic neoplasms, were reported in the decades that followed, but progress in understanding their nature was very slow until the development of cell culture assays in the late 1950s and the development of *in vitro* genetic and cell biological approaches to study replication and transformation. The discovery of reverse transcriptase in 1970 and of the origin and mechanism of action of viral oncogenes in the decade following led to an explosion of research activity, with results justifying the intensive study.

Taxonomy and Classification

The avian leukosis viruses comprise a single genus *Alpharetrovirus*, of the family *Retroviridae*. Although they share structural and biological characteristics with the mammalian C-type viruses (such as murine leukemia virus) these two groups are not closely related. All ALVs are closely related to one another sharing considerable sequence and antigenic identity. Isolates are differentiated by subgroup (i.e. receptor utilization) and the presence or absence of oncogenes.

Distribution, Host Range and Propagation

ALVs are endemic in flocks of domestic chickens (*Gallus gallus*) worldwide, and natural infections seem limited to this species, within which they are of some economic importance. Related endogenous viruses are found in ring-necked and golden pheasant (but not other related birds, such as turkeys), but exogenous viruses have not been isolated from other species. ALV will replicate efficiently in species closely related to the chicken such as quail, turkeys and pheasants, but less so in more distant species such as ducks. RSV of some subgroups can transform mammalian cells and induce tumors in mammals, but with greatly reduced efficiency, and virus replication in mammalian cells cannot be reproducibly observed. The restriction of the virus to avian species is due both to a lack of suitable receptors for most subgroups as well as a block to expression of virus-encoded proteins. The rare transformants that arise in RSV-infected mammalian cells often display rearrangements in proviral DNA that relieve this block.

A variety of cell types from gallinaceous birds (including chickens, turkeys and quail) can be used to propagate ALVs and their relatives. Primary and secondary fibroblast cultures are most commonly applied to this purpose, since permanent cell lines with the exception of those derived from some quail tumors (e.g. QT6) have only recently become available for most avian species. The cell lines can be productively infected and are useful for some purposes. To avoid problems associated with frequent recombination, it is advisable to use cells that do not contain related endogenous proviruses, such as cells from species other than chickens or from chickens bred to contain no such proviruses.

Properties of the Virion

Like all retroviruses, avian leukosis viruses are transmitted as enveloped virions of about 100 nm diameter derived by budding from the host cell membrane. Within the retrovirus family, they are defined as having a C-type morphology. Virions are modified by the inclusion of peplomers consisting of trimers of the two *env* encoded proteins, SU (surface) and TM (transmembrane). The internal core of the virion is of uncertain symmetry in mature virions but appears in electron micrographs as a centrally located, roughly spherical structure about 30 nm diameter. Immature virions seen during or shortly after budding have a more open, spherical core structure, substantially larger in diameter than the processed one. The core comprises about 2500 copies each of the four *gag*-encoded proteins (as well as protease) and about 100 copies each of reverse transcriptase and integrase.

Properties of the Genome

The avian leukosis virus genome consists of a homodimer of plus sense single-stranded (ss) RNA about 7500 bases in length. Transforming viruses, in which an oncogene has been inserted, have genomes varying in length from about 3.2 kb (for UR2 virus) to about 9.3 kb (for nondefective Rous sarcoma virus). In most of these viruses, the oncogene has replaced some of the normal genome, leading to genetically defective virus, which requires co-infection with helper ALV for replication. The genome is modified in ways resembling cellular mRNAs, reflecting its synthesis and processing by cell machinery. It contains a 5′ m^7GpppGm capping group and a 3′ poly(A) sequence, as well as some internal m^6A residues. In *in vitro* translation systems, it is capable of serving as mRNA for the *gag-pro* and *gag-pro-pol* gene products. As with all retroviruses, the order of genes is 5′-*gag-pro-pol-env*-3′.

Important noncoding regions found near the end of the genome are necessary to provide signals for virus replication. These include an 18–21 base sequence (R) repeated at each end as well as unique sequences U3 (ca 250 bases) near the 3′ end and U5 (ca 80 bases) near the 5′ end which are duplicated into the long terminal repeat (LTR) during reverse transcription. Adjacent to these are the sites for initiation of reverse transcription: the primer binding (PB) region consisting of 18 bases complementary to the 3′ end of $tRNA^{trp}$ next to U5, and a polypurine (PP) sequence next to U3. Between PB and the beginning of *gag* is an approximately 300-base leader region which contains signals important for the packaging of the genome into virions.

Properties of the Proteins

The virion contains nine proteins, the products of four coding regions. The Gag proteins constitute the major structural components and are sufficient to form recognizable virions if expressed alone. The Gag-Pro precursor is processed during release of virus into four proteins: MA (matrix, about 19 kDa) which interacts with the cell membrane; p10, a 10 kDa protein of unknown function and location; CA (capsid, about 27 kDa) which forms the core shell structure; and NC (nucleocapsid, about 12 kDa) an RNA-binding protein necessary for specific encapsidation of genome RNA. The Gag-Pro precursor also contains the 15 kDa PR (protease) peptide necessary for processing all internal virion proteins. The Pol read-

ing frame is expressed as a fusion protein with Gag and Pro and processed to yield reverse transcriptase (RT, usually present as a heterodimer of 98 and 66 kDa reflecting a partial processing by PR), and integrase (IN, about 32 kDa) the two enzymatic activators necessary for synthesis and integration of the DNA provirus. The env protein encodes a precursor (Pr^{env}) which is processed as a membrane protein and cleaved by host cell proteases to yield the SU glycoprotein which has an apparent molecular weight of about 85 kDa, about half of which is due to the provision of ca. 14 N-linked carbohydrate side chains and the TM glycoprotein, which has an apparent molecular weight of about 37 kDa. The SU and TM products remain as a disulfide-bonded heterodimer with SU containing the activity necessary for receptor binding and TM anchoring the structure into the virus envelope.

Physical Properties

Virions of ALV have an equilibrium density in sucrose solutions of about 1.16 g ml^{-1} and a sedimentation coefficient of about 600S. They are quite labile and are readily inactivated by extremes of pH, as well as by heat or mild detergent treatments. They are somewhat radiation resistant, perhaps reflecting the recombinational repair capability provided by the dimeric genome.

Replication

Replication of ALV is like that of other retroviruses, and this group of viruses provided some of the important early models for studying the process. Entry of the virion follows interaction with a specific receptor on the cell surface. Genetically, at least eight subgroups (A–I) have been identified on the basis of distinct receptor recognition. The presence of receptors for specific subgroups is polymorphic among birds. Three unlinked genetic loci for ALV receptors have been genetically identified in chickens. These are called *Tv-a, Tv-b* and *Tv-c*. The dominance of susceptibility over resistance alleles at each of these loci implies that they encode the receptor directly. The *tv-b* locus has several alleles, controlling susceptibility to subgroups B, D and E. The Tv-a and Tv-b receptors have been cloned. They encode quite different membrane proteins with Tv-a resembling a portion of the receptor for low-density lipoprotein and Tv-b, the Fas receptor. Entry of the virion core into the cell is by fusion of viral and cellular members, perhaps following endocytosis.

Once within the cytoplasm of the infected cell, the process of reverse transcription within the poorly defined core structure copies the ssRNA genome into a molecule of double-stranded (ds) DNA. This process – which varies little from that of other retroviruses – includes a series of 'jumps' from one end of the template to the other. The product is a dsDNA molecule which differs from the genomic RNA by the presence at either end of the LTR. The LTR contains sequences necessary for DNA integration, and for synthesis and processing of viral RNA.

Integration of viral DNA into more or less random sites in the cell genome is accomplished by the IN protein which has entered the cell with the virion and remains with the DNA in an ill-defined structure. The process of integration leads to the insertion of the viral DNA into cell DNA in the same general organization as both genome and unintegrated DNA. Integrated ALV DNA is characterized by the loss of two bases from each end of the viral sequence and the duplication of six bases of cell DNA at the integration site.

Transcription of the provirus into genome and mRNA is mediated by cellular RNA polymerase II directed to the correct initiation site by promoter and enhancer sequences in the LTR. The strength of the enhancer elements is a major factor distinguishing pathogenic from nonpathogenic ALV isolates. Unlike some other retroviruses, there is no apparent role of virus-encoded proteins in regulating the transcription process. Processing of the viral transcripts includes addition of poly(A) following a canonical signal (AAUAAA) in the RNA derived from the 3′ LTR and splicing of the fraction of the transcripts destined to become mRNA for the *env* gene. The splicing removes most of the *gag*, *pro* and *pol* sequences, leaving the beginning of *gag* fused to *env*.

Translation of the full-length RNA leads to two products: the Gag-Pro precursor of about 76 kDa and the Gag-Pro-Pol precursor of about 180 kDa. Synthesis of the latter molecule is made possible by a −1 translational frameshift about 5% of the time, bypassing the termination codon at the end of Pro. Assembly of these precursors is at the cell surface, and is coincident with budding, implying a simultaneous association of the precursors with the genome, with the cell membrane, and with one another. The use of readthrough synthesis apparently ensures the correct ratio of RT to Gag proteins in the virion. Release of the immature particle (characterized by a hollow, symmetrical core which almost fills the virion) is rapidly followed by cleavage of the Gag-Pro and Gag-Pro-Pol precursors to yield the finished proteins. This cleavage is accompanied by condensation of the core into its mature form. Since the PR protein embedded in the Gag-Pro precursor contains only one-half of the active site, dimerization of this domain is necessary

for cleavage to occur. This requirement probably helps to delay cleavage until the appropriate time.

Once infected, the host cell is usually not killed by the virus, but can continue to divide and release virions indefinitely. A strong superinfection resistance due to blockade or loss of viral receptors develops soon after infection and prevents accumulation of proviruses by reinfection. In some cases, weak or slow development of superinfection resistance is associated with a cytopathic interaction of the virus with its host cell.

Transformation

A unique characteristic of ALV and a few other retroviruses is their ability to incorporate certain host sequences into their genome and alter the function of these proto-oncogenes into oncogenes. The presence of an oncogene renders the virus capable of inducing malignant transformation of cells in culture and one of a variety of malignant and rapidly fatal diseases in birds. At least 20 distinct cell sequences have been incorporated by ALV into a very large number of distinct isolates. RSV which contains *src* is the prototype oncogene-containing virus. Other notable oncogene-containing ALV variants include avian myeloblastosis virus (AMV; containing *myb*); avian myelocytomatosis virus-29 (MC-29; *myc*); avian erythroblastosis virus (AEV; *erb*-A and *erb*-B); Fujinami sarcoma virus (FSV; *fps*) and University of Rochester sarcoma virus-2 (RU-2; *ros*). Study of the genetic alterations that distinguish these oncogenes from proto-oncogenes, and the enzymatic and physiological function of the proteins they encode has been a keystone of modern cancer research. Incorporation of oncogenes into the virus genome is usually at the expense of some viral genes and co-infection of a cell with a wild-type (helper) ALV is thus necessary to provide viral proteins for replication of oncogene-containing viruses.

Endogenous Viruses

Another unique feature shared by ALV and a few other retrovirus groups is their ability to become established in the germline and inherited stably as endogenous proviruses. Naturally occurring endogenous proviruses form a distinct lineage of ALVs, showing a specific host range (subgroup E) for which many domestic chickens lack receptors (a phenomenon known as xenotropism), and a reduced replication capacity and pathogenicity relative to exogenous viruses. Endogenous viruses are usually expressed at a very low rate, due largely to methylation of CpG residues in the proviral DNA, and are often (but not always) defective in sequence.

Genetics

Strain differences among ALV isolates are primarily in host range and are encoded by differences within the central portion of SU; other parts of the genome, with the exception of the U3 end of the LTR, are quite highly conserved. Like other retroviruses, ALVs exhibit very high rates of homologous recombination – a consequence of the diploid genome and the 'jumping' mechanism of reverse transcription. The latter also permits relatively high rates of non-homologous recombination, leading to frequent (but usually lethal) rearrangements of the genome as well as the occasional acquisition of foreign sequences such as oncogenes.

Evolution

Amino acid sequence relationships reveal a common origin of all retroviruses, but the ALV group forms a divergent branch, with its closest relative being the mouse mammary tumor virus. Whereas the recent spread of viruses among chickens is probably due largely to human intervention, the virus group is of considerable antiquity, since distantly related endogenous viruses are widespread in the genomes of avian and even mammalian species. The closely related endogenous viruses seem to be recent introductions derived by germline infection with exogenous virus since they are found only in *Gallus gallus*, and not in other species of *Gallus*, although they do appear in more distantly related pheasants.

Transmission and Tissue Tropism

Transmission of virus is principally vertical by infection of the offspring through virus secreted into the egg. Indeed, high titers of ALV are often detectable in commercial hen's eggs. Horizontal spread of virus is naturally much more rare, requiring close contact, but virus can be readily spread from infected birds via contaminated needles during vaccination or through vaccines prepared from infected eggs or cell cultures.

All isolates of ALV replicate efficiently in fibroblast cultures and in the bursa. Tropism for other tissues varies among isolates and is determined by both *env* and LTR sequences.

Pathogenicity

ALVs induce a wide spectrum of disease in naturally or experimentally infected animals. The prototypic

disease induced by ALV is a B cell lymphoma arising in the bursa of Fabricius starting a few months after infection and spreading to the liver and other organs during its course (hence the synonym visceral lymphomatosis). Other malignancies, including erythroleukemia, sarcoma and others, are not uncommon depending on the strain of virus and bird and the time and route of inoculation. The malignant diseases induced by viruses which do not contain oncogenes are the consequence of insertional activation of cellular proto-oncogenes (such as c-*myc* in the case of lymphoma, c-*erb*-B in erythroleukemia, and others). In addition to malignancies, these viruses also induce hemangiomas, osteopetrosis and wasting diseases the mechanisms of which are not as clear. In some cases, an immune response against infected cells may be important; in others, cytopathic effects of the sort noted above may play a significant role.

Acquisition of oncogenes by ALVs greatly alters the nature and course of the disease. Infection of newly hatched chicks, with AMV, for example, can lead to their death from myeloblastic leukemia in as few as 5 days. Moribund animals display enormously elevated myeloblast counts and a level of viremia sufficient to render the plasmid noticeably turbid. Similarly, birds inoculated with RSV develop rapidly growing, usually fatal, sarcomas at the site of injection. It should be noted that the oncogene-containing viruses are not efficiently transmitted from one animal to another due to their rapid pathogenicity. In most cases, they have probably arisen in the animal from which they were isolated and would have died out if not brought into the laboratory.

Not all members of this group are highly pathogenic. RAV-0 (an endogenous virus) can infect susceptible chickens and induce viremia, but disease is rare and occurs only after a long latent period. The reduced virulence is probably an important feature of viruses inherited in the germline.

Immune Response

In infected birds, the only significant immune response is the appearance of type-specific neutralizing antibodies which apparently recognize the regions of Env involved in receptor recognition. Group specific responses against Env or other proteins are not usually observed in infected chickens, although inoculation of virus into mammals induces antibodies capable of recognizing all virion proteins in the absence of subgroup-specific reactivity. The limited immune response observed in infected chickens has been attributed to the presence of endogenous proviruses whose expression (even at a low level) can induce tolerance to antigens in common with infecting virus. Indeed, it has been suggested that induction of tolerance might be a desirable feature for the animal, since it could prevent or limit immunopathological sequelae of infection. Postinfection immune response seems to be of little consequence in preventing subsequent malignant disease, since the cells which will eventually form the tumor are probably infected quite soon after infection, and the long latency reflects the necessity for subsequent rare events (such as mutations in other genes) rather than a continuing period of virus replication.

Prevention and Control

ALV-induced disease is a cause of some economic loss to the poultry industry in the United States, and occasional more serious epizootics (such as a recent outbreak of hemangioma in Israel) due to ALV have occurred. Control of infection is generally by detection and culling of infected individuals. No useful vaccination strategy has been developed. In principal, it should be possible to virtually eliminate the disease by breeding the appropriate *Tv-a* and *Tv-b* alleles into commercial strains; in practice this has not been done very often. A more recent strategy is to introduce defective proviruses encoding envelope protein into the germline of birds; these can block infection by inducing superinfection resistance.

Future

Although of economic importance to the poultry industry, the value of ALV and the related oncogene-containing viruses to science has been far greater. Although the use of ALV as a model for retrovirus replication has been largely supplanted by the more directly relevant human retroviruses and advances in technology have led to the development of ways to study oncogenes without complications introduced by viruses. Nevertheless, the study of these viruses as models will continue to illuminate fundamental aspects of retrovirus biology. Also, continued searches for new transforming viruses are likely to yield novel and important oncogenes. Indeed, two of the most interesting viral oncogenes – jun (a transcription factor) and crk (a hybrid tyrosine kinase) – were identified only within the past decade. The goal of eradication of ALV disease from commercial chickens is attainable with present technology; its realization is largely a matter of logistic and economic considerations.

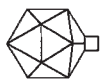
BACILLUS PHAGE ϕ29 (*PODOVIRIDAE*)



Margarita Salas, Centro de Biología Molecular 'Severo Ochoa' (CSIC-UAM), Universidad Autónoma, Cantoblanco, Madrid, Spain

ϕ29 and Related Phages: General Features

Phage ϕ29, first isolated from soil by B.E. Reilly, and the related phages PZE, PZA, ϕ15, Nf, M2Y, B103, SF5 and GA-1, are the smallest *Bacillus subtilis* phages isolated so far. The phages fall into three serological groups: phages ϕ29, PZE, PZA and ϕ15 form one group, phages Nf, M2Y and B103 another, and phage GA-1, and probably SF5, form a third group.

Phage ϕ29 forms very small plaques on lawns of *B. subtilis* 168, although it productively infects this bacterium in liquid medium. Large plaques are formed on asporogenous variants of strain 168 carrying the A12 mutation. Glucosylated teichoic acid has been shown to be essential for ϕ29 adsorption. Phage ϕ29 infects very efficiently *B. amyloliquefaciens* H. The burst size is about 200, although it varies with the growth conditions. ϕ29 also infects varieties of *B. liqueniformis* and *B. pumilus*. The host ranges of phages GA-1 and SF5 differ from those of the other phages.

ϕ29 is a lytic phage, although it has very little effect on the host cell functions, and macromolecular synthesis remains essentially unaltered until very late in phage development.

When ϕ29 infects sporulating cells phage multiplication is inhibited at a very early stage of cell development and the phage DNA is incorporated into spores in a heat-stable form. After germination and outgrowth of the spore, expression of the incorporated phage genome takes place.

Classification

Phage ϕ29 is an unassigned species in the *Podoviridae* family.

Genetics

Temperature-sensitive (*ts*) and suppressor sensitive (*sus*) mutants of phage ϕ29 are available. Quantitative complementation allowed to locate the mutants in 17 cistrons. Recombination frequencies determined by two-factor crosses were used to construct a linear genetic map of 24.4 recombination units. The genes are numbered sequentially from left to right (1 to 17) according to their relative map position. In addition, gene 8.5 was located between genes 8 and 9 and was shown to code for the head fibers, that are dispensable. Genes 1 to 6 and gene 17 are early genes, whereas genes 7 to 16 are late ones. *Sus* mutants are available in all genes, except gene 5; *ts* mutants are available in most of the genes, except in genes 1, 4, 8.5, 14, 15 and 17.

Comparison of the nucleotide sequence of phages ϕ29, ϕ15 and PZA has shown that deletions in the central and carboxy-terminal parts of gene 17 are tolerated, whereas the region corresponding to 83 amino acids from the amino-end of the protein has to be conserved to encode a functional protein.

Cells infected with a spontaneous deletion mutant of phage ϕ29 with a 1117 bp deletion, that covers almost the complete sequence of genes 14 and 15, including the early promoter B2, support normal phage development, but lysis is very delayed. Gene 14

mutants exhibit a delayed lysis phenotype. Gene 14 encodes a holin, and sequence and biochemical analysis of gene 15 suggest that it encodes a lysozyme, although a possible role in phage morphogenesis has also been described. Therefore, the products of genes 14 and 15, as well as the early B2 promoter, seem to be dispensable for ϕ29 development.

The EcoRI cleavage map of ϕ29 DNA has been ordered relative to the genetic map by marker rescue experiments.

DNA Structure

The ϕ29 genome consists of a double-stranded DNA 19 285 bp long with a protein covalently linked at the two 5′ DNA ends. This protein is the product of the viral gene 3 and it is named p3 or terminal protein (TP). The TP is linked to the DNA as a result of the initiation reaction that it primes in the replication of the viral DNA. The linkage is a phosphoester bond between the OH group of residue serine 232 in the TP and 5′ dAMP, the terminal nucleotide at both 5′ DNA ends. The genome of the ϕ29-related phage PZA is 19 366 bp long and that of phage B103 is 18 630 bp long. The DNA of the other related phages has a similar size, except that of phage GA-1, which is a little longer. The sequence of phage PZA DNA is very similar to that of ϕ29 DNA. Phage M2Y seems to have originated from phage Nf, by deletion of a particular region of the genome. In most of the ϕ29-related phages a TP covalently linked at the 5′ DNA ends has been characterized.

Phage ϕ29 and all the related phages have a short, inverted terminal repeat six nucleotides long (5′ AAAGTA) for ϕ29, PZA, ϕ15 and B103 DNAs, eight nucleotides long (AAAGTAAG) for Nf and M2Y DNAs, and seven nucleotides long (AAATAGA) for GA-1 DNA.

In addition, the sequence of the first 18 nucleotides at the left DNA end and that of the first 13 nucleotides at the right end is identical for phages ϕ29, PZA, ϕ15, Nf, M2Y and B103. There are homologies from nucleotides 19 to 50 at the left DNA end of the latter phages, and an identical sequence from nucleotide 27 to 38 at the right end. The remainder of the known sequence of the DNA of phages ϕ29, PZA and ϕ15 is very similar and different from that of phages Nf, M2Y and B103, which share a similar sequence. The sequence of GA-1 DNA is unrelated to that of the other phages, except for the three terminal nucleotides and the sequence from nucleotides 29 to 41 at the right end, which is almost identical to that present from nucleotides 27 to 38 in the other phage DNAs.

Virion Structure and Proteins

The phage ϕ29 particle, of molecular mass about 18×10^6 Da, consists of a prolate head, a neck and a short, non-contractile tail. The head is 415 Å long and 315 Å wide and contains a high amount of fibers. The neck consists of two collars, an upper one or connector, required for head assembly, and a lower one, from which twelve spindle-shaped appendages are attached. The connector is assembled in a circular structure with a hole in its center and twelve morphological units in the periphery. The appendages are required for adsorption of the phage to the bacterial cell wall. The tail is about 300 Å long and is enlarged at the distal part. Some of the ϕ29-related phages, like M2Y, GA-1 and SF5, lack the fibers, which in ϕ29 have been shown to be dispensable.

By sodium dodecyl sulfate (SDS)–polyacrylamide gel electrophoresis, six structural proteins have been characterized. Protein p8 is the major head protein, p8.5 forms the fibers, p10 forms the connector, p11 is the lower collar protein, p12 forms the neck appendages and p9 forms the tail. Protein p12 is synthesized as a precursor, p12*, that is processed before its assembly in the phage particle.

The open reading frames (ORFs) corresponding to the different genes have been characterized in the ϕ29 DNA sequence. They all start with the ATG triplet and end with either TAA, TAG or TGA termination triplets. In general, the initiation triplet of the different genes is very close to the termination triplet of the preceding one. Overlapping sequences exist between the gene coding for the TP p3 and the transcriptional regulator p4. In the case of genes 8 and 8.5, the termination triplet of gene 8 overlaps with the initiation codon of gene 8.5; for genes 10 and 11, the termination triplet of gene 10 overlaps 8 bp with gene 11. In general, the Shine–Dalgarno sequences are strong and with the correct spacing. The predicted size of the different gene products and their function are shown in **Table 1.** By SDS–polyacrylamide gel electrophoresis all proteins, except the gene 13 and 14 products, have been characterized. All PZA genes are identical in size to the corresponding ones of ϕ29, except genes 1 and 17 that are 8 and 7 amino acids longer, respectively.

In addition to the ORFs corresponding to the genes characterized, three small ORFs that could code for proteins of 47 to 58 amino acids are present downstream of gene 1, at the left end of the ϕ29 and PZA genomes, where early genes are located, and one ORF, that could code for a protein of 66 amino acids, is found between genes 5 and 6. At the left of gene 17, five ORFs are present in ϕ29, PZA, ϕ15 and B103 that could code for proteins of 37 to 130 amino acids.

Table 1 Genes of phage ϕ29

Gene	Protein or phenotype	nt[a]	aa[b]	kDa[b]
1	DNA replication	1126–857	89	10.3
2	DNA polymerase[c]	2863–1145	572	65.2
3	Terminal protein	3686–2886	266	31.1
4	Transcriptional activator	3952–3575	125	15.1
5	ssDNA binding protein	4345–3971	124	13.4
6	dsDNA binding protein	4921–4609	104	12.0
7	Scaffolding protein	5222–5518	98	11.2
8	Major head protein	5549–6895	448	49.7
8.5	Head fiber protein	6895–7737	280	29.6
9	Tail protein	7751–9550	599	67.7
10	Upper collar protein (connector)	9555–10484	309	35.9
11	Lower collar protein	10477–11358	293	33.6
12	Preneck appendage protein	11371–13935	854	92.4
13	Morphogenesis (tail assembly)	13947–15044	365	41.0
14	Lysis	15063–15458	131	14.9
15	Lysozyme, morphogenesis	15460–16236	258	26.9
16	DNA encapsidation	16247–17245	332	38.9
17	DNA replication	19083–18583	167	19.4

[a] Both the initiation and termination codons have been considered.
[b] The initiation methionine was considered for the calculations.
[c] The position of two possible initiation codons is given.

These ORFs have been named 16.9, 16.8, 16.7, 16.6 and 16.5. ORFs 16.7 and 16.5, encoding for 130 and 137 amino acids, respectively, are the most conserved ones among these phages. Computer-assisted analysis of the deduced amino acid sequence of ORF16.7 revealed it to contain a membrane-spanning domain located at its N-terminus which is followed by three positively charged lysine residues. The gene product of ORF16.7 was detected in ϕ29-infected *B. subtilis* cells early after infection. The native protein p16.7 was shown to be an integral membrane protein.

Replication of the Phage DNA

Replicative intermediates

Two types of replicative intermediates are observed by electron microscopy in ϕ29-infected *B. subtilis:* type I molecules which consist of double-stranded DNA with single-stranded tails coming from one or from the two DNA ends, and type II molecules which are partially double-stranded and partially single-stranded. Analysis of these molecules showed that replication starts at either DNA end, non-simultaneously, and proceeds towards the other end by strand-displacement. The same type of replicative intermediates produced *in vivo* are formed in the *in vitro* system described below.

Proteins involved in replication

Genes 1, 2, 3, 5, 6 and 17 are required for the synthesis of ϕ29 DNA *in vivo*. Genes 2 and 3, coding for the DNA polymerase and the TP, respectively, are essential for the initiation of ϕ29 DNA replication, both *in vivo* and *in vitro*. Gene 5 codes for a single-stranded DNA binding protein (SSB) that is essential for elongation in *in vivo* replication; it stimulates *in vitro* replication. Gene 6 codes for a double-stranded DNA binding protein that is also required for *in vivo* replication; it stimulates the initiation of replication *in vitro*. The gene 1 product is a membrane-associated protein, essential for *in vivo* replication, that is likely to recruit TP and DNA polymerase to form a membrane-associated multiprotein complex that would enable nascent viral DNA molecules to become membrane-associated when its synthesis begins. The product of gene 17 is dispensable for *in vivo* replication when infection takes place at high multiplicity, although it is required when low multiplicity of infection is used. Protein p17 stimulates *in vitro* replication under conditions of low input DNA and low amounts of initiation proteins. Development of ϕ29 occurs in most of the *B. subtilis* replication mutants available. Three genes, G, E and T, are involved in the replication of phage M2Y DNA. Genes G and E correspond to the ϕ29 genes 2 and 3, respectively.

ϕ29 genes 2, 3, 5, 6 and 17 have been cloned in *Escherichia coli* under the control of the P_L promoter of phage lambda or under the control of the ϕ10 promoter of phage T7, and the proteins have been overproduced and highly purified in a functional form. Proteins p5 and p6 are very abundant in ϕ29-infected *B. subtilis* and they have also been purified from phage-infected bacteria. Gene 1 has also been cloned under the control of the phage lambda P_L promoter. The overproduced protein has been purified from an insoluble fraction.

Role of TP and DNA polymerase in replication

Replication of ϕ29 DNA occurs by a protein-priming mechanism in which, in the presence of the ϕ29 TP–DNA complex (TP–DNA) as template, dATP and Mg^{2+}, the viral DNA polymerase catalyzes the formation of a covalent linkage between dAMP and the OH group of residue Ser232 of a free TP molecule (priming protein). Mn^{2+} ions are better activators of the initiation reaction than Mg^{2+}, due to a 25-fold decrease in the K_m value for dATP. The initiation reaction is greatly stimulated by NH_4^+ ions because they stabilize the formation of a heterodimer between ϕ29 DNA polymerase and TP. The TP–dAMP complex formed is elongated by the viral DNA polymerase to produce full-length ϕ29 DNA in a very processive way. When primed M13-DNA is used as template, the ϕ29 DNA polymerase synthesizes DNA chains greater than 70 kb, also in a very processive way. Therefore, the ϕ29 DNA polymerase is able to produce strand-displacement very processively without need of accessory proteins. The ϕ29 DNA polymerase, in addition to initiation and polymerization activities, has $3' \rightarrow 5'$ exonuclease activity that is about 10-fold higher on single- than on double-stranded DNA, and shows a marked preference for excision of a mismatched relative to a correctly paired 3′ terminus. These characteristics enable the ϕ29 DNA polymerase to act as a proofreading enzyme. A pyrophosphorolytic activity has also been characterized in the ϕ29 DNA polymerase. This activity requires a high concentration of pyrophosphate and a duplex DNA with a protruding 5′ single-strand, and it is reversed by polymerization.

Replication origins

Proteinase K-treated ϕ29 DNA is not a template for the initiation reaction. However, piperidine-treated ϕ29 DNA is active, although the activity is reduced 5–10-fold from that obtained with TP–DNA. Terminal fragments from the left and right ϕ29 DNA ends have been cloned; fragments released by restriction nuclease digestion, containing the ϕ29 DNA terminal sequences at the DNA ends, are active templates. However, no template activity is obtained with the circular plasmid or when the terminal sequences are not placed at the DNA end. The minimal origins of replication are located within the terminal 12 bp at each ϕ29 DNA end. A change of the second or third A in the ϕ29 DNA sequence into a C completely abolishes the template activity, whereas changes at positions 4 to 12 are tolerated to a great extent.

Although the parental TP seems to be partially dispensable *in vitro*, no replication is obtained *in vivo* after transfection of *B. subtilis* protoplasts with ϕ29 DNA molecules lacking the parental TP.

Single-stranded oligonucleotides with the sequence corresponding to the 3′ terminus of ϕ29 DNA give rise to the formation of the TP–dAMP initiation complex, the preferred nucleotide being dAMP. Initiation activity is also obtained with unspecific single-stranded DNA such as poly(dC), with the formation of TP–dGMP complex. Deoxynucleotidylation of the TP with any of the four dNMPs, catalyzed by the ϕ29 DNA polymerase, is also detected in the absence of any template, although in this case the affinity for the dNTPs is greatly reduced relative to the template-dependent reaction.

Replication of the displaced strand

When recombinant ϕ29 DNA molecules containing parental TP at only one DNA end are used to transfect *B. subtilis* protoplasts, no replication is obtained, suggesting that the fully displaced DNA strand is not an active template for replication *in vivo*. The same type of ϕ29 DNA molecules used as templates in the *in vitro* replication system leads to both an accumulation of full-length single-stranded DNA molecules and a lack of type II replicative intermediates. Moreover, when the TP–DNA complex is used as template, type II replicative intermediates are found at incubation times at which no synthesis of full-length ϕ29 DNA is detected, indicating that the appearance of type II molecules does not require synthesis of full-length DNA and displacement of the strand. Altogether, the results support a model in which initiation of replication can occur from both DNA ends, and type II molecules are produced by separation of the two displacement forks when they meet.

Functional domains in the ϕ29 TP

By deletion analysis, two DNA polymerase-binding regions in the TP have been found, at positions 72–80 and 241–261. On the other hand, the amino acid regions of the TP at positions 13–18, 30–51 and 56–71 are important for DNA binding.

By site-directed mutagenesis, Ser232 in the TP has been changed into Thr. The purified mutant protein is completely inactive in the initiation reaction. A change of Ser232 into Cys results in a TP with about 0.7% of the priming activity of the wild-type TP. Changes of Leu220, Ser223 and Ser226 into Pro give rise to mutant proteins with 3%, 140% and 1% of the priming activity of the wild-type protein, respectively. All the mutant TPs can interact with DNA polymerase and DNA, suggesting that Leu220 and Ser226 are involved in the initiation reaction, in addition to Ser232. These three amino acid residues are conserved in the TP of phages PZA, Nf and B103.

The ϕ29, PZA, Nf, M2Y and B103 TPs have, at positions 256–258, the sequence Arg-Gly-Asp (RGD), found in cell-adhesive proteins. The synthetic peptide RGD, but not RGE, inhibits transfection of ϕ29 and M2Y DNAs, as well as the *in vitro* initiation reaction. A role of the RGD motif in the interaction of the ϕ29 TP with DNA polymerase has been shown.

Residues Asp80 and Tyr82, conserved in the TPs of phages ϕ29, PZA, Nf, B103 and GA-1, are important for the interaction between the primer TP and the parental TP.

By using an *in vivo trans*-complementation assay, it has been shown that the ϕ29 TP functionally substitutes the TP of PZA but not that of Nf.

Functional domains in the ϕ29 DNA polymerase

The ϕ29 DNA polymerase is inhibited by aphidicolin, phosphonoacetic acid and the nucleotide analogues butylanilino dATP (BuAdATP) and butylphenyl dGTP (BuPdGTP), known inhibitors of eukaryotic DNA polymerase α. These functional, as well as structural criteria, have allowed classification of the ϕ29 DNA polymerase as belonging to the family of α-like or eukaryotic-like DNA polymerases. Less related to this group are the *E. coli* DNA polymerase I (pol I)-like DNA polymerases, although significant amino acid sequence similarity has been found among the two groups of DNA polymerases, both at the amino-terminal part and at the carboxy-terminal region.

Three regions of amino acid sequence homology have been found at the amino-terminal part of eukaryotic- and pol I-like DNA polymerases, containing the 3′ → 5′ exonuclease domain in Pol I, that have been named Exo I, Exo II and Exo III. Site-directed mutants in the ϕ29 DNA polymerase at residues Asp12 and Glu14 in region Exo I, Asp66 in region Exo II, and Tyr165 and Asp169 in region Exo III demonstrated a role of these residues in catalysis of the 3′–5′ exonuclease, supporting the idea that the geometry of the Pol I 3′–5′ exonuclease active site and the two-metal ion mechanism proposed for this enzyme can be extrapolated to ϕ29 DNA polymerase. None of those mutants were affected in the initiation and polymerization activities. However, the strand-displacement activity was impaired, indicating that this activity of the ϕ29 DNA polymerase is located in the amino-terminal domain, somehow overlapping with the 3′–5′ exonuclease active site.

Other amino acid residues are structurally and functionally conserved at the exonuclease domain of most prokaryotic and eukaryotic DNA polymerases. Among them, ϕ29 DNA polymerase residues Thr15 and Asn62, located at the Exo I and Exo II motifs, respectively, act as single-stranded DNA ligands, having a critical role in the stabilization of the frayed primer terminus at the 3′–5′ exonuclease active site. These residues do not have a role in the strand-displacement capacity of the ϕ29 DNA polymerase.

An invariant lysine residue, found in the eukaryotic-type DNA polymerases between the Exo II and Exo III motifs, has been shown by site-directed mutagenesis in the ϕ29 DNA polymerase (residue Lys143), to be involved in catalysis at the 3′–5′ exonuclease active site. Mutants at Lys143 also showed a reduced polymerization capacity, but only when DNA synthesis was coupled to strand-displacement.

At the carboxyl part of the DNA polymerases, containing the polymerization domain in Pol I, five main regions of amino acid sequence homology have been found and named 1, 2a, 2b, 3 and 4. Site-directed mutants in the five regions of the ϕ29 DNA polymerase, characterized by the consensus motifs Dx_2SLYP, Kx_3NSxYG, Tx_2GR, YxDTDS and KxY, respectively, have been obtained. The mutational analysis demonstrated that the C-terminal two-thirds of the ϕ29 DNA polymerase polypeptide constitutes the polymerization and protein-primed initiation domains, containing sites for interaction with the metal activator, dNTPs and DNA. Three Asp residues, invariant in all members of the eukaryotic-type DNA polymerases, are involved in metal binding and catalysis at the polymerization active site. These ϕ29 DNA polymerase residues, Asp249 (motif Dx_2SLYP), and Asp456 and Asp458 (motif YxDTDS), are predicted to form a metal binding tripod, analogous to that found in other DNA polymerases. In addition, Arg458 (motif Tx_2GR) was also proposed to play a role in catalysis of the polymerization reaction. Three Tyr residues, and one Lys, invariant or highly conserved in the eukaryotic-type DNA polymerases, are directly or indirectly involved in interaction with dNTPs. These residues are Tyr254 (motif Dx_2SLYP), Lys383 and Tyr390 (motif Kx_3NSxYG), and Tyr454 (motif YxDTDS). Tyr254 and Tyr390 are also involved in nucleotide binding

selection, playing a critical role in the fidelity of DNA replication. Eight residues, invariant or highly conserved in eukaryotic-type DNA polymerases, are involved in binding template-primer structures. These residues are Ser252 (motif Dx_2SLYP), Asn387, Gly391 and Phe393 (motif Kx_3NSxYG), Thr434 and Arg438 (motif Tx_2GR) and Lys498 and Tyr500 (motif KxY). In addition, residues Thr434 and Arg438 (motif Tx_2GR) are involved in TP binding. The 3′–5′ exonuclease activity is not affected in any of the mutants mentioned above.

A conserved motif (YxGG/A), located between the 3′–5′ exonuclease and polymerization domains of eukaryotic-type DNA polymerases, is a DNA binding motif that plays a role in the coordination between DNA synthesis and proofreading.

A C-terminal deletion derivative of ϕ29 DNA polymerase, containing the first 188 N-terminal amino acid residues (including the three Exo motifs), was independently expressed in *E. coli* cells and purified. This N-terminal domain was devoid of any synthetic activity (TP-primed initiation and DNA polymerization), but retained some 3′–5′ exonuclease activity. In addition, a N-terminal deletion derivative of ϕ29 DNA polymerase, lacking the first 188 N-terminal amino acid residues has been expressed in *E. coli* cells and purified. As expected, the 44 kDa C-terminal fragment lacks 3′–5′ exonuclease activity and strand-displacement capacity. On the other hand, it retained polymerase activity when Mn^{2+} was used as metal activator, although the catalytic efficiency was greatly reduced with respect to that of the complete enzyme, and polymerization was distributive, in contrast to the high processivity of the complete ϕ29 DNA polymerase. These polymerization defects could be related to a strong impairment in DNA binding, suggesting that contacts present in the N-terminal domain are important for an optimal stabilization and translocation of the DNA during polymerization. The C-terminal domain also showed a very reduced capacity to initiate TP-primed DNA replication, as a consequence of a weakened interaction with the TP primer and a lack of activation by protein p6. Thus, the C-terminal portion of ϕ29 DNA polymerase (residues 188–575), although having a structural entity as the domain responsible for the synthetic activities, requires the N-terminal domain to provide important contacts for the two different substrates, DNA and TP, that prime DNA synthesis.

Temperature-sensitive mutants available in the ϕ29 DNA polymerase gene, *ts*2 (24) and *ts*2 (98), consist in the change Ala355 into Val (A355V) and Ala492 into Val (A492V), respectively. The A355V mutation is located between regions 1 and 2a, in a conserved region present only in protein-primed DNA polymerases. The mutant DNA polymerase has a *ts* phenotype, both in initiation and elongation, as well as in pyrophosphorolytic activity. The *ts*2 (98) mutant DNA polymerase is rather insensitive to temperature, but its initiation and elongation activities are activated by Mn^{2+} ions to a greater extent than the wild-type ϕ29 DNA polymerase. The *ts*2 (98) mutation is located in region 4.

Gene 6 product

Purified protein p6, a dimer of 24 000 Da, stimulates the formation of the TP–dAMP initiation complex, decreasing the K_m value for dATP. Protein p6 also stimulates the transition from the initiation complex to the first elongation products TP–$(dAMP)_2$ and TP–$(dAMP)_3$. DNAase I footprinting shows that protein p6 binds to double-stranded DNA fragments containing the left or right terminal sequences of ϕ29 DNA, producing a pattern of hypersensitive bands located 24 nucleotides apart along 200–300 bp, flanking protected regions. By hydroxyl radical footprinting, protein p6 bound to ϕ29 DNA terminal fragments gives rise to a specific pattern of protected regions of 3–4 nucleotides regularly spaced every 12 nucleotides, also spanning 200–300 bp, and shifted four nucleotides from each other in the two DNA strands. These regions define the contact sites that are flanked by strong DNaseI hypersensitive sites on alternative strands. The repeated motif, from a strong DNaseI hypersensitive site to the next one in the same DNA strand, contains two contact sites. The fact that the repeated unit is formed by two contact sites suggests that p6 binds as a dimer every 24 nucleotides. Protein p6 interacts with DNA through the minor groove; in agreement with this, distamycin A, which binds in the minor groove, displaces p6 from DNA and inhibits the p6 stimulation of ϕ29 DNA replication. These results and the fact that binding of protein p6 to circular DNA restrains positive supercoiling, support a model in which a DNA right-handed superhelix tightly wraps around a multimeric protein p6 core. The compaction of the DNA in the complex was shown to be 4.2-fold. The parameters that define the path followed by the DNA in the protein p6 complex have been determined: one superhelical turn has 63 bp with a pitch of 5.1 nm and a diameter of 6.6 nm. Consequently, the DNA should be slightly bent (66° every 12 bp) and underwound (11.5 bp/turn).

Main protein p6-recognition sequences are located between nucleotides 62 and 125 at the right ϕ29 DNA end and between nucleotides 46 and 68 at the left end. Since no sequence similarity exists in these regions, protein p6 does not seem to recognize a specific sequence in the DNA but rather a structural feature,

which could be the ability of the DNA to be bent every 12 bp. The activity of protein p6 in the initiation of replication requires the correct positioning of the complex relative to the ϕ29 DNA ends, as shown by insertion of 4 bp, 12 bp or 24 bp between the minimal replication origin and the main protein p6 binding determinants at the right ϕ29 DNA end. As expected, the distance of the p6 molecules with respect to the DNA end is increased in the +4 and +12 mutants by 4 bp and 12 bp, respectively, whereas it is conserved in the +24 mutant. No stimulation of the initiation reaction by p6 is observed in the +4 and +12 mutants, whereas the same stimulation as in the wild-type DNA is observed in the +24 mutant. These results suggest that other proteins involved in the initiation of replication recognize, at a precise position, either the p6 core or the conformational change induced by p6. By using the protein p6 counterparts of phages Nf and GA-1, as well as the TP and DNA polymerase from these phages, in addition to the TP–DNA complexes of ϕ29, Nf and GA-1, it has been shown that the activation of the initiation of replication requires not only the formation of a specific nucleoprotein complex but also its specific recognition by the proteins involved in the initiation of DNA replication.

Deletion mutagenesis has shown that the 14 C-terminal amino acids of protein p6 are dispensable; the activity of the protein decreases with deletions from 23 to 39 amino acids and is undetectable when 44 amino acids are removed. Deletion of 5 amino acids at the N-end greatly decreases the activity of protein p6, that is undetectable after removal of 13 amino acids. These two mutant proteins cannot interact specifically with the ϕ29 DNA ends, but they interfere with the binding of the wild-type protein p6, suggesting that the N-terminal region of protein p6, predicted to form an amphipatic α-helix, is involved in DNA binding. Indeed, site-directed mutants at the polar side of the putative α-helix showed impaired DNA binding and activation of initiation of ϕ29 DNA replication.

Protein p6 is among the most abundant viral proteins in ϕ29-infected *B. subtilis* cells, constituting about 700 000 copies/cell at late infection. By electron microscopy it has been shown that, *in vitro*, protein p6 forms heterogeneously-sized complexes all along ϕ29 DNA, suggesting that p6 may have a role in genome organization, besides its role in replication and transcription (see later).

Gene 5 product

The gene 5 product, essential for *in vivo* ϕ29 DNA replication, is one of the most abundant proteins in ϕ29-infected *B. subtilis* cells, constituting about 1.5×10^6 molecules/cell at late infection times. Purified protein p5 binds to single-stranded DNA, producing a twofold reduction in the DNA length as shown by electron microscopy. No effect of protein p5 on the formation of the TP–dAMP complex has been found. Protein p5 greatly stimulates TP–DNA replication at incubation times when the replication in the absence of protein p5 levels off. Protein p5 has helix-destabilizing activity and stimulates the rate of elongation in ϕ29 DNA replication when ϕ29 DNA polymerase mutants impaired in strand-displacement activity are used. The replication of primed M13-ssDNA is also stimulated by protein p5. Other SSB proteins such as *E. coli* SSB, phage T4 gp32, adenovirus DBP and human RF-A, as well as phage PRD1 protein p12, can functionally substitute for protein p5. Protein p5 binds to single-stranded DNA in the ϕ29 replicative intermediates produced *in vitro*, which are similar in structure to those observed *in vivo*. Altogether, the data available indicate that protein p5 is the ϕ29 SSB protein active during ϕ29 DNA replication.

Interaction of ϕ29 SSB with ssDNA leads to a quenching of its tyrosine-dependent intrinsic fluorescence, with a maximal value of 95%. The stoichiometry (n) of p5 binding to ssDNA is 3–4 nucleotides per ϕ29 SSB monomer. The effective binding constant ($K_{eff} = K_w$) to poly(dT) was 2×10^5 M^{-1}, the intrinsic binding constant (k) and the cooperativity parameter (w) being 4×10^3 M^{-1} and 50–70, respectively. Based on its translational frictional coefficient and its rotational correlation time, ϕ29 SSB has been modeled as a nearly spherical ellipsoid of revolution. The fluorescence properties of the ϕ29 SSB tyrosines (Tyr50, Tyr57 and Tyr76) are consistent with a direct participation in complex formation with single-stranded DNA. Site-directed mutagenesis indicated that, indeed, the three tyrosine residues of ϕ29 SSB, particularly Tyr76, are involved in single-stranded DNA binding.

In vitro amplification of ϕ29 DNA

By using appropriate amounts of four purified ϕ29 replication proteins – TP, DNA polymerase, protein p6 (double-stranded DNA-binding protein) and protein p5 (SSB) – it has been possible to amplify *in vitro* small amounts (0.5 ng) of the 19 285 bp long ϕ29 DNA by three orders of magnitude after 1 h of incubation at 30°C. The quality of the amplified material was demonstrated by transfection experiments, in which the infectivity of the amplified DNA, measured as the ability to produce phage particles,

was identical to that of the natural ϕ29 DNA obtained from virions.

In vitro ϕ29 DNA amplification in the absence of the ϕ29 SSB protein gives rise to the production of short DNA molecules that originate preferentially from the left ϕ29 DNA end. These short molecules consist in an inverted duplication of one of the DNA ends and they are produced by a template-switching mechanism. After their formation they would replicate by means of hairpin intermediates. Amplification of these short DNA molecules requires TP, DNA polymerase and protein p6, but ϕ29 SSB is no longer needed.

A sliding-back mechanism for protein-primed DNA replication

By using as templates synthetic oligonucleotides with either the wild-type sequence at the right or left ϕ29 DNA ends or with mutations at one of the three terminal Ts, it was shown that ϕ29 DNA replication does not start at the 3′ terminal nucleotide, but occurs opposite the second nucleotide at the 3′ end of the template. Nonetheless, all the nucleotides of the template, including the 3′ terminal one, are replicated. Taking these results into account, as well as the need of a terminal repetition of at least two nucleotides for an efficient elongation, a sliding-back model has been proposed with a special transition step from initiation to elongation. After formation of the TP–dAMP initiation complex directed by the second 3′ terminal nucleotide, the TP–dAMP complex would slide backwards to locate the dAMP residue in front of the 3′ terminal T, the second T acting again as a director for the incorporation of the second A residue. A sliding-back mechanism has been also shown to occur in the protein-primed replication of phage GA-1.

The DNA polymerase-primer TP heterodimer is not dissociated immediately after initiation nor in the sliding-back step. There is a transition stage in which the DNA polymerase synthesizes a five nucleotide-long DNA molecule while complexed with the primer TP, undergoes some structural change during replication of nucleotides 6–9, and finally dissociates from the primer protein when nucleotide 10 is inserted into the nascent DNA chain. This behavior probably reflects the polymerase requirement for a DNA primer of a minimum length to efficiently catalyze DNA elongation. The significance of such a limiting transition stage is supported by the finding of abortive replication products consisting of the primer TP linked up to eight nucleotides, detected during *in vitro* replication of TP–DNA, particularly under conditions that decrease the strand displacement capacity of ϕ29 DNA polymerase.

Transcription of the Phage ϕ29 Genome

Transcription map

Transcription of the early genes, located at the two ϕ29 DNA ends, occurs from right to left and is initiated at eight promoters named A1, A2a, A2b, A2c, B1, B2, C1 and C2, recognized by the *B. subtilis* σ^A RNA polymerase. Transcription of the late genes, clustered in the midle of the genome, takes place from left to right from a single promoter named A3 and requires, in addition to the σ^A RNA polymerase, the product of the viral early gene 4. Transcription starting at the A2a, A2b and A2c promoters, at the left part of the genome, gives rise to the viral proteins p6, p5, p4, p3, p2 and p1. The A1 promoter, located at the left DNA end, is involved in the production of a 174 nucleotides-long RNA, involved in the packaging of ϕ29 DNA into the proheads. The weak promoters B1 and B2 are located at the central part of the genome in a region coding for late genes, in which no ORF of significant length coding for early genes is present. The transcripts originating from the B1 and B2 promoters may act as antisense RNAs that would downregulate the expression of particular genes of the late polycistronic mRNA. Transcription from the C2 promoter, at the right ϕ29 DNA end, gives rise to protein p17. No function has been proposed for transcripts initiated at the C1 promoter, also located at the right part of the genome, although they contain the sequence for two small ORFs that are conserved among phages ϕ29, PZA, ϕ15 and B103. Transcription initiated at the late A3 promoter gives rise to the late proteins p7, p8, p8.5, p9, p10, p11, p12, p13, p14, p15 and p16, and does not require synthesis of the viral DNA. The eight early promoters have consensus sequences that correspond to the ones recognized by the *B. subtilis* σ^A RNA polymerase (TTGACA and TATAAT at the −35 and −10 regions, respectively). The late promoter has the TATAAT sequence at the −10 region, but no consensus sequence is present at the −35 region.

Termination of transcription of the early genes located at the left end of the genome occurs both at the very end of the DNA and at the beginning of gene 4, at the ρ-independent terminator named TA1. Therefore, a significant number of transcripts terminate at TA1 and code only for proteins p6 and p5, that are synthesized in large amounts in ϕ29-infected cells. Transcription termination of the early gene(s) located at the right ϕ29 DNA end, initiated at the C1 and C2 promoters, occurs at the ρ-independent bidirectional

terminator named TD1. Transcripts starting at the B2 promoter terminate at terminators TB1 and TB2 whereas those starting at promoter B1 do not terminate at a defined position. Transcription starting at the late promoter A3 terminates at the bidirectional terminator TD1.

Transcription regulation

***In vivo* transcription** The abundance of the transcripts produced from each viral promoter throughout the infection cycle has been analyzed. The early promoters A1, A2b, A2c and to a lesser extent, C2, and the late promoter A3 are the strongest ϕ29 promoters. Interestingly, protein p4, in addition to activate the late A3 promoter, is a repressor of the early promoters A2b and A2c, although repression is not complete and both promoters are still active at late times of infection.

***In vitro* transcription** The gene 4 product, required for *in vivo* transcription from the late A3 promoter and acting also as a repressor of the A2b and A2c promoters, has been cloned in *E. coli* under the control of the P_L promoter of phage lambda, and protein p4 has been overproduced. The purified protein p4 promotes the *in vitro* transcription from the late promoter when added to the *B. subtilis* σ^A RNA polymerase. Protein p4 has been characterized as a transcriptional activator required for the binding of σ^A RNA polymerase to the A3 promoter. By DNAaseI footprint analysis protein p4 was shown to bind to a region from nucleotides -58 to -104 from the transcription start site. The sequences specifically recognized by protein p4 are included in two 8 bp inverted sequences, as shown by hydroxyl-radical interference and methylation interference experiments. The protein p4-binding region in the A3 promoter has a sequence-dependent curvature of about 45°. Binding of protein p4 increases bending of the above DNA region to 80–85°.

Protein p4, 125 amino acids long, is a dimer in solution, and binds to DNA as a tetramer. The analysis of protein p4 mutants with deletions and substitutions at the carboxyl end, which is positively charged, have indicated that DNA bending induced by protein p4 has a role in the activation of transcription. Bending would be induced in two steps: first, binding of two dimers of protein p4 to the inverted recognition sequences and interaction between them, would bend the DNA between the inverted repeats; then, non-specific electrostatic interaction between the positively charged carboxyl-end of the protein and the negatively charged DNA backbone would produce bending at both sides of the protein p4 binding sites. Deletion of the first five amino acids at the amino-end of protein p4 gives rise to a stable protein that does not bind to the promoter.

Binding of protein p4 to its recognition region induces the binding of σ^A RNA polymerase to the late promoter through the formation of a closed complex. There is evidence indicating that direct contacts between protein p4 and σ^A RNA polymerase do exist. Interestingly, protein p4 deletion mutants at the carboxyl-end that do not induce a complete DNA bending are not active as transcriptional activators and do not favor the binding of σ^A RNA polymerase to the promoter. The curvature increase induced by protein p4 is likely to correctly orient protein p4 towards the σ^A RNA polymerase so that adequate contacts can be made. Activation at a distance by protein p4 can occur, and it seems to involve a DNA loop held by the interaction of protein p4 and σ^A RNA polymerase. Site-directed mutants at the carboxyl-end of protein p4 have been obtained. The results showed that Arg120 is the most critical residue for activation, probably mediating the interaction with RNA polymerase. Several basic residues have been identified, including Arg120, that contribute to maintain the DNA bending, probably via electrostatic interactions with the DNA backbone. The degree or stability of the induced bend apparently relies on the additive contribution of all basic residues of the carboxyl end of the protein. Therefore, the activation and DNA bending surfaces overlap, and Arg120 should interact with both DNA and RNA polymerase. Since protein p4 is a dimer in solution and binds to DNA as a tetramer, a model has been proposed in which two of the p4 subunits interact with the DNA, bending it, while the other two subunits remain accessible to interact with the RNA polymerase.

Protein p4 promotes the binding of purified *B. subtilis* RNA polymerase α subunit to the A3 promoter in a cooperative way. Binding is abolished by deletion of the last 15 amino acids of the α subunit. RNA polymerase reconstituted with a deleted α subunit lacking 15 amino acids at the carboxyl end could transcribe viral promoters not activated by protein p4, but lost the ability to recognize the A3 promoter in the presence of p4. In addition, the reconstituted RNA polymerase could not interact with protein p4. Thus, protein p4 activation of the A3 promoter requires an interaction between the carboxyl end of p4 and the carboxyl end of the α subunit of *B. subtilis* RNA polymerase to stabilize the RNA polymerase at the promoter.

Protein p4 does not interact with the *E. coli* RNA polymerase and cannot activate transcription with this enzyme. A chimerical α subunit containing the amino-terminal domain of the *E. coli* α subunit and

the carboxy-terminal domain (CTD) of the *B. subtilis* α subunit was reconstituted with the *E. coli* β and β' subunits and the vegetative σ factor from either *E. coli* (σ^{70}) or *B. subtilis* (σ^{A}). Both hybrid enzymes were responsive to protein p4 and efficiently supported activation at the A3 promoter through the same activation surface used with *B. subtilis* RNA polymerase. Therefore, the *B. subtilis* α-CTD allows activation by p4 even when the rest of the RNA polymerase subunits belong to *E. coli,* a distantly related bacteria.

Protein p4 binding site at the late A3 promoter overlaps with part of the main early promoter A2b. *In vitro* studies have shown that protein p4 represses the A2b promoter by excluding σ^{A} RNA polymerase from the latter directing it to the late promoter. In addition, the curvature induced by p4 binding impairs transcription from the A2b promoter.

Protein p4 also represses the early A2c promoter by binding to DNA immediately upstream from RNA polymerase in a way that does not hinder RNA polymerase binding; rather, the two proteins bind cooperatively to DNA. In the presence of p4, RNA polymerase can form an initiated complex at the A2c promoter that generates short abortive transcripts, but cannot leave the promoter. Mutation of protein p4 residue Arg120, which relieves the contact between the two proteins, leads to a loss of repression. Protein p4 could form a complex at the A2c promoter with wild-type α subunit, but not with a deletion mutant lacking the 15 carboxy-terminal amino acids. In addition, promoter repression by p4 was impaired when a reconstituted RNA polymerase lacking the 15 carboxy-terminal amino acids of the α subunit was used. Protein p4 could not interact with this mutant RNA polymerase at promoter A2c. Thus, the carboxy-terminal domain of the α subunit can receive regulatory signals, not only from transcriptional activators but also from repressors. On the other hand, the contact between protein p4 and RNA polymerase through the p4 domain containing Arg120 can activate or repress transcription, depending on the promoter. The position of protein p4 relative to that of RNA polymerase, which is different at the A3 and A2c promoters does not dictate the outcome of the interaction. Rather, it is the absence or presence of a -35 consensus box for the vegetative RNA polymerase that determines whether activation or repression occurs. Thus, stabilization of RNA polymerase at the promoter over a threshold level leads to repression.

The early protein p6, which stimulates DNA replication, modulates the expression of the right early genes repressing transcription from the C1 and C2 promoters. In addition, protein p6 represses transcription from the early A2c promoter, but only in the presence of protein p4. Thus, early transcripts from the left ϕ29 DNA end are repressed at two levels. On the one hand by repression of the A2b and A2c promoters by p4. On the other, by repression of the A2c promoter by protein p6 when p4 is present. Nonetheless, since *in vivo* repression of the early genes transcribed from the A2b and A2c promoters is not complete, it is likely that protein p4 is produced in limiting amounts, not being bound to all viral DNA molecules present in the cell at a given time.

Studies of the consequences on replication of collisions between ϕ29 DNA polymerase and the transcription machinery showed that codirectional collisions with stalled transcription ternary complexes at the early ϕ29 promoters C2, C1, B2 and B1 blocked replication fork progression. Upon collision, the DNA polymerase remained on the template and was able to resume elongation once the RNA polymerase was allowed to move. Collisions with RNA molecules moving in the same direction also interfered with replication, causing a decrease in the replication rate. It is likely that temporal regulation of transcription and the low probability that the replication and transcription processes colocalize *in vivo* contribute to achieving minimal interference between the two events.

Morphogenesis of Phage ϕ29

Phage ϕ29 assembly occurs by a single pathway in which the neck and tail proteins are incorporated into the DNA-containing head.

As a first step in ϕ29 morphogenesis the major head protein p8 and the nonstructural protein p7 (scaffolding protein) interact to get head assembly. The fiber protein p8.5 is not needed since phage ϕ29 mutants lacking this protein produce fiberless infective phage particles. To get a prolate head, the connector protein p10 must be functional since mutants in cistron 10 produce isometric heads; these heads have an electron-dense internal core and they contain, in addition to proteins p8 and p8.5, the nonstructural protein p7. In addition, the *in vivo* interaction of only proteins p7 and p8 produces particles with variable size and shape. However, in the presence of the connector protein p10, particles with uniform size and shape are produced. The scaffolding protein p7 and the connector protein p10 have been shown to interact *in vitro*. Proteolytic cleavage of p10 that results in the loss of 16 and 19 amino acids from the amino- and carboxy-termini, respectively, abolish the DNA-binding activity of the protein, but the general shape and size of the connector is not changed, as revealed by electron microscopy. Mutation of the three acidic

amino acids at the carboxyl end of p7 prevented it from interacting with p8.

In the absence of DNA synthesis or of protein p16 a prolate head more rounded at the corners than complete phage particles, and with an internal core is accumulated, that contains the head proteins p8 and p8.5, the connector protein p10 and the nonstructural protein p7. These particles seem to be intermediates in phage morphogenesis.

In order to get DNA encapsidation the tail protein p9 must be functional since infection with gene 9 mutants gives rise to prolate heads similar to the ones described above but containing, in addition to proteins p8, p8.5, p10 and p7, the nonstructural proteins p15 and p16. The latter is a DNA-packaging ATPase.

Once DNA encapsidation occurs, mediated by protein p16, the nonstructural proteins p7, p15 and p16 are no longer present in the assembly intermediates. The lower collar protein p11 is then assembled into the DNA-containing heads, followed by the tail protein p9, that requires the nonstructural protein p13 for functional assembly. Finally, the precursor of the neck appendages, p12*, once proteolytically processed into the mature protein p12, is assembled into the tail-containing particles.

A highly sensitive system for the *in vitro* assembly of phage ϕ29 has been developed. The system consists of: (1) recombinant procapsids obtained from *E. coli* extracts; (2) TP–DNA; (3) protein p16; (4) packaging RNA (pRNA; see below); (5) tail protein expressed in *E. coli* alone or coexpressed with the structural proteins of recombinant procapsids in *E. coli;* (6) extracts containing the coexpressed lower collar protein p11, the appendage protein p12 and the morphogenetic protein p13; (7) ATP.

DNA Encapsidation

In vitro encapsidation of TP–DNA has been obtained using extracts containing ϕ29 proheads and protein p16. Proteinase K-treated ϕ29 DNA is not packaged. Restriction nuclease digestion of TP–DNA shows that left end fragments of sizes ranging from 0.9×10^6 to 8×10^6 Da are selectively packaged. The packaging of a left end fragment of 4.1×10^6 Da (one-third of the genome) results in the exit of the scaffolding protein p7 from the proheads and the transition to the angular morphology characteristic of the complete ϕ29 particles. The oriented packaging from the left end is in agreement with the finding that this DNA end is the last to be released from the phage particles. When a system consisting of purified proheads and protein p16 is used, both left and right end TP–DNA fragments are packaged, although the efficiency of right end fragment packaging is about threefold lower than that of the left end. Internal fragments are also packaged, with efficiencies of 10–15%. Selective packaging of TP–DNA left ends is restored by the addition of bacterial cell extracts or glycerol.

The steps in *in vitro* packaging of TP–DNA in the purified system have been determined. Protein p16 first binds to and is modified by the prohead. The prohead–p16 complex then binds to TP–DNA and gives rise to a second modification of protein p16 that allows binding of ATP. The hydrolysis of ATP occurs concomitant with TP–DNA packaging. Binding and hydrolysis of ATP are dependent on both prohead and TP–DNA. Approximately one molecule of ATP has been reported to be used in the packaging of 2 bp of DNA. Protein p16 contains both the 'A-type' and the 'B-type' ATP-binding consensus sequences and the predicted secondary structure for ATP binding.

A small RNA 174 nucleotides long has been found in the proheads that are active for DNA packaging. Similar RNA has been isolated from the proheads of the ϕ29-related phages ϕ15 and SF5. Such RNA is not present in the mature virion. This small RNA is transcribed from the early A1 promoter, located at the left ϕ29 DNA end. During prohead purification 54 residues are removed from the 3′ end by nucleases giving rise to a 120 nucleotides-long pRNA fully active in prohead binding and DNA packaging. A conformational change of pRNA seems to occur in the presence of Mg^{2+} that leads to prohead binding. On the other hand, TP–DNA has a maturation pathway in which TP and the packaging protein p16 supercoil the DNA ends, probably as a prerequisite for efficient interaction with the prohead.

Both 5′ and 3′ ends of the 120 nucleotides-long pRNA are essential for DNA packaging and they become proximate in the formation of secondary structure. A deletion analysis showed that bases 6–113 comprised the minimum sequence required for full connector binding activity; connectors are the structural component in the procapsids to which pRNA binds. Bases 1–117 comprised the minimum sequence needed for full packaging activity. These data indicate that the helical region composed of bases 1–6 and 113–117 plays a crucial role in DNA translocation, but is dispensable for connector binding.

Mutant pRNA that prevents the formation of secondary structure at the 5′ and 3′ ends completely blocked *in vivo* phage assembly in cells expressing such a mutant pRNA. Phage ϕ29 assembly was also severely reduced *in vitro* in the presence of the mutant pRNA. On the other hand, mutation of the DNA packaging domain resulted in a pRNA with no DNA

packaging activity but intact procapsid binding capacity.

Six copies of the pRNA are present in the procapsids isolated from phage-infected cells. The pRNA associates with the procapsid during the DNA translocation process and leaves the procapsid after the DNA packaging reaction is complete. Evidence has been obtained that suggests that the six pRNAs per procapsid that are required for DNA packaging act consecutively. Breaking of any one of the individual links would ressult in the termination of the process.

Proheads of bacteriophage lambda, that contain the ϕ29 connector instead of that of lambda, have been obtained *in vitro*. The chimeric proheads can package both lambda and ϕ29 DNA. Thus, the connector domains involved in both head assembly and DNA packaging seem to be functionally similar in phages ϕ29 and lambda. Moreover, either the ϕ29 protein p16 or the lambda terminase complex can be used in the *in vitro* packaging system. Treatment of the proheads with RNAase A abolish packaging activity, that is restored by the addition of *E. coli* ribosomal RNAs. The DNA-containing λ–ϕ29 proheads can be complemented *in vitro* with ϕ29 proteins to yield infective particles capable of DNA transfer.

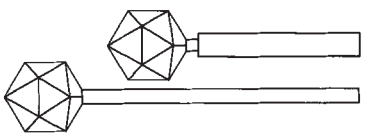
BACILLUS SUBTILIS PHAGES



H. Ernest Hemphill, Department of Biology, Syracuse University, Syracuse, New York, USA

Introduction

Bacillus subtilis and related species of bacilli are common inhabitants of the soil. This same environment has been the source of a large variety of phages which infect these bacteria. Most have been little studied and are poorly characterized, but there are a few generalities. All known *B. subtilis* phages contain double-stranded (ds) DNA; neither single-stranded DNA nor RNA phages have been reported. The virions of *B. subtilis* phages have icosohedral heads and are tailed; helical forms have not been discovered. *B. subtilis* phages are commonly grouped into virulent phages which infect cells and complete their life cycles within a well-defined period of time, and temperate phages which are able to lysogenize their host. A third category of convenience, 'pseudotemperate phages', includes virulent phages with an extended and irregular latent period that mimics lysogeny, but does not involve a stable prophage.

packaging activity but intact procapsid binding capacity.

Six copies of the pRNA are present in the procapsids isolated from phage-infected cells. The pRNA associates with the procapsid during the DNA translocation process and leaves the procapsid after the DNA packaging reaction is complete. Evidence has been obtained that suggests that the six pRNAs per procapsid that are required for DNA packaging act consecutively. Breaking of any one of the individual links would ressult in the termination of the process.

Proheads of bacteriophage lambda, that contain the ϕ29 connector instead of that of lambda, have been obtained *in vitro*. The chimeric proheads can package both lambda and ϕ29 DNA. Thus, the connector domains involved in both head assembly and DNA packaging seem to be functionally similar in phages ϕ29 and lambda. Moreover, either the ϕ29 protein p16 or the lambda terminase complex can be used in the *in vitro* packaging system. Treatment of the proheads with RNAase A abolish packaging activity, that is restored by the addition of *E. coli* ribosomal RNAs. The DNA-containing λ–ϕ29 proheads can be complemented *in vitro* with ϕ29 proteins to yield infective particles capable of DNA transfer.

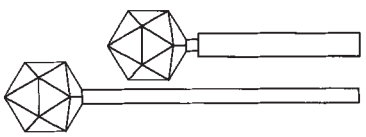
BACILLUS SUBTILIS PHAGES



H. Ernest Hemphill, Department of Biology, Syracuse University, Syracuse, New York, USA

Introduction

Bacillus subtilis and related species of bacilli are common inhabitants of the soil. This same environment has been the source of a large variety of phages which infect these bacteria. Most have been little studied and are poorly characterized, but there are a few generalities. All known *B. subtilis* phages contain double-stranded (ds) DNA; neither single-stranded DNA nor RNA phages have been reported. The virions of *B. subtilis* phages have icosohedral heads and are tailed; helical forms have not been discovered. *B. subtilis* phages are commonly grouped into virulent phages which infect cells and complete their life cycles within a well-defined period of time, and temperate phages which are able to lysogenize their host. A third category of convenience, 'pseudotemperate phages', includes virulent phages with an extended and irregular latent period that mimics lysogeny, but does not involve a stable prophage.

Table 1 Representative *B. subtilis* phages

Phage	Size (nm) Head	Tail	DNA size (kb)	Related phages	Comments
Virulent phages					
SPO1	87	19 × 140 plus 25 × 60 baseplate	145	SP82, ϕ25, ϕe, SP8	Hydroxymethyluracil replaces thymine in DNA
SP50	80	25 × 70	140	ϕ1	
SPP1	45	6.5 × 140	41	SF6	
ϕ29	31.5 × 41.5	6 × 32.5	1.9	ϕ15, NF	Virion DNA covalently linked to a terminal protein
Pseudotemperate phages					
PBS1	120	22 × 240	290	PMB12	Uracil replaces thymine in DNA
SP15	120	15 × 250	385		5-dihydroxypentyl uracil partially replaces thymine; DNA glucosylated
SP10	90	17 × 160	120	PMB1	DNA contains some α-glutamylthymine
Temperate phages					
ϕ105	52	10 × 220	40	ρ6, ρ10, ρ14	
SPO2	50	10 × 180	40		
SPβ	72 × 82	12 × 358	126	ρ11, ϕ3, Z, SPR, I61, I63, I64, H1	
PBSX	45	20 × 200	13	PBSZ	Defective phage, head contains bacterial DNA

The species *B. subtilis* includes strains which show considerable variation from one another, and the distinction between *B. subtilis* and related species such as *B. pumilus*, *B. amyloliquefaciens* and *B. licheniformis* is sometimes ambiguous. A particular phage may be capable of infecting strains labeled as different species, but unable to infect all isolates of *B. subtilis*. Most of the phages discussed here are able to productively infect *B. subtilis* strain 168. This bacterium is John Spizizen's original transformable *Bacillus*, and is thought to be derived from the type species *B. subtilis* Marburg. ϕ29 and SP16 which are included in this survey infect strain 168, but grow equally well or better on other species.

Table 1 lists some *B. subtilis* phages of current interest. Those in which the molecular biology and genetics have been analyzed in detail are considered below.

Virulent Phages

SPO1

Phage SPO1 is representative of a group of common phages distinguished by the fact that their DNA contains a base substitution of hydroxymethyluracil (hmUra) in place of thymine. The virion has an icosahedral head and a complex 140 nm tail; the latter includes a central tube and contractile sheath and terminates in an elaborate baseplate 25 × 60 nm. The head contains 145 kilobase-pairs (kb) of DNA, which includes a 12.6 kb region of terminal redundancy as a direct repeat.

Phage SPO1 (and relatives SP82, 2C and ϕe) contain a group I, self-splicing intron within the structural gene for the DNA polymerase essential for phage replication. The intron contains an open reading frame encoding an endonuclease, although one with unique cleavage and DNA preferences compared to 'homing' endonucleases known in other introns. The intron in SPO1 was the first reported in Gram-positive bacteria. Subsequently, another group I self-splicing intron was reported in the thymidylate synthetase gene of the unrelated *B. subtilis* phage β22.

RNA transcription in SPO1 is conveniently divided into three temporally distinguishable phases called early, middle and late, which are regulated by a cascade of 'sigma factors' that modify the bacterial RNA polymerase. Viral RNA synthesis begins about 1 min after infection from promoters of early genes located predominantly in the regions of terminal redundancy. The synthesis of early RNA is catalyzed by unmodified host RNA polymerase. As expected, the early promoters have consensus nucleotide sequences (allowing for the hmUra substitution) similar to those of *B. subtilis* chromosomal genes read by core polymerase in conjunction with σ^A, the primary host sigma factor. Among the early genes is one (gene *28*)

which encodes a 220 amino acid protein (gp28) that binds to the bacterial core RNA polymerase, partially replacing σ^A. Beginning 4 min after infection, the modified enzyme initiates transcription of middle genes by recognizing novel 'middle' promoters which precede these genes. These promoters have a consensus sequence quite different from those associated with early SPO1 genes. Two middle genes, *33* and *34*, encode proteins gp33 (101 amino acids) and gp34 (197 amino acids) which further modify the host RNA polymerase allowing it to initiate transcription from a third class of promoters preceding late genes. These, too, have a unique consensus sequence. As the SPO1 latent period progresses, not only are new transcripts synthesized, but early and middle genes are shut-off. The repression of middle genes appears to be at least partially associated with SPO1-encoded DNA-binding protein TF1, because mutations in the *TF1* gene continue to synthesize some middle gene products. TF1 protein binds preferentially to specific sites within the hmUra-containing SPO1 DNA, causing bending of the DNA. It is possible that this bending interferes with transcription of middle genes.

Host DNA, RNA and protein syntheses are almost completely suppressed by 6–8 min after SPO1 infection, although there is no detectable degradation of the bacterial genome. The inhibition of RNA synthesis is selective, with transcription of rRNA and the mRNA for ribosomal proteins continuing late into infection. It is likely the reduction of general protein synthesis results from the failure to produce associated mRNAs. At least some of the suppression of RNA synthesis is associated with the product of SPO1 gene *e3*, which appears to target the β subunit of RNA polymerase, possibly causing premature termination of transcription. Since early phage RNAs are synthesized using unmodified host RNA polymerase, it is possible E3 protein may also play a role in suppression of transcription of early phage genes as the infection progresses.

ϕ29

ϕ29 with a genome size of 19 285 base pairs is among the smallest dsDNA viruses. A total of 18 genes are known. Seven genes controlling early functions expressed immediately after infection are located at both ends of the genome, and are transcribed in the same polarity. Eleven late genes are located near the center of the genome, and are transcribed in opposite polarity on the complementary DNA strand from the early genes. The ϕ29 virion contains only seven types of structural proteins, but is surprisingly complex, with intricate head projections and tail appendages originating near the collar.

Synthesis of both early and late ϕ29 RNA is catalyzed by unmodified host RNA polymerase. The initiation of late transcription requires protein p4, the product of early gene 4. This protein apparently binds to ϕ29 DNA in the region of the single late promoter A3, and acts as a transcription activator of late genes. However, promoter A3 is located within a complex of early promoters A2a, A2b and A2c, and binding of p4 represses the transcription from A2b and A2c even as it activates late functions. Whether this repression has a regulatory role during infection is not clear, because p4 apparently simultaneously increases transcription from A3 and early promoter A2a. The latter is thought to serve as a promoter for the same genes as does A2b.

Several transcription terminators have been localized on the ϕ29 genome. All have stem–loop structures followed by uridine-rich sequences, suggesting transcription termination in ϕ29 occurs by a rho-independent mechanism. Variations in the efficiency of terminators may play a role in regulating the quantities of specific transcripts and their associated proteins made during the infection. Two promoters give rise to transcripts that do not contain open reading frames, and it has been proposed that these are antisense RNAs which downregulate certain late genes.

ϕ29 DNA molecules isolated from viral particles have a 31 kDa terminal protein (TP) covalently linked at the two 5′ ends, and are in the form of circles and concatamers. Proteolytic cleavage converts the DNA into unit-length linear molecules, but simultaneously results in loss of transfecting activity. This suggests the ϕ29 DNA–TP complex is required for DNA synthesis. In a purified system, synthesis of new DNA strands is initiated at either DNA end when free molecules of TP, in the presence of an already existing ϕ29 DNA–protein TP complex as template, react with dATP to form a phosphodiester bond between the hydroxyl group of a serine at position 232 on the protein and 5′-dAMP. The generation of this protein–nucleotide complex is one of two reactions catalyzed by ϕ29 DNA polymerase. Subsequently, the newly synthesized TP–dAMP covalent complex serves as a primer to provide the 3′-OH group needed for elongation of a new strand of DNA, a reaction also catalyzed by the ϕ29 DNA polymerase. *In vivo*, as many as six phage genes appear to be involved in DNA synthesis, although the functions of some are not clear. The product of viral gene *6* (p6) stimulates formation of the TP–dAMP initiation complex, and the product of viral gene *5* is probably a single-stranded DNA-binding protein.

ϕ29 has been the focus of extensive studies of virion assembly and morphogenesis. *In vitro*, a precursor

prohead composed largely of a single capsid protein and a portal protein packages the phage DNA when it is complexed to virus protein gp3. The packaging requires an ATPase (virus protein gp16) and a 120 base virus-encoded RNA. The latter binds to the portal vertex of the procapsid as an initial step in DNA packaging, but is not detected in the mature virion. Once the DNA is encapsidated in the head, the three proteins of the neck and tail can be assembled to yield the mature virion.

Pseudotemperate Phages

Pseudotemperate phages are a diverse group of essentially virulent phages sharing in common a life cycle somewhat resembling that of temperate phages. They produce turbid plaques; bacteria cultured from these plaques appear to be immune to superinfection with the same phage and release infectious virions into the surrounding medium. However, there is no evidence that the phage genome becomes integrated into the bacterial chromosome as a prophage, nor does the viral DNA appear to replicate as a plasmid in the manner of *Escherichia coli* phage P1. Indeed, given that many pseudotemperate phages have DNA base substitutions, neither form of stable prophage seems likely. Apparently, 'pseudolysogeny' results from a delayed or very extended latent period following penetration. Host macromolecular syntheses are not suppressed, cells continue to divide, and a high percentage of spores produced from infected *B. subtilis* cultures are cured of the virus. At any given time, however, some portion of the phage complete a lytic cycle, lyse the host bacteria and are released into the environment. Phage titers as high as 10^{10} ml^{-1} have been reported in cultures of SP10-infected bacteria. Cured cells which occur in a growing culture are probably quickly reinfected by these free virions, thus perpetuating the pseudolysogen. Many pseudotemperate phages also carry out generalized transduction.

There are great differences in size, morphology and DNA composition (including base substitutions) among pseudotemperate *B. subtilis* phages. This may suggest that pseudolysogeny is an incidental and unprogrammed variation on lytic infection. However, there are some intriguing suggestions that the relationship between host and parasite is more complex. Clear-plaque mutants with a reduced capacity to establish a carrier stage have been reported. Several pseudotemperate phages have been found to enhance wild-type sporulation, increase the sporulation frequencies of various oligosporogenic or sporulation-negative mutants, and/or relieve glucose-mediated catabolite repression of sporulation in some *Bacillus* species. Genetic analysis of *B. subtilis* strain W23 phage PMB12 indicates at least three genes are required for it to enhance host cell sporulation. *B. thuringiensis* phage TP-13 converts oligosporogenic, acrystalliferous mutants into a spore-positive phenotype which also produces the insecticidal crystal protein typical of this species.

PBS1

The most widely used pseudotemperate *B. subtilis* phage is PBS1, although this attention reflects its importance in mediating generalized transduction more than an interest in its life cycle. PBS1 is a very large phage (see **Table 1**), and its 190 megadalton genome contains a total base substitution of uracil in place of thymine. In contrast to most *B. subtilis* phages which adsorb to the cell wall, PBS1 attaches to the flagellum and will efficiently infect only highly motile strains of its host. The virion possesses helical tail fibers (8 × 125 nm) which probably fasten to the bacterial flagellum, but the mechanism by which the viral DNA penetrates the cell is unclear. Following infection, PBS1, possibly using a virion protein, apparently modifies some of the host RNA polymerase to a form which is resistant to rifampin and lipiarmycin, drugs which ordinarily inhibit this enzyme. Still later a completely new RNA polymerase is synthesized and used to transcribe late functions. What, if any, role these polymerase changes have in pseudolyogeny is unknown.

Temperate Phages

B. subtilis 168 is naturally lysogenic for the prophage of SPβ, and many other temperate phages for this bacterium have been isolated from soil. Although there is indirect evidence suggesting SP16 could exist in a plasmid state, the three temperate phages which have been studied in detail (ϕ105, SPO2, SPβ) have life cycles similar to that of *E. coli* phage lambda. Following adsorption, linear DNA is injected, cyclizes and then is apparently inserted into the bacterial chromosome by a reciprocal recombination between attachment sites *att*P and *att*B on the phage and bacterial genomes, respectively. The site of incorporation into the bacterial chromosome is specific for each phage; no transposon-like phages with multiple insertion sites similar to *E. coli* phage Mu have been found among *B. subtilis* phages.

ϕ105

Phage ϕ105 is representative of a group of small temperate phages that have been isolated by several investigators. The 26 MDa viral genome has complementary single-stranded cohesive ends ($cos_{\phi 105}$) of

seven bases. The linear DNA cyclizes following infection and the prophage inserts at 244° on the 360° circular *B. subtilis* chromosome map. The ϕ105 repressor gene *cI* encodes a 144 amino acid polypeptide, which in its active tetrameric form binds to six apparent operators, five of which are located near two promoters, P_M and P_R, that are proximal to gene *cI*. The repressor stimulates transcription from P_M which is the promoter for the repressor gene. The repressor inhibits transcription from P_R and thereby probably blocks synthesis of functions required to initiate a lytic cycle. The prophage can be induced by ultraviolet light or mitomycin C; temperature-inducible mutants with heat-sensitive repressors have been isolated. Induction begins with several rounds of prophage DNA replication before the prophage is excised from the bacterial chromosome. This DNA replication actually extends into nearby bacterial markers. Replicating ϕ105 DNA is concatenated, and appears to be replicated by host enzymes.

SPO2

Phage SPO2 is approximately the same size as ϕ105, and the two viruses share a 5.7 kb region of partial homology near the centers of their genomes. However, SPO2 prophage inserts at 15° on the circular *B. subtilis* 168 chromosome. The linear virion DNA has cohesive ends and apparently circularizes following injection. The SPO2 prophage is a circular permutation of the virion DNA. Unlike ϕ105 which uses the host's DNA polymerase III during lytic growth, SPO2 encodes its own DNA polymerase similar to bacterial DNA polymerase I. Although there is no evidence that SPO2 alters or replaces the host RNA polymerase, the lytic cycle involves several temporally distinguishable classes of mRNA.

SPβ

As already noted, *B. subtilis* 168 carries the prophage of a virus called SPβ. Small numbers of infectious virions are present in the supernatants of strain 168 cultures, and the phage can be induced with UV or mitomycin C. The 126 kb prophage extends from about 183° to 192° on the *B. subtilis* map, a region close to the terminus of chromosomal replication. The gene order in SPβ prophage is a circular permutation of the order of markers in the linear virion DNA. A 27 kb region of nonessential DNA overlaps the phage attachment site $attP_{SP\beta}$ and is the site of numerous deletion mutations. Lysogens of SPβ contain rare specialized transducing particles in which a portion of this nonessential region may be substituted by bacterial DNA.

SPβ is closely related to temperate phages ρ11, ϕ3T and Z. Collectively, phages of this group are noted for their converting properties. With the notable exception of SPβ itself, all carry a structural gene for thymidylate synthetase (*thy*P) that is expressed in the prophage state. Thymine auxotrophs of *B. subtilis* lacking this enzyme are converted into prototrophy following lysogenization with any of these phages except SPβ. Bacteria lysogenic for SPβ or Z release a bacteriocin (betacin) which kills nonlysogens of the same strain. The presence of SPβ prophage makes cells refractile to infection with unrelated virulent phage ϕ1*m*. This inhibition is mediated by the product of the prophage *mpi* gene.

During lytic growth, most SPβ-related phages produce DNA methyltransferases that methylate cytidylic acids within the palindromes recognized by restriction endonucleases *Hae*III, *Fnu*4HI and others. Isoschizomers of these enzymes are made by some strains of *Bacillus;* thus the methylations could protect the viral DNA when infecting new hosts. However, it has not been established that the phages themselves produce corresponding restriction endonucleases.

Defective prophages

When *B. subtilis* strains are exposed to UV or mitomycin C, virtually all release phage particles with notably small heads and large, complex tails. These phages are defective and cannot productively infect new hosts. The best studied is PBSX which is carried as a prophage by *B. subtilis* 168. (As noted above, strain 168 is also lysogenic for nondefective phage SPβ.) Virions of PBSX contain a random assortment of 13 kb fragments of bacterial rather that viral DNA. The phage particles adsorb to and kill *B. subtilis* strains not lysogenic for the homologous prophage. However, the method of killing is unknown; the apparent contractile tail of PBSX does not inject even the bacterial DNA contained in the head. Indeed, the tails alone are reported to act as bacteriocins. Immunity and sensitivity to the defective phages is probably related to differences in cell wall components, since there is no infecting phage DNA that might be the target of endogenous repressors. For example, PBSX binds to erythritol teichoic acid found in *B. subtilis* W23, and it kills this strain. The homologous defective phage PBSZ released by *B. subtilis* W23 kills *B. subtilis* 168, which contains glycerol teichoic acid in its wall.

The prophage of PBSX is located at 112° on the *B. subtilis* map, between the markers *met*A and *pho*S. More than 33 kb of PBSX DNA fragments have been cloned, an amount greater than could be contained in

the virion head. The fragments include the presumptive PBSX repressor gene *xre*, a replication origin, 21 kb of what appears to be a single 'late operon', and various probable 'early' genes. Expression of the defective prophage is precisely regulated. The repressor binds to four operators, two of which block putative promoters associated with genes involved in lytic functions, and two which may be involved in autoregulation of *xre*. Transcription of all late functions is apparently initiated from one promoter, P_L, and involves positive control factor, Pcf. The latter protein is the product of an early or middle gene, and has an amino acid sequence similar to known *B. subtilis* sigma factors.

As already noted, defective phages similar to PBSX are widespread in *B. subtilis* strains and related species of this genus. This may imply these prophages are maintained because they offer some benefit to their hosts, since the viruses themselves cannot establish new lysogens. It has been suggested that the bacteriocin activity associated with these viruses provides a competitive advantage against related species of bacilli. However, this presumed advantage requires altruism on the part of some bacteria in the deme or clone, because those cells which release the phage die. Others argue that a phage gene or a bacterial gene transposed into the prophage serves some vital function. However, if the latter is the case, it is difficult to understand why so much of the prophage has been maintained, given its lethal potential.

Generalized Transduction

The premier generalized transducing phage for *B. subtilis* is PBS1. A single virion of this virus can incorporate 5–10% of the bacterial chromosome, allowing linkage of quite distant markers. This was instrumental in constructing the circular map of the *B. subtilis* chromosome. PBS1 appears to encapsidate bacterial DNA randomly, and there is no evidence of preferred packaging sites (*pac* sites) such as occur in *Salmonella* phage p22. Transducing particles of PBS1 contain only bacterial DNA and differ in buoyant density from infectious virions; the two can be separated on CsC1 density gradients. Small DNA molecules such as plasmids are not efficiently transduced by PBS1, but can be transduced by the small virulent phage SPP1.

Generalized transduction has been observed with many pseudotemperate phages including SP10 and SP15. However, PBS1 remains the phage of choice both for consistency with previous studies and because linkage and genetic distances are better calibrated in this virus.

Specialized Transduction

Specialized transduction has been carefully studied in SPβ and related phages, but it is also mediated by ϕ105. Lysates of the SPβ contain small numbers of transducing phages carrying bacterial markers proximal to the normal attachment site $att\mathrm{B}_{\mathrm{SP}\beta}$. In addition, SP$\beta$ prophage occasionally becomes inserted at aberrant positions in *B. subtilis* deletion mutants lacking $att\mathrm{B}_{\mathrm{SP}\beta}$. Induction of these lysogens gives rise to specialized transducing particles carrying markers close to the novel sites of prophage integration. SPβ variants containing transposon Tn*917* have been constructed. During lysogenization such phages insert into Tn*917* transposons located throughout the *B. subtilis* chromosome, and subsequently can transduce nearby bacterial markers.

SPβ specialized transducing particles probably originate from errors of prophage excision in which a portion of the viral DNA is replaced by bacterial DNA. As a result, virtually all transducing particles are defective and cannot produce plaques on new hosts. Two types of transduction have been recognized in the SPβ system. In 'replacement transduction' the bacterial portion of the infecting DNA undergoes recombination with and replaces the homologous region of the genome of the recipient. In 'addition transduction' the infecting phage-bacterial DNA becomes incorporated as a prophage, resulting in a bacterium diploid for the *B. subtilis* markers carried on the prophage. Addition transduction apparently occurs more readily if the recipient is already lysogenic for SPβ.

Transfection

When grown in a minimal salts medium, *B. subtilis* 168 becomes competent for the uptake of exogenous DNA, including DNA of bacteriophages (transfection). However, the process by which DNA enters the cell has been explored most thoroughly in transformation. In the latter, one strand of transforming DNA is hydrolyzed in the process of penetrating the cell wall and membrane, resulting in a single-stranded product in the cytoplasm. This DNA then displaces the homologous strand of the chromosomal DNA while hydrogen-bonding to the complementary strand.

It is assumed that transfecting viral DNA is also subject to degradation by nucleases during entry into the competent bacterium. Even when very high molecular weight SPO1 or SP82 DNA is used, completion of a lytic cycle and formation of new virions occurs only if the target cell incorporates several intact copies of the viral DNA. These

presumably undergo recombination with each other to form at least one functional genome which eventually yields progeny phage. Fragmented phage DNA can be used in marker rescue experiments in which competent cells are first exposed to phage DNA and then infected with mutant phage lacking the gene function to be rescued.

Transfection of ϕ29 DNA may proceed differently. DNA of this phage treated with proteolytic enzymes loses transfecting activity. This suggests the terminal protein on the ϕ29 genome enters the competent bacterium to continue its role in DNA synthesis.

Protoplasts of *B. subtilis* can be transfected with phage DNA in the presence of polyethylene glycol. In this situation, the viral DNA is apparently not degraded, and protoplast transfection is used in recovering viable phage following incorporation of cloned DNA into phage vector systems.

Phage Vectors for Gene Cloning

A number of *B. subtilis* phages have been examined as potential cloning vectors, but most useful are ϕ105 and SPβ. The genomes of both these phages have regions not required for lytic growth which can be replaced by cloned DNA.

Several strategies have been used in cloning DNA in *B. subtilis* phages; three are considered here. In 'direct transfection', ϕ105J119 DNA (ϕ105J119 is a variant of ϕ105) is circularized *in vitro* by ligating its complementary single-stranded cohesive ends. The vector is then again linearized by digesting with a restriction endonuclease such as *Sal*I, which cuts a unique site in the DNA. The target DNA is restricted with *Mbo*I. To prevent the DNA of vector and target from self-ligating, the unique cohesive ends of each are partially filled-in using the Klenow fragment of DNA polymerase I and, respectively, dCTP and dTTP or dATP and dGTP. The target DNA and ϕ105J119 vector are then ligated together and transfected into protoplasts of *B. subtilis*. The progeny phages that arise from transfected cells constitute a library of recombinant DNAs which subsequently must be screened to locate the desired clone.

A second cloning strategy called 'prophage transformation' has been used with a number of phages including ρ11 and ϕ105. The phage DNA and (usually) wild-type *B. subtilis* chromosomal DNA are digested with the same restriction enzyme. The two are then mixed together and ligated to form a mixture of phage–bacterial DNA hybrids. The latter is then used to transform an auxotrophic strain of *B. subtilis* already lysogenic for the temperate phage being used as a cloning vector. Protrophic transformants are selected on an appropriate medium; many of these transformants have the bacterial DNA inserted into the prophage. A small fraction of the latter can be induced to release nondefective specialized transducing phages carrying the selected marker. Lysates of such phage are a potential source of the cloned DNA.

A third strategy involves plasmid pCV1, a vector which contains a cloning site between two regions of homology to transposon Tn*917*. The plasmid is treated with both *Bam*HI and *Sst*I to produce equal amounts of two vector arms, which have Tn*917* sequences on their respective left or right ends. These are ligated to target DNA digested with *Sau*3A to form a mixture which includes some Tn*917*–left vector arm–target DNA–right vector arm–Tn*917* concatemers. These are then transformed into *B. subtilis* lysogenic for SPβ*c*2 *del*2::Tn*917*, a heat-inducible deletion mutant of SPβ which also contains transposon Tn*917*. The latter acts as a region of homology for the transforming DNA, some of which becomes inserted into the prophage. The transformants are selected for resistance to chloramphenicol which is conferred by a gene on plasmid pCV1.

Future Perspectives

Historically, interest in *B. subtilis* phages centered on using these viruses in genetic studies of their host. PBS1 was vital in creating a linkage map of the *B. subtilis* chromosome. Later SPO1 and SP82 were prototypes for understanding control of genes through manipulation of sigma factors, and continue to be useful in studies of how phages alter host functions. Interest continues in ϕ29 gene regulation, transcription activators and the terminal protein involved in DNA replication in this phage. ϕ29 and SPP1 are important models for the study of how DNA is encapsidated in phage heads. The discovery of specialized transduction and the development of techniques for cloning in phage have been and are likely to continue to be important in determining how *B. subtilis* regulates transcription, particularly of genes associated with sporulation.

Included in the genus *Bacillus* are bacteria which produce useful enzymes, some of which synthesize insecticides or are themselves insect pathogens, and a few capable of infecting vertebrates. All of these are parasitized by phages, including transducing phages, similar to those studied in *B. subtilis* 168. Attempts are being made to genetically manipulate these bacteria to increase production, insect pathogenicity, host ranges of insecticides, and to understand the nature of pathogenicity. Both phage and plasmid vectors are likely to play an important role in these studies.

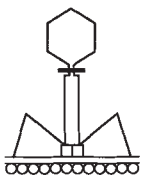
BACTERIAL IDENTIFICATION — USE OF PHAGES



Michael S. DuBow, McGill University, Montreal, Quebec, Canada

Introduction

Bacteriophages have been used in bacterial identification and classification since the pioneering work of Sonnenschein in 1925. The specificity of phage adsorption and lytic propagation on bacterial species and strains made them ideal agents for bacterial identification and the process, known as 'phage typing', is still an important use of bacteriophages. Between 1987 and 1991, at least 45 papers per year using phage typing were published.

In the middle twentieth century, phage typing was as popular as other means of bacterial identification, including biochemical/physiological markers and serological tests, but biotechnological advances have led to its diminished importance over the last decade. However, phage typing is frequently used in the 'battery of tests' approach to bacterial identification.

The main advantages of phage typing are relative ease of use and lack of necessity for sophisticated equipment. Many of the sets of typing phages are extremely stable, readily available, and can be stored for long periods. Additionally, automated phage typing allows rapid performance of multiple tests, a particular necessity in clinical situations. Phage typing also has industrial and environmental applications where it is desirable to keep track of a limited number of bacterial species and/or strains. Bacterial strains causing a particular industrial or epidemiological problem may differ from other strains in only a limited number of characteristics, and phages can be used to track these. Such characteristics include the presence of a particular surface antigen which the phage may use as an adsorption site, a particular restriction and modification system of the host, or even the presence of a particular temperate phage. These host characteristics may play a role in the complete lytic development of the phage after infection, and their absence or presence can be rapidly detected by the growth (or lack thereof) of a particular set of typing phages. As knowledge of bacterial characteristics improves, phage typing may also develop through the use of new and/or mutant phages for the characterization and identification of bacterial species and subspecies.

History

Throughout the 1920s and 1930s, many phages were isolated for use in the identification and classification of bacterial species and strains. It was found that few phages were capable of lysing all strains of a bacterial species, and also that many enterobacterial phages

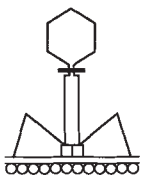
BACTERIAL IDENTIFICATION — USE OF PHAGES



Michael S. DuBow, McGill University, Montreal, Quebec, Canada

Introduction

Bacteriophages have been used in bacterial identification and classification since the pioneering work of Sonnenschein in 1925. The specificity of phage adsorption and lytic propagation on bacterial species and strains made them ideal agents for bacterial identification and the process, known as 'phage typing', is still an important use of bacteriophages. Between 1987 and 1991, at least 45 papers per year using phage typing were published.

In the middle twentieth century, phage typing was as popular as other means of bacterial identification, including biochemical/physiological markers and serological tests, but biotechnological advances have led to its diminished importance over the last decade. However, phage typing is frequently used in the 'battery of tests' approach to bacterial identification.

The main advantages of phage typing are relative ease of use and lack of necessity for sophisticated equipment. Many of the sets of typing phages are extremely stable, readily available, and can be stored for long periods. Additionally, automated phage typing allows rapid performance of multiple tests, a particular necessity in clinical situations. Phage typing also has industrial and environmental applications where it is desirable to keep track of a limited number of bacterial species and/or strains. Bacterial strains causing a particular industrial or epidemiological problem may differ from other strains in only a limited number of characteristics, and phages can be used to track these. Such characteristics include the presence of a particular surface antigen which the phage may use as an adsorption site, a particular restriction and modification system of the host, or even the presence of a particular temperate phage. These host characteristics may play a role in the complete lytic development of the phage after infection, and their absence or presence can be rapidly detected by the growth (or lack thereof) of a particular set of typing phages. As knowledge of bacterial characteristics improves, phage typing may also develop through the use of new and/or mutant phages for the characterization and identification of bacterial species and subspecies.

History

Throughout the 1920s and 1930s, many phages were isolated for use in the identification and classification of bacterial species and strains. It was found that few phages were capable of lysing all strains of a bacterial species, and also that many enterobacterial phages

were capable of lytically infecting more than one bacterial species. It was also discovered that surface antigens of the bacterium (identified serologically) could be correlated with phage sensitivity or resistance. Different colony-specific morphologies of bacterial strains were shown to correlate with growth of a particular phage, and these characteristics were useful in understanding microbial pathogenicity as well as virus–host interactions.

The discovery in 1934 of the Vi antigen on the surface of the typhoid bacillus *Salmonella typhi* led to the isolation of Vi phages capable of lysing the typhoid bacillus, but only if it expressed the Vi antigen. These phages made possible the differentiation and typing of this medically important bacterial species. In 1938, Craigie and Yen isolated a phage called ViII that would only grow on the previous strain from which it was propagated. This 'adaptation' allowed them to recognize and differentiate 11 types of the typhoid bacillus. This method of phage typing was soon standardized and achieved wide acceptance in the field.

Many other phages were isolated for phage typing schemes for both gram negative and gram positive bacterial strains. Most phage typing schemes are for bacteria of medical significance. However, there are phage typing schemes for bacteria involved in industrial fermentations and cheese formation. Although not phage typing *per se*, bacteriophages can be used as indicators of contamination by their hosts, for example the use of coliphages to detect fecal contamination of water.

The Technique

The first requirement for phage typing is phages that can discriminate between the bacteria under study. The phages are generally stored and used as sterile lysates. However, some are stable when dried, and can be placed on filter paper discs where they may be spotted using dispensers similar to those used in antibiotic sensitivity testing. The bacterial culture is spread as a lawn on the surface of a nutrient agar petri dish and, after drying, phages are spotted on to particular areas of the petri dish in a recognizable pattern. After incubation for 5–48 h, the lawn of bacteria is scored for areas of lytic growth of phages, and the particular phages that cause or do not cause lysis are noted. The degree of lysis and the size and morphology of the plaque can be important criteria for differentiating bacterial species and strains.

Automation of phage typing includes a variety of machines for the withdrawal and placement of the phages on to the bacterial lawn. In recent years, several machines have been designed that use trans-illuminant light to examine the petri dishes via computer scanners. Cluster analysis of the different lytic reactions is then carried out, and a computer printout giving probable bacterial identification is provided.

The development and use of the routine test dilution (RTD) concept was crucial for the establishment of phage typing. RTD is generally defined as the lowest dilution of the phage lysate that yields complete lysis of the particular test strain and/or bacterial strain used for phage propagation. It is important in preventing 'lysis from without' which can occur at high multiplicities of infection giving rise to false positives (or negatives) in phage typing. RTD avoids the problem of contaminating bacteriophages in the phage lysate lysing the bacteria and so obscuring the results. The use of the RTD prevents interference by any phage host-range mutants arising.

Isolation of Typing Phages

Phages are generally isolated from the environments in which the host bacterial strain under study ordinarily grows and lives, e.g. from sewage, feces, soil, water or, in the case of temperate phages, from the bacterium itself. The phages to be used in a typing scheme can have several properties, not all of which need to be common to all of the phages. For example, one may want to have a phage that can lytically grow on all strains of a particular species and thus provide positive identification for that species, in addition to phages that can discriminate between the subspecies or strains of a particular bacterial species. The levels of specificity and discrimination required will depend upon the needs of the particular phage typing scheme to be developed.

Lytic phages form clear plaques due to the complete lysis of the host, and these plaques are easier to score than the turbid ones of temperate phages. Nonetheless, temperate phages can discriminate between strains that are lysogenic for homoimmune phages and those that are not. If lytic phages are unavailable for the particular strain to be identified, then the culture may either be irradiated to induce any prophages that may be present, or the bacterial cell-free supernatant may be examined for any spontaneously induced temperate phages.

The host strain that will be used for propagation of the typing phages is also of importance. The term 'adapted phages' refers to the process of propagating a particular phage on a particular bacterial host. This can be used to select for host-range variants of a phage that will allow for increased discrimination by the typing scheme. It may also be useful in isolating phages whose DNA is modified according to the

pattern of DNA modification enzymes present in a particular host strain. The numerous restriction and modification systems of species and subspecies of bacteria make adapted phages useful and extend their powers of discrimination and specificity.

Many plasmids encode functions that can inhibit or enhance the growth of particular bacterial phages. For example, the F plasmid inhibits the lytic growth of phage T7, yet is necessary (due to the F pilus as the adsorption organelle) for the growth of male specific phages (e.g. Qβ, M13) in the bacterium *E. coli*. If a phage can or cannot be propagated on a particular strain, then this characteristic may be used to detect the presence or absence of a plasmid that encodes a particular determinant.

Phages used in phage typing must be stable, grow quickly enough and yield reproducible lysis and plaque morphology; there must be a sufficiently large number of different phages for adequate classification and identification for the bacteria under study; and the results of the typing scheme should be reproducible.

Host Characteristics and Typing Phages

The experimental end-point of phage typing schemes is the determination of which phages can and which cannot undergo a productive lytic infection of a particular bacterial isolate. These typing schemes are not only useful for bacterial identification but, with sufficient knowledge, can yield important information about the underlying genetics and physiology of the particular bacterial strain.

If one is using a typing scheme that includes temperate phages, then the capacity of these phages to grow may indicate the presence of a particular prophage which displays immunity (or pseudoimmunity) to superinfection. In *E. coli*, the presence of a λ prophage can be tested by the incapacity of λ phage to grow on that strain, as well as the incapacity of a mutant of the lytic phage T4 (T4rII) to grow due to the expression of the *rex* genes from the λ prophage. Many phages require bacterial appendages encoded by plasmids for their adsorption to the host cell, and inclusion of these phages in a typing scheme can allow discrimination between strains that contain these plasmids and those that do not. As many bacterial pathogenicity determinants are encoded by plasmids, this may be of clinical significance.

Lytic phage growth is dependent upon the presence of particular surface antigens (receptors) for phage adsorption. These surface antigens may include not only proteins located on the outer surface of the bacterium, but also lipopolysaccharides and capsules. Thus, phage typing schemes can track important surface properties of the bacterium that may be crucial in understanding bacterial spread and pathogenesis as well as the origins of a particular strain. Phages are dependent upon host cell physiology to complete their lytic cycle, and many parameters that are important epidemiologically can be discriminated and selected with the appropriate phage type. Examples of this include host-controlled restriction and modification systems, the presence of particular plasmids and plasmid-encoded gene products, as well as the enzyme systems required for the transcription, translation and replication of the viral genome and its assembly into a mature capsid followed by lysis of the host cell.

Rapid and automated tests that measure bacterial fermentation and growth on particular substrates, the use of monoclonal antibodies, sodium dodecyl sulfate–polyacrylamide gel electrophoresis (SDS–PAGE) patterns of bacterial proteins, as well as restriction fragment patterns and DNA probes for bacterial and gene identification are some of the technologies that are increasingly popular in microbiology. Also important is the use of the polymerase chain reaction (PCR) where a particular gene target whose DNA has been sequenced is the focus of study. Nonetheless, phage typing will continue to be an important tool for the rapid and accurate identification of a particular microorganism. The continued popularity of phage typing rests with its ease of use, capacity for automation, low cost and long history, with many typing phages and schemes present in the literature and widely available. Where one does not have access to sophisticated technology, phage typing has proved to be a method of choice for bacterial identification and tracing.

synthesis occurs during infection, due in part to the accumulation of large amounts of RNA 2 which is a very active messenger.

A small fraction of cultured *Drosophila* line 1 cells routinely survives infection with FHV and on examination the cells are found to be persistently infected. Viruses isolated from persistently infected cultures replicate poorly even in fresh cells, because their coat protein genes have accumulated multiple mutations. However, the establishment of persistence has been attributed to cellular changes rather than the mutations in the viral capsid gene which arise later. Defective viral RNAs that have suffered substantial deletions and rearrangements can be isolated from viruses harvested from persistently infected cultures, and the structures of these RNAs may provide insight into the *cis*-acting sequences necessary for RNA replication and encapsidation.

Epidemiology and Pathogenesis

The readiness with which alpha nodaviruses establish persistent infections in cell culture probably reflects their propensity to establish inapparent and persistent infections in their insect hosts. These infections can reduce egg viability and slow the development of the host without causing significant mortality. Under other conditions, such as overcrowding of the host, however, nodaviruses cause epizootic infections with high mortality. Such infections can be economically damaging in the case of SJNNV disease among hatchery-reared fish larvae. Large numbers of SJNNV particles are found in the brain and other cells of the central nervous system, and the infected larvae show abnormal swimming behavior and nervous necrosis.

Intraperitoneal inoculation of NOV into mice less than about 14 days old causes severe hind limb paralysis due to replication of the virus in the hind limb musculature and degeneration of spinal cord neurons. Mice inoculated when they are older than about 21 days show no signs of disease. It is not clear whether this change is due solely to the development of a responsive immune system, but 7-day-old mice born to or suckled by immunized mothers are completely resistant to intraperitoneal challenge with NOV. In wax moth larvae, NOV replicates predominantly in muscle cells, but cells of many other tissues are also susceptible to infection which kills the larvae.

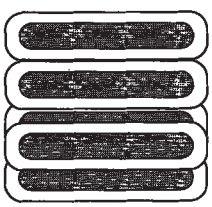
NONOCCLUDED BACULOVIRUSES



John P Burand, University of Massachusetts – Amherst, Amherst, Massachusetts, USA

History

The nonoccluded baculoviruses (NOB) are a loosely associated group of enveloped, rod-shaped viruses which, in many respects resemble the occluded baculoviruses except that they are not found associated with a protein crystal occlusion body. Only three NOBs have been studied to any significant extent. The first NOB to be identified was the *Oryctes* virus (Or-1V). The isolation of this virus resulted from a field study conducted throughout Southeast Asia in 1963, to find an agent that could be used to control the rhinoceros beetle, *Oryctes rhinoceros*, a pest on tropical palm plantations in the South Pacific. The virus was not naturally occurring in areas of the South Pacific where *O. rhinoceros* had been accidentally introduced and had become a pest. Since its initial discovery the virus has been found in insect populations in the Philippines, Sumatra, West Kalimantan, Thailand and India. Today, the virus is used to control beetle populations and serves as the best model for the use of a virus for insect pest control.

The newest addition to the NOB group is the Hz-2 virus (Hz-2V) or gonad-specific virus (GSV) which was identified in 1995 in electron micrographs of reproductive tissues from *Helicoverpa zea* moths, originating from a bollworm colony that was established at the USDA-ARS Southern Insect Management Laboratory in Stoneville, Mississippi. Adults from this colony showed lower than normal oviposition rates, and the symptoms of Hz-2V infection in these insects were described as atrophy of ovarian and testicular organs. These abnormalities could be transmitted to progeny insects by both diseased males and females and occurred in 63–78% of the individuals throughout five successive generations of insects.

The best characterized NOB is the Hz-1 virus (Hz-1V). Hz-1V was first identified in 1978 as a persistent agent in IMC-Hz-1 cells. This cell line was originally established from adult ovarian tissues of *H. zea* and attempts to infect these cells with other baculoviruses resulted in death of the cells without occlusion body formation. In retrospect, this was probably due to induction of the persistent Hz-1 virus. The first indication that IMC-Hz-1 cells were persistently infected with a virus came from observations made in 1972, that long, virus-like particles were visible in electron micrographs of these cells. In addition, these cells were found to periodically undergo a crisis phase where a large number of the cells became granulated and died. The virus persisting in these cells was eventually recovery and propagation in *Spodoptera frugiperda* (IPLB-SF-21) and *Trichoplusia ni* (TN-368) cells by Granados in 1978.

Properties of the Virion and Genome

All of the NOBs are rod-shaped enveloped particles with supercoiled, double-stranded DNA genomes ranging in size from 130 kilobase pairs (kb) for Or-1V to 220 and 230 kb for Hz-2V and Hz-1V, respectively. The genomes of both Or-1V and Hz-1V have been physically mapped and six regions of reiterated sequences were identified on the Or-1V genome. No such regions have been identified for either the Hz-1V or Hz-2V genome.

The Or-1V enveloped virus particle is 220 × 120 nm and has been reported to have a tail-like structure at one end.

Virion Proteins

The virus is composed of 27 structural proteins ranging in size from 9.5 to 215 kDa. A total of 14 of these proteins are thought to be envelope proteins. Hz-1V is longer and narrower than the Or-1V measuring 414 × 80 nm and is composed of 28 structural proteins ranging from 150 to 14 kDa in size. Of these proteins 14 are thought to be envelope glycoproteins since they were found to be radioactivity labeled in virus grown in the presence of N-[^{3}H]acetylglucosamine and [^{3}H]mannose. Hz-2V is also about 415 × 80 nm in size and is composed of only about 12 structural proteins. The envelope of Hz-2V is distinctive in that it appears to be slightly irregular with folds or ridges associated with individual filaments of approximately 5 nm in diameter located between the envelope and the nucleocapsid.

Replication

Or-1V replication has been studied *in vitro* using a cell line derived from the black beetle, *Heteronychus arator* (DSIR-HA-1179). Virus entry into these cells is thought to occur by pinocytosis and the first sign of viral cytopathic effect (CPE) is the rounding of these normally fibroblast-like cells, with complete cell lysis occurring by 3–4 days postinoculation (dpi). The first signs of virus replication, which include nuclear hypertrophy and migration of nuclear chromatin occur by about 7 hours postinfection (pi). Envelope material then accumulates in chromatin-free areas in the nucleus. Virus assembly begins with the formation of envelopes and nucleocapsid shells in the chromatin-free areas. The shells are then filled with an electron-dense core containing the viral DNA. Virus replication peaks at between 12 and 36 h pi. Virus particles enter the cytoplasm during this time, and are ultimately released from the cells by budding from the cytoplasmic membrane.

Eight of the reported 27 Or-1V structural proteins were detected in virus-infected, HA cells pulse labeled with [^{35}S]methionine. The two structural proteins, p4.6 and p10 were first detected at 4 hpi whereas the p11.5 protein was first detected at 10 hpi. The remaining six viral proteins p46.5, p40, p27, p25, p22 and p13 were all first detected at 6 hpi. Since Or-1V does not actively shut off HA cell protein synthesis during replication, the inability to detect the synthesis of the remaining virus structural proteins or any additional virus-induced intracellular proteins may be due to the presence of a large number of labeled cell proteins found in these samples. It is also possible that the remaining proteins contained a low level or were completely lacking methionine residues.

The CPE of Hz-1V replication in TN-368 cells begins with the rounding of the cells followed by nuclear hypertrophy. Virus replication and assembly takes place in the nucleus of infected cells in a manner similar to that observed for Or-1V. First, membrane vesicles appear in the nucleus, then these vesicles are filled with electron-dense capsids containing viral

DNA, giving rise to mature enveloped nucleocapsids. Virus replication culminates with release of infectious virus through the lysis of both the nuclear and cytoplasmic membranes. Enveloped virus particles inside the cell are complete and infectious prior to release by lysis.

The replication cycle of Hz-1V has been divided into three stages; an early stage, from 0 to 4 hpi, which is prior to the onset of viral DNA replication, an intermediate phase, from 4 to 8 hpi and a late phase, beyond 8 hpi. Pulse labeling of Hz-1V-infected cells with [^{35}S]methionine revealed a total of 37 virus-specific intracellular proteins. The sequential expression of these viral-induced proteins appears to follow a cascade pattern very reminiscent of the pattern of viral protein synthesis found in insect cells infected with occluded baculoviruses. One of the Hz-1V-induced proteins was first detected at 2 hpi and 25 others were detected first by 7 hpi. All remaining 11 viral-specific proteins were first detected after 8 hpi. Although not clearly demonstrated, it appears likely that the viral-specific proteins synthesized early during virus replication are required for the expression of proteins made later during Hz-1V replication. The pattern of expression of the viral-specific intracellular proteins differs in cells infected with defective interfering particles (DIPs), compared to the pattern of protein synthesis found in cells infected with standard virus particles. Infection of cells with DIPs has been shown to lead to the establishment of cell lines persistently infected with Hz-1V. At the present time it is unclear what this difference in the pattern of expression of viral proteins means or how it is related to the establishment of persistently infected cell lines by Hz-1V.

During productive Hz-1V replication, a total of 101 viral-specific transcripts ranging in size from 0.8 to over 9.5 kb in length have been detected. These transcripts map to dispersed regions along the viral genome and follow a pattern of temporal expression similar to that of virus-specific intracellular proteins. Of the 24 viral transcripts detected at 2 hpi, only three are highly expressed and one, a 2.9 kb transcript, is constitutively expressed (CE 2.90) throughout virus replication. An additional 30, 21 and 16 viral transcripts are made at 4, 6 and 8 hpi, respectively, and no new viral transcripts are made at later times after infection.

Two Hz-1V late genes have been characterized. The first was the p34 gene which is located between 50.3 and 52.5 map units on the viral genome, and which contains a 765 nucleotide (nt) open reading frame (ORF) capable of encoding a 34 kDa polypeptide. The second, is the p51 gene which maps between 40 and 44.6 map units, and contains a 1152 nt ORF potentially coding for a 51 kDa protein. The upstream, 5′ regulatory regions of both p34 and p51 have a conserved nine base sequence TTATAGTAT which is thought to contain the Hz-1V late promoter. Transcripts from both these genes (two transcripts of p34 and the major transcript of p51) were found to be initiated at sites within this nonanucleotide sequence. This putative, late, promoter sequence identified for Hz-1V late genes, is significantly different from the late baculovirus promoter motif NTAAG, suggesting that the transcription of Hz-1V late genes occurs differently from that of late, occluded baculovirus genes and likely via a different viral RNA polymerase.

Pathology and Transmission

Infection of *O. rhinoceros* larvae by Or-1V occurs primarily through the consumption of virus contaminated food, whereas adult insects can become infected when visiting contaminated breeding sites. The virus can also be transmitted by adults during mating, most likely through oral contact with virus from an infected partner. Midgut epithelial cells of both larvae and adults are the primary site of replication and from there the virus spreads to other tissues including the fat body. In larvae, virus replication in the midgut epithelium leads to the appearance of chalky white bodies under the abdominal integument just prior to death of the insect. The abdomen of infected larvae may become turgid and glassy or pearly in appearance. Eventually the fat body disintegrates and the larvae appear translucent.

The disease is commonly fatal in larvae and pupae as well as in adult beetles, however, in adults the infection is often more chronic with infected insects showing no external symptoms of the disease. Virus replication in the adult results in a tumor-like growth of densely packed, virus-filled cells in the midgut which appears swollen and whitish in color. The gut of infected beetles then, becomes filled with virus particles which are eventually defecated. Soon after infection, feeding and egg laying ceases, however, infected adults are capable of flying and mating. Infected beetles usually die within 30 days of infection. During this time these insects can serve as reservoirs and are capable of spreading the virus, via contaminated feces, when visiting breeding sites. Once it was determined that the virus was carried to breeding sites by infected adults, the virus was introduced as a control agent, into pest populations, simply by releasing virus-infected beetles. These releases led to dissemination of the virus in the population and long-term suppression of the rhinoceros beetle on islands in the South Pacific and in Tanzania. Today, a natural equilibrium appears to be

established between the level of the virus and the beetle population in these release sites with virus prevalence fluctuating between 30 and 50%.

The agonadal condition caused by Hz-2V results in female moths having enlarged common and lateral oviducts, a deformed bursa copulatrix and malformed or missing ovaries, accessory glands and/or spermatheca. Affected males have very small testes and are lacking seminal vesicles, vasa deferentia and/or accessory glands. These individuals are sterile and most infected females have a white, 'waxy plug' protruding from the vulva. This plug contains a high concentration of virus particles located inside vesicles which resemble baculovirus occlusion bodies but which lack the dense protein matrix characteristic of occlusion bodies. The replication of Hz-2V appears to be confined to reproductive tissues since the virus is readily observed in the nucleus of cells in these tissues and has not been found in any other tissues of infected animals.

Although most adult moths infected with Hz-2V exhibit agonadal pathology and are sterile, some infected individuals are fertile and can transmit the virus during mating. Both males and females can be asymptomatic carriers of the virus and are capable of transmitting the virus to progeny insects. Larvae and pupae from matings between Hz-2V carriers and uninfected moths appear normal, however, some emerge as sterile, agonadal, adults. Male and female moths injected or fed Hz-2V prior to mating can also transmit the virus to progeny insects. Moreover, it is also possible for the virus to be transmitted on the surface of eggs and by feeding or injecting it into larvae.

Persistence

Without the protection provided by a protein crystal occlusion body, typical of occluded baculoviruses, NOBs are rapidly inactivated outside their insect host. The limited survival of these viruses outside the host has led to the evolution of modes of transmission involving a closer association between them and their host which often involves the virus becoming latent or persistent. Or-1V, for example, is transmitted primarily through fecal contamination of nesting sites, whereas Hz-2V is sexually transmitted during matings with infected male or female moths. Not only is Hz-1V capable of productive replication in insect cells, but it is also able to establish persistent infections in cell culture. The persistence of Hz-1V is mediated by DIPs and involves the expression of a single 2.9 kb viral transcript known as the persistently associated transcript (PAT1). PAT1 is constitutively expressed in cells persistently infected with the virus and its expression is required for the establishment and maintenance of Hz-1V persistent infections. The unique biology of Hz-2V also involves a close association between the virus and its host with the virus remaining in a latent state throughout a major portion of the life cycle of the infected insect. The successful use of Or-1V for insect control is due largely to the close association it has with its host and its persistence in rhinoceros beetle populations. This success also suggests that other NOBs have potential for future use in insect pest control programs. Since the NOBs Hz-1V and Hz-2V can establish persistent associations with their hosts, these viruses also have potential for use as models not only for use in gaining information on the nature of viral persistence but also for use as tools for altering the genetic make-up of insects.

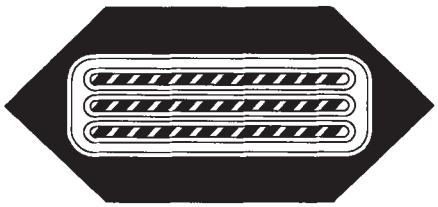
BACULOVIRUSES (*BACULOVIRIDAE*)



Contents

Granuloviruses

Doreen Winstanley, Horticulture Research International, Wellesbourne, Warwick, UK

David O'Reilly, Imperial College of Science, Technology and Medicine, London, UK

Introduction

The *Baculoviridae* are a family of large DNA viruses found only in invertebrates. They are characterized by the possession of a rod-shaped nucleocapsid (hence 'baculovirus', from *baculum*, meaning rod), a circular double-stranded DNA genome, and the ability to form proteinaceous occlusion bodies within infected cells. The family is subdivided into two genera, the genus *Granulovirus* (GVs) and the genus *Nucleopolyhedrovirus* (NPVs). The granuloviruses (or granulosis viruses) have only been isolated from the larvae of lepidopteran insects (butterflies and moths). The term 'granulosis' derives from the characteristic granular appearance of cells infected by these viruses, due to the presence of large numbers of occlusion bodies within the cells.

Taxonomy and Classification

The subdivision of the family *Baculoviridae* into genera is based on occlusion body morphology. NPVs form large polyhedral occlusion bodies that contain multiple virus particles, whereas GVs form a much smaller, ovoid occlusion body that generally only contains a single virion. Below the genus level, GVs have traditionally been assigned a species name solely on the basis of the host species from which they were first isolated. This is rather unsatisfactory from a taxonomic viewpoint because examples both of individual GVs infecting multiple hosts, and several distinct GVs infecting the same host, are not uncommon. In practice, it is necessary to confirm the identity of a GV isolate by restriction endonuclease mapping of its genome. In recent years, the increase in the amount of sequence data available for baculoviruses has enabled preliminary studies of the phylogeny of this virus family. Such studies have now been carried out using the sequences of several different genes (e.g. polyhedrin/granulin, **Fig. 1**). These studies uniformly confirm that the NPVs and GVs represent two well-separated clades, suggesting that the divergence of baculoviruses into NPVs and GVs took place early in the evolution of this group. As yet, the number of GVs for which suitable sequence data are available is too small, but in the future phylogenetic studies of this type should provide a more rational means of classifying GVs below the genus level.

Structure

GV virions comprise rod-shaped enveloped nucleocapsids (**Fig. 2A**) that contain a single molecule of supercoiled double-stranded DNA ranging in size

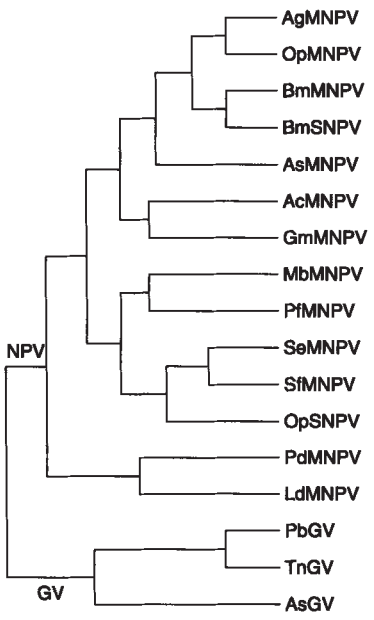


Figure 1 Baculovirus phylogeny based on polyhedrin and granulin protein sequences. The deep division between the NPV and GV clades is clear. (Modified with permission from Zanotto *et al* (1994) *J. Invertebr. Pathol.* 62: 147–164.)

from approximately 100 to 180 kb. The nucleocapsids resemble those of the NPVs and are typically 30–60 nm in diameter and 200–300 nm long. The cylindrical body of the capsid appears to be constructed as a helical stacked ring structure that repeats every third ring. The ends of the capsid are different, both from each other and from the body of the capsid. Like the NPVs, it seems probable that GV virions occur in two morphologically distinct forms, a budded form that buds from infected cells (**Fig. 2B**), giving rise to extracellular virus, and an occluded form found within occlusion bodies formed inside infected cells. SDS-polyacrylamide gel electrophoresis analysis of GV virions suggest they contain in excess of 18 different polypeptides, with budded virions and occluded virions displaying different protein profiles.

GV occlusion bodies; often referred to as capsules or granules, have a roughly oval morphology, with a major axis diameter of 300–500 nm and a minor axis diameter of 120–300 nm. They typically contain a single nucleocapsid (**Fig. 2C, D**), although occasionally capsules with several nucleocapsids have been observed. Electron micrographs of GV capsules suggest they are surrounded by an outer layer which is likely to be similar to the calyx surrounding NPV occlusion bodies. The major protein of GV capsules is known as granulin. Granulin proteins have a size of 28–30 kDa and are related at the amino acid sequence level to the polyhedrin proteins of NPVs. High-resolution visualization of the matrix of the capsule reveals that it is highly crystalline (**Fig. 2C, D**). It is thought that multimers of granulin form the subunits of this crystalline lattice.

Genome Organization and Expression

Field isolates of many GVs show considerable genomic heterogeneity. It is likely that a typical GV infection in the field often comprises multiple genomic variants coinfecting the host insects. For several GVs, detailed restriction endonuclease maps of individual GV genotypes have now been prepared. These maps will provide the framework for future characterization of the precise differences between genomic variants present in field isolates. At least some of the variation is due to the insertion of transposable elements from the lepidopteran host genome into the viral DNA. The horizontal transfer of transposable elements from the genomes of *Cryptophlebia leucotreta* (false codling moth) and *Cydia pomonella* (codling moth) into the *C. pomonella* GV genome has been demonstrated. These transposable elements belong to the family of Tc1-like transposons found in *Drosophila* and *Caenorhabditis* species. Such transposition events are likely to play a significant role in the evolution of GV diversity.

Typical GV genomes are likely to contain between 150 and 200 genes, based on comparison with the gene density observed in completely sequenced NPV genomes. A number of large scale sequencing projects of GV genomes are currently underway, so that the number of sequenced GV genes is increasing rapidly. It is likely that the first complete sequence of a GV genome will be available in the near future. Presently, approximately 35 GV genes with homologues in the databases have been identified. Most of these represent genes previously identified in NPV genomes. However, in many cases, these identifications are very tentative, often being based on incomplete sequence data. It is likely that GVs will encode a significant number of genes not found in NPVs. Characterization of such genes should provide fascinating insights into the molecular basis for the remarkable biology of these viruses (see below).

Of the potential GV genes identified to date, only a small number have been subjected to any form of functional characterization. Currently these are the *granulin, enhancin, iap, odvp-6E, egt* and *cathepsin* genes. All of these have NPV homologues. Several *granulin* gene sequences are now available from different GVs. The *granulin* gene encodes the major protein of the GV occlusion body, as described above. It is homologous to the *polyhedrin* genes of the NPVs (**Fig. 1**), in agreement with their similar function. Recent experiments, in which the *polyhedrin* gene of *Bombyx mori* (silk moth) NPV was replaced by the *granulin* gene of *Trichoplusia ni* (cabbage looper) GV (TnGV), show that the different morphology of NPV and GV occlusion bodies is not an intrinsic property of the polyhedrin/granulin gene alone, The BmNPV recombinant expressing the TnGV *granulin* gene formed large cuboid occlusion bodies, more similar to those normally formed by BmNPV and quite different from the small, ovoid occlusion bodies formed by TnGV. Gene expression studies in cell culture following CpGV infection suggest that there is only a single hyperexpressed viral gene product (granulin) present late in infection. A GV homologue of the NPV p10 gene has yet to be identified.

Enhancin genes have been identified in a range of GVs. The enhancin protein is a metalloproteinase whose function appears to be to digest the peritrophic membrane lining the midgut of the insect host to facilitate the initiation of the infection process. Until recently, enhancin was thought to be unique to GVs but it is now known that the *Lymantria dispar* (gypsy moth) NPV encodes an enhancin. The protein encoded by the *iap* gene acts to block apoptosis (programmed cell death) in infected cells (*i*nhibitor of

Figure 2 GV morphology. *ap*optosis). This was first identified in the CpGV genome, but it is now known that most baculoviruses possess one or several *iap* genes. ODVP-6E is a structural protein found in the envelope of virions contained within occlusion bodies. The *odvp-6E* gene has been identified in several NPVs and GVs. After polyhedrin/granulin, *egt* represents the baculovirus gene that has been sequenced most frequently. It appears to be present in a wide range of, if not all, baculoviruses. The EGT protein enables the baculovirus to interfere with the development of the infected host by inactivating the insects' ecdysteroid molting hormones. Finally, cathepsin is a cysteine protease involved in degradation of the host tissues and cuticle to facilitate release of the progeny virus.

Little is known about gene order in GVs, but available evidence suggests that there are regions in which the gene order is conserved between GVs and NPVs, and regions where extensive gene rearrangements have taken place. Similar to the NPVs, GV genes generally seem to be closely spaced, but without much overlap between them. A number of homologous repeated sequences have been described in the genome of TnGV. Homologous repeats (*hrs*) are a prominent feature of NPV genomes, where they are believed to act as enhancers of gene expression and origins of DNA replication. However, a characteristic feature of *hr* elements in NPVs is that each *hr* is composed of numerous short direct and inverted repeats and palindromic sequences. Such an internal structure is not observed in the repeat sequences identified in TnGV, so it remains to be seen whether the TnGV repeats are functionally equivalent to the NPV *hrs*.

Studies of the control of NPV gene expression have shown that NPV genes are expressed in a cascade fashion. Three broad transcriptional classes can be recognized – early, late and very late – based on the time in the viral infection process a gene is expressed. Late and very late NPV genes are transcribed by a novel, virus-induced RNA polymerase that recognizes the motif TAAG at the transcription start site. Temporal studies on viral gene expression in GV infections are limited because of the lack of highly permissive cell lines. *In vivo* studies that have been carried out are complicated by the involvement of different tissues, as well as by the lack of synchronous infection. However, GV genes that one would expect to be expressed late in infection generally have one or more TAAG sequences upstream of the start codon. In a few cases, transcription has been shown to initiate from this motif. Furthermore, a recombinant BmNPV has been constructed that includes the CpGV *cathepsin* gene and promoter. Transcription of the *cathepsin* initiates from the TAAG motif in the GV promoter, suggesting there are significant similarities between the transcription control mechanisms of GVs and NPVs.

Replication

Difficulties in achieving growth of GVs in cell culture have prevented the detailed studies of replication that have been possible with some NPVs. As a result, our understanding of GV replication is based primarily on *in vivo* studies using electron microscopy. Although there appear to be differences in detail between the various *in vivo* GV studies, depending on the virus, host and tissue, the overall cytopathology is similar. The infection process initiates when an insect consumes food contaminated with GV granules. The alkaline pH of the lepidopteran midgut promotes the dissociation of the occlusion bodies, with the consequent release of the virus particles into the lumen of the midgut. For many GVs, enhancin protein associated with the granules is believed to catalyze the partial disruption of the peritrophic membrane lining the midgut. This allows the virus particles easier access to the midgut epithelial cells. Virus entry is thought to be by fusion between the viral membrane and the midgut microvilli. The nucleocapsids migrate to the nuclear membrane. There is some evidence to suggest that the nucleocapsid uncoats at the nuclear pore (TnGV and *Estigmene acrea* (saltmarsh caterpillar) GV) and/or in the nucleus (*Scotogramma trifollii* (clover cutworm) GV). Once in the nucleus, there are major differences between the cytopathology of GV and NPV infections. Unlike NPVs, in GV infections the nuclear membrane breaks down before occlusion body formation. There appear to be two phases of nucleocapsid production, one prior to the fragmentation of the nuclear membrane and one postfragmentation. The early stages of GV infection resemble the prophase stage of mitosis. There is nuclear 'clearing' as a result of the chromatin and nucleolar complex becoming marginated. The granular and fibrillar components of the nucleolus separate and the nuclear pores become larger. Empty capsids form in the clear area of the nucleus and fill with nucleoprotein; the nucleocapsids appear scattered separately throughout the nucleus (**Fig. 3A**). The nuclear membrane then fragments, liberating the nucleocapsids into the cytoplasm. The nucleocapsids migrate to the periphery of the cell and align themselves with their conical end perpendicular to the thickened area of the plasma membrane, where budding occurs. While budding is occurring there is further proliferation of nucleocapsids at the virogenic stroma in the portion of the cell once occupied by the nucleus. The progeny nucleo-

(**C**) *In vitro* replication of CpGV. *C. pomonella* cell late in infection containing occluded virus particles (capsules). Bar = 1 μm.

capsids migrate to the periphery of the cell, where they either bud or accumulate in areas rich in vesicular membranes, where envelopment occurs. The nucleocapsids align perpendicularly on membrane structures, where they become enveloped. The deposition of granulin on the virion envelope initiates occlusion, which usually progresses by the crystallization of granulin from one end of the rod-shaped virion (**Fig. 3B**). During occlusion all stages in viral replication are evident in the cell. The capsules form

in the periphery of the cell. In cell culture the cells generally round up and fill with occlusion bodies (**Fig. 3C**); *in vivo* cells detach from the basal laminar and from adjacent cells. In infected insects membrane-bound vesicles enclosing occlusion bodies may be observed in some cells, historically named 'boules hyaline'. These may be hemocytes which phagocytose capsules released into the hemolymph. This phenomenon has also been observed in a *C. pomonella* cell line. Capsules are released from the cells by the rupture of the plasma membrane and accumulate in the center of the fat body, the main site of occlusion body production, and in the hemolymph. As a result, just before death, the infected larva becomes milky/paler due to the accumulation of capsules. After death the cadaver will melanize and either liquefy or dessicate, depending on the type of GV infection.

Host Range and Pathology

The host range of most GVs is relatively narrow, with infection being confined to one or more species within the same family as the original host. The few crosstransmission studies where the progeny virus has been identified have shown that in some cases the resulting virus is in fact the homologous virus of the host and probably resulted from activation of an inapparent virus or a contaminant in the inoculum. However, at least four GVs are known to have a relatively wide host range, CpGV, *Heliothis armigera* (cotton bollworm) GV (HaGV), *Spodoptera frugiperda* (fall armyworm) GV and *Xestia c-nigrum* (spotted cutworm) GV (XcGV).

Tissue tropism is an important factor in determining the development of disease in a GV-infected host. The pathogenicity of different GVs is correlated with the extent of infection of various organs in larvae. GVs have recently been grouped into three types based on their tissue tropism. Type 1 have a relatively narrow tissue tropism with infection occurring only in the midgut and fat body; type 2 exhibit wider tissue tropism involving midgut, fat body, epidermis and possibly tracheal matrix and malpighian tubules; type 3 shows stringent tissue tropism, replicating only in the midgut. *Harrisina brillians* (Western grapeleaf skeletonizer) GV is the only recorded lepidopteran baculovirus where GV replication is confined to the midgut epithelium. The infection spreads from cell to cell, with or without the production of budded virus. It is one of the few examples where the virus is more pathogenic to older instars, with first instars dying after approximately 17 days and third instars at 8 days. The larvae die of dehydration due to chronic diarrhea when the occlusion body-filled cells slough off from the gut. However, in general, the speed of kill of a GV depends on several parameters such as dose and susceptibility of the host as well as the tissue tropism. In most GV infections the fat body is the main site of virus replication and occlusion body production. GVs have also been described as 'slow' or 'fast' GVs. The 'slow' GVs (which include many noctuid GVs, e.g. TnGV, HaGV, *Lacanobia oleracea* (tomato moth) GV, *Agrotis segetum* (cutworm) GV, XcGV) have high LD_{50} values, with death being prolonged, as long as 10–20 days, far beyond the normal larval stage. Some of the slow noctuid GVs have much larger genomes in the region of 170 kb, e.g. TnGV, HaGV, XcGV. The 'fast' GVs (e.g. *Artogeia rapae* (small white butterfly) GV (ArGV), CpGV and *Plutella xylostella* (diamond back moth) GV) are highly infectious, have low LD_{50} values <5 capsules per neonate and rapid speeds of kill. The epidermal cells are not infected in the slow/type 1 GVs and the infected insects do not liquefy on death but melanize, shrink and develop a leathery epidermis.

Ecology

GVs are known to be responsible for epizootics in gregarious lepidoptera where the larvae sporadically reach high populations (e.g. *A. rapae*) as a result of contamination of feeding surfaces by virus released from the remains of infected larvae. GV-infected larvae generally climb late in infection and hang by their prolegs. Liquefaction of the dead larvae releases infectious capsules on to surfaces below and aids dissemination of the virus. Epizootics contribute significantly to the natural control of lepidopteran pests, e.g. *A. rapae* and *S. trifolii*. There are reports of the interaction of parasitoids in conjunction with GV-infected hosts and in the transmission of GVs to healthy larvae. Parasitoids that develop in GV-infected larvae are able subsequently to transmit the disease to healthy hosts. Predators produce virus-contaminated excrement after feeding on infected larvae and it appears that several predators actually prefer virus-infected to healthy prey. Among predators, birds are probably more efficient in spreading disease because of the large numbers of insects they consume and the great distances they travel. Occluded virus can remain infectious in the soil for many years, protected from UV damage. Factors such as rain or seed germination are most likely responsible for movement of virus from the soil reservoir on to plants.

GVs as Insecticides

GVs have been successfully used for the control of many pests in small-scale field trials; however, only a

few viruses have been used on a larger scale, e.g. ArGV to control *A. rapae* in China, and *Erinnyis ello* GV to control cassava hornworm in Brazil. Up to 18 GV products have been, or are being, registered and produced, e.g. CpGV is marketed in Europe and has provided effective control of *C. pomonella*, a major pest of apples and a lesser pest of pears and several other fruits. GVs have an important role to play in the control of insecticide resistant pests such as *P. xylostella*, which is a major pest of Cruciferae crops, particularly in countries like Malaysia.

Nucleopolyhedrovirus

George F Rohrmann, Department of Microbiology, Oregon State University, Corvallis, USA

History

As early as 4000 BC, corresponding to the advent of silk production in Asia, came an awareness of a variety of silkworm diseases that posed a constant threat to this emerging industry. One of the major diseases affecting silkworms was likely caused by nucleopolyhedrovirus infection. Protocols for the identification and elimination of infected silkworms were established well before the agents of silkworm diseases were identified. In the mid-nineteenth century, following the development of microscopy, a silkworm disease was identified that was characterized by the presence of massive numbers of polyhedron-shaped, highly refractile, crystalline occlusion bodies present in the infected insect. The disease was called 'polyhedrosis' and by the early twentieth century, polyhedrosis disease was shown to be transmitted by a virus. In the mid-1930s, two distinct polyhedrosis diseases were differentiated by the nuclear or cytoplasmic location of the occlusion bodies, or polyhedra. Subsequently the nuclear polyhedrosis viruses (nucleopolyhedroviruses) were classified as a genus in a new family of viruses, the *Baculoviridae*, whereas the cytoplasmic polyhedrosis viruses were found to have double-stranded, segmented, RNA genomes and were therefore placed in the *Reoviridae*. Concurrent with the finding that these viruses cause a disease of beneficial insects, was the observation that certain insect pests were also afflicted with a similar disease. Therefore, the early impetus for studying nucleopolyhedroviruses was for their potential in insect control programs. More recently nucleopolyhedroviruses have achieved widespread use in both basic and applied biomedical research because of their ability to produce large quantities of proteins from foreign genes that have been inserted into the viral genome under the control of the occlusion body protein promoter.

Taxonomy and Host Distribution

Nucleopolyhedroviruses (NPVs) of the genus *Nucleopolyhedrovirus* are members of the *Baculoviridae*, a family of DNA viruses, characterized by the occlusion of the virions in a crystalline protein matrix. NPV virions contain a single molecule of circular, supercoiled, double stranded (ds) DNA that ranges in size from approximately 90 to over 170 kb in different species of the virus. The genome is packaged in enveloped, rod-shaped (the name baculovirus is derived from the Latin word, *baculum* meaning rod) nucleocapsids, 30–60 nm in diameter and 250–300 nm in length. The two genera of baculoviruses (*Nucleopolyhedrovirus* and *Granulovirus*) are distinguished by the size and morphology of the occlusion body.

NPVs replicate in cell nuclei and are characterized by the occlusion of virions in large (1–15 μm) polyhedron-shaped occlusion bodies comprised predominantly of a single protein called polyhedrin. The occlusion body is surrounded by a structure called the polyhedron envelope or polyhedron calyx (**Fig. 1**). Virions may be present as either single (SNPV) or multiple (MNPV) nucleocapsids within a viral envelope (**Fig. 1**). Although this differentiation is commonly used in describing NPVs, the significance of these morphotypes is unclear and does not appear to be a definitive phylogenetic feature. NPVs are named after the insect host from which they were first described. Such terminology is confusing because the

few viruses have been used on a larger scale, e.g. ArGV to control *A. rapae* in China, and *Erinnyis ello* GV to control cassava hornworm in Brazil. Up to 18 GV products have been, or are being, registered and produced, e.g. CpGV is marketed in Europe and has provided effective control of *C. pomonella*, a major pest of apples and a lesser pest of pears and several other fruits. GVs have an important role to play in the control of insecticide resistant pests such as *P. xylostella*, which is a major pest of Cruciferae crops, particularly in countries like Malaysia.

The occlusion body is surrounded by a structure called the polyhedron envelope or polyhedron calyx (**Fig. 1**). Virions may be present as either single (SNPV) or multiple (MNPV) nucleocapsids within a viral envelope (**Fig. 1**). Although this differentiation is commonly used in describing NPVs, the significance of these morphotypes is unclear and does not appear to be a definitive phylogenetic feature. NPVs are named after the insect host from which they were first described. Such terminology is confusing because the

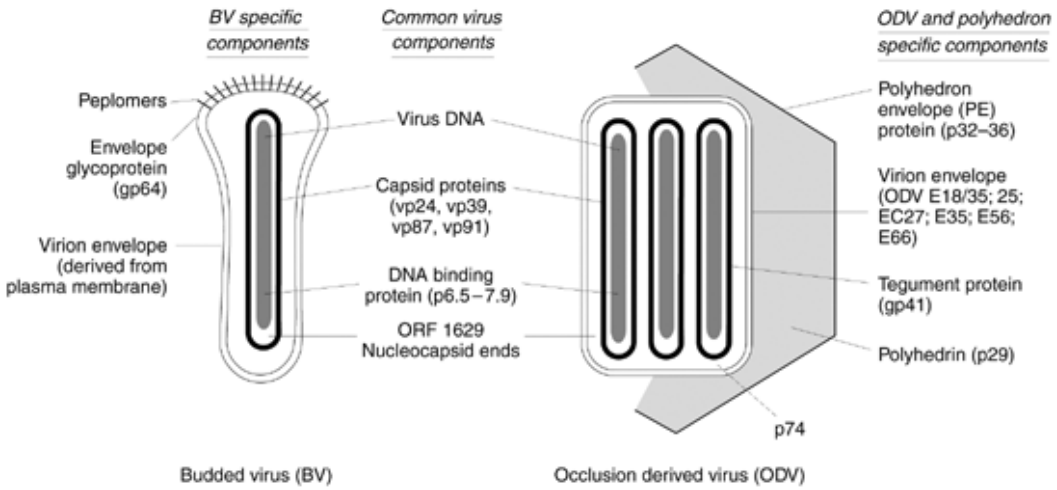

Figure 1 Location of baculovirus structural components. The two baculovirus phenotypes are shown with shared and phenotype-specific components indicated. The dashed line indicates that the location of p74 has not been determined. (Modified with permission from Blissard GW and Rohrmann GF (1990) Baculovirus diversity and molecular biology. *Annu. Rev. Entomol.* 35: 125, by Annual Reviews Inc.)

same virus may infect several insect species and therefore may be called by a variety of names. Some of the most commonly studied baculoviruses are *Autographa californica* MNPV (AcMNPV), *Bombyx mori* NPV (BmNPV), *Lymantria dispar* MNPV (LdMNPV), and *Orgyia pseudotsugata* MNPV (OpMNPV). Their hosts are the alfalfa looper, silkworm, gypsy moth and Douglas-fir tussock moth, respectively.

The granuloviruses (GVs) are occluded in small (0.15–0.5 μm) ellipsoidal-shaped occlusion bodies composed predominantly of a single protein called granulin that is related in amino acid sequence to polyhedrin. The GV virions are normally present as single nucleocapsids within an envelope.

Several nonoccluded rod-shaped DNA viruses pathogenic for insects have been described. These have previously been assigned to a nonoccluded genus of the *Baculoviridae*. However, due to the lack of definitive information on their phylogenetic status, they have been moved to a nonassigned category.

Host Range

Infection by baculoviruses is limited exclusively to arthropods, predominantly holometabolous insects (those undergoing complete metamorphosis). Whereas GVs are pathogenic only for members of the order Lepidoptera (butterflies and moths), NPVs are not only infectious for Lepidoptera, but also for Diptera (flies), Hymenoptera (sawflies) and Trichoptera (caddis flies). In addition, NPVs are infectious for several species of the crustacean order, Decapoda (shrimp), and are a major problem in the shrimp farming industry in Asia. GVs reportedly infect about 150 species of Lepidoptera. NPVs have been reported to infect about 300 species of Lepidoptera, 20 species each of Diptera and Hymenoptera, and a single species of Trichoptera. Individual viruses have a very limited host range and normally only infect closely related insects within a single order.

Genome Structure, Replication and Transposable Elements

Baculoviruses have double-stranded, circular, supercoiled DNA genomes that vary greatly in size from about 100 kb to over 170 kb. The AcMNPV, BmNPV, and OpMNPV genomes have been sequenced and are of similar size (134, 128 and 132 kb, respectively) and are predicted to encode for about 150 proteins. Whereas the AcMNPV and BmNPV genomes are closely related in organization and gene content, the genome of OpMNPV lacks 28 putative genes found in AcMNPV, but contains 26 genes not present in the AcMNPV genome. In addition, the average amino acid sequence identity between predicted open reading frames (ORFs) in AcMNPV and OpMNPV is 56%. In contrast, the *Lymantria dispar* NPV (LdMNPV) genome is much larger (161 kb) than those from AcMNPV and OpMNPV. Furthermore, the pattern of organization for many LdMNPV genes appears to be unrelated to the pattern observed in AcMNPV and OpMNPV. The AcMNPV genome contains a series of eight homologous repeated (*hr*) sequences each containing a series of repeated

imperfect palindromes centered around an EcoR1 site. These repeated sequences have been shown to act as enhancer elements for both early and late gene expression. Related *hr* sequences have been found in a number of other baculoviruses.

The replication of the baculovirus genome is not well-characterized. Recent evidence suggests that the *hr*-enhancer sequences may also function as origins of DNA replication. Three ORFs with sequence similarity to genes encoding proteins involved in DNA replication in other organisms have been identified in the AcMNPV genome. These include genes with homology to DNA polymerase, proliferating cell nuclear antigen (PCNA, that stimulates DNA polymerase δ in other organisms), and helicase (helicase is likely to be involved in the unwinding of duplex DNA during replication). Transient replication assays have identified six genes that are essential for DNA replication. Two of these genes, *dna polymerase* and *p143(helicase)* have homology to genes involved in replication in other organisms. In addition, one of the essential genes, *late expression factor-3 (lef-3)* has the properties of a single-stranded (SS) DNA binding protein, whereas another (*lef-2*) has a primase-like domain that is essential for its function. The viral transactivator, *ie-1* is also required for DNA replication and may function as an origin binding protein as it has been shown to bind to *hr* sequences. Although a role has not been determined for the sixth essential replication gene, *lef-1,* it has been shown to interact with *lef-2*. The mechanism of DNA replication is poorly understood. However, it has been shown that *hr*-containing plasmids replicated in the transient assay appear to be present as high-molecular-weight concatemers suggesting that they may replicate via a 'rolling circle' mechanism. In addition, high-molecular-weight putative concatemers of viral genomic DNA have been observed in DNA extracted from infected cells.

Transposable elements are often reported to be present in baculovirus genomes and likely play an important role in baculovirus evolution. The transposable elements that have been identified include a retrotransposon and a number of different apparently nonautonomous transposable elements. Both these types of transposable elements appear to originate from multicopy DNA in the host cell genome indicating that exchange of genetic information between host cells and viral genomes occurs.

Regulation of Gene Expression

Progression through the viral infection cycle is governed by a cascade of early, late and very late gene transcription. Early transcription begins before the initiation of replication of the viral genome and is inhibited by α-amanitin indicating that early transcription is RNA polymerase II dependent. Investigations using reporter gene constructs transfected into insect cells suggest that the level of transcription from early gene promoters is modulated by at least two viral transactivating factors and *hr* enhancer sequences. Both transactivation and enhancement probably contribute to the speed and facility with which the NPVs are capable of directing the host cell metabolic machinery to selectively transcribe genes necessary for viral replication. Following initiation of viral DNA replication, late gene expression is initiated and the transcription of some, if not all, host genes is repressed. Very late in infection, two genes involved in occlusion body formation (polyhedrin and p10), are hyperexpressed. The transcription of late genes is dependent on the presence of an α-amanitin-resistant RNA polymerase with a unique subunit composition that is distinct from that of the three host RNA polymerases. This polymerase recognizes baculovirus late promoters that normally contain the sequence motif A/G/T TAAG. The late mRNAs normally initiate within the promoter sequence. Eighteen baculovirus genes have been identified that are essential or stimulatory for late gene expression. Because of the nature of the assay used for the identification of these genes, they include the complement of genes also required for DNA replication. However, in addition to the gene required for DNA replication are two genes encoding proteins that have limited homology to the two largest subunits of RNA polymerase II. At least two additional genes have been implicated in very late transcription.

Baculovirus genes are frequently clustered into transcription units that produce overlapping RNAs both in the same or opposite orientation. The differential expression of baculovirus genes may be influenced by these overlapping transcripts. Although splicing does not appear to play a major role in the regulation of most baculovirus genes, the mRNA encoding the AcMNPV transactivating factor gene (IE1) appears to be spliced and this may create several differentially expressed forms of the IE1 protein.

The NPV Life Cycle and Pathogenesis

In the NPVs that have been most intensively studied (e.g. AcMNPV and OpMNPV), the life cycle involves the production of two structurally distinct viral phenotypes (**Fig. 1**). Each phenotype has a specific role during the baculovirus life cycle (**Fig. 2**). The budded virus (BV) phenotype (also known as extracellular virus, ECV or EV) is produced during the early stages of infection and is responsible for the

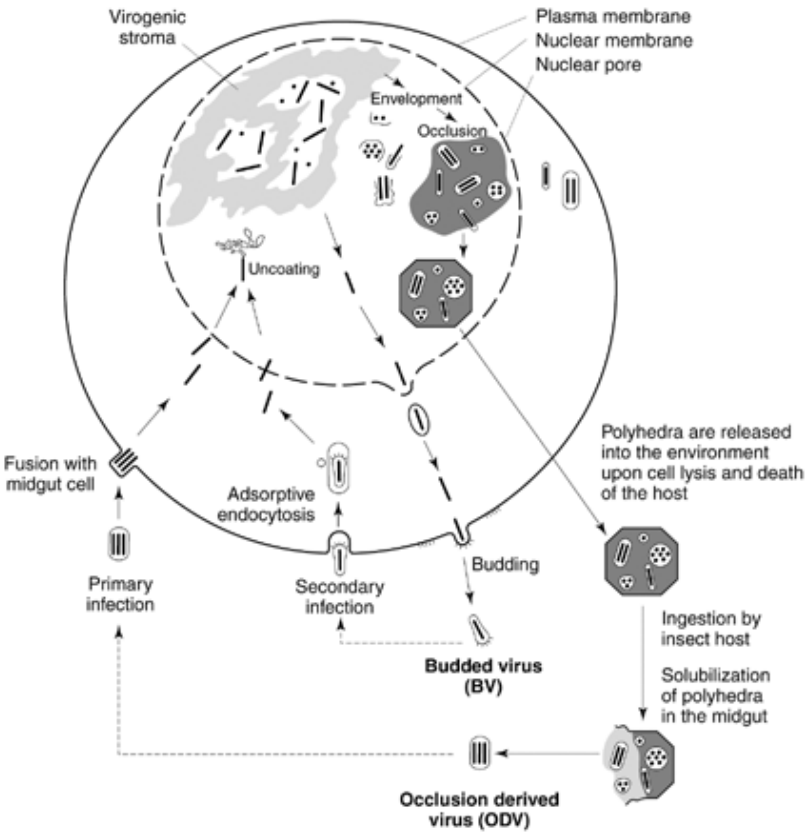

Figure 2 Diagram of the infection cycle of a nucleopolyhedrovirus. See text for description. (Modified with permission from Blissard GW and Rohrmann GF (1990) Baculovirus diversity and molecular biology. *Annu. Rev. Entomol.* 35: 125, by Annual Reviews Inc.)

systemic spread of the virus within the insect. It is also highly infectious for cultured cells. In contrast, the occlusion-derived virion (ODV) phenotype (also known as polyhedron-derived virus, PDV, or occluded virus, OV) is produced during the terminal stages of the viral infection and is occluded within polyhedra. Occluded ODV are capable of persisting for extended periods outside the host insect. Although the nucleocapsids of the two phenotypes appear to be identical, their envelopes are derived from different sources.

The initiation of infection by different NPVs requires from less than 50 to several thousand occlusion bodies per insect and fatal infections take from four days to three weeks. The duration of NPV infections is dependent on factors governing virulence, that are not well characterized. In addition, the species of insect, the larval instar, viral dose and the ambient temperature also influence the length of time of the infection.

Studies with AcMNPV indicate that after ingestion of polyhedra by a susceptible insect, the polyhedra pass through the insect foregut and dissolve when they encounter the alkaline pH of the midgut. ODV are released from the dissolved occlusion bodies and infect both the columnar epithelial cells (that border on the gut lumen) and regenerative cells (that are not exposed to the lumen). The virus appears initially to replicate in the epithelial cells and bud from the cells in a polar manner such that the virus moves away from the gut lumen. The virus has been shown to infect tracheolar cells which apparently act as a conduit for the spread of the infection throughout the insect. In contrast to the pathology outlined above, the replication of the hymenopteran virus, *Neodiprion sertifer* SNPV, appears to be confined to gut cells.

At the cellular level, infection causes cells to become round, and the nuclei enlarge such that they appear to fill the majority of the cell. A distinctive structure called the virogenic stroma develops in the nucleus. This structure is thought to be the major site of viral replication and assembly. Once assembled within the nucleus, nucleocapsids destined to become BV are transported through the cytoplasm and obtain an envelope as they bud through the plasma mem-

brane that has been modified by at least one virally encoded protein. In contrast, ODV become surrounded by an envelope that assembles within the nucleus. Subsequently, they become occluded and are released on the death of the cell.

NPV infection initially results in few symptoms and infected larvae continue feeding. In some insect cells, AcMNPV infection initiates an apoptotic response. However, AcMNPV is capable of blocking apoptosis with a unique protein, p35, which has only been found in AcMNPV and the closely related BmNPV. Other baculoviruses lack p35, but contain an unrelated gene called inhibitor of apoptosis (*iap*) that is also capable of blocking apoptosis. Since their discovery in baculoviruses, *iap* homologues have been identified in a variety of eukaryotes.

As the viral infection progresses, molting of the larval instars is blocked by the production of a virally encoded enzyme, UDP-glucosyltransferase. This enzyme inactivates ecdysteroids that are involved in larval molts and pupation. This block may facilitate increased levels of viral production by keeping the insects in a feeding phase. The late stages of infection are characterized by the production of massive numbers of polyhedron-shaped occlusion bodies within the infected cell nucleus. Near the end of the infection cycle the insects become sluggish and cease feeding. Their epidermis becomes fragile and may rupture, and frequently they seek out the highest nearby location and die in an inverted position. Two virus-encoded proteins, a cathepsin-like protease and a chitinase, appear to contribute to the disintegration of the insect during the final stages of infection. This is thought to facilitate the dissemination of the virus.

Viral Structures and Composition

Structural proteins of polyhedra

Polyhedra contain all the structural components of occluded virions (ODV), as well as two well-characterized components: polyhedrin and the polyhedron envelope protein (**Fig. 1**). Another protein, p10, appears to be associated with the formation of polyhedra. Polyhedrin is a protein composed of about 245 amino acids (29 kDa) and is the major component of polyhedra. Polyhedrin has received considerable attention because it is hyperexpressed and comprises up to 18% or more of the total cellular alkali-soluble protein late in infection.

Polyhedra are surrounded by an electron-dense envelope that has been called the polyhedron envelope, polyhedron membrane or polyhedron calyx. When polyhedra are subjected to alkaline dissolution in the laboratory, the bag-like polyhedron envelope remains with many virions trapped inside. A protein of 34–36 kDa appears to be a major component of the polyhedron envelope of AcMNPV and OpMNPV. In addition to polyhedrin, another baculovirus protein, p10, is also highly expressed late in infection. It forms extensive fibrillar structures that are found in both the nucleus and cytoplasm of infected cells. The p10-containing fibrillar structures show a close association with the developing polyhedron envelope.

Structural proteins of the nucleocapsid

The nucleocapsids of BV and ODV appear to be very similar in composition. The nucleocapsid is composed of at least one small putative DNA binding protein, a protein apparently specific to the basal end structure, and a number of capsid proteins, and the viral genome (**Fig. 1**).

Baculoviruses have large genomes that must be highly condensed to be efficiently packaged within a nucleocapsid. Histones do not appear to be associated with DNA packaging within nucleocapsids. In AcMNPV, a small gene has been identified that encodes an arginine/serine–threonine rich protein of 54 amino acids (termed p6.9) that is thought to be a DNA-binding protein. Homologues of the AcMNPV p6.9 gene have been isolated from other NPVs. These proteins consist of more than 40% arginine and approximately 30% serine or threonine residues. It has been suggested that the basic arginine residues of the DNA-binding protein neutralize the acidic residues of the viral DNA to enable condensation of the viral genome. Upon entry into an insect cell, serine and threonine residues on the DNA binding protein may become phosphorylated by a protein kinase. This would result in the unpackaging of the viral DNA. This hypothesis is supported by the observation that protein kinase activity is associated with purified capsids of granulosis viruses and with both BV and ODV of AcMNPV.

In addition to a DNA-binding protein, a protein of approximately 39 kDa (vp39) has been identified that appears to be a major component of the nucleocapsid of NPVs. This protein is present in both BV and ODV virions at a relatively high concentration. Immunoelectron microscopy confirmed that the vp39 protein is a component of the nucleocapsid and showed that it was randomly distributed over the entire surface of the nucleocapsid. In addition to vp39, vp80 (p87 in OpMNPV), p24 (OpMNPV) and vp91 (OpMNPV) have been found associated with nucleocapsids (**Fig. 1**). A phosphoprotein called ORF 1629 or pp78/83 has been shown to be associated with capsid basal end structures.

Proteins of the budded virus envelope

The major virally encoded protein found associated with the BV envelope is called gp64 (or gp67) and has been characterized in both AcMNPV and OpMNPV (**Fig. 1**). Both immunoelectron and immunofluorescence microscopy indicate that gp64 is concentrated at the plasma membrane. Nucleocapsids become enveloped with the gp64-modified plasma membrane (**Fig. 2**) during their exit from cells. Budded virus primarily enter cells by endocytosis. In this process, the entire virion is endocytosed into an intracellular vesicle called an endosome. It is thought that gp64 may be involved in the fusion of the viral envelope with the endosomal membrane.

The gp64 protein contains a signal peptide sequence at its N-terminus that appears to be cleaved to form the mature protein. Signal peptides are associated with nascent secretory and membrane proteins and are involved in protein trafficking across the membrane of rough endoplasmic reticulum (ER). Signal peptides are normally cleaved off during this process. Once within the ER, secretory proteins move to the cell surface via the Golgi complex where glycosylation may occur. The gp64 amino acid sequence contains five to seven sites for N-linked glycosylation and has been shown to be highly glycosylated (as much as 10 kDa of the molecular weight is contributed by sugar residues). A putative C-terminal anchor domain has also been identified in gp64. The anchor domain is a membrane-spanning domain (that is hydrophobic) followed by a hydrophilic domain that remains on the cytosol side of the membrane. Such domains serve to anchor a protein into the plasma membrane. In addition, palmitic acid is ester-linked to the AcMNPV gp64 peptide making it the major acylated protein associated with BV.

Other viral-specific components of the BV envelope have not yet been reported.

The ODV envelope and other structures

ODVs display a classic bilayer envelope structure that may play an important role in the initiation of infection in the insect gut and could also be essential for the association of the ODV with polyhedrin in the nucleus. The source of the ODV envelope has not been clearly defined but it may be derived from invaginations of the inner nuclear membrane that result in the formation of microvesicles in which a number of ODV envelope-specific proteins are associated. Virally encoded proteins associated with the ODV envelope include E18/35, E25, EC27, E35, E56 and E66. EC27 is found both in the ODV envelope and capsid. In addition, a glycoprotein, gp41, appears to be localized in the space between the nucleocapsids and the envelope (or tegument) in ODV.

A gene, essential for insect infection, called p74, has been identified. AcMNPV mutants, in which the p74 gene has been inactivated, are capable of replicating in cultured cells. However, occluded virus produced in cell culture is noninfectious when fed to insects. This indicates that p74 is required for infectivity when ingested by insects and also suggests that the protein must be associated with ODV.

Ecology

Baculoviruses play a major role in regulating the level of insect populations in the environment. Many insect populations are characterized by cycles of expansion and subsequent collapse. As the number of insects increases, occlusion bodies that contaminate soil or vegetation from past baculovirus epidemics are ingested by susceptible insects and initiate an infectious cycle. When the insects die they disintegrate and contaminate surrounding vegetation. This leads to the virus being disseminated by wind, birds and insects. Thus the virus can spread over vast areas and can significantly contribute to the eventual collapse of an insect population. For example, in forest ecosystems, insect infestations can encompass several million hectares and baculoviruses often play a prominent role in the eventual collapse of these large populations.

Economic Importance

Baculovirus Insecticides

NPVs are highly virulent for insect pests and have been shown to be effective in insect control programs. Currently an NPV pathogenic for the velvetbean caterpillar is used to treat approximately one million hectares of soybeans per year in Brazil. Despite such instances, the use of NPVs for pest control is not widespread. This can be attributed to both the narrow host range of individual NPVs, and the fact that insects may survive for several weeks after infection. During this time they continue feeding and therefore can inflict extensive crop damage prior to death. This limits the commercial potential of NPVs compared to chemical insecticides that are often rapidly toxic to a large number of different insect pests. However, because broad-spectrum chemical insecticides often destroy beneficial insects, and can be acutely toxic to vertebrates, alternative means of controlling insects have become increasingly attractive. With the advent of genetic engineering, insect-specific toxin genes have been inserted into the AcMNPV genome and have been shown to signifi-

cantly accelerate the speed that the virus kills a target insect. Such recombinants may also have an extended host range because insect mortality is not dependent on a completed viral infection cycle. Therefore, NPVs may become more extensively used in future pest control programs.

Baculovirus expression vectors

For baculoviruses to efficiently occlude large numbers of virions, massive amounts of polyhedrin must be produced during the infectious cycle. Although polyhedrin is a hyperexpressed gene product, it is not necessary for growth of the virus in cell culture. This has been exploited in the development of the baculovirus expression system that utilizes recombinant NPVs for the production of foreign gene products. A number of transfer plasmids have been constructed that permit the insertion of foreign genes between polyhedrin flanking sequences and under the control of the polyhedrin promoter. The engineered plasmid DNA is then cotransfected along with wild-type viral DNA into insect cells. Homologous recombination between the flanking sequences of the transfer plasmid and the identical sequences in the viral genome occurs at a relatively high frequency. In the resulting recombinant viruses, the polyhedrin gene is replaced by the foreign gene. These recombinants can then be identified by their polyhedrin negative phenotype. This system has become widely used in biomedical research laboratories in recent years because of the relative simplicity of engineering baculovirus expression vectors and their ability to produce high levels of proteins that are post-transcriptionally modified in a manner similar to higher eukaryotes.

BARNAVIRUSES (*BARNAVIRIDAE*)

C Peter Romaine, Department of Plant Pathology, The Pennsylvania State University, University Park, USA

History and Classification

Our appreciation for viral infection of fungi originated in 1962 with the discovery by M. Hollings of several morphologically distinct virus-like particles (VLPs) in cultivated mushrooms (*Agaricus bisporus*) affected by a serious malady known as La France disease. Among the VLPs observed was a 19 × 50 nm bacilliform particle bearing a striking resemblance to a plant virus, alfalfa mosaic virus (AIMV). Mushroom bacilliform virus (MBV) was isolated in the early 1980s and found to be a unique fungal virus, in that it possessed a positive polarity, single-stranded (ss) RNA genome, a feature common to most plant viruses, rather than a double-stranded (ds) RNA genome typifying the vast majority of fungal viruses. Interestingly, amino acid sequence analysis of the putative replicase and the coat suggests an evolutionary relationship between MBV and plant viruses, particularly luteoviruses and carmoviruses.

MBV is the sole member of the genus *Barnavirus* belonging to the family *Barnaviridae* (*Barna* derived from *ba*cilliform-shaped *RNA* virus). Thus, the key features distinguishing this genus in the family *Barnaviridae* from other taxa of fungal viruses is a ssRNA genome and a bacilliform-shaped virion. Viruses in the other genus of the *Barnaviridae* family infect plants and the genus is exemplified by maize rayado fino virus.

Virus Structure and Composition

Virions of MBV are bacilliform, 18–20 nm wide and 48–53 nm long, and lack prominent surface projec-

cantly accelerate the speed that the virus kills a target insect. Such recombinants may also have an extended host range because insect mortality is not dependent on a completed viral infection cycle. Therefore, NPVs may become more extensively used in future pest control programs.

History and Classification

Our appreciation for viral infection of fungi originated in 1962 with the discovery by M. Hollings of several morphologically distinct virus-like particles (VLPs) in cultivated mushrooms (*Agaricus bisporus*) affected by a serious malady known as La France disease. Among the VLPs observed was a 19 × 50 nm bacilliform particle bearing a striking resemblance to a plant virus, alfalfa mosaic virus (AIMV). Mushroom bacilliform virus (MBV) was isolated in the early 1980s and found to be a unique fungal virus, in that it possessed a positive polarity, single-stranded (ss) RNA genome, a feature common to most plant viruses, rather than a double-stranded (ds) RNA genome typifying the vast majority of fungal viruses. Interestingly, amino acid sequence analysis of the putative replicase and the coat suggests an evolutionary relationship between MBV and plant viruses, particularly luteoviruses and carmoviruses.

MBV is the sole member of the genus *Barnavirus* belonging to the family *Barnaviridae* (*Barna* derived from *ba*cilliform-shaped *RNA* virus). Thus, the key features distinguishing this genus in the family *Barnaviridae* from other taxa of fungal viruses is a ssRNA genome and a bacilliform-shaped virion. Viruses in the other genus of the *Barnaviridae* family infect plants and the genus is exemplified by maize rayado fino virus.

Virus Structure and Composition

Virions of MBV are bacilliform, 18–20 nm wide and 48–53 nm long, and lack prominent surface projec-

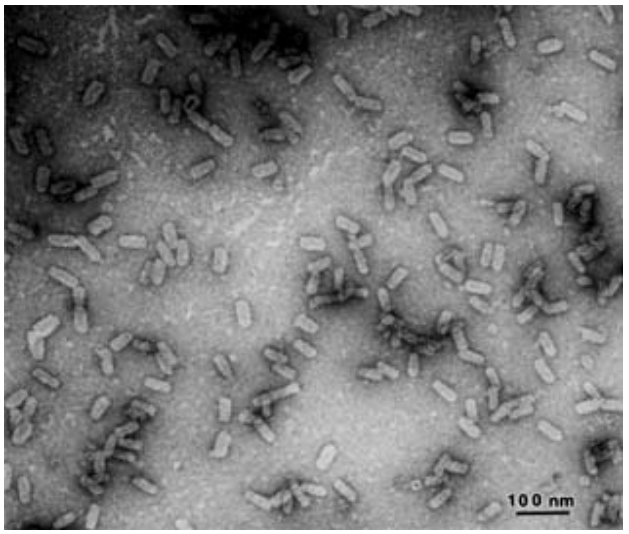

Figure 1 Electron micrograph depicting the 19 × 50 nm bacilliform-shaped virions of MBV.

tions and an envelope (**Fig. 1**). Optical diffraction patterns of the virions resemble those of A1MV, suggesting a morphological subunit diameter of approximately 10 nm and a $T = 1$ icosahedral symmetry.

MBV is stable between pH 6 and 8 and an ionic strength of 0.01 to 0.1 mol L^{-1} phosphate, and is insensitive to chloroform. Purified virus preparations show a single UV-absorbing component following rate-zonal centrifugation in sucrose density gradients and equilibrium centrifugation in cesium sulphate gradients. Virions have a molecular weight of *c.* 7.1 × 10^6 Da and a buoyant density in cesium sulphate of 1.32 g mL^{-1}.

A single molecule of a linear ssRNA of 4 kb constitutes *c.* 20% of the virion by weight. There are an estimated 240 molecules of a single major polypeptide of 24.4 kDa (based on electrophoretic mobility under denaturing conditions) forming the capsid.

Genome Structure

The complete nucleotide sequence of the MBV genome has been determined. The genome is composed of a linear, positive-sense, ssRNA, which is 4009 nucleotides in length. The genomic RNA contains four major open reading frames (ORFs) and has 5′ terminus and 3′ terminus noncoding regions of 60 nucleotides and 250 nucleotides, respectively (**Fig. 2**). The RNA is neither capped at the 5′ terminus nor polyadenylated at the 3′ terminus.

ORF 1 commences at the first AUG codon at nucleotide 61 and ends with UAA at nucleotide 598. ORF 2 is in the +1 reading frame, commencing at nucleotide 68 and terminating at nucleotide 2039 with UAG. ORF 3 is in the same reading frame as ORF 1 (−1 relative to ORF 2), beginning at nucleotide 1882 and ending with a UAA codon at nucleotide 3144. An overlap of 259 nucleotides exists between ORF 2 and ORF 3. ORF 4 initiates at nucleotide 3162, 18 nucleotides downstream of the ORF 3 termination codon in the same reading frame, and terminates with a UGA at nucleotide 3757.

ORFs 1–4 are capable of encoding polypeptides of 20, 73, 47 and 22 kDa, respectively. ORF 3 encodes a putative replicase and ORF 4 encodes the capsid protein. The deduced amino acid sequences of ORFs 2 and 3 both contain putative helicase-like motifs. Three minor ORFs (5–7) potentially encode polypeptides of 8, 6.5 and 6 kDa, respectively. The putative polypeptides encoded by ORFs 1, 5, 6 and 7 show no homology to known polypeptides. In a cell-free system, the RNA directs the synthesis of a major polypeptide (77 kDa), and possibly several minor polypeptides (21–37 kDa).

Host Range and Geographic Distribution

The known host range of MBV is limited to the cultivated button mushroom, *A. bisporus*; however, bacilliform particles that are morphologically similar to MBV have been observed in the field mushroom, *A.*

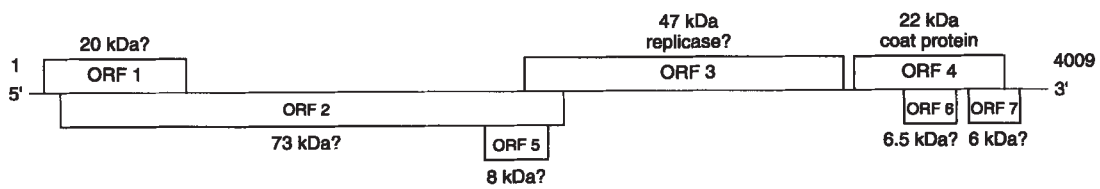

Figure 2 Genome organization of MBV. The genomic RNA (4009 nucleotides) is shown as a bold solid line with the four major opening reading frames (ORFs) 1–4 and the three minor ORFs 5–7 denoted by open rectangles. Numbers below or above the ORFs indicate the size of the polypeptide they may encode. ORF 4 encodes the major capsid protein of 22 kDa and ORF 3 encodes a putative RNA-dependent RNA polymerase (47 kDa).

campestris. The distribution of MBV coincides with that of the commercial cultivation of *A. bisporus*; the virus has been reported in most major mushroom-growing countries.

Transmission and Pathogenicity

Horizontal transmission of MBV is thought to occur through hyphal anastomosis between noninfected mycelium and infected mycelium and basidiospore germlings. MBV can infect *A. bisporus* singly, but is more commonly found as a double infection with La France isometric virus (LIV), a dsRNA genome virus implicated in the etiology of La France disease. MBV is not required in pathogenesis involving LIV, but it remains to be determined if it is a minor cause of La France disease, the causative agent of an unrecognized pathology, or benign. In support of a nonpathogenic nature, a line of *A. bisporus* infected by MBV did not show any overt phenotypic changes in the vegetative and reproductive stages.

Serology

MBV is highly immunogenic. Antibody titers of 1/1024 determined by Ouchterlony double diffusion test can be readily obtained to purified virus. Serotypes have been detected among isolates of MBV, but their possible biological significance is not known. Antibodies raised against MBV do not crossreact with LIV or AlMV.

Detection

Virions of MBV accumulate singly or as aggregates in the cytoplasm of stem and cap tissues of *A. bisporus*. The amount of virus that can be purified from mushrooms singly-infected by MBV is typically several orders of magnitude lower than that obtained from La France disease-affected mushrooms coinfected by LIV. MBV can be detected in apparently healthy and diseased mushrooms by reverse transcription–polymerase chain reaction using primers targeting a sequence in the putative replicase gene.

BENYVIRUSES

Tetsuo Tamada, Research Institute of Bioresources, Okayama University, Kurashiki, Japan

Taxonomy and Classification

The benyviruses (type species beet necrotic yellow vein virus, BNYVV) were formerly classified as possible members of the *Furovirus* genus, which have rigid rod-shaped virions, plus-strand RNA genomes, are generally bipartite and are transmitted by soil-borne fungi of the family Plasmodiophorales. Based on genome organization and sequence relatedness, these viruses have been recently reclassified in the following genera: *Furovirus* (type species soil-borne wheat mosaic virus), *Pecluvirus* (type species peanut

campestris. The distribution of MBV coincides with that of the commercial cultivation of *A. bisporus*; the virus has been reported in most major mushroom-growing countries.

Transmission and Pathogenicity

Horizontal transmission of MBV is thought to occur through hyphal anastomosis between noninfected mycelium and infected mycelium and basidiospore germlings. MBV can infect *A. bisporus* singly, but is more commonly found as a double infection with La France isometric virus (LIV), a dsRNA genome virus implicated in the etiology of La France disease. MBV is not required in pathogenesis involving LIV, but it remains to be determined if it is a minor cause of La France disease, the causative agent of an unrecognized pathology, or benign. In support of a nonpathogenic nature, a line of *A. bisporus* infected by MBV did not show any overt phenotypic changes in the vegetative and reproductive stages.

Serology

MBV is highly immunogenic. Antibody titers of 1/1024 determined by Ouchterlony double diffusion test can be readily obtained to purified virus. Serotypes have been detected among isolates of MBV, but their possible biological significance is not known. Antibodies raised against MBV do not crossreact with LIV or AlMV.

Detection

Virions of MBV accumulate singly or as aggregates in the cytoplasm of stem and cap tissues of *A. bisporus*. The amount of virus that can be purified from mushrooms singly-infected by MBV is typically several orders of magnitude lower than that obtained from La France disease-affected mushrooms coinfected by LIV. MBV can be detected in apparently healthy and diseased mushrooms by reverse transcription–polymerase chain reaction using primers targeting a sequence in the putative replicase gene.

BNYVV is also found in Poland, Kazakstan, Kirgizia and Mongolia. Based on Asher (1993).

clump virus), *Pomovirus* (type species potato mop-top virus) and *Benyvirus* (type species BNYVV). These genera have not been assigned to a family or families.

Benyvirus (BNYVV) differs from these and other viruses with rod-shaped particles, including *Tobamovirus*, *Tobravirus* and *Hordeivirus*, in polymerase phylogeny, genome organization and expression strategy. For example, BNYVV RNA is 3′-polyadenylated, whereas the 3′ ends of other virus RNAs are not polyadenylated but can be folded into a tRNA-like structure. The putative replication-associated protein of BNYVV RNA is encoded by a single long open reading frame (ORF) producing a large product, which is autocatalytically processed to give the two species of products. In contrast, other viruses contain motifs for these functions on two ORFs separated by a leaky stop codon or by two respective genomes. Based on the polymerase phylogeny, BNYVV is included in a cluster together with animal *Togavirus* in the alphavirus-like superfamily.

The other *Benyvirus* members include beet soil-borne mosaic virus (BSBMV) and burdock mottle virus (BdMV), both of which are of similar genome organization and sequence homology to BNYVV. BNYVV and BSBMV are more closely related to each other than to BdMV.

Geographic Distribution

BNYVV causes the rhizomania disease of sugarbeet (*Beta vulgaris* var. *saccharifera*). The disease was first found in Italy during the 1950s, in the Po Plain and Adige Valley, but the causal virus was not identified until the 1970s, although the soil-inhabiting fungus *Polymyxa betae* had been found to be associated with the disease. Subsequent first reports of rhizomania in other countries from around the world are shown in **Table 1.** From 1971 to 1983 it was observed in an increasing number of countries, from central and southern Europe to eastern and northern Europe. In 1987, a single focus was discovered in eastern England, since when several more foci have been found in the same area of the UK. BNYVV is presently considered to occur in most sugarbeet-growing countries in Europe, but has not yet been recorded in the Republic of Ireland or in the Scandinavian countries – Denmark, Sweden and Finland.

In Japan, BNYVV was first found in 1965 and spread in sugarbeet-growing areas in Hokkaido. In China, since the first recorded finding in 1987, BNYVV has spread throughout the districts along the Yellow River and Xinjiang Uygur. In the USA, BNYVV was first recorded in California in 1983 and in Texas in 1987. Between 1992 and 1994, the disease was found in Colorado, Idaho, Nebraska and Wyoming.

BSBMV is widely distributed in the USA, but has not been identified from other countries. BdMV was first found in burdock (*Arctium lappa* L.) in Japan in 1970.

Economic Importance

BNYVV causes severe damage in sugarbeet. Yield losses depend greatly on the inoculum level in the soil, the weather conditions and the time of infection. Severe infection leads to reduction in yield of 50% or more; in particular, the sugar content is reduced from

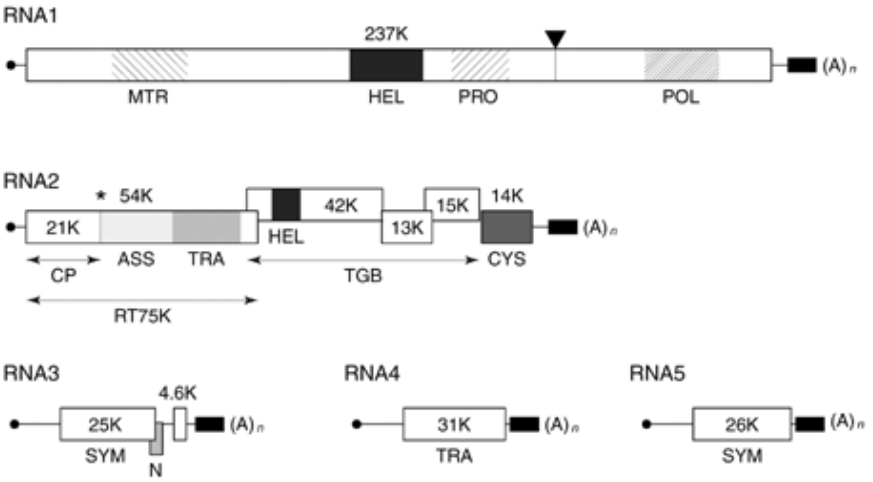

Figure 1 Genome organization of beet necrotic yellow vein virus. The filled circles indicate the cap structures, the boxes indicate ORFs, and the black rectangles indicate conserved common sequences preceding the 3′ poly(A) tail. The sizes of polypeptide products are given as K (kDa). The black triangle indicates the location of the predicted cleavage site and the asterisk indicates a readthrough amber terminal codon. The coat protein (CP), the readthrough protein (RT) and the triple gene block (TGB) are shown by arrows. The methyltransferase domain (MTR), the NTP-binding/helicase domain (HEL), the papain-like proteinase domain (PRO), the GDD replicase domain (POL), the cystein-rich (CYS) region and those involved in virus assembly (ASS), transmission (TRA), symptom expression (SYM) and necrosis (N) are indicated.

16–18% to less than 10%. Since BNYVV survives in the soil for many years without any decrease in infectivity, its presence makes it necessary to avoid growing sugarbeet in heavily infested soils.

BNYVV shows a great capacity for local dispersal from infested fields and for spread to regions previously uninfested. For example, although the exact origin of the epidemic since the 1970s is obscure, it is certain that large areas of beet cultivation in Europe, the USA and China were free from BNYVV until recently, but there has been considerable spread within Europe and elsewhere (**Table 1**). Its absence from certain countries and regions has been confirmed by intensive surveying. It is thus only in the last 15–20 years that BNYVV has developed into a serious problem in many sugarbeet-growing regions of the world.

Virus Structure

BNYVV particles are hollow, rigid nucleoprotein rods around 20 nm in diameter, with essentially two dominant particle lengths of 390 nm (RNA1) and 270 nm (RNA2). BNYVV has shorter particles of 105, 90 and 80 nm, corresponding to smaller RNA species of RNA3, -4 and -5, respectively. For BNYVV, the single-stranded right-handed helix has a 2.6 nm pitch with an axial repeat of four turns, involving 49 subunits of a 21 kDa protein, which encapsidate each single-stranded genomic RNA component separately. RNA contains about 5% of the particle weight.

Genome Structure and Molecular Biology

The genome of BNYVV consists of five plus-strand RNA components designated RNA1 to RNA5 in order of decreasing size. A genetic map of the viral RNAs is shown in **Fig. 1.** All five viral RNAs have cap structures at their 5′-termini and terminate in a 3′-poly(A) tail. Close sequence homology among the five RNAs is limited to the 5′-terminal 8–9 nucleotides and the last 70 nucleotides preceding the 3′-poly(A) tail.

RNA1 contains a single long ORF encoding a polypeptide of 237 kDa which contains the information necessary for replication of the viral genome. This ORF contains three distinct replication-associated domains: a methyltransferase domain, an NTP-binding/helicase domain and a polymerase domain. The primary translation product of RNA1 can be cleaved autocatalytically into two species of 150 kDa and 66 kDa by a papain-like protease motif between the helicase domain and the polymerase domain. The 66 kDa protein which contains the entire polymerase domain is detected immunologically in virus-infected protoplasts.

RNA2 consists of six ORFs. The 5′-proximal ORF of RNA2 encodes the 21 kDa coat protein. The coat protein cistron is separated from a long (54 kDa) in-phase ORF by a single amber termination codon which is suppressed about 10% of the time to produce a coat protein-54 kDa fusion protein of 75 kDa (read-

through protein). The 75 kDa readthrough protein is involved in virus assembly and fungus transmission.

The central portion of RNA2 contains a cluster of three slightly overlapping genes known as the triple gene block (TGB), encoding proteins of 42 kDa, 13 kDa and 15 kDa. Synthesis of 42 kDa protein is directed by subgenomic RNA2, whereas synthesis of both 13 kDa and 15 kDa proteins is probably directed by a dicistronic subgenomic RNA2. The TGB has amino acid sequence homology and similar hydrophobicity to equivalent proteins involved in cell-to-cell movement of a number of other plant viruses, including the potex-, carla-, hordei- pomo- and pecluviruses. The first TGB protein (42 kDa) has sequence motifs characteristic of a superfamily 1 DNA or RNA helicase, including a 'P-loop' ATP/GTP-binding domain. This protein possesses nucleic acid-binding activity. The binding site is situated near the N-terminus, but the P-loop motif is not required for nucleic acid-binding. The second TGB protein (13 kDa) has two potentially membrane-spanning hydrophobic domains separated by a hydrophilic sequence that contains a highly conserved peptide motif of unknown significance. The N-terminal portion of the third TGB protein (15 kDa) is hydrophobic. The 42 kDa and 13 kDa proteins are detected in a membrane-enriched subcellular fraction.

The 3′-proximal ORF of RNA2 encodes a cystein-rich 14 kDa protein which is expressed from a subgenomic RNA. The 14 kDa protein is soluble and binds zinc ions *in vitro*, suggesting that it may bind RNA and/or DNA to regulate host genome expression.

RNA3 encodes a 25 kDa protein. The 3′-terminal 600 nucleotides of RNA3 are easily detected *in vivo* as an unencapsidated, subgenomic mRNA which encodes a 4.6 kDa polypeptide of unknown function. A short ORF N (necrosis) overlaps the 3′-terminal portion of the 25 kDa ORF. The 25 kDa protein is soluble *in vivo* and localized in both cytoplasm and nuclei of infected leaves. RNA3 is involved in symptom expression. RNA4 has a longer ORF for a 31 kDa protein which is soluble *in vivo*. The RNA4 is important for fungus transmission. RNA5 contains a single ORF encoding a 26 kDa protein which is involved in symptom expression. RNA3, -4 and -5 have unusually long 5′-noncoding regions of 445, 379 and 443 nucleotides, respectively.

Genetics

BNYVV RNAs 1 and 2 have 'housekeeping' genes involved in replication, assembly and cell-to-cell movement, whereas RNA3, -4 and -5 are associated in vector-mediated infection of sugarbeet roots. RNA1 is able to replicate by itself in protoplasts, indicating that it contains all the information needed for replication.

RNA2 encodes the coat protein at its 5′ end. This ORF must be expressed very efficiently. The readthrough protein of the coat protein is a minor component of virions and is located at the ends of the viral particles. The readthrough domain consists of two subdomains, in which a region within the N-terminal half of the domain is involved in virus assembly, whereas the C-terminal portion contains sequences important for vector transmission. Alanine scanning mutagenesis of the C-terminal region shows a KTER motif which is important for fungal transmission.

Cell-to-cell movement is controlled by the three slightly overlapping TGB genes (42 kDa, 13 kDa and 15 kDa). Expression of the first two proteins can complement independently, but overexpression of 15 kDa inhibits cell-to-cell movement of the virus infection. The cystein-rich 14 kDa protein may bind RNA and/or DNA to regulate host genome expression. Indeed, there is evidence that the 14 kDa protein acts *in cis* to stimulate the accumulation of RNA2, but also acts independently and *in trans* as an enhancer of viral coat protein synthesis.

Despite the essential functions of RNA1 and RNA2 for virus multiplication, natural field isolates always include RNA3 and RNA4, or in addition RNA5. The 25 kDa protein encoded by RNA3 increases virus multiplication in roots and is responsible for rhizomania symptoms, and the RNA4-encoded 31 kDa protein facilitates fungus transmission. RNA5, encoding the 26 kDa protein, is associated with the severity of symptom expression in roots. Synergistic interactions are found between RNA3 and RNA4 or RNA5 and RNA4.

When leaves of laboratory hosts such as *Tetragonia expansa* are mechanically inoculated with BNYVV, RNA3, -4 and -5 can be eliminated intentionally from the isolate, or if present at the outset, they may disappear spontaneously or undergo extensive internal deletion during virus propagation. RNA3 has dramatic effects on symptoms on leaves. Virus isolates containing RNA3 produce bright yellow local lesions on *T. expansa* whereas isolates lacking RNA3 produce much milder symptoms. Mutagenic analysis reveals that the 25 kDa protein is responsible for these yellow spot lesion phenotypes. In addition, there is a short ORF, called N (necrosis), which overlaps the C-terminus of the 25 kDa ORF. The N gene is not detectably expressed from full-length RNA3, but can induce necrotic local lesions when activated by deletion of upstream sequences, or when inserted into another plant virus replicon.

The smaller RNAs of BNYVV are a useful material for the identification of sequences that are recognized *in cis* by the viral replication process, because they do not encode factors required for their own replication. At the 3′-terminus the *cis*-active domain is thus located within the last 70 residues preceding the 3′-poly(A) tail, in which the region can be folded into a double hairpin secondary structure which is common to the five viral RNAs. This structure probably comprises the promoter for initiation of minus-strand RNA synthesis. At the 5′-terminus, *cis*-active sequence elements are located in the first 292 residues of RNA3, in which at least two of the essential subdomains appear to be important in the formation of secondary structure. A sequence about 200 nucleotides from the 5′-terminus contains a *cis*-active encapsidation signal for RNA3. For RNA4, the 5′-proximal *cis*-essential elements are limited to the first 400 residues, but essential subdomains within this region have not been mapped. These sequences are presumably important for initiation of synthesis of the RNA plus-strand.

Serological Relationships and Variability

BNYVV and BSBMV are serologically related but distinct. BNYVV and BdMV are not serologically related. No serological differences are found among BNYVV isolates. However, the majority of the virus isolates may be classified into two major groups (A and B types) by single-strand conformation polymorphisms of immunocapture reverse transcriptase–polymerase chain reaction (RT-PCR) products. The nucleotide sequences of A and B types are about 97% identical when averaged over all four RNAs. The A type is found in most European countries, USA, China and Japan, whereas the B type is detected in Germany and France. It is not known whether the A and B types differ in pathogenicity. In a region of France, a third type has been found, called P, which contains RNA5. RNA5 is also detected in BNYVV isolates from Japan and China. The isolates containing RNA5 show a much stronger virulence than isolates lacking RNA5. Considerable sequence variation is also found between RNA5 molecules from French and Japanese isolates.

Host Range, Symptoms and Diseases Caused

Benyviruses (BNYVV, BSBMV and BdMV) have a narrow host range: Chenopodiaceae plant species such as the genera *Beta* and *Chenopodium,* and *T. expansa* are especially susceptible. BNYVV infects most species of the family Chenopodiaceae and several species belonging to the Aizoaceae, the Amarathaceae, the Caryophyllaceae and the Solanaceae. The virus tends to be restricted to the inoculated leaves of most host plants, when inoculated mechanically by sap. Symptoms appear as chlorotic or yellow spots which spread along the veins. The virus systemically infects *Beta macrocarpa* and spinach, causing stunting and conspicuous leaf mottling.

In nature, BNYVV infects sugarbeet, fodder beet, Swiss chard and spinach. The disease is usually distributed as foci (patches) in the sugarbeet field. The most useful leaf symptom is visible at the end of the growing season. Leaves become pale yellow in color, with long petioles and upright growth. Symptoms are characterized by root stunting and proliferation on lateral rootlets on the main taproot, and yellow-brown vascular bundles. These are typical root symptoms of BNYVV, called rhizomania. In early and severe infection, the plants are stunted, wilted and eventually die. The taproots are very small and lateral roots and rootlets proliferate. In this condition, the bright yellow color followed by necrosis along veins (giving the virus the name necrotic yellow vein) is very rarely seen. This symptom only results from movement of virus to leaves. Slight and later infection may produce no obvious symptoms.

BSBMV shows milder symptoms in sugarbeet than BNYVV in greenhouse tests. Systemic foliar symptoms caused by BSBMV appear more frequently than those caused by BNYVV. The symptoms are slight leaf distortion, mottling and yellow vein banding. Although BSBMV often causes no obvious symptoms in sugarbeet roots, some plants systemically infected with BSBMV may show similar symptoms to rhizomania. BSBMV and BNYVV are also found in the same field and even in the same plant in rhizomania-infested areas.

BdMV causes faint leaf chlorosis in burdock plants.

Detection and Diagnosis

Because foliage and root symptoms of benyviruses are obscure, as described above, ELISA is the best method for the efficient and accurate diagnosis of BNYVV. Samples should be extracted from lateral roots or from the tip of the taproot. Nucleic acid hybridization and RT-PCR assays have been developed for the detection of BNYVV. These techniques are specific, but not yet suitable for routine tests of large numbers of samples. They are used for distinguishing BNYVV strains or variants which contain different smaller RNAs. In soil or adherent soil, a biological test is possible. Beet bait plants are grown in suspected soil, and their rootlets are tested by ELISA. Bait plant tests to estimate soil infestation with BNYVV using

pregrown sugarbeet seedlings can be used to estimate the level of infestation as well as to calculate potential yield losses.

Transmission by Fungus

BNYVV and BSBMV are transmitted by the soil-inhabiting fungus *Polymyxa betae*. No vectors are known for BdMV, but its genome structure suggests that it is fungus-transmissible. *P. betae* belongs to the family Plasmodiophoraceae and is an obligate parasite of root tissue of mostly Chenopodiaceae plant species, including sugarbeet. The genus *Polymyxa* includes *P. graminis*, which is a vector of many viruses belonging to *Furovirus*, *Pecluvirus* and *Bymovirus*. *P. betae* and *P. graminis* are morphologically indistinguishable, but have different host ranges. The life cycle of these fungi consists of biflagellate zoospores, multinucleate plasmodia, zoosporangia and thick-walled resting spores in clusters or cystosori, but all lack a mycelial stage.

BNYVV can survive in soil within the long-lived resting spores of the vector. There is no evidence for virus replication inside the fungal vector. The virus is acquired by *P. betae* only *in vivo* from infected root cells. Virus particles are internal, because transmission cannot be reduced by treating viruliferous zoospores with virus-specific antiserum or by washing resting spores with acid or alkali. When a viruliferous zoospore comes into contact with a healthy plant root, it becomes encysted and the contents, including virus particles, enter the epidermal cell. During growth of the plasmodium, the virus is probably released into the host cell cytoplasm. The plasmodium becomes either a zoosporangium or a cystosorus with clusters of resting spores, from which viruliferous zoospores are eventually released for infection of further host plants.

Molecular studies for BNYVV transmission show that the C-terminal region of readthrough proteins of coat protein encoded by RNA2 is essential for fungal transmission. In addition, other genome components have an indirect effect on fungal transmission: the 31 kDa protein (RNA4) is important for transmission efficiency. Although RNA3 and RNA5 are not involved in fungal transmission, the 25 kDa protein (RNA3) is responsible for rhizomania of sugarbeet, and the abnormal proliferation of fine rootlets seems to be favorable for the multiplication of *P. betae*. Thus, there may be a symbiotic interaction between BNYVV and *P. betae*. In the case of BNYVV, RNA3, -4 and -5 play important, but different, roles in the vector-mediated infection of sugarbeet roots.

Epidemiology

BNYVV is not transmitted by seed or pollen; however, the spread of the virus can result from soil contamination of seeds which have been produced in infested areas. Dried infected roots or air-dried soils have been shown to retain the infectivity for more than 15 years. A similar longevity of the fungus is observed in field conditions. Thus the virus disease has occurred when sugarbeet has been grown in fields in which no crops have been cultivated for 10–15 years.

The spread of BNYVV (with resting spores of viruliferous *P. betae*) is brought about by the use of machinery on contaminated land, transportation of infested soil (beet roots, potatoes, possible beet seed or any vegetables grown on infested land) and application of irrigation. Factory waste, washing water and agricultural equipment are potentially significant in the spread of the disease. Stable manure can play a role in the dispersal of BNYVV, because *P. betae* is capable of passing undamaged through the digestive tracts of animals. Fungal resting spores can be dispersed by floods or wind.

The most important factors affecting the development of disease in infected fields are the level of inoculum, the temperature of and the moisture in soil. As a zoosporic fungus, *P. betae* requires a high soil moisture level for maximum activity: water is essential to enable cysts to germinate and zoospores to swim to roots. Thus, the development of the disease becomes severe where there is poor soil structure, inadequate drainage, frequent heavy rainfall or the use of (excessive) irrigation. A relatively high temperature of about 25°C is suitable for *P. betae* activity. Soil temperature in the spring and early summer may therefore be of particular importance because the earlier that the plants are infected, the more severe the damage. *P. betae* infects most rapidly and actively in neutral or alkaline soils.

Control

Control of diseased fields is not likely to be achieved by management of cultural or agronomic practices. Some chemicals, especially soil fumigants, have been partially effective in reducing yield losses but are generally not economic. The search for tolerant or resistant cultivars has been actively carried out since 1978: the results obtained have been very encouraging. Forecasting or estimating the level of infestation which corresponds to losses in yield would be helpful for adaptation of resistant varieties and other control measures.

In moderately or heavily infested areas, agronomic factors and cultural practices appear to be of minor, if any, importance in disease management. However, in areas where BNYVV is still absent or the inoculum potential is low, measures such as wider crop rotation, controlled irrigation and effective drainage can delay the spread and incidence of the disease.

In general, soil fumigants such as dichloropropene, dichloropropene and dichloropropane, chloropicrin and methyl bromide have been proved to be effective. Treatments with such fumigants may be economically worthwhile where the disease is seriously widespread and no other control measures are available; however, they are only partially effective because, although resting spores of the fungus in the upper layers of the soil may be killed, reinfestation from lower layers occurs during the growing season and treatments must be repeated each time a crop is grown.

Several resistant cultivars such as Rizor have been developed and are presently grown in rhizomania-infested regions of continental Europe and other countries. The resistance of such cultivars is caused by a restriction of virus multiplication and/or translocation in the roots, but not by resistance to infection by the vector *P. betae*. In general, resistant and tolerant cultivars that have been so far developed yield about 10% less than standard cultivars in normal conditions. The continuing efforts of plant breeders should ensure that new varieties that are higher yielding and more resistant will be developed, either by conventional breeding or by biotechnological methods, in the future.

BIRNAVIRUSES – ANIMAL (*BIRNAVIRIDAE*)

Hermann Becht, Linden, Germany

History and Definition

The family *Birnaviridae* was established in 1986 to describe and classify a group of viruses which carry a bisegmented double-stranded RNA (dsRNA) genome as their prominent characteristic. Further unique features can be noted for this family: the genomic segments are circularized by a genome-linked protein; segment A of the genome is structurally and functionally bicistronic, and the main translation product is a polyprotein cleaved by a virus-coded protease. The two main representatives of this virus family are the infectious pancreatic necrosis virus of fish (IPNV) and the causative agent of infectious bursal disease of chickens (IBDV). Infectious pancreatic necrosis was described for the first time in Canada in 1940; the viral nature of the causative agent was defined in 1960, and in subsequent years the structure and molecular biology of this virus has been studied extensively.

In 1962 an outbreak of a novel disease in a chicken flock was described in Gumboro, Delaware, USA, and according to this location of the first description further outbreaks have subsequently been referred to as 'Gumboro disease'. The most prominent lesion of the preferentially affected organ coined the designation 'infectious bursal disease' and IBDV as the causative virus. The first attempts to clarify the etiological agent mostly depended on electron micro-

In moderately or heavily infested areas, agronomic factors and cultural practices appear to be of minor, if any, importance in disease management. However, in areas where BNYVV is still absent or the inoculum potential is low, measures such as wider crop rotation, controlled irrigation and effective drainage can delay the spread and incidence of the disease.

In general, soil fumigants such as dichloropropene, dichloropropene and dichloropropane, chloropicrin and methyl bromide have been proved to be effective. Treatments with such fumigants may be economically worthwhile where the disease is seriously widespread and no other control measures are available; however, they are only partially effective because, although resting spores of the fungus in the upper layers of the soil may be killed, reinfestation from lower layers occurs during the growing season and treatments must be repeated each time a crop is grown.

Several resistant cultivars such as Rizor have been developed and are presently grown in rhizomania-infested regions of continental Europe and other countries. The resistance of such cultivars is caused by a restriction of virus multiplication and/or translocation in the roots, but not by resistance to infection by the vector *P. betae*. In general, resistant and tolerant cultivars that have been so far developed yield about 10% less than standard cultivars in normal conditions. The continuing efforts of plant breeders should ensure that new varieties that are higher yielding and more resistant will be developed, either by conventional breeding or by biotechnological methods, in the future.

BIRNAVIRUSES – ANIMAL (*BIRNAVIRIDAE*)

Hermann Becht, Linden, Germany

History and Definition

The family *Birnaviridae* was established in 1986 to describe and classify a group of viruses which carry a bisegmented double-stranded RNA (dsRNA) genome as their prominent characteristic. Further unique features can be noted for this family: the genomic segments are circularized by a genome-linked protein; segment A of the genome is structurally and functionally bicistronic, and the main translation product is a polyprotein cleaved by a virus-coded protease. The two main representatives of this virus family are the infectious pancreatic necrosis virus of fish (IPNV) and the causative agent of infectious bursal disease of chickens (IBDV). Infectious pancreatic necrosis was described for the first time in Canada in 1940; the viral nature of the causative agent was defined in 1960, and in subsequent years the structure and molecular biology of this virus has been studied extensively.

In 1962 an outbreak of a novel disease in a chicken flock was described in Gumboro, Delaware, USA, and according to this location of the first description further outbreaks have subsequently been referred to as 'Gumboro disease'. The most prominent lesion of the preferentially affected organ coined the designation 'infectious bursal disease' and IBDV as the causative virus. The first attempts to clarify the etiological agent mostly depended on electron micro-

scopy of virus particles which are found abundantly in the target organ, the bursa of Fabricius (BF). From these pictures IBDV was tentatively classified as a picornavirus, adenovirus, reovirus or orbivirus, until the essential structural features of a plaque-purified isolate were determined and showed remarkable similarities with the previously defined IPNV.

Besides these two prominent representatives other virus strains have been identified which possess the structural criteria of a birnavirus: Drosophila X virus (DXV) isolated accidentally from the fruit fly, Tellina virus (TV) and Oyster virus (OV) from bivalve molluscs. A virus with birnavirus characteristics has been isolated from European eels (EV) affected by stomatopapillomas. Tumors, however, could not be induced by isolated virus, although it has been claimed to cause 50% mortality in young eels. Considerable damage can be caused by yellowtail ascitic virus (YAV) in cultured yellowtail fingerlings with signs of ascites and hemorrhage in the liver.

In mammals, birnavirus-like agents have only been observed in fecal samples of humans, rats, guineapigs and pigs. Differences from true birnaviruses have been noted in size, length of genome segments, buoyant density; the designation 'picobirnaviruses' has therefore been proposed. Association of these agents with outbreaks of diarrhea is still uncertain.

Since infectious bursitis in chickens and infectious pancreatic necrosis in salmids cause considerable economic losses, only these viruses have been studied in detail and will be considered here.

Taxonomy and Classification

Since confirmation of the occurrence of a true birnavirus in mammals is still missing, classification of this family, Birnaviridae, contains three genera: genus *Avibirnavirus* (type species infectious bursal disease virus, IBDV); genus *Aquabirnavirus* (type species infectious pancreatic necrosis virus, IPNV); genus *Entomobirnavirus* (type species Drosophila X virus, DXV).

Properties of the Virion, Genome and Proteins

The prominent characteristic of a birnavirus is the genomic bisegmented dsRNA (**Fig. 1**). It is enclosed in an icosahedral capsid, about 60 nm in diameter, which is arranged as a single shell (**Fig. 2**). For the fine architecture of the capsid a symmetry of $T = 13$ has been determined. The handedness for the strains examined was dextro for IBDV and EV and laevo for IPNV. Four structural proteins could be identified in purified virus particles, two of which constitute the

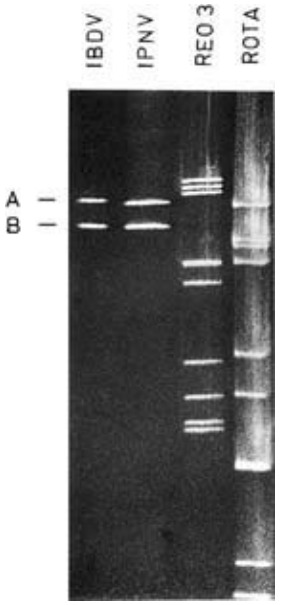

Figure 1 The two genomic segments of dsRNA of infectious bursal disease virus and infectious pancreatic necrosis virus in comparison to the genomic segments of reovirus 3 and rotavirus after polyacrylamide gel electrophoresis.

major structural components. In IBDV the two major proteins (VP2, mol. wt 40 kDa; VP3, 32 kDa) are present in almost equal quantities, whereas in IPNV VP2 (60 kDa) amounts to more than 50% of the total protein mass. The minor proteins comprise the large component VP1 (90 kDa) and VP4 (28–29 kDa). The latter is incorporated into IPNV particles only in minute amounts, whereas the infected cell carries this protein abundantly; hence the designation NS for nonstructural in the IPNV nomenclature. Structural similarities among aquatic birnaviruses can be detected by serological crossreactions. Subgroups have been established by crossneutralization of different isolates.

Host Range and Epidemiology

IPNV has been isolated from brook trout and rainbow trout, where considerable economic losses can occur mainly in hatchery-reared young fish not older than 6 months. Surviving or subclinically infected fish may become life-long carriers. Recent epizootics have been reported with mortality rates of 10–20%. In other reports mortality exceeded 50%. The virus is shed with urine, feces and sex products and is easily transmitted. The virus has also been isolated from Atlantic salmon, but its pathogenic significance for this fish remains uncertain. Other subclinically infected fish species are considered as virus carriers

and as a potential source of infection. Although IPNV is distributed worldwide, preferential habitats seem to exist for individual serotypes. In Norway serotypes 2 and 3 have been isolated from farmed rainbow trout and Atlantic salmon, whereas serotype 1 has not so far been detected.

IBDV has also a worldwide distribution and can cause considerable damage to the poultry industry. The serotypes determine the host range of this virus. Serotype I is exclusively pathogenic for chickens; infections in turkeys are subclinical. Serotype II, on the other hand, has been isolated from turkeys affected with coryza and diarrhea, but it remains unclear whether this serotype has any true pathogenic significance. Infections of chickens with serotype II do not cause clinical manifestations or noticeable lesions, and natural infections are uncommon. Transfer of the virus usually takes place via the fecal–oral route.

Stability of Viruses

Both viruses are highly stable under different environmental conditions. IPNV remains fully infective for months in freshwater or seawater. Progressive inactivation occurs after drying or heating at 60°C or storage at extreme pH conditions (pH 2 or pH 9). It is rapidly inactivated by exposure to chlorine, iodine and ultraviolet irradiation. IBDV can persist in poultry houses even after thorough cleaning and disinfection. This complicates attempts to control infections by hygienic means and makes vaccination inevitable. This virus is more resistant to heat and ultraviolet light than reovirus. It is inactivated at pH 12.0, but remains infective at pH 2.0. Infectivity is markedly reduced by exposure to 1% formalin for 1 h; 1% phenol or cresol inactivates the virus within 1 h.

Clinical Signs and Pathology

Fish infected by IPNV usually darken; they may move in spirals around their long axis, may develop exophthalmia, abdominal dilatation and ventral hemorrhages. Livers and spleens are pale, the viscera may be covered with multiple petechia. A clear or milky mucus in the stomach and anterior intestine is taken as indication of IPNV. Histologic examination reveals necrotic foci in acinar and islet tissue of the pancreas. As high virus titers are usually present in kidney tissue, this organ is a preferred site for virus isolation.

Chickens infected by a pathogenic strain of IBDV show symptoms of general distress and apathy after an incubation period of 2–3 days. Severity of these general manifestations progresses rapidly, and the birds usually die within 1–3 days. The most conspicuous lesions concern the BF. The organ is enlarged, edematous and in some cases hemorrhagic. Petechial or diffuse hemorrhages may be found in muscular tissue. Lymphoid follicles of the BF are totally necrotic, and in surviving birds the follicles are devoid of lymphoid cells.

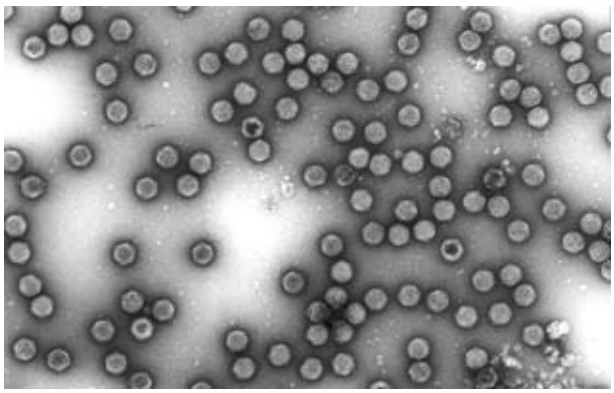

Figure 2 Electron micrograph of purified particles of infectious bursal disease virus; average diameter about 60 nm.

Pathogenic Properties

A single passage of a virus sample derived from a BF infected with IBDV is sufficient to reduce pathogenic properties of the isolate. Although continuous animal-to-animal passages of a virulent strain are lethal to almost 100% of birds, *in vitro* cultivation in chick embryo cells (CEC) abrogates the lethal outcome of an infection with this type of material. In that case, birds hardly show any clinical signs. However, the BF is still severely affected and all follicles are almost completely depleted of lymphoid tissue. In the small plaque variant, obtained after undiluted passages or by selection of a small plaque from the plaque population, the pathogenic properties are even more reduced. Infection of chickens with a small plaque variant is tolerated by the animals without exhibiting any clinical signs, and only limited necrotic foci are visible in lymphoid tissue of the BF. The isolated lesions are repaired so that immunodeficiencies do not result from such an infection, which stimulates the production of virus-specific antibodies.

For IPNV this correlation between plaque size and virulence has not been established. A high variability among pathogenic properties of different isolates has been reported, and continuous passage in cell culture did not invariably lead to attenuation of the virus.

Cell Tropism of IBDV

The pivotal position of the BF for virus replication in the natural disease, which becomes decisive for the

outcome of an infection, has been underlined by experiments in which bursectomized birds survived a lethal infection without any clinical manifestation. Lymphoid cells from the BF obviously represent optimal host cells for rapid production of maximal numbers of infectious virus particles. The bursal stage of differentiation of B cells is decisive for virus replication, because stem cells or peripheral B cells are completely refractory and do not replicate the virus. Among lymphoid cells isolated from the BF only a fraction can be infected *in vitro*. This is in contrast to the situation *in vivo* where in thin sections of the BF viral antigen can be demonstrated by immunofluorescence in virtually all cells of a follicle. This means that besides the stage of differentiation of B cells the microenvironment of the BF has a considerable impact on the functioning of B lymphoid cells as ideal host cells for IBDV. Expression of Ig-receptors at the surface of bursal cells does not seem to influence their sensitivity towards IBDV infections. This exquisite tropism for bursal cells determines the age-dependent sensitivity of chicks towards IBDV infections. Lethal infections are mostly restricted to 3–6 weeks of age when the BF has reached its maximal stage of development.

In Vitro Replication

IPNV replicates to high titers of 10^8–10^9 PFU ml^{-1} in a number of cell lines derived from fishes. The RTG-2 cell has been most commonly used for *in vitro* studies. Various cell lines of amphibian, avian or mammalian origin do not support replication of the virus. The virus replicates well at 10–26°C, poorly at 4°C and not at all at 30°C. Cell-associated virus can be demonstrated at about 4 h postinfection, virus starts to be released at about 7 h after infection and reaches maximal levels at about 16 h postinfection.

IBDV strains can be propagated in CEC where plaque formation is helpful for virus titration. It has been a common observation, however, that highly pathogenic strains can be isolated in cell culture only with great difficulty or not at all. After an eclipse period of about 4 h virus titers increase to reach a maximum of about 10^7 PFU ml^{-1} at 12–16 h after infection. Virus replication has also been noted in Vero cells and other continuous cell lines, where prolonged replication cycles have been observedI.

The consecutive steps involved in virus replication have not been traced individually. The most serious obstacle encountered in biochemical analysis has been the failure of birnaviruses to block synthesis of cellular constituents. It has been particularly difficult to direct sufficient label into newly synthesized IBDV RNA. Cellular background synthesis could not be repressed by actinomycin D which can normally be used for selective inhibition of cellular RNA synthesis, because these viruses proved to be highly sensitive towards low doses of this drug. Some differences in the dose of actinomycin D inhibiting IPNV replication has been noted in dependence on the host cells used. No nuclear phase is involved in birnavirus replication. Virus particles become transcriptionally active without pretreatment of the virion with chymotrypsin. Precursor molecules can reach the polymerase–template complex through the single shell of the capsid and can initiate transcription and RNA replication. For the intracellular replication cycle these *in vitro* findings mean that there is no definite need for uncoating or degradation of the capsid. *In vitro* polymerase activity yielded two species of RNA sedimenting at 24S and 14S which hybridized with the two segments of genomic RNA. During the first 10 min after the *in vitro* reaction had been started, newly synthesized RNA remained restrained to a complex containing intermediate products which were partly RNase sensitive and barely entered the polyacrylamide gel. The newly synthesized 14S component could be identified as the two segments of the genomic RNA, since their migration rate in polyacrylamide gels and the RNase resistance was identical to the genomic form of RNA (**Fig. 3**). The 24S RNA species consisted of single-stranded (ss)RNA which did not self-anneal, was RNase sensitive and supported synthesis of virus-specific proteins in an *in vitro* translation system. All structural viral components could be precipitated with virus-specific antibodies from the reaction mixture.

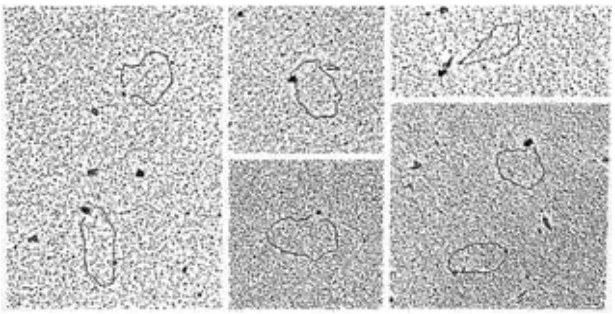

Figure 3 Electron micrograph of circular dsRNA–protein complexes released from infectious bursal disease virus particles by heating in the presence of 1.5% sodium dodecyl sulfate. (Courtesy H. Müller.).

Protein synthesis is followed by processing of the polyprotein coded by segment A. The autocatalytic cleavage of this precursor attributed to the activity of VP4 is only indirectly deduced from the activity of truncated regions of segment A expressed in *Escher-*

ichia coli; there is no proof whether the second level of processing, which involves the transit of the precursor VP2a to the main structural element VP2, might also be a function of VP4 or whether the trimming of this precursor is carried out by cellular proteases. In extracts from IBDV-infected cells only the 50 kDa precursor could be demonstrated in substantial amounts; the final major structural component VP2 does not accumulate in the cell but is assembled into the virion immediately before virus particles are released into the medium. Since virus particles could be isolated from the BF which had a high specific infectivity in spite of their lower density due to the 50 kDa precursor, cleavage could take place on the assembled particles, at least in some types of host cells. Truly 'incomplete' particles with greatly reduced infectivity, reduced density and excessive amounts of the 50 kDa precursor besides a series of aberrant proteins, are preferentially formed during undiluted passages. Stable small plaques are formed under these von Magnus conditions.

This is in contrast to findings with IPNV where undiluted passages did not increase the yield of defective interfering (DI) particles, but nevertheless their interference was held responsible for the survival of host cells. Incomplete particles could not be separated from standard virus by isopycnic centrifugation.

Organization of the Genome, Processing and Functional Significance of Gene Products

When routine methods for RNA sequencing became available, the coding region of birnavirus genomes were defined, nucleotide sequence of various isolates and serotypes were compared, and the genomic organization of both segments could be delineated. On segment A one open reading frame (ORF 1) coding for a polyprotein of 110 kDa is arranged in the following order: NH_2-VP2-VP4(NS for IPNV)-VP3-COOH. This primary translation product is rapidly cleaved into the precursor protein of VP2 (pVP2 or VP2a), VP4 and VP3. There is good evidence that this first step of processing is autocatalytically carried out by VP4. A cellular protease is most likely responsible for the following step of the VP2 precursor cleavage which proceeds more slowly and less efficiently, so VP2a can regularly be found in virus particles in proportions of a minor structural protein. It has been firmly established now that VP2 is the structural protein responsible for the induction of neutralizing antibodies, whereas VP3, the other major structural component, does not have this capacity.

ORF 2, which precedes and partially overlaps ORF 1, encodes a protein (VP5) of 145 amino acids in IBDV and a 17 kDa protein in IPNV, which is not incorporated into virus particles. This nonstructural protein was demonstrated in the cytoplasm of infected cells. Very recently a VP5-defective mutant was generated by site-directed mutagenesis. Although this mutant replicated at a slower rate in permissive cells, virus yields finally reached the levels of the original strain. This means that VP5 is not essential for virus replication. Its deletion may be useful as a marker, if tracing a particular virus strain is desired.

Figure 4 outlines the entire genome of IBDV including the terminal noncoding regions which were determined only recently. The 5′-NCR of segment A consists of 96 nucleotides adjacent to the start codon of the *VP5* gene; the terminal region of segment B spans 111 nucleotides to the start codon of the *VP1* gene. There is extensive homology between the 5′ noncoding region of segments A and B, particularly along the 32 5′ nucleotides. No homologies exist, however, in the 3′ terminal sequences of the two

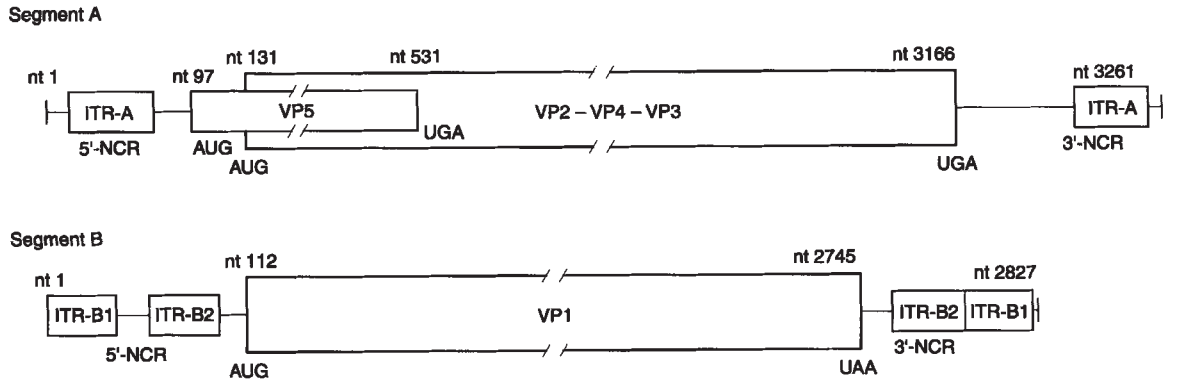

Figure 4 Model of the genomic organization of segments A and B of the IBDV genome. Number of nucleotides (nt), the startcodons and stopcodons of the ORFs, the different inverted terminal repeats (ITR) and the alignment of the codons for the viral proteins VP1–VP5 are indicated. (Courtesy E. Mundt and H. Müller.).

segments. Different inverted repeats were noted in both segments. This type of structure also appears to hold true for IPNV. Some interesting speculations have been put forward with respect to the functional significance of some of these sites. A sequence of 13 nucleotides in the 5′ terminus of both segments corresponds to the binding site of chicken 18S rRNA. An exchange of one nucleotide in the 5′ end of segment A of an attenuated strain might be indicative for the genetic constellation determining the pathogenic property of a particular strain. Secondary structures, derived from these terminal sequences, might be involved in virus replication, packaging of viral elements and possibly in determining the range of susceptible host cells.

Elegant proof that the sequences presented for segments A and B comprise the entire viral genome was obtained when a full yield of infectious virus resulted from cells which had been transfected with RNA transcribed from cloned DNA. Fidelity of replication induced by this synthetic positive-stranded RNA was ascertained by the introduction of tagged sequences into the transfecting RNA which could be recovered in the genome of the newly generated virus.

Comparison of the nucleotide sequence of ORF 1 of three European isolates and an Australian strain has established a close relatedness, the greatest difference being 7.8% among nucleotides and 2.7% at the amino acid level. VP4 was found to be fully conserved, some amino acid changes are scattered throughout VP3 and VP2 except for a tight cluster of exchanges in protein VP2. These variable regions provide the structural basis for the formation of the epitope which is responsible for the induction of neutralizing antibodies. It has now been established with certainty that VP2 is the reaction partner for neutralizing antibodies.

Genome segment B codes for a single protein, the structural component VP1. This protein has been found to be the stabilizing link between the ends of the dsRNA segments to form ring-like structures. During the first attempts to determine the size of the RNA segments no protease or fully denaturing conditions had been applied for the isolation of genomic RNA. Conservation of intact RNA circles, which remained closed by the protein under these conditions, explains why considerably higher molecular weights had initially been determined for both genomic RNA segments.

The close association of this protein with viral RNA had insinuated a polymerase function. Indeed, VP1 turned out to be a multifunctional enzyme. Its role as a replicase and transcriptase became evident by the *in vitro* demonstration of dsRNA products which had the size of the genomic segments, and by the production of mRNA which could code for the *in vitro* synthesis of virus-specific proteins. Formation of a VP1–GMP complex shows how this protein is indispensable for capping of mRNA. This means that besides polymerase activities this protein functions as a guanylyltransferase and most likely as a methyltransferase. It has even been postulated that VP1 serves as a primer for *in vitro* transcription which is carried on in a semiconservative strand displacement mechanism. This concept has to be reconsidered in view of the recent finding that plus strand RNA from both segments is sufficient to initiate virus replication.

Antigenic Structure

Neutralization has been the most sensitive and widely used method for serotyping birnavirus isolates. Among most IPNV strains some crossneutralization has been observed, but three different groups have been established with the following reference strains: VR 299 for serotype 1, Ab for serotype 2 and Sp for serotype 3. A further strain N1 with a distinct antigenic structure has recently been isolated from Atlantic salmon in Norway. All aquatic birnaviruses crossreact serologically to some extent. A high degree of crossneutralization has been noted for OV and TV; fluorescent antibodies crossreacted with IPNV and TV.

For IBDV two definite serotypes could be established which show some residual crossneutralization. Serotype I encompasses the classical strains causing bursal disease in chicks, whereas serotype II differentiates the nonpathogenic strains originally isolated from turkeys.

Neutralizing antibodies raised against either serotype of IBDV precipitated VP2 in extracts prepared from infected CEC; these antibodies did not bind in immunoblots. It can be concluded, therefore, that the antigenic site responsible for the induction of neutralizing antibodies is highly conformation-dependent. The isolation of escape-mutants with neutralizing antibodies as selection barriers clearly showed that at least three independent types of epitope exist in the domain responsible for the induction of neutralizing antibodies. The structural basis for the formation of this conformation-dependent epitope is provided by two hydrophilic regions in the central part of the VP2 peptide. Exchange of one amino acid in one of the hypdrophilic parts is sufficient for altering the neutralizing specificity. Towards the C-terminal end of VP2, adjacent to this conformational site, identical amino acid sequences form a sequence-dependent epitope crossreacting with both serotypes. Considerable variation in the degree of neutralization has been noted among

isolates in America, and vaccination failures have been attributed to these 'variants'. Such an antigenic drift could not be confirmed for strains isolated in Europe or in Africa.

Antigenic differences between serotypes I and II not only reside in VP2; structural protein VP3 can also be used for differentiating the two serotypes. Monoclonal antibodies could be prepared which were directed against VP3 of one serotype only, whereas other antibodies recognized a common epitope. The serotype-specific and the common epitopes are arranged on VP3 in a nonoverlapping manner. Formation of the common and type-specific epitopes is in agreement with identical and mismatching amino acid sequences yielding hydrophilic segments on the VP3 polypeptide. Amino acid exchanges clustered in hydrophobic parts did not interfere with the antigenic specificity. There is no serologic crossreactivity between IBDV and other birnaviruses.

Immune Response

Antibodies against IBDV appear rapidly; 3 days after infection neutralization assays are positive. A protective immunity fully depends on neutralization. Accordingly, antibodies to serotype II do not protect chicks against infections with virulent type I viruses. Birds that survive an acute infection, or animals that become infected during the insensitive age shortly after hatching, are likely to suffer from a severe general immunosuppression. The tropism of IBDV for B cells in the BF destroys all lymphoid follicles in this organ and blocks further supply of immunocompetent mature peripheral B cells. Frequent consequences of this immunosuppressive viral infection are opportunistic infections by various agents which are mostly lethal for the animals during the weeks which follow an infection.

Laboratory Diagnosis

Infections by IPNV are confirmed by virus isolation in permanent fish cells which are preferentially inoculated with samples of kidney tissue. Virus can be titrated in these cells by plaque assay. Direct diagnosis can be established by immunofluorescence with thin sections from internal organs.

Agar gel precipitation is the most feasible and economic method to demonstrate IBDV-specific antigens in extracts from bursal tissue. Antigen containing cells can be easily identified by immunofluorescence with impression smears of bursal lymphoid tissue or frozen sections of this organ. Virus can be isolated in embryonated eggs or CEC under the previously mentioned restrictions. Neutralization or ELISA are efficient and feasible methods for serodiagnosis. Whole purified virus produced *in vitro* should be used for coating ELISA plates. Use has been made of standard polymerase chain reaction (PCR) techniques. Since the nucleotide sequence of the entire genome is now known, primers can be selected according to conserved or variable regions to diagnose infections and differentiate virus strains.

Prevention and Control

Live and killed vaccines are available to control IBDV. Recombinant strains have been generated and their use in the field is being evaluated. Attenuated strains mostly have a reduced replication rate *in vitro* and only produce limited foci in the BF which regenerate without any significant loss of lymphoid tissue. For one of these attenuated strains formation of small plaques could be used as an *in vitro* marker. Vaccination protocols try to guarantee protective antibody levels during the first weeks of life by passive transfer of maternal antibodies. Killed vaccines can, therefore, be used to boost high antibody levels in laying hens. Application of attenuated virus should try to fill the gap between the fading passive immunity and the production of own antibodies.

Prophylaxis of IPNV infections is mainly based on hygienic measures, such as exchange of contaminated water and addition of disinfecting iodophores during the fertilization period. Immunoprophylaxis is hampered by the circumstance that during the sensitive period fry are not protected by maternal antibodies, and about 30 days elapse before young fish acquire immunocompetence. Furthermore, the lack of cross-protection between serotypes makes the requirements for a protective immunity uncertain.

Future Perspectives

At the molecular level a number of steps have yet to be elucidated for a full description of the replication cycle of birnaviruses. A paradox phenomenon in the state of our current knowledge is the cytopathic consequence of birnavirus infections in the absence of a shutdown of cellular synthetic events. The successful establishment of a reverse genetics system will greatly facilitate future studies about replication and gene expression. The fascinating aspect of infectious bursal disease, the exquisite tropism of the virus for B cells at the bursal stage of development with deleterious effects for lymphoid tissue, is far from being resolved and will require profound description of B cell differentiation in the BF. Finally, nothing is yet known about the immediate cause of death during an acute infection. Since removal of the primary

target organ has no immediate consequences on the health of the affected bird, other vital organ systems must be expected to fail by the fatal attack of the heavy load of virus which has been produced in the BF and is flooding the organism. Attempts have hardly been successful to define the genomic constellation responsible for pathogenic properties of IBDV by comparing nucleotide sequences of strains with widely differing pathogenicity. Since the entire viral genome is known now, the potential contribution of the noncoding regions to the pathogenic property of a virus strain will be amenable to experimental trials. The recent development of a reverse genetics system will certainly be helpful in this respect, and besides other questions about virus replication at the molecular level, this type of approach will be useful to design a new generation of vaccines according to current needs. The occurrence and pathogenic properties of birna-like viruses in mammals will merit special attention.

BORNA DISEASE VIRUS (*BORNAVIRIDAE*)

Lothar Stitz and **Rudolf Rott**, Bundesforschungsanstalt für Viruskrankheiten der Tiere, Tübingen, Justus-Liebig-Universität Giessen, Giessen, Germany

History

Disease symptoms comparable to those observed nowadays after natural infection with Borna disease virus (BDV) in horses and sheep have been reported in the literature of veterinary science for more than 200 years. Synonyms such as disease of the head (Kopfkrankheit), brain fever, subacute meningitis or hypersomnia of horses reflect the restriction of the disease to the central nervous system. The current name of this disease was adopted in 1895 after an epidemic among horses of a cavalry regiment in the town of Borna in Saxony near Leipzig (Borna disease, BD). Many important studies, which have greatly contributed to the understanding of the disease in its natural host but also in experimental animals, were performed in the 1920s. Viral etiology was established as early as 1925 by Zwick and Seyfried. In the course of these studies histological examination of the brain revealed extensive pathological changes as a prominent sign of this central nervous system disease. Since then detailed studies have been performed on the spectrum of susceptible host species and on manifestations of the disease. Unusual features such as RNA splicing, overlap of transcription units and transcription signals, aspects of genome organization and

BORNA DISEASE VIRUS (*BORNAVIRIDAE*)

Lothar Stitz and **Rudolf Rott**, Bundesforschungsanstalt für Viruskrankheiten der Tiere, Tübingen, Justus-Liebig-Universität Giessen, Giessen, Germany

History

Disease symptoms comparable to those observed nowadays after natural infection with Borna disease virus (BDV) in horses and sheep have been reported in the literature of veterinary science for more than 200 years. Synonyms such as disease of the head (Kopfkrankheit), brain fever, subacute meningitis or hypersomnia of horses reflect the restriction of the disease to the central nervous system. The current name of this disease was adopted in 1895 after an epidemic among horses of a cavalry regiment in the town of Borna in Saxony near Leipzig (Borna disease, BD). Many important studies, which have greatly contributed to the understanding of the disease in its natural host but also in experimental animals, were performed in the 1920s. Viral etiology was established as early as 1925 by Zwick and Seyfried. In the course of these studies histological examination of the brain revealed extensive pathological changes as a prominent sign of this central nervous system disease. Since then detailed studies have been performed on the spectrum of susceptible host species and on manifestations of the disease. Unusual features such as RNA splicing, overlap of transcription units and transcription signals, aspects of genome organization and

deduced protein sequence led to the classification of BDV in the genus *Bornavirus* of the family *Bornaviridae*.

Properties of the Virion

In agreement with earlier filtration experiments, electron microscopic studies of thin sections of infected cells and on partially purified virus revealed the presence of spherical enveloped virus particles with a diameter of 50–100 nm. The presence of an envelope was demonstrated by the sensitivity of virus infectivity to lipid solvents as well as the recent characterization of virus-specific glycoproteins. Earlier experiments with inhibitors of nucleic acid synthesis suggested that BDV is an RNA virus, a finding that has recently been substantiated by molecular biological techniques.

Properties of the Genome

Data on the nature of the BDV genome have been obtained from complementary DNA clones using libraries prepared either from the brain of BDV-infected rats or from cell cultures. The genomic single-stranded (ss) RNA of 9.5 kb with complementary 3′ and 5′ termini has been shown to be of negative polarity. Investigations of the organization of the genome have revealed five major open reading frames (ORFs) on the antiviral genome. Several unusual aspects for an ssRNA virus have been recognized in molecular biological studies, in particular an overlap of reading frames, a post-translational processing of subgenomic RNAs (RNA splicing) and nuclear phases indispensable for virus replication. Results of sequence analyses of viruses obtained from various animal species, human or tissue culture, revealed a remarkable conservation of coding sequences.

Properties of the Viral Proteins

Immunoprecipitation with polyclonal and monoclonal antibodies can detect several proteins in infected brains and in tissue cultures, with approximate relative molecular masses of 60, 38–39, 24 and 14 kDa. The most abundant viral proteins in infected cells as well as in viral particles have a molecular mass of 38–39 and 24 kDa. The expression of the identified ORFs in various expression systems permitted the closer characterization of the major virus-specific proteins. So far, five proteins have been identified and in part characterized. ORF 1, which is the prominent 3′ ORF, encodes the 38–39 kDa protein (also known as p40), the putative nucleoprotein (NP). ORF 2 codes for a 24 kDa protein (also known as p23), a protein phosphorylated in its serine residues, representing the putative phosphoprotein (P). Recently, an additional open reading frame (ORF X1) has been identified, greatly overlapping with ORF 2, encoding a non-glycosylated BDV protein designated p10. The third open reading frame (ORF 3) encodes the p16 protein which is glycosylated post-translationally, resulting in gp18 (also known as the 14 kDa protein), representing the putative membrane protein (M). ORF 4 encodes p57 that is found in its *N*-glycosylated form at approximately 90 kDa (described as gp84 and gp94) and represents the putative precursor glycoprotein of the virus (GP); cleavage products of this GP have been reported to result in molecular masses of approximately 40 kDa by the subtilisin-like cellular protease furin. The products of ORF 1 and ORF 2 (p40 and p24) have been shown to form a complex which has been deduced from coprecipitation by monoclonal antibodies as well as from one-dimensional peptide digestion. Finally, the gene product of ORF 5, which is localized at the 5′ end of the viral antigenome, has not so far been identified. This ORF predicts a protein of 180–190 kDa and is expected to represent the RNA-dependent RNA polymerase of BDV.

With respect to the intracellular localization of these virus-specific proteins, extensive analyses have been performed. It appears that proteins p10, p24 and p40 are found mainly in the nucleus of infected cells. A colocalization of p24 and p10 on the one hand and p40 and p10 on the other, might be explained by the fact that sequences within the p10 sequence have been identified which are typical for nuclear export trafficking. The p10 itself has been demonstrated both in the nucleus and the cytoplasm. In addition, evidence has been presented that indicates the presence of a nuclear targeting sequence in the 39 kDa protein which is not present in the 38 kDa protein. This results in accumulation of the 39 kDa protein in the nucleus, whereas the 38 kDa protein is found in both the nucleus and the cytoplasm. The heavily *N*-glycosylated gp94 has been seen both intracytoplasmically in the endoplasmic reticulum as well as on the cell surface, and its function is seen in context with viral entry, assembly and budding of BDV. The gp94 as well as the gp18 apparently contain epitopes inducing the production of neutralizing antibodies, which can be found late after infection.

Physical Properties

BDV does not differ in its physical properties from any other known enveloped virus. It has been shown to be sensitive to lipid solvents, such as chloroform or acetone, and to detergents. At low temperature and at

pH 5–12 BDV is rather stable, whereas infectivity is destroyed by high temperatures and pH lower than 5.

Replication

BDV replicates to relatively low titers of approximately 10^6 $TCID_{50}$ ml^{-1} in embryonic brain cells of various provenance, including human. Besides neural cells, other cell types isolated from the brain, such as astrocytes and oligodendrocytes, support virus production. A variety of different cell lines not derived from the central nervous system have been found to be susceptible to infection. Such cell lines, supporting the growth of BDV, e.g. MDCK or Vero cells, readily become persistently infected. It was estimated that a single cell produces only one infectious virus particle, although a large amount of viral antigen can be demonstrated immunohistologically.

Little is known of the consecutive steps involved in virus replication. There is some evidence that the major glycoprotein (gp94) mediates penetration by membrane fusion after the fusion peptide becomes exposed by proteolytic cleavage of the glycoprotein. In contrast to other nonsegmented RNA viruses, the BDV genome is replicated and transcribed in the nucleus of infected cells. The cellular splicing machinery is required to process some of the primary RNA transcripts. A variety of mechanisms are used to regulate gene expression, including the use of overlapping reading frames, overlapping transcription units, alternate RNA splicing and leaking scanning of ribosomes during protein translation. The replication cycle seems to be completed within 24 h. Only a little of infectious virus, if any, is released from infected cells.

In situ hybridization was successful in various cell types of the nervous system, such as neurons of various brain regions, in Purkinje cells and in ventral motor neurons of the spinal cord in accordance with the detection of BDV-specific proteins by immunocytochemical methods. Astrocytes, oligodendroglia, ependymal cells and Schwann cells have also been identified as target cells for BDV. In addition, the normally strictly neurotropic virus can also replicate in cells of peripheral organs under defined circumstances, such as after infection of newborns or in long-term immunosuppressed animals.

Geographic Distribution

BD was originally described as a disease restricted to certain endemic areas in eastern and southern Germany and Switzerland. Recent seroepidemiological studies, however, have shown that natural infection is much more widely distributed than previously anticipated. These investigations revealed seropositive horses throughout Germany, but also in other European countries, North America and Japan, findings which strongly support the notion that BD might have a worldwide distribution.

Host Range and Virus Propagation

Natural infection with BDV has originally been shown to occur in horses, sheep, cattle and rabbits. Recently, cats, ostriches and various zoo ruminants have been identified as natural hosts. Reports on infection of other species, such as goat, deer and donkey, are rare, and BDV etiology has not been proven unequivocally, although such cases seem likely in view of the extremely broad experimental host spectrum of the virus. During recent years it has been proposed that BDV or a closely related virus might also be involved in infections of humans. There was a prevalence of seropositive reactions in patients with psychiatric disorders from Germany, the USA and Japan. The specificity of this reaction could be substantiated when a BDV-specific protein translated by RNAs which had been derived from a BDV-specific cDNA clone was used for the assay. Recently, the presence of virus-specific nucleic acid has been demonstrated in postmortem brain samples of schizophrenic patients and patients with bipolar disorders, and possibly even in normal human brain tissue, but not in samples from patients with multiple sclerosis, Alzheimer's disease or Parkinson's disease. Similar results were obtained in some postmortem samples that had been investigated immunocytochemically. There are no confirmed reports of virus isolation from humans and thus final proof as to whether BDV can be implicated in human disease must await further verification.

Experimental hosts comprise a wide variety of species ranging from birds to nonhuman primates. The most thoroughly investigated experimental BDV infection in rats has contributed considerably to the elucidation of the disease process. As disease symptoms of horses and rats do not differ significantly from each other, and as cell types and location of cells involved in the inflammatory reaction in both species are fully comparable, experimental BDV infection of rats can be regarded as a model system for natural infection. Efforts to establish a mouse model of BD have only recently been successful. Interestingly, adult infected mice show infectious virus persisting in the brain, but only very rarely does clinical disease become apparent and most animals appear to be resistant to the disease. In contrast, the infection of suckling mice results in neurological symptoms with

an incidence of 20–100%, depending on the mouse strain.

The virus readily replicates in the brain of infected animals. After adaptation the virus grows to titers of approximately 10^6 $TCID_{50}$ g^{-1} tissue. In contrast to intracerebrally infected experimental animals, where the virus can be detected throughout the brain, in naturally infected hosts the presence of virus is found to be restricted to certain or single areas in the brain without evidence for virus-specific antigen in other brain regions.

Serological Relationship and Variability

Serologically, no distinction can be made between different virus isolates by using polyclonal antibodies. Variable detectability of viral antigens in brain specimens by monoclonal antibodies indicates, however, that some strain variation may exist. No conclusive data are available on the occurrence of biologically different virus strains in natural hosts. It remains to be seen whether inapparent infections in horses and sheep might be due to variant strains. All virus strains used for infection of experimental animals originate from brain tissue of naturally infected diseased horses. These isolates mostly underwent serial passages in rabbits and were adapted thereafter to different animals. Different biological properties of virus isolated at various times after infection from rats could also point to the existence of variants. In this context it should be emphasized that virus isolates exist that cause extreme obesity syndrome or behavioral alterations in infected rats.

Sequence analyses confirmed the general view of highly conserved regions in the BDV genome.

Epidemiology

Originally BD was considered an endemic disease occurring sporadically in central Europe. Recent seroepidemiological investigations in horses have revealed virus-specific antibodies in 12% of randomly collected horse sera from Germany, Switzerland and other European countries. Most of these animals were without clinical signs of BD, but some exhibited disease symptoms within an observation period of 1 year. Since the chance of contact between horses has increased tremendously during recent years as a result of worldwide horse trading and international sporting activities, worldwide distribution of BD cannot be excluded. No data are available on the reservoir of the virus. There is some evidence that virus is shed during inapparent infection of horses and sheep, which also could lead to further propagation of the infection. If one takes into account that persistent infections can be established in tolerant infected rats and that these animals continuously shed virus, this mode of infection appears to be a possiblity for maintaining BDV in the horse population. Whether persistently infected tolerant rats or other rodents could represent a virus reservoir has not been investigated.

Transmission and Tissue Tropism

Intranasal infection seems to be the most likely route of natural infection, since nerve endings in the nasal mucosa are readily accessible to the virus. Furthermore, certain pathological peculiarities observed in naturally infected horses, such as edema of the bulbus olfactorius, can be found in experimentally infected animals only after intranasal infection. Another possible route of infection might be orally, via the trigeminal nerve, which has been found to contain BDV-specific antigen in horses; however, the possibility still exists that positive reactions in the nerve are rather due to early centrifugal spread of BDV via this nerve. In its natural hosts and also in adult experimentally infected animals the virus shows a strict neurotropism. After the virus has entered the nerves it migrates axonally to the central nervous system, where it replicates in neurons and astrocytes, especially in neurons of the hypothalamus. With time the virus spreads throughout the central nervous system. Various routes of infection have been shown to result in clinical disease in susceptible animals. Experimentally, the most common is the intracerebral infection, but it has also been demonstrated that hosts get sick after intranasal, intraperitoneal or even intravenous inoculation of the virus. In rats infected as adults the virus shows the same strict neurotropism as in the natural hosts. Infectious virus is found in the brain as early as 7 days after infection and reaches titers of 10^6 $TCID_{50}$ ml^{-1}. Infectious virus can also be detected in the spinal cord, in ganglia of the autonomic nervous system, in peripheral nerves, in the adrenal glands and neural cells of the retina, although at considerably lower titers or by immunocytochemistry only. No infectivity can be found in the eyes of rats late during the course of infection, which coincides with severe degeneration of neurons in the retina. In all neuronal tissues mentioned above, infectivity can be found throughout the life of the infected animal, i.e. they develop a persistent productive infection. In sharp contrast to rats infected as adults, neonatally infected rats harbored infectious virus not only in the central nervous system but also in cells of peripheral organs. Since in neonatally infected rats infectious virus was also found in salivary glands, lacrimal fluid and urine, those animals have to be regarded as infectious chronic carriers of BDV. A similar pattern of

distribution of BDV was found in long-term immunosuppressed adult rats. Loss of immunocompetence in athymic rats or in animals treated with a single application of cyclophosphamide does not result in virus replication in organs outside the central nervous system. This phenomenon remains unexplained.

Pathogenicity

Virus strains isolated from naturally infected animals are equally pathogenic. This comparable degree of pathogenicity, however, might not represent the entire picture *in vivo*, as BDV has been exclusively isolated from diseased animals. Besides these highly pathogenic strains, variants with reduced pathogenicity may exist in inapparently infected animals. The potential existence of such virus variants has been documented in rats, where strains of different origin could cause different clinical manifestations or inapparent infections. All of the BDV strains originating from brain tissue of diseased horses or sheep induced disease in rabbits as well as in rats. Infection with the same virus did not induce disease in adult mice and hamsters but replicated in the brains of these experimental animals. This type of infection led to behavioral disorders and neurological symptoms in rats, or it only resulted in behavioral alterations and premature senility in tree shrews. The question of why in some species infection remains subclinical cannot yet be answered. Similarly, no conclusive data exist to explain why certain experimentally infected rats develop obesity; different pathogenicity associated with virus variants is one of the options.

Immune Response

The immune response to BDV has been shown to represent the basis of the pathogenesis of the disease. Whereas infection of adult immunocompetent animals regularly results in disease, infection of newborn or athymic rats or animals rendered immunodeficient by drugs leads neither to encephalitis nor disease, despite the persistence of the virus. These findings, in conjunction with the property of BDV being a noncytolytic virus that persists in the brain of immunocompromised hosts at titers comparable to those in immunocompetent animals, provide all the characteristics of an immunopathological disease. In rats infected as adults a vigorous antibody response to BDV antigens can be observed, which obviously does not participate in the immunopathogenesis of the disease because BDV-specific antibodies adoptively transferred to immunoincompetent recipients do not induce pathological changes or disease; the same is true for the appearance of antibodies in rats infected as newborns. Furthermore, rats immunosuppressed by cyclosporin A and still capable of mounting a cellular immune response under experimental conditions do not synthesize virus-specific antibodies but develop BD. The cellular basis of the immune-mediated disease was strengthened by the fact that adoptive transfer of immune cells induces BD in infected immunosuppressed recipients. The role of virus-specific T cells in the pathogenesis of BD was demonstrated by the induction of disease after passive transfer of *in vitro* established homogeneous BDV-specific CD4+ T cell lines. Those recipients regularly develop clinical symptoms characteristic for BD in rats. However, there is convincing evidence that CD4+ T cells do not cause disease by themselves but seem to induce the activity of cytolytic CD8+ T cells. In the absence of CD8+ T cells no disease or immunopathology is seen, even if CD4+ T cells can be detected in the brain. Furthermore, CD8+ T cells have been shown to synthesize mRNA for perforin, the major molecule involved in cytolysis of target cells by CD8+ T cells, in parallel to the occurrence of destruction of cells in the brain resulting in brain atrophy. Other mechanisms are still under investigation, such as proinflammatory cytokines or radicals which may contribute to cytotoxicity in this CD4+ T cell-dependent disease, with CD8+ T cells acting as effector cells. Interestingly, virus-specific major histocompatibility complex (MHC) class II restricted T cells, when applied before infection, prevent the manifestation of clinical signs in rats; again, functional CD8+ T cells can be found in the brains of those animals. Antibodies to virus-specific antigens are synthesized early after infection in all BDV-infected animals but neutralizing activity becomes effective after long and variable periods postinfection and only reaches very low titers.

Clinical Features of Infection

After incubation times varying from weeks to months, and possibly even longer, the disease occurs sporadically in natural hosts. If the infection becomes manifest, the disease is characterized during the early phase by disturbances of sensory functions, impaired posture of the limbs, temporary immobility and excitations, ataxia, hyperesthesia, vision disorders and nystagmus, together with anorexia, fever and colics. The early neurological symptoms are mainly disorders of functions governed by the limbic system, whereas during the later stages of the disease dysfunctions of the motor system, such as paralysis and pareses, predominate. Most naturally infected animals die 1–2 weeks after onset of the disease, but recoveries or recurrence of disease were also ob-

served. Essentially the same sequence and comparable disease symptoms can be observed after infection of experimental animals with virus obtained from naturally infected horses or sheep, namely rats, rabbits, chicken and monkeys infected with virus strains that produce neurological disease. The disease starts with alertness and loss of fear. Later, rats show movements of the head even at rest and incoordination with increasing hyperactivity and aggressiveness. Thereafter, most rats enter a stage of disease where passiveness and hypersomnia dominate. These symptoms are at least in part attributable to developing blindness. In the chronic stage of the disease, signs of dementia, chronic debility and behavioral abnormalities, including severe learning deficiencies, prevail. In individual animals, and dependent on the virus strain used, paralysis and even paresis can be observed; however, only very few rats succumb to the disease in general, as a consequence of wasting disease due to the inability to take food and water.

Pathology and Histopathology

Pathological changes after BDV infection are restricted to the central nervous system, i.e. the brain, spinal cord and the retina. In naturally infected hosts a massive, perivascular as well as parenchymal inflammation is found. The sequence and development of pathological changes have been extensively studied in rats, and appear to be very similar to the situation in naturally infected hosts. BDV-infected rats develop a severe nonpurulent disseminated mononuclear meningoencephalitis, with the most intense inflammatory reaction restricted to the grey matter of cortex and diencephalon. Macrophages and T lymphocytes are the most numerous cell populations present in the inflammatory lesions during the earlier phases of the local reaction in both experimentally infected rats and in naturally infected horses and sheep, and B lymphocytes predominate in the histological picture at later stages. The initial reaction is characterized by a focal accumulation of mononuclear cells in the leptomeninges at day 8–10. Thereafter, perivascular and parenchymal infiltrations are observed, which intensify during the course of the disease and consist of massive accumulations of inflammatory cells in perivascular spaces and the neuropil between days 20 and 30 postinfection, when the maximal extent of the lesions is seen. Beyond day 30 postinfection the intensity of the inflammatory reaction decreases, and late after infection (> 60 days) the number and intensity of the inflammatory infiltrates is significantly reduced, although the level of infectious virus remains constant. Simultaneously with the development of the encephalitis, degenerative lesions can be found in hippocampal and cortical regions. One of the consequences of the necrotic process is a dilatation of the lateral ventricles resulting in a marked hydrocephalus accompanied by a severe cortical brain atrophy, most probably due to a progressive loss of neurons. Reactive astrogliosis is found in all areas with inflammatory lesions which is a common feature in brain inflammation. In infected neurons intranuclear acidophilic inclusion bodies (Joest–Degen inclusion bodies) can be found and have been regarded as pathognomonic of BD. In the brain the virus is predominantly found in neurons, but viral antigen is also detected in astrocytes, oligodendrocytes and ependymal cells. Histopathological lesions in the eye of infected rats and rabbits are seen almost exclusively in the retina, resulting in a degeneration of rods and cones and ultimately in a progressive disappearance of neurons from the inner and outer nuclear layers. The complete loss of neurons is the reason for the increasing blindness of infected animals, and late after infection 'burned-out' eyes are found, devoid of any inflammatory reaction. This finding explains the absence of the virus from the eye. A peculiarity of natural BDV infection in horses, and also found in rats infected intranasally, is the edema of the bulbus olfactorius which lends support to the hypothesis that natural infection occurs via the nasal route.

Prevention and Control

No vaccine is available which could mediate protection against the disease. Since prevention and control of virus diseases greatly depend on knowledge of the route of natural infection and the epidemiological situation, seroepidemiological studies in countries with intensive horse breeding and trading is an urgent need and have been initiated only recently. Therefore, during recent years the laborious demonstration of antiviral antibodies by immunofluorescence on persistently infected indicator cells has been complemented by the development of more feasible and sensitive serological assays such as enzyme-linked immunosorbent assay (ELISA) and immune blotting, which facilitates the procedure for the determination of BDV-specific antibodies. The diagnosis can be confirmed by virus isolation in sensitive tissue-culture cells. With the advent of viral sequence information, new diagnostic reagents for BDV infection have been introduced for serology as well as oligonucleotide primers for molecular studies. More recently *in situ* hybridization and polymerase chain reactions have become valuable tools for diagnosis. The control of the disease has to focus on the identification of potential carrier animals which spread the virus and

are responsible for its distribution in a given population. These animals should be eliminated. Data from studies in humans with psychiatric disorders provide an increasing body of evidence that BDV is able to infect humans and may represent a human pathogen. It is not yet known how humans get infected, as no convincing correlation between human patients and contact with infected individual animals or herds has been found. The potential role of BDV as a human pathogen requires substantiation. There is a controversal discussion about the stipulation that blood monocytes of psychiatric patients contain BDV nucleic acid. Several researchers reported that they were able to detect the presence of viral RNA components in those cells, whereas others were not successful.

Future Perspectives

Of great and urgent importance is the refinement of reliable methods for routine diagnosis. This includes assay systems for antiviral antibodies as well as the virus itself. These methods should be used in seroepidemiological studies in natural hosts and in humans with various psychiatric disorders. Considerable efforts have been made in this respect but generally-accepted assay systems have not been developed so far. When available, the test methods will not only be employed in studies in humans, but will be used in studying the dissemination of BDV in animals in general. Furthermore, the molecular characterization and the classification of BDV needs further effort. In particular, all virus-specific antigens, including the glycoproteins against which antibodies in other virus diseases have been shown to be protective, have to be analyzed in more detail. Finally, although progress on the pathogenetic pathways of this immune-mediated disease after persistent virus infection has been made, many questions concerning the immunopathogenesis remain to be solved for both BD as well as for the model of a virus-induced immune-mediated inflammatory reaction in the brain.

BOVINE DIARRHEA VIRUS AND BORDER DISEASE VIRUS (*FLAVIVIRIDAE*)

Edward J Dubovi, Department of Population Medicine and Diagnostic Science, College of Veterinary Medicine, Cornell University, Ithaca, New York, USA

Introduction

For the purposes of this entry, bovine viral diarrhea virus (BVDV) and border disease virus (BDV) will be considered a single viral entity, with different sources of the isolates – either bovine or ovine; there are, however, data indicating that BDV can be separated from BVDV at the molecular level. A closely related virus, classical swine fever virus (CSFV) (also referred to as hog cholera virus), does have consistent antigenic differences from BVDV and BDV. Accordingly, CSFV will be addressed separately. Some confusion regarding BVDV may be encountered because of a lack of uniformity in the designation of this virus. Early reports described the agent as virus diarrhea (VD) virus while others working with isolates from a different clinical syndrome coined the term mucosal disease (MD) virus. When it became evident that the

are responsible for its distribution in a given population. These animals should be eliminated. Data from studies in humans with psychiatric disorders provide an increasing body of evidence that BDV is able to infect humans and may represent a human pathogen. It is not yet known how humans get infected, as no convincing correlation between human patients and contact with infected individual animals or herds has been found. The potential role of BDV as a human pathogen requires substantiation. There is a controversal discussion about the stipulation that blood monocytes of psychiatric patients contain BDV nucleic acid. Several researchers reported that they were able to detect the presence of viral RNA components in those cells, whereas others were not successful.

BOVINE DIARRHEA VIRUS AND BORDER DISEASE VIRUS (*FLAVIVIRIDAE*)

Edward J Dubovi, Department of Population Medicine and Diagnostic Science, College of Veterinary Medicine, Cornell University, Ithaca, New York, USA

Introduction

For the purposes of this entry, bovine viral diarrhea virus (BVDV) and border disease virus (BDV) will be considered a single viral entity, with different sources of the isolates – either bovine or ovine; there are, however, data indicating that BDV can be separated from BVDV at the molecular level. A closely related virus, classical swine fever virus (CSFV) (also referred to as hog cholera virus), does have consistent antigenic differences from BVDV and BDV. Accordingly, CSFV will be addressed separately. Some confusion regarding BVDV may be encountered because of a lack of uniformity in the designation of this virus. Early reports described the agent as virus diarrhea (VD) virus while others working with isolates from a different clinical syndrome coined the term mucosal disease (MD) virus. When it became evident that the

agents causing both clinical syndromes were similar, attempts were made to reconcile the terminology with bovine viral diarrhea–mucosal disease (BVD-MD) virus. With the advent of genotyping, designations such as BVDV type 1 and BVDV type 2 have appeared. Consistency of terminology has yet to be achieved.

History

The generally recognized beginning of the literature history of BVDV occurred in 1946 with the clinical description of an apparently new disease in cattle in New York State. A series of astute observations and experiments suggested a viral etiology, and the term virus diarrhea was applied to the clinical syndrome. Several other reports described disease syndromes similar to virus diarrhea but no attempt was made to define the etiological agent. In the early to mid-1950s, another clinical entity, which became known as mucosal disease, was described. While similar to virus diarrhea in some respects, mucosal disease was clearly different in the severity of the individual cases and in the small number of animals affected in a given herd. It was not until 1957 that an etiological agent was isolated in tissue culture from both virus diarrhea cases and mucosal disease cases. The initial isolate from the virus diarrhea-affected animals did not produce any cytopathic effects in cell culture, whereas the agent from the mucosal disease animals did. In 1960 a plaque assay was developed for a cytopathic isolate of BVDV. This test permitted a comparison by virus neutralization of the viruses isolated from cases of virus diarrhea and mucosal disease. The results of the comparison indicated that the agents involved in the two syndromes were essentially indistinguishable. The relationship between the cytopathic isolates and the noncytopathic isolates was not defined until the advent of molecular biology.

The descriptive history of BDV began about the same time as BVDV, in the late 1940s, but was more delayed in its development due to the lower incidence of severe clinical disease. The initial focus of interest was along the border between Wales and England, thus the name border disease. A viral etiology for the disease was suggested in the early 1970s through transmission studies using cell-free filtrates from affected animals. About the same time, a link to BVDV was indicated by the ability of ovine sera from experimentally infected animals to recognize BVDV antigens. It took several years longer to isolate a viral agent in cell culture and to reproduce the clinical disease seen in natural cases. As will be discussed later, BDV is closely related to BVDV, not only in its molecular characteristics but also in the clinical disease that it can produce.

Taxonomy and Classification

Early structure analyses of BVDV and CSFV indicated a virion architecture similar to the classic togaviruses. Since there was no apparent insect vector for these viruses, the term 'nonarthropod-borne togaviruses' was created to include BVDV, BDV, CSFV, equine arteritis virus, lactate dehydrogenase virus and rubella. With the establishment of the antigenic relationship of BVDV, BDV and CSFV, a new genus, *Pestivirus,* was created within the family *Togaviridae* in 1982. Data on the genomic structure of the pestiviruses indicated a closer relationship to viruses such as yellow fever virus and West Nile virus, and in 1991 the pestiviruses were reclassified in the genus *Pestivirus* within the *Flaviviridae* family. Yellow fever virus is in the genus *Flavivirus*. The hepatitis C group of viruses are also included within this family under the genus 'Hepatitis C-like viruses'.

Properties of the Virion

As indicated earlier, BVDV and BDV were considered togaviruses. As such, the virion is composed of an icosahedral core with a lipid envelope. The protein composition of the virion has been difficult to determine because of problems in purifying the virus. Recent work, mainly with CSFV, has provided substantial data on the virion structural proteins. These data, along with data on proteins expressed from genomic clones, provide the following picture. The envelope contains three glycoproteins, E^{RNS}, E1 and E2. The glycoproteins may exist in the virion as hetero- and homodimers. Most neutralizing monoclonal antibodies (MAbs) are directed against E2, while several have been reported to bind to E^{RNS}. The nucleocapsid protein C is the second protein of the open reading frame (ORF) rather than the first protein N^{PRO}, as assumed initially.

Properties of the Genome

The genome of pestiviruses is an RNA molecule of positive strand polarity (**Fig. 1A**). Sequence analysis of the genome indicates a size of about 12.3 kb, but some variation may be found for those isolates with host cell insertions and sequence duplications. The genomic RNA lacks polyadenylation at the 3′ end (3′ untranslated region, 3′ UTR) and the 5′ end lacks a cap structure. The 5′ UTR contains a complex stem–loop structure with secondary structure consistent with an internal ribosome entry site (IRES). The genomic RNA has significant secondary structure, as

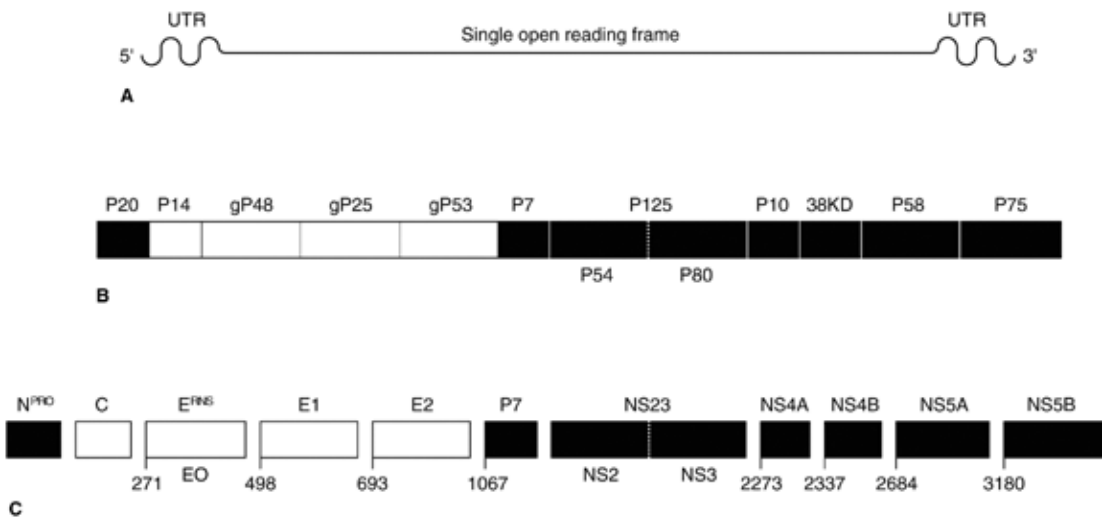

Figure 1 BVD virus genome and translation products. (**A**) Single-stranded genome of positive polarity with untranslated regions (UTR) at the 5′ and 3′ ends. (**B**) Polyprotein with the old designations for the processed proteins. (**C**) Processed proteins of BVD virus with the currently accepted nomenclature. The numbers at the left end of proteins are the N-terminal amino acids for that protein based on the SD-1 sequence. The white areas in (**B**) and (**C**) indicate structural proteins while the black areas are nonstructural proteins.

indicated by its sedimentation coefficient, resistance to low concentrations of RNase, and its solubility in high salt.

Properties of Proteins

Studies on the structure/function of the BVDV and BDV proteins are yet to be completed. The first protein at the 5′ end of the genome, N^{PRO} (N-terminal proteinase), possesses an autoprotease activity consistent with a serine protease specificity (**Fig. 1C**). The function of this protein is unknown, other than to cleave itself from the nascent polypeptide chain. The nucleocapsid protein C is located next to N^{PRO}. The three glycoproteins E^{RNS}, E1, and E2 are next in the coding sequence. As indicated earlier, these proteins are in the virion envelope, with E2 containing the majority of the neutralization sites. E^{RNS} (soluble RNA) is somewhat unusual in that it contains RNase activity, the significance of which is unknown.

The nonstructural proteins comprise approximately 75% of the coding capacity of the genome (**Fig. 1C**). The NS2 protein contains a zinc-finger-like domain, but its function has not been determined. The NS3 protein contains a serine proteinase activity which is responsible, along with NS4A, for cleavage of the polyprotein encompassing the rest of the nonstructural region. The NS3 protein also contains an NTPase activity as well as an RNA helicase activity. It has been suggested that NS5A and NS5B form the viral replicase complex. NS4B protein has been identified in infected cells, but its function is unknown. While most of the data on the proteins of pestiviruses have been done with BVDV, the limited data on BDV are consistent with those from BVDV.

Physical Properties

The physical properties of the virion are consistent with those of flaviviruses. The viral particle is 40–60 nm in diameter with a density of 1.15 g ml^{-1}. Estimates of sedimentation coefficients range from 100 to 150 S. The infectivity of the virus particle is sensitive to lipid solvents such as ether and chloroform. High temperature or low pH are also detrimental to infectivity.

Replication

Very little is known concerning the various aspects of the replication cycle of BVDV or BDV. Replication of the virus is not sensitive to inhibitors of DNA-dependent RNA synthesis such as actinomycin D. There is no evidence for the involvement of the cell nucleus in the replication cycle. The replication cycle time of the virus is 12–16 h for both the cytopathic and noncytopathic strains. In general, there are larger quantities of viral products in cells infected with the cytopathic strains of BVDV than with the noncytopathic strains. Immunofluorescent signals from cytopathic strain-infected cells are much stronger than those from noncytopathic strain-infected cells. In addition, detection of viral RNA in noncytopathic strain infected cells is difficult, whereas it is readily

detectable in cytopathic strain-infected cells. The replication complex of BVDV and BDV has not been characterized.

Characterization of Transcription, Translation, and Post-Translational Processing

All available evidence indicates that there is no subgenomic RNA produced in the infected cell as a part of the normal replication pattern. As will be discussed, defective interfering (DI) particle RNA does exist and can be translated into BVDV proteins.

Sequence analyses of BVDV and CSFV show a single ORF which spans the entire genome (**Fig. 1**). At the 5′ end of the genome are approximately 400 nucleotides that do not appear to code for a protein product. Sequence analysis of this region suggests an internal ribosome entry site consistent with translation initiation in a cap-independent manner. Experimental data support the use of this IRES for translation initiation.

With a single ORF spanning 12 kb of RNA, one could anticipate post-translational protein processing, and indeed it has been found. As indicated earlier, N^{PRO} is an autoprotease which results in its removal from the nascent polypeptide chain. The three virion glycoproteins can be found as a single glycoprotein gp116. Further processing of this protein produces the mature E2 and a precursor protein gp62. This protein is processed to E^{RNS} and E1. The protease(s) responsible for these cleavage reactions are presumably of cellular origin. Support for this comes from the expression of a portion of E1 and E2 in a vaccinia recombinant construct. In the absence of other BVDV proteins, the cleavage of this protein occurred such that all neutralizing sites on E2 as defined by MAbs were expressed in infected cells. A minor amount of E2 can be found in infected cells attached to p7. The significance of this structure is unknown, as is the function of p7.

The NS23 nonstructural protein contains the NS2 and NS3 proteins. The mechanisms for generating NS2 and NS3 may be different, depending on the virus used to initiate the infection. With cytopathic viruses, more accessible cleavage sites within the NS23 protein may be created to generate NS3. With NCP viruses, processing of NS23 to yield NS2 and NS3 may occur at a level that is undetectable. As discussed previously, NS3 possesses proteinase activity which processes the precursor protein for the other nonstructural proteins. p165 and p133 proteins have been detected, and p133 has been shown to be processed to NS5A and NS5B. With the exception of glycosylation, there are no reports of other modifications to the pestivirus proteins.

Assembly

The pestiviruses appear to mature by budding through intracellular membranes. Electron microscopic examination of infected cells shows virus-like particles in cytoplasmic vacuoles. Additionally, BVDV antigens have not been demonstrated on the surface of infected cells, thus supporting an internal maturation site for the virus.

Geographic and Seasonal Distribution

There is no geographic restriction for BVDV and BDV. These viruses exist wherever ruminants are found. There also does not appear to be any seasonal pattern to the disease outbreaks caused by these viruses. Some clustering may occur at those times of the year when animals are herded together, such as when range cattle are assembled into feedlots or dairy cattle are confined to sheltered areas in winter. For BDV, a greater awareness of the disease will usually occur at lambing when affected animals are detected. However, seasonality is not a factor in the epidemiology of these infections.

Host Range and Virus Propagation

The host range of BVDV (and BDV) may involve all of the cloven-hoofed ungulates of the order Artiodactyla. The pestiviruses can produce productive infections in cattle, sheep, swine and domestic goats. BVDV has been isolated from deer, giraffe, antelope of various species, American bison, musk ox and wildebeest. The ability of BVDV to infect sheep and produce clinical disease raised the question as to whether isolates from sheep could be considered a separate pestivirus. The significance of BVDV in the free-ranging ruminants is largely unknown, but the risk for these animals in zoological parks may be considerable. Evidence for a broad host range in ruminants is largely based on serological data from zoological parks. Experimentally, the rabbit can be infected with BVDV, but there is no evidence of natural infection.

BVDV can be propagated in cells originating from cattle, sheep, goats and swine. Cells from other sources have been found to be infected with BVDV, but these infections have arisen through the propagation of cells with fetal bovine serum contaminated with BVDV. Virtually all commercial lots of fetal bovine serum are contaminated with BVDV. Cell lines from rabbit, cat, deer, antelope, cattle, sheep, goat, pig, bison and dolphin have been shown to be

susceptible to BVDV. There is still no convincing evidence for BVDV propagation in human and nonhuman primate cells.

Genetics

The amount of data on the genetic relationships among the pestiviruses has increased dramatically in the 1990s. The most striking heritable difference found with BVDV and BDV is the existence of noncytopathic and cytopathic isolates. While the extent of cytopathic changes in cell culture is dependent on the cell type and culture conditions, noncytopathic isolates do not produce significant cytopathic changes in cell culture. The vast majority of field isolates of BVDV and BDV are noncytopathic and this biotype is responsible for most of the episodes of acute disease. The genetic basis for the biotypic differences is known for selected pairs of isolates. When virus-encoded proteins from infected cells are compared, the cytopathic isolates show a protein (NS3) not usually found in cells infected with noncytopathic isolates. An NS23 protein found with both biotypes contains all of the amino acids sequence found in NS3. With noncytopathic viruses, the NS3 protein is not produced, or is done so with such low efficiency as to go undetected.

When the nucleotide sequences of several cytopathic BVDV isolates were compared to the CSFV, it was found that the cytopathic BVDV isolates contained host cell sequences inserted into the NS23 region of the genome. One common host cell insertion is ubiquitin. Other insertions have been found in the NS23 gene, which were identified as duplicated regions of the viral genome. Insertions are often associated with viral gene duplications and/or rearrangements. The phenotypic result of these insertions is the enhanced production of NS3 and the development of cytopathology in cell culture. Similar results have been found for the cytopathic isolates of BDV.

Insertions and gene duplications produce viral genomes that are larger than the NCP viruses. However, it was found that subgenomic RNA was present with some of the cytopathic isolates. Analysis of these RNAs revealed the presence of DI particles with some unique attributes. One such DI had a deletion that included the entire structure gene complex along with the NS2 gene. The phenotypic result of this deletion is the enhanced production of NS3 if the cell is also co-infected with an NCP helper virus. Enhanced production of NS3 again produces a cytopathic effect in cell culture, but in this case the system is unstable, i.e. a cytopathic virus cannot be biologically cloned because of the need for the helper virus. While enhanced production of NS3 appears to be necessary for the development of cytopathology in cell culture, the mechanism for this process is unknown.

Evolution

The genetic relatedness of the pestiviruses was initially determined by analysis using polyclonal antibodies. While differences were noted among the viruses, the extent of the differences could not be accurately assessed. With the use of MAbs, it became evident that CSFV could be separated from BVDV and BDV. Sequence analyses of CSFV (Alfort) and BVDV (NADL) show 66% nucleotide and 85% amino acid homologies. Clearly, the viruses are closely related. At present, there are insufficient data to speculate on the origin of the pestiviruses, i.e. whether pestiviruses originated in ruminants with a spillover into swine, or the reverse.

As the comparative studies of the pestiviruses moved from MAb analyses to sequence analyses, the focus of attention centered on the 5′ untranslated region (UTR) of the genome. This region is highly conserved among the pestiviruses, but the data from it have been used to segregate pestiviruses into four major groups: CSFV-like viruses, 'true' border disease viruses, BVDV type 1 and BVDV type 2. A proposal has been made to use these groups as the basis of a new nomenclature for the pestiviruses, but this has not so far been accepted by the International Committee on the Taxonony of Viruses.

Serologic Relationships and Variability

As stated previously, BVDV, BDV and CSFV are antigenically related and the identification of etiological agents for their respective diseases was aided by their serological relationships. BVDV infection of pigs induces the production of antibodies which can recognize CSFV, but the neutralizing antibody titer against CSFV is very low, if detectable. These results suggested that some antigenic differences existed between CSFV and BVDV. The production of MAbs against CSFV and BVDV allowed a more thorough analysis of these differences. Some MAbs recognize all pestiviruses, while others are specific for CSFV and not BVDV or BDV. MAb analyses of ovine and bovine isolates suggested that ovine isolates might be different from the bovine isolates. Nucleic acid sequence data support the separation of bovine and ovine virus groups.

Antigenic variation within the BVDV isolates was not initially considered significant enough to warrant the designation of unique serotypes. However, there is

significant variation which impacts on both the biology of the disease and measures devised to control spread of the infection. Crossneutralization tests using serum specific for given isolates revealed 100–1000-fold differences in neutralizing titers. These differences are consistently found when comparisons are made using BVDV type 1 and type 2 viruses. Glycoprotein E2 appears to be the major antigen for the induction of neutralizing antibodies. MAbs specific for neutralizing sites on this protein show a wide range of reactivity with field isolates, indicating a high degree of variation. Amino acid sequence comparisons for this protein between strains Osloss and NADL show only a 78% homology. Variations in other areas of the genome are indicated by the fact that DNA probes have not been successful in detecting all strains tested.

Epidemiology

The key factor in the epidemiology of BVDV and BDV is the persistently infected animal. Infection of the bovine fetus with noncytopathic strains of BVDV prior to the development of immunological competence (approximately 120 days gestation) can result in the production of an animal that is persistently infected with BVDV throughout its life. The animal is immunologically tolerant to the strain of BVDV that initiated the infection. Virus can be cultured from all mucosal surfaces and blood can contain up to 10^6 infectious units per millilitre. The virus is maintained in the population through the persistently infected animal. Females that survive long enough to reproduce give birth to persistently infected offspring. Persistently infected males shed virus in semen, and through either natural or artificial breeding can transmit the virus to susceptible females. Acutely infected females can begin the cycle anew if they are carrying a fetus at the critical stage of gestation.

Transmission and Tissue Tropism

The main mode of transmission of BVDV and BDV is animal to animal through the oral route. Both acutely and persistently infected animals shed virus in all secretions or excretions, although urine and feces are not considered useful diagnostic samples. Venereal transmission through virus-containing semen or through virus-contaminated biologics used in embryo transfer procedures does occur, but is a minor consideration in the overall picture.

In most instances, virus initially replicates in the oronasal mucosa. There is some evidence of strain variation in the ability to replicate in the upper respiratory tract. Following replication at the initial site of infection, the virus can then spread systemically either as free virus in the blood or in circulating lymphoid cells. Acutely infected animals will generally show a transient leukopenia which resolves by 2 weeks postinfection. It is during this viremic stage that virus gains access to the fetus and establishes the persistent infection cycle. In the persistently infected animal, virus can be isolated from all tissue samples.

Pathogenicity

Many acute infections with BVDV and BDV are subclinical or inapparent, as indicated by a high seroprevalence of antibodies to BVDV or BDV without a corresponding amount of disease. The initial clinical description of BVDV infections included diarrhea as a major symptom, thus the original designation virus diarrhea virus. Recently, a more severe acute form of BVDV has been described. In many cases the initial signs were of a severe respiratory problem, although no lung pathology was noted. Mortality rates were high in unvaccinated herds and abortions were common in marginally vaccinated herds. The severity of the disease signs and the extent of the lesions in infected animals made it very difficult to distinguish these acute infections from classic cases of mucosal disease as described below (high fever, oral erosions and severe diarrhea). The viruses associated with this severe form of BVDV were more commonly the genotype 2 viruses. However, genotype as defined by the 5′ UTR is not linked to virulence.

A unique aspect of BVDV, and to some extent BDV, is the production of the disease complex known as mucosal disease. Mucosal disease was identified as a disease entity separate from virus diarrhea mainly because of the severity of the clinical symptoms and the low prevalence. The recognition that both forms of clinical expression were caused by the same virus did nothing to explain why mucosal disease animals invariably died. Current information indicates that mucosal disease starts with the persistently infected animal. These animals carrying a noncytopathic strain of BVDV or BDV become infected with a cytopathic strain which can arise as a *de novo* mutation or through challenge with a heterologous BVDV. The cytopathic virus appears to replicate unchecked in the persistently infected animal because of the tolerance to the noncytopathic virus. Severe clinical symptoms can develop, with subsequent death of the animal. Mucosal disease can only be reproduced experimentally if one uses a persistently infected animal in the challenge model.

Clinical Features of Infection

Experimentally infected animals show a biphasic fever response which might not be detected under field conditions. A consistent feature of BVDV infections is the production of a transient leukopenia. Both T and B cells may be reduced, along with a large reduction in neutrophils. Platelet counts can be affected to the extent that petechial hemorrhages develop on mucosal surfaces. Virus can be recovered from the blood for a highly variable period of time. In most cases, virus is cleared by 14 days postinfection, but it has been isolated for up to 7 weeks in experimental settings. Strain of virus and the age of the host may be factors generating the highly variable response. Infected animals may show a mild nasal discharge and/or mild-to-severe diarrhea by day 8–12 postinfection. Again, depending on the strain of virus, oral erosions, high fever, respiratory signs, severe diarrhea and petechial hemorrhages may be present.

The most significant aspect of BVDV and BDV infections relate to reproductive problems. Both viruses readily cross the placenta and infect the developing fetus. Infections early in gestation can result in the death of the embryo. The impact on the fetus at later stages of gestation is dependent upon the strain of the virus and the developmental age of the fetus. Infection of the fetus with noncytopathic strains before immunological competence can result in the production of persistently infected animals. Infection of the fetus can also result in abortion, stillbirths or mummification. If the fetus survives the infection, numerous congenital defects can result, such as cerebellar hypoplasia, hydranencephaly, retinal atrophy, cataracts, bone growth retardation, arthrogryposis, alopecia and hypotrichosis. The classic congenital anomaly produced by BDV is referred to as the 'hairy-shaker syndrome', in which the affected lambs have an abnormal hair coat and tremble or shake because of a demyelinating encephalopathy.

The clinical features of mucosal disease mirror the acute disease but with much greater severity. The onset of symptoms may be sudden or may extend over several weeks or months with recurrent overt symptoms. Animals generally show a high fever, anorexia and depression. Mucosal surfaces may show extensive erosions that can coalesce to form large areas of necrosis. A profuse watery diarrhea can develop and may turn bloody as the infection progresses. Under normal field conditions, all animals with mucosal disease die. For the chronic form of the disease the diarrhea will be intermittent with progressive weight loss and general unthriftiness. Chronic erosive lesions may be found in the mouth and on the skin. Death is also the inevitable outcome of this condition.

The persistently infected animals show a wide spectrum of clinical signs ranging from apparently normal to the unthrifty 'poor doer'. While the normal developing persistently infected animal exists, it is the exception rather than the rule. Such animals generally show a retarded growth rate and poor body condition. Many of these animals succumb to other pathogens in the environment that have little impact on their non-persistently infected herdmates. The deficit in the persistently infected animals' defense system which prevents clearance of agents not normally of clinical significance has not been defined.

Pathology and Histopathology

The lesions associated with acute BVDV and BDV infections may not be prominent. The lesions involving the oral mucosa are highly variable. If present, the lesion affects the stratified squamous epithelia with mild mononuclear cell infiltration of the lamina propria. The most significant histopathological finding involves the lymphoid tissue. Swelling and edema of mesenteric lymph nodes along with follicular lymphocytolysis has been observed following experimental BVDV infections. In addition, similar lesions were observed in the gut-associated lymphoid tissue. Lesions in the intestine were restricted to areas overlying the lymphoid areas. With mucosal disease and the severe forms of acute disease the oral erosions are much more severe and extensive, with necrosis and the formation of ulcers. The most significant and consistent lesion is the erosion of the gut-associated lymphoid tissue or Peyer's patches. The distinctive change in the Peyer's patches is necrosis of the centers of the lymph nodules. Similar changes may be seen in the mesenteric lymph nodes. Collapse of the intestinal mucosa overlying the lymphoid tissue gives rise to the characteristic erosions seen throughout the intestine.

Immune Response

While there is some belief that pestivirus infections are immunosuppressive, development of an antibody response to the viruses are as would be expected. Antibody may be detected as early as 10 days postinfection, although there are reports of very delayed responses. Antibody titers may continue to rise for several months following acute infection. Challenge of previously infected animals with the homologous virus results in no evidence of acute disease. Challenge with heterologous isolates may result in a transient infection such that fetal infection may occur before the viremia is checked. Persistently infected animals may also mount an antibody response to heterologous strains of BVDV, but this does not result in the

clearance of the virus which established the persistent infection. There are no data on cell-mediated immune reactions following BVDV infections.

Prevention and Control

The key factor in the control of BVDV and BDV is the prevention of the production of persistently infected animals. Various modified live and killed vaccines are available for BVDV. While these vaccines may prevent development of acute disease, they have not been shown consistently to prevent fetal infection, particularly when heterologous viruses are used as a challenge. Contamination of biologics with BVDV will continue to be a potential source of virus for susceptible animals.

In areas where the prevalence of the virus is very low and movements of cattle are controlled, eradication programs have been instituted. Detection of the persistently infected animals is essential to these efforts. The success of these programs may depend on the lack of a wildlife reservoir for the virus.

Future Perspectives

From the molecular biology perspective, efforts will continue to determine the structure/function relationships of the viral-encoded proteins. The construction of infectious clones of the pestiviruses will greatly accelerate these studies. In addition, the function of NS3 can be approached in a systematic fashion with designed mutants. Issues of virulence and the role of specific proteins can now be addressed. The mucosal disease complex is perhaps the most unique viral disease entity in virology. While the economic impact of this disease is not significant, the delineation of its pathogenesis will continue to intrigue researchers. The control of pestivirus infections will require the development of vaccines that can protect the developing fetus, and more data are needed on the significance of the antigenic variation that exists with BVDV and BDV.

BOVINE HERPESVIRUS (*HERPESVIRIDAE*)

Michael J Studdert, School of Veterinary Science, The University of Melbourne, Parkville, Victoria, Australia

History

Clinical diseases caused by herpesviruses in members of the family *Bovidae* have been recognized for centuries. However, it was not until the first and probably most important virus now called bovine herpesvirus 1 (BHV1) was isolated from the genital disease coital exanthema also called in the female infectious pustular vulvovaginitis (IPV) and from the respiratory disease infectious bovine rhinotracheitis (IBR) in the late 1950s that any of these diseases was confirmed to be caused by a herpesvirus. Historically IPV and its male counterpart infectious pustular balanoposthitis (collectively the male and female diseases are termed coital exanthema or Blaschenausschlag) were commonly described diseases in central Europe throughout the 19th century. It was common for a single bull in a village to serve all the female cattle in that village and where distances were small also in nearby villages and Blaschenausschlag

clearance of the virus which established the persistent infection. There are no data on cell-mediated immune reactions following BVDV infections.

Prevention and Control

The key factor in the control of BVDV and BDV is the prevention of the production of persistently infected animals. Various modified live and killed vaccines are available for BVDV. It was common for a single bull in a village to serve all the female cattle in that village and where distances were small also in nearby villages and Blaschenausschlag

Table 1 Herpesviruses of members of the family *Bovidae*

Designation	Common name (synonyms)	Genome		
		Subfamily	G + C (mole %)	size kb
Bovine herpesvirus 1	Infectious bovine rhinotracheitis HV, coital exanthema	α	72	140
Bovine herpesvirus 2	Bovine mammillitis virus; Allerton virus, pseudolumpy skin disease HV	α	64	133
Bovine herpesvirus 4	Movar HV	γ	50	145
Bovine herpesvirus 5	Bovine encephalitis HV	α	72	140
Ovine herpesvirus 1	Sheep pulmonary adenomatosis associated HV	γ		137
Ovine herpesvirus 2	Sheep assoc. malignant catarrhal fever of cattle HV	γ		
Caprine herpesvirus 1	Goat HV	α		
Alcelaphine herpesvirus 1	Wildebeest HV, malignant catarrhal fever HV of European cattle	γ	61	160
Alcelaphine herpesvirus 2	Hartebeest HV	γ		
Cervid herpesvirus 1	Red deer HV	α		
Cervid herpesvirus 2	Reindeer HV	α		

was a frequently observed sequel to mating. The isolation of IBR virus in 1957 and IPV virus in 1958 and subsequent work that established that the two viruses were essentially identical led to the designation of BHV1.

A second bovine herpesvirus, BHV2, was recognized as a cause of pseudolumpy skin disease and, as an independent syndrome, mammillitis about 1960 although both diseases were known clinically well before this time. The disease known as bovine malignant catarrhal fever has also been described for at least a century and the causative herpesvirus of the African form of the disease, formerly designated BHV3 (sometimes BHV4), was first isolated in 1968. However, the natural host for the best characterized malignant catarrhal fever herpesvirus, acquired by European cattle as originally reported in Southern Africa, is the wildebeest (*Connochaetes gnu*) and this virus is now termed Alcelaphine herpesvirus 1. A slowly growing, highly cell-associated herpesvirus, uncertainly associated with a number of disease syndromes in cattle, is called BHV4. In European breeds of cattle a distinctly different virus causes encephalitis and this virus is tentatively designated BHV5 pending definition of its definitive host, which may not be European cattle. No alphaherpesviruses of sheep have been isolated. A poorly characterized gammaherpesvirus associated with ovine pulmonary adenomatosis has been described and a second ovine gammaherpesvirus is the cause of sheep-associated bovine malignant catarrhal fever.

Classification

A complete list of herpesviruses affecting members of the family *Bovidae* and their classification as to subfamily either *Alphaherpesvirinae* or *Gammaherpesvirinae* together with some other salient properties of each including guanine + cytosine content (moles%), and genome size in kilobases are shown in **Table 1.**

Structure

Each of the viruses listed in **Table 1** has a typical herpesvirus morphology. Virions are enveloped and about 150 nm in diameter. The double-stranded DNA genome is wrapped around a fibrous spool-like core. There is an icosahedral nucleocapsid 100 nm in diameter composed of 162 hollow capsomers: 150 hexamers and 12 pentamers. The nucleocapsid is surrounded by a layer of globular material called the tegument that is enclosed by a typical bilayer lipoprotein envelope within which are embedded glycoproteins some of which appear as projecting spikes in negatively stained electron micrographs. There are about 12 distinct glycoproteins associated with the envelope spikes. Though the size of the DNA genome varies (**Table 1**) there is evidence that there

are up to 76 open reading frames (genes) coding for a corresponding number of individual proteins. About 40 of these proteins are structural, i.e. associated with the virion, whereas the remainder are nonstructural, being found only in infected cells. Repeat DNA sequences are found in the genomes of all bovine herpesviruses. For the alphaherpesviruses a set of two indirect repeats brackets the so-called short region of the genome. The gammaherpesviruses have a set terminal repeat structure within each of which, a variable number of tandemly repeated sequence motifs is found.

Replication

Virus replication occurs in the nucleus of cells and typically results in the production of large intranuclear, eosinophilic inclusion bodies. The replication cycle involves at least three classes of genes termed α, β and γ or immediate early, early and late, the expression of which is coordinately regulated in a cascade manner during the replication cycle.

Geographic Distribution

In general, each of the bovine herpesviruses occurs worldwide paralleling the distribution of the host species. The bovine viruses, with minor exceptions, have a restricted host range. None is known to affect nonbovine species, most are restricted to the primary host species the notable exceptions are the viruses causing malignant catarrhal fever in European cattle that are acquired from wildebeest or sheep.

Antigenic Relationships

Bovine herpesviruses are genetically stable with only a single antigenic type described for each species and no observable changes in antigenicity over time have been recognized. Some intratypic (within species) differences are detectable using restriction endonuclease DNA fingerprinting but these differences have not been correlated with antigenic differences in the proteins coded for by the variable regions.

Epidemiology

In general, transmission requires close contact, particularly the kinds of physical contact that bring moist epithelial surfaces into apposition, e.g. coitus, or licking and nuzzling as between mother and offspring. In large closely confined populations such as cattle feedlots or zoo collections short distance aerosol is an important mode of transmission.

Pathogenesis

Alphaherpesviruses typically cause localized lesions, particularly of mucosal surfaces of the respiratory and genital tracts or the skin, that are characterized by the sequential production of vesicles, pustules and shallow ulcers that become covered by a pseudomembrane and heal after 10–14 days, usually without scar formation.

Generalized alphaherpesvirus infections may occur in very young calves or in a fetus prior to abortion. Encephalitis produced by bovine encephalitis herpesvirus occurs as a consequence of spread from the nasal cavity to the brain, via trigeminal nerve branches.

The gammaherpesvirus BHV4 is associated with low-grade clinical infection. Malignant catarrhal fever is a uniformly fatal disease associated with mucosal erosions, ophthalmia and encephalitis that appear to be immune mediated. Lesions are characterized by infiltration and proliferation of lymphocytes. It is still not known which lymphocyte population is targeted by the virus but it is probably B lymphocytes. Immune complexes involving viral antigens are probably also produced and contribute to pathology.

Latency, whereby the genome, probably as a circularized episome, persists in ganglion cells typically the trigeminal and sciatic in the case of alphaherpesviruses, and in white blood cells in the case of gammaherpesviruses, is a hallmark of bovine herpesviruses. From these sites of latency, virus is periodically shed to give rise to recurrent disease, shedding and transmission to incontact animals.

Clinical Diseases

Bovine herpesvirus 1 causes coital exanthema and infectious bovine rhinotracheitis. Both diseases are a consequence of lesions of the mucous membrane at the two sites. The extent and severity of the lesions may vary from mild subclinical disease to acute complicated severe clinical disease that is more likely to occur in the case of IBR in feedlot cattle where the disease is complicated by secondary bacterial infections. Complicated cases of IBR in feedlot cattle are not infrequently fatal.

BHV1 may occasionally cause enteritis in calves. Encephalitis caused by BHV1 has not been confirmed; all cases of alphaherpesvirus encephalitis in cattle have been caused by a distinctly different virus designated bovine encephalitis herpesvirus or BHV5. In groups of young calves the mortality caused by BHV5 encephalitis may approach 100%.

Mammillitis caused by BHV2 may be acute leading to loss of skin from the teats, udder and perineal

regions following vesicle and pustule formation. Pseudolumpy skin disease caused by BHV2 appears to be a consequence of viremic spread, possibly as a cell-associated viremia with localization of the virus in the skin resulting in large golf-ball-sized subcutaneous swellings. These eventually resolve after 3–4 weeks.

Caprine herpesvirus 1 disease is characterized by a variety of clinical signs including conjunctivitis and lesions of the respiratory, gastrointestinal or genital tracts. Abortion may occur.

The red deer and reindeer alphaherpesviruses probably cause clinical disease and have a similar natural history to BHV1.

Bovine malignant catarrhal fever, caused by either alcelaphine herpesvirus 1 or 2 or a putative sheep-associated herpesvirus, follows an incubation period of 3 weeks and is characterized by fever, depression, leucopenia, profuse nasal and ocular discharge, generalized lymphadenopathy, extensive mucosal erosions, central nervous system signs and bilateral ophthalmia, that begins as a keratoconjunctivitis and extends to a panophthalmitis. Death, which is invariable, occurs about 1 week after the onset of clinical signs.

Immune Response

Both antibody and cell-mediated immune responses are generated during herpesvirus infections. Neutralizing antibody primarily directed against envelope glycoproteins is probably important in long-term immunity. Viral antigens, some of which may be nonstructural, immediate early and early proteins, are incorporated into the cell membrane and serve as targets for cytotoxic T lymphocytes. The immune response does not prevent the establishment of latency and its role in regulating reactivation of latent virus and recurrent disease and shedding is debated. A central contradiction of herpesvirus immunity is that following natural infection, immune animals are also animals that are infected for life.

Inactivated, attenuated live and deletion mutant recombinant DNA live virus and DNA vaccines are available or in development for the control of BHV1. Vaccines are not generally available for the control of other bovine herpesvirus diseases.

Prevention and Control

BHV1 genital disease can be controlled by eliminating carrier cattle identified either serologically or by reactivation and isolation of virus following the administration of corticosteroids such as dexamethasone. Alternatively, where it is important to do so, such as for bulls in artificial breeding centers, a two herd system may be established. IBR is often associated with stress of transport, intercurrent disease, overcrowding and the mixing together of cattle from different sources all of which are typically associated with feedlot operations. Awareness and minimization of these predisposing factors can reduce the severity of clinical disease. In an increasing number of countries test and slaughter programs have achieved total eradication of BHV1 from national herds.

The epidemiology of BHV2 is not well understood and the only possible approach to prevention and control would be to consider removal of known infected cattle.

Malignant catarrhal fever, since it is acquired from a second, heterologous host (wildebeest, sheep), is clearly preventable by avoiding contact. The sporadic nature of the disease and the lack of detailed knowledge of the putative sheep-associated virus make avoidance difficult. In zoo collections bovid species known to harbor alcelaphine herpesviruses 1 and 2 should not be cohabited with those species known to be susceptible to malignant catarrhal fever.

Future

There is considerable interest in the molecular biology of the bovine herpesviruses; the entire nucleotide sequence of BHV1 has been determined, and substantial amounts of the genomes of BHV4 and alcelaphine herpesvirus 1 have also been sequenced. Characterization of the transcripts and proteins of the viruses continues. Progress in developing better vaccines and diagnostic reagents for BHV1 based on recombinant DNA technologies, including DNA vaccines, is continuing. The unusual epidemiologies of BHV2 and BHV5 are matters for future inquiry. The unusual pathogenesis of malignant catarrhal fever and the characterization of the sheep-associated virus responsible for most cases of malignant catarrhal fever in the western world are a part of ongoing work. There are many members of the family *Bovidae* for which herpesviruses have not been identified and over time it may be expected that more viruses will be isolated.

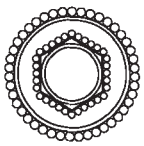
BOVINE IMMUNODEFICIENCY VIRUS (*RETROVIRIDAE*)



Matthew A Gonda, Program Resources, Inc./DynCorp,
National Cancer Institute – Frederick Cancer Research and Development Center,
Frederick, Maryland, USA

History

Retroviruses have been found in a variety of species from fish to man. They are causally associated with an assortment of pathologic states, including malignant and nonmalignant cytopathic diseases, such as leukemias and immunodeficiencies, respectively, while some infections are inapparent or without consequence. Animal retroviruses received a considerable amount of attention during the last several decades, especially after the discovery that they encoded a novel enzyme, reverse transcriptase (RT), and transduced oncogenes. Novel findings about their biology helped propel improvements in technology and investigations that led to the identification and isolation of the first human retroviruses.

In the late 1960s the intensive search for an infectious agent that might be the cause of enzootic bovine leukemia/lymphosarcoma led to the discovery and isolation of three morphologically and biologically distinct classes of retroviruses in cattle. One of these retroviruses was a bovine lentivirus, which recently was extensively characterized by Gonda and colleagues (1987); the name bovine immunodeficiency virus (BIV) was adopted for this unique lentivirus because of the striking morphologic, serologic and genetic features shared with the human and simian immunodeficiency viruses (HIV and SIV respectively). The other two retroviruses discovered were: bovine syncytial virus (BSV), a 'foamy virus' or spumavirus; and bovine leukemia virus (BLV), an oncovirus.

BIV was originally isolated by Van Der Maaten and colleagues (1972) from a Holstein cow obtained from a herd in Louisiana with persistent lymphocytosis, which is one of the associated diseases of BLV infection. The BIV-infected animal was purported to have clinical signs of disease that included a mild persistent lymphocytosis, generalized hyperplasia of lymph (hemolymph) nodes, central nervous system lesions, weakness and emaciation. BIV, isolated from this animal and propagated in tissue culture, was inoculated into specific-pathogen-free calves, where it caused a mild lymphocytosis and lymphadenopathy. Because this bovine lentivirus was not the intensively sought after viral agent of leukemia/lymphosarcoma, it was put into low-temperature storage and its biology went unstudied for nearly a decade and a half after its initial discovery. With the breakthrough that HIV-1 is a retrovirus and a member of the lentivirus subfamily, interest in BIV, and lentiviruses in general, has been renewed; and, much progress has been made in characterizing the microbiology and macrobiology of the retrovirus BIV.

Taxonomy and Classification

The family *Retroviridae* is comprised of seven genera. BIV is the only member of the Lentivirus genus of retroviruses isolated from cattle, and because of this relationship, it shares many traits in common with members of this genus of retroviruses.

All retroviruses are protein-enveloped, positive-stranded RNA viruses that encode a unique enzyme, RT, capable of catalyzing the flow of genetic information from RNA to DNA, counter to that of most biologic systems. Thus, retroviruses have a DNA intermediate in their life cycle that can integrate into the host genome. Retroviruses can be further categorized based on whether they are horizontally or vertically (germline) transmitted. Classification into

History

Retroviruses have been found in a variety of species from fish to man. They are causally associated with an assortment of pathologic states, including malignant and nonmalignant cytopathic diseases, such as leukemias and immunodeficiencies, respectively, while some infections are inapparent or without consequence. Animal retroviruses received a considerable amount of attention during the last several decades, especially after the discovery that they encoded a novel enzyme, reverse transcriptase (RT), and transduced oncogenes. Novel findings about their biology helped propel improvements in technology and investigations that led to the identification and isolation of the first human retroviruses.

In the late 1960s the intensive search for an infectious agent that might be the cause of enzootic bovine leukemia/lymphosarcoma led to the discovery and isolation of three morphologically and biologically distinct classes of retroviruses in cattle. One of these retroviruses was a bovine lentivirus, which recently was extensively characterized by Gonda and colleagues (1987); the name bovine immunodeficiency virus (BIV) was adopted for this unique lentivirus because of the striking morphologic, serologic and genetic features shared with the human and simian immunodeficiency viruses (HIV and SIV respectively). The other two retroviruses discovered were: bovine syncytial virus (BSV), a 'foamy virus' or spumavirus; and bovine leukemia virus (BLV), an oncovirus.

BIV was originally isolated by Van Der Maaten and colleagues (1972) from a Holstein cow obtained from a herd in Louisiana with persistent lymphocytosis, which is one of the associated diseases of BLV infection. The BIV-infected animal was purported to have clinical signs of disease that included a mild persistent lymphocytosis, generalized hyperplasia of lymph (hemolymph) nodes, central nervous system lesions, weakness and emaciation. BIV, isolated from this animal and propagated in tissue culture, was inoculated into specific-pathogen-free calves, where it caused a mild lymphocytosis and lymphadenopathy. Because this bovine lentivirus was not the intensively sought after viral agent of leukemia/lymphosarcoma, it was put into low-temperature storage and its biology went unstudied for nearly a decade and a half after its initial discovery. With the breakthrough that HIV-1 is a retrovirus and a member of the lentivirus subfamily, interest in BIV, and lentiviruses in general, has been renewed; and, much progress has been made in characterizing the microbiology and macrobiology of the retrovirus BIV.

Taxonomy and Classification

The family *Retroviridae* is comprised of seven genera. BIV is the only member of the Lentivirus genus of retroviruses isolated from cattle, and because of this relationship, it shares many traits in common with members of this genus of retroviruses.

All retroviruses are protein-enveloped, positive-stranded RNA viruses that encode a unique enzyme, RT, capable of catalyzing the flow of genetic information from RNA to DNA, counter to that of most biologic systems. Thus, retroviruses have a DNA intermediate in their life cycle that can integrate into the host genome. Retroviruses can be further categorized based on whether they are horizontally or vertically (germline) transmitted. Classification into

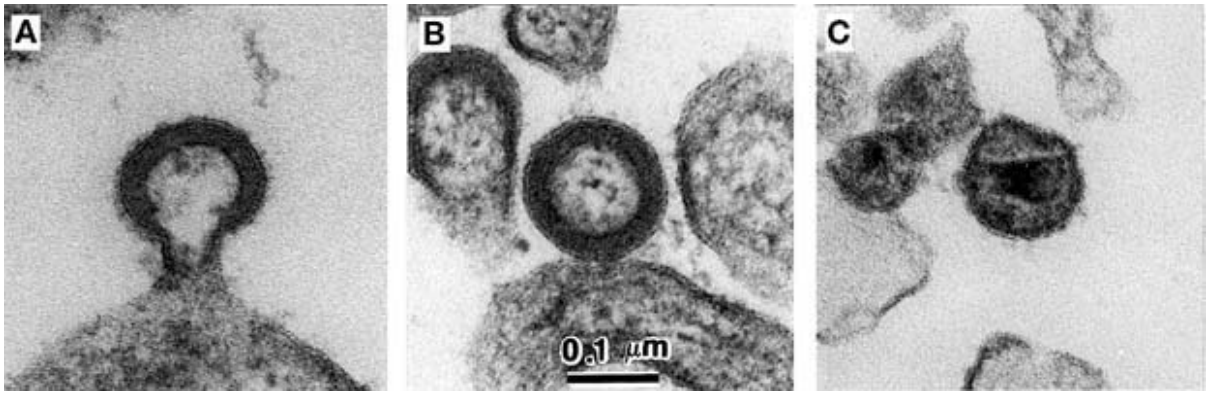

Figure 1 Morphogenesis of the bovine immunodeficiency virus (BIV) virion. (**A**) Cell-associated particle in the initial stage of budding. (**B**) Immature extracellular virus. (**C**) Mature extracellular particle with bar- or cone-shaped nucleoid.

one of the three retrovirus subfamilies most commonly is based on their morphology as observed in the electron microscope, select features of their biology and pathobiology, and the organization of their genome. The lentiviruses are exogenously acquired retroviruses that are often associated with slow, persistent and debilitating infections that may lead to death.

Properties of the Virion

The morphogenesis of the BIV virion observed by electron microscopy is typical of that of most retroviruses wherein particle assembly begins at the plasma membrane (**Fig. 1**). Initially, at the site of particle formation, a crescent-shaped, variably electron dense shell (virus core/nucleocapsid) forms beneath the plasma membrane and becomes more concentric as assembly proceeds. A distinct dark thin rim, which becomes a ring in the more advanced stages of morphogenesis, is visible at the innermost region of the electron dense shell. The electron dense shell is composed of Gag and Gag–Pol precursor proteins, although it has been demonstrated that the *gag* open reading frame (ORF) contains the minimal information necessary for particle formation. The outer envelope of cell-associated virus is studded with projections (10 nm) when observed in preparations specially stained with tannic acid; the projections are believed to be the surface (SU) envelope protein which is anchored to the viral envelope by the transmembrane (TM) envelope protein. Shedding of virus particles by the infected cell is accomplished by the process called budding, something similar to exocytosis, wherein a completely enveloped spherical virion, which has captured the genome-length, positive-stranded RNA, is released by a pinching off of the membrane at the base of the virus. These cell-free virions are still immature and are believed to be noninfectious. Morphogenesis of the immature virion is completed outside the cell when the viral protease (PR) cleaves the Gag and Gag–Pol precursors into the individual subunits; concomitantly, the spherical nucleocapsid condenses into a bar or cone shape. There is an electron lucent region between the denser cone-shaped core and amorphous material beneath the viral envelope in mature virions. The mature virions are 120–130 nm in diameter.

Properties of the Genome

The virus particle is believed to contain two copies of a single-stranded RNA genome as found in other retroviruses. The replication intermediates of lentiviruses can be double-stranded linear and/or circular DNA molecules. The genome-length, positive-sense RNA genome contains all the coding capacity of the DNA intermediate. The full-length RNA genome and all subgenomic messages have a common 5′ leader sequence and 3′ terminal poly(A) tracts. Lentivirus genomes are organizationally similar, but may differ in complexity. In the form of the linear DNA intermediate, the BIV genome (**Fig. 2**) contains the obligatory retrovirus structural genes, in the invariable order, *gag*, *pol* and *env*, flanked on the 5′ and 3′ ends by a complete copy of a long terminal repeat (LTR). The LTRs contain the promoters, enhancers and terminators of transcription. In addition, the genomes of lentiviruses are more complex than those of most oncoviruses in that they contain accessory (nonstructural/regulatory) genes in, and overlapping, the central region between the *pol* and *env* genes; and, in several viruses, post-*env*. The accessory genes appear to orchestrate virus expression, infectivity and replication.

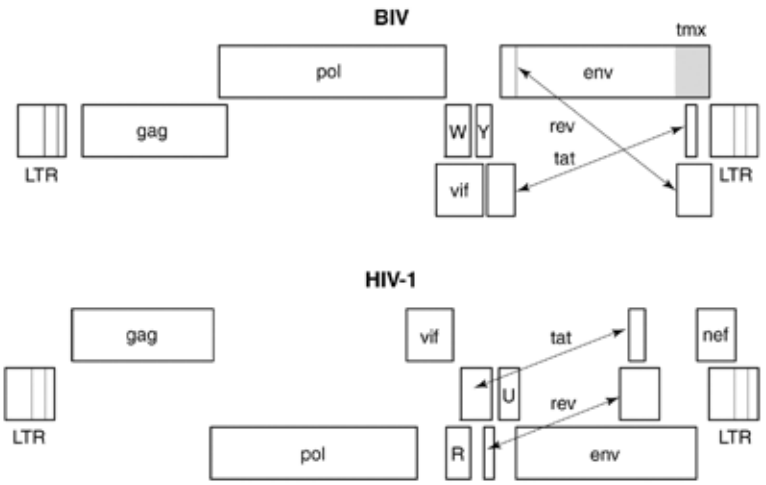

Figure 2 Comparative genome organization of BIV and HIV-I. The location of major open reading frames (ORFs) corresponding to the structural genes (*gag, pol* and *env*), flanked on the 5′ and 3′ ends by long terminal repeats (LTRs) are shown as well as those corresponding to the nonstructural/regulatory or accessory genes of BIV (*vif, tat, rev, tmx, W* and *Y*) or HIV-I (*vif, tat, rev, nef, R* and *U*) deduced from analysis of all three reading frames of their respective DNA sequence. Adapted from Gonda *et al.* (1990) In: *Animal Models in AIDS*, with permission of the editors and Elsevier Science Publishers, Inc.)

In terms of genome organization, BIV is the most complex nonprimate lentivirus characterized to date. It has several ORFs in, or overlapping, the central region that potentially encode at least five accessory genes that have been designated *tat, rev, vif, W* and Y, a single gene *tmx* is found post-*env* (**Fig. 2**). The predicted and/or known gene products of the accessory genes *vif* and *tat*, as well as those of the structural genes *gag*, *pol* and *env*, of BIV have some sequence similarity to their counterparts in HIV-1, which has aided in their identification. Nevertheless, the genomes of BIV and HIV-1 have diverged greatly overall, with the predicted products of the *gag* and *pol* ORFs having the greatest sequence similarity. The genome locations and other conserved traits in predicted products of *rev* and W and Y ORFs suggest that they are probably analogous to *rev* and *R, U,* and *X* genes, respectively, found in the primate lentiviruses. The function of the BIV *tmx* gene is not known, but it resides in the 3′ end of the genome in a position analogous to the *nef* gene of primate lentiviruses.

Characterization of Transcription and Translation

The transcriptional pattern of BIV is also very complex; there are at least five size classes (8.5, 4.1, 3.8, 1.7 and 1.4 kb) of mRNA related to the BIV infection, which supports the intricate nature of the genome (**Fig. 3**). The largest transcript (8.5 kb) contains sequences from all regions of the genome and, by analogy to other retroviruses, serves as the genomic RNA as well as the mRNA for expression of *gag* and *gag–pol* frameshift products. A number of splice donor and acceptor sites are strategically situated throughout the genome permitting the precise splicing out of introns to connect coding exons. The *env* and accessory gene mRNAs of BIV are derived from the primary transcript by single- or multiple-splicing events, respectively. In all singly or multiply spliced messages, an intron is removed between the end of the common leader sequence, which starts at the cap site in the 5′ LTR and ends at a splice-donor site before the initiation of the *gag* gene, and the beginning of the structural or accessory gene. The 4.1 kb RNA may encode *vif*, but it has not been unambiguously identified. The 3.8 and 1.7 kb RNAs are the *env* and *tat* spliced messages, respectively; the 1.4 kb RNA band contains at least the *rev* and *tmx* spliced messages. cDNA cloning experiments have shown that BIV's *tat* and *rev* genes contain two exons; the first is in or overlapping the central region and the second is in the 3′ end of the *env* region of the genome, but in a different reading frame from *env*. Thus, *tat* and *rev* mRNAs are translated from doubly spliced primary transcripts; the BIV *tmx* gene is singly spliced. The identity and structure of the W and Y mRNAs are not known. The function of the BIV *tat* product, to enhance transcription from the viral LTR, has been demonstrated; cellular factors also appear to play a role in activating or enhancing transcription from the viral LTR. At present, the functions of the *vif, rev, tmx* W and Y products in BIV are under investigation.

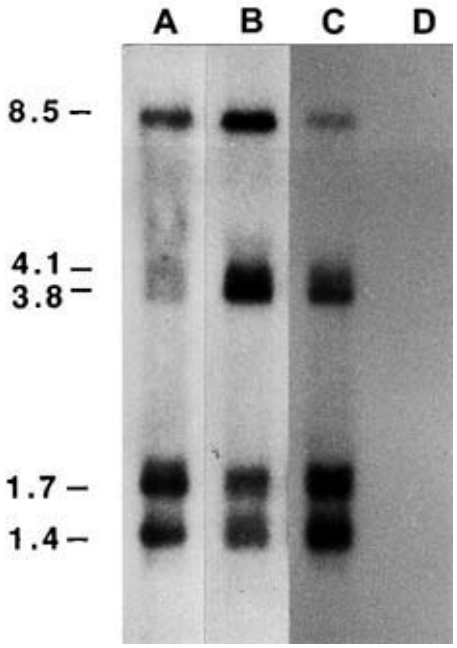

Figure 3 Northern blot analysis of BIV transcripts. (**A**) BIV 106-infected; (**B**) BIV 127-infected; (**C**) BIV parental (R-29)-infected; and (**D**) uninfected BLAC-20 cells. A ^{32}P-labeled probe representing the entire BIV proviral sequence was used to detect the viral RNA. Adapted from Oberste *et al.* (1991) *J. Virol.*, with permission of the American Society for Microbiology.

The primary Gag precursor (Pr53) and the Gag–Pol polyprotein (p174) are translated from the genome-length viral RNA. Since the *gag* and *pol* genes of BIV overlap and are in different reading frames, the synthesis of the Pol is via the Gag–Pol polyprotein and requires a −1 frameshift in the translation of this mRNA. The viral PR resides in the amino proximal region of the Pol precursor and is required for correct processing of Gag and Pol proteins into functional subunits. The viral PR becomes active after budding of the virus particle from the plasma membrane. It specifically cleaves sites between the Gag and Pol precursors in the polyprotein and within the Gag and Pol precursors. There are at least three functional Gag subunit proteins found in the Gag precursors, in the order, matrix (MA), capsid (CA) and nucleocapsid (NC), going from N- to C-terminus. The MA protein of BIV is a nonmyristylated 16 kD protein which inserts into the plasma membrane. The CA protein is 26 kD and is the major constituent of the cone-shaped core and contains the most commonly found cross-reactive epitopes of lentiviruses. The NC protein migrates as a 13 kD protein; however, amino acid sequencing has demonstrated that the BIV NC protein has a molecular weight of 7 kD. It is unclear whether BIV's NC protein migrates as a dimer or whether other physicochemical features cause it to migrate abnormally slow. The NC protein functions in binding the genomic RNA into the core during budding. By analogy to other retro-viruses, there are believed to be three Pol subunit proteins, PR, RT and endonuclease/integrase (IN); they have not been individually identified in BIV-infected cells or virions, but the existence of PR, RT and IN in virions has been demonstrated through functional studies.

The SU and TM envelope proteins of BIV are also synthesized as a precursor polyprotein. The SU, TM and precursor Env proteins of BIV are highly glycosylated. Carbohydrate accounts for up to 50% of the empirically determined molecular weight of the SU Env protein. The BIV Env precursor, gp 145, is a protein of 145 kD that is cleaved at the peptide sequence KPR$^{\downarrow}$AVG into SU (gp 100) and TM (gp 45) glycoproteins of 100 and 45 kD, respectively. The function of the SU protein is to act as the viral receptor and that of the TM protein is to anchor the SU to the exterior of the virus particle; both proteins are involved in the cell fusion activity of the virus.

Geographic Distribution

Our knowledge of the world-wide distribution of BIV is limited. Surveys have recently begun to reveal seroepidemiologic data on the prevalence of BIV in the US. Strikingly, BIV infections appear to be more prevalent in southern than in northern locales in the US. Within positive herds, the prevalence of BIV infection can be as high as 80%. Frequently, herds that are largely infected with BIV are also infected with the bovine retroviruses BLV and BSV; a high percentage of the animals in these herds found positive for BIV, and tested for BLV, are found to be dually infected. Recent serologic findings indicate that BIV may exist in Europe as well as Central and South America.

Host Range and Virus Propagation

The host range of lentiviruses is normally very restricted and is limited to the natural host and closely related species. *In vitro,* BIV is a cytopathic virus that induces syncytium (multinucleated giant cell) formation when an infected cell comes into contact with an uninfected cell. The formation of syncytia leads to cell death. Cell-to-cell transmission of the virus is the most effective means of infecting cells *in vitro. In vitro,* BIV infects primary embryonic bovine cells of lung, brain, thymus, and spleen. Virus can be recovered from bovine peripheral blood leukocytes by coculture, but peripheral blood leukocytes have proved difficult to grow and therefore

difficult to infect *in vitro*. Embryonic bovine spleen is the preferred tissue for the rescue and propagation of field isolates of BIV. In addition, BIV has been shown to infect epithelial bovine trachea (EBTr), canine fetal thymus (Cf2Th) and embryonic rabbit epithelial (EREp) established cell lines, but these cells are not as sensitive to virus infection as the embryonic bovine spleen cells. Nevertheless, EBTr, Cf2Th and EREp, since they are adapted to long-term passage, are the best vehicle for propagating BIV for antigen. BIV replication is best detected *in vitro* by immunofluorescence, RT, syncytia induction and electron microscopy assays and polymerase chain reaction (PCR) amplification of viral DNA sequences. BIV does not infect primary or established human cells and thus, it does not appear to be a threat to humans. The *in vivo* host range of BIV is also broader than that of most lentiviruses. In addition to cattle, BIV has been shown persistently to infect several breeds of rabbits. At least in the case of rabbits, the infection targets the immune system and viral sequences have been detected primarily in spleen, lymph nodes and bone marrow. Mice, rats, guinea pigs and sheep appear to be refractive to infection. Infected rabbits will prove important in the study of the biology of BIV.

Evolution

Lentiviruses are a genetically diverse group of retroviruses. Despite this genetic diversity, there are certain regions of the genome of all retroviruses that are highly conserved and upon which evolutionary relationships can be readily derived. One such region is the N-terminus of the RT domain of the *pol* gene (**Fig. 4A**). Phylogenetic analyses (derivation of phylogenetic trees) for this region of the genome have shown that BIV clusters with the retroviruses whose RTs require Mg^{2+} as cation, which is in keeping with known biological data (**Fig. 4B**). More importantly, BIV is a distinct member of the lentivirus subfamily of retroviruses and evolutionarily closer to the hypothetical ancestral virus that gave rise to all other lentiviruses. For this conserved segment of *pol*, BIV appears to be equidistant in its relationship to all other lentiviruses. Sequence comparisons from other ORFs of the genome give alternate protein-dependent tree topographies, often with BIV being closer to the primate lentiviruses.

Serologic Relationships and Variability

The serological relationship of BIV, other lentiviruses and retroviruses, can be assessed by various methods. In Western blots, BIV antiserum and CA antigen cross-react with corresponding CA antigen and antisera, respectively, from equine infectious anemia virus (EIAV), SIV and HIV-1. Cross-reactivity has also been found between the NC proteins of BIV and HIV-1. Heterologous competitive radioimmunoassays using radiolabeled HIVp24 (CA antigen) as competing antigen and a polyvalent BIV serum that contains reactivity to BIV CA antigen also have proved most informative in determining the serologic relationship of BIV to other lentiviruses (**Fig. 5**). In this assay, the lentiviruses, BIV, HIV-1, EIAV and SIV, all appear to compete completely; no other lentivirus or oncovirus gives appreciable competition. Thus, this assay indicates that the CA proteins of the competing lentiviruses share some common antigenic determinants that can be detected with precipitating anti-BIV serum.

Several functional proviral molecular clones of BIV have been sequenced, permitting an assessment of the amount of genetic variability which exists within a single isolate. Numerous point mutations are present within the genome; those which cause coding substitutions are most prevalent in the *env* coding region. The present data suggest that BIV displays significant genomic variability. It is not yet known whether coding substitutions in Env translate into antigenic variants, as has been shown for visna virus and EIAV.

Transmission and Tissue Tropism

Lentiviruses, in general, are spread by exchange of body fluids. Aerosols do not appear to play a role in the infectious transfer, although insect borne transmission has been demonstrated for EIAV. Cell-associated virus is the most efficient mechanism of transferring the infection. For HIV-1, the transmission issue has been carefully assessed; blood and sexual transmission appear to be the most common modes. In the case of BIV, the issue has not been thoroughly addressed; however, it appears that iatrogenic transmission of infected blood may be the main mode since very small amounts of infected blood are capable of passing the infection to an uninfected animal. The reuse of hypodermic needles, failure to cleanse between rectal examinations frequently used to assess fetal development during pregnancy, or failure to clean instruments used in de-horning are three probable mechanisms for introducing infectious material. It is also possible that common troughs containing waste milk from BIV-infected mothers that are used to feed calves may be a source of infectious virus.

The target cell and receptor for BIV are not known. BIV can readily be recovered from peripheral blood leukocytes of infected animals by coculturing with bovine embryonic spleen cells. There are a significant

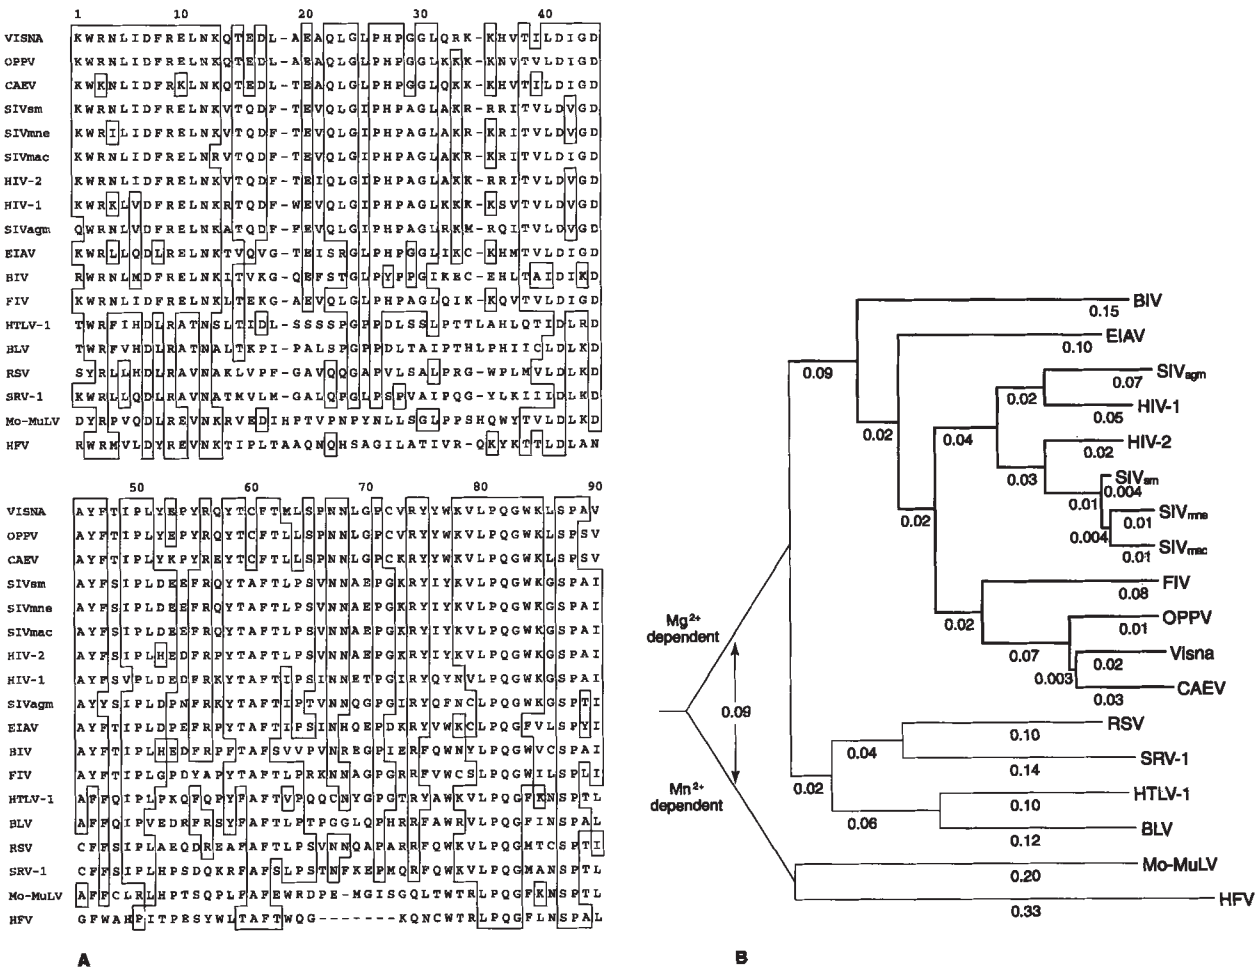

Figure 4 Evolutionary relationship of BIV. (**A**) Alignment of 90 consecutive amino acids in the conserved reverse transcriptase (RT) domain of the *pol* genes from lentiviruses with those of other retroviruses. Retroviruses used were visna virus, OPPV, CAEV, SIV_{sm}, SIV_{mne}, SIV_{mac}, HIV-2, HIV-1, SIV_{agm}, EIAV, BIV, FIV, HTLV-1, BLV, RSV, SRV-1, Mo-MuLV and HFV. The alignment shown is generally that found to be optimal with visna virus; slight improvements in the other pairwise alignment scores can be made by minor shifts in the placement of gaps. Shaded boxes are drawn around identical residues when seven or more lentiviruses share that residue. (**B**) Fitch–Margoliash phylogenetic tree based on analysis of 90 amino acids from the highly conserved RT domain of Pol of lentiviruses and, for comparison, those of other retroviruses, as presented in Garvey *et al.* (1990). Branch lengths are in units of $-\log M$ where M is the frequency of matching residues. The tree was rooted with HFV (spumavirus) and Mo-MuLV (oncovirus) as the outgroup taxons because they consistently had the lowest alignment scores and because their RTs preferentially use Mn^{2+} cations as cofactor. The average percent deviation of the tree was 5.17. Reprinted from Garvey *et al.* (1990) *Virology,* with permission of the editors and Academic Press, Inc.

number of monocytes in these preparations and, if BIV follows the trend of other lentiviruses, monocytes/macrophages are the most likely candidate target cells. Moreover, viral antigen has been demonstrated in monocytes/macrophages in the spleens of infected rabbits.

Pathogenicity

Short-term experimental studies in calves have demonstrated that BIV can cause a mild lymphadenopathy and lymphocytosis. This has been repeated with proviral molecular clones. Very little else is known of the pathobiology of BIV infections in its natural host.

Immune Response

The immune response of animals transfused with BIV-infected blood or experimentally infected with tissue culture-derived cell-associated virus has been studied in some detail. Transfused and experimentally inoculated animals initially appear to respond to the infection similarly. By 2 weeks post-transfusion or

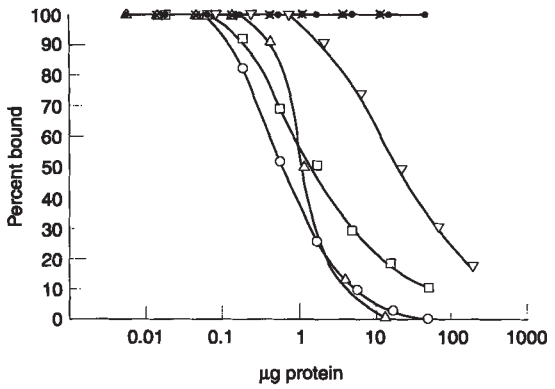

Figure 5 Immunological relatedness of major core or CA proteins of retroviruses using a heterologous competitive radioimmunoassay for the major Gag (p24) protein of HIV. The viruses (or mock virus preparations) used to compete were HIV (○), BIV (△), STLV-III (□), visna virus and CAEV (×), EIAV (▽) and FeLV, BLV, HTLV-I, HTLV-II and uninfected concentrated H9 cell supernates (•). The antiserum was a rabbit antibody to BIV and the radiolabeled antigen was HIV p24. Reprinted from Gonda *et al.* (1987) *Nature* (London), with permission of the editors and Macmillan Magazines Ltd.

post-inoculation, there is a measurable humoral immune response which increases with time and plateaus at about 2 months. ELISA titers of 1:12500 to 25000 are not uncommon. Virus rescue can be achieved early but becomes more difficult after three months postinfection. However, infection and humoral response appear to persist for the life of the animal. The same is the case for rabbits experimentally inoculated with tissue culture-derived virus. The cell mediated arm of the immune response has not yet been directly measured.

Prevention and Control

The epidemiology of BIV infection of cattle herds has only recently indicated the scope of infection in natural populations. Therefore, there is no current plan to attempt to eradicate BIV. However, since BIV is an infectious retrovirus, vaccination is the most likely scenario for its potential control. This may prove a difficult, although not impossible, task considering the experience encountered with other vaccination attempts with retroviruses.

Future Perspectives

Despite the fact that BIV has been recognized for over 20 years, the microbiology and macrobiology of BIV have only recently come under investigation. A great deal has been learned about the molecular biology of this virus. BIV does not appear to be a threat to humans. A better understanding of the pathogenesis and epidemiology of BIV is needed to assess further the need for control measures. An understanding of the pathogenesis, or lack thereof, may provide clues as to how lentiviruses cause disease. In this regard, the study of the biology of BIV in both rabbits and cattle may provide clues useful in understanding and preventing HIV-1 infections.

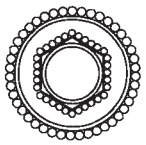
BOVINE LEUKEMIA VIRUS (*RETROVIRIDAE*)



Kathryn Radke, Animal Science Department, University of California at Davis, Davis, California, USA

History

Bovine leukemia virus (BLV) is the etiologic agent of enzootic bovine leukosis, a multicentric cancer of B lymphocytes. This disease of mature cattle was first described in Germany in 1878. By the early 1900s, it was known to be present continuously within herds of dairy cattle, but to affect only some of the animals. Hematologic observations subsequently revealed that more cattle had abnormally high numbers of blood lymphocytes (lymphocytosis) than actually developed leukosis. Patterns of natural and experimental transmission indicated that enzootic leukosis was caused by an infectious agent that appeared to be bloodborne. This was supported by the realization in the early 1960s that lymphocytosis and leukosis frequently occurred in Swedish dairy herds vaccinated against babesiosis with whole bovine blood. In 1969, C-type retroviral particles were identified in cultures of mitogen-stimulated lymphocytes obtained from peripheral blood of cattle with lymphocytosis or leukosis, and from blood of calves inoculated with tumor tissue or blood from such cattle. The virus was shown in 1972 to be infectious in cattle and sheep, and oncogenic in sheep. With the demonstration in 1974 that virions contained reverse transcriptase activity, BLV was unequivocally identified as a retrovirus. A close relationship between BLV and human T-cell leukemia virus was discovered in the early 1980s.

Taxonomy and Classification

BLV is a replication-competent, oncogenic retrovirus (family *Retroviridae*) that composes the genus *Deltaretrovirus* along with the human T-cell leukemia viruses (HTLV-1 and -2) and simian T-cell leukemia virus (STLV-1). These viruses have a unique mechanism of tumorigenesis. Their genomes lack cell-derived oncogenes that are present in rapidly transforming retroviruses such as Rous sarcoma virus. Tumors are clonal outgrowths of one virus-infected cell, but the proviral DNA genome is integrated at different sites in the host cell genome in tumors from separate individuals. Thus, BLV and HTLV are not integrated adjacent to a host cell oncogene such as c-*myc* that could be overexpressed by viral promoters and enhancers of transcription, as happens during tumor induction by avian leukosis virus and murine leukemia virus. Tumorigenesis by BLV and HTLV is thought to be initiated by alterations in host cell gene expression that are mediated by the viral Tax protein, a positive regulator of viral transcription. Consequent alterations in cell proliferation may render infected cells susceptible to mutations in host genes that are likely to be necessary for tumorigenesis. The long asymptomatic period between infection and development of clonal tumors, together with the low incidence of tumors among infected individuals, suggests that infection of a cell with BLV or HTLV is only one of several genetic alterations required for tumor formation.

Virion and Genome Structure

BLV virions are spherical particles 90–120 nm in diameter with a buoyant density of 1.15–1.17 g ml^{-1}. A membranous envelope encloses a centrally located, electron-dense icosahedral capsid or core of 60–80 nm in diameter, which contains the RNA genome. Both virions and virus-infected lymphocytes are heat-sensitive: pasteurization of milk by heating rapidly (15–20 s) to 72.5°C or slowly (30 min) to 62°C destroys infectivity. Disruption of the virion's lipid envelope by detergents or organic solvents also ablates infectivity, as envelope-associated viral proteins mediate binding and entry into cells.

The virion genome is a dimer of two identical, polyadenylated, plus strand RNAs of 8419 nucleotides. (Nucleotide numbers refer to a representative BLV genome sequence having NCBI Genbank Accession Number AF033818.) $tRNA^{Pro}$ is base-paired to genomic RNA where it primes minus strand DNA synthesis by reverse transcriptase. The 8.7 kb double-stranded DNA proviral genome (**Fig. 1**) is bounded by long terminal repeats (LTRs) formed during reverse transcription of terminal repeats (R) and sequences unique to the 5′ (U5) and 3′ (U3) ends of the RNA genome. Each LTR (533 nt) has the sequence U3 (211/213 nt)-R (234 nt)-U5 (88/86 nt). BLV and HTLV have unusually long R regions that separate the polyadenylation signal within U3 from the polyadenylation site at the end of R. From the 5′ end of the genome, BLV encodes the *gag*, *pro*, *pol* and *env* genes common to all replication-competent retro-

viruses. In addition, the 3′ end encodes a nontranslated region, *orf III* and *orf IV*, and *tax/rex* genes unique to BLV and HTLV. Open reading frames for *pro, pol* and *env* each overlap the preceding gene. A nontranslated region (>400 nt) following *env* and preceding *orf III* and *orf IV* is conserved in length among BLV isolates, suggesting that it serves some important function. Complete sequences of proviruses have been derived from tumors of Japanese, Belgian and Australian cattle.

Viral Proteins

Eight BLV-encoded proteins are found in virions. The RNA genome is coated by nucleocapsid protein (p12NC), a very basic, phosphorylated protein that binds RNA without sequence specificity. This protein contains two copies of a sequence (Cys-X_2-Cys-X_4-His-X_4-Cys) that resembles zinc-finger domains of DNA-binding proteins. The hydrophobic capsid protein (p24CA) forms the shell of the viral core, which contains the genome–NC complex as well as three enzymes: protease, reverse transcriptase and integrase. The pepstatin-sensitive aspartyl protease (p14PR) cleaves polyproteins containing Gag, Gag-Pro and probably Gag-Pro-Pol sequences into the proteins found in mature virions. The BLV reverse transcriptase (p70RT) is both an RNA-dependent and a DNA-dependent DNA polymerase that preferentially uses Mg^{2+} as a divalent cation. Although the BLV integrase (p32IN) has not been studied, it is most probably an endonuclease that mediates integration of the provirus into host DNA.

The interface between cores and the virion envelope is formed by the matrix protein (p15MA). The N-terminal glycine of this phosphoprotein is covalently linked to the fatty acid myristate, conferring affinity for membranes. MA binds specifically to BLV RNA in a region of U5-5′ *gag* and may assist in formation of RNA dimers during virion assembly. p15MA is processed to p10MA and p4, whose function is unknown.

The virion envelope, derived from the host cell plasma membrane, contains two viral glycoproteins. The surface (gp60SU) glycoprotein is anchored to the envelope by a labile association with the extracellular domain of the transmembrane glycoprotein (gp30TM). SU binds to cell-surface receptors and is the target of neutralizing antibodies. TM mediates membrane fusion via 28 hydrophobic, N-terminal amino acids (aa) and spans the lipid envelope by a more distal hydrophobic stretch of 20 aa. The 57 aa cytoplasmic domain of TM encodes three Tyr-x-x-Leu/Ile motifs, two of which can participate in signal transduction in a chimeric protein. SU has a 31 kDa protein backbone containing eight potential *N*-linked glycosylation sites and eight Cys residues. TM has a 24 kDa protein backbone containing two potential *N*-linked glycosylation sites and six Cys residues.

Two BLV-encoded regulatory proteins are present in BLV-expressing cells but not in virions. The nuclear Tax protein (34–38 kDa) *trans*-activates transcription from the BLV promoter. This activity requires an N-terminal, zinc-finger-like Cys-His motif. A central, leucine-rich segment functions as an activator domain when expressed as a chimera with the yeast GAL4 protein. The nuclear phosphoprotein Rex (16–19 kDa) acts post-transcriptionally to promote the cytoplasmic expression of unspliced and singly spliced viral mRNAs encoding the structural proteins and enzymes composing virions.

Sequences encoding novel proteins termed R3 and G4 are present in unusual spliced transcripts of the *orf III* and *orf IV* regions that lie upstream of *tax/rex*. These transcripts were cloned from infected lymphocytes obtained from calves early during infection (*orf III*) or from cattle with persistent lymphocytosis (*orf IV*). Roles for these proteins in the BLV life cycle are unknown. Deletion of *orf III* and *orf IV* restricts BLV propagation in animals and delays tumor development.

Replication

BLV binds to a cell-surface receptor and fuses with the host cell membrane upon exposure of the fusion domain of TM. Release of viral cores into the cytoplasm, reverse transcription of the viral genome, transport of proviral DNA into the nucleus, and integration into the host cell genome at essentially random sites presumably proceed similarly as for other oncogenic retroviruses. Stable integration of the provirus is thought to require mitotically active host cells. Like all known retroviruses and other retrotransposable elements, TG...CA residues form the boundaries of the integrated BLV provirus, which is flanked by 6 bp direct repeats in host cell DNA.

Transcription of the provirus by host cell RNA polymerase II begins at the start of R (+1; cap site) in the 5′ LTR, and is governed by *cis*-acting promoter and enhancer sequences in the U3 region. The TATA box is 44 nt upstream from the start site and a CAAT box is at −97. The viral Tax protein activates transcription from the viral promoter in *trans*. Tax response elements are three 21 bp imperfect direct repeats centered at −54, −129 and −154, each containing a cyclic AMP response element (CRE) and an AP-4 binding site. Bovine CRE-binding protein (CREB)-2 binds to these elements, as do activating transcription factors (ATF)-1 and -2. Tax facilitates dimerization of CREB/ATF factors by

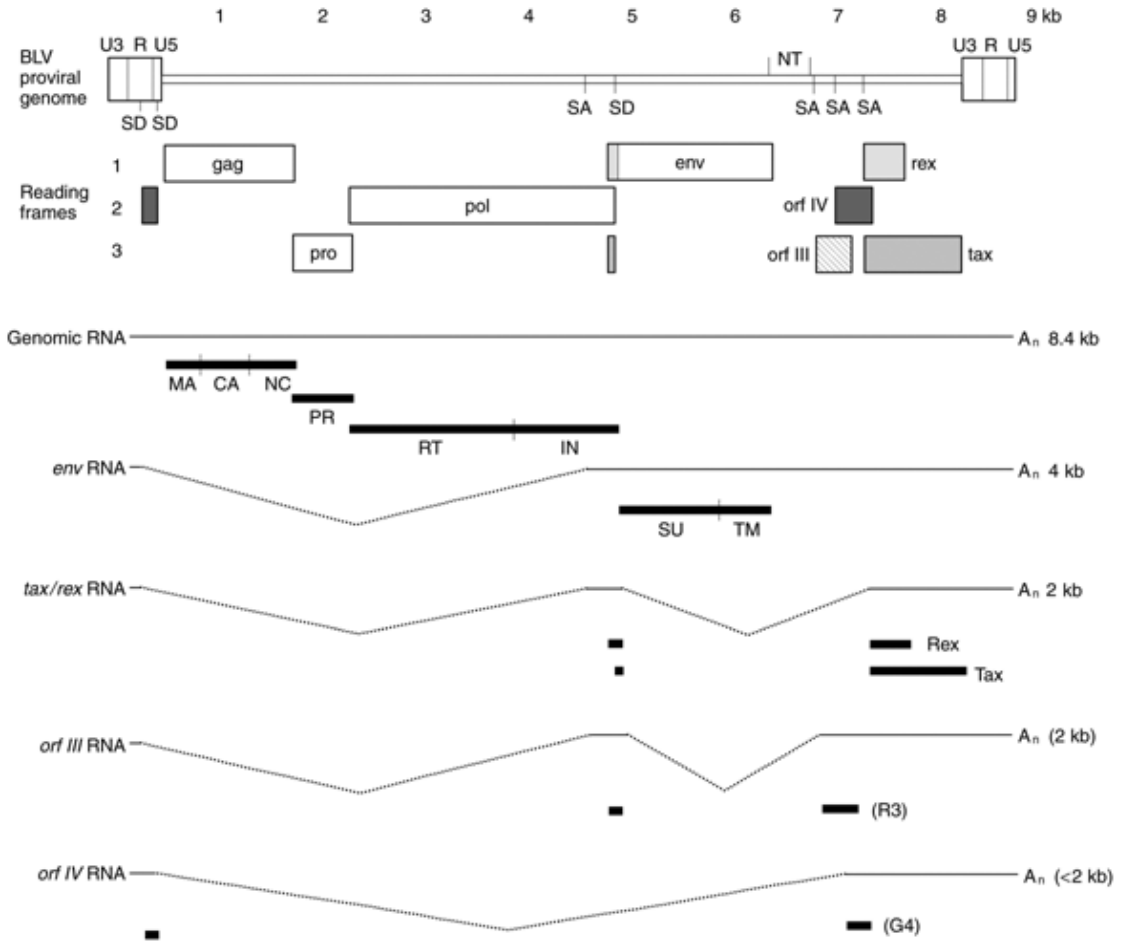


Figure 1 Bovine leukemia virus (BLV) genes, transcripts and proteins. The proviral genome is shown approximately to scale, with open reading frames indicated below it. NT is the putative nontranslated region. Splice donor (SD) and acceptor (SA) sites are marked on the proviral genome. Exons present in BLV transcripts are indicated with medium lines and introns with dotted lines. Proteins encoded by each transcript are designated with thick lines. See text for details. The transcripts shown for *orf III* and *orf IV* and their encoded proteins are provisional.

interacting with their basic-leucine zipper domains, thereby increasing their binding to the CREs. Transcription from the BLV LTR cannot entirely depend upon Tax, since this viral protein must be translated from newly transcribed RNA during early viral expression. NF-κB transcription factors bind between the two promoter-proximal CREs and increase BLV expression both in the presence and absence of Tax. Interferon regulatory factors (IRF)-1 and -2, for which a binding site is located in the U5 region of the LTR, may also affect Tax-independent transcription. A glucocorticoid response-like element is located just upstream of the promoter-proximal CRE. *Cis*-acting elements in the 5′ U3 region can act as positive or negative regulators of LTR expression, depending upon the cell type.

By analogy to HTLV-1, the 3′ *cis*-acting polyadenylation signal in U3 and poly(A) site at the end of R are brought together by a secondary structure formed at the 3′ ends of transcripts. This Rex response element acts in *cis* and in a position-dependent manner to confer post-transcriptional regulation of viral mRNAs by the BLV Rex protein.

Full-length 8.4 kb transcripts serve both as mRNA and as new genomes; all other BLV transcripts are spliced derivatives of this species (**Fig. 1**). The splice donor in R has been mapped to nucleotide 94, with an acceptor at 4443 for 4 kb *env* mRNA. A second donor at position 4665 has an acceptor at 7042 for 2 kb *tax/rex* mRNA and at 6619 or 6812 for 2 kb *orf III* mRNA. The splice donor for 2 kb *orf IV* mRNA is at 293 and the acceptor is at 6860.

Early transcription yields all classes of mRNA in the nucleus, but only 2 kb RNAs are cytoplasmic. During early expression, Tax and Rex proteins are translated from doubly spliced transcripts in

different, overlapping reading frames. Tax synthesis initiates at an AUG immediately preceding the second splice donor site. Rex translation begins at the *env* initiation codon in the second exon, so the N-terminus of Rex contains the first 17 aa of Env. When Rex accumulates, viral expression enters the late stage in which 8.4 and 4 kb transcripts encoding virion proteins are also transported into the cytoplasm and are translated.

Three polyprotein precursors, Pr45 Gag, Pr70 Gag-Pro, and Pr145 Gag-Pro-Pol, are translated on free ribosomes from unspliced, 8.4 kb RNA templates. Each protein domain is encoded by a different open reading frame, which is opened by a −1 frameshift that may be mediated by a $tRNA^{Asn}$ containing a highly modified queuine base in its anticodon loop. Frameshifting is inefficient, so the larger proteins are produced in correspondingly smaller amounts. The singly spliced, 4 kb *env* transcript is translated on membrane-bound ribosomes into the polyprotein precursor, gPr72 Env. This protein is glycosylated in the rough endoplasmic reticulum and Golgi apparatus, where it is cleaved into SU and TM by subtilisin/kexin-like host cell proteases. The viral glycoproteins are then transported to the plasma membrane.

All Gag polyproteins can associate with the inner face of the plasma membrane via their N-terminal, myristylated glycine residue. During virus assembly, MA protein may promote dimerization of full-length viral RNA. Each of two noncontiguous RNA encapsidation signals has a stable stem–loop structure. Assembly of capsids underneath the plasma membrane coincides with budding of immature virions from the plasma membrane where they acquire viral envelope proteins. Virions initially have an electron-lucent center that becomes electron-dense upon maturation, when Gag polyproteins are cleaved by the viral PR. Mature BLV virions are often associated with the surface of infected cells and can be found within intracellular vacuoles. BLV is not known to be lytic. Some types of infected cells form multinucleated syncytia in culture.

Evolution

The origin of BLV is unknown. It is not derived from an endogenous retrovirus of cattle. BLV is more closely related to HTLV than to other retroviruses, based on the degree of similarity in nucleotide and amino acid sequences of the viral Pol, NC and CA proteins, and on structural similarity of the envelope proteins. BLV and HTLV differ from mammalian C-type retroviruses by the preference of their reverse transcriptases for Mg^{2+} rather than Mn^{2+}, and by the presence of two copies rather than one of a Cys-His motif in the nucleocapsid protein. These features are also shared by avian and certain mammalian retroviruses that are clearly distinct from BLV and HTLV.

The *tax* and *rex* regulatory genes of BLV and HTLV are not related to any known genes or protein products. Further, little similarity is evident between BLV and HTLV for either gene, yet the strategy for expression is the same for both viruses and the products have analogous functions. Tax proteins of BLV and HTLV *trans*-activate transcription from the autologous viral promoter, but do not function reciprocally. In contrast, Rex proteins of BLV and HTLV function interchangeably in post-transcriptional regulation of viral expression.

Geographic Distribution and Epidemiology

BLV infection is worldwide, clustering within geographic areas as well as within herds in those areas. Higher percentages of dairy cattle are infected than beef cattle. Tumors occur in 1–10% of infected animals, a frequency that is probably lower than if cattle were allowed to live for their potential lifespan of 25–30 years. Beef cattle are usually slaughtered before 2 years, and dairy cattle by approximately 5 years. Infection is more likely to occur when cattle are in close confinement; the incidence of infection rises with age. Susceptibility to infection, to development of lymphocytosis and to formation of tumors is independently influenced by host genetic factors, some of which are encoded within the bovine major histocompatibility complex (MHC).

Host Range and Virus Propagation

Cattle are the predominant natural host for BLV infection, but domesticated zebu and water buffalo, sheep and wild capybara (a South American rodent) have also become infected. A number of animals can be infected experimentally. Sheep are widely used as experimental subjects because they are very sensitive to infection and a large percentage develop disease. Goats become infected, but very few develop tumors. Rabbits become persistently infected and immunosuppressed but do not develop tumors. Chimpanzees, rhesus monkeys, deer, pigs, cats and rats can be infected, but do not develop disease. There is no serological evidence that humans become infected with BLV and no consistent epidemiologic association between bovine leukosis and human leukemia.

A broad range of cells is susceptible to BLV infection in culture, including bovine, ovine, canine, feline, rodent and human cells. However, many infected cells do not express viral genes. The cellular

receptor for BLV is distinct from receptors for a large number of other retroviruses, including HTLV. Continuous lines of fetal lamb kidney cells and bat lung cells are the standard laboratory sources of BLV. Bioassay is by induction of syncytia following infection of early-passage embryonic bovine spleen or ovine cells, or of the CC81 line of feline cells transformed by murine sarcoma virus. Focal infectivity can also be scored using antibodies to the BLV CA protein.

Several infectious molecular clones of BLV exist; two are known to be pathogenic in sheep. Direct injection of provirus into sheep results in infection and tumorigenesis.

Genetic and Serologic Variability

BLV sequences are highly conserved among isolates from different parts of the world. Proviral sequences of three tumor isolates from Belgium, Japan and Australia differ by 3%, mainly in point mutations scattered throughout the genome. Variants display some restriction enzyme polymorphism. Envelope genes of a larger number of isolates show little variation; substitutions present at 6% of the nucleotides alter 4.3% of the encoded amino acids. HTLV-1 is similarly conserved in sequence.

Antibodies from BLV-infected animals are widely crossreactive. The N-terminal portion of the SU glycoprotein contains three conformational epitopes (F, G, H) that are dependent upon glycosylation and disulfide bonding. These epitopes are the targets of neutralizing antibodies; the H epitope plays a role in membrane fusion. Different isolates of BLV lack one or even two of these epitopes, but not all three.

Transmission

BLV-infected animals are rarely if ever viremic, so natural transmission is by transfer of infected lymphocytes in blood or perhaps secretions. Cell-free virus can establish experimental infections. Transfer of infected cells is facilitated by direct contact between cattle. The probability of infection depends on the frequency of virus-infected cells, which is elevated in animals with lymphocytosis. As little as 0.1 μl of blood can transmit an experimental infection. Milk and colostrum contain virus-infected cells but pasteurization inactivates BLV. Tracheal and bronchoalveolar washings, nasal secretions and saliva have proven at least once to contain infective cells. Urine, semen, plasma and serum do not transmit infection.

Transplacental infection occurs at a low rate, but transfer of embryos from infected to uninfected cows does not transmit BLV. Blood and tissues in common maternity pens are likely vehicles for transmission. Calves are susceptible to oral exposure by colostrum or milk from birth to 3 days, but colostral antibodies usually prevent infection and can persist for 6 months after birth. During dehorning, blood can be acquired from gouges and from other treated calves in the same pen. Sniffing, coughing and sneezing can aerosolize lymphocytes, but open wounds and the avid licking behavior of cattle are probably significant routes of transmission. Sheep do not transmit BLV horizontally.

Veterinarians and farmers can transfer blood between cattle by serially using the same obstetrical sleeve during rectal palpation to detect pregnancy, or by serially using needles and syringes for vaccination or blood sampling. Transmission by these routes is preventable. Cattle are highly sensitive to intradermal infection, so biting insects could be vectors, especially in tropical areas. However, insects have not yet transmitted BLV in experiments testing normal feeding conditions.

Cell Tropism

B lymphocytes are the predominant hosts for BLV *in vivo*. Peripheral blood mononuclear cells cultured for a few hours to induce viral expression, but not long enough to permit spread of infection, contain cells positive for cytoplasmic viral CA protein and surface immunoglobulin (Ig)M. Monocytes, CD8+ T cells and granulocytes have been found to contain provirus at very low levels *in vivo*. CD4+ and CD8+ T lymphocytes and endothelial cells can become infected in long-term cultures of peripheral blood mononuclear cells. BLV antigen has been demonstrated in bovine mammary epithelial cells.

Pathogenesis

A number of features of pathogenesis are shared by BLV and HTLV. Many individuals become infected and develop antibodies but never display overt clinical symptoms. Infected individuals are not viremic and most infected lymphocytes do not express the virus *in vivo* at any given time. However, expression can be induced by culturing blood mononuclear cells. Virus production is expected to occur intermittently or at very low levels in tissues because antibody synthesis continues throughout many years of infection. Numbers of infected host cells increase with time as well. A small percentage of infected individuals develop clonal tumors with long latency after infection. Tumor cells do not contain readily detectable viral gene products.

When a naive animal acquires BLV-infected lymphocytes, virus is produced and establishes a lifelong infection of the new host. The sites of BLV replication are not well defined, because few infected cells express viral genes. In experiments that tested the potential of tissues from experimentally infected calves to transmit BLV infection to sheep, spleen cells consistently did so. However, a persistent infection could be established in splenectomized calves. Cells from bone marrow (the source of blood monocytes) and lymph nodes were sometimes infectious for sheep. In another study of early infection in calves, BLV SU glycoprotein was present on a few mononuclear leukocytic cells in sections of intestinal mucosa, spleen and lymph nodes. Thus, BLV can replicate at multiple sites.

Overt viremia could occur very early after infection but has not been demonstrated. Antibodies specific for the viral SU glycoprotein and CA protein are evident within 2–4 weeks after experimental infection, but may take longer to develop in natural infections involving small amounts of virus. Virus replication is intense during the early weeks of experimental infections, but infected mononuclear blood cells contain few if any viral transcripts as they circulate. Infected cells express BLV in culture more readily at this time than a few months later. Early increases in B cells and CD8+ T cells have been demonstrated in experimentally infected calves and in sheep infected with large, but not small, numbers of virus-positive cells.

BLV is silently present in most circulating, infected mononuclear cells. This may result from repression of virus transcription as well as the lack of appropriate activation signals. Since BLV is adapted to the life cycle of lymphocytes, virus expression is likely to be regulated by the cellular pathways activated during an immune response. Productive expression of BLV *in vivo* would recruit new host cells into the population at risk for tumorigenesis. When cultured, infected cells rapidly transcribe BLV and gene expression is characterized by early regulatory and late productive stages. Polyclonal activators of lymphocytes such as lipopolysaccharide, anti-IgM, pokeweed mitogen, concanavalin A and phytohemagglutinin (PHA) increase transcription of BLV within a few hours. PHA greatly increases production of BLV proteins, either by an autonomous effect of the lectin on B-cell signaling pathways, or by a paracrine effect of lymphokines produced by T cells, or both. Signaling pathways mediated by protein kinase C and calmodulin participate in the induction of BLV expression by cultured lymphocytes.

Expression of the BLV Tax protein affects transcription of host cell genes as well as viral genes. Transcription of the c-*fos* and somatostatin promoters is activated threefold in the presence of Tax. However, other candidate genes whose expression might alter host cell proliferation remain unidentified. Very low levels of transcripts encoding Tax, Rex R3, G4 and structural proteins have been detected in circulating cells using the polymerase chain reaction (PCR). These transcripts could be distributed among cells in early stages of viral expression and in rare cells activated to full BLV expression. Upon overexpression, either Tax or G4 protein can cooperate with the Ras oncogene protein of Harvey murine sarcoma virus to immortalize and transform primary rat embryo fibroblasts in culture. The cells are tumorigenic in nude mice. By itself, Tax extends the lifespan of primary fibroblasts. For Tax to extend the lifespan of infected B cells would require its expression in these cells *in vivo*. In culture, infected B cells from peripheral blood of BLV-infected sheep exhibit delayed apoptosis.

About 30% of infected cattle develop persistent lymphocytosis in which the absolute lymphocyte count is increased significantly above the average for age and breed. Cattle can develop tumors without having had persistent lymphocytosis and not all cattle with persistent lymphocytosis go on to develop tumors within their productive lifespans. Some investigators report that sheep develop persistent lymphocytosis, but others find that lymphocyte increases signal the onset of tumor formation in this host. B cells are expanded in persistent lymphocytosis; some are polyclonally infected with BLV. These excess B cells are activated, having surface IgM, class II MHC proteins and integrins at high density; many are CD5-positive. Some are in the S and G_2/M phases of the cell cycle. B cells from these animals proliferate in culture in response to interleukin (IL)-2; their expansion may be stimulated *in vivo* by increased cytokine production. Blood mononuclear cells from cattle in persistent lymphocytosis show increased levels of IL-2 and IL-10 transcripts, whereas those from animals with normal lymphocyte counts have interferon-γ transcripts elevated as well. An extended lifespan could contribute to increased numbers of B cells; the ratio of Bcl-2 protein to Bax protein is increased in blood cells from cattle with persistent lymphocytosis and in tumors. Blood lymphocytes from cattle with persistent lymphocytosis have been used for many studies of virus expression, since the infected population is large and the cells readily express BLV in culture.

Tumors develop in 1–10% of infected cattle during their productive lives; most occur 4–8 years after infection. A large percentage of experimentally infected sheep develop tumors with latencies of less

than 1 to more than 6 years, depending on the size of the initial virus inoculum. Tumors, termed lymphomas or lymphosarcomas, are multicentric and infiltrating, with B cell characteristics including rearranged Ig genes and expression of class II MHC antigens, IgG or IgM and often CD5. The cells resemble lymphoblasts, prolymphocytes and mature lymphocytes. In addition, histiocytes and macrophages are often found in tumor tissue. When large numbers of neoplastic B cells are present in blood, this is termed leukemia.

With tumor growth, animals present a variety of symptoms, including decreased milk production, enlargement of lymph nodes, loss of appetite and weight, depression, heart problems, fever, diarrhea, bulging eyes and posterior paralysis, depending upon which organs have been affected by tumors or infiltrated with tumor cells. Lymph nodes, abomasum, heart, uterus, spinal canal and orbital cavity are commonly involved. Tumor masses can be as large as a person's head. Tumors are inevitably fatal, and animals usually live only a short time after diagnosis. BLV is not involved in three types of sporadic bovine leukosis: calf lymphosarcoma, thymic lymphosarcoma and skin leukosis.

Tumors within each animal are rare clonal outgrowths of a single, BLV-infected cell that contains 1–3 copies of the provirus. Many tumors contain full-length provirus, but deleted proviruses retaining the 3′ *tax/rex* region have also been found. Viral RNA is detected only at very low levels within tumor cells, indicating that overt BLV expression is not required to maintain the tumor state. Mutated host cell genes are thought to participate in tumorigenesis. Missense mutations in p53 have been identified in about half of BLV-induced tumors in cows, but not in sheep.

Immune Response

Titers of antibodies against the BLV SU glycoprotein and CA protein increase with the duration of infection. Neutralizing antibodies directed against the SU glycoprotein are evident within several weeks after infection and increase sharply at the time when the frequency of infected cells increases transiently in blood. Complement-dependent, cytotoxic antibodies specific for SU have been demonstrated. Antibodies against the intracellular Rex regulatory protein appear episodically throughout infection in sheep. Killing of BLV-infected cells by MHC-restricted cytotoxic T-cells or by natural killer cells has been difficult to characterize due to the lack of suitable target cells.

Infected animals are not obviously immunosuppressed or highly susceptible to infectious diseases. Subtle alterations in immune function have been reported, including lower levels of secretory IgM, diminished responsiveness to antigens, production of immunoglobulins with impaired reactivity, and persistence of ringworm infections. Levels of IgM increase in persistent lymphocytosis. BLV-infected milking cows are more likely to be culled from a herd, but no statistically significant association has been established with decreased milk production or reproductive capacity.

Prevention and Control

Original efforts to control enzootic bovine leukosis were based on identification and removal from herds of cattle with lymphosarcoma or with persistent lymphocytosis. Eradication programs implemented in Denmark and Germany succeeded in greatly reducing the number of herds with leukosis. Development of assays for viral antibodies enabled identification of infected animals with normal lymphocyte counts; these animals were then eliminated or segregated from the rest of the herd. Precipitating antibodies against the viral envelope proteins are easily detected using an inexpensive immunodiffusion assay, but enzyme-linked immunosorbent assays for envelope- or CA-specific antibodies are more sensitive. Since animals may be seronegative in the earliest stages of infection, the most sensitive diagnostic technique is amplification of BLV proviral DNA present in blood lymphocytes by PCR. A few copies of provirus can be detected in 10^5–10^6 cells. Prudent management can greatly reduce transfer of BLV-infected lymphocytes to uninfected animals. Vaccination to prevent infection has been attempted using inactivated virus, uninfected lymphoid cell lines and viral glycoprotein, either purified or expressed from a vaccinia virus vector. No approach has consistently prevented short-term infection and no effective vaccine exists at present.

Future Perspectives

BLV is a valuable animal model for understanding pathogenesis of HTLV. The isolation of molecular clones of BLV that are infectious and pathogenic has allowed testing of mutated proviruses. The sites at which BLV replicates *in vivo* await identification. Cellular and immunological factors controlling virus expression and production are being investigated. An understanding of early and late stages of abnormal host cell proliferation requires identification of the host cell genes whose expression is altered by the BLV Tax protein. Subsequent genetic changes that lead to tumor formation remain unidentified. BLV lends itself

to investigations of the role of co-infections in development of disease and of host genetic factors affecting infection and development of disease. Approaches to vaccination can be tested. The role of the cell-mediated immune response in protection from infection or from development of tumors remains a challenging area for investigation.

Introduction and Classification

The bromoviruses are a genus of icosahedral viruses in the *Bromoviridae*, a family of multipartite, positive-strand RNA viruses that infect plants. Although not a cause of major economic losses, bromoviruses have been extensively studied as experimental models for basic investigations of virus replication and gene expression, virus–host interactions, virion assembly, and general molecular biology.

The type and best-studied member of the bromoviruses is brome mosaic virus (BMV). BMV infects a number of cereal grains and other grasses and is distributed throughout most of the world with the exception of Australia. Other known bromoviruses include cowpea chlorotic mottle virus (CCMV), broad bean mottle virus (BBMV), melandrium yellow fleck virus, spring beauty latent virus and cassia yellow blotch virus. Of these latter viruses, the legume-infecting CCMV and BBMV are the best characterized.

Among the five genera presently classified in the *Bromoviridae*, bromoviruses are most closely related to the cucumoviruses, a genus of plant viruses of

to investigations of the role of co-infections in development of disease and of host genetic factors affecting infection and development of disease. Approaches to vaccination can be tested. The role of the cell-mediated immune response in protection from infection or from development of tumors remains a challenging area for investigation.

Introduction and Classification

The bromoviruses are a genus of icosahedral viruses in the *Bromoviridae*, a family of multipartite, positive-strand RNA viruses that infect plants. Although not a cause of major economic losses, bromoviruses have been extensively studied as experimental models for basic investigations of virus replication and gene expression, virus–host interactions, virion assembly, and general molecular biology.

The type and best-studied member of the bromoviruses is brome mosaic virus (BMV). BMV infects a number of cereal grains and other grasses and is distributed throughout most of the world with the exception of Australia. Other known bromoviruses include cowpea chlorotic mottle virus (CCMV), broad bean mottle virus (BBMV), melandrium yellow fleck virus, spring beauty latent virus and cassia yellow blotch virus. Of these latter viruses, the legume-infecting CCMV and BBMV are the best characterized.

Among the five genera presently classified in the *Bromoviridae*, bromoviruses are most closely related to the cucumoviruses, a genus of plant viruses of

substantial agricultural significance. These two genera share many properties, including similar virion structure and genome organization, similarities in the sequence of all three nonstructural proteins, and similar noncoding sequences. At a more distant level, bromovirus-encoded RNA replication factors share amino acid sequence similarity with proteins encoded by many morphologically and genetically diverse positive-strand RNA viruses of plants and animals, including tobacco mosaic virus, the animal alphaviruses, and others. Thus, bromoviruses are members of what has sometimes been called the alphavirus-like replicative superfamily of positive-strand RNA viruses.

Virion Structure

Bromovirus virions are nonenveloped particles approximately 28 nm in diameter. The outer capsid is composed of 180 copies of a single 20 kDa coat protein arranged with $T = 3$ quasi-icosahedral symmetry. Cryoelectron microscope reconstructions show that BMV and CCMV have extremely similar capsid structures. The capsid structure of CCMV has been solved to high resolution by x-ray crystallography (**Fig. 1**), and the detailed features cited below are derived from this structure. The coat protein subunits contain a core β-barrel fold similar to that found in the coat proteins of many other isometric virions. However, in contrast to most other virions, these barrels are oriented with their β-strands nearly perpendicular to the capsid surface, causing significant protuberance of the hexameric and pentameric capsomeres in which the subunits cluster. Adjacent coat protein subunits in these individual capsomeres interact primarily by hydrophobic residues. In addition, the hexameric capsomeres are further stabilized by the cooperative interaction of an N-proximal portion of each coat protein to form a hexameric β-strand ring or tubule at the quasi-sixfold axis.

The individual pentameric and hexameric capsomeres are linked into a comprehensive network by the coat protein C-termini. These C-termini extend radially from the capsomeres, allowing each coat protein subunit to participate in a reciprocal exchange of C-termini with a directly opposed partner subunit in a neighboring capsomere. Each extended C-terminus is anchored by being clamped between the β-barrel core and an N-proximal loop of its partner subunit. This reciprocal C-terminal exchange appears responsible for the existence of unassembled coat proteins as dimers, and thus may be one of the earliest interactions in capsid assembly. Coat protein linkage by C-terminal extensions has not been found to date in other RNA viruses but has been found in a similarly clamped form in the DNA papovaviruses, SV40 and polyoma.

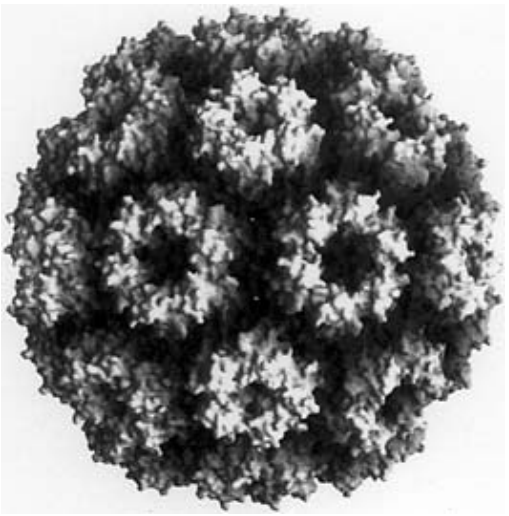

Figure 1 Surface structure of the CCMV capsid as determined by x-ray crystallography. The diameter of the capsid is approximately 28 nm. The hexameric and pentameric capsomeres generated by the arrangement of the 180 coat protein subunits in $T = 3$ quasi-icosahedral symmetry are visible. More detailed features of the capsid architecture are described in the text. (GRASP image produced by J.-Y. Sgro from the crystallography data of J. Speir, J. Johnson and colleagues.)

Inside the capsid, the single-stranded viral RNA is arranged as an interior subshell, leaving the virion center hollow. The N-terminal 26 amino acids of the coat protein, which are highly basic and required for RNA packaging, extend into the interior of the capsid in a crystallographically disordered state and interact with the RNA to neutralize phosphate charges. Additionally, the RNA interacts with 13 of the amino acids that are crystallographically ordered on the interior capsid surface. These include ionic interactions with a number of lysines and arginines and a stacking interaction between the bases of two consecutive RNA nucleotides and a tryptophan side chain.

Bromovirus capsids are stable at pH 5.0. At pH 7.0 in the absence of Ca^{2+} or Mg^{2+}, the capsid diameter swells approximately 10% due to repulsion among negatively charged residues at a calcium-binding site at the quasi-threefold axes. Although this repulsion creates large openings in the capsid at the quasi-threefold axes, the viral RNA is not spontaneously released, rendering the swelling reversible. Since some mutational results indicate that virion competence for swelling is not essential to initiate infection, the biological significance of this reaction is still under study.

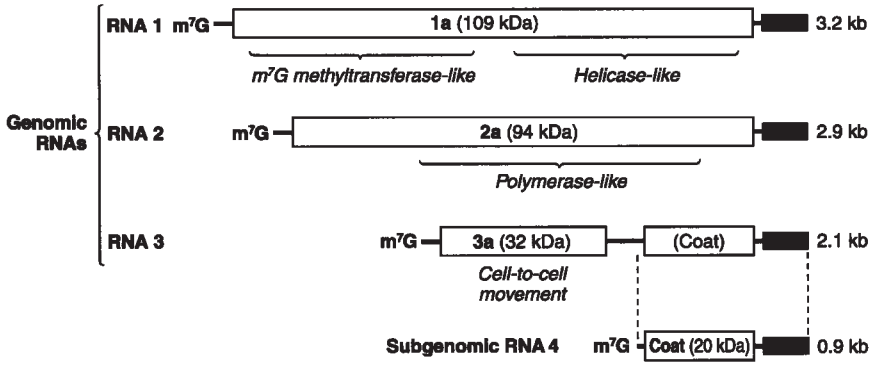

Figure 2 Map of a typical bromovirus genome, showing genomic RNAs 1, 2 and 3 and subgenomic RNA4. The four open reading frames that are known to be expressed are shown along with the sizes of the encoded 1a, 2a, 3a and coat proteins. Within the *1a* and *2a* genes, the bracketed sections encode the polymerase-like, helicase-like, and m^7G methyltransferase-like protein domains that show conservation with other viruses (see text). As indicated, all four RNAs are capped at the 5′ end with m^7Gppp and at the 3′ end bear conserved tRNA-like regions (dark boxes) with aminoacylable -CCA_{OH} termini. The RNA and protein sizes shown are those of BMV; these sizes vary slightly for other bromoviruses.

Genome Structure and Expression

High resolution density gradients separate the virions of each bromovirus into three classes with identical capsids but differing RNA contents. The highest density particles each contain a single copy of a 3.2 kb RNA designated RNA1, the lowest density particles each contain a single copy of 2.9 kb RNA2, and the intermediate density particles each contain one copy of 2.1–2.2 kb RNA3 plus one copy of 0.9 kb RNA4. Because the viral genetic information is divided among these RNA types and virion types as described below, all three virion types must infect a cell to initiate a productive bromovirus infection.

All four encapsidated bromovirus RNAs are 5′-capped, messenger-sense RNAs (**Fig. 2**). RNA1, RNA2 and RNA3 comprise the total genome. Each of these genomic RNAs serves as mRNA for a separate noncapsid protein: RNA1 and RNA2 encode the 1a and 2a proteins, respectively, which are involved in viral RNA replication and transcription. RNA3 serves as the mRNA for the 3a nonstructural protein, which is required for the cell-to-cell spread of infection in plants. RNA4 is a subgenomic coat protein mRNA derived from the 3′ half of RNA3.

Translation of bromovirus coat protein from subgenomic RNA4 ensures that significant coat protein synthesis only initiates in secondary stages of infection, after sufficient nonstructural protein has been produced to support RNA replication complex assembly and negative-strand RNA synthesis, and synthesis of positive-strand genomic and subgenomic mRNA has begun.

Conversely, when increasing amounts of BMV virion RNA are added to wheat germ translation extracts, the high translation efficiency of RNA4 competitively inhibits translation of nonstructural proteins, particularly 3a, from the genomic RNAs. Late in infection when viral RNAs have accumulated to high levels and translation factors may become limiting, this competitive inhibition could provide a simple mechanism to downregulate nonstructural protein expression while preferentially synthesizing the large amounts of coat protein necessary for encapsidation.

As for most positive-strand RNA viruses, the combined bromovirus genomic RNAs are infectious. Similarly, *in vitro* transcripts from complete cDNA clones of all three genomic RNAs are infectious in combination. The specific infectivity of such *in vitro* transcripts is greatly reduced unless their 5′ ends are capped and have no more than one additional nonviral residue. DNA containing bromovirus cDNA appropriately fused to a suitable DNA-dependent RNA polymerase promoter can also be directly infectious.

RNA Replication

Bromoviruses replicate in a completely RNA-dependent fashion, producing a negative-strand RNA intermediate for each genomic RNA. Negative- and positive-strand RNA accumulations are regulated independently, yielding an approximately 100-fold excess of positive-strand, i.e. virion sense, RNA late in infection.

As discussed further below, bromovirus host ranges for systemic infection are relatively limited. However, protoplast and other experiments show that bromoviruses replicate their RNA and assemble virions in directly inoculated cells from a wide variety of plants, including plants that are not hosts for systemic infection. Furthermore, BMV RNAs are replicated and direct subgenomic mRNA synthesis in 1a- and 2a-expressing cells of the well-studied yeast *Saccharomyces cerevisiae*. BMV RNA-dependent RNA synthesis in yeast duplicates the known features of BMV RNA synthesis in plant cells, including dependence on the 1a and 2a proteins and the same *cis*-acting RNA replication signals identified in plant cell studies, equivalent intracellular localization, similar ratios of positive- to negative-strand RNA, etc. Yeast therefore must contain BMV-compatible forms of all host factors essential for BMV RNA replication and subgenomic mRNA synthesis.

Bromovirus RNA replication and subgenomic RNA4 synthesis require the viral 1a and 2a proteins but not the 3a or coat proteins. The 1a and 2a proteins interact *in vitro* and, in plant and yeast cells, co-localize on membranes bearing endoplasmic reticulum markers. *In vivo* labeling shows that these sites of 1a and 2a accumulation are the sites of viral RNA synthesis.

Two large domains in protein 1a and one domain in protein 2a show sequence conservation with proteins encoded by other members of the alphavirus-like superfamily (**Fig. 2**). Mutations in any of these three conserved regions can block or alter bromovirus RNA replication. The C-terminal conserved domain in protein 1a contains conserved motifs of the DEAD box protein family, some of which have been shown to be RNA helicases. Mutations in this region interfere with genomic RNA replication and subgenomic RNA4 synthesis. The N-terminal conserved domain in protein 1a is related to alphavirus protein nsP1, which encodes methyltransferase and potential guanylyl transferase activities implicated in RNA capping. The conserved central domain in protein 2a is related in sequence to RNA-dependent RNA polymerases from the picornaviruses and some other viruses. The C-terminal 2a segment following this region is dispensable for RNA synthesis in protoplasts, whereas the N-terminal 2a segment preceding the polymerase-like domain interacts with the helicase-like domain of 1a.

Although the N- and C-terminal domains of 1a are related to the proteolytically processed alphavirus proteins nsP1 and nsP2, mutations in these two domains of 1a fail to genetically complement each other, suggesting that these domains may function cooperatively at one or more steps of RNA replication. Similarly, the known interaction of 1a and 2a may organize multiple steps and activities of RNA synthesis in a single, coordinated complex. Gene exchanges between bromoviruses indicate that positive-strand RNA synthesis depends on some aspect of protein 1a–2a interaction that is not required for negative-strand RNA synthesis.

For *in vitro* study, template-dependent RNA-dependent RNA polymerase activities can be isolated from bromovirus-infected cells. These infection-specific activities are initially membrane-associated but can be solubilized with appropriate detergents. Such extracts have high template specificity in negative-strand synthesis, copying bromovirus RNAs but not other viral or cellular RNAs. Immunoprecipitation and copurification results with such extracts suggest that host proteins may be complexed with proteins 1a and 2a, and may have roles in the conduct or regulation of RNA synthesis, as noted below.

Cis-Acting Sequences in Bromovirus RNA Synthesis

The regulatory signals for genomic RNA replication and RNA4 transcription have been mapped on several bromovirus RNAs. One interesting regulatory feature of bromovirus RNAs is their tRNA-like 3′ termini (**Fig. 2**). The last 200 bases of the three genomic RNAs are almost identical within each virus and similar between viruses, and form an extensive secondary and tertiary structure whose major features are conserved among bromoviruses and cucumoviruses. This 3′ structure contains the promoter sequences for negative-strand RNA synthesis and participates in several tRNA-specific reactions. Bromovirus RNAs lacking the terminal A of their normal, tRNA-like -CCA(3′-OH) end, e.g. can be adenylated by cellular tRNA nucleotidyltransferase. This adenylation reaction appears to be a normal step in the maturation of bromovirus RNA, since negative-strand synthesis initiates on the penultimate C of virion RNAs and therefore incorporation of the final 3′ A residue on progeny positive strands must involve nontemplated nucleotide addition. tRNA nucleotidyltransferase thus appears to perform a telomerase-like role in maintaining the ends of bromovirus genomic RNAs. The mature -CCA(3′-OH) end can be aminoacylated with tyrosine by the cellular tyrosyl tRNA synthetase. Though indicating highly specific tRNA mimicry, the functions of this aminoacylation, possibly including roles in RNA synthesis, stabilization, or both, are not yet well established.

5′-proximal sequences are also required in *cis* for bromovirus RNA amplification, presumably to mediate positive-strand initiation, to enhance RNA

stability, or both. In addition, for some RNAs, internal sequences are required in *cis* for efficient viral RNA accumulation. The 5′ noncoding regions of bromovirus genomic RNAs and an intercistronic segment required for efficient BMV RNA3 accumulation all contain exact copies or close approximations of the sequence motif GGUUCAAyyCC, where y = U or C. This is one of two consensus motifs in cellular RNA polymerase III promoters and also corresponds to the invariant residues of tRNA TΨC loops. Mutations in these consensus elements reduce bromovirus RNA accumulation in *cis*, showing that sequence elements recognized by host cell factors play significant roles in bromovirus RNA synthesis.

Experiments *in vitro* show that the subgenomic coat protein mRNA, RNA4, is produced by internal initiation of transcription on negative strand RNA3. The signals directing this transcription reside within a 100 base segment upstream from the BMV coat gene. Sequences within the first 20 bases upstream of the coat protein constitute a core promoter sufficient to direct site-specific transcription initiation at a low level. Additional upstream sequences, including a 16–22 base oligo(A) tract and partial repeats of core promoter sequences, stimulate the level of transcription. A similar core promoter sequence and 35–45 base oligo(A) tract are present upstream of the CCMV coat gene. Extensive studies on the effects of nucleotide changes in the core promoters for BMV subgenomic mRNA synthesis and negative-strand RNA synthesis have been conducted to identify key residues in each promoter.

Host Gene Dependence of BMV RNA Replication

Probable dependence of bromovirus RNA replication on host factors was suggested by the role of tRNA nucleotidyltransferase in viral RNA maturation, the presence of tRNA-like sequence features and functions in multiple *cis*-acting RNA replication signals, the association of viral RNA synthesis with cellular membranes, cofractionation of some cellular proteins with bromovirus RNA-dependent RNA polymerase activity, host-specific differences in viral RNA accumulation, and other results. More direct evidence for the dependence of bromovirus replication on host factors has been derived from the ability of BMV to replicate in yeast. By applying yeast genetic approaches to selectable and screenable marker genes expressed from BMV RNA replicons, mutant yeast strains have been selected that are unable to support normal levels of BMV RNA replication and subgenomic mRNA synthesis. Such BMV-inhibiting mutations occur in multiple yeast complementation groups with distinguishable effects on the virus. Thus, multiple host factors appear to contribute to a variety of steps in bromovirus replication.

Genetics

Both homologous and nonhomologous recombination between genomic RNAs can be observed in bromovirus infections when appropriate selection pressure is applied. Deletions introduced into the 3′ tRNA-like region of one genomic RNA, e.g. can be repaired by recombination with the wild-type tRNA-like region of another genomic RNA. In addition to helping maintain the conserved 3′ ends, recombination is presumed to have played an important evolutionary role in initially establishing common ends on the separate RNAs of the tripartite bromovirus genomes. Recombination has also contributed to the divergence of individual bromoviruses, as shown by several clearly bounded insertion/deletion differences between the BMV, CCMV and BBMV genomes.

Recombination can regenerate wild-type CCMV RNA3 from two co-inoculated mutants with inactivating mutations in the 3a and coat genes, respectively. The ability to assemble functional genomic RNAs from independently disabled mutants should help to offset the negative effects of the high mutation rates commonly found in RNA virus replication while allowing bromoviruses to realize the survival benefits of high variability.

Recombination events can be targeted between two bromovirus RNAs by engineering duplications that serve as hotspots for homologous recombination, or by engineering complementary regions that create the potential for forming heteroduplexes. These potential heteroduplexes become the sites of recombinational crossovers between the two RNAs. Mutations in the 1a or 2a RNA replication genes can influence the frequency and distribution of recombinational crossovers between bromovirus RNAs. Together with the engineered heteroduplex results, this suggests that template switching during RNA replication may be one mechanism for bromovirus RNA recombination.

Transmission

In the laboratory, bromoviruses are efficiently transmitted between plants by mechanical inoculation. In the field, bromoviruses can be mechanically transmitted by human activity, including walking, and presumably also by machinery. Seed transmission tests with bromoviruses have generally been negative, though seed transmission of BMV in one South African wheat cultivar has been reported.

Beetles reproducibly transmit bromoviruses, though inefficiently and for short periods of time. Nematodes have also been shown to transmit BMV. Aphid transmission tests with bromoviruses have been consistently negative except for one report using concentrated BMV as a feeding source. Despite experimental demonstrations, the natural significance of invertebrate vectors in bromovirus field epidemiology is uncertain. Multiyear field trials in the presence of potential beetle vectors found no spread of CCMV from infected source plants to surrounding cowpea or soybean plants. Lack of an efficient invertebrate vector may be one reason why bromovirus infections characteristically produce large yields of virus (1–5 mg g^{-1} infected tissue).

Infection Spread and Host Range for Systemic Infection

Although bromoviruses replicate and encapsidate their RNAs in directly inoculated cells from a wide variety of plants, they have fairly restricted host ranges for systemic infection of whole plants. The effective host range for bromovirus infection thus appears to be determined frequently at the level of initiating or sustaining infection spread from the sites of primary infection.

When CCMV is inoculated onto a leaf of a cowpea plant, a permissive host for CCMV systemic infection, infection initially spreads from primary inoculated cells only into directly contacting cells. Such direct cell-to-cell spread continues to expand the radius of the infection site at a rate of approximately one additional cell diameter per 5 h. When the infection reaches vascular elements, it advances along them more rapidly and secondary infections emerging from vascular elements become the dominant mode of infection spread.

Both RNA3 genes, *3a* and *coat*, are dispensable for RNA replication but required for systemic spread. Disruption of the *3a* gene blocks cell-to-cell infection spread, limiting infection to individual, directly inoculated cells. The 3a protein has a number of properties common to cell-to-cell movement proteins of other viruses, including the ability to bind cooperatively to single stranded RNA, to localize to the plasmodesmatal connections that are the presumed route of infection spread between cells, and to induce the formation of virion-containing tubules from the surface of BMV-infected protoplasts. For CCMV, disruption of the coat gene allows short-range cell-to-cell spread of infection at a reduced rate, but inhibits vascular spread, slowing spread within inoculated leaves and blocking virus spread to noninoculated leaves. For BMV, disruption of the coat gene similarly stops virus spread to noninoculated leaves. In at least some virus–host combinations, disruption of the BMV coat protein also appears to block cell-to-cell spread.

Exchanging genomic RNAs and individual genes shows that the host-specific adaptation of BMV to monocotyledonous plants and of CCMV to dicotyledonous plants depend on differences in multiple viral genes. These include the *3a* gene of RNA3 and incompletely determined features of RNA1 and RNA2. Some host-specificity determinants in bromovirus genes might alter the ability of virus-encoded functions to actively direct infection spread in particular plants, perhaps by adapting viral components to interact successfully with essential host factors that display some variation from host to host. Certain changes in BMV RNA1 that enhance systemic spread in cowpea plants, e.g. are correlated with a cowpea-specific increase in viral RNA accumulation. Alternatively or in addition, viral host specificity determinants might modulate induction of host defense responses, which appear to be a limiting factor for infection of some plants. Replacing the cowpea-adapted CCMV *3a* cell-to-cell movement gene with the monocot-adapted BMV *3a* gene, for example stops infection spread at an early stage, but only after multiple rounds of cell-to-cell spread. Thus, the misadapted *3a* gene is able to mediate cell-to-cell spread even in an inappropriate host, and further observations suggest that the eventual block to spread is associated with virus-induced host responses. Significantly for evolutionary considerations, only one or a small number of amino acid changes are needed to allow the monocot-adapted BMV *3a* gene to support systemic infection spread in dicot hosts.

Pathology

The external symptoms of bromovirus infections can vary markedly depending on the strain of virus, the host genotype, and the ambient physical conditions. BMV infections in cereals typically produce a mosaic or streaked pattern of chlorosis in infected leaves, often accompanied by stunting. The effects of CCMV and BBMV infections can range from a lack of visible symptoms to mild variegated chlorosis to a vivid yellow mottling. Particularly in directly inoculated primary leaves, localized reddish spots may also occur. Overall, there is not a simple correlation between symptom severity and bromovirus yield. Some changes in bromovirus symptoms, including dramatic exacerbation of chlorosis, have been associated with changes in the coat protein or in the subgenomic promoter sequences upstream of the coat protein gene.

Studies of bromovirus cytopathology have revealed a number of intracellular changes. Cytoplasmic vesicles, possibly derived by budding from the endoplasmic reticulum, occur and form part of cytoplasmic inclusion bodies that also include portions of the endoplasmic reticulum, virus particles, and electron-dense material. As infection proceeds, massive accumulation of virus particles occurs in the cytoplasm and sometimes in the central vacuole. RNA measurements indicate that up to several million progeny genomes accumulate per cell in bromovirus infection. Structurally altered chloroplasts have been seen in leaf cells from chlorotic tissue infected with CCMV. In later stages of bromovirus infection, reductions in the number and size of mitochondrial cristae have been reported.

General features

Neal Nathanson and **Francisco González-Scarano**, Departments of Microbiology and Neurology, University of Pennsylvania Medical Center, Philadelphia, Pennsylvania, USA

Introduction

The family *Bunyaviridae* (named after Bunyamwera, the type virus) is the largest single family of animal viruses, consisting of more than 300 individual virus species grouped into five genera: *Bunyavirus, Phlebovirus, Nairovirus, Hantavirus* and *Tospovirus*. The defining features of the family are both molecular and biological. They have a virion structure that consists of a lipid envelope about 100 nm in diameter surrounding an inner nucleocapsid, and possess a trisegmented genome of negative polarity with a roughly consistent coding pattern within each genome segment. However, the phleboviruses and tospoviruses use an ambisense coding strategy for one or two gene segments. Biologically, they are arboviruses, transmitted by arthropods and maintained in a vector–host cycle, although there are important exceptions: the hantaviruses appear to be transmitted from vertebrate-to-vertebrate without an intermediate vector, and the tospoviruses have a plant rather than an animal host.

The profusion of distinct viral species is probably explained by the arthropod-borne maintenance cycle, which limits the geographic distribution of individual viruses to the confined range of different vector species. Many different insect species, including mosquitoes, ticks, midges, flies and thrips can transmit bunyaviruses, but each individual virus is usually transmitted by a limited number of insect species. Since each vector species usually prefers to feed on a few preferred hosts, each virus is maintained in nature in a rather narrow cycle. Viruses cause nonlethal lifelong persistent infections in the insect vector but generally cause acute immunizing infections in the vertebrate host. Most bunyaviruses never infect humans or domestic animals, but a few infect and cause significant disease in humans and/or

domestic animals. Humans are accidentally infected and almost always constitute deadend hosts without further transmission.

Taxonomy and Classification

The very large number of bunyaviruses in the family *Bunyaviridae* offer a taxonomic challenge. Molecular features are used to define genera, particularly the conserved nucleotide sequences at the termini of each RNA segment and the genome organization within each RNA segment. Classical serological methods are used to define serogroups within each genus. In general the complement fixation test defines antigenic determinants on the nucleocapsid protein, which tend to be conserved and will link related viruses, whereas the neutralization and hemagglutination inhibition define epitopes on the glycoproteins, and can be used to distinguish between different viruses. Currently, the individual bunyaviruses are grouped in over 30 serogroups within five genera, but there are more than 80 viruses that are not yet assigned to specific genera and/or serogroups (**Table 1**). Many bunyaviruses are poorly characterized as to their natural vectors and vertebrate hosts.

Structure and Organization of the Virion

Virions average about 100 nm in diameter (range 80–120 nm) and are spherical or pleomorphic depending on the method used for fixation and visualization (**Fig. 1**). There is an outer lipid envelope (about 4 nm thick) containing glycoprotein spikes (about 10 nm long) that surrounds a core containing the viral genome and its associated proteins (nucleoproteins and polymerase). During replication, the virions mature by budding through intracytoplasmic vesicles associated with the Golgi apparatus. Virions are

After Calisher CH (1996) History, classification, and taxonomy of viruses in the family *Bunyaviridae*, p. 1. In: Elliott RM (ed.) *The Bunyaviridae*, New York: Plenum Press.

released by transport of vesicles to the cell surface followed by exocytosis or by lysis of the cell.

Bunyaviruses have a buoyant density of about 1.16 g per cm^3 in sucrose gradients and a sedimentation constant of about 450 S. The virion consists of nucleic acid (1–2% by weight), protein (>50% by weight), lipid (>30% by weight) and carbohydrate (2–7% by weight). When the virion is disrupted with nonionic detergents, the nucleocapsids can be isolated and resolved into three sizes by rate-zonal centrifugation. Bunyaviruses are readily inactivated by lipid solvents, detergents or betapropriolactone, and by exposure to 56°C or to low pH.

Bunyaviruses contain a single-stranded genome of negative polarity (see exceptions below) that is divided into three segments, large (L), middle-sized (M) and small (S). The L RNA segment codes for a single large (L) protein that is an RNA polymerase, the M RNA segment codes for two glycoproteins (G1 and G2) and a nonstructural protein (NSm), and the S RNA segment codes for the nucleocapsid (N) and a nonstructural (NSs) protein.

RNA segments and proteins differ in size in different bunyavirus genera. The L RNA segment is in the range 6.4–11.3 kb, the M RNA segment about 3.2–4.9 kb, and the S RNA segment 1–2.9 kb. The L protein is in the range 180–330 kDa, the G1 protein 55–125 kDa, the G2 protein 30–60 kDa, and the N protein 20–50 kDa for different genera. The L RNA segment encodes a single large open reading frame (ORF) in the virus-complementary sense. The M RNA segment encodes a single ORF in the virus-complementary sense and the polyprotein is processed into G1, G2 and NSm proteins. For the *Tospovirus* genus, the M RNA is ambisense since it has an additional virus-sense ORF, that encodes a 'movement' protein thought to be important for the cell-to-cell transmission of the viral nucleocapsids through the plasmodesmata of plant tissues. The S RNA segment encodes the N protein in the virus-complementary sense in all genera. The NSs protein is encoded in the same ORF used for the N protein in *Nairovirus* and *Hantavirus* genera, and in a different virus-complementary sense ORF for the *Bunyavirus* genus. In the *Phlebovirus* and *Tospovirus* genera, the NSs protein is encoded in a virus-sense ORF so that the S RNA segment utilizes an ambisense coding strategy for these genera.

In each virion there are about 600 copies of each of the glycoproteins, 2000 copies of the N protein, and 25 copies of the L protein. Each virion contains three nucleocapsids, each arranged in a noncovalently closed circle with a panhandle due to association of complementary sequences at the 3′ and 5′ ends of each RNA segment. The bases at both 3′ and 5′ ends of the genome are conserved for 9–11 nucleotides, and the two ends form a complementary palindrome. The terminal sequences are identical for all three RNA segments for all members of each genus, but differ between genera.

For viruses in the bunyavirus genus, the larger glycoprotein (G1) has been shown to carry several important biological properties, such as attachment to the putative receptor on animal cells, hemagglutination, neutralization and certain aspects of virulence. Fusion is probably dependent on both the G1 and G2 glycoproteins, since the G1 protein undergoes a conformational change at the pH of fusion while the G2 may carry the fusion domain. It has been postulated that the G2 protein is the ligand for a putative receptor on insect cells. The G1 and G2 proteins are sometimes referred to as GN and GC for their order on the ORF (GN = amino terminal; GC = carboxy terminal).

Cell Culture

Bunyaviruses replicate readily in many types of animal cell cultures although some, such as the hantaviruses, are very fastidious. Most bunyaviruses will replicate well in either BHK-21 or VERO E-6 cells, which are frequently used for virus isolation and the preparation of virus stocks. Bunyaviruses are cytolytic and usually plaque well in permissive animal cells, although some, such as the hantaviruses, are relative noncytolytic. Bunyaviruses will also replicate in insect cells such as mosquito cells, in which they typically cause persistent infections with relatively little or no cell death.

Genetics

Temperature sensitive (ts) mutants of bunyaviruses are easily obtained by standard methods. Within each bunyavirus serogroup, ts mutants readily complement each other if the mutations are in different gene segments. A complementation index can be obtained by initiating a dual infection at the restrictive temperature and then comparing the yield with that obtained when each of the mutants is grown separately at the restrictive temperature.

Reassortment of gene segments can occur between members of the same serogroup but apparently not between members of different serogroups even within the same genus. Reassortants can be constructed by co-infecting a permissive cell culture with two different viruses and then plaquing the progeny to obtain discrete genetic clones. To facilitate the selection of reassortants, ts mutants may be used as parental viruses and the progeny can be selected at the

restrictive temperature, assuming that the parental viruses have ts mutations in different RNA segments. The frequency of reassortment can be estimated by co-infecting cultures at the permissive temperature and assaying the progeny at both permissive and restrictive temperature. When two ts mutants in the California serogroup are crossed in this manner, the frequency of reassortants is 5–50%. Reassortment can also be obtained with clones that are not temperature sensitive, but requires use of genotyping to identify reassortants. Reassortment can occur in dually infected mosquitoes and analysis of field isolates suggests that some bunyaviruses may reassort in nature. Defective interfering virus can be generated by high multiplicity passage of bunyaviruses, and stocks containing high titers of defective virus can interfere with the replication of standard virus.

Infection of Vertebrate Hosts

Vertebrate hosts are usually infected by an insect bite, so that the virus is injected intradermally or subcutaneously. The early events after intracutaneous infection have not been studied in detail, but the virus probably moves via lymphatic channels into the blood whence it is distributed to peripheral tissues in which it can replicate, such as striated muscle in the case of California serogroup viruses. Peripheral replication leads to an active plasma viremia, which lasts for a relatively short interval, usually less than one week. Only during this limited period can the vertebrate host transmit to arthropod vectors. Viremia also delivers the virus to target organs, such as the brain, where replication leads to disease. Infection is acute and, if the host survives, virus is cleared between one and two weeks after exposure. Bunyaviruses elicit brisk immune responses, which lead to termination of viremia and sterilization of tissues. Likewise, a single infection probably produces lifelong immunity.

Host variables that influence susceptibility to infection include age and genetic determinants. Newborn animals are much more susceptible to peripheral infection than are older animals; they develop much higher titers of viremia and are readily killed, whereas older animals often undergo mild or inapparent immunizing infection. Individual inbred strains of mice or rats may exhibit dramatic differences in their susceptibility to infection and in the target organs affected, for instance, the brain or liver.

Laboratory strains of the California serogroup viruses can vary markedly in their ability to infect or cause disease, after either peripheral or intracerebral injection. Experiments with reassortant viruses have shown that attenuation of virulence can be associated with mutations in either the L RNA segment or the M RNA segment. Variant virus clones selected with monoclonal neutralizing antibodies against the G1 protein can be attenuated, indicating that single epitopes on the major glycoprotein can influence pathogenicity. Some variants are attenuated after peripheral injection only whereas others are attenuated after both peripheral and intracerebral injection. Reduced peripheral virulence is associated with reduced ability to replicate in striated muscle, the main tissue in which extraneural virus amplification occurs, whereas reduced intracerebral virulence is associated with reduced ability to replicate in neurons.

Infection of Invertebrate Hosts

Bunyavirus infection of arthropods has been studied most extensively in mosquitoes. Following the ingestion of virus, the cells lining the midgut are infected, with subsequent spread of virus to the hemocele from which it disseminates to many sites including neural and reproductive tissues, and the salivary gland. Large numbers of virions are discharged into the lumen of the salivary gland and these can be injected when the mosquito takes its next blood meal. The extrinsic incubation period (time between initial infection and development of infectivity) is 7–14 days for La Crosse virus. Infection produces little if any deleterious effects on the mosquito host and is lifelong.

Infection of ovaries, including oocytes, occurs as part of the systemic infection of mosquitoes with La Crosse virus. Transovarial transmission can then occur, with vertical transmission to both male and female mosquitoes. This permits further spread within the mosquito population, by venereal transmission and by further transovarial transmission.

Transmission, Ecology and Epidemiology

The patterns of transmission of different bunyaviruses are remarkably diverse between genera although they are quite consistent within each genus. Three of the five genera (*Bunyavirus, Phlebovirus, Nairovirus*) are arthropod-borne and are maintained in vector–vertebrate cycles, one (*Tospovirus*) is arthropod-borne but is maintained in a vector–plant cycle, and one (*Hantavirus*) is maintained in an exclusively animal-to-animal cycle. Each genus is transmitted by a limited range of insects, mainly mosquitoes (*Bunyavirus, Phlebovirus*), ticks (*Nairovirus*) or thrips (*Tospovirus*). Infection of insects is nonlethal and persistent, whereas infection of vertebrates is acute, with or without disease, and produces

a brief period of viremia during which transmission may occur. Infection of plants is also acute and often causes severe lesions and death. Many bunyaviruses have an alternative mode of virus perpetuation in which the virus is maintained exclusively in the insect host by transovarial and trans-stadial transmission (see above).

Hantaviruses differ from the other four genera in that there is no evidence for arthropod vectors. Each hantavirus is perpetuated in one or a few rodent species in which it causes persistent asymptomatic infection, which markedly enhances the probability of further transmission.

Human infections with most members of the family *Bunyaviridae* are incidental and occur only when humans intrude on the natural routes of transmission. In most instances, infected insect vectors mediate transmission to humans. However, hantavirus infections are caused by close contact with the natural rodent hosts. Nairoviruses and phleboviruses deserve special mention since Rift Valley fever and Crimean–Congo hemorrhagic fever viruses can be transmitted to humans by an alternate nonvectored route, i.e. exposure to infected animal tissue. Crimean–Congo hemorrhagic fever virus can also be transmitted by exposure to infected humans other body fluids as evidenced by numerous nosocomial outbreaks. Transmission not involving an insect is presumably mediated by aerosol or percutanoueous routes.

Epizootics and epidemics occur when the ecological variables lead to an amplification of the number of vectors and the proportion of vectors that are infected. For example, outbreaks of Rift Valley fever and Oropouche disease are often associated with conditions, such as heavy rainfall, which are conducive to intense vector breeding.

Bunyavirus Genus

The *Bunyavirus* genus is named after Bunyamwera virus and includes more than 150 individual viruses classified in 18 serogroups. Mosquitoes transmit almost all viruses in the genus (although *Culicoides* midges transmit a few) but they have a wide variety of vertebrate hosts. Some of the California serogroup viruses cause encephalitis in humans and a number of other viruses in the genus cause febrile illnesses in humans. A few of the Simbu complex viruses cause severe disease in livestock.

The California serogroup includes 14 viruses, each of which is transmitted by a few mosquito species, has a narrow range of vertebrate hosts, and a limited geographic distribution. Of these viruses, the most important pathogen is La Crosse virus, which is transmitted by *Aedes triseriatus* and infects woodland rodents, such as squirrels and chipmunks. La Crosse virus is also maintained by transovarial transmission in the absence of vertebrate infection. The virus occurs throughout the eastern United States, but most human infections and disease are limited to the midwestern United States. It is estimated that annually there are at least 100 cases of encephalitis, and well over 100 000 infections in humans. Most cases occur during the summer months in children and young adults who are exposed in wooded areas. Humans are dead-end hosts, and there is no human-to-human transmission. Encephalitis is relatively benign, with very few fatalities, and over 90% of patients recover without residual disease; the most common sequel is convulsions. The recent importation from Southeast Asia into the United States of *Aedes albopictus* could enhance the transmission of La Crosse virus to humans, since this mosquito is a major transmitter of other viruses of humans such as dengue virus and a competent vector for La Crosse virus.

La Crosse virus infects laboratory mice and produces encephalitis, with a spectrum of severity that depends on age, and route of injection. Strains of California serogroup viruses may vary in their virulence, either by subcutaneous or intracerebral routes of infection. The pathogenesis of infection involves stepwise replication of virus in striated muscle, viremia and invasion of the central nervous system, followed by cytolytic replication in neurons and encephalitis. Construction of reassortant viruses has been used to show that attenuation of virulence may be associated with mutations in either the large or the middle RNA segment, with reduced replication in striated muscle or in neurons, respectively.

The Simbu serogroup includes two pathogenic viruses, Oropouche and Akabane. Oropouche virus is transmitted by *Culicoides* midges, mainly *C. paraensis*, and causes large epidemics of febrile illness in humans in the Amazon delta of northern Brazil. It is postulated that the virus is maintained in a sylvatic cycle, but the vertebrate host(s) have not been identified. During epidemics, which are limited to the rainy season, the virus may be maintained in a midge–human cycle.

Akabane virus is transmitted by *C. brevitarsus* in Australia and probably by other *Culicoides* species in Japan, and is presumably maintained in a wildlife host, which has not been identified. Infection of pregnant cattle and sheep causes a variety of fetal anomalies (hydrancephaly, arthrogryposis, and poliomyelitis) depending on the gestational age at infection. Experimental infection of sheep or cattle reproduces the diseases seen under field conditions.

Cache Valley virus (**Fig. 1**) has recently been associated with a few cases of human encephalitis.

Hantavirus Genus

Hantaviruses are named after Hantaan virus, the cause of Korean hemorrhagic fever. With one exception, hantaviruses are rodent-borne viruses. Each hantavirus appears to be associated with a single (or a few) rodent species, with which it has coevolved, and the distribution of the virus is coextensive with the range of its rodent host(s). In its natural host, each virus causes lifelong infection with persistence in lungs, saliva, kidneys and urine, and is probably transmitted between rodents by contaminated urine or saliva. Transmission to humans is limited to persons who are in intimate contact with the rodent host, and is presumed to occur through aerosolization of contaminated excreta. In general, human-to-human transmission does not occur, although a recent outbreak of hantavirus pulmonary syndrome in South America appeared to involve person-to-person spread. Hantaviruses are notoriously fastidious but most of them replicate well in the Vero E-6 cell line.

The hantavirus genus is currently divided into three broad groups based on antigenic and genetic relationships and rodent reservoir host (the Murinae, Arvicolinae and Sigmodontinae subfamilies). Murinae-vectored viruses include the Hantaan (host *Apodemus agrarius*), Dobrava (*A. flavicollis*), and Seoul (*Rattus norvegicus*) viruses that cause hemorrhagic fever with renal syndrome (HFRS) of severe (Hantaan and Dobrava) to moderate (Seoul) severity in various areas of Asia and Europe. Hantaan virus, isolated near the Hantaan River in Korea, was discovered to be the cause of Korean hemorrhagic fever, after more than 25 years of searching for the etiologic agent. Hantaan virus occurs from Korea through northern Asia into Europe, and its most important host is the striped field mouse, *A. agrarius*. Seoul virus infects rats (*R. norvegicus*) and can be found in seaports throughout the world, as well as in colonies of laboratory rats.

The most significant Arvocolinae-vectored virus is Puumala virus, a cause of mild HFRS. Puumala virus occurs in Scandinavia, northern Europe, and western Russia, and its primary host is the bank vole, *Clethrionymus glareolus*.

The Sigmodontinae-vectored viruses were discovered with the identification of a newly recognized disease, hantavirus pulmonary syndrome (HPS). In 1993, a new disease was reported in the southwest United States involving pulmonary edema and a mortality of more than 50%. In a remarkable coordinated research effort, the agent was identified within one month, as a previously unknown hantavirus, that was subsequently named Sin Nombre (no name) virus. Sin Nombre virus occurs throughout the western and northeastern United States where the primary host is the deer mouse, *Peromyscus maniculatus* or the white-footed mouse, *P. leucopus*. Sin Nombre virus is the major cause of HPS in North America, although cases can also be associated with New York (*P. leucopus*), Black Creek Canal (*Sigmodon hispicus*), and Bayou viruses (*Oryzomys palustris*). Viruses related to Sin Nombre virus occur in South America. Andes (*Oligoryzomys longicaudatus*), Laguna Negra (*Calomys laucha*) and Juquitiba (host unknown) viruses have been associated with HPS outbreaks in Argentina, Paraguay and Brazil. Interestingly, a rare instance of hantavirus human-to-human transmission has been documented to have occurred during the Andes virus outbreak in Patagonia, Argentina.

Phlebovirus (and *Uukuvirus*) Genus

The genus *Phlebovirus* has been expanded to include the uukuviruses, which were originally considered to be a separate genus, in view of similarities in genome organization. The genus is named after phlebotomus fever virus. The genus *Phlebovirus* includes over 50 viruses. Of these, Rift Valley fever virus and the phlebotomus fever viruses cause significant illness in humans. Viruses in this genus are transmitted by mosquitoes or by phlebotomine flies (sandflies).

Rift Valley fever virus can be transmitted by a rather wide variety of mosquito species, including *Culex pipiens, Aedes* species and *Culex theileri*, and is probably maintained in several different wildlife cycles, although the vertebrate hosts have never been well defined. Epizootics characteristically occur in diverse ecological settings and are sporadic and unpredictable. During an epizootic, disease usually occurs first in domestic animals, particularly sheep, cattle and goats. Lambs experience a high mortality of about 90%, adult sheep about 25%, and pregnant ewes usually abort. The virus can be transmitted to humans both by mosquito bite and by contact with infected animals, the latter probably being the most important source of infection. Rift Valley fever virus has long been recognized to produce infection by aerosols, and those working with the virus must take extreme precautions.

Rift Valley fever virus has caused recurrent outbreaks throughout sub-Saharan Africa, and occasionally in West Africa and Egypt. In the Egyptian epidemic of 1977–79, there was an intense epizootic in sheep and cattle, and an estimated 200 000 human illnesses with 600 deaths. There are several types of human disease: an influenza-like syndrome, hepatitis with hemorrhagic manifestations, meningoencephalitis and retinitis. In sheep, hepatic necrosis and

hemorrhagic complications are the primary cause of death. In addition, the virus infects a wide variety of laboratory and domestic animals, and is often lethal. Inactivated vaccines have been made for Rift Valley fever and, although unlicensed, these have been used in laboratory personnel and probably protect against illness if not infection. Antiviral compounds, particularly ribavirin, have been shown to have some effect when used to treat experimental animal infections.

Phlebotomus fever viruses are transmitted by phlebotomus flies (sandflies), which are small flies, the size of midges, of the *Phlebotomus, Sergentomyia* and *Lutzomyia* genera. Sandfly fever viruses are enzootic in the Mediterranean basin, in the Middle East and across the Arabian peninsula into Pakistan and northwest India. Presumably, sandfly fever viruses are maintained in a vector–vertebrate cycle, but the vertebrate hosts have never been identified. During World War II, there were epidemics of sandfly fever in military troops, and these viruses continue to cause infections in North Africa and southwest Asia and are a potential risk for travelers. Toscana virus, a related virus, causes febrile illness and aseptic meningitis in Tuscany. In addition, similar viruses are found in South America, where they are probably maintained in sylvatic cycles, and cause sporadic infections in forest travelers. Phlebotomus fever is an acute febrile illness with associated malaise, which lasts 2–4 days, with complete recovery. Sandfly fever viruses replicate well in Vero cell cultures, are cytocidal, and produce plaques. However, these viruses replicate poorly in laboratory animals, even suckling mice, and there is no animal model of infection.

Nairovirus Genus

Nairoviruses are named after Nairobi sheep disease virus, the type virus. There are more than 30 viruses in the genus classified into seven serogroups. The most distinctive feature of nairoviruses is that they are tick-borne, although a few have been isolated from mosquitoes. Crimean–Congo hemorrhagic fever is the most medically important of these viruses.

Crimean–Congo hemorrhagic fever (CCHF) virus is transmitted by Hyalomma ticks, and is found over the wide geographic range of these ticks, extending from South Africa to the Middle East and into western China. CCHF virus is probably maintained in nature by two cycles, a transovarial and transstadial cycle in ticks, and a tick–vertebrate cycle. In South Africa the wildlife hosts include large herbivores (wild and domestic) and hares. Infection of humans is relatively infrequent even in enzootic areas, and occurs either by tick bite or by direct contact with infected animals or their tissues. Agricultural and abattoir workers are particularly at risk. In addition to tick and zoonotic transmission, person to person spread can also occur and has caused many small nosocomial outbreaks. In humans, CCHF is a serious disease with a mortality of 10–50%. After an initial febrile and influenza-like illness, hepatitis and hemorrhagic signs develop, that often progress to a fatal shock syndrome. Although CCHF virus will cause encephalitis in laboratory animals, there is no model for the hemorrhagic syndrome seen in humans.

Tospovirus Genus

The *Tospovirus* genus is named after its type species, tomato spotted wilt virus (TSWV). Tospoviruses are arthropod-borne viruses, that are transmitted by several species of thrips, minute insects that feed exclusively on plants. Thrips can be infected only during the larval stages and can transmit during the last larval stage and throughout adulthood. Thus, tospoviruses differ from other bunyavirus genera where many of the vectors can be infected only as adults. To date, five distinct groups, including seven viruses, have been defined based on serology and genetic sequence, and additional viruses continue to be identified. The most distinctive genetic feature of tospoviruses is the presence of an additional virus sense ORF in the M RNA segment. This ORF codes for a movement protein involved in the intercellular spread of nucleocapsids through plasmodesmata – channels in the rigid cellulose walls that separate plant cells.

TSWV was first described as a distinct disease of tomatoes in 1915, was shown to be a virus disease in 1930, and only identified as a bunyavirus in the 1980s. TSWV is known for its broad host range, including both monocots and dicots, and can infect over 500 plant species, many of which are members of the Solanaceae and Compositae families. TSWV is endemic worldwide in the tropics, subtropics and temperate zones. The virus has recently spread extensively in North America and Europe causing considerable economic losses in agriculture and horticulture. The pathological changes caused by TSWV vary widely, due both to variation in the virulence of different virus strains circulating in nature and to different responses of different host plants to the same virus strain. Symptoms range from severe widespread necrosis, to mosaic or mild discoloration of leaves, and the infection usually becomes systemic but may remain localized to the site of inoculation in a few hosts. Ultrastructural studies indicate that the morphogenesis of the virus particle is similar, but not identical, to that observed with other

species of bunyaviruses. TSWV produces cytoplasmic inclusion bodies, associated with accumulation of either N or NSs protein, which has not been reported for other bunyaviruses.

Introduction

Currently more than 300 mainly arthropod-transmitted viruses are contained within the family *Bunyaviridae*. The majority of these viruses are classified into one of five genera: *Bunyavirus, Hantavirus, Nairovirus, Phlebovirus* and *Tospovirus* (the only plant-infecting members of the family). The basic features which unite these viruses are similar virion morphology, tripartite single-stranded RNA genome and cytoplasmic site of viral replication with intracellular maturation in the Golgi. However, considering the large number of viruses within this one taxonomic grouping, it is not surprising that considerable diversity exists in terms of genome coding and replication strategies. In this article, gross generalizations are made based on results from one virus in a particular genus; future research may invalidate such generalizations. Where possible, genus-specific traits are indicated with the terms bunyavirus, hantavirus, etc., with the term *Bunyaviridae* being reserved for familial traits.

Virion Proteins and RNA Segments

The spherical *Bunyaviridae* virion consists of four structural proteins: two internal proteins (N and L) and two (perhaps three in some nairoviruses) external glycoproteins which are inserted in the viral membrane (**Fig. 1**).

By convention, the glycoprotein of greater molecular weight (or slower electrophoretic mobility in sodium dodecyl sulfate–polyacrylamide gels) is termed G1. There is no equivalent of a matrix protein to stabilize the virion structure. The three genomic RNA segments, which are designated L (large), M (medium) and S (small), characteristically have complementary terminal sequences, which are similar for the three segments of viruses within a genus; the genus-specific consensus sequences are shown in **Table 1.** A consequence of the terminal complementarity is that the ends of the RNAs may base-pair, and circular or panhandle *Bunyaviridae* RNAs have been seen in the electron microscope. Each RNA segment is associated with the N (~2100 copies per particle) and L (~25 copies per particle) proteins to form a ribonucleic protein complex known as the nucleocapsid. *Bunyaviridae* nucleocapsids are also circular, and the ends of the RNA segments are base-paired within these structures. It is probable that the

encapsidation signal for the N protein is at the 5′ end of the RNA.

Coding Strategies of the Viral Genomes

Complete nucleotide sequences have been determined for at least one representative of each genus in the *Bunyaviridae* which has allowed the coding strategies of the individual genome segments to be elucidated. These are shown schematically in **Fig. 2.**

The L RNA encodes the L protein using a conventional negative-strand strategy, i.e. in a complementary positive-sense mRNA. The L protein contains motifs found in all RNA polymerases, and expression of the Bunyamwera bunyavirus and Rift Valley fever phlebovirus L proteins using recombinant vaccinia viruses demonstrated the L had RNA synthesis activity. The L protein is therefore a component, at least, of the virion-associated transcriptase.

The M segment encodes in the complementary sense mRNA the virion glycoproteins in the form of a precursor polyprotein; in the case of bunyaviruses, hantaviruses and phleboviruses this is cotranslationally cleaved to yield the mature proteins which are

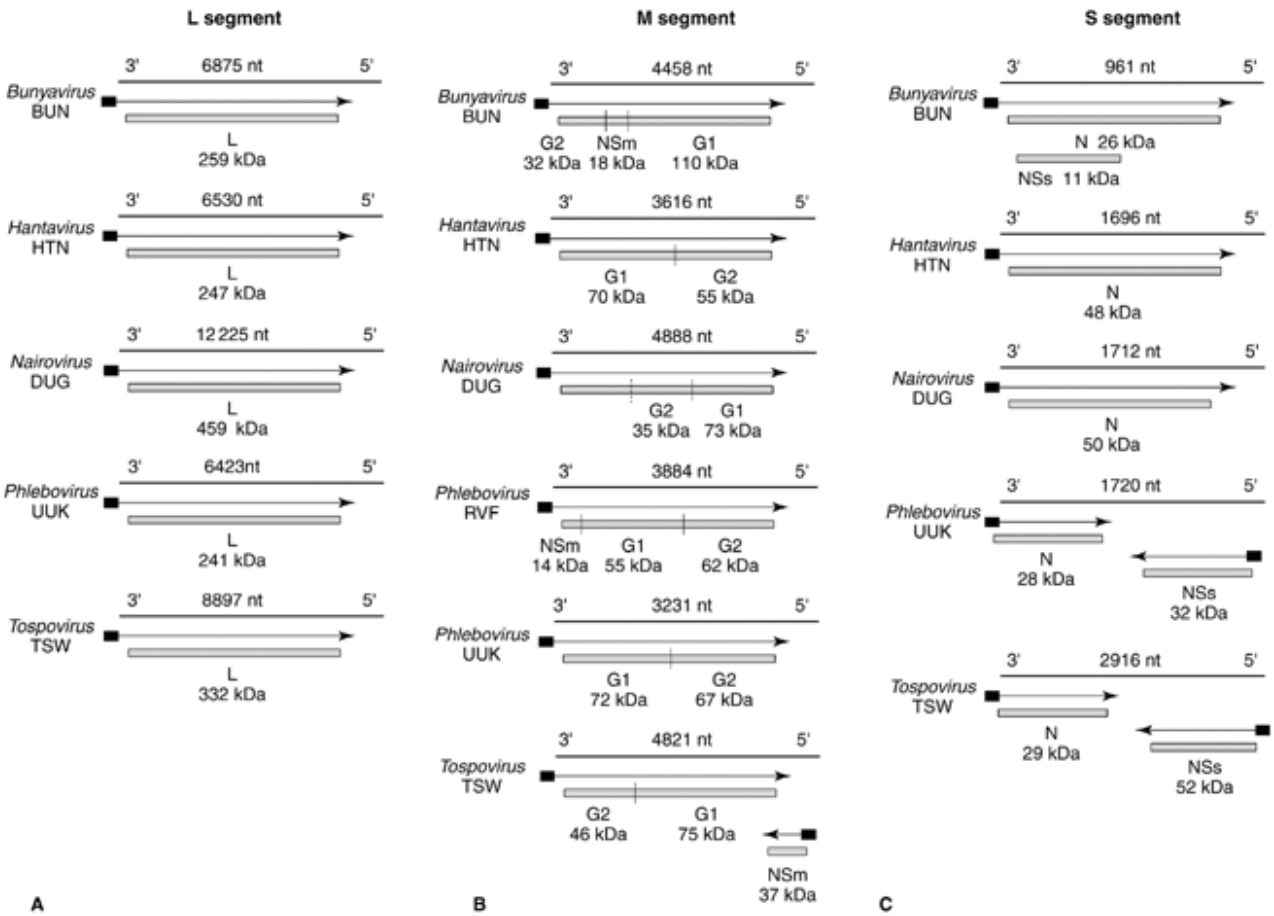

Figure 2 Coding strategies of *Bunyaviridae* genome segments. (**A**) L segment; (**B**) M segment; (**C**) S segment. Genomic RNAs are represented by thin lines (the length in nucleotides is given above each segment) and the mRNAs are shown as arrows (■ indicates host-derived sequences at 5′ end, ➤ indicates 3′ end). Gene products, with their apparent M_r, are represented by stippled boxes. Two examples of phlebovirus M segments are given which differ with respect to the presence or absence of NSm. Abbreviations: BUN, Bunyamwera virus; DUG, Dugbe virus; HTN, Hantaan virus; UUK, Uukuniemi virus; TSW, tomato spotted wilt virus; RVF, Rift Valley fever virus.

characteristically rich in cysteine residues. Processing of the nairovirus polyprotein is more complex, occurs over a period of several hours and is not yet understood. The M segment gene products have been implicated in many biological attributes of the virus including hemagglutination, virulence, tissue tropism, neutralization and cell fusion. For bunyaviruses and some phleboviruses a nonstructural protein, NSm, of unknown function, is also encoded as part of the precursor. Tospoviruses encode an NSm protein, which functions as a movement protein, using an ambisense strategy. The NSm coding region is contained in the 5′ terminal part of the viral genomic RNA, but is translated from a subgenomic mRNA. This mRNA is transcribed from the full-length complement of the genomic RNA.

The S RNA segments also show great diversity in their coding strategies. The bunyavirus S segment encodes two proteins, N, and a nonstructural protein, NSs, in different overlapping reading frames in the complementary-sense RNA. The two proteins are translated from the same mRNA species, the result of alternative initiation at different AUG codons. For hantaviruses and nairoviruses a single open reading frame, encoding the N protein, is found in the S segment complementary-sense RNA. The S segments of phleboviruses and tospoviruses employ an ambisense coding strategy: the N protein is encoded in the complementary-sense RNA corresponding to the 3′ half of the genomic S segment, whereas the coding sequence for the NSs protein is contained in the 5′ half of the genomic RNA. The proteins are translated from separate subgenomic mRNAs.

The function(s) of the NSs protein is unknown. It is noteworthy that viruses which apparently do not encode NSs (hanta- and nairoviruses) have N proteins about twice as large as those that do encode NSs (**Fig. 2**), so one might speculate that the function of NSs may have been transferred to the larger N protein.

Viral Replication Cycle

Attachment, entry and uncoating

Infection of the target cell is mediated by one or both of the virion glycoproteins interacting with the cellular receptor, though no receptor has yet been identified for any member of the *Bunyaviridae*. The relative importance of either of the glycoproteins in attachment has not been fully elucidated and may differ between the genera. For bunyaviruses, it has been suggested that G1 is the major attachment protein for vertebrate cells, whereas G2 may contain the major determinants for attachment to mosquito cells. Neutralization and hemagglutination-inhibition sites have been mapped to both glycoproteins encoded by hantaviruses and phleboviruses, suggesting that for these viruses both G1 and G2 may be involved in attachment. In common with many other enveloped viruses the *Bunyaviridae* can fuse cells at acidic pH; for bunyaviruses at least this is accompanied by a conformational change in G1. Based on electron microscopic studies of phleboviruses, entry into cells is by endocytosis. It is probable that uncoating occurs when endosomes become acidified, thus initiating fusion of the viral membrane and endosomal membrane, followed by release of the nucleocapsids into the cytoplasm.

Transcription

The classical scheme for replication of a negative-strand RNA virus is that the infecting genome is first transcribed into mRNAs by the virion-associated RNA polymerase or transcriptase (**Fig. 3**). This process, termed primary transcription, is independent of ongoing protein synthesis. Following translation of the primary transcripts into viral proteins, the genome is replicated via a complementary full-length positive-strand RNA, the antigenome, and then further mRNA synthesis (secondary transcription) ensues. Transcriptase activity has been detected in detergent-disrupted virion preparations of representatives of most *Bunyaviridae* genera. The enzymatic activity was weak compared to, for example, the transcriptase of vesicular stomatitis virus, which has hampered extensive biochemical characterization of the enzyme. However, the bunyavirus transcriptase was shown to be stimulated by oligonucleotides of the (A)nG series, cap analogues (e.g. mGpppAm) and natural mRNAs such as alfalfa mosaic virus RNA 4. These appeared to act as primers for transcription. Further support for this notion was provided by sequencing studies of the 5′ ends of both *in vivo* and *in vitro* synthesized mRNAs, which showed they contained an additional 10–18 nontemplated nucleotides; a cap structure was present at the 5′ terminus. *In vitro*, an endonuclease activity which specifically cleaved methylated capped mRNAs was detected. Taken together, these data indicate that bunyavirus transcription is markedly similar to that of influenza viruses in using a 'cap-snatch' mechanism to prime transcription. In contrast to influenza viruses, bunyavirus transcription is not sensitive to actinomycin D or α-amanitin, and occurs in the cytoplasm of infected cells. The apparent reiteration of viral terminal sequences at the junction between the primer and viral sequence itself suggests that the polymerase may slip during transcription; further analysis of hantavirus RNAs suggests that this may occur during

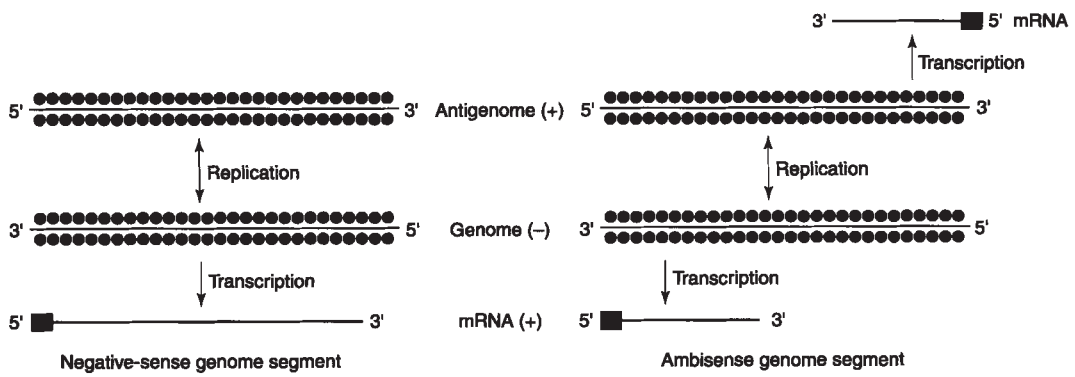

Figure 3 Transcription and replication scheme of *Bunyaviridae* genome segments. The left panel shows the scheme for a negative-strand segment and the right panel that for an ambisense segment. The genome RNA and the positive-sense complementary RNA known as the antigenome RNA are only found as ribonucleoprotein complexes and are encapsidated by N protein (•). The mRNA species contain host-derived primer sequences at their 5′ ends (■) and are truncated at the 3′ end relative to the vRNA template; the mRNAs are not polyadenylated. (Adapted from Elliot RM (1997) Emerging viruses: the *Bunyaviridae*. *Molecular Medicine* 3: 572–577, with permission, Picower Institute Press).

replication as well, and has been dubbed 'prime and realign'.

Analysis of bunyavirus primary transcription *in vivo*, however, appeared initially to produce results incompatible with the presence of a virion transcriptase, in that no mRNA synthesis could be detected in the presence of protein synthesis inhibitors in certain virus-cell systems. Further work showed that only short transcripts were produced in the absence of protein synthesis *in vivo;* subsequent gel electrophoresis analyses of the *in vitro* transcriptase products showed that these too were short transcripts. If the *in vitro* reaction was supplemented with rabbit reticulocyte lysate, however, full length RNAs were synthesized. The translational requirement was not at the level of mRNA initiation, but rather during elongation, or more precisely to prevent the transcriptase from terminating prematurely. A model to account for these observations proposes that in the absence of ribosome binding and protein translation the nascent mRNA chain and its template can base-pair, thereby preventing progression of the transcriptase enzyme. This translational requirement is not ubiquitous, however, since concurrent translation is not needed for efficient readthrough of premature termination sites in some strains of BHK cells or in the C6/36 mosquito cell line. Reconstitution and mixing experiments suggest that the translational requirement is mediated by a host cell factor, present in some BHK cell lines, which may promote interaction between the nascent mRNA and its template.

The 3′ ends of the *Bunyaviridae* mRNAs are not coterminal with their genome templates. For the nonambisense segments, mRNAs terminate 50–100 nucleotides before the end of the template, though there does not appear to be a universal termination signal in the *Bunyaviridae*: for instance 3′ GUUUUU 5′ and 3′ ACCCC 5′ are two sequences that have been mapped as termination sites. The subgenomic mRNAs transcribed from ambisense S segments terminate within the noncoding intergenic sequences in the RNA; for some, but not all, viruses the intergenic region has the potential to form a stable hairpin structure, though the role of secondary structure in transcription termination is unclear. *Bunyaviridae* mRNAs are probably not 3′ polyadenylated, but many have the potential to form stem–loop structures which may confer stability.

Genome replication

In order to replicate the negative-sense genome RNA a full-length complementary, positive-sense RNA, the antigenome, must be synthesized (**Fig. 3**). This molecule differs from the positive-sense mRNA in that it does not have the 5′ primer sequences and the 3′ end extends to the 5′ terminus of the genomic RNA template. It is not known what controls the switch from transcriptive to replicative mode of the polymerase. Two events differ between transcription and replication: initiation, which does not require a primer, and readthrough of the mRNA termination signal. The difference in initiation may be because the RNA polymerase is modified by another viral or cellular protein. In the infected cell antigenomes are only found as nucleocapsids; therefore encapsidation of the nascent antigenome RNA may prevent its interaction with the template, thereby overcoming the mRNA termination signal.

Assembly and release

Maturation of the *Bunyaviridae* characteristically occurs at the smooth membranes in the Golgi apparatus, and hence is inhibited by monensin, a monovalent ionophore. The viral glycoproteins accumulate in the Golgi complex and cause a progressive vacuolization. However, the morphologically altered Golgi complex remains functionally active in its ability to glycosylate and transport glycoproteins destined for the plasma membrane. Using vaccinia virus recombinants it has been shown that the targetting of the *Bunyaviridae* glycoproteins to the Golgi is a property of the glycoproteins alone, and does not require other viral proteins or virus assembly. Electron microscopic studies revealed that viral nucleocapsids condense on the cytoplasmic side of areas of the Golgi vesicles where viral glycoproteins are present on the luminal side. The absence of a matrix-like protein in the *Bunyaviridae,* which for other viruses may function as a bridge between the nucleocapsid and the glycoproteins, suggests that direct transmembrane interactions between the *Bunyaviridae* nucleocapsid and the glycoproteins may be a prerequisite for budding. After budding into the Golgi cisternae, vesicles containing viral particles are transported to the cell surface via the exocytic pathway, eventually releasing their contents to the exterior.

There are important exceptions, however, to the above maturation scheme; Rift Valley fever phlebovirus has been observed to bud at the surface of infected rat hepatocytes, and it appears that a characteristic of the newly described American hantaviruses which cause hantavirus pulmonary syndrome is that assembly and maturation occur at the plasma membrane.

Reverse Genetics

Reverse genetic approaches to the study of bunyavirus and phlebovirus RNA synthesis have been described, in which transiently expressed recombinant N and L proteins transcribe and replicate synthetic RNA transcripts containing a reporter gene. More recently a system to recover infectious bunyavirus entirely from cloned cDNA copies of the three genome segments has been developed. This is a significant accomplishment which promises to allow future in-depth studies on the functions of all the viral proteins as well as detailed investigation of biological properties such as virulence, tissue tropism, vector competence, etc. It is expected that similar systems will soon be developed for the other *Bunyaviridae* genera, and in the longer term the design of modified viruses having potential as vaccines may be feasible.

Persistent Infections

Arboviruses share a common biological property in their capacity to replicate in both vertebrate and invertebrate cells. The outcomes of these infections can be markedly different: whereas infection of vertebrate cells is often lytic, leading to cell death, infection of invertebrate cells is often asymptomatic, self-limiting and leads to a persistent infection. For the *Bunyaviridae* this has been demonstrated both at the organismic level and in cultured cells. Studies on bunyavirus persistent infections of mosquito cells showed no inhibition of host cell protein synthesis in sharp contrast to the situation in mammalian cells. A feature of the persistently infected cells was the excess amount of S segment RNA they contained, but although the level of S mRNA remained high the amount of N protein translated declined. The block to N protein synthesis was shown to be because N was able to encapsidate its own mRNA, thereby preventing its translation. Defective L segment RNAs were also found in the persistently infected cells, but these were not packaged into virions. In contrast, a novel type of defective interfering particle was produced which contained only S segment RNA. It is highly probable that host cell factors contribute to these events, but the identity of these factors awaits further investigation.

C

CALICIVIRUSES (*CALICIVIRIDAE*)

Michael J Studdert, The University of Melbourne, School of Veterinary Science, Victoria, Australia

History

In 1932 there occurred in southern California in pigs fed uncooked garbage a vesicular disease that was provisionally diagnosed as foot and mouth disease. The disease was eradicated by slaughter and quarantine. However, in 1933 the disease recurred at which time it was realized that the disease was not foot and mouth disease but a new disease that was called vesicular exanthema of swine. Between 1932 and 1951, the disease continued to occur in southern California and more than 2.5 million pigs or 21% of the total pig population in southern California were involved in outbreaks. There was a clear linkage between the disease and the feeding of raw, i.e. uncooked, garbage containing, it was assumed, pork scraps and outbreaks of the disease continued to occur despite the introduction of laws requiring that all garbage fed to pigs be cooked. In late 1951, a train left San Francisco and off-loaded in Wyoming, to a pig rancher, garbage containing pork scraps that were fed to his pigs. When a few of the pigs in the herd developed vesicular lesions the owner shipped the pigs for sale following which, between 1952 and 1956, outbreaks of vesicular exanthema occurred in 40 of the 48 states. The last outbreak occurred in New Jersey in 1951. By 1956 rigid enforcement of laws that required all garbage fed to pigs be cooked or a total ban on the feeding of garbage resulted in the disappearance of the disease from the national swine herd in the United States, the only country in which it has ever occurred and no further outbreaks of the disease have been recorded.

In 1972 a calicivirus was isolated from sea lions during an investigation of an outbreak of abortion on San Miguel Island off the southern Californian coast. This virus closely resembles vesicular exanthema virus and is transmissible to pigs. It is believed that the origin of vesicular exanthema virus was a consequence of feeding uncooked sea lion carcasses that were washed up on the beaches of southern California, to pigs. Subsequently caliciviruses have been isolated from other pinniped species including Northern fur seals inhabiting the Pribilof Islands, Alaska.

Acute upper respiratory disease of cats is common and in 1957 the first feline calicivirus, originally identified as a picornavirus, was isolated and shown to be one of the two major viral causes of respiratory disease in cats, the other virus being feline herpesvirus.

In 1984 a new, highly infectious disease of the European rabbit, *Oryctolagus cuniculus*, was identified in China. It was characterized by hemorrhagic lesions particularly affecting the lungs and liver, that was eventually called rabbit hemorrhagic disease. It killed some 470 000 rabbits in the first six months and by 1985 had spread throughout China. By 1988 it had spread throughout eastern and western Europe and had reached North Africa. In December 1988 cases occurred in Mexico City. Both wild and domestic *O. cuniculus* were affected, but all other species of mammals except the European hare appear to be resistant to infection. The disease was unknown in Europe before 1984; however a very similar disease called European brown hare syndrome had been recognized in the early 1980s affecting *Lepus europaeus* and subsequently some other *Lepus* spp. Rabbit hemorrhagic disease is caused by a calicivirus that is different from the virus that causes European brown hare syndrome.

Rabbit hemorrhagic disease virus was imported into Australia in 1991 to a high security laboratory. Australian native animal species susceptibility studies were conducted prior to determining whether the virus would be a safe and effective biocontrol agent. In Australia, rabbits are in plague numbers perhaps as many as 100 million and are estimated to cause $600 million in annual losses some of which, including native species and habitat destruction, may be permanent. The virus was transferred from the high security laboratory to Wardang Island for further pen trials and during these trials it escaped to the mainland

possibly by insect vector transmission (mosquitoes, bush flies) or carrion-eating birds (crows, eagles) and subsequently spread to many areas prior to 'official' release as a biocontrol agent. In New Zealand in mid-1997 the virus was illegally introduced and spread probably by farmers, who were irate after a decision of the government not to allow legal importation of the virus until more was known about it particularly in relation to its known or potential host range.

Viruses with typical calicivirus morphology have been identified but not cultivated often from enteric infections from other species including humans, cattle, swine (new type), dog, rabbit, chicken, reptile, amphibian and insects. Human hepatitis E is also caused by a calicivirus-like although the final classification of this virus is debated.

Classification and Properties

Although superficially resembling picornaviruses, with which they were once classified, in some of their properties the distinctive properties led to the creation of the family *Caliciviridae*. The family *Caliciviridae* contains four genera: two of which contain members that are the subject of this entry one of which includes the related viruses of vesicular exanthema virus and San Miguel sea lion virus as well as feline calicivirus (*Vesiculovirus* genus) and the second the related viruses that cause rabbit hemorrhagic disease and European brown hare syndrome (*Lagovirus* genus). Two other genera include Norwalk ('Norwalk-like viruses') and Sapporo viruses ('Sapporo-like viruses') that cause diarrhea in humans. Hepatitis E virus ('hepatitis-E-like viruses' genus) and a related virus isolated from pigs in midwestern USA have not been assigned to a family. Probable caliciviruses have also been recovered from monkeys, cattle, mink, swine (in addition to vesicular exanthema virus), dog, rabbit, chicken, reptile, amphibian and insect, but have not been fully characterized; viruses from some of these animal species cause gastroenteritis, and a probable strain has been isolated from dogs with a vesicular genital disease.

The family name *Caliciviridae* derives from the cup-shaped (*calix* = cup) surface depressions that give the virion its unique appearance. By cryoelectron microscopy virions are 40.5 nm with 32 cup-shaped surface structures comprising 90 arch-like capsomers arranged in $T = 3$ icosahedral symmetry. The individual capsomers are dimers of the ~60 kDa capsid protein and have three main structural domains consisting of an upper bilobed structure, a central stem and a lower shell. The capsid protein has six regions (A–F) that probably form hypervariable, loop-like structures on the surface of the folded protein and are sites of antigenic variation. Some calicivirus isolates lack the characteristic morphology and have a fuzzy edge. The virion is relatively resistant to heat and intermediate in its pH stability (>99% inactivated at pH 3).

The genomes are ~7.5 kb, positive sense, polyadenylated single-stranded (ss) RNA. The sequence of the genomes of feline calicivirus, rabbit hemorrhagic disease virus and European brown hare syndrome virus have been determined. Two different arrangements for the coding region, exemplified by feline calicivirus and rabbit hemorrhagic disease virus, in which there is a different arrangement of open reading frame (ORF) usage at the polymerase–capsid boundary. In the case of rabbit hemorrhagic disease virus the nonstructural proteins and the structural protein are encoded as a single polyprotein whereas for feline calicivirus these are separately encoded. There are three ORFs. For feline calicivirus, and probably also vesicular exanthema virus, two polyadenylated RNA species, one corresponding to the genome of 7.6 kb and the second, a subgenomic species of 2.4 kb that is bicistronic encode ORFs 2 and 3. Similar polyadenylated RNA species (7.5 and 2.2 kb) are recognized for rabbit hemorrhagic disease virus and it has been shown that both species are probably packaged into either the same or separate virions. The initiation codon for ORF 1 is at nucleotide 20 and for feline calicivirus the polyprotein encoded is 1763 amino acids whereas for rabbit hemorrhagic disease virus the polyprotein is 2344 amino acids. The nucleotide sequence at the junction between the polyprotein termination codon and the ORF 2 initiation codon is absolutely conserved and ORF 2 has a −1 frame shift relative to ORF 1. The 3′ terminal ORF 3 encodes a basic protein of 116 amino acids of unidentified function that is translated from the 2.4 kb mRNA with a −1 frame shift relative to ORF 2; it is not necessary for capsid assembly but may itself be a capsid protein. The 10–15 kDa VPg protein is bound to the 5′ terminus of both RNA species. The nonstructural proteins, 2C helicase, 3C trypsin-like serine protease and 3D polymerase, are similar to those found in picornaviruses. The individual nonstructural proteins are released from the polyprotein by specific viral protease activity in a cascade similar to that of picornaviruses.

Geographic Distribution

As noted, vesicular exanthema between 1932 and 1951 occurred only in southern California and subsequently in 40 of the 48 states of the USA before it was eradicated in 1956. Caliciviruses, including San Miguel sea lion virus, remain endemic in pinniped

species particularly along the western seaboard of North America. Feline calicivirus is the cause of a common, everyday disease of cats throughout the world. Rabbit hemorrhagic disease has occurred in China, eastern and western Europe, North Africa, Korea, probably Mexico and is now endemic in Australia and New Zealand.

Host Range and Virus Propagation

Pigs are a significant alternative host for at least some of the pinniped caliciviruses. The extent to which pinniped and perhaps other marine species share as hosts their caliciviruses has not been fully defined. Feline calicivirus is restricted to members of the family *Felidae* although most commonly infections are recognized in domestic cats. Rabbit hemorrhagic disease virus is known to infect and cause disease in the European brown hare (*Lepus europaeus*) and some other *Lepus* spp.

The pig, pinniped and feline viruses grow readily and rapidly in monolayer cell cultures derived from pig and feline tissues, respectively; most strains of vesicular exanthema virus grow in Vero cells. Rabbit hemorrhagic disease virus has not been cultivated in cell culture.

Serologic Relationships and Variability

Based on serum neutralization assays and cross-protection studies in pigs vesicular exanthema virus has a very high number of antigenic types. It was not uncommon for more than one type to be isolated during a single outbreak of disease or indeed for more than one virus type to be isolated from a single pig. The exact number of types cannot be recorded with certainty since some of the early collections of viruses were lost although at least 13 distinct antigenic types exist in one collection of viruses.

A similar pattern of antigenic variation (types) was recognized among feline caliciviruses, i.e. when rabbit antisera were used in serum neutralization assays, a large number of different antigenic types was identified in collections examined by the few individual laboratories that attempted the studies; all feline caliciviruses have never been examined by a single set of typing criteria. Curiously, however, when antisera raised in specific pathogen-free cats were used in virus neutralization assays to examine reasonably large collections of feline caliciviruses, although considerable antigenic variation was recognized, extensive crossreactions were identified essentially between all viruses. It was concluded that feline caliciviruses were related as a single antigenic type and these findings paved the way for the development of monotypic vaccines. Antigenic variation among rabbit hemorrhagic disease virus isolates has not been much studied primarily because of the lack of a cell culture system; however monotypic vaccines appear to be fully effective.

Epidemiology

Vesicular exanthema was initially and on an ongoing basis transmitted to pigs by the feeding of uncooked pinniped carcass meat and additional transmission occurred by feeding uncooked garbage containing pork scraps. Within a herd pig-to-pig transmission occurred since ruptured vesicles shed large quantities of virus into the environment such that transmission would readily occur by contact or via fomites.

Feline caliciviruses are transmitted by contact and particularly by sneezing when cats are closely confined as in multiple cat households, breeding and boarding establishments, cat shelters and veterinary hospitals. Recovered cats remain persistently infected with virus for many months or years presumably as a consequence of low-grade infection in pharyngeal tonsillar tissues.

Rabbit hemorrhagic disease virus is readily transmitted between rabbits via a fecal–oral route and over longer distances apparently by fomites including contaminated vehicles. Insects were believed to have played a role as mechanical vectors in the escape and subsequent dissemination of rabbit hemorrhagic disease virus from an offshore island location to the mainland of Australia. Infected rabbit carcass meat could be carried over considerable distances by predatory and carrion-eating mammalian and avian species.

Pathogenesis

Vesicular exanthema virus gains entry via abrasions usually around the snout and mouth or on the feet. Secondary vesicles may occur as a result of direct local spread or following viremia. Abortion may occur and death of baby pigs from agalactia in their dams also occurs.

Feline calicivirus produces vesicular lesions on the muzzle, and within the oral cavity and the respiratory tract. These tend to rupture quickly.

Rabbit hemorrhagic disease is a generalized infection in which viremic spread results in lesions in a wide range of tissues, which at post mortem are particularly evident as hemorrhagic necrosis of the liver and lung. The key to the pathogenesis is massive liver necrosis leading to disseminated intravascular coagulation.

Clinical Signs

Vesicular exanthema of pigs is clinically indistinguishable from the other three, so called vesicular diseases that affect pigs, i.e. foot and mouth disease, vesicular stomatitis and swine vesicular disease. Following an incubation period of 12–48 h there is a marked febrile response, anorexia and listlessness. Primary vesicles are blanched, raised areas of epithelium up to 3 cm diameter and up to 1 cm high filled with a serous virus-rich fluid. They easily rupture leaving raw, bleeding, exceedingly painful ulcers that subsequently become covered with a fibrinous pseudomembrane. Secondary vesicles appear 48–72 h postinfection. Notably these appear on the soles of the feet and in the interdigital space and at the coronary band. There is severe four-footed lameness. Secondary bacterial infection of lesions particularly of the feet occurs and prolongs recovery where slaughter and eradication are not pursued.

Feline calicivirus infection may produce subclinical, or an acute or subacute disease usually characterized by conjunctivitis, rhinitis, tracheitis, pneumonia (usually in young kittens) and by vesiculation/ulceration of the epithelium of the oral cavity and muzzle. There is fever, anorexia, lethargy, stiff gait and usually a profuse ocular and nasal discharge. Morbidity is high and mortality in untreated cases may reach 30%.

Rabbit hemorrhagic disease affects rabbits over two months of age; curiously rabbits less than 2 months old do not develop clinical disease following infection. The disease is often peracute, characterized by sudden death following a 6–24 h period of depression and fever. Infection is via the fecal–oral route. Morbidity rates of 100% and mortality rates of 90% are observed in rabbits older than 2 months. At postmortem there is congestion and hemorrhage in the lungs, with accentuated lobular markings, necrosis of the liver and splenomegaly. Massive blood clots are present throughout the vasculature.

Immunity

Recovered pigs are immune to the particular antigenic type of vesicular exanthema virus with which they were infected but not to other types. Since slaughter and eradication policies are pursued the questions of long-term immunity and vaccine development are not at issue.

Cats recovered from feline calicivirus infection or immunized with feline calicivirus vaccine appear to remain relatively free of disease when exposed further. This appears to be the case despite the considerable degree of antigenic variability recognized among feline caliciviruses. It is practice to recommend annual boosting of immunity.

Vaccines have been developed against rabbit hemorrhagic disease and are widely used particularly in those countries such as China and Italy where rabbit farming for meat and pelt production is a major industry, and also for the protection of pet and laboratory rabbits.

The basic features of calicivirus immunity have been best studied for the feline calicivirus in which antibody and cell-mediated immunity including the generation of cytotoxic T lymphocyte responses able to lyse autologous cells have been demonstrated.

Prevention and Control

Vesicular exanthema is effectively controlled by slaughter and is now considered an extinct virus disease.

Feline calicivirus infection is most difficult to control in large open cat populations. Vaccination is an important means of control. Clinically ill cats should be isolated and incoming cats of uncertain status should be held in isolation for at least a week before being introduced into the general colony. Although recovered cats remain persistently infected the amount of virus spread is not usually large so they do not pose the same threat by contact with other cats as do cats with obvious clinical disease.

Preventing entry of rabbit hemorrhagic disease virus into commercial rabbitries, either via fomites or via infected wild rabbits, creates a major challenge in control. Where feed and other supplies are delivered to multiple farms special care is required. Feeding of pellets that are sterilized should minimize transmission. Vaccines for the control of the disease are prepared as inactivated, adjuvanted, homogenates of infected rabbit tissues. Virus-like particles produced by recombinant DNA technology in baculovirus expression systems are effective as a vaccine following parenteral or oral administration but are not available commercially.

Future

Vigilance will be required to avoid the re-emergence of vesicular exanthema of swine either from marine sources or from laboratory escape sources. The host range of the virus strains currently known requires constant monitoring as does the emergence of variant strains. A clearer understanding of the molecular basis for virulence remains a major challenge. The molecular basis for antigenic variation among feline caliciviruses could be a research objective although research budgets for this work are difficult to identify

with a sense that currently used vaccines appear effective. The nature of the carrier state requires further understanding.

Further details of the molecular events in the replication cycle of caliciviruses in general including a definition of the total number of messenger RNA transcripts and their regulation should continue to emerge in the coming few years. The sequencing of the genome of at least one vesicular exanthema of swine virus should be undertaken. For rabbit hemorrhagic disease, in some ways the future arrived early; although the most recently identified calicivirus, the entire nucleotide sequence, comprising 7437 nucleotides was reported in 1991 and was the first calicivirus genome to be completely sequenced. Comparative sequence analysis among the caliciviruses will be as interesting and fascinating as it has been for other viruses.

At a more prosaic level the need to cultivate rabbit hemorrhagic disease virus is a high priority as is the need to understand why rabbit kittens less than two months of age are not susceptible to disease, a phenomenon contrary to and seemingly without precedent in any other virus disease.

For those countries such as Australia and New Zealand where wild rabbits are a plague upon the nations, reducing profits from farming and degrading the land, continuing assessment and enhancement of the effectiveness of rabbit hemorrhagic disease virus to control rabbits will be ongoing. The emergence of a smooth possibly nonvirulent virion form of rabbit hemorrhagic disease virus in Europe presumably as a mutation rather than a phenotypic change due to enzymatic digestion of outer peptide residues of the virion surface may be one of many factors that may in the long term diminish the effectiveness of rabbit hemorrhagic disease virus as a biocontrol agent. In many areas of Australia, rabbit numbers have declined precipitously (>60%) and there is evidence for the restoration of original habitats and species in unfarmed areas. It is too early to assess the long-term effectiveness and benefits following the introduction of the virus into Australia and New Zealand but it is likely that it, together with other established methods of control including myxomatosis (in Australia), will bring long-term benefit. The use of rabbit hemorrhagic disease virus as a biocontrol agent has caused conflict among farming groups and animal welfare groups on the one hand and those other greens among us concerned with the preservation and return of the environment to its more natural state as was before the arrival of the rabbit in Australia and New Zealand. The paradox created by the use of the virus as a lethal biocontrol and the recovery of some environments to near pristine state with the reappearance of native plant and animal species that were either much depleted or considered extinct will continue to be discussed. As in much of the rest of the world it is now essential in Australia and New Zealand to have effective vaccination programs in place to protect farmed, pet and laboratory rabbits. In contrast to the situation in the antipodes the preservation of wild rabbit populations for gun/dog hunting purposes throughout all of Europe has been a contentious political issue and the mass immunization of these wild populations will be considered.

CAPILLOVIRUSES

LF Salazar, Department of Pathology, International Potato Center (CIP), Lima, Perú

Taxonomy and Classification

Members in the genus *Capillovirus* (from Latin *capillus* = hair) have not been assigned to a family. Potato virus T (PVT), was previously included in the genus *Capillovirus*, is now a member of genus *Trichovirus*. Viruses in these genera have particles with the same typical flexuous morphology but differ in their coat protein sequences and in their genome organization and replication strategy. Members of the genus *Capillovirus* are apple stem grooving virus (ASGV), citrus tatter leaf virus (CTLV) and lilac chlorotic leafspot virus (LCLV).

Virus Structure and Physicochemical Properties

ASGV and CTLV have flexuous filament virions of 640 × 12 nm, whereas LCLV has particles with a modal length of 1536 nm. Particles are built with nine or ten protein subunits per turn of the primary helix, with a pitch 3.4 nm, although 3.69 nm was reported for LCLV and 3.9 nm for NSPV. Particles have an $s_{20,w}$ of 96–112S, and their isoelectric point is about pH 4.3 at ionic strength 0.1 mol l^{-1}.

ASGV and CTLV contain a linear positive-sense single-stranded RNA of 6.5 kb that constitutes 5% of particle weight. The RNA is polyadenylated at its 3′ end. The complete sequence of ASGV and CTLV genomic RNA has been determined. Virus particles are composed of a single protein with an M_r about 27×10^3.

Host Range and Symptoms

Host range is restricted for NSPV and wide (nine plant families) for ASGV, CTLV and LCLV. Symptoms in natural hosts are stem grooves, graft union abnormalities, malformed leaves, interveinal chlorosis and symptomless infections. Symptoms in inoculated hosts are mainly chlorotic or necrotic, local and/or systemic.

Transmission

No vectors are known for capilloviruses. Seed transmission of ASGV and CTLV has been reported in *Chenopodium quinoa* and CTLV in seeds of lily. All viruses are transmitted by grafting and, excepting NSPV, also by sap inoculation.

Geographic Distribution

ASGV is probably distributed worldwide in apples. CTLV has been reported from China, Japan, Korea, the USA, Australia, Taiwan and South Africa. LCLV has been found in England and The Netherlands. NSPV was reported from the USA.

Detection and Control

The use of clean planting materials and elimination of infected plants from the field is the most effective method of control; therefore, sensitive and accurate methods for virus detection are fundamental. Capilloviruses are moderately inmunogenic and can be detected by enzyme-linked inmunosorbent assay (ELISA). For viruses that can be transmitted by sap inoculation, *Chenopodium quinoa* is a good indicator host. Heat therapy has been used to eliminate ASGV from some apple scions.

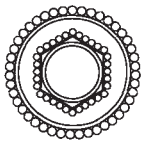
CAPRINE ARTHRITIS ENCEPHALITIS VIRUS (*RETROVIRIDAE*)



Gilles Quérat and **Robert Vigne**, INSERM U372, Campus de Luminy, Marseille, France

History

Caprine arthritis encephalitis (CAE) syndrome was first described in the USA by Cork, Hadlow, Crawford, Gorham and Piper, in 1974. This chronic disease in goats was primarily characterized by a progressive arthritis in adult animals, and by a demyelinating encephalomyelitis in goats younger than 6 months. It has been more recently recognized that arthritic adult ewes also suffer from mammitis and pneumonitis. The CAE syndrome is caused by a virus that was isolated from synovial membrane explants from an arthritic goat, in 1980, by Crawford, Adams, Cheevers and Cork. This virus was named caprine arthritis encephalitis virus (CAEV). Encephalomyelitis in CAE resembles visna, a demyelinating disease of sheep that reached epidemic proportions in Iceland in the 1940s. This disease was caused by visna virus, which was introduced into Iceland by a few Karakul sheep imported from Germany. The disease and the virus were eradicated from Iceland by the extensive slaughtering of affected flocks. Viruses similar to visna virus, however, are still in circulation in sheep and have been associated with pulmonary diseases (progressive pneumonia or maedi) in many countries. Similarly, infection and inflammatory diseases caused by CAEV in goats are almost worldwide in distribution.

Classification

CAEV belongs to the *Lentivirus* genus of the *Retroviridae* family. It can be further classified as an exogenous, nononcogenic retrovirus with a complex genome. In addition to CAEV and visna virus, the lentiviruses include human immunodeficiency viruses (HIV-1 and HIV-2), immunodeficiency viruses of numerous species of monkeys (SIV), equine infectious anemia virus (EIAV), feline immunodeficiency virus (FIV) and bovine immunodeficiency virus (BIV). Comparison of the nucleotide sequence of various isolates of lentiviruses infecting sheep and goats, i.e. visna virus and CAEV, reveal that these viruses are closely related and show less similarity to the other animal and human lentiviruses.

Lentiviruses cause lifelong persistent infections in spite of a vigorous immune response. They induce either degenerative and inflammatory diseases of specific connective tissue (CAEV and visna virus) or pathological changes to the immune system resulting in severe immune deficiency syndromes (immunodeficiency viruses).

Virion Particle and Genomic Structure of CAEV

CAE virions are enveloped particles 80–120 nm in diameter, with surface spikes of 8 nm, and an electron dense core resembling a truncated cone. The isopyknic density in a sucrose gradient is close to 1.155 g ml^{-1}. The genome is diploid, consisting of two usually identical, positive-sense, polyadenylated single-strand RNA molecules, 9.2 kb in size, which are noncovalently bound as a dimer with a strong secondary structure. The base composition of the genomic RNA is 38.2% A, 16% C, 25.1% G and 20.8% U.

The core shell (**Fig. 1**) is formed by the *gag*-derived capsid protein (CA, 25 kDa), bearing the group specific antigen. In the core, the nucleic acid binding protein (NC) is associated with the genomic RNA. It is a very basic protein with a calculated molecular weight of 9 kDa but which migrates in denaturing polyacrylamide gels as a 14 kDa protein. The core also encases, but in a minor proportion, the *pol*-derived enzymes, namely the heterodimer of reverse transcriptase (RT) and its associated RNase H (p66/p51), protease (PR, 12 kDa), dUTPase (DU, 17 kDa) and integrase (IN, 29 kDa). The matrix protein (MA, 17 kDa), unlike most of its counterparts in other mammalian retroviruses, is probably not myristoylated according to the predicted amino acid sequence and we still do not know how the *gag* and *gag-pol* polyproteins precursors migrate to the cellular membrane for virion assembly and budding. MA is believed to interact with the *env*-derived transmembrane protein (TM), although this has not been formally demonstrated for CAEV. The virion envelope originates from the cell membrane and bears the viral-specific 125 kDa surface glycoprotein (SU), the 38 kDa TM and probably numerous other cell-derived proteins.

In addition to the classical *gag*, *pol* and *env* genes common to all replication-competent retroviruses,

Figure 2

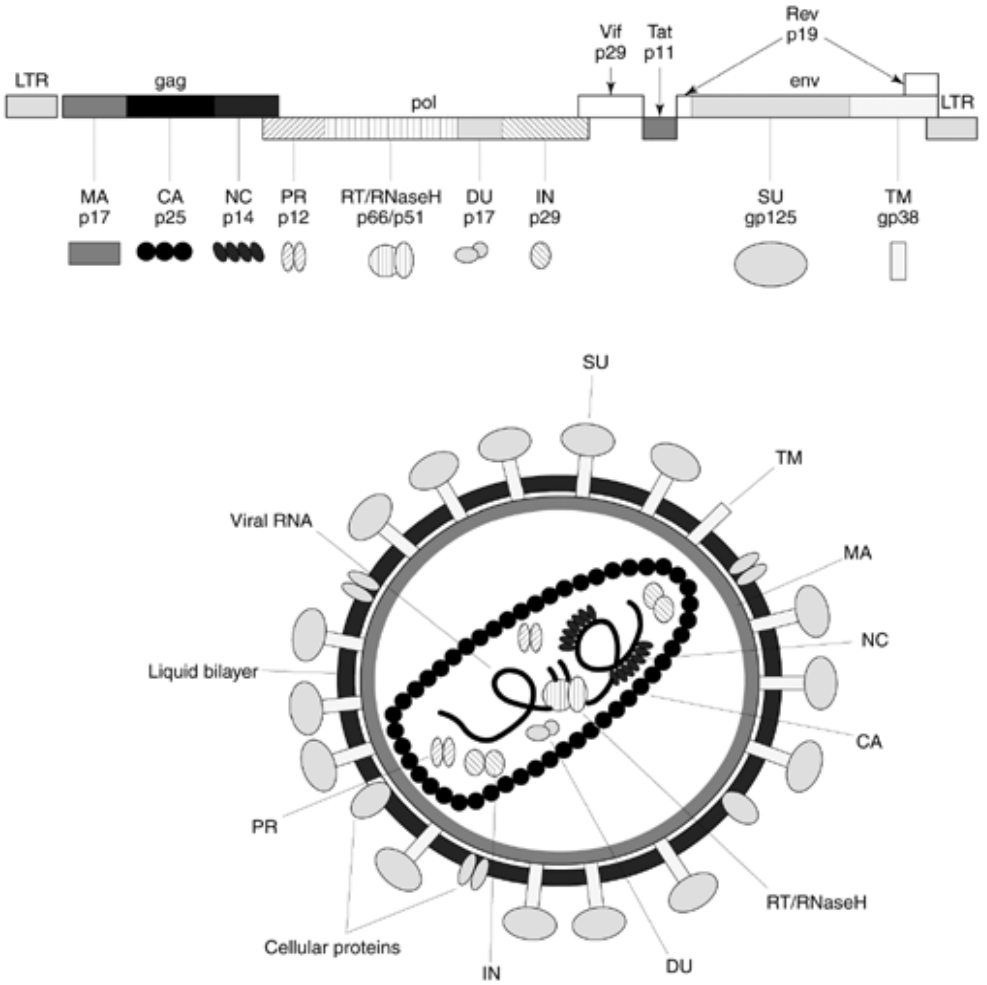


Figure 1 Genetic organization of the CAEV provirus and schematic representation of the viral particle.

CAEV and its close relative visna virus possess four other genes (**Fig. 1**).

Vif is believed to be analogous to the *vif* gene of HIV and SIV because of similar length (230 amino acids), location in the genome, overall composition of certain amino acids (rich in tryptophan) and its requirement for full replicative ability of the virus. Vif-mutants of CAEV have been engineered and were shown to replicate poorly in goat synovial membrane cells and very poorly in goat primary macrophages. Experimental infection of goats with *vif*-CAEV or *in vivo* transfection with the mutated proviral DNA led to seroconversion, but viral recovery from explanted tissues was unsucessful, further demonstrating the requirement of *vif* for efficient replication. Vif has been shown to act late in the viral replicative cycle at the stage of virion formation, release or maturation.

The *tat* gene (formally called ORF S) encodes a small protein (87 residues), which activates the viral transcription in *trans*. Unlike its HIV counterpart TAT_{CAEV} does not bind directly to viral RNA (nor DNA). The closely related Tat protein of visna virus is believed to interact with proteins of the fos/jun family and its target is believed to be an AP-1 recognition sequence upstream of the initiation site of transcription. The level of Tat-induced transactivation of expression for CAEV and visna virus seems to be considerably weaker than for HIV (at most 40 times, versus a thousand times), although this might reflect the strong basal activity of the visna and CAEV promotor in the cell type studied. There have been some conflicting data about the requirement of Tat for viral replication but it now appears that tat_{CAEV} is neither required for replication in goat synovial membrane cells in culture nor in goats experimentally infected with *tat*-mutant CAEV.

CAEV Rev is a protein which upregulates in *trans* the cytoplasmic level of viral RNA containing its

target, the Rev responsive element (RRE). Like its counterpart in HIV, RRE is a stable secondary structure of RNA, 200 nucleotides in length, present in the *env* gene region. In the absence of the *rev* gene product, all RNAs that contain RREs are sequestered in the nucleus, and only the multispliced *tat* and *tat-rev* mRNAs are accumulated in the cytoplasm. In the presence of Rev, the RRE-containing genomic and messenger RNAs which code for the structural Gag, Pol and Env proteins are efficiently transported to the cytoplasm. Rev_{CAEV} is encoded by two exons, the first one corresponds to the first 37 N-terminal residues of the env precursor, and the second one is located at the 3′ end of the genome, making a Rev protein of 133 amino acids. CAEV and visna Rev contain two distinct functional domains: a basic domain which is thought to be responsible for both nuclear localization and binding to the RRE; and a leucine-rich motif which corresponds to the activation domain and which may act as a nuclear export signal for the protein and its associated RRE-containing RNAs. Unlike *vif* and *tat* genes, *rev* is absolutely required for viral replication.

The dUTPase gene, which was formally called pseudoprotease, is located in the *pol* gene between the RNase H and the integrase domains. It encodes a virion-associated 17 kDa protein which breaks down dUTP into dUMP and PPi. This activity is superfluous for viral replication in dividing cells like goat synovial membrane cells but accelerates the replicative cycle in nondividing primary goat macrophages. Although the viral dUTPase is dispensable for replication *in vivo*, it definitely confers a replicative advantage in experimentally infected goats, as a revertant of a single point mutant appears during replication. DU was also found to be necessary for the timely development of bilateral arthritic lesions in goats. Lastly, DU prevents accumulation of G to A substitutions in the genome *in vivo*.

Replication of CAEV: Transcription, Translation and Virion Maturation

The virus binds to the target cell via the interaction of its surface envelope protein SU to an unknown receptor, which leads to fusion of the viral and the cell membranes. Reverse transcription of genomic RNA into proviral DNA begins in the cytoplasm and ends in the nucleus. The primer for minus-strand synthesis is a $tRNA^{Lys1,2}$, which is believed to be linked to the genomic RNA and the reverse transcriptase in the viral nucleocapsid. Once in the nucleus, some of the proviral DNA molecules integrate into the host chromosomal DNA. It has not been formally demonstrated that integration is a prerequisite for the transcription of mRNAs, although this seems likely owing to what is known in the HIV system.

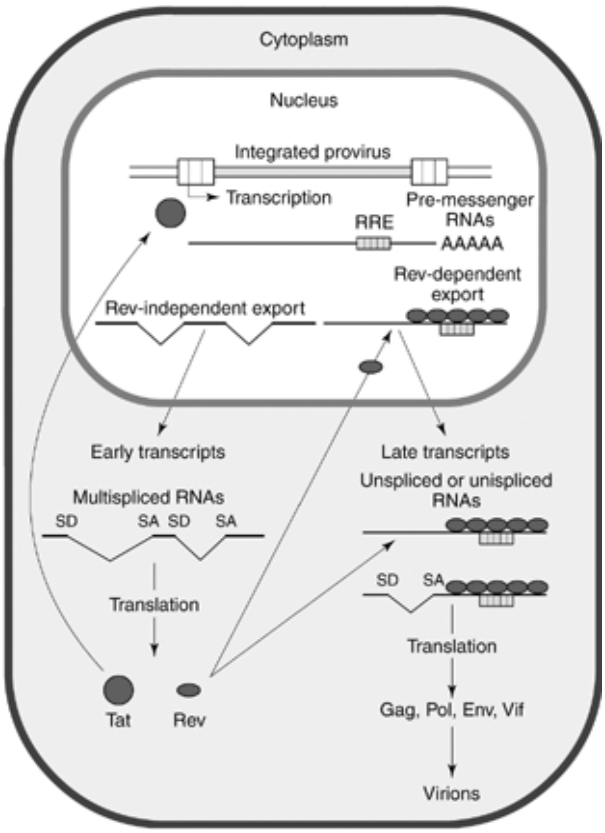

Figure 2 Regulation of the viral gene expression.

In permissive goat synovial membrane cell cultures, the transcription is a two-step process. Early after infection (24 h), the overall level of transcription is low and the major classes of cytoplasmic mRNAs are the multispliced *rev* and *tat-rev* RNAs of 1.2 and 1.5 kb. Later, i.e. 48 h after infection, there is a dramatic increase in the level of transcription and the appearance in the cytoplasm of a large amount of unspliced or singly spliced RRE-containing mRNAs coding for the structural proteins of the virion, i.e. Gag, Pol and Env, and the regulatory protein Vif (**Fig. 2**).

The genomic-sized RNA codes for the *gag* and *pol* gene products either as a $Pr55^{gag}$ polyprotein precursor or as a $Pr150^{gag\text{-}pol}$ precursor resulting from a (-1)-ribosomal frame shifting in the overlap between *gag* and *pol* reading frames. The precursors are then processed by the viral protease PR which is autocatalytically released from the Gag-Pol precursor, to yield (beginning from the N-terminus) MA-CA-NC for the *gag*-related products and PR-RT-DU-IN for

the *pol*-related products. Unlike most retroviruses, however, for which the processing of *gag*- and *pol*-related products takes place only at the budding stage of virion assembly, some of these precursors mature in the cytoplasm of the infected cells.

The Env precursor is translated from the 3.5 kb mRNA as a 107 kDa polyprotein with an unusually long N-terminal sequence preceding the hydrophobic signal peptide (about 80 residues), which is then cleaved after glycosylation of the precursor. The sequence RKKR/GVG defines the cleavage site of the precursor to yield the mature gp125 surface protein and the transmembrane gp38 protein.

Assembly of the viral particles takes place at the cell membrane during budding, as for a classical type C retrovirus, although there are some indications that it can also occur at the vacuole membrane of activated macrophages, therefore yielding a productively infected macrophage which releases a few viral particles into the extracellular space. Nevertheless, as previously mentioned, the mechanisms of targeting of the Gag and Gag-Pol precursors to the cell membrane are probably different from those of classical lentivirus like HIV, which exhibits myristoylated precursors.

In contrast to the high level of expression in acutely infected permissive cells *in vitro,* the expression of CAEV is highly restricted *in vivo,* particularly in circulating blood monocytes. There is no detectable free virus in the plasma and the cell-associated viral load, which is measured by the number of monocytes required to successfully explant the virus, is in the range of 1 in 10^5 monocytes. The differentiation of monocytes into macrophages in certain fluids or tissues, such as milk or lung, is accompanied by an activation of viral gene expression. Consequently the cell-associated viral load in either milk macrophages or alveolar macrophages is much higher and the proportion of macrophages expressing viral RNAs, as measured by *in situ* hybridization experiments, can amount to 1%. The mechanisms for the activation of expression of the viral genome *in vivo* from a restricted (possibly latent) state are presently largely unknown, although the differentiation-induced activation of *fos* and *jun* gene products, which are thought to act on the AP-1 sites of CAEV promoter, could well be implicated. The acute myeloid factor 1 (AML-1) which has been described as a binding factor in the long terminal repeat (LTR) of the ovine EV-1 lentivirus, may also enhance the CAEV transcription upon macrophage activation. Local secretions of interferon γ (IFN-γ) by activated lymphocytes could also lead to viral activation in bystander macrophages, owing to the presence of an IFN-γ-responsive element (GAS) in the LTR. It is worthy of note that *in situ* hybridization studies of synovia from infected goats have shown that viral transcription in tissue macrophages often colocalizes with IFN-γ-expressing T lymphocytes.

Host Range and Viral Propagation

Although CAEV is distributed worldwide and is associated with inflammatory diseases in goats, it is possible that it could propagate through the sheep species concomittantly with ovine lentiviruses (visna virus), as CAEV-like strains have been isolated from sheep with progressive pneumonia in the USA and Western Europe. These small ruminant viruses do not appear to have any hosts other than sheep and goats. The presence of related lentiviruses in wild ungulate animals is, however, not excluded.

Infected monocytes and macrophages are the cellular vectors that spread the virus into the specific target tissues within the same animal and probably from animal to animal. In the case of horizontal transmission to kids in the field, the colostrum is the major source of infectious virus. This secretory fluid contains infected macrophages which may convey the infection to the neonatal animals through the gastrointestinal tract. Prenatal transmission of the closely related visna virus has also been documented but its relevance for CAEV transmission and the epidemiology is not known. Horizontal transmission of CAEV is also possible between adult goats, either via the respiratory route by the dry cough containing free virions and/or infected macrophages or via the mammary glands from udder to udder by infected milk contaminating the milking machine.

Genetics and Evolution

Lentiviruses are notorious for their genetic variation. The molecular explanation for this variation is that the reverse transcriptase step occurs in the absence of a proofreading mechanism. Replication in nondividing cells like macrophages, where deoxynucleotide pools are low and highly imbalanced, may also lead to numerous nucleotide misincorporations. The additional guanine-to-adenosine hypermutation tendency that occurs in lentiviruses may also contribute to the high adenosine content of their genomes (*c.* 38% for CAEV) relative to other retroviruses (*c.* 24% for the oncovirus Rous sarcoma virus).

Comparison of the sequences from various field isolates of either ovine or caprine lentiviruses originating in Europe and the USA show that they form a group of the *Lentivirus* genus with nucleotide divergences in the range of 10–20% for the *gag* and

pol genes and 20–30% for the *env* gene. Phylogenetic studies suggest that the caprine lentiviruses originated from the ovine viruses clade. Previous attempts to date the divergences of the various lentivirus clades must be taken with caution as numerous studies have shown that there is no universal molecular clock.

Comparative sequence analysis of a hypervariable *env* gene domain during experimental infection suggests that the mutation rate of these viruses is approximately $5\ 10^{-3}$ nucleotide substitutions per site per year. Because misincorporation occurs only during replication, this rate reflects the number of replicative cycles per year in the animal. This rate is within the same range (but slightly lower) than those observed for HIV and SIV, suggesting that, although the viral replication in blood cells is considerably lower than observed for the primate lentiviruses, CAEV replicates quite actively in other organs of the body, such as synovia, lung or udder.

Epidemiology

Serological surveys show that the infection is common in goats, with a level of prevalence of around 70% in adult goats of US origin and of some countries of Europe (for example, France and Norway). Comparison of detections of the virus by either ELISA serology or polymerase chain reaction (PCR) show greater sensitivity but lower specificity for the PCR at the present time, although the PCR assay for CAEV and visna virus detection is still in its infancy.

The higher incidence of goats infected with CAEV, compared with visna virus in sheep, is probably due to the common practice in the dairy goat industry of feeding kids with pooled colostrum and milk from dairy mothers. In contrast, pooled milk is rarely fed to lambs. This enhanced transmission in dairy goats may therefore explain the high prevalence of CAEV infection in goats in Western Europe, Australia and North America, and the lack of such infections in African countries that have no dairy goat operations based on Western models. This marked difference in prevalence of infection between dairy and nondairy goats was also observed in Australia, where it was reported that Angora goats were much less infected than dairy goats.

Pathogenicity

The manifestation of the disease resulting from CAEV infection is a complicated process involving very complex interactions between the virus and host. Pathogenesis studies with CAEV mutants failed to pinpoint any 'pathogenic gene', suggesting that the overall level of viral replication in a particular tissue may be the best viral correlate to the level of tissue injuries. Any mutations affecting the fitness of the virus is therefore likely to affect its pathogenic potential. The host environment is also critical and a variety of host factors such as immune status, genetic background, age and nutritional status may be determinant factors. As an example of the relevance of the genetic background, it was reported that some class I major histocompatibility complex (MHC) haplotypes of the Saanen breed of Switzerland may be less sensitive to the CAE syndrome. Similarly, the European veterinary community pointed out the relative resistance of the ovine Merino breeds to visna and maedi syndromes. The relevance of the immune status and the age dependence is again questioned, as it is remarkable that the CAE syndrome has a high incidence in newborn goats and that the most severe clinical signs appear when the maternal antibodies disappear.

Clinical Features and Histopathology

CAEV is associated with several inflammatory diseases affecting the joints, brain, mammary glands and lungs of goats. Encephalomyelitis is the most frequent clinical symptom of infection in goat kids, occurring at between 2 and 6 months of age. The clinical feature of infection is posterior paresis, which sometimes progresses to paralysis of the hind legs and eventually to tetraplegia. When the affected kids recover from the neurological disease, they develop severe arthritis when they become adults. A slow progressive encephalitis rarely occurs in adult goats. This disease has clinical features that are very similar to those of visna in sheep. Arthritic disease is encountered most frequently in adult goats. It progresses over the years, with a gradual swelling in the carpal (knee) joints. In advanced cases, carpal swelling may be marked and hard, with extensive periarticular fibrosis and mineralization. Some animals are lame and lean. Chronic interstitial pneumonia with progressive dyspnea and weight loss, symptoms resembling maedi in sheep, are also observed in arthritic goats. Recently, mastitis was recognized as a prevalent ailment in arthritic dairy goats, with an acute phase at the kidding period. The consequence of this frequent manifestation is a decrease in the milk secretion.

Histopathological studies reveal that in all the target organs the lesions are of an inflammatory nature, with infiltration of a large number of plasmocytes (50–70% of all inflammatory cells in the synovium) and MHC class II-activated lympho-

cytes and macrophages. Arthritis is characterized by marked hyperplasia of the synovial membrane and villosities and by mineralization and fibrosis of the soft tissues. Lymphoid foci are numerous and often surround vessels. In the brain, inflammatory lesions are distributed in a multifocal pattern and are most prevalent in the periventricular white matter and/or the midbrain. In the spinal cord, focal necrosis is observed in the lateral white matter. The pulmonary lesions are similar to those described for progressive pneumonia in sheep, particularly with respect to the focal and diffuse infiltration of lymphocytes to the alveolar septa, mild septal fibrosis and hyperplasia of the cells lining the alveoli. Lastly, the interstitium of the mammary gland is diffusely infiltrated with mononuclear cells, although lymphoid foci may form around the mammary gland secretory ducts and/or within interlobular septa. In all the target tissues, the infected cells, detected by *in situ* hybridization, are predominantly macrophages, but other types of cell, such as epithelial, endothelial and fibroblast cells, are also infected.

The finding of many concomitant bacterial and parasitic infections, such as *Corynebacterium pseudotuberculosis* lymphadenitis, *Mycoplasma ovipneumoniae, Müllerius capillaris* pneumonia and intestinal coccidiosis, in the CAEV-infected goats suggests that CAEV, like HIV, may compromise the immune system.

Immune Response

A common characteristic among all lentiviral infections is that neither the cellular nor the humoral immune response is capable of eliminating the pathogenic agent from its natural host. Infected goats produce antibodies against all virus polypeptides, and specifically against envelope proteins, but these antibodies are poor at neutralizing the infectivity of the agent. Immunization of goats with attenuated live virus, killed virus or detergent-treated infected cells failed to induce protective, sterilizing immunity against homologous virus given as challenge. Moreover, for reasons that are still unclear, in some instances such a challenge was reported to result in a more severe pathology.

The immune system may even be responsible for some of the pathological changes in the affected tissues, as, for example, a high level of anti-SU antibodies is a good predictor of the development and severity of arthritic lesions. Immunodominant epitopes in the TM have also been described but their role in the pathogenesis is still unknown. Studies of cytokine expressions in the joints have suggested that either early after infection (6–12 days), or in older but clinically asymptomatic joints, the activated lymphocytes express predominantly IFN-γ, interleukin 2 (IL-2) and IL-10. This kind of pattern is consistent with a type 1 (Th1) response of T helper cells, leading to predominantly cellular immunity. In contrast, clinical arthritis is associated by predominant expression of tumor necrosis factor α (TNFα), IL-6 and MCP-1, a monocyte chemoattractant factor, a pattern which is consistent with a Th2 or predominantly humoral response. However, even in late clinical arthritis, foci of both kinds of cytokine expression patterns are present in a single synovia, suggesting that the evolution of the immunopathogenesis may be more complicated than a simple shift from Th1 to Th2 response.

Future Perspectives

CAEV infection of goats is an ideal model for studying the pathogenesis of macrophage-tropic lentiviruses in their natural host. Research efforts should be directed towards analyzing CAEV replication *in vivo* to determine the exact role of the different genes of CAEV in the rate of viral replication, the severity of the disease and the interaction of lentiviruses with different target cells. It is important to determine the role of *rev* and *tat* in maintaining the lentivirus as a latent form in undifferentiated blood monocytes. The receptor of CAEV on macrophages also needs to be identified in order to better characterize the cells that harbor and replicate the virus *in vivo*.

Research on the immune response is needed to improve our knowledge of the mechanisms implicated in the immunopathological changes. Very little is known about the T cell-mediated cytotoxic response, its target epitopes and its efficacy at killing the infected macrophages. The interplay between cytokine secretions, soluble viral regulatory proteins and the direct cytotoxicity of these molecules also needs to be investigated, as well as the possible presence of superantigens or of autoimmune responses. Such studies may permit us to find new therapeutic approaches to lentiviral diseases.

Vaccination research has many opportunities here, from the live attenuated virus to the naked DNA expressing a specific viral gene, in combination (or not) with specific cytokines.

CARDIOVIRUSES (*PICORNAVIRIDAE*)

Douglas G Scraba (deceased, October 1997), University of Alberta, Edmonton, Alberta, Canada

Ann C Palmenberg, Institute for Molecular Virology, and Department of Biochemistry, University of Wisconsin, Madison, USA

History

The first cardioviruses were discovered inadvertently during attempts to adapt human polioviruses to laboratory mice. Following the protocol of Armstrong, who in 1939 successfully transferred the Lansing strain (type 2) of poliomyelitis from monkeys to cotton rats to mice, Jungeblut and Sanders, at Columbia University, reported the adaptation of the Yale-SK poliovirus to mice. Subsequent immunological studies, however, led to the conclusion that the agent, which caused a flaccid paralysis of the hind limbs of mice, followed by death, was a new and different neurotropic virus; it was designated Columbia-SK. In 1943, Jungeblut and Dalldorf made another attempt, starting with brainstem material from a fatal case (MM) of poliomyelitis. The result was the same: after intracerebral transfers in monkeys and hamsters a virus was isolated which induced encephalitic symptoms (tremor, uncertain movements), paralysis and death in mice, but which was not poliovirus. In retrospect, it seems most likely that the Columbia-SK and MM viruses were endemic in the laboratory mice, and that their virulence was enhanced by direct intracerebral transfer. However, it is possible that they came from the monkeys used in the experiments, because rhesus monkeys inoculated with brain tissue from dead mice developed a mild febrile illness.

In 1945, Helwig and Schmidt recovered pleural fluids from a gibbon and a chimpanzee which had died in captivity in Miami from pulmonary edema and myocarditis. When these edema fluids were inoculated into mice by the intracerebral (i.c.), intraperitoneal (i.p.) or intravenous (i.v.) route, the pathogen they contained produced hind limb paralysis, myocarditis and death within a week. The 'myocarditis-producing agent' was subsequently shown to be a virus, and was named encephalomyocarditis (EMC) virus. It probably originated from a group of wild rats that lived on the same farm as the primates; about half of the rats that were later trapped and examined had antibodies to EMC virus.

In 1948, Mengo virus was isolated by Dick, Smithburn and Haddow, at the Yellow Fever Research Institute at Entebbe in the Mengo district of Uganda, from a captive rhesus monkey that had developed lower limb paralysis. Blood or spinal fluid from this animal, when inoculated intracerebrally into mice, produced hind limb paralysis followed by prostration and death within a few days. The filterable Mengo virus was also isolated from mosquitoes and from a (healthy) captured mongoose. Crossneutralization studies done in 1949 showed that the Columbia-SK, MM, EMC and Mengo viruses were antigenically very closely related, and distinct from Theiler's murine encephalitis viruses.

A fifth member of this cardiovirus serological group was isolated by Gronnert, at the Bayer laboratories in West Germany in 1949, from the intestinal tissues of a sick mouse; this was called mouse-encephalomyelitis or maus-Elberfeld (ME) virus.

Taxonomy and Classification

The cardioviruses constitute a separate genus, *Cardiovirus*, in the family *Picornaviridae*. They are distinguished from other picornaviruses by special features of their genome organization, common pathological properties, and the dissociability of their virions at pHs between 5 and 7 (in 0.1 M NaCl). The intrinsic fragility of the cardiovirus capsid is reflected

CARDIOVIRUSES (*PICORNAVIRIDAE*)

Douglas G Scraba (deceased, October 1997), University of Alberta, Edmonton, Alberta, Canada

Ann C Palmenberg, Institute for Molecular Virology, and Department of Biochemistry, University of Wisconsin, Madison, USA

History

The first cardioviruses were discovered inadvertently during attempts to adapt human polioviruses to laboratory mice. Following the protocol of Armstrong, who in 1939 successfully transferred the Lansing strain (type 2) of poliomyelitis from monkeys to cotton rats to mice, Jungeblut and Sanders, at Columbia University, reported the adaptation of the Yale-SK poliovirus to mice. Subsequent immunological studies, however, led to the conclusion that the agent, which caused a flaccid paralysis of the hind limbs of mice, followed by death, was a new and different neurotropic virus; it was designated Columbia-SK. In 1943, Jungeblut and Dalldorf made another attempt, starting with brainstem material from a fatal case (MM) of poliomyelitis. The result was the same: after intracerebral transfers in monkeys and hamsters a virus was isolated which induced encephalitic symptoms (tremor, uncertain movements), paralysis and death in mice, but which was not poliovirus. In retrospect, it seems most likely that the Columbia-SK and MM viruses were endemic in the laboratory mice, and that their virulence was enhanced by direct intracerebral transfer. However, it is possible that they came from the monkeys used in the experiments, because rhesus monkeys inoculated with brain tissue from dead mice developed a mild febrile illness.

In 1945, Helwig and Schmidt recovered pleural fluids from a gibbon and a chimpanzee which had died in captivity in Miami from pulmonary edema and myocarditis. When these edema fluids were inoculated into mice by the intracerebral (i.c.), intraperitoneal (i.p.) or intravenous (i.v.) route, the pathogen they contained produced hind limb paralysis, myocarditis and death within a week. The 'myocarditis-producing agent' was subsequently shown to be a virus, and was named encephalomyocarditis (EMC) virus. It probably originated from a group of wild rats that lived on the same farm as the primates; about half of the rats that were later trapped and examined had antibodies to EMC virus.

In 1948, Mengo virus was isolated by Dick, Smithburn and Haddow, at the Yellow Fever Research Institute at Entebbe in the Mengo district of Uganda, from a captive rhesus monkey that had developed lower limb paralysis. Blood or spinal fluid from this animal, when inoculated intracerebrally into mice, produced hind limb paralysis followed by prostration and death within a few days. The filterable Mengo virus was also isolated from mosquitoes and from a (healthy) captured mongoose. Crossneutralization studies done in 1949 showed that the Columbia-SK, MM, EMC and Mengo viruses were antigenically very closely related, and distinct from Theiler's murine encephalitis viruses.

A fifth member of this cardiovirus serological group was isolated by Gronnert, at the Bayer laboratories in West Germany in 1949, from the intestinal tissues of a sick mouse; this was called mouse-encephalomyelitis or maus-Elberfeld (ME) virus.

Taxonomy and Classification

The cardioviruses constitute a separate genus, *Cardiovirus*, in the family *Picornaviridae*. They are distinguished from other picornaviruses by special features of their genome organization, common pathological properties, and the dissociability of their virions at pHs between 5 and 7 (in 0.1 M NaCl). The intrinsic fragility of the cardiovirus capsid is reflected

in the fact that empty capsids have never been isolated.

Comparative analyses of the RNA sequences from a variety of isolates have confirmed the homologous relationship (>45% nucleotide identity in both the coding and noncoding regions) among all cardiovirus genomes. Special features of the 5′ noncoding region (presence or absence of a poly(C) tract), the lengths of virion protein surface loops and serology allow subclassification into the EMC-like viruses (EMC, Mengo, MM, ME, Columbia-SK), the Theiler's-like viruses (BeAn, DA and GD VII strains). The Vilyuisk viruses, isolated in 1954–1957 by Farmanova and Chumachenko from clinical specimens of humans with acute and chronic encephalitis, share many genomic and sequence characteristics with other members of the genus, and a strain designated 'V1' has been proposed as a type species for a third subgroup of cardioviruses.

Properties of the Virion

The cardiovirion consists of a genomic single-stranded RNA molecule (molecular weight, K^+ salt $= 2.8 \times 10^6$) enclosed in an icosahedral capsid. The 20 amino acid residue protein, VPg, is covalently linked to the 5′-uridine residue of the RNA by a phosphotyrosine bond. There are four different polypeptide species (VP1, VP2, VP3 and VP4) in the capsid, and 60 copies of each are required for the complete structure. The molecular weights of the Mengo capsid polypeptides, in order, are 31700, 29000, 25100 and 7200. The viral RNA is tightly packed within the capsid, occupying about 75% of the available interior volume (**Table 1**). The remainder is filled with water, various polyamines and salts that neutralize the charge of the RNA. Minus-strand viral RNAs, cellular mRNAs and tRNAs are never detected in the particles. Nor do the particles contain other exogenously packaged viral or cellular proteins, although the viral protein $3D^{pol}$ sometimes appears to copurify with virions because of a strong hydrophylic interaction with the capsid surface.

Table 1 Physicochemical properties of the cardiovirion

Hydrated diameter	30 nm
Thickness of the capsid shell	5 nm
Diameter of the RNA-containing core	20 nm
Sedimentation coefficient ($s_{20,w}$)	155×10^{-13} s^{-1}
Diffusion coefficient ($D_{20,w}$)	1.47×10^{-7} cm^2 s^{-1}
Partial specific volume (ν)	0.67 ml g^{-1}
Particle weight	8.4×10^6
Percentage RNA by weight	33%
Virions/A_{260} unit	9.5×10^{12}

Virus Capsid: Three-dimensional Structure

X-ray crystallographic analysis of the Mengo virion at 0.3 nm resolution was reported in 1987 by Luo *et al.* The overall architecture of the capsid follows $T = 1$ icosahedral symmetry, with one asymmetric unit comprising one molecule each of VP1, VP2 and VP3. The 60 VP4 molecules occupy internal positions, extending from under the threefold axes to form part of an annular structure under the fivefold axes; there are no extensions of VP4, or the other capsid proteins into the RNA-containing core. The shell-forming domain of each of the VP1, 2 and 3 proteins is a wedge-shaped, eight-stranded antiparallel β barrel. This folding pattern has been called the RNA virus core (RVC) motif because it is shared by the capsid proteins of all picornaviruses and by the $T = 3$ icosahedral plant viruses. While Nature has adopted a common mode for capsid shell construction for both of these groups of viruses, the specific portions of the polypeptide chains which link the eight β strands (designated A to H from N- to C-terminal) are different for each virus and for each VP protein type within each virus. It is essentially the composite of these differences that distinguish the various species.

The arrangement of the RVC domains of the capsid polypeptides with respect to the surface of the Mengo virion is shown in **Fig. 1**. The asymmetric structure unit, or protomer, is outlined by a thick line, as is the pentameric subunit which serves as the assembly unit for the construction of progeny virions *in vivo*. The protomer is stabilized by extensive noncovalent interactions among the RVC domains of the three polypeptides and between the N-terminal extensions of VP1 and VP3, which are located on the inner surface of the capsid. Protomers can only be dissociated *in vitro* by boiling in sodium dodecyl sulfate (SDS). The association of protomers into pentamers, which is the first step in progeny virion assembly, is facilitated by hydrophobic contacts between the N-terminal extensions of VP3 and VP4 (actually, VP0 at the time of pentamer formation), which together form a β annulus in the interior portion of the shell directly under the fivefold symmetry axis. Pentamers can be dissociated into protomers by 2 M urea. The 12 pentamers that comprise the cardioviral capsid are held together by electrostatic interactions among the VP2 and VP3 polypeptides along the twofold and around the threefold axes; these can be broken in the presence of 0.14 M chloride or bromide ions at $5.6 < \text{pH} < 6.4$. Polio-, rhino- or foot-and-mouth disease (FMD)

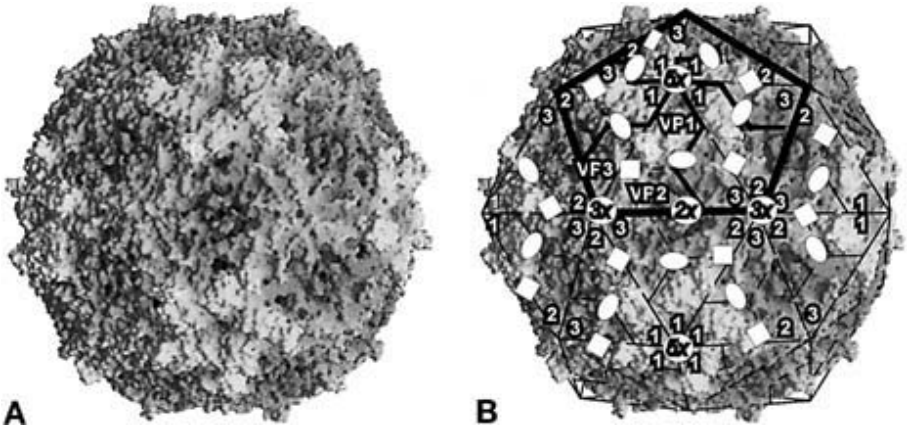

Figure 1 Exterior surface of the Mengo virus capsid. (**A**) Computer graphics representation of the Mengo virion surface at a resolution of 3.0 Å (Luo *et al.*, 1987). Light-colored regions define the higher 'massif' regions on the virion surface relative to the lower, dark-colored regions. (**B**) The surface figure is highlighted with the icosametric arrangement of polypeptides, protomers and pentamers (one pentamer, and the five protomers within it are outlined with thick lines). The icosahedral fivefold, threefold and twofold axes are marked, as are the locations of the 'pits', the putative receptor-binding sites (ovals) and the composite antigenic determinant (squares). The VP4 polypeptides occupy internal locations. Figures A and B, together, form a stereopair for three-dimensional perspective.

virions do not share this capsid fragility because their pentamer–pentamer contacts are more extensive: adjacent pentamers in polio- or rhinovirions actually interdigitate and those in FMD virions overlap, while the Mengo pentamers simply abut one another.

Among the noticeable surface features of the Mengo capsid is the regular disposition of 60 depressions, or 'pits', which are about 3 nm in diameter at the top and 2.2 nm deep. In accordance with Rossmann's 'canyon hypothesis', indirect experimental evidence implicates the 'pits' and the adjacent walls of the nearby fivefold 'massifs' as virion-attachment or receptor-binding sites. The outer diameter of the 'pit' is small enough to prohibit access by an antibody molecule (whose combining-site 'footprint' is about 3.5 nm in diameter), yet large enough to accommodate an elongated cell surface glycoprotein. Mutations changing amino acid residues around the 'pit' would be permitted, whereas the residues which line the 'pit' would have to be conserved in order for virus–cell interaction to occur. The immunoglobulin VCAM has been proposed as a cell surface receptor for the EMC-like cardioviruses; however, EMC and Mengo are also very efficient at agglutinating erythrocytes, and the specific receptor for this function on human cells is the sialoglycoprotein, glycophorin A. The sialic acid moiety of glycophorin A is specifically required for erythrocyte binding.

Figure 1 also shows the location of the composite antigenic determinant defined by a panel of neutralizing monoclonal antibodies. Although each antibody recognizes a specific epitope within the determinant (generally a conformational rather than a linear array of amino acid residues), crossneutralization experiments have shown that most epitopes are physically overlapping. The determinant involves residues in VP1 (T1100; in the conventional numbering system the first digit refers to the capsid polypeptide and the next three identify its position in the chain from the N-terminus), VP2 (K2075, N2144, R2145, S2147 and K1248) and VP3 (K3057 and S3068). These residues were identified by sequencing the capsid-coding regions of RNAs from neutralization-escape mutants. As expected, all of these residues are on the virion surface, generally near the outer wall of the 'massif' at the center of each asymmetric protomer, and spatially removed from the 'pit' areas.

Structure of the Genomic RNA

Cardioviral genomes are single-stranded, positive-sense RNA molecules of 7600 to 8000 nucleotides. The 3′ ends of cardioviral RNAs are polyadenylated. The 5′ ends are not capped as with typical eucaryotic mRNAs, but instead have a small, viral-coded, genome-linked protein (VPg) attached by a tyrosine-O^4-phosphodiester bond to the 5′-terminal uridylyl nucleotide. VPg sequences are rich in basic, hydrophilic amino acids and have only one tyrosine residue (the attachment site) at position 3 from the amino end of the peptide.

The genomic sequence begins with an unusually long 5′ untranslated region (5′ UTR), followed by an open reading frame for a large polyprotein, and terminates with a short 3′ UTR (**Fig. 2**). The EMC-

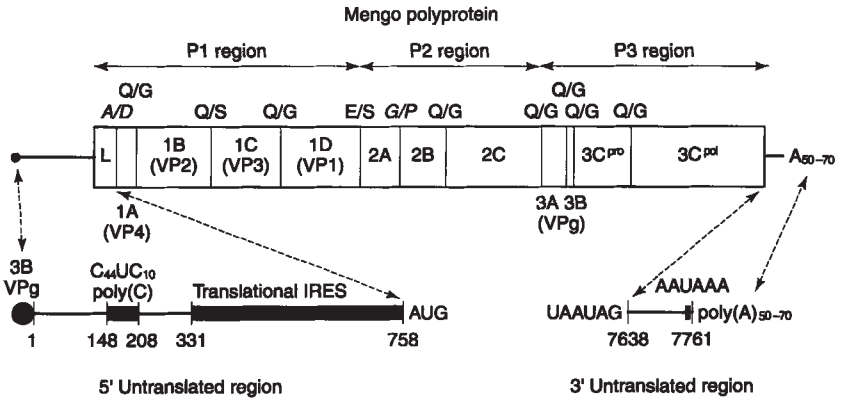

Figure 2 Mengo virus genomic RNA. The protein-coding region is indicated by the rectangle, and the nucleotide sequence coding for each gene product is to scale. There are 70 amino acid residues in VP4, 256 in VP2, 231 in VP3 and 277 in VP1. The total number of nucleotides (excluding the 3′ poly(A) tail) is 7761. The EMC RNA is 7835 nucleotides in length, the extra residues being accounted for by a longer poly(C) tract in the 5′ noncoding region.

like cardioviruses additionally contain an unusual polypyrimidine tract within the distal region of their 5′ UTRs. The tract can vary in length from 60 to 420 residues, depending upon the strain of virus; for Mengo(M) and EMC(R) the tracts have been sequenced as $C_{44}UC_{10}$ and $C_{125}UCUC_3UC_{10}$ respectively. Occasional U residues notwithstanding, this segment is referred to as the 'poly(C)'.

Computer modeling, biochemical data and phylogenetic comparisons suggest that, except for poly(C) region which is single-stranded, most cardiovirus RNAs have extensive, well-conserved base-paired structures within the remainder of their 5′ UTRs. Viral translation is directed by a 5′ IRES, or internal ribosomal entry site, that directs the viral RNA to act as an mRNA once it is free within the cellular cytoplasm. In EMC, the IRES is comprised of 430 bases arranged in multiple ordered structures, immediately 5′ to the AUG which begins the polyprotein (nucleotides 400–833). Translation actually begins at the sixth AUG from the 5′ end of Mengo RNA (nucleotides 759–761) and at the 12th AUG (834–836) in EMC RNA. Once a ribosome initiates protein synthesis, it continues along the RNA template through the entire coding region until it reaches the tandem termination signal (nucleotides 7638–7643 in Mengo RNA, 7710–7715 in EMC RNA) near the 3′ end.

The 3′ UTRs of cardiovirus, at 124–126 nucleotides in length, are the longest in any picornavirus. A poly(A) tail of 20–70 nucleotides is attached to the 3′ UTR. Approximately 20 of these poly(A) bases are template-encoded during viral RNA replication; the remainder are presumed to be added by cellular poly(A) elongation enzymes. In the EMC-like cardioviruses, the sequence AAUAAA precedes the poly(A) tract by seven and ten nucleotides. Although these are the only picornaviruses to display a polyadenylation initiation signal at the right place in their genomes, these signals are apparently not functional. Deletion of the complete poly(A) in genetically engineered Mengo or EMC is lethal, and viral RNA transcripts with fewer than 15 As are not recognized or repaired by cellular enzymes. The 3′ viral poly(A) is part of a recognition unit bound by recombinant $3D^{pol}$, and this sequence, plus nearby secondary and tertiary structures, is required for the initiation of minus-strand RNA synthesis.

Unencapsidated cardioviral RNAs are infectious to cultured cells and to animals. Whether extracted from virions, or synthesized as full-length transcripts from viral cDNAs, preparations of the intact RNAs, free of any protein, can initiate an infectious cycle when transfected into permissive cells (HeLa, L cells, BHK or others) or mice (with liposomes). The RNAs do not need to be capped or attached to 5′ VPgs to observe infectivities as high as 10^6 PFU (plaque forming units) per microgram of RNA.

Protein Expression and Processing

The cardioviruses have evolved robust and effective mechanisms to express their proteins. The IRESs allow these genomes to bypass normal translational requirements for 5′ cap structures, and efficiently lure the ribosomes into viral instead of cellular pathways. The captured ribosomes pass down the single, long open reading frame (2200 codons), creating polyproteins that are in reality tandem linkages of all structural and enzymatic units necessary for virulent infection. The individual protein fragments are liberated cotranslationally and post-translationally

in a proteolytic cascade that is a defining feature of the genus. No fewer that three viral encoded catalytic entities are required for complete processing, none of which has an exact cellular analogue. The special property of cardiovirus RNAs to initiate efficient translation in cell-free extracts and the remarkable completeness of the processing cascade during these reactions are hallmarks of these genomes.

The first, or primary cleavage within the processing cascade, occurs cotranslationally, as ribosomes traverse the middle (P2) region of the genome, and releases the N-terminal capsid precursor (L-P1-2A) from the growing polypeptide chain. With rhino- and enteroviruses, protein 2A, a product of P2 region translation, is responsible for this reaction: the *cis*-acting 2A protease cleaves its polyprotein at a Tyr-Gly junction between the P1 and P2 regions (1D/2A), and bears recognizable sequence and catalytic similarity to a second viral protease, $3C^{pro}$, encoded within the more distal region of the genome. The cardioviruses use a different mechanism for primary cleavage. The EMC polyprotein is cotranslationally cleaved at the 2A–2B junction by a short protein fragment, centering on an Asn-Pro-Gly-Pro (NPGP) sequence at this site, that has an inherent propensity for autocatalytic self-cleavage. The unusual 'suicide' activity and the sequence which causes it are unique among the cardio-, aphtho- and group-C rotaviruses.

After the primary break in the polyprotein, the secondary cardioviral processing cascade is carried out by viral protease $3C^{pro}$. This cysteine-reactive, chymotrypsin-like enzyme catalyzes a series of monomolecular and bimolecular reactions within the viral precursors, to the (near) exclusion of reactions with cellular proteins. Nearly all $3C^{pro}$ viral cleavage sites are at Gln-Gly or Gln-Ser sequences, but Glu-Ser, Glu-Asn and Gln-Ala substrates are found in some viruses. The EMC $3C^{pro}$ sequence is proteolytically active in each of its precursor forms (P3, 3ABC, 3CD). The use of each form, as well as the polyprotein sequence context and protein structure, have important regulatory roles that govern the orderly release of viral proteins throughout the infectious cycle; indeed, every aspect of the viral replication is strongly influenced, if not determined, by the rates at which individual polyprotein sites are selected and processed by the $3C^{pro}$ enzyme and its precursors' autocatalytic activities. Mutations that impinge on these pathways are invariably fatal, though sometimes for reasons not anticipated from study of mature protein products. For example, the proper binding of replicase precursor proteins (P2 + P3) to the 3′ UTR of the virion RNA probably helps display these substrates for efficient post-translational cleavage, and may even be an absolute requirement for $3C^{pro}$ cleavage at the 3A–3B site, a proteolytic reaction that is never observed in the absence of active RNA synthesis. Introduced mutations that prevent RNA synthesis also prevent cleavage of 3A–3B, even in the presence of $3C^{pro}$ or its precursors.

The final cleavage within picornaviral polyproteins, the maturation of the 1AB peptide (also called VP0), is not catalyzed by any identified viral or cellular proteases. Maturation reactions are normally observed *in vivo* only during the final stages of virion morphogenesis and are dependent upon RNA association into large capsid assembly structures. The cleavages occur at the interior surface of the protein capsid where it interfaces the RNA, leading to the assumption that the RNA itself may have a direct catalytic involvement. However, it is more likely that a transitional protein conformation, triggered by the unnaturally tight proximity of the packaged RNA, is responsible for VP0 cleavage. Mature cardiovirions contain 58–59 copies each (on average) of VP2 + VP4, the VP0 cleavage products, and an additional 1–2 copies of uncleaved VP0.

Polyprotein Organization

Cardioviral proteins and their precursors take their names (L, P1, P2, P3) from their locations within the polyprotein. The EMC and Mengo leader or 'L' proteins are about 7000 kDa in molecular weight and play an undefined role in host or tissue tropism. Genetically engineered Theiler's viruses with altered L sequences exhibit altered neurovirulence in mice. L may also be involved in translational regulation of the IRES. The four P1 peptides, 1A, 1B, 1C and 1D, are the capsid proteins. After incorporation into virions, they are called VP4, VP2, VP3 and VP1, respectively. VP0 is the uncleaved precursor of VP4 + VP2. The capsid proteins derived from a common P1 precursor stay together as a protomer unit throughout particle assembly. The P2 portion of the polyprotein contains peptides 2A, 2B and 2C (in Mengo: 16000, 17000, and 36000 kDa). Beside encoding the primary cleavage peptide, and possible roles in RNA synthesis, the functions of 2A and 2B are unknown. Protein 2C is the genetic locus of the guanidine resistance marker, a compound that affects the initiation of RNA synthesis. All cardiovirus 2C sequences contain RNA helicase and nucleotide-binding motifs. However, 2C is not a polymerase, and its contribution to the replication cycle remains unclear. The P3 peptides, 3A, 3B, 3C and 3D (in Mengo: 10000, 2000, 22000, and 51000 kDa) are more closely associated with RNA replication. Preparations of $3D^{pol}$ can catalyze elongation of nascent RNA chains in primer-dependent reactions, an activity that identifies this enzyme

as the central element of viral polymerase complexes. Protein 3B is VPg, the peptide attached to the 5′ end of the genome. Initiation of positive- and negative-strand RNA synthesis requires VPg, perhaps as free protein, or as part of a donor peptide, 3AB. Protein $3C^{pro}$ is the viral protease described above, and is the primary catalyst of the polyprotein cleavage cascade.

Initiation of Infection

The cardiovirion initiates infection by attaching to a specific cell surface glycoprotein receptor. Interactions between the receptor and amino acid residues in the 'pit' cause conformational changes which affect the pentamer–pentamer contacts and dispose the capsid to dissociation. Polio- and rhinovirions undergo a two-stage dissociation process: after attachment and conformational alteration, these virions are taken into the cell in endocytic vesicles, and subsequent acidification is required to release VPg-RNA from the capsid and into the cytoplasm. Such a two-stage process may not apply to the cardioviruses. The noncovalent pentamer–pentamer interactions which maintain the integrity of the cardiovirus capsid are much less extensive than those in other picornavirions: either interaction with a cellular receptor or decreasing the pH of a physiological salt solution will cause the cardiovirion to dissociate into pentamers, with the release of VPg-RNA and the VP4 polypeptides. Also, treatment of cells with chemicals which raise the pH of endosomes causes a significant reduction in the infectivity of polio- or rhinovirions, but not of cardiovirions. It has been proposed that a cardiovirion is uncoated at the cell plasma membrane as an immediate consequence of binding to the receptor, and that VPg-RNA enters the cytoplasm, perhaps with the assistance of myristoylated VP4s, directly from that site.

Synthesis of Components for Progeny Virions

Once in the cellular cytoplasm, the infecting viral RNA (with its VPg removed) acts as messenger RNA. The translation of this RNA into a polyprotein and the proteolytic processing of the polyprotein have been discussed. The infecting RNA must also be able, at some stage, to free itself from the translation machinery and act as a template for the synthesis of a complementary (minus-strand) RNA. How this is accomplished is not known. The minus-strand RNA acts as a template for the synthesis of progeny plus strands (virion RNAs), with several plus strands being synthesized simultaneously. These structures can be isolated from endoplasmic membrane fractions

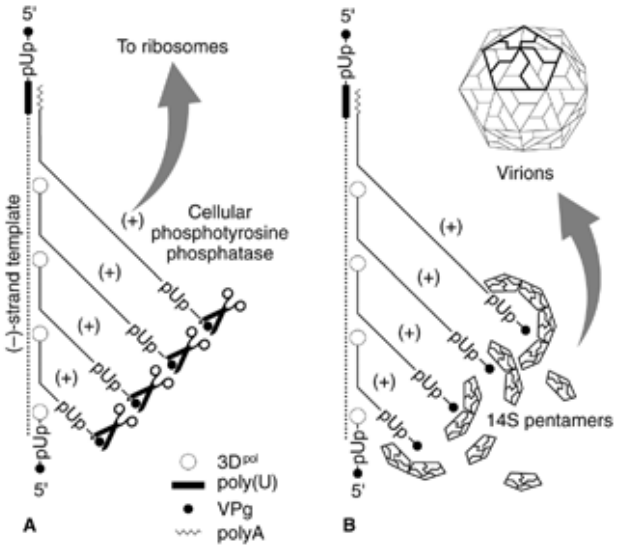

Figure 3 Regulation of cardiovirus replication. **(A)** At early times after infection (0–5 h), the cellular phosphotyrosine phosphatase has easy access to the nascent plus-strands of viral RNA in RI replicative intermediate structures. It removes the 5′-VPg proteins from these RNAs, making them templates for continuing viral protein biosynthesis. **(B)** At later times (5–10 h), 14S pentamers accumulate and compete with the phosphatase for the VPg RNAs. As time goes on, more progeny plus-strand RNAs from the RIs are packaged into progeny virions, and fewer become mRNAs.

of infected cells, and are called replicative intermediates (RIs; **Fig. 3**). The proteins encoded by the P2 and P3 region of the viral genome are responsible for RNA replication: VPg initiates each newly synthesized molecule, plus or minus strand, and $3D^{pol}$ is the elongation polymerase. There is a dramatic asymmetry in RNA synthesis, with a large excess of plus strands and no evidence for RIs composed of a plus-strand template and nascent minus strands. The mechanism(s) by which RNA synthesis is regulated is not understood.

Inhibition of Host Cell RNA and Protein Synthesis

Cellular RNA and protein biosynthesis begin to decline within the first few hours after cardiovirus infection, at about the time viral RNA synthesis enters its exponential phase. The decrease in cellular RNA synthesis, which can fall to ~10% of normal, depending upon the type of cell infected, may reflect a competition among polymerases for ribonucleoside triphosphates. The decrease in host cell protein synthesis is similar in magnitude, and is caused primarily by the ability of the IRES in the 5′-noncoding region of the viral RNA to outcompete capped cellular mRNAs for ribosomes and initiation

factors. There is no virus-induced cleavage of the p220 component of the cap-binding complex, eIF–4F, in cardiovirus-infected cells; this is in contrast to the situation in cells infected with poliovirus, rhinovirus or FMD viruses. Cardioviruses may gain their competitive advantage in part by causing modifications to ribosomes (an inhibitor of the translation of capped mRNAs *in vitro* can be washed off ribosomes from Mengo virus-infected cells) and/or to eIF2 (partial phosphorylation results in partial inactivation with respect to cellular, but not viral, mRNAs).

Assembly of Progeny Virions

One molecule each of VP0, VP3 and VP1 generated by $3C^{pro}$ cleavage of a P1 precursor remain together as a capsid protomer, which sediments at 6 S and can be isolated. The proteolytic release of L from P1 during the $3C^{pro}$ processing cascade, allows the N-terminal sequence of P1 (G-N-S-T-S-) to be recognized by a cellular enzyme and *N*-myristoylated. This covalent modification, and the $3C^{pro}$-mediated cleavages between VP0 and VP3, VP3 and VP1 and VP1 and 2A, must be completed before the protomer can build further. Five mature protomers associate by (largely) hydrophobic interactions to form the pentameric assembly unit, which sediments at 14 S. Cardiovirus pentamers will not form empty capsids in infected cells because such structures are intrinsically unstable; therefore, virion assembly may begin with a specific attachment of VPg RNA, extruded from active replication complexes, to a free pentamer. It is possible that protein–protein interaction between VPg and the inner surface of the pentamer (the *N*-myristoyl moieties may be involved) is the triggering event. Once initiated, the assembly process continues with the addition of another 11 pentamers, the condensation and enclosure of the RNA and the RNA-dependent cleavage of 58–59 VP0 molecules to VP4 + VP2.

Assuming that a pentamer–RNA interaction may initiate progeny virion assembly, overall regulation of the viral replicative process could be achieved as shown in **Fig. 3.**

Geographic Distribution and Host Range

Cardioviruses have a worldwide distribution and are associated with a wide variety of species including humans, other primates, domestic animals, rodents, birds and mosquitoes. A study done in Hawaii in 1978 found EMC virus-neutralizing antibodies in humans (6% of individuals tested), cats (3%), cows (20%), pigs (23%), mongooses (36%), rats (36%), boobies (9%) and shearwaters (20%). The natural reservoir of these viruses would appear to be rodents, with susceptibility to infection varying among species. Rats or mice, which can be infected orally, will contact a mild illness and recover (unless the virus dose is high). They can transmit the virus to other species; for example, an epizootic outbreak of EMC virus disease among pigs in New South Wales in 1986, which affected 37 separate piggeries, coincided with an infestation of mice.

In pigs, cardiovirus infection is associated with reproductive failure or abortions in sows, and systemic infections of newborn or young animals with resultant high mortality (15–20%). From 1986 to 1991, outbreaks were reported in Greece, Minnesota, Western Australia and Quebec. A survey done in Italy in 1989 estimated that approximately 70% of the total swine population in that country were seropositive for EMC virus.

Virus Propagation

Laboratory animals such as mice, hamsters, gerbils and cotton rats can undergo a rapid and fatal infection after the administration of virus by any route. Guinea pigs usually develop a fever, which may be followed by hind limb paralysis. Subcutaneous inoculation of baboons or African green monkeys with 10^6 PFU of EMC virus causes myocardial and central nervous system damage leading to death within a week, whereas rabbits or albino rats acquire an inapparent infection at the same dose level. Cardioviruses grow well in a wide variety of cultured cells, including: primary mouse embryo fibroblast, adrenal or myocardial cells; Ehrlich or Krebs ascites tumor cells; L-929 mouse fibroblast cells; human cell lines such as HeLa or HEp-2; BHK (hamster) cells; and guinea pig embryo fibroblasts or tumor cell lines. They will also grow in embryonated eggs, but not in chick embryo fibroblasts. An abortive infection of Maden–Darby bovine kidney cells by Mengo virus has been described; these cells exhibit the usual cytopathology and eventually die, but progeny virus production is minimal (1000-fold less than in L-929 cells).

Genetics, Evolution and Serotype Stability

The complete nucleotide sequences of the genomic RNAs of EMC (strains R, B and D) and Mengo (strain M) viruses have been determined and many of these sequences have been cloned into infectious cDNAs. A comparison of these genomes reveals the evolutionary constraints on the propagation of naturally occurring mutations. Mutations may arise

Table 2 Differences in genomic nucleotide sequences and in polyprotein amino acid sequences between EMC(R) and Mengo(M) viruses

	Nucleotides		*Amino acids*	
Genome segment[a]	*Changes*	*%*	*Changes*	*%*
Total genome[b]	1453	18.9	—	—
Polyprotein	1383	20.1	148	6.5
5′ NTR[b]	56	6.6	—	—
L region	35	17.4	5	7.5
P1 region	517	20.7	25	3.0
P2 region	368	19.9	65	8.6
P3 region	463	20.0	65	8.4
3′ NTR	14	11.2	—	—

[a] The subdivisions of the genome are illustrated in **Fig. 2.**
[b] The comparison does not include the length differences in the poly(C) tract in the 5′ NTR (nontranslated region).

during viral RNA replication because the polymerase ($3D^{pol}$) lacks a 3′–5′ proofreading exonuclease activity; the mutation rate has been estimated to be about one incorrect nucleotide per 10^4 incorporated, or about one per progeny genome. Nevertheless, the common laboratory strains of EMC and Mengo have changed very little in their genomic sequence, relative to their original isolates, during more than 40 years of replication in cultured cells.

As **Table 2** shows, there is an overall divergence of nearly 20% between the EMC and Mengo genomic RNAs at the nucleotide level. In the capsid protein-coding (P1) region, however, only 3% of the amino acid residues are different, i.e. in this region nucleotide changes have been almost exclusively restricted to third positions in codons. Thus, there is little flexibility in capsid or nonstructural protein design among the cardioviruses, and a great pressure to maintain a common serotype.

Transmission and Tissue Tropism

Natural infections are acquired by the ingestion of virus-contaminated material. Gastrointestinal disease of infected mice, rats, squirrels or voles remains limited and is quickly resolved. When swine are infected per os, the virus replicates in the gut and is excreted in the feces. Viremia is detectable within a few days, and an unchecked infection can result in acute myocarditis and sudden death. Cardiovirus infections in breeding sows can result in stillborn or mummified fetuses; surviving piglets will suffer (and usually die) from interstitial pneumonia, meningoencephalitis and/or myocarditis. Surviving animals develop high levels of neutralizing antibodies, and possess immunity to reinfection. There have been reports that humans are susceptible to cardiovirus-induced disease. Dick, when first isolating Mengo virus, suffered 'an acute febrile illness characterized by signs and symptoms referable to the central nervous system' and virus was recovered from his serum. From 1949 to 1953, EMC virus isolates were reported from individual patients with Guillain–Barré syndrome, asceptic meningitis or paralytic poliomyelitis. In 1945–1946, an epidemic of a relatively mild '3 day fever' afflicted American soldiers stationed in Manila. EMC virus-neutralizing antibodies were found in a significant number of convalescent patients. Whether cardioviruses were primary pathogens in any of these cases is debatable; previous subclinical infection with these viruses is a plausible alternative. Few specific human illnesses associated with cardioviruses have been noted in recent years, despite the fact that many laboratory workers (and probably farmers and veterinarians) in contact with EMC or related viruses have developed neutralizing antibodies.

Pathogenicity in Laboratory Mice

Notwithstanding differences in virulence among laboratory strains of cardiovirus, and diversities in response to these viruses by genetically distinct strains of mice, inoculation by any route (i.p., i.v., i.m. or s.c.) generally leads to a severe and usually fatal encephalitis. As few as 100 PFU can be lethal. High titers of virus are recoverable from brain tissues, and a common sequela of infection is an acute, moderate to severe myocarditis. If virions are inoculated directly into the brain, 10 PFU or less will cause neurological symptoms followed by hind limb paralysis and death within 7–10 days.

In 1968, Craighead discovered a strain of EMC virus which, following intraperitoneal inoculation, produced diabetes mellitus in 'adult male mice'. Subsequent investigations of the EMC(D) variant revealed that it causes diabetes by specifically destroying the pancreatic β cells. Neither the relatively low interferon-inducing ability of EMC(D) nor an autoimmune destruction of the β cells appear to be major factors in the development of diabetes in EMC(D)-infected mice. RNA sequence comparisons between a nondiabetogenic strain (B) of EMC virus and the diabetogenic strain have implicated a mutation causing an amino acid change at residue 152 of capsid protein VP1 (T in EMC(B), A in EMC(D)). This residue is located on the surface of the virion, along one edge of a depression, or 'pit', which is most likely to form the binding site for a cellular receptor. Thus, it appears to be the unique ability of the EMC(D)

virus to bind to, infect and destroy pancreatic β cells, which eventually leads to diabetes in laboratory mice.

Cytopathology of Infected Cells

Electron micrographs of picornavirus (including cardiovirus)-infected cells reveal a characteristic cytopathological picture, the most striking feature of which is the dramatic proliferation of endoplasmic smooth membranes and vacuoles. As the infectious process continues, these vacuoles accumulate in the central part of the cell, displacing and compressing the nucleus. Virus replication occurs in the cytoplasm, with the smooth membranes providing anchorages for viral RNA replication complexes. Quasi-crystalline arrays of progeny virions can be visualized in the peripheral cytoplasm before the cell membrane ruptures at multiple sites and the cellular integrity is lost (8–12 h after infection). The yield of progeny virions per infected cell is about 100 000.

Immune Response

In mice, recovery from cardiovirus infection involves the production of virus-neutralizing antibodies. These bivalent reagents may reduce the infectivity of virions by crosslinking several particles into one effective unit, by crosslinking two pentameric structure units in a single virion and inhibiting its uncoating after contact with a susceptible cell, or by causing a conformational change in the viral capsid such that the receptor-binding sites are altered or occluded. Neutralization-resistant mutants, selected *in vitro* in the presence of monoclonal antibodies, have been used to map antibody-attachment sites (via RNA sequence comparisons) in the capsid structure. Such sites are found on surface loops or ridges, and usually comprise amino acid residues from more than one polypeptide (discontinuous epitopes).

Only mice with fully developed and functional immune systems have any likelihood of surviving an intraperitoneal injection of cardioviruses. Short-term immunity can be transferred to naive animals by injection of neutralizing IgG, but cell-mediated responses are crucial to recovery and to the development of long-term immunity. Studies using synthetic peptides to stimulate the proliferation of lymph node leukocytes from mice immunized with UV-inactivated Mengo virus have identified segments in VP2 (residues 2118–2132) and VP3 (3051–3063) as containing T cell epitopes. The cells that were stimulated to proliferate were CD4+, and the response was not H-2 restricted. No T cell epitopes were found in the VP1 or VP4 proteins.

Prevention and Control of Cardiovirus Infections

Given that the introduction of cardioviruses to domestic swine, zoo populations or captive primate colonies can constitute a considerable veterinary and economic problem, it would be desirable to have efficacious cardiovirus vaccines available to prevent epidemics.

In 1989, Duke and Palmenberg prepared several Mengo cDNAs in order to determine the nucleotide sequence of the genome. Their enzymatic procedures accidentally truncated the poly(C) tracts in the 5′ UTRs of several cDNAs (e.g. $C_{44}UC_{10}$ became $C_{13}UC_{10}$). The RNA transcripts from these cDNAs were discovered to be infectious upon transfection into HeLa cells, and genetically stable progeny virions could be propagated in the same manner as the wild-type isolates. However, these short poly(C) tract viruses, as well as subsequent, deliberately engineered isolates with deleted poly(C)s, were found to be significantly attenuated for virulence for laboratory mice, and at the same time to stimulate the production of high titer, long-lived neutralizing antibodies in innoculated animals. The truncation of the poly(C) apparently renders the virus suceptible to the full range of antiviral activities by the host, and even an initial injection of 10^{11} PFU (e.g strains vMC_{24} or vMC_0) is not enough to overcome the animal's immune response. The attenuated strains have proven safe and efficacious live vaccines in a wide variety of domestic and zoo animals (11 species of primates, pigs, tapirs, babirusa, peccaries, guanacos and porcupines), and can probably protect any animal (or human) suceptible to cardiovirus infection.

Acknowledgement

In the fall of 1997, Douglas Scraba passed away after a heroic bout with cancer. Honest and enthusiastic, with a positive influence on everyone he encountered, Doug was passionate about his research, and his family. This entry contains many of his seminal contributions that helped define the field of cardiovirology. An irreplacable colleague who is deeply missed, Doug has the lasting respect of everyone who had the privilege to work with him.

CARLAVIRUSES

Sergei K Zavriev, Institute of Agricultural Biotechnology, Moscow, Russia

History

The carlaviruses acquired their name from the then best studied type member of this group, *Carnation latent virus* (CLV). The carlavirus-associated diseases of the infected plants usually are mild and in many cases symptomless. The first report of a carlavirus-linked infection dates back to 1923 when Schultz and Folsom described a leafrolling mosaic of American potato variety Green Mountain. Later this disease was found to be associated with a carlavirus potato virus M (PVM). Until recently carlaviruses did not attract special attention of phytopathologists since, with rare exceptions, they do not cause serious plant diseases – a characteristic feature of carlaviruses is the latency of infection. The finding of potato virus S (PVS) in 1964 prompted active studies on this virus group, because it turned out that PVS is found worldwide and infects most of the commercial potato varieties.

Taxonomy and Classification

Definite as well as possible or poorly characterized members of the genus *Carlavirus*, *Closteroviridae* family, are listed in **Table 1.** Many viruses have been included in the genus *Carlavirus* based mainly on their serological relatedness with CLV and their host range. The taxonomic status of a number of them still has to be verified. For example, a detailed molecular-biological study of the narcissus latent virus, which has always been considered a definite member of the genus *Carlavirus*, has shown that it has properties distinct from those of any previously described virus genus.

Virus Structure and Composition

The virions of carlaviruses are flexible rods of modal length 610–690 nm and diameter 12–14 nm. The fine structure of carlaviruses is characterized by rows of subunits separated by about four longitudinal furrows. Crossbanding and an axial canal are usually not visible. The viral particles are composed of 1600–2000 coat protein subunits of M_r 3.2×10^3–3.8×10^3 and a linear single-stranded RNA of M_r 2.3×10^6–3.0×10^6, arranged as a helix (pitch 3.3–3.4 nm) and constituting 5–7% of the particle weight. Purified preparations of some carlaviruses (potato virus S (PVS), Helenium Virus S (HVS)) contain small amounts of encapsidated subgenomic RNAs (sgRNAs).

Physicochemical Properties

The physicochemical properties of carlaviruses are known for only a few members. The thermal inactivation point for most carlaviruses is between 55 and 70°C, and the infectivity in sap at room temperature remains from 2 to 5 days. The UV-absorbance spectra of carlaviruses have maxima at 258–260 nm, and minima at 243–248 nm, with A_{max} / A_{min} ratios of 1.1–1.3. Particles sediment at 147–176S, and have a buoyant density in CsCl of 1.31–1.33 g cm^{-3}.

The carlavirus virions can be broken down with denaturing agents such as sodium dodecyl sulfate (SDS), pyridine, pyrrolidine, guanidine hydrochloride, urea, acetic acid or alkali. In most viruses of this group the capsid protein is partly degraded during purification and storage of virus preparations, which may give rise to errors in determining the molecular mass of the coat protein.

The taxonomic status of a number of them still has to be verified. For example, a detailed molecular-biological study of the narcissus latent virus, which has always been considered a definite member of the genus *Carlavirus*, has shown that it has properties distinct from those of any previously described virus genus.

Virus Structure and Composition

The virions of carlaviruses are flexible rods of modal length 610–690 nm and diameter 12–14 nm. The fine structure of carlaviruses is characterized by rows of subunits separated by about four longitudinal furrows. Crossbanding and an axial canal are usually not visible. The viral particles are composed of 1600–2000 coat protein subunits of M_r 3.2×10^3–3.8×10^3 and a linear single-stranded RNA of M_r 2.3×10^6–3.0×10^6, arranged as a helix (pitch 3.3–3.4 nm) and constituting 5–7% of the particle weight. Purified preparations of some carlaviruses (potato virus S (PVS), Helenium Virus S (HVS)) contain small amounts of encapsidated subgenomic RNAs (sgRNAs).

Physicochemical Properties

The physicochemical properties of carlaviruses are known for only a few members. The thermal inactivation point for most carlaviruses is between 55 and 70°C, and the infectivity in sap at room temperature remains from 2 to 5 days. The UV-absorbance spectra of carlaviruses have maxima at 258–260 nm, and minima at 243–248 nm, with A_{max} / A_{min} ratios of 1.1–1.3. Particles sediment at 147–176S, and have a buoyant density in CsCl of 1.31–1.33 g cm^{-3}.

The carlavirus virions can be broken down with denaturing agents such as sodium dodecyl sulfate (SDS), pyridine, pyrrolidine, guanidine hydrochloride, urea, acetic acid or alkali. In most viruses of this group the capsid protein is partly degraded during purification and storage of virus preparations, which may give rise to errors in determining the molecular mass of the coat protein.

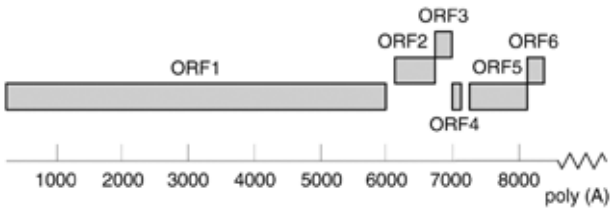

Figure 1 Schematic representation of the general structural organization of the carlavirus genome.

The concentration reached by carlaviruses in plant sap is moderate; dilution end point is usually 10^{-3}–10^{-4}. For PVS and red clover vein mosaic virus (RCVMV) in some hosts it reaches 10^{-6}. The purified viral RNA is far less infective than the intact virus containing an equimolar amount of RNA (with PVS the infectivity of the RNA is only 0.18%).

Genome Structure

The genome of carlaviruses consists of a monopartite plus-sense single-stranded (SS) RNA, which is encapsidated in the virus particles. To date, we know the complete genome structure of three carlaviruses, potato virus M (PVM) (8534 nucleotides (nt) long), blueberry scorch virus (BBSV) (8514 nt long), and garlic common latent virus (GaCLV) (8353 nt long) and extensive 3′ terminal regions of PVS (strains O and An), poplar mosaic virus (POPMV), lily symptomless virus (LSV), chrysanthemum virus B (CVB), HVS, carnation latent virus (CLV), shallot latent virus (SLV) and cowpea mild mottle virus (CPMMV). The RNA of carlaviruses is polyadenylated at the 3′ end, and there are several indirect evidences that it is capped at its 5′ end. The genome structures of the carlaviruses mentioned is very similar (with the only exception of SLV in some parameters), and can be schematically represented as in **Fig. 1.** The open reading frame (ORF) 1 codes for the putative virus-specific RNA replicase with a M_r 223 000 (for PVM and BBSV) and 219 000 (for GaLV).

Sequence analysis of the ORF 1 polypeptide has revealed that this product also contains putative methyltransferase and NTP-binding/helicase domains. In addition, it has been demonstrated that *in vitro* BBSV ORF 1 protein is autocatalytically processed by a papain-like proteinase. ORFs 2, 3 and 4 (the triple gene block) code respectively for proteins of M_r about 25 000, 12 000 and 7000 which are most probably involved in the virus transport and cell membrane modification. As with other triple gene block-containing viruses the ORF 2 protein contains a duplicate of the NTP-binding/helicase domain. All triple gene block proteins are possibly expressed *in vivo* in very small amounts – none of them could have been detected in extracts from carlavirus-infected plants. ORFs 2 and 3 proteins contain highly hydrophobic regions and may associate with membranes *in planta*. It has been shown that all of the triple block proteins of white clover mosaic potexvirus are required for transport. Since the design of the triple gene block of carla- and potexviruses is almost identical, it can be suggested that all of the triple gene block proteins of carlaviruses are involved in the virus transport.

ORF 5 encodes the virus coat protein of M_r 32 000–36 000, depending on the individual carlavirus. ORF 6 encodes a cysteine-rich protein of M_r 12 000–15 000 which contains a zinc finger motif and in the case of PVM has been shown to bind with single- and double-stranded nucleic acids *in vitro*. Genes encoding cysteine-rich proteins are also found in hordei-, furo- and tobravirus groups. The possible functions suggested for this protein are the ability of the virus to be vectored, the assistance in initiating viral assembly, and a regulatory role in the transcription or/and translation of the genome.

The viral RNA is flanked by noncoding regions; there are also two short internal noncoding regions between ORF 1 and ORF 2, and between ORF 4 and ORF 5. In CVB there is an additional 17 nt-long noncoding region between ORF 5 and ORF 6. Both the 3′ and 5′ noncoding RNA regions of carlaviruses sequenced to date are highly conserved. The 5′ terminal nontranslated leaders are less than 80 nt long, and the corresponding 3′ terminal non-coding regions vary in length from 51 to 107 nt, terminating in the poly(A) tail.

The only carlavirus for which a full-length infectious cDNA clone has been reported is BBSV.

The overall genome organization of carlaviruses is very close to that of potexviruses, with the exception that the latter lack ORF 6, and shallot virus X (ShVX) related viruses, which have an additional 40 000 M_r ORF between the triple gene block and the coat protein gene. There is a high level of homology in the amino acid sequences of the corresponding proteins within the carlavirus group, as well as between the carla-, potex- and ShVX-related viruses. It has been suggested that carlaviruses, potexviruses and ShVX-related viruses form a 'supergroup' of related plant viruses.

Viral Multiplication

Little is known of the carlavirus RNA replication mechanism. Carlavirus-infected plants contain double-stranded replicative forms of RNA (dsRNA) corresponding in molecular mass to genomic viral

RNA. Thus virus-specific dsRNAs of 5.5 MDa have been found in plants infected with RCVMV, pea streak virus (PeSV), dandelion latent virus (DLV), PVS, KLV, and CPMMV, and a dsRNA of 5 MDa in those infected with PVM. In all probability, besides the virus-encoded RNA replicase, the replication complex includes several host-cell factors.

Genome Expression

Only the virus-encoded RNA replicase (the ORF 1 protein) appears to be expressed from the genomic carlavirus RNA, whereas the other genes are expressed with the help of two major sgRNA about 3.0 and 1.5 kb long, which have been demonstrated in carlavirus-infected (PVS, PVM, HVS and BBSV) plants by Northern blot hybridization. Both sgRNA species identified are 3′ co-terminal to the genomic RNA and polyadenylated. It is believed that the ORF 2, ORF 3 and ORF 4 proteins are expressed from the long sgRNA, whereas the coat protein (the ORF 5 protein) and the ORF 6 protein from the short sgRNA. Possible promoters for the sgRNA synthesis have been identified for several carlaviruses – the sequence C/UUUAGGU, 19–43 residues upstream from both putative sgRNA initiation sites is suggested to be a part of the promoter region. No minor sgRNAs for expression of ORFs 3, 4 and 6 proteins were detected in carlavirus-infected plants. In case of PVS the 101 nucleotide-long sequence upstream from the AUG initiation codon of the coat protein gene was shown to act as a translational enchancer *in vitro* and *in vivo*.

Translation

The data on genomic RNA translation are available for PVS, PVM, CLV, BBSV, AHLV and HVS. Translation of PVM RNA *in vitro* (rabbit reticulocyte lysates) and *in vivo* (*Chenopodium quinoa* protoplasts) gives rise to a heterogeneous set of proteins, the largest of which has an M_r of 185 000–190 000. No viral coat protein is translated *in vitro* from the genomic RNA. The virion RNA of PVS (Andean strain) *in vivo* in the protoplasts of *Solanum tuberosum* directs the synthesis of three major products with M_r of 123 000 and 104 000 and the 34 000 M_r capsid protein. *In vitro* translation of the virion RNA of PVS (Peruvian strain) in rabbit reticulocyte lysates produces the coat protein and several high M_r polypeptides, the longest corresponding to M_r 130,000. These data confirm the suggestion that the ORF 1 polyprotein contains a proteinase domain, which provides for the autocatalytic processing step in the carlavirus translation strategy. Expression of the PVS coat protein from the virion RNA *in vitro* is most probably due to the presence in the virions of some sgRNA for the coat protein. Genomic HelVS RNA *in vitro* produces 190 000 and 160 000 M_r proteins whereas the coat protein is only translated from the appropriate 1.5 kb-long sgRNA.

For the 3′ terminal gene cluster (coat protein and the ORF 6 protein) of PVM, two *in vitro* translational strategies operating in the ORF 6 encoded gene have been identified. An internal initiation, resulting in the synthesis of an M_r 12 000 protein and a polypeptide as a coat protein and ORF 6 protein transframe product by ribosomal frameshifting. The products of about M_r 45 000–50 000 corresponding to the M_r of the coat protein and ORF 6 translational fusions, which can be immunoprecipitated with antisera against the virus particles, have been detected from the *in vitro* translational products of PVS, HVS and AHLV.

Viral Transmission

Carlaviruses are easily spread by vegetative propagation, transmitted mechanically and usually, nonpersistently, by aphids. The latter appears to be the most common way of transmission in nature. The efficiency of aphid transmission varies for different viruses and particular strains. Thus with PVM, PVS and PeSV the transmission efficiency for different strains varies greatly even with the same aphid species. No aphid or other vector has been found for Mulberry latent virus (MLV), Passiflora latent virus (PLV), PMV and CPMMV. For PMV, transmission by root grafts has been considered. As a rule, carlaviruses are not seed-transmitted, although for CPMMV it has been shown with three leguminous hosts that 2–90% of the seeds transmit the virus. Some carla-like viruses are transmitted by whiteflies. Particularly, transmission by whitefly *Bermisia tabaci* was shown for CPMMV.

Cytopathology

The distribution of carlaviruses in the infected plant is not tissue-specific; the particles are mostly found in the cytoplasm of various plant tissues, singly or more often in large aggregates which are sometimes banded. The virus particles have not been found in chloroplasts, nuclei or other organelles. They sometimes occur in bundles, or in groups with one end attached to membranes. Carlaviruses do not induce any pronounced cytopathological effects by which infection can be recognized. Infection with carlaviruses usually does not give rise to virus-specific inclusions in plant tissues. RCVMV is the only carlavirus that induces in infected plants crystalline cyto-

Table 1 Definite and possible members of the genus *Carlavirus*

Definite members	*Possible members*
American hop latent virus (AHLV)	Artichoke latent virus (ArLV)
Blueberry scorch virus (BBSV)	Caper vein binding virus (CapVBV)
Cactus virus 2 (CV-2)	Cardamine latent virus (CaLV)
Caper latent virus (CapLV)	Cassia mild mosaic virus (CasMMV)
Carnation latent virus (CLV)	Cassia brown streak virus (CasBSV)
Chrysanthemum virus B (CVB)	Chicory blotch virus (ChiBV)
Cowpea mild mottle virus (CPMMV) (tentative member)	Cole latent virus (CoLV)
Dandelion latent virus (DLV)	Cowpea mild mottle virus (CpMMV)
Elderberry carlavirus (ECV)	Cynodon mosaic virus (CynMV)
Garlic common latent virus (GaCLV)	Daphne virus S (DaVS)
Helenium virus S (HVS)	Dulcamara carlavirus A (DuCVA)
Honeysuckle latent virus (HnLV)	Dulcamara carlavirus B (DuCVB)
Hop latent virus (HpLV)	Eggplant mild mottle virus (EMMV)
Hop mosaic virus (HpMV)	Fig virus S (FVS)
Hydrangea latent virus (HdLV)	Fuchsia latent virus (FuLV)
Kalanchoe latent virus (KLV) (including strains named kalanchoe virus 1 and kalanchoe virus 2)	Gentiana carlavirus (GeCV)
Lilac mottle virus (LiMV)	Gladiolus carlavirus (GCV)
Lily symptomless virus (LSV)	Groundnut crinkle virus (GrCV)
Mulberry latent virus (MLV)	Gynura latent virus (GyLV)
Muskmelon vein necrosis virus (MuVNV)	Helleborus carlavirus (HeCV)
Nerine latent virus (NeLV)	Kalanchoe carlavirus (KaCV)
Passiflora latent virus (PLV)	Nasturtium mosaic virus (NasMV)
Pea streak virus (PeSV)	Plantain virus 8 (PlV8)
Pepino latent virus (PeLV)	Southern potato virus (SPV)

Sint-Jem's onion latent virus (SJOLV)	
Strawberry pseudo mild yellow edge virus (SPMYEV)	

plasmic inclusions consisting of protein and nucleic acid and containing spherical granules. CPMMV forms unusual brush-like intracellular inclusions.

Serology

In many cases the relatedness of a new virus to carlaviruses has been tested using an antiserum to CLV. Therefore, except for PMV, SLV and HLV all the viruses listed in **Table 1** are serologically close to CLV. Serological relationships among the intact particles of carlaviruses have been studied by different approaches which revealed similar groupings. A number of carlaviruses are more or less closely interrelated, with SDIs ranging from about 3.5 to 6.5, e.g. LV, CVB, HVS, PLV, PeSV, PeLV, PVM, PVS and CVMV. It is interesting that these viruses (PVS–VB and CLV–CVB) have different host ranges whereas two most remote pairs (RCVMV–PeSV and PVM–PVS) have similar host ranges.

Geographical Distribution

Most carlaviruses are found wherever their hosts are grown, some are restricted to certain parts of the world, and for others the distribution is somewhat nonuniform. Thus PeSV is found only in the USA, PVM is mostly encountered in the East European countries, and PVS is spread over practically all potato-growing regions worldwide.

Viral Epidemiology and Control

Carlaviruses usually produce symptomless infection in many plants. One of the main factors hindering virus detection is the lack of suit-

testing problem is especially important for carlaviruses infecting monocots. In this connection, carlavirus detection and testing mostly relies on serological and electron-microscopic methods. For industrial-scale virus control in the seed material, ELISA kits are commercially available for PVS and PVM. AGDIA, Inc. (IN, USA) also offers ELISA kits and reagents for BBSV, CLV, CVB, KLV, LSV and SLV. A polymerase chain reaction test based on degenerate carlavirus-specific primers can be used for the universal detection of carlaviruses in infected plants. This test is available now from AGDIA Inc. Most countries producing seed potatoes include obligatory tests for PVS. Meristem tip culture is known to be the most promising technique for the production of virus-free mother plants in vegetatively propagated crops. This technique is often used in combination with thermotherapy and the use of antiviral compounds which are simply incorporated in the medium during thermotherapy – in the case of carlaviruses this approach is found to be especially effective. PVS is the only carlavirus for which transgenic plants (potato and *Nicotiana debneyii*) resistant to virus infection have been reported.

Host Range

The host range of individual viruses is rather narrow, but taken together the group encompasses a wide range of monocotyledonous and dicotyledonous hosts. One plant group in which the carlaviruses are not detected are serial crops – no one definite carlavirus is detected in these plants.

Symptomatology

Most carlaviruses develop latently in infected plants, which is reflected in the names of many members of this group (see **Table 1**). In some cases stunting and mosaic symptoms are produced. Sometimes latency is found in certain hosts but not in others. A severe reduction of flower and pod formation numbers has been observed on RCVMV-infected chickpea plants.

Economic Significance and Ecology

Although a large portion of carlaviruses cause symptomless infection, some of them (PMV and legume carlaviruses) in their natural hosts cause serious diseases such as chlorosis, wilting, growth retardation, etc. Therefore, PMV and carlaviruses afflicting pea and red clover are a considerable economic problem. It should be noted that though the natural host range of carlaviruses is rather narrow, under experimental conditions they can heavily afflict plants of various families. The severity of the plant disease also depends on the virus strain (isolate) and on the plant variety. The main studies on this problem have been carried out with PVM. Thus, the leafrolling mosaic strain and the paracrinckle strain of PVM cause diseases of many potato varieties, which result in significant yield losses. In mixed infection carlaviruses appear to be capable of potentiating the pathogenicity of the partner virus: thus a complex of SLV with leek yellow stripe potyvirus induce a serious form of necrotic stripe and sometimes causes death of infected leek plants.

Evolution

Analysis of the RNA nucleotide sequences of a number of carlaviruses (see Genome Structure) allows them to be related to the supergroup of Sindbis-like phytoviruses. On the basis of the primary structure of the functionally important conserved domains in proteins, first of all those encoded in the triple gene block, carlaviruses can be united with four groups of other representatives of Sindbis-like phytoviruses: potex-, furo-, hordei- and ShVX-related viruses (the latter is not yet distinguished as a separate group). Taking into account the primary structure and the general genomic organization of carlaviruses, they can be considered most closely related to potexviruses and ShVX-related viruses.

CARMOVIRUSES (*TOMBUSVIRIDAE*)

Feng Qu and **T Jack Morris**, School of Biological Sciences, University of Nebraska, Lincoln, Nebraska, USA

Taxonomy, Classification and Evolutionary Relationships

Carmovirus is one of two officially recognized genera of *Tombusviridae*. Members of *Tombusviridae* all have icosahedral virions of about 30 nm in diameter with $T = 3$ symmetry that consists of 180 coat protein (CP) subunits of about 38–43 kDa and a single-stranded (ss) RNA genome ranging in size from 4.0 to 4.7 kb. Carmoviruses share recognizable sequence similarity in both the polymerase and structural genes with members of the other genus, *Tombusvirus*. Sequence comparisons and phylogenetic analysis of these genes support the view that the genera are distinct but closely related. In addition, the genome organization of the carmoviruses is characteristically different from that of the tombusviruses.

Carmoviruses contain a single-component positive-sense genome of about 4.0 kb. The genome, as exemplified by turnip crinkle virus (TCV) in **Fig. 1**, consists of five open reading frames (ORFs) which encode proteins of about 28, 88, 8, 9 and 38 kDa from the 5′ to the 3′ end, respectively. The virions are icosahedral and consist of 180 CP subunits of approximately 38 kDa. The genus name is derived from the first member of the genus to be sequenced, carnation mottle virus (CarMV). Much more detailed knowledge about virus structure and genome function is, however, known for TCV because its crystal structure has been determined and it was the first carmovirus for which infectious transcripts were produced from a cDNA clone of the genome. To date, the nucleotide sequences of six definitive carmoviruses have been determined (**Table 1**). These sequenced members share similar morphological and physicochemical properties with about 20 other viruses listed in **Table 1** that are recognized as species or tentative species, depending on the characterized molecular detail of the viruses. Unlike the majority of tombusviruses, carmoviruses are sufficiently distant from each other to prevent them crossreacting in standard RNA hybridization or serological tests.

Carmoviruses and tombusviruses share properties with numerous other small spherical RNA viruses. Structural similarities with members of the *Dianthovirus* genus (e.g. red clover necrotic mosaic virus, RCNMV) are significant and include sequence similarity of CP as well as similarity in subunit topology and interactions within the virion. There also exists a marked sequence similarity in the RNA-dependent RNA polymerase (RDRP) genes of carmoviruses and viruses of the following genera: *Dianthovirus, Necrovirus* (e.g. tobacco necrosis virus, TNV), *Machlomovirus* (e.g. maize chlorotic mottle virus, MCMV) and *Luteovirus* (e.g. barley yellow dwarf viruses of the PAV type). Several newly sequenced viruses have been proposed for consideration as new genera of *Tombusviridae,* based primarily on similarities of nucleotide sequences and genome organization (e.g. pathos latent virus, oat chlorotic stunt virus and panicum mosaic virus). In a broader context, phylogenetic comparisons of viral RNA polymerase genes have identified the *Tombusviridae* as a representative plant virus cluster for one of three RNA virus supergroups with relatedness to animal viruses of *Flaviviridae* and the family of small RNA phage (*Leviviridae*).

Distribution, Host Range, Transmission and Economic Significance

Carmoviruses occur worldwide and are generally reported to cause mild asymptomatic infections on relatively restricted natural host ranges. Most accumulate to high concentrations in infected tissues and are mechanically transmitted with facility. Beetle transmission has been reported for a number of members, as has transmission in association with soil and/or irrigation water, and in some cases in association with fungal zoospores. Most of the viruses have been reported to cause diseases in a limited number of plants or plant types.

A number of carmoviruses have been identified in association with ornamental hosts and have been widely distributed in such hosts by vegetative propagation. CarMV is the most noteworthy, being widespread in cultivated carnations, and recognized as one of the more important components of viral disease complexes in this crop worldwide. It accumulates to high concentrations without producing severe symptoms and spreads primarily by contact transmission and vegetative propagation. It has a broad experimental host range that includes over 30 species in 15 plant families. PFBV is widespread in vegetatively propagated *Pelargonium* species, causing disease in association with other viruses. The incidence of NTNV in

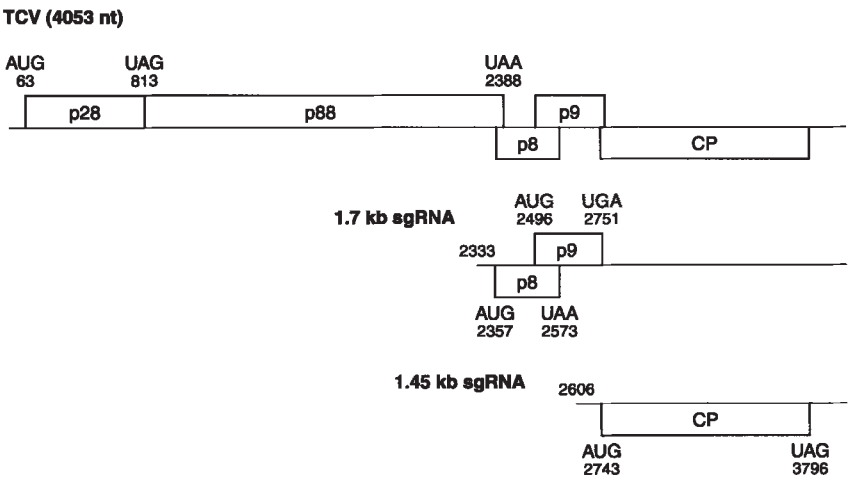

Figure 1 Genome organization of a typical carmovirus as represented by turnip crinkle virus. The genomic and subgenomic RNAs are depicted as solid lines and the sizes of the RNAs are noted. The ORFs are indicated by the boxes, with the numbers in the boxes identifying the polypeptide encoded by the ORF. The numbers above and below the diagrams give the transcriptional start sites for the sgRNAs and the nucleotide locations of the codons defining each ORF.

Narcissus cultivars and HCRSV in *Hibiscus* primarily reflects distribution of infected nursery stock.

Numerous small RNA viruses have been reported to naturally infect cucurbits, causing significant disease problems. Several of these viruses are recognized tombusviruses, while others such as MNSV, CLSV, CSBV have been identified as carmoviruses based on sequence and genome organization properties. MNSV occurs worldwide in greenhouse cucurbits and is both soil and seed transmitted, while CSBV has been primarily restricted to infrequent outbreaks around the Mediterranean. All three viruses have been reported to be transmitted in association with the fungus *Olpidium bornovanus*.

Several carmoviruses have been discovered in natural leguminous hosts, with GMoV being potentially the most important, causing serious disease losses in legumes in Africa. BMMV has been reported to be a latent virus widely distributed in bean cultivars in El Salvador, and BMoV has been found in *Vigna* species in Asia. Beetle vectors have been identified for these viruses, but seed transmission may also be an important factor in their distribution.

TCV is neither common nor widespread in nature in spite of the fact that it is reportedly beetle transmitted. It has a relatively wide experimental host range in some 20 plant families, including experimentally useful *Arabidopsis* and *Brassica* species, in which it accumulates to extremely high concentrations, often approaching a level equivalent to 0.5% of the fresh weight of the plant tissue. CCFV was first discovered in the Mount Kosiusko alpine region of Australia in *Cardamine lilacina*, a wild perennial *Brassica*. It has also been shown to infect *Arabidopsis* and other *Brassica* species.

Table 1 List of species in the genus *Carmovirus*

Sequenced species	
Carnation mottle	(CarMV)
Cardamine chlorotic fleck	(CCFV)
Cowpea mottle	(CPMoV)
Melon necrotic spot	(MNSV)
Saguaro cactus	(SCV)
Turnip crinkle	(TCV)
Classified species	
Ahlum water-borne	(AWBV)
Bean mild mosaic	(BMMV)
Cucumber leaf spot	(CLSV)
Cucumber soil-borne	(CSBV)
Galinsoga mosaic	(GaMV)
Hibiscus chlorotic ringspot	(HCRSV)
Pelargonium flower break	(PFBV)
Weddel water-borne	(WWBV)
Tentative species	
Blackgram mottle	(BMoV)
Elderberry latent	(ELV)
Glycine mottle	(GMoV)
Narcissus tip necrosis	(NTNV)
Plaintain 6	(PIV-6)
Squash necrosis	(SqNV)
Tephrosia symptomless	(TeSV)

Other carmoviruses have been isolated worldwide from natural hosts with little apparent disease and are presumably of little agricultural concern. These include TeSV from legumes in Kenya, GMoV from glycine in Australia, SCV from saguaro cactus in Arizona, GaMV from potato weed in Australia and PIV-6 from plantain weed in England. The infrequent isolation of these genetically similar viruses in remote locations around the world has prompted the speculation that ancestor carmoviruses may have been introduced into their natural hosts well before the last Ice Age and have since coevolved in isolation in their diverse host plants.

Virion Structure and Assembly

TCV is the only carmovirus for which refined structural studies, including high resolution X-ray crystallography, have been performed. The detailed information about CP structure and subunit–subunit interactions established that TCV and tomato bushy stunt tombusvirus (TBSV) share marked structural conservation. In this regard, the common structural features shared by other members of *Tombusviridae* have been primarily deduced from alignment of the amino acid sequence of the coat proteins of TBSV and TCV. TCV consists of a $T = 3$ icosahedral capsid of 180 subunits of the 38 kDa CP. The individual CP subunit folds into three distinct domains typical of the CP subunit of the tombusviruses. The relatively basic N-terminal R domain extends into the interior of the virus particle and presumably interacts with viral RNA. The R domain is connected by an arm to the S domain which constitutes the virion shell. The S domain is attached through a hinge to the P domain which projects outward from the virion surface. The protein subunits are believed to form dimers in solution and during assembly.

TCV is also the only carmovirus on which detailed *in vitro* assembly studies have been performed. The virion has been shown to dissociate at elevated pH and ionic strength to produce a stable RNA–CP complex (rp-complex) and free CP subunits. Reassembly under physiological conditions in solution could be demonstrated using the isolated rp-complex and the soluble CP subunits. This rp-complex, consisting of six CP subunits tightly attached to viral RNA, could be generated *in vitro* and was shown to be important in selective assembly of TCV RNA. A model for assembly was proposed in which three sets of dimeric CP interact with a unique site on the viral RNA to form an initiation complex to which additional subunit dimers could rapidly bind. Preliminary characterization of the 'origin of assembly' for this virus identified two possible sites based on the identification of RNA fragments in the rp-complex protected from RNase digestion by CP. Further *in vivo* studies narrowed the assembly origin site to a bulged hairpin loop of 28 nt within a 180 nt region at the 3′ end of the CP gene.

Genome Structure

Complete nucleotide sequences have been determined for six carmoviruses as listed in **Table 1**: CarMV (4003 nt), TCV (4053–4054 nt), MNSV (4262 nt), CCFV (4041–4072 nt), CPMoV (4029 nt), and SCV (3879 nt). Comparative studies of the deduced ORFs revealed that all these viruses encode a similar set of genes that are closely related and in the same gene order as illustrated for TCV in **Fig. 1.** The genome organization of the carmoviruses is quite compact, with most of the identified ORFs overlapping each other. Both the product of the most 5′ proximal ORF (26–28 kDa) and its readthrough product (86–89 kDa) have been shown to be essential for replication of the TCV genome. The 3′ proximal gene encodes the viral CP which varies from 37 to 42 kDa for the different viruses. All of the sequenced carmoviruses characteristically encode two small ORFs in the middle of the genome that have been shown in TCV to both be indispensable for cell-to-cell movement (movement proteins or MPs). Although the genome organizations of all sequenced carmoviruses are quite similar, there are some unique features evident in the individual carmoviruses. In CarMV, a second readthrough event could extend the translation of the polymerase gene into the p9 MP gene to produce a p98 product. This double readthrough event is not predicted for any other carmovirus. In another example, the two small central ORFs in MNSV (p7a and p7b) are connected by an in-frame amber codon that could result in the production of a 14 kDa fusion protein of the two ORFs. An unusual feature of the CPMoV sequence is the prediction of a sixth ORF (p28) nested within the 3′ proximal CP gene.

There is no direct evidence for the existence of a cap structure at the 5′ end of carmovirus genomes. Absence of a cap seems most likely given the recent identification of cap-independent translational enhancer sequences in the leaders of the genomic and subgenomic RNAs of TCV. The 5′ noncoding region varies from 34 nt in CPMoV to 88 nt in MNSV. No extensive sequence homology was observed within this region. The 3′ noncoding region of carmoviruses varies from about 200 to 300 nt in length and possesses neither a poly(A) tail nor a tRNA-like structure.

Replication and Gene Expression

Carmoviruses replicate to very high concentrations in protoplast infections, with the genomic RNA accumulating to levels approaching that of the ribosomal RNAs. Upon infection of susceptible plants, carmoviruses transcribe two 3′ coterminal subgenomic RNAs (sgRNAs) for expression of the MP and CP genes. The smaller sgRNA (*c.* 1.5 kb) is the mRNA for CP. The larger sgRNA (*c.* 1.7 kb) presumably functions as the mRNA for the two MP genes utilizing a leaky scanning mechanism. This is supported from *in vitro* translation experiments performed for TCV and SCV. Recent results involving transgenic expression of the p8 and p9 gene products of TCV in *Arabidopsis* plants has demonstrated that both of them are essential for viral cell-to-cell movement and that they function by *in trans* complementation in the same cell. It was also shown that cell-to-cell movement of TCV in *Arabidopsis* does not require the CP gene.

Viral specific double-stranded RNAs (dsRNAs), corresponding in size to the genomic RNA and sgRNAs, characteristically accumulate in infected plant tissue. The product of the 5′ proximal ORF (p28 in TCV) and its readthough product (p88 in TCV) are the only virus encoded components of the polymerase complex. Mutagenesis studies demonstrated that p28 and p88 are both essential for viral RNA replication in protoplasts. When expressed from two separate molecules, p28 and p88 complemented *in trans* to enable the genome replication. Putative host factors needed for viral RNA replication have not yet been well studied, although extracts from infected turnip plants have been shown to contain RDRP activity capable of synthesizing complementary full-length molecules from both (+)-strand and (−)-strand TCV associated RNA templates. Experiments utilizing these RDRP extracts have provided useful information about *cis*-elements important in replication and gene expression. For example, a stable stem–loop structure at the 3′ end of the TCV genome has been identified as the promoter for (−)-strand synthesis from the (+)-strand TCV genome. A similar stem–loop structure has also been identified in other carmoviruses, including CarMV and CCFV, by sequence comparisons. The essential promoter sequences for the two subgenomic RNAs have also been mapped in TCV. The promoter for (+)-strand genomic RNA synthesis has not yet been identified. Another potentially important *cis*-acting hairpin structure in TCV (the FaFf element, see **Fig. 1**) has been identified in the vicinity of the UAG stop codon that punctuates the polymerase gene. A regulatory function for this element is proposed because it binds CP with high affinity, and disruption of the RNA structure, but not the coding sequence, abolishes replication.

Satellites, Defective-Interfering RNAs and RNA Recombination

TCV is the only carmovirus in which replication of associated small subviral RNAs in infected plants has been characterized and the situation for this virus is curiously complex. For example, TCV infections have been shown to contain defective-interfering RNAs derived totally from the parent genome (e.g. RNA G of 342–346 nt), satellite RNAs of nonviral origin (e.g. RNAs D, 194 nt and F, 230 nt), and chimeric RNAs (e.g. RNA C of 356 nt) with a 5′ region derived from satellite RNA D and a 3′ region derived from the 3′ end of the TCV genome. All three types of small RNAs depend on the helper virus for their replication and encapsidation within the infected plant. The different satellite and defective-interfering RNAs have been shown to affect viral infections in different ways. Both RNA C and G intensify viral symptoms while interfering with the replication of the helper virus, whereas RNAs D and F seem to produce no detectable effects on either expression of symptoms or helper virus replication.

TCV has proved to be a good model for studies on RNA recombination. The frequency and diversity of the small RNA species that appear to have arisen spontaneously in plant infections suggests that RNA recombination occurs frequently and with facility. The *de novo* generation of defective-interfering RNAs in plants after inoculation with cDNA-derived transcripts of the genome is an obvious example. Detailed studies in Anne Simon's laboratory, utilizing the chimeric satellite RNA C as a model, have provided some detailed insight into the copy-choice mechanisms that are important in viral RNA recombination. They have shown, for example, that the majority of recombinants produced are not viable for further replication. These studies have also identified a novel 3′-end repair mechanism by which the RDRP complex synthesizes short oligoribonucleotides (up to 8 nt) complementary to the 3′ end of TCV RNA, which in turn serve as primer for RNA synthesis using a different template (e.g. satellite RNA C with 3′ end up to 6 nt deleted).

Virus–Host Interaction

Studies are beginning to emerge in the area of viral–host interactions utilizing *Arabidopsis* and TCV as a model system. In one study from L. A. Heaton's laboratory an *Arabidopsis* encoded protein, Apt8, was identified as interacting specifically with the TCV

p8 protein in a yeast two-hybrid screen. Apt8 was shown to be localized in plasma membrane and possibly linked to the cytoskeleton. Transgenic *Arabidopsis* and tobacco plants expressing antisense Apt8 mRNA were resistant to TCV infection.

Some studies suggest that the CP of carmoviruses may also interact with host plants in other ways besides assembly. For example, minor amino acid changes within TCV CP have been shown to modify symptoms of infection. In addition, the CP has been implicated as a possible viral determinant in the observed resistance of *Arabidopsis thaliana* ecotype Di-0 to TCV infection. In these studies, systemic invasion by chimeric virus occurred in the Di-0 ecotype when the TCV CP ORF was replaced by the CCFV CP ORF. It was also shown that TCV replicated normally in Di-0 protoplasts and inoculated leaves, suggesting the genetic resistance was due to restricted systemic movement.

CP has also been found to be important in satellite RNA C interactions in the host plant. Normally, the presence of RNA C results in symptom intensification in TCV infections. However, when the TCV CP ORF is either deleted or replaced by the CCFV CP ORF (see above), RNA C will then attenuate symptoms caused by the helper virus. Additional experiments in protoplasts suggested that the CP either downregulated the replication of RNA C or enhanced its own competitiveness.

Finally, the replicase gene has also been implicated in the symptom modification by satellite RNA C. The 3′ end of the TCV genome, common in TCV RNA, RNA C and defective-interfering RNA G, was also suggested to be a symptom determinant. Environmental conditions were also found to affect the extent of resistance of *Arabidopsis* plants to TCV.

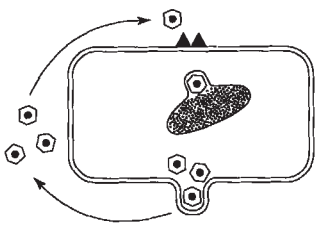
CELL STRUCTURE AND FUNCTION IN VIRUS INFECTIONS



Samuel Dales, Rockefeller University, New York, USA

Introduction

The subject matter of this article concerns the structure and function of a prototypical animal cell in its role as a host for viruses (**Fig. 1**). It is now clearly evident from the information acquired during the recent past, particularly from data developed by molecular biology techniques, that viruses in the form of quasi-autonomous macromolecular complexes are propagated by expression of genomes which originated from their hosts. The viral genes have undergone alteration to a varying degree during evolutionary selection so as to give the virus parasite an advantage in metabolic efficiency. Detailed knowledge about cell organization reveals the existence of a great variety of relationships connecting cellular components of direct relevance to every stage of the infectious process with individual virus types. Owing to the brevity of this treatise it has been necessary to omit information about cell organelles and structures that have only a minor or peripheral relationship to the virus life cycle.

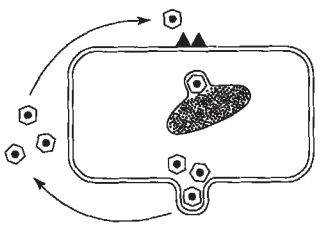
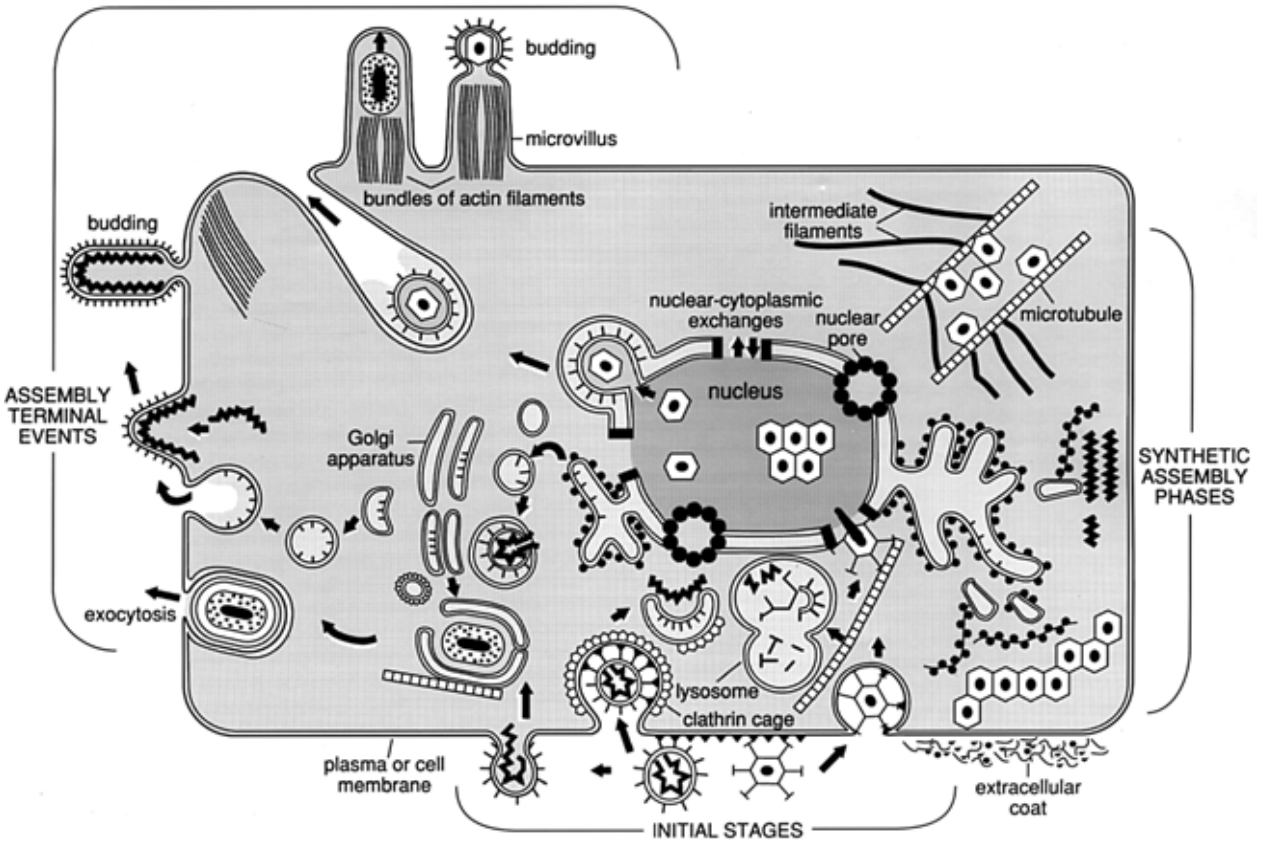
CELL STRUCTURE AND FUNCTION IN VIRUS INFECTIONS



Samuel Dales, Rockefeller University, New York, USA

Introduction

The subject matter of this article concerns the structure and function of a prototypical animal cell in its role as a host for viruses (**Fig. 1**). It is now clearly evident from the information acquired during the recent past, particularly from data developed by molecular biology techniques, that viruses in the form of quasi-autonomous macromolecular complexes are propagated by expression of genomes which originated from their hosts. The viral genes have undergone alteration to a varying degree during evolutionary selection so as to give the virus parasite an advantage in metabolic efficiency. Detailed knowledge about cell organization reveals the existence of a great variety of relationships connecting cellular components of direct relevance to every stage of the infectious process with individual virus types. Owing to the brevity of this treatise it has been necessary to omit information about cell organelles and structures that have only a minor or peripheral relationship to the virus life cycle.



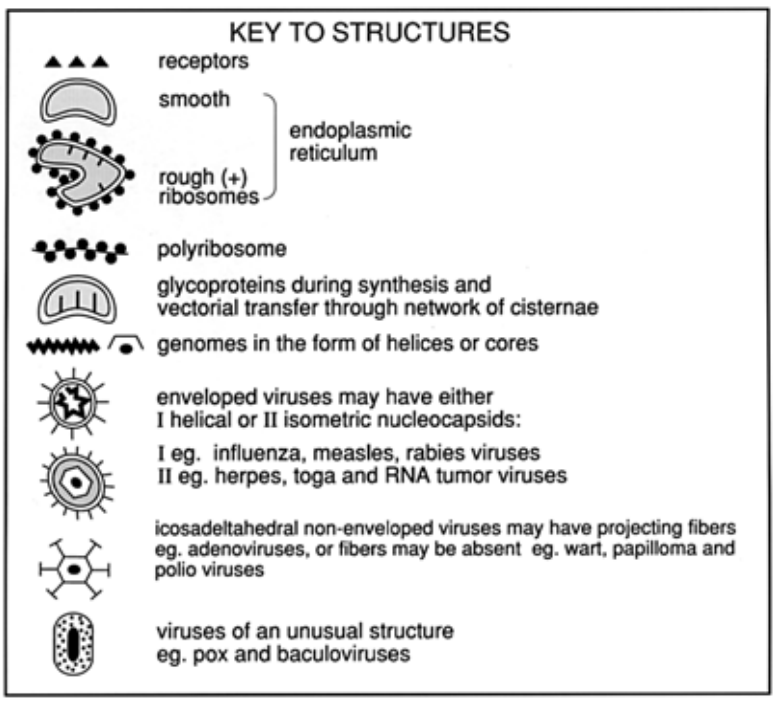


Figure 1 Schematic representation of a prototypical animal cell. The illustration emphasizes cellular organization as it relates to various phases of the virus replication cycle.

The Surface

Tissue organization and cell polarity

When discussing cellular structure and function with respect to virology, one must realize that within the animal host, initiation and spread of virus infections frequently follows encounters at epithelial and endothelial surfaces such as those in skin, lung, gut and vascular lining. These surface sheets are assemblies of polarized cells that possess apical and basolateral membranes exposed to the fluid milieu. The free movement of particulates from one side of these sheets to the other is, however restricted by lateral cell-to-cell contacts termed tight junctions. This manner of organization at cellular surfaces determines the routes of virus ingress, egress and dissemination within the animal. Data derived from infected animals and explants of cultured epithelia demonstrate that specific viral receptors may be confined to either the apical or basolateral surfaces, depending on the virus type, although dual receptors at opposite sides of polarized cells have been uncovered. Cell polarization also influences the membrane sites at which envelopment and assembly of viruses can occur. This may be due primarily to mechanisms for sorting and vectorial transfer of nascent glycoproteins destined for incorporation into the virus progeny within specialized membrane components. The interrelationship between molecular sorting and vectorial transfer is clearly exemplified by differences between influenza virus, which is assembled on the apical side, vesicular stomatitis virus, which buds preferentially on the basolateral face, and the coronaviruses, which use for assembly membranes of intracellular vesicles neighboring the Golgi apparatus. The direction of vectorial movement through the cellular membrane network is actually inherent in specific amino acid sequences of polypeptides and glycoproteins, whether they are encoded by cells or viruses.

Extracellular coats

Ubiquitous glycoprotein and glycolipid molecules, which are integral to the organization of the plasma membrane bilayer, are usually decorated by extracellular branched polysaccharide chains. A surface meshwork of such chains forms the glycocalyx. Carbohydrate residues of the glycocalyx provide initial attachment sites for ligands on the virus inoculum, exemplified by adsorption of influenza hemagglutinin to *N*-acetylneuraminic (or sialic) acid of the cell receptor. At the terminal formative stages of enveloped viruses, regions of cell surface contiguous to those of the emerging particles become desialylated by viral neuraminidases, thereby ensuring that individual virions are released efficiently from the glycocalyx. Other types of carbohydrates such as the elongated mucopolysaccharides that coat cells of the respiratory epithelium represent another type of barrier which must be dispersed by enzyme on the virus before the inoculum can reach the cell receptor to establish a stable link. Other types of extensive coats also exist, termed extracellular matrix, with various properties adapted to specialized functions of the tissue where they occur. The substances present in the extracellular matrix include hydrated gel-like glycosaminoglycans linked to proteins forming proteoglycans. Proteoglycans can be permeated by a meshwork of fibrous proteins, exemplified by collagen and materials such as fibronectin and laminin, which promote cell adhesion to supporting layers. The extracellular matrix is involved in kidney diseases such as certain forms of glomerulonephritis which may develop during chronic persistent infections when massive quantities of virus–antibody immune complexes filtrated out of the circulation are deposited in the matrix. This disease process occurs among human carriers chronically infected with hepatitis B virus and other agents.

The cell or plasma membrane

The cell membrane, interchangeably termed plasma membrane, forms a semipermeable barrier enclosing the contents of the cell. Like all cellular membranes it is organized into a bilayer of amphipathic phospholipids and glycolipids, transversed by a great variety of transmembrane polypeptides and glycoprotein molecules. The carbohydrates of the glycoproteins, present as multiple branches of oligosaccharides, are frequently attached to the externally protruding N-termini of the polypeptide. Organization into bilayers favors a high degree of membrane flexibility during a constant state of flux and the lateral mobility of molecules inserted within the bilayer. The dynamic state of membranes allows for their rapid deformability into invaginations from the surface leading to formation of vesicles. Evaginations may result in the formation of transient elongations and more permanent processes such as microvilli. Membrane dynamics also provide mechanisms for membrane-to-membrane fusion or, conversely, separation between neighboring membrane segments, phenomena that occur frequently throughout the cell and do not compromise the bilayer continuity. These properties of membranes make the plasma membrane a site for the formation of autonomous endocytic vesicles, and coalescence with shuttle vesicles, which carry materials for exocytosis. Sealing between membranes can be promoted by the influence of fusogenic proteins. The

constant traffic away from and towards the surface facilitates continuous circulation and turnover of membrane components not only at the surface but throughout the cell. Sideways mobility of molecules within the plane of the lipid bilayer provides a mechanism for establishing intermolecular contacts and conformational changes related to metabolic activities. Specificity of interactions within the membrane bilayer between proteins and glycoproteins can create heteromeric or multimeric molecular assemblies, functioning themselves as receptors or via connections to the receptors. Such groupings of molecules are commonly involved with immune response phenomena, with formation of toxins or transmitter-gated channels of the type present in interneural and neuromuscular junctions. Rapid physiological responses can occur at the surface initiated via receptors recognizing extracellular signals, whether they are of the autocrine variety like lectins and growth factors, of an endocrine type such as insulin or in the category of second messengers represented by the cyclic nucleotides. The rapid transfer of externally initiated signals towards intracellular response foci can be mediated through connections provided by elements of the cytoskeleton, or by membrane-to-membrane coupling or through vesicular shuttles trafficking between membrane-enclosed compartments and the cell exterior.

Homeostasis of the cell with respect to cell volume, ion concentration and pH is maintained by means of proteinaceous ion pumps present in the plasma membrane. Such pumps facilitate internalization of Na^+ and Cl^- and removal of excess H^+ or $HCO3^-$ derived from cell metabolism. Other membrane proteins catalyze transmembrane transport of metabolites or, inadvertently, the uptake of chemotherapeutic drugs. Overall the cell membrane can be conceptualized as a mosaic of domains, with each type of domain fulfilling a specialized function in the life of a cell. Regions of dense coat along the inner cytoplasmic face of the plasma membrane are due to formation of cages or basket-like scaffolds organized out of triskeletal macromolecular assemblies of the protein clathrin. Clathrin cages also enclose endocytic and other specialized vesicles shuttling to and from the surface. Other types of specialized coated vesicles, surrounded by proteins other than clathrin, can also be formed and participate in trafficking with the plasma membrane.

As one of its primary functions, which also has a bearing on viruses, the plasma membrane selectively concentrates and internalizes extracellular material. Sequestration of particulates inside endocytic vesicles is termed endocytosis, and uptake of fluid-phase components is pinocytosis. Endocytosis becomes highly efficient and selective due to the sequential binding via a zippering-like process termed receptor-mediated endocytosis of ligands. The ligands present on the particulate destined for engulfment become bound to multiple receptors mobilized by lateral diffusion along the plasma membrane. Receptor-mediated endocytosis decrees the precise configuration of envelopment in endosomes. The internal milieu of newly formed endosomes is close to neutrality, but during their inward movement away from the surface the fluid contents of endosomes become acidified by accumulation of H^+ pumped out of the cytosol. The presence of a repertoire of acidic hydrolases, acquired via transfer vesicles from the Golgi apparatus, converts the late endosomes into prelysosomes, the latter predestined to coalesce with mature lysosomes. The lysosomes containing acidic enzymes able to hydrolyze lipids, nucleic acids and proteins function as the primary sites for intracellular digestion to dispose of damaged organelles or any undesirable materials acquired accidentally by engulfment. The strategies that viruses employ to utilize the properties of the plasma membrane during initial and terminal stages of their life cycle clearly manifest coevolutionary origin with that of the host. A stable attachment is established when a virus ligand makes contact with host cell receptor during the initial collisions at the surface. The presence of multiple ligands on the virus surface and an abundance of receptors, perhaps 10^4–10^6 on each host cell, increases the probability that a productive encounter will occur. The display of certain receptors on specific differentiated cell types and/or along specialized cell surfaces can be the determinant regulating tissue or organ tropisms for different virus types. Among notable examples are CD4 molecules on human T cells which function as receptors for the human immunodeficiency virus (HIV), β-adrenergic receptors on neurons in mouse brain which can bind reovirus type 3, receptors for the neurotransmitter acetylcholine at neuromuscular junctions where attachment of rabies virus is evident and the asialoglycosphingolipids in gut epithelium which function as receptors for rotaviruses. Receptors for polio-, rhino- and cardiovirus groups are macromolecules that are functional in uninfected cells related to a super family of glycoproteins with the basic configuration of immunoglobulin. As already mentioned, dual receptors for viruses such as herpes simplex can occur on distinctive surfaces on polarized epithelial cells, or alternative receptors may be present on different host cells, as is evident with attachment of HIV to either its principal T cell CD4 receptors or to galactocerebroside receptors on certain glial cells in the nervous system.

The entry of virus inoculum particles to effect an intracellular release or uncoating of their genomes depends on fusogenic activity carried by the virus which is used to disrupt temporarily membrane integrity. Viral fusogens are rapidly activated at the surface by specific host proteases. Fusion of this type, exemplified by paramyxoviruses, can be activated at neutral pH, bringing about a comingling between viral and cell membranes at the surface so as to create an entrance for the virus nucleocapsid into the cytosol. Access of encapsidated virus genomes into the cytosol, facilitated by fusion of viral envelopes with the cell membrane, can be regulated by interactions with coreceptors. With HIV they are chemokine receptors CCR5 in the case of macrophage tropic and CXCR for T lymphocyte tropic virus strains.

Other fusogens are activated under acidic conditions inside endosomes where virus membrane fusion creates an escape passage, observed during penetration of influenza, rhabdo-, toga-, adeno- and other virus groups. Sequestration inside endosomes rapidly destabilizes the icosahedral picornavirus coats effecting release of the RNA genome, which then passes across the membrane into the cytosol. Other types of icosahedral agents such as the adenoviruses can rupture endosome membranes, escaping thereby into the cytosol without apparent loss of integrity (**Fig. 2**). From the above examples it should be evident that viruses are able to initiate infections successfully because they circumvent the usual transfer and hydrolysis of engulfed particulates in lysosomes. Under circumstances that abolish or block the activity of viral fusogens, as happens on denaturation at elevated temperature or as a result of steric hindrance after attachment of specific antibodies, the engulfed inoculum virus is, in fact, transferred into lysosomes where it is destroyed.

Membrane network

The intracellular network of membrane-enclosed cisternae, vesicles and membranous organelles occupies about one-half of the volume of the cytoplasmic or cytosol compartment. Numerous membranous organelles that reside in the cytosol, among them the mitochondria, which are involved in energy metabolism, and microbodies, which participate in detoxification reactions, are omitted from **Fig. 1** and are not further discussed because they have only a peripheral role in virus infections. The predominant structures enclosed by membranes are the endoplasmic reticulum (ER) and Golgi apparatus, which are transiently interconnected with each other and the plasma membrane by transport vesicles. A specialized continuum of the ER are the cisternae enclosed by the nuclear envelopes surrounding the nucleus. This network of lacunae functions as a conduit for an orderly flow of materials between intracellular compartments and the exterior.

Some regions of the ER which are devoid of ribosomes are termed smooth ER (SER) whereas other regions encrusted with ribosomes on the membrane facing the cytosol are designated as the rough ER (RER). Synthesis of proteins destined for cisternae or membrane-enclosed organelles or for transfer to the cell surface is initiated on RER when ribosomes already engaged with messenger or mRNA in a translation complex become bound to receptors on the SER. The growing polypeptide chain is orientated from the ribosome across the membrane into the lumen of ER cisternae. The vectorial insertion of the nascent polypeptide is due to recognition of signal sequences of hydrophobic amino acids. The destination to which polypeptides synthesized in RER are dispatched is also determined by specific amino acid sequences. Some nascent molecules enter into organelles such as the lysosomes and mitochondria, others are destined to become plasma membrane components, and yet others are scheduled for removal from the cell by exocytosis. Many proteins moving through the ER are modified by addition of carbohydrate chains in a complex sequence of reactions involving enzymes bound to the luminal side of the membrane, termed glycosyltransferases. Following the formation of intermediate mannose-rich oligosaccharide chains linked to a dolichol lipid carrier, the carbohydrate becomes attached to asparagine residues at specific signal sites on the polypeptide forming an N-linkage. In addition to a role in producing proteins and glycoproteins, the other functions of the ER include synthesis of phospholipids and glycolipids required for membrane addition and turnover throughout the cell.

The ER provides a surface for enzymes such as those that catalyze the detoxification of drugs prominent in the liver, and as an attachment surface for ion pumps such as those for sequestering Ca^{2+} in the sarcoplasmic reticulum of muscle. Carrier vesicles engaged in transfer of materials between various cisternae are also generated from the ER. The Golgi apparatus, which is organized into aggregates or stacks of flat interconnected cisternae, is the compartment in which completion of synthesis, sorting and distribution of glycoproteins towards various membrane compartments takes place. The groups of Golgi cisternae facing towards the cell interior, termed *cis*, are involved in dispatching molecules to centrally positioned organelles, whereas *trans* cisternae, oriented towards the surface, are associated with products transferred to the lysosomes or to the

plasma membrane by carrier vesicles, some enclosed within clathrin cages. Additional glycosyltransferase enzymes in the Golgi are used to modify the N-linked oligosaccharides, produced in the ER, by deletion and terminal addition of carbohydrate. These enzymes also synthesize exclusively in the Golgi oligosaccharides attached by the -O- linkage to serine residues of the polypeptide. Certain virus groups such as the coronaviruses, which possess the O-linked carbohydrate of an envelope glycoprotein, are assembled not at the cell surface but on membranes of Golgi vesicles. The majority of enveloped virus types is organized into particles by budding from the plasma membrane (**Fig. 3**). Therefore, the cell surface becomes a region

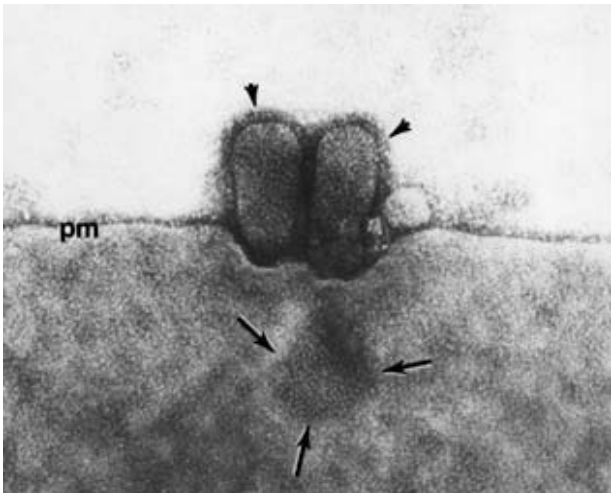

Figure 3 Emergence of influenza virus by budding from the plasma membrane (pm). In the electron micrograph of an infected primate cell arrowheads indicate presence of peplomers on the virions' surface. Arrows point towards a grouping of peplomers where a presumptive virion is assembling; magnification ×165 000. (Reproduced from Choppin PW (1963) *Virology* 21: 278.)

for organizing the glycoprotein molecules that constitute the peplomers or spikes on the virus envelope after they have been delivered to the plasma membrane in transfer vesicles from the Golgi cisternae. Once they are in place, peplomers become foci for mobilizing the nucleocapsid and inner membrane protein(s), then budding takes place. Some virus-induced glycoproteins, which are not a constituent *per se* of virus particles, are nevertheless inserted into cell membranes, thus altering their properties. For example, the cisternae may be formed into rigid channels through which particles of herpes simplex virus can pass to the cell surface, or, as in the case of poxviruses, membrane modifications promote recognition between surfaces on the virus and Golgi vesicles which then surround the virus particle and fuse with each other to form a continuous double-membrane cisterna. The wrapped virus is moved towards the surface where exocytosis occurs as a result of fusion between the outer wrapping and plasma membranes (**Fig. 4**).

The Cytosol

The cytosolic compartment occupies the cytoplasm exclusive of the membrane network and membrane-enclosed organelles. Proteins formed in the cytosol, termed 'free', are translated from mRNA on polyribosomal complexes that do not become attached to the ER. The 'free' proteins, whether they remain in the cytosol or enter into the nuclear compartment, are components of enzyme assemblies, which may be attached to membranes on the cytosolic side. They also form organelles such as the ribosomes, fibrous filaments of the cytoskeleton and nucleosome proteins of the chromatin. It is notable that the polyribosomes engaged in synthesis of large precursor polyproteins of viruses such as polio are attached to SER vesicles at one end. Virus-specified proteins synthesized in the cytosol accumulate into pools of material out of which individual icosahedral virions can be assembled. The proteins are sometimes sufficiently abundant for formation of higher order crystalline aggregates out of assembled virus particles (**Fig. 5**).

The cytoskeleton represents an array of three principal types of fibrous materials, actin microfilaments arranged in bundles, intermediate filaments of several types and cylindrical microtubules. These three elements are interconnected with each other, and can make contacts via a large repertoire of associated proteins with membranes around cell organelles, the nucleus and at the cell surface. Actin filament bundles, prominent in the peripheral cortex region of the cytosol and inside microvilli, are involved in surface mobility during formation of pseudopodia and participate in other changes in cell form. The filaments which have a directional polarity are continually disassembled and reassembled from actin protomers. Circumstantial evidence connects actin filaments with virus infections during initial stages of penetration, migration of the progeny through microvilli and assembly by budding at the cell surface. The intermediate filaments contain four chemically distinguishable but related fibrous proteins. In all cells, they form a net of nuclear lamins situated next to the nuclear envelopes. The organ or tissue in which a cell occurs determines the composition of the intermediate filament(s). Intermediate filaments in cells of epithelia, connective tissue, muscle and the nervous system contain respectively cytokeratins, vimentin, desmin, glial fibrillary acidic protein and neurofilament protein. Contact between intermediate filaments and other components most probably plays a role in mechanical support, as, for example, in neuronal and astrocytic processes and intercellular contacts where adhesion foci, such as the desmosomes, are present. Intermediate filaments have been implicated in the assembly of some picorna- and reoviruses by their presence among the progeny aggregates of virus. Microtubules, the thickest of the cytoskeletal elements, contain α and/or β tubulins organized into cylindrical walls of helical protofilaments. The presence of microtubules imparts the shape and polarity to cells and provides a mechanism for orderly segregation of daughters during cell division. The microtubules provide surfaces along

which movement of vesicles and other membrane-enclosed organelles can be directed. Among the notable functions are: (1) fast axonal transport along groups of microtubules which connect the region of synthesis in the cell body with synaptic termini, (2) involvement in the beating of cilia or flagella and (3) as pathways for the rapid and reversible movement of granules in pigment epithelial cells. The energy for effecting translocations along the microtubules is obtained from the hydrolysis of ATP.

Microtubules are utilized by viruses during infection in various ways. They provide attachment sites for inoculum adeno- and herpes simplex viruses and for conveying them vectorially towards the nuclear pore complexes where uncoating and injection of the DNA occur (**Fig. 2**). The virions may be propelled along the microtubules by the action of a molecular motor, kinesin. Microtubules and connected intermediate filaments become loci for assembly of reovirus type 3 progeny, as is evident in fibroblasts and axons of neurons.

With another virus type there exists an interaction between neuronal microtubules and the N nucleocapsid protein of coronavirus JHM (**Fig. 6**). This relationship occurs perhaps due to molecular mimicry, as revealed by sequence relatedness of N with cellular microtubule-associated proteins *tau* and MAP-4 (**Fig. 7**). This mimicry draws attention to evolution of viruses which, as intracellular parasites, exploit the cell's structure and function properties for self propagation.

The Nucleus

Maintained as an autonomous compartment during the interphase of the cell cycle, the nucleus is where

Figure 5 An area of the cytosol in a human cell infected 7 h previously with poliovirus type 1. A prominent crystalline aggregate of virions occupies the center of the electron micrograph. Magnification ×83 000. (Reproduced from Dales S *et al* (1965) *Virology* 26: 379.)

synthesis occurs relevant to duplication of the DNA and gene expression in the form of transcription into messenger, ribosomal, transfer and other RNA species. The genomic DNA of the cell and associated proteins, including such basic proteins as the histones, form the chromatin, which consists of a multitude of primary units, the nucleosomes. Nucleosomes are organized into hierarchical orders to form the ultimate units of structure, the chromosomes. At interphase, during the most active synthetic phase, the chromatin is dispersed maximally. Chromatin compaction into cytologically identifiable chromosomes commences upon initiation of cell division. In the chromatin, individual genes can be expressed transcriptionally as units. DNA synthesis and transcription each require specific polymerase enzymes and numerous additional cofactors. These factors, some acting cooperatively and others competing with the polymerases, can bring about relaxation of the double-stranded DNA template, promote the copying of the forward and retrograde DNA strands and act in transcription of individual genes. Since the DNA is organized into interrupted stretches of informational sequences (exons) separated by intervening noncoding sequences (introns), a functional RNA template for translation into protein is formed from the primary RNA transcript by removal or splicing out of the introns, usually catalyzed by specific protein complexes termed spliceosomes. Further enzymatic modifications of the RNA template bring about an addition at the 5′ end of specific nucleotide sequences termed 'caps' and at the 3′ end stretches of polyadenylic acid. The above metabolic activities within the cell nucleus are diverted for their own use by viruses with a nuclear phase of their life cycles. Members of the papovavirus group, which possess circular DNA genomes organized as nucleosomes, can subvert DNA and RNA polymerases as well as other cellular factors to promote viral gene expression by splicing and terminal modifications of the mRNA in the manner of the host. To initiate their replication, papovaviruses require the host DNA to be in a synthetic phase of the cell cycle. The viral genome expression is favored over that of the host because a sequence at the origin of viral DNA replication can bind avidly the virus-induced T antigen protein which, in turn, has a high binding affinity for host polymerase. Other DNA viruses, including those of the herpes- and adenovirus groups, also initiate their replication by utilizing, to a varying degree, host polymerases. Replication of influenza viruses exemplifies another highly specific, albeit limited, requirement for the cell's metabolism. These agents possess fragmented RNA genomes of the minus sense which are transcribed into mRNAs by an RNA polymerase carried within the inoculum particles. However, to become functional, the influenza mRNAs must acquire their 5′ terminal caps from among those synthesized inside the nucleus under the aegis of host enzymes. Thus, association of influenza viruses with the nucleus is best explained in terms of transcapping of the viral mRNAs.

Nuclear–Cytoplasmic Exchanges

The mRNA, transfer RNA and ribosomal RNAs of large and small subunits are products of the nucleus which become components of a cytoplasmic translation complex. The individual ribosomal subunits are assembled in the nucleolus, a specialized site of the nucleus, out of ribosomal RNA and numerous types of ribosomal polypeptides, the latter synthesized in the cytoplasm. Compartmentalization of the above synthetic events highlights the necessity for a continual and efficient transfer of transcription products into the cytoplasm and the reverse movement of proteins made in the cytoplasm into the nucleus. Passive transfer of smaller proteins of less than

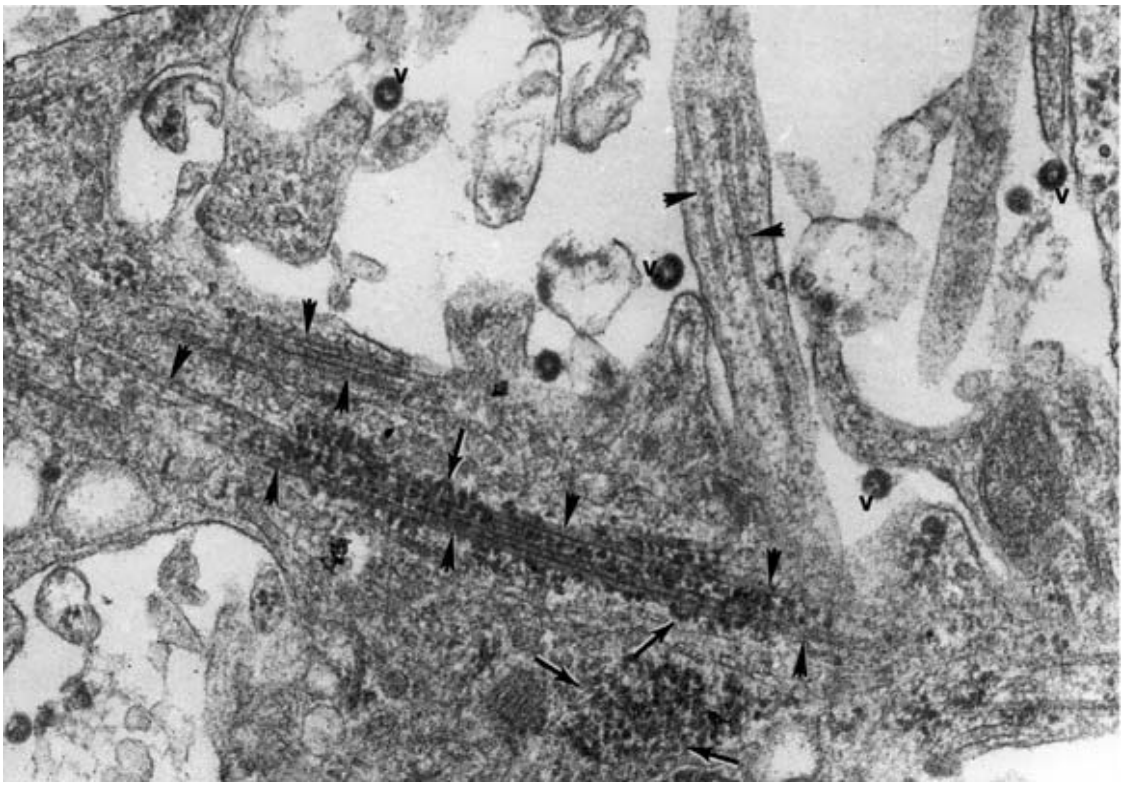

Figure 6 Association between the nucleocapsids of coronavirus JHM (arrows) and bundles of microtubules (arrowheads) within neurites of an infected hippocampal neuron of a mouse. 20 kDa occurs rapidly, within 2 min of synthesis, and that of larger proteins of about 40 kDa takes place more slowly, after perhaps 30 min. Proteins of even greater molecular mass can enter the nucleus only by means of active transport. Such proteins are first bound to specific receptors on the cytoplasmic side of nuclear pores, and are then able to enter into the nucleus because they possess specific signal sequences for import through the pores, as is evident in the case of 90 kDa T antigen of papovavirus. Another function of nuclear–cytoplasmic exchanges in virus infections includes uncoating by injection of adenovirus and baculovirus DNA through nuclear pores (**Fig. 2**). Cytological evidence for the presence inside nuclei of large numbers of assembled adeno- and herpesvirus particles, sometimes grouped into crystalline arrays, demonstrates that large quantities of viral proteins can enter the nucleus. This type of evidence is supported by biochemical studies which reveal very rapid and efficient intranuclear sequestration of nascent viral polypeptides.

Concluding Remarks

This very brief account of cellular structure and function emphasizes throughout the contribution of the host towards the infectious process. The depen-

dence and close intimacy between viruses and their host cells demonstrates adaptation through evolution by the parasite to take every advantage for self-propagation. The examples used to describe cell organization and metabolism in the context of virology should provide the reader with hints about the use that has been made of viruses as incisive probes of the living cell itself.

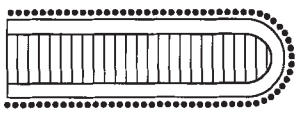
CHANDIPURA, PIRY AND ISFAHAN VIRUSES (*RHABDOVIRIDAE*)



P. De Bishnu and **Amiya K. Banerjee**, Department of Molecular Biology,
The Lerner Research Institute, The Cleveland Clinic Foundation, Cleveland, Ohio, USA

History and Classification

Chandipura, Piry and Isfahan viruses are members of the genus *Vesiculovirus* of the family *Rhabdoviridae*. The prototype of this genus is the vesicular stomatitis virus (VSV) of two serotypes, VSV-New Jersey (VSV_{NJ}) and VSV-Indiana (VSV_{IND}), which is known for its association with sporadic epizootics of vesicular disease among horses, cattle, and swine. Chandipura, Piry and Isfahan viruses along with a number of other viruses such as Alagoas, Calchaqui, Cocal, Jurona, La Joya, Maraba, Perinet and Yug Bugdanovac are the least studied members of this genus.

Chandipura (CHP) virus was first isolated by P. N. Bhatt and F. M. Rodrigues in 1965 from human patients at Nagpur county, India. Thus it is quite distinct from VSV with respect to geographic origin and host species origin, because the latter has been isolated almost exclusively from horses and cattles in the western hemispere. Piry virus was isolated by R. E. Shope in 1960 from spleen and liver samples of an opossum (Philander opossum) at Belem, Brazil. Isfahan (ISF) virus was isolated by R. B. Tesh and coworkers in 1975 from humans as well as gerbils and sand flies at Isfahan province, Iran.

These viruses have been classified as *Rhabdoviridae* based on their typical bullet-shaped morphology, approximately 180 nm in length and 65 nm in width, as well as nucleic acid and protein compositions which are similar to those of VSV (**Fig. 1A**). A low level but distinct crossneutralization of CHP and Piry viruses with VSV-IND was previously reported. However, subsequent studies using hyperimmune guinea pig as well as rabbit serum failed to detect any crossreactivity between these viruses, even when the infective ribonucleoprotein (RNP) particles were used, indicating that these viruses possess distinct antigenic determinants. The Piry virus constituent proteins were also found to be antigenically distinct from several other viruses such as lymphocytic choriomeningitis virus, herpes simplex virus, and 62 arboviruses.

Molecular Aspects: Properties of Genomes and Proteins

The molecular biology of these viruses remains less studied as compared to that of VSV. Complementation studies and analysis of transcription initiation, termination and intergenic sequences of CHP and Piry virus indicate that the organization of the genome is similar to that of VSV (**Fig. 1B**). The CHP virus has a single-stranded negative-sense RNA genome of approximately 11 kb long which encodes five structural proteins: the nucleocapsid protein N, the phosphoprotein P, the matrix protein M, the glycoprotein G and the large protein L. The genome RNA is tightly encapsidated by the N protein and is associated with the RNA polymerase (a complex of L and P protein) to form an RNP complex. Transcription of the genome RNA by RNA polymerase gives rise to five

History and Classification

Chandipura, Piry and Isfahan viruses are members of the genus *Vesiculovirus* of the family *Rhabdoviridae*. The prototype of this genus is the vesicular stomatitis virus (VSV) of two serotypes, VSV-New Jersey (VSV_{NJ}) and VSV-Indiana (VSV_{IND}), which is known for its association with sporadic epizootics of vesicular disease among horses, cattle, and swine. Chandipura, Piry and Isfahan viruses along with a number of other viruses such as Alagoas, Calchaqui, Cocal, Jurona, La Joya, Maraba, Perinet and Yug Bugdanovac are the least studied members of this genus.

Chandipura (CHP) virus was first isolated by P. N. Bhatt and F. M. Rodrigues in 1965 from human patients at Nagpur county, India. Thus it is quite distinct from VSV with respect to geographic origin and host species origin, because the latter has been isolated almost exclusively from horses and cattles in the western hemispere. Piry virus was isolated by R. E. Shope in 1960 from spleen and liver samples of an opossum (Philander opossum) at Belem, Brazil. Isfahan (ISF) virus was isolated by R. B. Tesh and coworkers in 1975 from humans as well as gerbils and sand flies at Isfahan province, Iran.

These viruses have been classified as *Rhabdoviridae* based on their typical bullet-shaped morphology, approximately 180 nm in length and 65 nm in width, as well as nucleic acid and protein compositions which are similar to those of VSV (**Fig. 1A**). A low level but distinct crossneutralization of CHP and Piry viruses with VSV-IND was previously reported. However, subsequent studies using hyperimmune guinea pig as well as rabbit serum failed to detect any crossreactivity between these viruses, even when the infective ribonucleoprotein (RNP) particles were used, indicating that these viruses possess distinct antigenic determinants. The Piry virus constituent proteins were also found to be antigenically distinct from several other viruses such as lymphocytic choriomeningitis virus, herpes simplex virus, and 62 arboviruses.

Molecular Aspects: Properties of Genomes and Proteins

The molecular biology of these viruses remains less studied as compared to that of VSV. Complementation studies and analysis of transcription initiation, termination and intergenic sequences of CHP and Piry virus indicate that the organization of the genome is similar to that of VSV (**Fig. 1B**). The CHP virus has a single-stranded negative-sense RNA genome of approximately 11 kb long which encodes five structural proteins: the nucleocapsid protein N, the phosphoprotein P, the matrix protein M, the glycoprotein G and the large protein L. The genome RNA is tightly encapsidated by the N protein and is associated with the RNA polymerase (a complex of L and P protein) to form an RNP complex. Transcription of the genome RNA by RNA polymerase gives rise to five

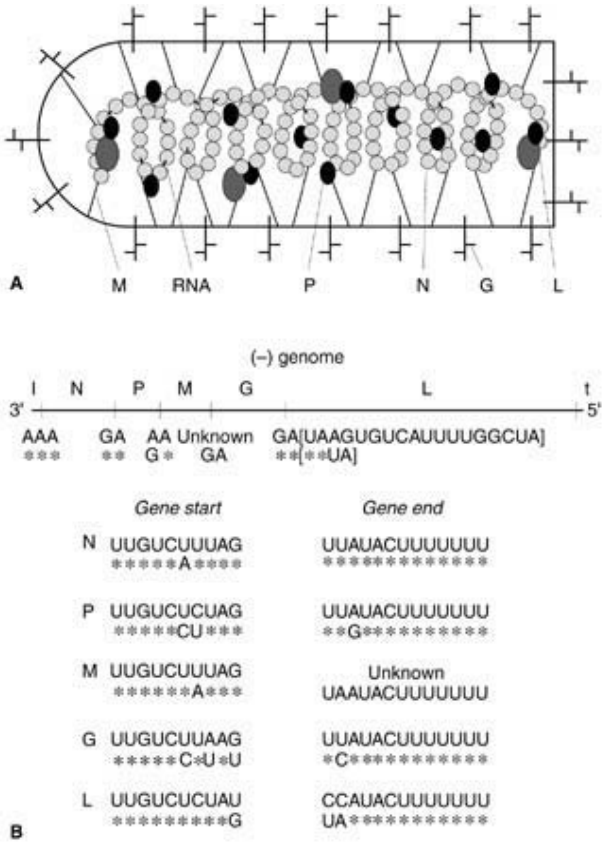

Figure 1 (**A**) Schematic representation of the morphology of vesiculoviruses. The envelope, inner nucleocapsid, and associated proteins are shown. (**B**) The gene order and intergenic regulatory sequences of CHP (upper) and Piry (lower). Asterisks indicate identical sequence in Piry virus. The sequence in brackets represents the insert in the G-L junction.

mRNAs for the five structural proteins. In agreement with serological studies, very little nucleotide sequence homology is found between CHP, Piry and VSV in genomic RNA hybridization analysis.

Nucleotide sequences of the *N*, *P* and *G* genes, G-L junction, part of the *L* gene and the 3′ end of the genome of CHP and Piry virus are known (**Table 1**). Comparison of the deduced amino acid sequences of these proteins with the corresponding sequences of various serotypes of VSV and other rhabdoviruses indicate that these viruses maintain a close evolutionary relationship. In the case of CHP virus, the N mRNA is 1291 nucleotides (nt) long and encodes a protein of 422 amino acids. The N protein is at least 50% homologous to the N proteins of each of the VSV serotypes, and a region near the center of the protein has been identified which is conserved among members of both the rhabdovirus and paramyxovirus families. The P mRNA is 908 nt long and encodes a protein of 293 amino acids. Comparison of P protein sequence with those of the two serotypes of VSV revealed homologies of only about 22%. Although no consecutive stretches of more than four amino acids were identical among these P proteins, a predominantly basic 20 amino acid-long region near the C-termini appears to be highly conserved. Interestingly, overall structure of these P proteins, as assessed by amino acid composition and by the relative hydropathicity distribution, is very similar. Recently, by using bacterially expressed P protein, the phosphorylation of P has been shown to be mediated by the cellular casein kinase II (CK II). By site-directed mutagenesis, Ser62 was identified as the site of phosphorylation. Substitution of Ser62 by Ala resulted in the total loss of P protein function in transcription indicating that the CK II-mediated phosphorylation at Ser62 is required for CHP virus transcription. Interestingly, CK II phosphorylates the VSV_{NJ} P protein in Ser59 and Ser61 and the VSV_{IND} P protein in Ser60, Thr62 and Ser64 residues whereas CHP virus P protein is phosphorylated at a single site, Ser62, in the corresponding region. Importantly, in all these cases CK II-mediated phosphorylation is required for P protein function in transcription. Furthermore, like VSV_{NJ} P protein, the CHP virus P protein also formed dimers after phosphorylation with a concomitant increase in alpha-helicity which is believed to favor transcription activation. The G mRNA is 1681 nt long and encodes a protein of 524 amino acids. The amino acid sequence alignment revealed that the CHP virus G glycoproteins is 39% homologous to each of the VSV G proteins. Analyses of the primary sequence of CHP glycoprotein also revealed the presence of the following consensus motifs: a cytoplasmic face at the C-terminus marked by an abundance of charged amino acid residues (this region contains four cysteines which are potential sites for palmitic acid attachment via thioester linkage); a highly hydrophobic sequence (VVLILVVVLIYGVL) just upstream of the cytoplasmic domain which may serve as a membrane anchor domain. In the case of piry virus, by sequencing the 3′ half of the genome, it has been established that the piry virus, like other vesiculoviruses, contains the genes for N, P, M, G and L in that order. The N mRNA is 1338 nt long and encodes a protein of 427 amino acids. Comparison of amino acid sequences of the N protein of piry virus with that of CHP and VSV, showed about 50% identity, indicating that piry virus is as distantly related to Chandipura virus as it is to the VSV. Analysis of the G protein sequence suggests that piry and CHP are related to each other as closely as the two serotypes of VSV to each other. The P mRNA is 999 nt long and encodes a protein of 328 amino acids. The deduced amino acid sequences of P proteins of piry and VSV

Nucleotide lengths of mRNAs excluding poly(A) tail are shown, with the protein size in amino acids in parentheses. The asterisks indicate CKII phosphorylation sites. In the case of Piry virus, the phosphorylation site(s) remains unknown. However, three Ser residues, Ser 72, Ser 89 and Ser 94 in an acidic region (not shown) conform to the consensus CKII recognition motif.

are highly dissimilar. However, the hydropathicity patterns of these proteins are similar, indicating that the overall secondary structure of P proteins may be conserved. Gene sequences of ISF virus are not known to date.

Host Range, Transmission, Geographic Distribution and Pathogenicity

All three viruses, CHP, piry and ISF, display a wide host range encompassing a large number of species including vertebrates and insects. In nature, these viruses are found in mammals as well as in blood-sucking arthropods such as sand flies, ticks, and mosquitoes, hence their classification as arboviruses. As in the case of other vesiculoviruses, the reservoir cycles for these viruses are poorly understood. Although originally isolated from a human patient, CHP virus was later also recovered from infected hedgehogs (*Atelerix albiventris*) in Nigeria, Africa, and phlebotomine sand flies in West Africa. Antibody to CHP virus has been detected in a variety of mammals, such as horse, donkey, cattle, sheep and goat from various parts of India. Available evidence indicates that insects can act both as host and as vector for transmission between mammals in nature. Transmission of CHP virus by experimentally infected mosquitoes of various species and phlebotomine sand flies to laboratory animals has been documented. Transovarial (vertical) transmission of CHP virus in sand flies has been demonstrated, and the virus has been shown to grow up to 4 logs within 24 h of intrathoracic inoculation in sand flies. Antibody to Piry virus is found in many marsupials as well as in monkeys, edentates, rodents, pigs and water buffaloes. In the laboratory, all three viruses grow well when injected intracerebrally into newborn (suckling) mice, causing viremia and eventual death. Frozen brains of such mice are excellent media for long-term storage of virus specimens. These viruses grow in most mammalian and avian cell lines producing characteristic cytopathic effect (CPE) in liquid cultures and viral plaques under agar.

Mosquitoes infected with rhabdoviruses including CHP, Piry, and ISF develop a lethal sensitivity to CO_2 (cf. Sigma rhabdoviruses of *Drosophila*). Although *Culex* (*Culex quinquefasciatus*) and *Toxorhynchites* (*Toxorhynchites amboinensis*) mosquitoes are CO_2-sensitized by all three viruses, *Aedes* (*Aedes albopictus*) mosquitoes are CO_2-sensitized by CHP and Piry viruses only. In addition, Piry and ISF viruses also produce enhanced CO_2-sensitivity in the fruit fly, *Drosophila melanogaster* (see below), although it has no detectable CPE in *Drosophila* cells *in vitro*.

Serological evidence of natural infection with these viruses has been demonstrated in a wide variety of wild and domestic mammals. The available data suggest that mammals may represent a dead-end host rather than a vector because horizontal transmission is rare and viremia is transient. CHP and Piry viruses have been reported to produce disease in humans. The disease is usually characterized by an influenza-like illness with fever, myalgia, headache, and malaise of 3–6 days duration. Human laboratory infection with Piry virus has been reported due to aerosol inhalation, splashing virus in the eye and contamination of a cut or scratch with infected material. Antibodies to ISF virus have also been reported in humans, but it is unknown whether this infection resulted in clinical illness. No epizootic or epidemic is known for these viruses. Pathogenicity and immunogenicity of CHP and ISF viruses for laboratory animals have been studied. Both viruses were highly pathogenic for mice by the intracerebral route.

Genetics

Spontaneous and mutagen-induced temperature-sensitive (ts) mutants of CHP virus have been classified into complementation groups. Analysis of 50 ts mutants resulted in the identification of six groups designated ChI to ChVI containing 44, 2, 1, 1, 1 and 1 mutant, respectively. These results are in agreement with the presence of five protein-coding genes in the virions. The sixth complementation group probably represents a protein encoded by an alternative open reading frame in the P protein gene. The group ChI, which contains the majority of the mutants, presumably represents the largest gene *L* (see below). Group ChII may represent the gene encoding the glycoprotein G, whereas group ChV may represent the matrix protein M gene. In addition to having a viral degradation phenotype *in vivo*, a mutant of group V overproduced viral mRNAs, suggesting a negative regulatory role of M protein in transcription, as observed for the M protein of VSV *in vitro*. Complementation between ts mutants derived from CHP and different serotypes of VSV is not observed.

Conditional ts mutants of CHP that are unable to multiply in chick-embryo cells at 39°C, the tdCE phenotype, exhibit thermosensitive *in vitro* RNA polymerase activity. Viral protein synthesis was reduced or absent in chick-embryo cells at 39°C indicating that transcription was also defective *in vivo* under these conditions. Although the exact mechanism of inhibition is unknown, it does not appear to involve a defect in methylation of the mRNA 5′ cap structure. Host-induced inactivation of the viral polymerase at the nonpermissive temperature remains a possibility.

Host range mutants of Piry virus designated agD (affected growth in *Drosophila*) that have reduced ability to multiply and induce CO_2 sensitivity in adult *D. melanogaster* (Paris strain) have been isolated. The majority of them were also ts in chicken embryo cells, and some were classified into complementation groups. In the case of one of these mutants, it was shown that the restriction was under the control of a gene on chromosome III. The host gene that affects the multiplication of Piry virus was not one of the five genes known to be involved in the control of sigma virus. However, another class of ts mutant of Piry virus may be restricted by a *Drosophila* gene (*ref*) which also restricts sigma virus. Most agD mutants are generally restricted in all strains of *Drosophila*, whereas other mutants designated rgD (rapid growth in *Drosophila*) have lost general restriction in *Drosophila* but retained specific restriction in the Paris strain. Both agD and rgD mutants have been classified into complementation groups by a UV-inactivation–rescue procedure in which cells are infected with one mutant at low multiplicity in the presence of UV-inactivated wild-type virus or another mutant. The complementation analyses suggest that both kinds of mutants were L protein mutants resulting in a loss of the RNA transcriptase function under nonpermissive conditions. These observations are consistent with the belief that host range properties of vesiculoviruses are determined primarily by specific interactions between cellular factors and the viral polymerase.

CHIKUNGUNYA, O'NYONG NYONG AND MAYARO VIRUSES (*TOGAVIRIDAE*)

Charles H Calisher, Arthropod Borne and Infections Diseases Laboratory, Colorado State University, Foothills Campus, Fort Collins, Colorado, USA

History

Chikungunya (CHIK) means 'that which bends up', in the language of the people of the Makonde plateau, Newala Province, Tanzania (formerly Tanganyika). It is also the name given to a virus first isolated from human serum collected during an outbreak of febrile illness in that country in 1953. A second outbreak of CHIK fever occurred in South Africa in 1956, and CHIK virus continues to cause epidemics in Africa and elsewhere (see Geographic Distribution, below). O'nyong nyong (ONN) virus was first isolated in 1959 from the serum of a febrile human during an epidemic in Acholi, Uganda; ONN means 'weakening of the joints' in the Acholi dialect. This epidemic of ONN subsequently spread through Uganda to Kenya, Tanzania, Zambia, Malawi and Mozambique, involving several millions of humans. Both the CHIK and ONN epidemics were originally thought to be dengue. Although ONN virus was first isolated during an epidemic in 1959, it was not isolated again until 1978. In 1996 ONN fever reappeared in Uganda after a 35-year absence, although serologic studies of febrile patients in Kenya in 1994 and 1995 suggested that this virus may have been circulating there at that time.

Mayaro (MAY) virus was first isolated from the serum of a human in Mayaro County, southeastern Trinidad, in 1954; although not febrile at the time the serum was collected, the person became febrile the next day; MAY virus was isolated from other patients in Trinidad that year. In 1955, MAY virus was isolated from quarry and forest workers during an epidemic near Belém, Brazil and, also during an epidemic, from recent settlers from Okinawa who were living in a rain forest in eastern Bolivia. MAY virus continues to cause periodic outbreaks of disease, including Brazilian outbreaks in 1991–1993. MAY virus was isolated for the first time in Peru in 1994; as is common with CHIK and ONN, these cases were first diagnosed as dengue fever. Additional cases occurred in Peru in 1997, further suggesting the endemic nature of this virus in Amazonia.

Classification

CHIK, ONN and MAY viruses have been placed in the genus *Alphavirus* of the family *Togaviridae;* the other genus in the family (*Rubivirus*) includes rubella virus. MAY virion diameter is 60–65 nm (cores are 40 nm), and the nucleocapsid is surrounded by a lipid envelope, which is apparently derived from host cell membrane during budding. Originally classified by antigenic means, the togaviruses were designated 'Group A' arboviruses (*ar*thropod-*b*orne *viruses*), along with eastern equine encephalitis, western equine encephalitis, Venezuelan equine encephalitis, Getah, Ross River, Sagiyama, Semliki Forest, Sindbis and others. The two envelope glycoproteins, E1 and E2, compose the external surface of the virion and take part in attachment of virions to cell surfaces, hemagglutination and neutralization. Antigenic subtypes and varieties are numerous for most viruses of this genus.

Geographic and Seasonal Distributions

CHIK virus has been isolated from humans and mosquitoes in Tanzania, South Africa, and most areas of tropical Africa (Angola, Central African Republic, Nigeria, Senegal, Uganda, Zaïre, Zambia, Zimbabwe), and tropical Asia (Campuchea, India, Malaysia, Thailand), including Indonesia. CHIK virus caused large epidemics, outbreaks or isolated cases in Burma, India, Philippines, Sri Lanka, Thailand and Vietnam. Because of the prominent articular manifestations and other clinical criteria, it has been suggested that CHIK caused epidemics in Indonesia (1779), East Africa (1823, 1870), India (1824, 1871, 1901, 1923), the Far East (1901–1902), West Africa (1925), and the southern United States (1827–1828).

The epidemic of ONN spread from Uganda to Kenya, Tanzania, Zambia, Malawi and Mozambique, as shown by virus isolation or antibody detection. In addition, ONN virus has been isolated in Senegal.

MAY virus has been isolated from humans in Trinidad, Brazil, Bolivia and Suriname; a single isolation of MAY virus was made from a northbound migrant bird in Louisiana in April 1967.

Human infections with CHIK, ONN and MAY viruses occur primarily in the rainy season, when mosquito populations are highest. Antibody surveys have shown that 20–90% of a given population may

be immune to CHIK virus. In addition to virus isolation data, such surveys provide evidence for the widespread presence of the virus on the African and Asian continents.

Host Range and Virus Propagation

Humans, laboratory mice and other rodents (*Mystromys albicaudatus*), African vervet (*Cercopithecus aethiops*) and Asian monkeys and other primates (rhesus monkey *Macaca radiata,* baboon *Papio ursinus*), prosimians (*Galago senegalensis*) and bats (*Tadarida, Pipistrellus* and *Scotophilus*) are susceptible to CHIK virus and develop high titer viremias. ONN virus has been isolated only from humans, mosquitoes and sentinel mice. MAY virus has been isolated from a rodent (*Tropidurus torquatus hispidus*) and a lizard (*Ameiva ameiva ameiva*) in Brazil and from a migrating bird entering Louisiana. Development of viremia does not necessarily correlate with production of disease in experimentally infected animals. Antibody to CHIK, ONN and MAY has been detected in various primates and domestic animals and in other vertebrates. Field strains of CHIK, ONN and MAY viruses are nonpathogenic to adult mice but are pathogenic for suckling mice inoculated intracranially; suckling mice are less susceptible to ONN than to CHIK and MAY viruses. Birds appear to be refractory to infection with CHIK virus.

Various cell cultures from vertebrates (Vero, LLCMK2, BHK-21, hamster kidney, chicken embryo, duck embryo) and invertebrates (C6/36 cells from *Aedes albopictus* mosquitoes) are susceptible to these viruses and useful for characterizing them. These cells can be used as substrates for enzyme-linked immunosorbent assays (ELISA) or for tests to detect neutralizing antibodies to CHIK, ONN and MAY viruses, in which these viruses form plaques and cause cytopathic effects.

Genetics

Increasingly, genetic information is becoming available for CHIK, MAY and ONN viruses. An abundance of information is available about eastern equine encephalitis, Ross River, Sindbis and Semliki Forest viruses. Alphavirus genomes contain about 12 000 nucleotides arranged as single, nonsegmented positive sense strands of RNA. The genomes are polyadenylated at the 3′ end and capped with 7-methylguanosine at the 5′ end. Preliminary phylogenetic studies indicate that CHIK and ONN viruses occupy distinct evolutionary lineages and provide no support for the hypothesis that ONN outbreaks result from the emergence and epidemiological alteration of African CHIK virus strains. Phylogenetic relationships among isolates of MAY virus are being done by reverse transcription–polymerase chain reaction but results are not yet available.

Genome transfer into the cytoplasm of the infected cell precedes three sequential stages of viral amplification, i.e. ranslation, transcription and replication of genomic RNA. Subgenomic mRNA (referred to as 26S RNA) is formed during replication and contains about 4100 nucleotides, the sequence of which is identical to the 3′ terminal third of the genomic RNA. This RNA is also polyadenylated and capped and is the template for the four viral structural proteins; the 49S RNA nonstructural region serves as the template for four nonstructural proteins and the capsid. Alphavirus genomes can accept mutations in the conserved regions without destroying biologic activity. Only sequences at the 3′ and 5′ termini are indispensable for the genome to be amplified and packaged. In the region of the junction of nonstructural and structural genes, 19 nucleotides upstream from the beginning of the 26S RNA sequence and five nucleotides downstream from it are needed for production of 26S RNA.

Evolution

Although both structural and nonstructural proteins of alphaviruses are conserved to some extent, the latter are more conserved than the former. Because amino acid sequences of various alphaviruses are encoded by different codons, alphavirus replication may allow the use of different paths to the finished product but retention of similar requirements for accomplishment of fundamentals. Indeed, the original antigenic classification of the alphaviruses depended on the phenotypic expression (antigens) of the gene sequences (genotype). Because the protein structure of Sindbis alphavirus corresponds to (is conserved among) protein structures of certain plant viruses that have genomic organizations dissimilar from that of the alphaviruses, because all alphaviruses and many plant viruses are arthropod-borne at some stage in their natural cycle and because mosquitoes belonging to some of the species that transmit alphaviruses typically feed on plants as well as on vertebrates, alphaviruses and plant viruses may have had common ancestors. Highly conserved regions of alphavirus genomes may provide insights into more recent phylogeny. Relatively minor differences between viruses and virus variants may indicate relatively recent evolutionary drifts, and relatively major differences between viruses may indicate more remote genetic shifts.

Serologic Relationships and Variability

Alphaviruses have common antigenic determinants, as shown by many serologic tests, including hemagglutination–inhibition, complement-fixation, ELISA and immunofluorescence. These viruses have been classified as belonging to one of six antigenic complexes. Viruses in such complexes are more closely related to each other than they are to other viruses within the serogroup (Group A arboviruses). The six complexes are: (1) eastern equine encephalitis; (2) Middelburg; (3) Ndumu; (4) Semliki Forest; (5) Venezuelan equine encephalitis; and (6) western equine encephalitis. CHIK, ONN and MAY viruses belong to the Semliki Forest complex, which includes four viruses: Semliki Forest, CHIK [subtypes CHIK (several varieties) and ONN], Getah (subtypes (Getah, Sagiyama, Bebaru and Ross River) and MAY (subtypes MAY and Una). These viruses can be distinguished from one another by the use of virus- or strain-specific monoclonal antibodies employed in hemagglutination–inhibition, neutralization, ELISA and other tests. Because no two virus isolates are exactly the same, the definition and identification of an alphavirus depends on generalities as to placement in the serogroup, specific identification as to its nearest antigenic neighbor, and final placement with regard to type, subtype or variety. When type-specific antigens (polypeptides) and antibodies (against glycoproteins E1 and E2 and against nucleocapsids) become available, they can be used as reagents for rapid determination of serogroup, complex and virus type and for serodiagnosis of alphavirus infections. Distinguishing CHIK and ONN viruses from each other (MAY virus occurs only in the Americas, where neither CHIK nor ONN are known to occur; ONN has been recognized only in Africa) and from other alphaviruses can be done using neutralization and other tests.

Both antigenic and biologic variation have been detected between strains of CHIK virus from widely different geographic areas. Although antigens participating in hemagglutination and neutralization appear to be conserved, plaque-reduction neutralization tests to distinguish CHIK and ONN viruses are successful when single-dose (infection-immune) antisera are used. African and Asian strains of CHIK virus have been distinguished by using kinetic hemagglutination–inhibition tests or by using monoclonal antibodies in any of various tests, including ELISA.

Epidemiology

CHIK, ONN and MAY viruses are transmitted between vertebrate hosts by hematophagous mosquitoes; aerosol transmission of CHIK virus has been recorded and poses a threat to laboratory workers. In the savannahs and forests of tropical Africa, CHIK has been isolated from mosquitoes of the genus *Aedes*, including *Ae. aegypti, Ae. africanus, Ae. cordillieri, Ae. furcifer, Ae. luteocephalus, Ae. otok* and *Ae. taylori* and also from *Mansonia africana* and from mosquitoes of other genera and species. The principal epidemic vectors in Africa are thought to be those belonging to the *Ae. furcifer-taylori* group, with secondary transmission by *M. africana*. No evidence of transovarial transmission in arthropods has been found.

Humans develop high titer viremias and the peridomestic *Ae. aegypti* transmits CHIK virus to humans in urban and village settings. Nonhuman primates are the primary vertebrate hosts, with human infections occurring secondarily under epidemic conditions (virus, climatic factors that regulate populations of competent mosquito vectors, and nonhuman primate and human populations with low herd immunity).

CHIK virus is maintained in Asia in a human-to-human cycle, with *Ae. aegypti* mosquitoes transmitting the virus. Although Asian nonhuman primates develop high titer viremia, they do not appear to serve as the principal vector or reservoir of CHIK virus, as they do in Africa. Devastating epidemics, some lasting 4–6 years, others sweeping through a city and infecting essentially all the human populace within a few months, have been recorded.

The mosquito vectors of ONN virus are *Anopheles funestus* and *An. gambiae. An. funestus* rests in huts and feeds in the evenings, presumably the reason that human cases of ONN cluster by home, compound or village. Primate and other vertebrate hosts of ONN virus are unknown.

MAY virus has been isolated principally from *Haemagogus janthinomys* mosquitoes. Experimentally infected marmosets and other primates develop high titer viremia. Little else is known about the epidemiology of this virus.

Transmission and Tissue Tropism

These viruses are transmitted to humans by the bite of transmission-competent, infected mosquitoes. When human viremic titers reach such levels that subsequently feeding mosquitoes become infected by feeding on them, these mosquitoes can then transmit virus to people on whom they next feed. If an infected human does not develop a high viremia titer, that person cannot serve as a virus reservoir and becomes a dead-end host. The target tissues for these viruses is

unknown but may include circulatory, synovial, and epidermal cells.

Pathogenicity

These three viruses are pathogenic for humans and other animals, although only some infected persons develop signs and symptoms of illness. Different strains of these viruses do not appear to differ in pathogenic potential.

Clinical Features of Infection

CHIK, ONN and MAY viruses cause illnesses characterized by sudden onset, fever, severe chills, arthralgias, leukopenia and rash. After an incubation period of 2–3 days (range, 1–12 days), otherwise healthy humans infected with CHIK virus typically fall suddenly and seriously into a state of illness. Fever and shaking chills lasting 2–3 days herald the onset; biphasic fevers occur. Severe polyarthralgia commences at or soon after onset of other symptoms. These predominantly affect the small joints of the hands, wrists, ankles and feet but migrate among joints and may affect more than one joint at a time. Joint pain is intense, aggravated by exercise, and relieved but not abolished by rest; generalized myalgias are common. Arthralgias usually resolve within a week after onset but may persist for weeks, months or, rarely, years. More than 12% of patients with CHIK disease develop chronic joint symptoms. Maculopapular rash has been seen from as early as the day of onset to as late as the tenth day after onset. However, rash usually appears at the time the fever abates and lasts 1–5 days. Mild headache, photophobia, retroorbital pain, anorexia, nausea, vomiting, abdominal pains and other generalized signs and symptoms occur but are not usually severe or pathognomonic. Exanthema range from mild to extensive and are often confused with rashes caused by dengue viruses, with which CHIK virus is known to circulate. Petechiae may be present, but hemorrhagic manifestations are unusual. Severe arthralgia is the symptom most indicative of illness caused by CHIK virus.

The clinical syndrome caused by ONN virus is similar to that caused by CHIK virus. After at least an 8-day incubation period the patient experiences sudden onset of joint pain. Rash, often accompanied by resolution of illness, occurs about 4 days later in most patients and lasts 4–7 days. Fever is lower than in CHIK infections but, in contrast to CHIK virus infection, lymph nodes are enlarged. As determined by coordinated serologic and clinical surveys, most infections produce typical symptoms.

As with illnesses due to CHIK and ONN viruses, MAY virus infections are characterized by sudden onset, fever, chills, headache, myalgias and arthralgias of the small joints of the hands and feet. Between 2 and 5 days after onset, fever begins to resolve and a maculopapular rash appears. Arthralgias may persist for many months.

Virus isolation is the test of choice for laboratory diagnosis of these infections. CHIK, ONN or MAY virus can be isolated in either cell cultures or in suckling mice, although considerably more isolates of CHIK and MAY than ONN virus are pathogenic for suckling mice.

Pathology and Histopathology

Patients infected with CHIK, ONN or MAY virus usually do not die; therefore, tissues from these patients are not readily available for histologic examination. Biopsy of a skin lesion showed lymphocytic perivascular cuffing and extravasation of erythrocytes from superficial capillaries. A small proportion of children and an even smaller proportion of adults develop severe illness. In infants and young children infected with CHIK virus, mild hemorrhagic manifestations have been observed and the rare fatality recorded. Whether these were due to an underlying convulsive disorder or to some other preexisting abnormality is not known. Nevertheless, although rare convulsions in infants might be due to sudden febrile episodes, the occurrence of focal seizures, repeated seizures and convulsions in adults suggests that CHIK virus may directly involve the brain. Treatment of CHIK, ONN and MAY infections consists primarily of supportive therapy. Symptoms respond partially to nonsteroidal anti-inflammatory drugs and chloroquine phosphate has been evaluated for treatment of CHIK disease.

Immune Response

Infection with CHIK, ONN or MAY virus leads to production of immunoglobulin (Ig) M, IgG and, probably, IgA antibodies. As detected by IgM-capture ELISA, antibody to these viruses crossreacts with heterologous alphaviruses but is most reactive with other viruses of the same antigenic complex. That is, IgM antibody from patients with CHIK have highest titers to CHIK but higher titers to ONN and MAY viruses than to, for example, eastern equine encephalitis virus. IgM antibody peaks 2–3 weeks (3–5 weeks in CHIK virus infections) after onset and persists for about 2 months. IgG antibody also appears relatively soon after onset but, unlike IgM, persists for many months or years after the illness. Hemagglutination–

inhibition, complement-fixation, immunofluorescence and neutralization tests simply detect IgM and IgG antibodies in other configurations. IgM antibody is hemagglutinin-inhibiting, immunofluorescing and neutralizing; IgG antibody reacts in these tests and also in complement-fixation tests. Thus, IgM ELISA is the diagnostic test of choice for determining recent infections (if confirmed by neutralization tests) and may be applied to single serum samples in some instances. The presence of IgG antibody to any of these viruses is simply an indication of past infection and, without demonstration of a significant (fourfold or greater) increase or decrease between paired acute-phase and convalescent-phase serum samples, cannot be used to implicate the virus in the etiology of the illness; usefulness of IgG assays is limited because of crossreactivity.

Prevention and Control

Because CHIK, ONN and MAY viruses are transmitted by mosquitoes, prevention of human infection requires reduction of contact between the susceptible human and the vector. This can be effected by mosquito control operations, using larvicide or adulticide techniques, either on a large (spraying of insecticides from airplanes) or a small (spraying of insecticides from back-pack units) scale. Public education projects (with on-going publicity) and legal means are often used to direct intervention. On-going clinical, virologic, serologic and arthropod surveillance techniques should be used to ascertain the presence and prevalence of these viruses. In certain countries, this often requires considerable political will.

For preventing contact of mosquito vectors with humans, the use of netting and window and door screening is recommended. Removing and subsequently destroying mosquito breeding sites (source reduction), providing piped water, maintaining liquid waste systems and managing irrigation systems have been successful ways of reducing populations of both maintenance and amplification vectors.

Future Perspectives

If measures taken to control arthropod vectors of CHIK, ONN and MAY viruses are not effective or are not possible because of economic, political or geographic considerations, vaccines hold some potential for prevention of disease in humans at risk of infection. Although there may not be a need for a vaccine to prevent ONN virus infection, the prevalence of CHIK in both Africa and in Southeast Asia, the presence of competent vectors for this virus (*Ae. albopictus, Ae. aegypti*) in the United States and focally through a substantial portion of the Americas, and a human population completely susceptible to these viruses are sufficient justifications for developing such a vaccine. With rapid air transport, an increasing number of tourists are exposed to potential infection (one human infection with MAY virus was recently diagnosed in the US in a patient who had recently traveled to the Amazon region). Whether a return home in the incubation (viremic) periods of CHIK or MAY virus infections can infect local mosquito populations is unknown. An experimental vaccine against CHIK virus has recently been developed and is being tested in humans. Because of the close antigenic relationships between these viruses, a CHIK vaccine may prove to confer protection not only against CHIK virus but against ONN, MAY and other closely related pathogenic alphaviruses as well.

CLOSTEROVIRUSES (*CLOSTEROVIRIDAE*)

Sylvie German-Retana and **Thierry Candresse**, Station de Pathologie Végétale, Institut National de la Recherche Agronomique, Villenave d'Ornon, France

Giovanni Martelli, Dipartimento di Protezione delle Piante dalle Malatie, Universita degli Studi and Centro di Studio del CNR sui Virus e Virosi delle Colture Mediteranee, Bari, Italy

History

The name closterovirus was first coined in the early 1970s for a taxonomic group of plant viruses characterized by an elongated, very flexuous particle morphology and an open particle structure. The name is derived from the Greek 'kloster' meaning thread or filament. The group was approved by the International Committee on Taxonomy of Viruses in 1976.

Very early, it was observed that closteroviruses showed some variations in a number of their properties, such as genome size, cytopathology, tissue tropism and relation with insect vectors. This initially led to several attempts to divide the group. In the early 1990s, the availability of genomic sequences led to the splitting of the group to separate the trichoviruses from the true closteroviruses. Due to their localization in the phloem and the difficulties in particle purification, closteroviruses have traditionally been a genus which, with few exceptions, has attracted relatively little attention. However, recent years have seen a remarkable increase in the number of publications on closteroviruses. This can probably be explained by two factors: the significant improvement brought to these studies by the introduction of molecular biology techniques, and the emergence of a number of 'new' closteroviruses, apparently linked to the explosion of insect vector populations. As a result, characterization and sequence data are now accumulating at a rapid rate. This has already led to a further splitting of the *Closterovirus* genus, in order to accommodate in a separate taxon the species with a divided genome (*Crinivirus*). The two genera (*Closterovirus* and *Crinivirus*) are now included in the recently created *Closteroviridae* family.

Regardless of whether monopartite or bipartite, closterovirus genomes have a similar structure and contain unique genes coding for a homologue of the cellular heat shock protein (HSP) 70 proteins and a divergent copy of the coat protein. These genes are present in all species sequenced to date. Closteroviruses are phloem-associated and induce the formation of characteristic cytopathic structures in infected cells. Transmission is semipersistent by a variety of vectors, i.e. aphids, whiteflies, and pseudococcid or coccid mealybugs. Some can be transmitted (with difficulty) by mechanical inoculation. These properties are common to all species and should be regarded as characterizing traits of the family.

Taxonomy and Classification

The major problem in dealing with the taxonomy of members of the *Closteroviridae* is that, for many of these viruses, only limited information is available. This is mostly due to the fact that particles are difficult to purify because of low virus titer in the plants (linked with their phloem localization). The particles are also labile and they tend to break or aggregate during purification.

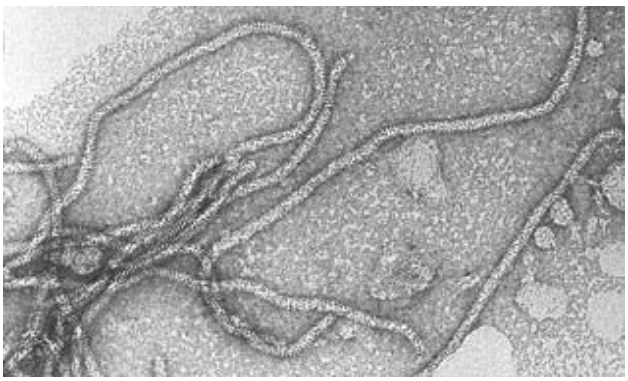

Figure 1 Particles of grapevine leafroll associated virus 2 (GLRaV-2) observed by electron microscopy. Original magnification approximately ×250 000.

Closterovirus taxonomy has rapidly evolved during the last few years as nucleotide sequence data began to accumulate. Major differences in genome size and organization, biological properties (type of vector, host range) and the results of phylogenetic analysis, suggested that the family *Closteroviridae* be divided into at least two genera (**Table 1**):

- Genus *Closterovirus*, typified by beet yellows virus (BYV), comprised of species with monopartite genomes, transmitted by aphids, mealybugs or whiteflies.
- Genus *rinivirus*, typified by lettuce infectious yellows virus (LIYV), comprised of whitefly-transmitted species with bipartite genomes.

Particle Structure and Composition

Although resembling that of some other flexuous filamentous plant viruses, such as tricho-, capillo- and vitiviruses, the very flexuous and open particle structure is still the most common and conspicuous trait of members of the *Closteroviridae* family (**Fig. 1**). In fact, in preliminary studies, this is often the only indication that a given virus might be a member of this family. Particles have, in general, a consistent diameter of about 12 nm, with a length varying between 650–900 and 2000 nm, depending on the virus. The RNA content is usually 5–6%. For some viruses (BYV, citrus tristeza virus (CTV), LIYV, beet yellows stunt virus (BYSV), little cherry virus (LChV)), two types of coat protein (CP) subunits have been identified: the genuine CP and a CP homologue that probably arose by gene duplication. With BYV and CTV, the duplicate protein coats an extremity of the virions, forming a distinct structure, for which the terms 'rattlesnake' or 'heterodimeric' have been coined. Given that the presence of a CP duplicate is found in all closteroviruses so far sequenced, such an unusual particle structure may well be a general characteristic of the family.

In addition to the end-to-end aggregation and breakage problems encountered during purification, it should be noted that closterovirus particles may assume slightly different dimensions depending on the negative stain used for electron microscopy, further complicating the determination of their size. In the case of CTV, smaller than full-length particles have been detected, which could encapsidate subgenomic or defective interfering RNAs.

The pitch of the primary helix, which can usually be measured from the obvious crossbanding of the particle, is in the 3–3.8 nm range, giving estimated ratios of four nucleotides per protein subunit and of about ten protein monomers per turn of the helix. The CPs of most members of the family fall in a restricted size range, usually 22–30 kDa. Notable exceptions are the CPs of mealybug-transmitted viruses, such as LChV or the grapevine leafroll associated viruses (GLRaVs), that have molecular masses of up to 46 kDa. An unusual property of the CP of some closteroviruses, such as BYV and carnation necrotic fleck virus (CNFV), is that they are devoid of tryptophan, which explains their high (1.4–1.8) A_{260}:A_{280} absorbance ratios. However, the CP of CTV does contain a significant amount of tryptophan (A_{260}:A_{280} of 1.21–1.22). The particles of several virus species such as CTV are not stable in CsCl solutions but are stable in Cs_2SO_4, with a buoyant density of 1.24–1.27 g ml^{-1}.

Genome Structure

Members of the *Closteroviridae* family have either monopartite or bipartite single-stranded RNA genomes of positive polarity. The genomic RNAs of BYV, CTV and LIYV are infectious, and have messenger activity *in vitro*. The genomic RNAs of

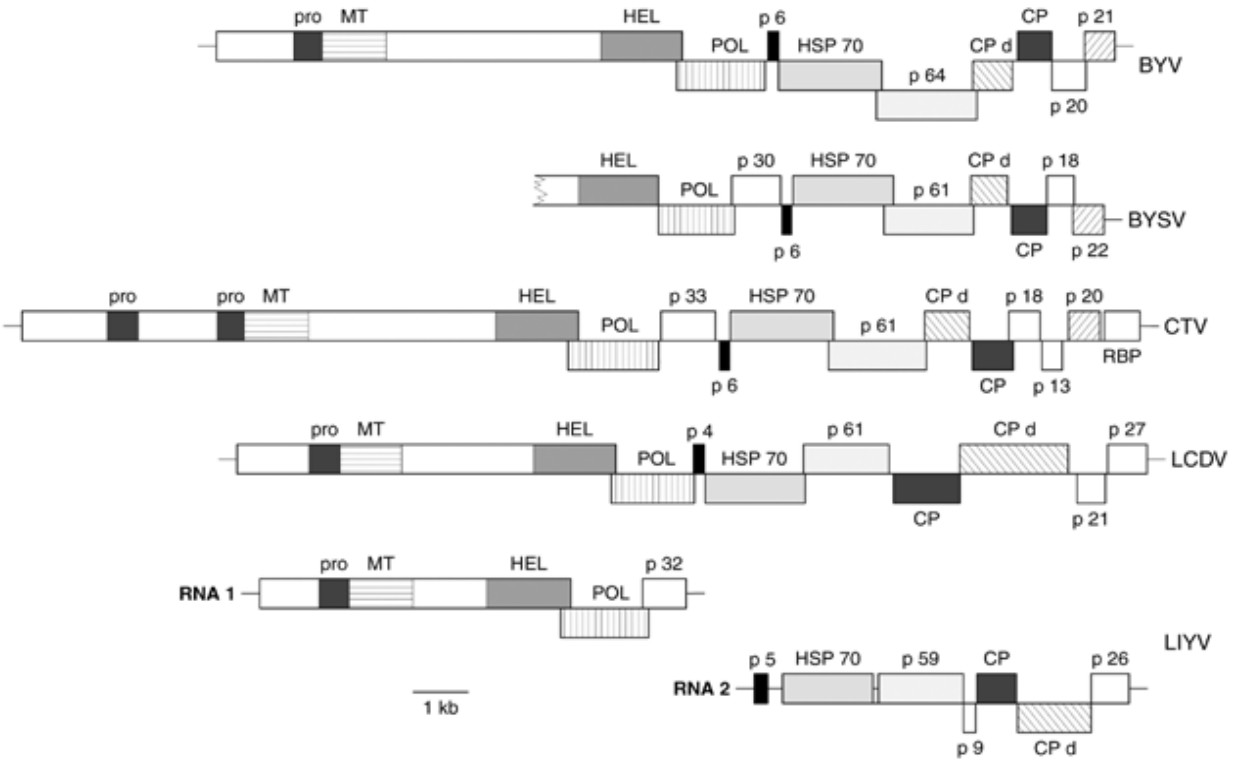

Figure 2 Genomic organization of some members of the *Closteroviridae* family. BYV, beet yellows virus; BYSV, beet yellow stunt virus; CTV, citrus tristeza virus; LChV, little cherry virus; LIYV, lettuce infectious yellows virus; pro, domain characteristic of papain-like proteinases; MT, methyltransferase domain; HEL, helicase domain; POL, RNA-dependent RNA polymerase domain; HSP 70, protein homologue of the cellular HSP 70 heat shock protein; CP, coat protein; CPd, diverged duplicate of coat protein; RBP, RNA-binding protein.

BYV, CTV, LChV and LIYV do not appear to include a poly(A) tract, but terminate with a heteropolymeric sequence devoid of conspicuous features other than the frequent presence of potential hairpins near the 3′ end. Indirect evidence suggests that the 5′ end of the genome of family members is capped.

Genome Organization and Expression: Affinities with Other Virus Taxa

To date, complete genomic sequences have been determined for only five viruses in the family: BYV, LIYV, LChV and two isolates of CTV (CTV-T36, a decline isolate from Florida, and CTV-VT, a yellows isolate from Israel), while the 3′-terminal sequence is available for beet yellows stunt virus (BYSV), grapevine leafroll-associated virus 2 (GLRaV-2), grapevine leafroll-associated virus 3 (GLRaV-3), and tomato infectious chlorosis virus (TICV). Relevant accession numbers are: (X73476: BYV), (RNA1 U15440, RNA2 U15441: LIYV), (Y10237: LChV), (U16304: CTV-T36), (U56902: CTV-VT), (U51931: BYSV), (Y14131: GLRaV-2).

The 15 500 nt genome of BYV shows an arrangement of nine open reading frames (ORFs) (**Fig. 2**). The largest 5′-proximal ORF, 1a, encodes a large polyprotein with calculated molecular mass of 295 kDa, containing domains characteristic of papain-like proteinase (P-PRO), methyltransferase (MT) and helicase (HEL). The downstream ORF 1b encodes a 48 kDa putative RNA-dependent RNA polymerase (POL), which is probably expressed via a +1 ribosomal frameshifting, as a 348 kDa ORF 1a/1b fusion protein. ORF 2 encodes a 6.4 kDa protein with membrane-binding properties, homologous to the small hydrophobic proteins of potex- and carlaviruses. ORF 3 codes for a 65 kDa homologue of the cellular HSP 70 heat shock proteins. The proteins of this family are molecular chaperones found in all cell types, and are implicated in protein–protein interactions. The 65 kDa protein of BYV has ATPase activity associated with the conserved N-terminal domain. However, it apparently lacks the ability to interact with unfolded protein chains, another property typical of cellular HSP 70 proteins. Recent experimental work indicates that this protein is essential for cell-to-cell movement of the virus. ORF

4 overlaps ORF 3 and encodes a 64 kDa protein with sequence similarity to proteins of the HSP 90 family of heat shock proteins. ORFs 6 and 5 code for the capsid protein (22 kDa) and its diverged duplicate (24 kDa), respectively. ORFs 7 and 8 code for proteins that do not have sequence similarity to any proteins in the database, with the exception of the homologous proteins of CTV. ORF 2, 3, 4, 5 and 6, coding for the small hydrophobic protein, the HSP 70 homologue, the HSP 90 homologue, the diverged copy of the CP and the CP itself, constitute a five-gene module present in all species sequenced so far.

The 19296 nt genome of CTV-T36 (the largest known plant virus genome) contains 12 ORFs potentially encoding at least 17 protein products. The general gene arrangement is similar to that of BYV, with two gene blocks or modules easily identified. The first block is the replication-associated complex (including the MT, HEL and POL domains, with the POL expressed via a +1 ribosomal frameshifting) preceded by a similar papain-like protease (apparently duplicated in the case of CTV). The second block is the five-gene module. Outside of these modules, other genes in CTV and BYV differ. In addition to a supplementary copy of the leader protease, CTV has four unique genes that do not have counterparts in the BYV genome, including a 3′-terminal ORF encoding a 23 kDa protein which probably has RNA-binding activity.

The genome of LIYV consists of two RNA components. The 8118 nt RNA1 contains three ORFs that include the domains for a papain-like protease, methyltransferase, helicase and RNA polymerase (expressed via a +1 ribosomal frameshift). The 7193 nt RNA2 includes six ORFs, which include the five-gene module. However, LIYV is distinct from monopartite closteroviruses in several ways: its genome consists of two RNAs; the order of the capsid protein gene and the gene for its diverged copy is reversed as compared to BYV and CTV (the same is also observed in the mealybug-transmitted LChV, GLRaV-3 and in the whitefly-transmitted sweet potato sunken vein virus (SPSVV)). The diverged copy (52 kDa) is also much larger than the CP (28 kDa) and could be the result of a triplication of the CP gene, with the CP gene followed by two fused, highly diverged duplicates. In addition, LIYV includes ORFs that are not related to ORFs found in the other viruses.

Members of the *Closteroviridae* share common and original expression mechanisms. In all members of the family for which sufficient information is available, the POL domain is encoded by a separate ORF overlapping with the 3′-terminal portion of the large upstream ORF, including the MT and HEL domains. It has been suggested that both ORFs are expressed as a large fusion protein resulting from a +1 ribosomal frameshifting. Such a +1 ribosomal frameshifting is a unique feature among positive-strand plant viruses. *In vitro* translation experiments have demonstrated the autocatalytic cleavage of the N-terminal portion of the ORF 1a product of BYV that contains the papain-like proteinase domain. Furthermore, site-directed mutagenesis of the predicted catalytic amino acid residues abolished the proteolysis, thus corroborating the identity of the protease. With BYV, CTV, BYSV and LIYV, the products of the ORFs downstream, ORFs 1a and 1b, are expressed via the formation of a nested set of 3′-coterminal subgenomic RNAs (sgRNA). Therefore, the genome expression of these viruses (and likely of all members of the family) is based on polyprotein processing, translational frameshifting and multiple sgRNA generation, thus resembling that of coronaviruses. However, unlike coronaviruses, the closterovirus polymerase belongs to the Sindbis virus-like lineage of polymerases.

Another common feature of members of the family is the presence of the gene coding for the HSP 70-related protein. This gene, first reported for BYV, has now been identified in 12 additional closteroviruses (CTV, LChV, BPYV, BYSV, CCSV, CNFV, GLRaV-1, GLRaV-2, GLRaV-3, GLRaV-7, PMWaV-1, PMWaV-2) and five criniviruses (CYSDV, TICV, LIYV, LCV, ToCV). In the cell, the molecular chaperones of the HSP 70 family perform several functions, including protein folding, protein trafficking and secretion. Like some HSP 70 proteins, the 65 kDa protein of BYV binds to microtubules *in vitro*, this binding being stimulated by ATP hydrolysis. Several functions have been postulated for this HSP 70 homologue: mediation of cell-to-cell movement through plasmodesmata via interactions with the cellular translocation machinery (such as cytoskeletal or secretional proteins); involvement in the assembly of multisubunit complexes for genome replication and/or subgenomic RNA synthesis, or assembly of viral particles. Recent evidence, showing that BYV mutants in which the expression of the HSP 70 protein is abolished are restricted to inoculated cells, demonstrates the role of this protein in cell-to-cell movement of the virus.

A further peculiarity of members of the *Closteroviridae* is the duplication of the capsid protein gene. To date, this is the only known case of such a duplication in viruses with elongated particles. The capsid proteins of BYV and CTV, and their homologues, show a high degree of sequence conservation and, according to the pattern of conserved amino acid residues, the duplicate copies probably retain the general spatial folding and some crucial properties of

the CPs. Interestingly, in LIYV, LChV, GLRaV-2 and GLRaV-3, the CP gene and its tandem copy have the opposite order as compared to BYV and CTV, and the similarity is much lower.

The large size of the *Closteroviridae* genomes has been proposed to be due to the acquisition of foreign coding sequences via RNA recombination (protease, HSP 70 protein) and gene duplication, which may also explain the significant variability in genome organization observed between genera and among members of the same genus. Phylogenetic reconstructions based on POL, HEL and MT amino acid sequence comparisons indicate that the *Closteroviridae* should be regarded as members of the 'alpha-like' supergroup of viruses, their closest affinities being with the family *Bromoviridae*. Sequence comparisons show that the CPs of BYV and CTV are related (24% homology). These proteins belong to a lineage that includes the CPs of many other filamentous plant viruses (carla-, potex-, capillo-, tricho-, viti- and potyviruses) but they are not closely related to the CPs of members of any of these groups.

Host Range and Geographic Distribution

Host ranges of individual members of the *Closteroviridae* vary considerably but are usually rather restricted. While BYV was reported to infect over 120 species in 15 families, many other viral species have host ranges limited to a single botanical family. This is the case of CNFV, CTV, wheat yellow leaf virus (WYLV), LChV, and the GLRaVs. Very different geographic distribution situations are reported, depending on the individual virus considered: while some viruses cover essentially the totality of their host's geographic range (e.g. CTV, BYV, CNFV, GLRaVs), others have rather restricted distributions.

Virus–Host Relations: Cytopathic Effects

Some closterovirus, but not crinivirus species, are transmitted by sap inoculation, though with great difficulty and low efficiency, most likely because of their phloem-restricted condition. The cells of infected plants show two types of cytopathic effects: nonspecific subcellular changes accompanying chlorotic or necrotic reactions (e.g. membrane proliferation, vesiculation of chloroplasts, degeneration and vesiculation of mitochondria, accumulation of osmiophilic granules) and specific reactions, in the form of inclusion bodies. Two types of inclusions are observed: aggregates of virions and membranous vesicles, or combinations of the two. Virions occur either in crossbanded aggregates made up of stacked tiers of particles packed side by side, or in loose wavy paracrystalline aggregates, or, more typically, in irregular bundles intermingled with single or clustered membranous vesicles containing a network of fine fibrils. Inclusion of the latter kind are one of the hallmarks of members of the *Closteroviridae*, and are often referred to as BYV-type inclusion bodies. They are limited to the phloem of infected cells, i.e. sieve tubes, companion cells and phloem parenchyma, but occasionally, as with BYV, can also be found in the mesophyll and epidermis near local lesions. The fibrillar material contained within the membranous vesicles has been interpreted as possible double-stranded RNA, thus suggesting a role for these structures in viral replication, a contention that needs experimental verification.

Virus Transmission

BYV, the type species of the *Closterovirus* genus, has aphid vectors. However, other types of vectors (mealybugs, whiteflies) have been reported for members of the same genus. In many cases, the mode of transmission or the vector has not been determined (**Table 1**). Studies have mostly dealt with aphid transmission of BYV and CTV. Information on the transmission of other viruses is still very limited and, in many instances, transmission has only been demonstrated under laboratory conditions. In the case of BYV, CTV and other closteroviruses, aphid transmission is semipersistent, i.e. long acquisition and transmission periods (minimum feeding time for acquisition and transmission in the range of 15 and 30 min, respectively), relatively long retention of the virus (up to 2–3 days) and absence of a latency period. The virus does not appear to be retained through molts or to be transmitted to the vector progeny. In general, relatively short acquisition or transmission feeding periods result in lower efficiency of transmission, this being correlated with the length of these periods (up to 24 h for acquisition, up to 6 h for transmission). The molecular bases of the semipersistent mode of aphid transmission are currently not understood. In particular, the localization of virions in viruliferous aphids is not known, nor are the reasons for the long retention period. On the other hand, the close association of the viruses with phloem tissues accounts for some of the transmission characteristics, such as the length of the acquisition and transmission feeding periods and the lack of transmission during brief probings. One hypothesis, which remains to be verified, is that the CP duplicate may facilitate the interaction between virions and the insect's foregut.

Vector ranges vary from rather wide to restricted, depending on the virus: BYV has been shown to be transmitted by 23 aphid species (*Myzus persicae* and *Aphis fabae* being the major natural vectors), CTV by seven species (*Toxoptera citricida* and *Aphis gossypii* being the most efficient vectors) and a number of other viruses, such as CNFV and WYLV, by a single species.

Some of the closterovirus species and all those of the *Crinivirus* genus are transmitted semipersistently by whiteflies: namely, BPYV, TICV and CCSV, transmitted by *Trialeurodes vaporariorum*; LIYV, CYSDV and SPSVV, transmitted by *Bemisia tabaci*; LCV, transmitted by *Bemisia argentifolii*; diodia vein chlorosis virus (DVCV) and abutilon yellow virus (AYV), transmitted by *Trialeurodes abutilonea*. Persistence and specificity of transmission of whitefly-transmitted viruses in their respective vectors has been used as a biological character for virus species differentiation. For example, LIYV is retained by viruliferous vectors for a maximum of 3 days, while LCV and CYSDV can be retained for 4 and 9 days, respectively.

Pseudococcid (*Planococcus, Pseudococcus, Phenacoccus, Saccharicoccus* and *Dysmicoccus*) and coccid (*Pulvinaria*) mealybugs have been reported to transmit five different closteroviruses (**Table 1**). The mode of transmission, determined so far only for GLRaV-3, is semipersistent, and may not be vector-specific, as this virus can be transmitted by both pseudococcid (*Planococcus* and *Pseudococcus*) and coccid (*Pulvinaria*) mealybug genera.

Diseases and Their Economic Significance

The most frequent type of symptoms induced by members of the *Closteroviridae* family are of the yellowing type, frequently accompanied by phloem necrosis. Phloem localization of these viruses probably accounts for these types of symptoms, which are also caused by luteoviruses, another group of phloem-restricted viruses. The economic impact varies widely with the virus: while some are known to affect weeds only, many others have a significant detrimental impact on crop plants. These include BYV, CTV, CNFV, whitefly-transmitted viruses like BPYV, LIYV, and the GLRaVs.

BYV is responsible for serious losses of beet and spinach. Together with beet mild yellowing and beet western yellows luteoviruses, this virus is responsible for the so-called yellowing diseases of beet. In some European countries, losses of sugar beet yield have been estimated to be as high as 15–30% in some years. This reduction is mostly due to decreased root yields, with only marginal effects on the sugar content. Severity of losses correlates with the time of infection and the susceptibility of the affected cultivar. In artificial infection trials, yield losses as high as 40–60% have been recorded, but late season infection has only marginal effects on the yield.

CTV is undoubtedly one of the major citrus pathogens, recognized as one of the top ten viruses with the highest economic impact in eight out of ten wide geographic areas of the world. It is estimated that over the past 50 years or so, CTV has caused the loss of over 80 million trees worldwide. The name 'tristeza' is derived from a condition leading to a quick decline of sweet orange and numerous other commercial citrus species grafted on sour orange rootstocks, a symptom due to a scion–rootstock combination problem, with no decline appearing on plants grafted on tolerant rootstock. The most devastating disease induced by CTV is probably stem pitting of a number of citrus species, such as grapefruits, some sweet orange varieties, and sour and sweet limes. Stem pitting is usually accompanied by loss of plant vigour, decline and reduced fruit size. Other major types of diseases caused by CTV include vein clearing of sour lime and seedling yellows, a severe stunting disorder developed by some varieties when infected at an early stage. The pattern of symptoms induced by CTV is complicated by large differences in species and varietal susceptibility and by the existence of an extremely large biological variability between CTV strains.

Whitefly-transmitted viruses are the widespread agents of emerging diseases causing major losses to a number of crops, such as lettuce, sugar beet and cucurbits. A clear-cut estimate of yield losses caused by viral infections is complicated by the difficulty of correctly identifying the agent, because field symptoms (stunting, yellowing and reduced vigour) can also be attributed to the whitefly vectors. In documented cases of severe LIYV infection, losses of up to 80% have been reported from southwestern USA. Epidemic virus outbreaks have been estimated to induce, in a single season, losses of lettuce, sugarbeet, melon and squash worth $US8 million. The recently observed increase in the impact of these viruses appears to be directly linked to the explosion of whitefly vector populations during the last few years, which may have been favoured by a number of factors, i.e. the widespread use of synthetic organic insecticides, resistance to pesticides, changing climatic conditions, intensified agricultural practices and international distribution of plant material contaminated by whitefly populations.

Leafroll disease is one of the most economically relevant diseases of the grapevine and occurs world-

wide. It causes yield losses of 10–70%, lowers the sugar content, soluble solids and phenolic compounds of the berries, and reduces graft take and rooting ability. The etiology of the disease is being unravelled, for at least three (GLRaV-1, GLRaV-3, and GLRaV-7) of the seven serologically distinct closteroviruses associated with it have been experimentally proven to be genuine leafroll agents. GLRaV-2 is the cause of both leafroll and a graft incompatibility condition.

Virus Epidemiology and Control

Transmission by vectors may not be the major means of long-distance closterovirus dispersal, which is primarily due to distribution of contaminated propagating material through trading. This is obviously the case for CTV, CNFV and GLRAVs, and the cause of the transfer of BYV from Europe to the USA. In regions where a given virus is absent, quarantine is the best protective measure. In infected areas, infections can be controlled through the production and use of virus-free propagative material, along with control of insect vector populations and destruction of virus reservoirs. When possible, these measures can be coupled with the use of resistant or tolerant varieties or rootstocks. A search for natural resistance has been successful for CTV, but not for GLRaVs, and is currently underway for criniviruses.

The most popular detection techniques for certification of propagation and planting material include bioassays on susceptible hosts (indexing) and enzyme-linked immunosorbent assays (ELISA). Detection of double-stranded RNAs associated with viral infection has also been used, though often inconclusively. The potential of molecular techniques (hybridization, polymerase chain reaction (PCR)) is increasingly being exploited. PCR appears of particular interest when targeting the conserved HSP70 coding region.

In most cases, it has been possible to obtain virus-free plants through the use of meristem tip culture, thermotherapy or a combination of both. A special mention should be made of the use of crossprotection to control tristeza. This strategy is based on the pre-inoculation of trees with mild CTV isolates to protect them from the expression of symptoms caused by more severe superinfecting isolates. Crossprotection is not without risk, but with CTV it has been used commercially and, in general, with great success in a number of countries, to protect several million trees.

Future Perspectives

Members of the *Closteroviridae* family are important pathogens of plants but, despite the recent remarkable advances, information on their genomic organization and interactions with hosts and vectors is still limited. Stumbling blocks are the large genome size of these viruses and the difficulties encountered with their characterization and purification. As molecular data has accumulated, the taxonomy of this formerly heterogeneous group of viruses, previously based on morphological criteria, has evolved towards more phylogenetically based groupings. In some crops, such as grapevine, new viruses continue to be discovered. At the same time, in the western USA, an explosion of the whitefly populations and establishment of the new species *B. argentifolii,* has led to the discovery of several new diseases and viruses. Comprising both very old diseases of high incidence and emerging viruses, the field of closterovirology is rapidly becoming a very active and dynamic research area. The recent development of synthetic inocula using cDNA clones from several of these viruses offers new opportunities for the understanding of the relationships with their hosts and vectors. At the same time, molecular biology techniques have greatly improved our ability to detect and characterize these viruses, which should rapidly translate into increased capability to fight the diseases they cause.

COLIPHAGE LAMBDA (*SIPHOVIRIDAE*)

Allan M Campbell, Stanford University, Stanford, California, USA

Introduction

The double-stranded (ds) DNA phage lambda belongs to a group of related temperate phages (the lambdoids) whose natural hosts are *Escherichia coli* and other members of the *Enterobacteriaceae* and whose distribution is worldwide. Most lambdoid phages share a common genetic map but have undergone substantial divergence in sequence and specificity of traits such as repression or prophage location; collectively they present a combinatorial array of such specificities almost certainly generated by natural recombination. The major collections of lambdoid phages used in comparative studies were isolated in France (phages 21, 82, 381, 424, 434, 466), Japan (ϕ80), Hong Kong ('HK' phages) and the area formerly known as the Soviet Union.

Lambda-related sequences are present in the genomes of many enterobacterial isolates, even where active phage is not produced. These appear to result from lysogenization followed by progressive mutation to loss of function, including deletion of large segments of the prophage. Lambda was found in the K-12 strain of *E. coli*, which harbors at least four incomplete lambdoid prophages. In research, a derivative phage selected for larger plaques and better lytic growth than shown by natural lambda is standardly used.

The K-12 strain was isolated from a Stanford hospital patient in 1926. The presence of lambda was first reported in 1951. Because the genetics of the host was already developed at that time, lambda was studied more intensively than other temperate phages. Largely because of this happenstance, lambda became the model temperate phage, in which repression, regulation and integration were studied in depth. When methods for DNA cloning were developed in the 1970s, the accumulated information on lambda facilitated manipulation of its genome to make it the most commonly used double-stranded phage cloning vector.

Taxonomy and Classification

Coliphage lambda is in the genus 'Lambda-like phages' of the *Siphoviridae* family.

Virion Structure

Each lambda virion contains one linear dsDNA molecule 48 514 bp in length, with complementary 12-base single-stranded 5′ overhangs at the ends. The DNA is packaged within a regular icosahedral head 54 nm in diameter, attached to a flexible tail 173 nm in length. The major capsid proteins (gp*D*, gp*E*) are present in 420 monomer units each, in a $T = 7$ configuration with gp*E* grouped as trimers and gp*D* as hexamers. Heads lacking gp*D* can package and inject DNA but have a smaller diameter than normal heads

and cannot package a full-length lambda genome. The major tail protein gp*V* forms a hollow tube 9 nm in diameter through which the DNA is injected on infection. The tail terminates in a single fiber 23 nm long composed of a few molecules of gp*J*, which binds to the maltose-uptake protein LamB of the bacterial envelope in the first step of attachment to the host cell.

Genome Structure

The complete DNA sequence of a laboratory strain of lambda has been determined. For natural lambdoid phages, some sequences of some complete or nearly complete genomes (as well as many shorter segments) are available. Genes are arranged in functional clusters, the main groups being (in order along the DNA) head genes, tail genes, integration genes, regulatory genes, replication genes and lysis genes. The recognition sites of proteins for regulation, integration and replication are generally close to or within the structural genes for these proteins, e.g. the origin of replication lies within the *O* gene, the product of which determines specificity of initiation.

When any two lambdoid phages are compared, the sequences are very similar in some parts of the genome and highly divergent in others, the transitions from similarity to dissimilarity generally being abrupt. Each phage pair has its unique pattern of similarity and dissimilarity indicating that the phages are related by frequent recombination in nature.

The base composition of lambda DNA is 50% AT:50% GC. Within each strand, the ratios of the four bases are close to 1:1:1:1. However, the base ratios are not statistically uniform throughout the genome. The left 44% of the genome is 57% GC, the right 56% is 44% GC and within each half smaller AT-rich and GC-rich segments occur. The same pattern of base sequence heterogeneity is observed in lambdoid phages, even within segments that have diverged extensively from lambda. Also, within a strand, the G:C ratio is not uniform throughout but shifts between regions of leftward and rightward transcription. As in *E. coli*, the G:C ratio within genes is slightly higher in the coding versus the noncoding strand, because of the pattern of codon usage.

Growth Cycle (Lytic)

In infection, DNA is injected through the phage tail and the cell envelope. Soon after injection the complementary 12 bp terminal overhangs pair, and the nicks are sealed by the host-encoded DNA ligase, converting the linear DNA into a ring. This ring subsequently replicates bidirectionally from a unique origin. At late times, the major mode of replication is rolling circle, where multigenomic double-stranded tails are spun off by replicating circles. These multigenomic tails are the major natural substrate for DNA packaging into preformed heads. Head assembly requires several viral proteins as well as the host-encoded chaperonin GroE. In packaging, DNA is cut at specific sites (*cos*) in a manner that generates the 12-base single-stranded overhangs ('cohesive sites') found in virion DNA. Packaging is processive and proceeds from left to right on the conventional map. Lambdoid phages frequently differ in their recognition sites for *cos* cutting and in their cognate recognition proteins even where the actual cutting sites are identical.

Replication proteins are preferentially synthesized at early times, whereas virion components and other assembly proteins and lysis proteins are made later. Temporal coordination of the various syntheses is achieved through a balance of positive regulation by antitermination and negative regulation by repression.

Following injection, early transcription by host RNA polymerase is initiated divergently from two promoter sites, *pL* and *pR*. The first gene transcribed leftward is gene *N*, whose product gp*N* renders transcripts from *pL* and *pR* resistant to termination at transcription stop signals, by a mechanism dependent on N-utilization (*nut*) sites downstream from and close to *pL* and *pR* respectively. Rightward transcription from *pR* produces Cro protein, which binds to sites overlapping *pL* and *pR* and represses transcription from them. When antiterminated by gp*N*, the rightward transcript proceeds through the replication genes *O* and *P* and the late regulator gene *Q*. Antitermination of the leftward transcript results in expression of genes (*red*) that affect recombination and enhance replication.

The accumulation of Cro protein with time gradually reduces early gene transcription. As transcription of the *cro* gene itself is repressed by Cro, the level never reaches the point where shutoff is complete. Concurrently, the number of phage genomes available for transcription is amplified by replication, and the late genes for lysis and virion components are turned on through antitermination effected by gp*Q*. The time of lysis is determined by the accumulation of gp*S*, which destroys the cell membrane, providing access of the other major lytic protein gp*R* to its substrate, the rigid murein layer of the cell envelope. At lysis, about 100 progeny virions per cell are liberated. The time from infection to lysis is about 35 min at 37°C.

Lysogeny

Only a fraction of infected cells undergo a lytic cycle. The others survive infection and thereafter harbor the phage genome as a quiescent prophage. The genetic switch determining which pathway is chosen has been studied intensively. The decision to survive and become lysogenic requires expression of gene *c*I (which encodes a repressor that shuts off lytic functions) and of gene *int* [which encodes the integrase protein which mediates reciprocal recombination between specific sites (*att*) on phage and host DNA, resulting in insertion of the circular phage DNA into the bacterial chromosome]. Synthesis of repressor and integrase is coordinated because both of their structural genes are transcribed from promoters that are activated by the same macromolecular effector, gp*c*II. The gp*c*II protein is subjected to rapid *in vitro* proteolysis unless stabilized by a second viral protein gp*c*II. Transcriptional activation by gp*c*II is highly concentration dependent. Because gp*c*II is unstable (even with gp*c*III), achievement of a concentration high enough to initiate the lysogenic pathway requires a rapid rate of gp*c*II synthesis.

The *c*II and *c*III genes are located in the early right and left transcript respectively downstream from the first site for transcription termination. Therefore, a high rate of *c*II and *c*III transcription requires antitermination by gp*N* and is prevented by repressing concentrations of Cro. Being fairly stable, Cro accumulates with time, eventually reducing the rate of early transcription so that an effective concentration of gp*c*II can never be achieved and the cell is committed to the lytic pathway. Thus the decision of an individual cell to lyse or to become lysogenic ultimately turns on a race between *c*II and *N* on the one hand and *cro* on the other. The system is so poised that, under a wide range of ambient conditions, some cells go in one direction and some in another. The proportion of cells choosing the lysogenic pathway increases with multiplicity of infection, with intracellular cyclic AMP concentration and with concentration of divalent cations.

Once lysogeny is established, repressor turns off the transcription of *c*II and *c*III as well as genes for repression and late gene activation. Repressor synthesis continues in the absence of gp*c*II because *c*I transcription is now initiated at a *c*II-independent promoter. The maintenance promoter is adjacent to the operator sites that control early rightward transcription and is activated by repressor binding, so that repressor synthesis, once established, is self-sustaining.

In a lysogenic culture, repression breaks down in occasional cells, which then switch to the lytic cycle. The prophage is excised from the chromosome, and phage development follows. The extent of the rare spontaneous derepression depends strongly on the host RecA protein.

Mass derepression of a lysogenic culture is induced by treatment with ultraviolet light or other DNA-damaging agents that turn on a battery of repair genes (SOS response). SOS induction results from cleavage of the LexA protein, which represses the repair genes. The initiating event is activation (by products of DNA damage) of the RecA protein's ability to accelerate LexA cleavage. The lambda repressor, like LexA, is cleaved in the presence of activated RecA. Mutations in the *c*I gene that alter the cleavage site render the repressor resistant to RecA and make the phage noninducible by SOS-inducing treatments.

More synchronous mass derepression is conveniently achieved experimentally by heating a lysogen, the prophage of which makes a mutant, thermolabile repressor.

Prophage insertion and excision require a phage protein, integrase. The site-specific recombination takes place within a 15 bp segment that is identical in phage and host. Initial cleavage at a precise position within the 15 bp on DNA strands of identical polarity in phage and host, with transient covalent binding of enzyme to DNA, is followed by crossjoining of the broken strands to give a Holliday structure. Branch migration by 7 bp occurs next, and crossjoining of the other two strands completes the recombination. All this proceeds without loss of phosphodiester bond energy or complete relaxing of supercoiling. The specific sequence required on the bacterial partner is 21 bp, including the 15 bp identical segment within which branch migration occurs. The specific sequence required on the phage DNA is more than 200 nucleotides and includes several integrase-binding sites in the arm regions flanking the crossover point. Several integrase molecules bind concurrently to these sites, bending the DNA around a complex termed an intasome. A host protein, integration host factor (IHF), required for insertion and excision, binds to DNA in the arm regions and promotes DNA binding. IHF is also a positive regulator of gp*c*II synthesis. Excision of prophage from the chromosome requires, in addition to integrase and IHF, a small protein, excisionase, encoded by a gene just upstream from *int* and overlapping it by 20 bp.

When an infected cell becomes committed to lysogeny, integrase is transcribed by a *c*II-activated promoter from a start site within the excisionase gene. Thus integrase but not excisionase is formed. In a derepressed prophage, excisionase and integrase are transcribed coordinately from *pL* on a transcript antiterminated by gp*N*. In infected cells committed to

lysis, leftward transcription begins in the same way; however, downstream from the *int* gene, the transcript consists of phage rather than host DNA and includes an RNase III processing site (*sib*) which allows 3′ → 5′ degradation of the transcript. This regulatory effect of a downstream site (retroregulation) serves to reduce the amount of integrase in cells committed to lysis. Finally, in a repressed prophage, integrase is expressed at a low basal level from the gp*c*II-activatable promoter, while excisionase expression is undetectable. Thus at every stage of the life cycle, the *int* and *xis* genes are regulated in a manner consistent with cell fate.

Genetic Recombination

Comparison of lambdoid phage genomes indicates that recombination in nature is frequent. The most common confrontation generating natural recombinants is probably between an infecting phage and a prophage or defective prophage of the host.

In the laboratory, recombination is generally studied by mixed infection. Three recombination pathways are known: the host pathway (dependent on the *recABCD* genes), the phage general recombination pathway (dependent on phage *redX* and *redB*) and the integrase pathway, causing recombination only at the *att* site. Phages mutant in *red* genes produce less DNA and fewer progeny than wild-type phage, indicating that the most direct role of the pathway in phage biology is probably resolution of replication intermediates rather than generation of diversity in natural phage populations. Individually and jointly, the *rec* and *red* pathways generate linear recombination maps congruent with the disposition of genes on linear virion DNA.

In Vitro Replication

The steps in replication initiation have been studied in detail and resemble those for *E. coli*. Initiation requires formation and subsequent dissociation of a specialized nucleoprotein complex. First, four dimers of lambda protein gpO bind to DNA sites at the replication origin. Protein–protein interactions bring the gp*O* dimers together, with a stretch of DNA wound around them. The lambda protein gp*P* forms a heterodimer with the host helicase DnaB, and two such heterodimers bind to gpO. Interaction with the host heat-shock protein complex DnaJ–DnaK–GrpE causes, in several steps (one of which is ATP-dependent), expulsion of gp*P* together with DnaJ–DnaK–GrpE. The two copies of DnaB then unwind the DNA in opposite directions initiating bidirectional replication.

The phage-coded proteins gpO and gp*P* thus function only in initiation, serving to position DnaB so that elongation can begin. Subsequent replication is carried out by host enzymes.

Restriction/Modification

Lambda is subject to the restriction/modification systems of the hosts on which it grows. The first Type I restriction system known (that distinguishing the K-12 and B strains of *E. coli*) was discovered with lambda. A phage gene, *ral*, reduces the severity of restriction, probably by promoting modification of infecting DNA before restriction enzymes reach it. Lambda does not encode any restriction/modification system of its own. However, lambda prophages interfere with the development of some unrelated phages (such as *r*II mutants of phage T4) by virtue of two genes *rexAB* cotranscribed with the repressor gene *c*I. Neither *rex* nor *ral* is required for the lytic or lysogenic cycle, and these genes are not present in all lambdoid phages.

Plasmid Formation

Wild-type lambda is not perpetuated as a plasmid. However, lambda mutants defective in the early regulatory gene *N* as well as certain deletions removing most of the lambda genome (λ *dv*) can persist as highly unstable plasmids. The minimal requirements for plasmid formation are the rightward promoter *p*R, the replication genes *O* and *P*, and the *cro* gene to prevent their overexpression.

Cloning Vehicles

The unique sequence of virion DNA, the ability to package DNA *in vitro* into phage particles, and the formation of stable lysogens have made lambda a convenient vector for DNA cloning. Many derivatives of lambda have been constructed with improved utility as cloning vectors.

In the early 1970s, lambda derivatives were engineered to contain single cleavage sites for some common restriction enzymes. A lambda-size DNA molecule is expected to contain about 10 cleavage sites for a six-cutter like *Eco*RI. Lambda contains five. Four were removed by deletion of nonessential DNA or by recombination with lambdoid phages to substitute segments that lacked *Eco*RI sites of lambda.

Lambda can package and inject DNA molecules about 75–110% of the normal 48 kb genome length. The genes necessary for lytic development comprise only about 60% of the 48 kb. Deletions removing most of the dispensable 40% increase the possible insert length. Even longer inserts can be cloned into

vectors containing the *cos* sites but lacking much of the functional phage DNA, which can be perpetuated in the presence of a helper lambda phage.

Early vector construction was influenced by safety regulations dictating minimization of the probability that lambda carrying foreign DNA might multiply outside the laboratory. Lytic replication was forestalled by the presence of multiple amber mutations. Survival as prophage was made unlikely by deletion of the insertion site and integrase gene and by mutation (or disruption during cloning) of the *cI* gene. The possibility of plasmid formation was reduced by deleting a terminator site for rightward transcription (*nin5* deletion), allowing lytic replication even in absence of gp*N*. Legal restrictions have now been relaxed, but some current vectors still bear traces of these early constructions.

COMOVIRUSES (*COMOVIRIDAE*)

George P Lomonossoff and **Michael Shanks**, Department of Virus Research, John Innes Centre, Norwich, UK

Taxonomy and Classification

There are 15 different viruses in the genus *Comovirus* of the family *Comoviridae*. These are cowpea mosaic virus (CPMV; type member of the group), Andean potato mottle virus (APMV), bean pod mottle virus (BPMV), bean rugose mosaic virus (BRMV), broad bean stain virus (BBSV), broad bean true mosaic virus (BBTMV), cowpea severe mosaic virus (CPSMV), glycine mosaic virus (GMV), pea green mottle virus (PGMV), pea mild mosaic virus* (PMiMV), quail pea mosaic virus (QPMV), radish mosaic virus (RaMV), red clover mottle virus (RCMV), squash mosaic virus (SqMV) and ullucus C virus (UCV). Two additional genera, *Fabavirus* and *Nepovirus*, are in the *Comoviridae* family.

Biological Properties of Viral Particles

Viral particles generally reach a yield of between 0.1 and 2 g per kg of fresh plant tissue. The thermal inactivation point of viral particles in plant sap is in the range 60–75°C and the particles have a longevity in sap of between 2 and 112 days at room temperature.

Serology

The viral particles of all comoviruses are good antigens in rabbits and antiserum titres of 1/1000 are easily obtainable. Occasionally titres as high as 1/8000 have been reported. Every member of the group has been shown to be serologically related to at least one other member, although sometimes the relationship is distant.

Physical Properties of Viral Particles

Comovirus preparations consist of nonenveloped isometric particles, 28 nm in diameter, which can be separated into three components designated top (T), middle (M) and bottom (B) by centrifugation on sucrose density gradients. The exact sedimentation coefficients of the components vary slightly with the virus being analysed but are typically in the range 50–60 S for T, 90–100 S for M and 110–120 S for B components. The three components have identical protein compositions, containing 60 copies each of a large (L) and small (S) coat protein. The sizes of the two proteins vary, depending on the virus, but lie in the ranges 37–49 kDa for the L protein and 18–26 kDa for the S protein. The difference between the three centrifugal components is in their RNA contents. Top components are devoid of RNA, while middle and bottom components each contain single molecules of RNA of approximately 3.5 and 6.0 kb, respectively. The two RNA molecules were originally termed middle (M) and bottom (B) component RNA after the component from which they were isolated; however, more recently they have been referred to as RNA2 and RNA1, respectively. The three-compo-

COLIPHAGE φX174 AND RELATED PHAGES (*MICROVIRIDAE*)

David T Denhardt, Department of Cell Biology and Neuroscience, Nelson Laboratories, Rutgers University, Piscataway, New Jersey, USA

Taxonomy, Classification and Ecology

φX174 and its close relative S13 are members of the family *Microviridae*, genus *Microvirus*. They were found to be among the smallest DNA bacteriophages in the early days of phage research (1920–1950) but they were not particularly popular as subjects of study because they were less easy to work with than the T phages and not as intriguing as temperate phages such as lambda. However, the physicochemical studies of Robert Sinsheimer and the genetic studies of Irwin Tessman convinced many members of a generation of phage workers to concentrate their efforts on these organisms (see Denhardt *et al* in the Further Reading list for a review of this period). A major defining characteristic of these phages is their possession of a single molecule of single-stranded circular DNA as their sole genetic material. Other members of this group, less closely related to φX, include α3, St-1 and G4. They all grow on various strains/species of Enterobacteriaceae, typically *Escherichia coli, Salmonella* and *Shigella* species, and are found wherever these bacteria are found. *E. coli* C is the best host for many isolates, though phage able to grow on *E. coli* B (e.g. α3) and *E. coli* K12 (e.g. St-1) are also known.

The reviews by Hayashi *et al* and Baas and Jansz in the Further Reading List contain details and references that of necessity are omitted here. Most of the specific information presented below concerns φX174 ('phi-ex'), and is assumed to apply to all members of this group unless indicated otherwise.

Virion Structure and Proteins

Several views of the virion are depicted in **Fig. 1**. There are 12 spikes projecting about 3 nm from an icosahedral core roughly 26 nm in diameter. The core capsid consists of 60 molecules each of F and J proteins enclosing a circular single-stranded DNA of 5386 nucleotides (almost 6000 for St-1). Interactions between the DNA and amino acids in the F and J proteins neutralize much of the negative charge on the DNA (polyamines and other cations neutralize the rest) and substantially restrict both base stacking and

Incardona, University of Tennessee–Memphis.)

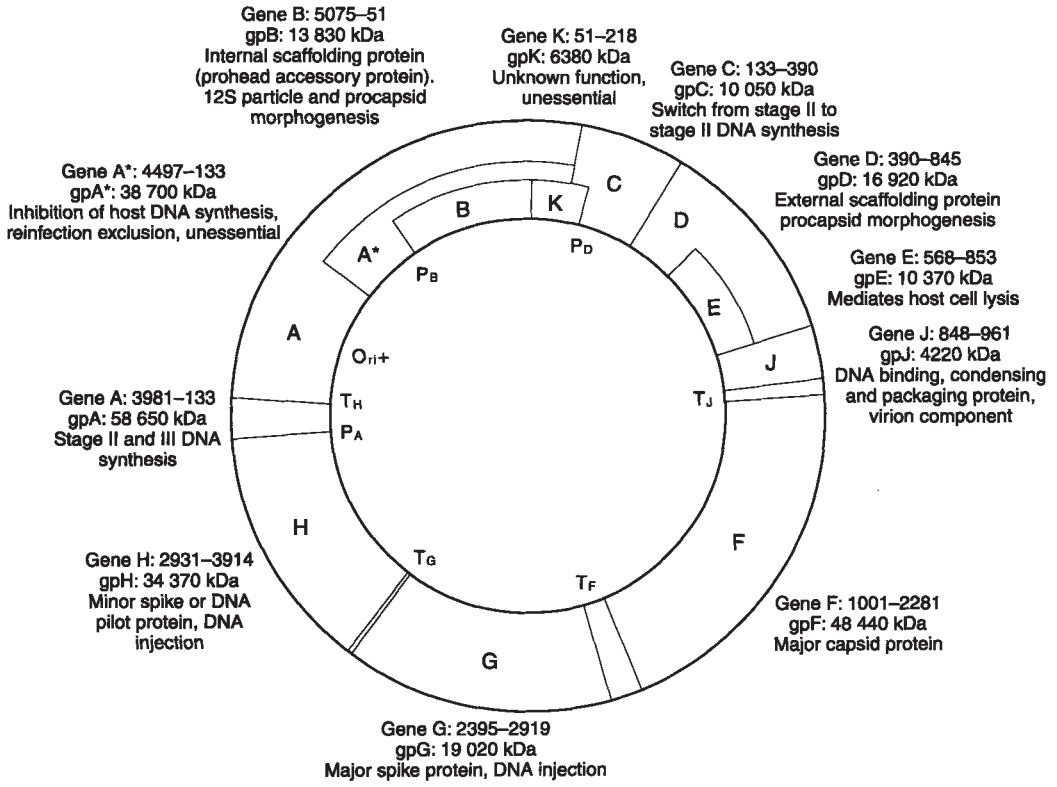

Figure 2 Genetic and functional map of ϕX174. The nucleotides in the 5386-nucleotide circle are numbered starting at the unique *PstI* site in gene A, which is near the 3′ end of the gene. Ori$^+$ indicates the site of gene A cleavage, the origin of RF replication. Genes A through H, K and J are shown along with the extent of gene overlap (B and E are completely within A and D respectively; K overlaps both A and C). The molecular weights indicated for each protein are those predicted by the base sequence. P_x and T_x indicate the major sites of transcription initiation and termination. Intergenic regions are unlabeled. Transcription of all the genes is in the clockwise direction. (Courtesy of Ben Fane.)

hairpin formation. Embedded in the capsid at the 12 vertices of the icosahedron with fivefold symmetry are the 12 spikes, each of which is composed of five molecules of protein G and one molecule of protein H. Mutations affecting host specificity have been found in genes F, G and H. The major motif in the F and G proteins is an eight-stranded antiparallel β barrel. About 180 water molecules stabilize the spike–capsid interactions. A hydrophilic channel that extends through each spike is plugged by a molecule of H protein.

Genome Structure

A genetic map of the circular genome with the approximate sizes and functions of the encoded proteins is shown in **Fig. 2**. The single-stranded DNA of each phage particle has the same polarity, defined as 'plus' since it is the same as the viral mRNA. ϕX was the first DNA-containing organism to have its genome completely sequenced, and a major surprise resulting from this work of Fred Sanger was the revelation that genes could overlap – that the same DNA sequence could encode information for more than one protein using different reading frames. This strategy to maximize genome utilization is of particular advantage to these phages because of the stringent limitation on the amount of DNA the capsid can contain. Some of the complications that arise as the consequence of gene overlap have been discussed (see Hayashi *et al* in the Further Reading list). Together, 11 genes have been defined by virtue of their protein products; eight of these (A, B, C, D, F, G, H and J) are essential for virus reproduction. Gene A* protein acts to suppress host DNA replication, gene E is responsible for cell lysis, and gene K appears somehow to enhance phage yields.

Replication

The virion attaches first to the core oligosaccharide of the lipopolysaccharide (LPS) of sensitive bacteria. Cooperative interactions of several spikes with several LPS molecules accompanied by host-induced

alterations in the coat structure of the virus make the adsorption process irreversible. Genetic analysis of host cell adsorption mutants suggests that uncoating and effective infection (eclipse) require the interaction of the virion proteins with several host cell proteins in the cell wall/membrane. Release of the circular single-stranded DNA through an opening in one of the spikes into the cell occurs at points of adhesion between the cell wall and the inner membrane.

As it enters the cell the DNA is rapidly complexed with single-stranded DNA binding protein (SSB) and becomes a template for the synthesis of a complementary minus strand (stage I synthesis). Some experiments suggest that *in vivo* this process is facilitated by the gene H protein (carried into the cell with the DNA) and host membrane proteins. A DNA sequence in the H/A intergenic region, called the 'reduction' or 'incompatibility' sequence, can, when already present in the cell in other DNA molecules, inhibit stage I DNA synthesis. This is presumably a sequence in the DNA that interacts with a cellular component, possibly a membrane site, present in very limited amounts in the cell. The result is to exclude superinfecting phages from establishing a successful infection. Initial effects of virus infection on host cell metabolic processes and macromolecular syntheses are minimal. Later in infection however the A* protein, which has the same amino acid sequence as the C-terminal two-thirds of the A protein, interrupts host DNA replication.

The replication of the viral genome occurs in three stages, models of which are shown in **Fig. 3**: stage I, synthesis of a complement (the 'minus' strand) to the viral strand; stage II, replication of the duplex viral DNA; stage III, generation of progeny single-stranded DNA. Interestingly, different members of the isometric and filamentous phages exploit different host enzyme systems to synthesize the complementary strand when the single-stranded DNA is complexed with SSB.

In stage I, the first event is the assembly of a preprimosome, composed of the proteins PriA, PriB, PriC, DnaT and DnaB, on single-stranded ϕX174 DNA coated with SSB. PriA recognizes a unique sequence (variously called n′ or *pas*, for primosome assembly site, in the F/G intergenic region) that is capable of forming stem-loop structures. PriB and PriC act as stability and specificity factors, while DnaT and DnaC promote the loading of DnaB. The hexameric DnaB is a bidirectional processive helicase that encircles ('clamps') the DNA. This preprimosome complex then associates with the DnaG primase to produce the primosome. As illustrated in **Fig. 3A**, the primosome migrates 5′ → 3′ (clockwise in **Fig. 2**) along the SSB-coated template strand, occasionally enabling the DnaG primase to synthesize a short RNA molecule that can serve to prime DNA synthesis by DNA polymerase III holoenzyme. After the RNA primers are replaced with DNA by DNA polymerase I, the adjacent DNA strands are joined by DNA ligase.

Unlike ϕX174, G4, α3 and St-1 all require only the DnaG primase to synthesize primers for complementary strand synthesis. This is because of the presence in the F/G (for G4) or G/H (for α3 and St-1) intergenic regions of a sequence forming several stem-loop structures that can interact with the DnaG protein in a manner that permits an RNA primer to be generated. As discussed elsewhere in this volume, the filamentous phages make use of RNA polymerase to synthesize a primer for complementary strand synthesis. None of the isometric phages appear to have a hairpin loop structure of the sort found in the filamentous phages that allows priming by RNA polymerase on SB-coated single-stranded DNA.

Completion of the complementary minus strand, including removal of RNA primers and ligation of the intermediate fragments, results in a closed circular duplex molecule called replicative form one (RFI). This molecule has a new topological property called

Figure 3 Replication of ϕX174 DNA. (**A**) Stage I synthesis starts in the upper left with the circular single-stranded DNA template (5′ → 3′ polarity is clockwise) coated everywhere with SSB except for the intergenic region between genes F and G which is believed to possess a stem-loop structure that renders it accessible to PriA protein (note that the orientation of the molecule differs from that shown in **Fig. 2**). Interactions with various bacterial proteins, described in the text, give rise to a protein complex (the primosome) that migrates around the circular DNA, leaving behind an occasional RNA primer synthesized in a retrograde fashion by primase. Successive actions by DNA polymerase III holoenzyme and DNA polymerase I generate a complementary minus-strand; polynucleotide ligase closes the nicks and generates a covalently closed circular RF structure, which becomes superhelical in part as the result of the action of DNA gyrase. The primosome may remain associated, as shown, with the RF molecule that contains the infecting viral strand, the 'parental' RF. (**B**) Both stage II and stage III synthesis begin with the cleavage of an RFI molecule by gpA at a unique location. The REP helicase interacts with gpA and begins to unwind the duplex. DNA polymerase III elongates the viral plus-strand to generate a new RF molecule shown largely complete at the lower right. The 'displaced' plus strand has two potential fates: in stage III synthesis, dependent upon gpC, it becomes incorporated into a virion as illustrated in **Fig. 4**. In stage II (RF replication) it is a substrate for minus-strand synthesis, which may occur by essentially the same process as described for stage I synthesis. (These illustrations are redrawn from Kornberg A and Baker T *DNA Replication*, 2nd edn, 1991, with permission from W. H. Freeman, New York.)

the winding number – the number of times each polydeoxynucleotide strand winds about the other. This number is a topological constant for any given closed circular duplex; it can be broken down into the sum of two other numbers, the duplex winding number and the superhelical winding number. The latter can be positive or negative, and in either case (when not zero) causes the RF molecule to be in a more compact, superhelical (or supercoil) structure. A break in a phosphodiester bond of either strand permits free rotation about the bond opposite the break, allowing the winding number to change. The resulting molecule, RFII, is still circular but no longer topologically constrained. It can be distinguished from RFI in various ways, particularly its response to intercalating agents. The linear duplex is known as RFIII.

In stage II, the duplex RF serves first as a substrate for the host RNA polymerase and second, when the ϕX174 gene A protein (gpA) appears, as a substrate for replication by host DNA replication enzymes. Gene A protein cleaves a phosphodiester bond in the RF molecule at a unique sequence within gene A (the 'origin' region consisting of some 30 bp) and becomes covalently bound to the 5′ phosphate of the viral plus strand via a tyrosine residue. The *E. coli* Rep helicase interacts with the gpA/RFII molecule and in an ATP-dependent process, likely facilitated by SSB, unwinds the two strands of the duplex. In a coordinated process DNA polymerase III holoenzyme, using the 3′-OH of the cleaved plus-strand as a primer, synthesizes a new plus-strand on the minus-strand template. This is called 'rolling circle' replication, the hallmark of which is a replication intermediate containing a longer-than-unit-length viral DNA molecule. When the primosome assembly site on the displaced SSB-coated single-stranded plus strand becomes available, the process of synthesizing a new minus-strand may commence in a manner considered similar to that used in stage I synthesis.

When the REP/gpA–5′DNA end complex completes its circuit around the circular minus-strand template, displacing the original plus-strand from its minus-strand partner, the bond joining the new and old viral strands (the regenerated origin) is cleaved, and the protein-bound 5′ end of the old viral strand is joined to its newly created 3′ end with transfer of gpA to the newly created 5′ end, thereby setting the stage for a new round of replication. There appear to be two nearby tyrosine residues in gpA that participate in this exchange reaction, taking turns during each round of replication in serving to join gpA to the 5′ terminus. Completion of synthesis of the new minus-strand on the displaced plus-strand, presumably by a process like that described for stage I synthesis, produces the second of the two products of RF replication. The obvious asymmetry in the two products of replication likely explains why the RF molecule with the original infecting viral strand is preferentially replicated in repeated rounds of replication (the 'parental' RF, possibly in association with a special region of the host cell inner membrane).

Stage II replication generates 10–50 RF molecules, all of which serve as templates for RNA synthesis; some of them also become substrates for the synthesis of progeny plus-strand circular DNA molecules that occurs during the second half of the ϕX life cycle. The switch from stage II to stage III is precipitated by gpC (not shown in **Fig. 3B**), which binds to the gpA/REP/RFII molecule and somehow blocks them from serving as substrates for RF replication and redirects them to participate in the exclusive synthesis of single-stranded viral DNA. This latter process requires additional virus-encoded proteins, and is intimately tied into the morphogenesis of the virus particle as shown in **Fig. 4**.

The first step in the morphogenesis of the virion entails the assembly of the F and G proteins into 9S and 6S pentamers, which then come together under the influence of the B protein to form the 12S subunit. Further interactions with monomeric H and tetrameric D proteins yield the 108S procapsid structure, which is poised to interact with an RF molecule made ready by interactions with the A, C, J and REP proteins to generate, with the help of host cell enzymes, a single-stranded circular DNA molecule. Studies by Incardona, Rossmann and their colleagues have established that proteins B and D serve as internal and external scaffolding proteins, stabilizing intermediate structures and catalyzing steps in the assembly of the virion. B protein is displaced from the virion by the J protein that enters with the DNA, consistent with the fact that B and J both interact with the same interaction site on F. Formation of the mature 114S phage particle and loss of the external scaffolding protein gpD is stimulated by the increase in Ca^{2+} that occurs upon cell lysis.

Shortly after the appearance of mature virus-particles the bacterial cells begin to lyse as the result of the expression of gene E. E protein is produced in small amounts (several hundred molecules per cell) because of a weak ribosome-binding site, the presence of many rare codons in the message and possibly competition from ribosomes translating the overlapping D gene. Frameshifting of ribosomes initially translating the gene D message may also contribute to gene E expression. Gene E protein is not a lysozyme, and no enzymatic activities that might cause cell wall degradation have been detected in ϕX-infected cells. Only growing cells with a fluid membrane, an active

proton motive force, and appropriate genotype (*sly*D$^+$, *lyt*A$^+$) are lysed. SlyD is a peptidyl-prolyl *cis-trans* isomerase, or rotamase, that potentiates E function. Lysis occurs as the result of a defect induced by E protein in the cell pole (site of cell elongation) or the incipient septum (site of cell division). This defect results in a tunnel through the cell wall through which the membrane-encased cytoplasm begins to extrude in the form of a bleb (**Fig. 5**). The bleb bursts (unless osmotically stabilized) and releases the cytoplasmic contents of the cell into the medium. Murein degradation is minimal; the lysed cell retains most of its structural integrity and most of the periplasmic proteins remain sequestered. Under favorable conditions a burst size of several hundred phages can be obtained; with certain mutant phages even larger burst sizes are observed.

Gene Expression/Transcription/ Translation/*Cis*-acting Proteins

Compared to other phages, these phages have one of the least elaborate sets of controls over gene expression. Most RNA transcripts originate (see **Fig. 2**) at one of three promoters (P_A, P_B and P_D) in the RF. The degree of superhelicity has a minor effect on the relative efficiency with which the different promoters are used. There are four major transcription terminators (T_J, T_F, T_G and T_H) acting with moderate efficiencies independently of *rho* for the most part and giving rise (with the three promoters) to some 10 species of RNA. With exceptions for the overlapping genes, particularly E, proteins needed in larger amounts are encoded in the more abundant classes of message. Most of the mRNA molecules are polycistronic, and each gene has its own translational start and stop signals. mRNA molecules terminating at T_J have a half-life a few minutes longer than the others because of the presence of a stabilizing sequence in the J/F intercistronic region. Also contributing to the differential synthesis of the viral proteins is the efficiency with which the viral mRNAs are translated.

The gene A protein is an example of what is known as a '*cis*-acting' protein. These are proteins that phenomenologically (in genetic complementation studies) appear to act only on the specific DNA molecule from which the mRNA encoding them is

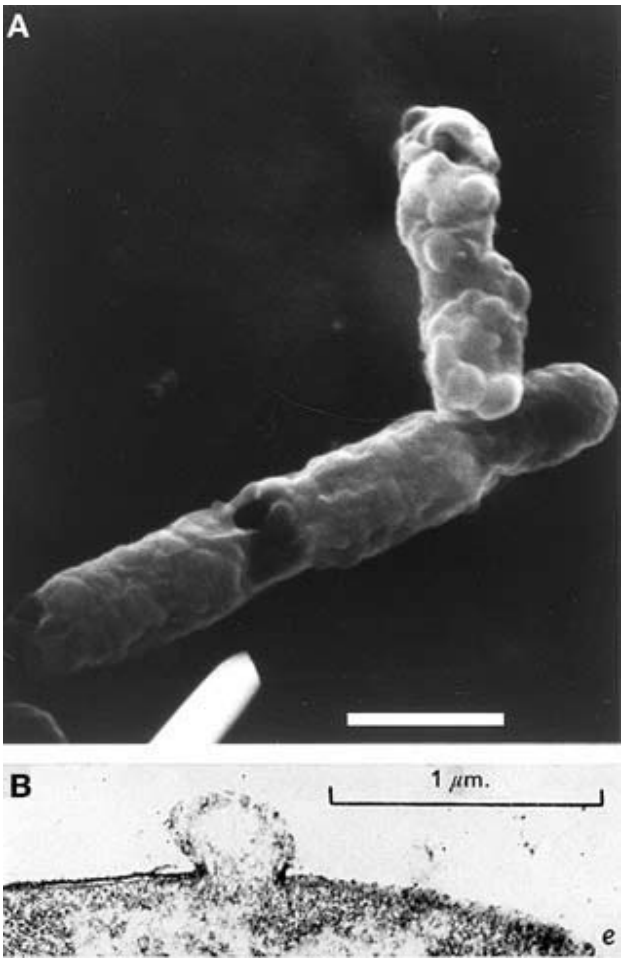

Figure 5 Gene E-mediated lysis. (**A**) is a high-resolution field emission scanning electron microscope image of an empty bacterial ghost after E-induced lysis. transcribed. Although other explanations are possible, a reasonable hypothesis is that such *cis*-acting proteins are proteins that bind to a DNA sequence in or near the gene encoding it; in this case gpA binds to the origin sequence within the gene. Most functionally inactive (mutant) versions of gpA likely retain the ability to bind to the origin sequence, and in these cases they would then physically prevent functional (nonmutant) gene A protein, made by another viral RF molecule at a geographically distant location, from accessing the substrate.

Recombination: Use as a Cloning Vehicle

The replicative forms of these phages appear to undergo normal recombination using host cell enzymes; however, because of the small size of the genome and the short life cycle, which limits the time available for recombination to occur, recombination is relatively rare and usually limited to a single event in any one infected cell.

Because of the constraints on the size of the DNA that can be incorporated into the mature virion, the isometric phages are not very useful as cloning vehicles; however, recent efforts to increase the amount of DNA that can be packaged by mutating the J protein have permitted larger amounts of DNA to be packaged.

In vitro Replication

The small size of the DNA of these phages made them extremely attractive experimental systems for the development of *in vitro* DNA-replicating systems. Because even such a simple step as the synthesis of a complement to the ϕX174 single-stranded DNA requires many of the same enzymes that *E. coli* requires for replicating its more complex duplex DNA, studies of this process have contributed enormously to our understanding of the enzymology of bacterial DNA replication. Pioneering efforts in the laboratories of Arthur Kornberg and Jerald Hurwitz uncovered many aspects of the process of synthesis of DNA complementary to the viral strand, and this work was later extended to studies on replication of the double-stranded RF molecule. Research in these laboratories and others using highly purified proteins and DNA templates complexed with the *E. coli* single-stranded DNA-binding protein has clarified many details of the *in vivo* replication process.

The conversion of the single-stranded circle to a double-stranded molecule is a model for the synthesis of Okazaki fragments on the so-called lagging strand of duplex DNA – that DNA strand whose polarity is such that it must be synthesized in the opposite direction from the direction the replicating fork is moving. The synthesis of the viral plus-strand has provided one model for how the 'leading strand' could be synthesized, at least at the origin of replication. Stage III replication and its dependence on phage morphogenesis was largely worked out in Masaki Hayashi's laboratory. Although biochemical studies in the test tube are essential for a complete understanding of events in the intact cell, they are only indicative of what *can* happen; proof that a mechanism elucidated *in vitro* accurately describes

the *in vivo* process requires that all aspects of the *in vivo* process be mimicked *in vitro*.

COLIPHAGE LAMBDA (*SIPHOVIRIDAE*)

Allan M Campbell, Stanford University, Stanford, California, USA

Introduction

The double-stranded (ds) DNA phage lambda belongs to a group of related temperate phages (the lambdoids) whose natural hosts are *Escherichia coli* and other members of the *Enterobacteriaceae* and whose distribution is worldwide. Most lambdoid phages share a common genetic map but have undergone substantial divergence in sequence and specificity of traits such as repression or prophage location; collectively they present a combinatorial array of such specificities almost certainly generated by natural recombination. The major collections of lambdoid phages used in comparative studies were isolated in France (phages 21, 82, 381, 424, 434, 466), Japan (ϕ80), Hong Kong ('HK' phages) and the area formerly known as the Soviet Union.

Lambda-related sequences are present in the genomes of many enterobacterial isolates, even where active phage is not produced. These appear to result from lysogenization followed by progressive mutation to loss of function, including deletion of large segments of the prophage. Lambda was found in the K-12 strain of *E. coli*, which harbors at least four incomplete lambdoid prophages. In research, a derivative phage selected for larger plaques and better lytic growth than shown by natural lambda is standardly used.

The K-12 strain was isolated from a Stanford hospital patient in 1926. The presence of lambda was first reported in 1951. Because the genetics of the host was already developed at that time, lambda was studied more intensively than other temperate phages. Largely because of this happenstance, lambda became the model temperate phage, in which repression, regulation and integration were studied in depth. When methods for DNA cloning were developed in the 1970s, the accumulated information on lambda facilitated manipulation of its genome to make it the most commonly used double-stranded phage cloning vector.

Taxonomy and Classification

Coliphage lambda is in the genus 'Lambda-like phages' of the *Siphoviridae* family.

Virion Structure

Each lambda virion contains one linear dsDNA molecule 48 514 bp in length, with complementary 12-base single-stranded 5′ overhangs at the ends. The DNA is packaged within a regular icosahedral head 54 nm in diameter, attached to a flexible tail 173 nm in length. The major capsid proteins (gp*D*, gp*E*) are present in 420 monomer units each, in a $T = 7$ configuration with gp*E* grouped as trimers and gp*D* as hexamers. Heads lacking gp*D* can package and inject DNA but have a smaller diameter than normal heads

vectors containing the *cos* sites but lacking much of the functional phage DNA, which can be perpetuated in the presence of a helper lambda phage.

Early vector construction was influenced by safety regulations dictating minimization of the probability that lambda carrying foreign DNA might multiply outside the laboratory. Lytic replication was forestalled by the presence of multiple amber mutations. Survival as prophage was made unlikely by deletion of the insertion site and integrase gene and by mutation (or disruption during cloning) of the *cI* gene. The possibility of plasmid formation was reduced by deleting a terminator site for rightward transcription (*nin5* deletion), allowing lytic replication even in absence of gp*N*. Legal restrictions have now been relaxed, but some current vectors still bear traces of these early constructions.

COMOVIRUSES (*COMOVIRIDAE*)

George P Lomonossoff and **Michael Shanks**, Department of Virus Research, John Innes Centre, Norwich, UK

Taxonomy and Classification

There are 15 different viruses in the genus *Comovirus* of the family *Comoviridae*. These are cowpea mosaic virus (CPMV; type member of the group), Andean potato mottle virus (APMV), bean pod mottle virus (BPMV), bean rugose mosaic virus (BRMV), broad bean stain virus (BBSV), broad bean true mosaic virus (BBTMV), cowpea severe mosaic virus (CPSMV), glycine mosaic virus (GMV), pea green mottle virus (PGMV), pea mild mosaic virus* (PMiMV), quail pea mosaic virus (QPMV), radish mosaic virus (RaMV), red clover mottle virus (RCMV), squash mosaic virus (SqMV) and ullucus C virus (UCV). Two additional genera, *Fabavirus* and *Nepovirus*, are in the *Comoviridae* family.

Biological Properties of Viral Particles

Viral particles generally reach a yield of between 0.1 and 2 g per kg of fresh plant tissue. The thermal inactivation point of viral particles in plant sap is in the range 60–75°C and the particles have a longevity in sap of between 2 and 112 days at room temperature.

Serology

The viral particles of all comoviruses are good antigens in rabbits and antiserum titres of 1/1000 are easily obtainable. Occasionally titres as high as 1/8000 have been reported. Every member of the group has been shown to be serologically related to at least one other member, although sometimes the relationship is distant.

Physical Properties of Viral Particles

Comovirus preparations consist of nonenveloped isometric particles, 28 nm in diameter, which can be separated into three components designated top (T), middle (M) and bottom (B) by centrifugation on sucrose density gradients. The exact sedimentation coefficients of the components vary slightly with the virus being analysed but are typically in the range 50–60 S for T, 90–100 S for M and 110–120 S for B components. The three components have identical protein compositions, containing 60 copies each of a large (L) and small (S) coat protein. The sizes of the two proteins vary, depending on the virus, but lie in the ranges 37–49 kDa for the L protein and 18–26 kDa for the S protein. The difference between the three centrifugal components is in their RNA contents. Top components are devoid of RNA, while middle and bottom components each contain single molecules of RNA of approximately 3.5 and 6.0 kb, respectively. The two RNA molecules were originally termed middle (M) and bottom (B) component RNA after the component from which they were isolated; however, more recently they have been referred to as RNA2 and RNA1, respectively. The three-compo-

* Commonly regarded as a strain of BBSV.

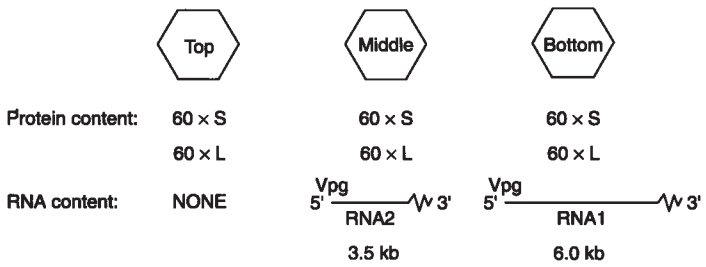

Figure 1 The three-component nature of comoviruses indicating the protein and RNA content of each component.

nent nature of comovirus preparations is summarized in **Fig. 1**.

Because of their differing RNA contents, the three components of comoviruses also differ in density and can hence be separated by isopyknic centrifugation. Generally, T, M and B components have densities of approximately 1.29, 1.40 and 1.41 g ml^{-1}, respectively. However, the pattern obtained is often more complex than that seen with sucrose gradients and depends on the precise conditions used and virus being examined. For example, while BPMV gives the expected three components when centrifuged on cesium chloride gradients under a wide range of conditions, the bottom component of CPMV can be resolved into two forms of differing density under alkaline conditions.

Preparations of comoviruses are often not only centrifugally heterogeneous but can also be separated into two forms, fast and slow, electrophoretically. Both electrophoretic forms contain all three centrifugal components. The proportion of the two electrophoretic forms in a given viral preparation varies, both with the time after infection at which the virus was isolated and the age of the preparation itself. Conversion of one form to the other has been shown to be caused by loss of amino acids from the C terminus of the S protein.

In a number of instances, comovirus particles have been shown to contain polyamines, particularly spermidine. Such polyamines are believed to have a role in the neutralization of the negative charges of the RNA within the particles. It is the exchange of such polyamines for cesium ions that leads to the two forms of bottom component of CPMV seen under alkaline conditions.

Viral Structure

X-ray crystallographic studies on CPMV and BPMV have provided a detailed picture of the arrangement of the two viral coat proteins in the three-dimensional structure of comoviruses. Overall, the virions are icosahedrally symmetrical, with 12 axes of fivefold and 20 axes of threefold symmetry, and resemble a classic $T = 3$ particle. The two coat proteins taken together consist of three distinct β-barrel domains, two being derived from the L and one from the S protein. Thus, in common with the $T = 3$ viruses, each CPMV particle is made up of 180 β-barrel structures. The S protein, with its single domain, is found at the fivefold symmetry axes and therefore occupies a position analogous to that of the A type subunits in $T = 3$ particles (**Fig. 2**). The N- and C-terminal domains of the L protein occur at the threefold axes and occupy the positions equivalent to those of the C and B type subunits of a $T = 3$ particle respectively (**Fig. 2**). Comovirus capsids are also structurally homologous to those of picornaviruses, with the N- and C-terminal domains of the L protein being equivalent to viral protein VP2 and viral protein VP3, respectively, and the S protein being equivalent to viral protein VP1 (**Fig. 2**). However, comoviral particles are structurally less sophisticated than those of picornaviruses. The L and S subunits lack the extended N- and C-termini found in VP2, VP3 and VP1 of picornaviruses and there is no equivalent of VP4. Moreover, comoviral subunits lack the relatively large insertions between the strands of β sheet, sequences which form the major antigenic determinants of picornaviruses. Knowledge of the three-dimensional structure of the capsids of CPMV has enabled the particles to be developed as carriers of foreign antigenic sites.

In the case of BPMV, crystals of purified middle component were found to contain strong electron density in the middle of the particle due to ordered RNA. Seven well-ordered ribonucleotides lie in a pocket formed by the covalently linked N- and C-terminal domains of each of the 60 copies of the L protein. The overall structure of the ordered RNA is that of one strand of an A-type RNA helix. The interactions of the RNA with the protein are mainly van der Waals. No equivalently ordered RNA is visible in the bottom component of BPMV or in either of the nucleoprotein components of CPMV. There are no obvious repeats in the sequence of BPMV RNA2

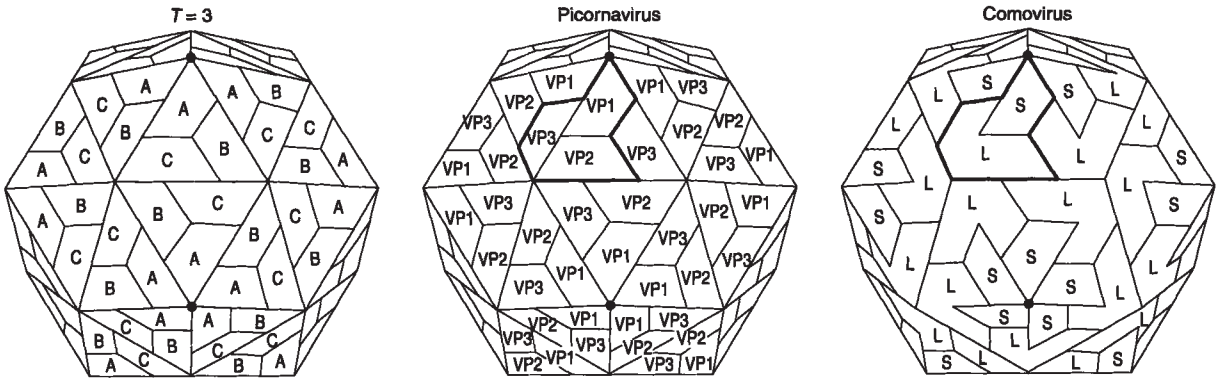

Figure 2 Arrangement of the coat protein subunits of comoviruses compared with those of simple $T = 3$ viruses and picornaviruses. The asymmetric unit of $T = 3$ viruses contains three β barrels contributed by three coat protein subunits with identical amino acid sequences (labelled A, B and C). The asymmetric unit of a picornavirus also contains three β barrels, but in this case each is contributed by a different coat protein (labelled viral protein VP1, viral protein VP2 and viral protein VP3). The comovirus capsid is similar to that of a picornavirus except that two of the β barrels (corresponding to viral protein VP2 and viral protein VP3) are fused to give the L protein. (Reproduced with permission from Lomonossoff *et al* (1991) *Proc. Phytochem. Soc. Eur.* 32: 76.)

which could account for this particular RNA being visible within particles.

Genome Structure

The genomes of comoviruses consist of the two RNAs (RNA1 and RNA2) encapsidated in bottom and middle components. Both RNA molecules are positive-sense and both are required for an infection of whole plants. However, in the case of CPMV, RNA1 has been shown to be capable of independent replication in isolated protoplasts. Both genomic RNAs have a small basic protein (VPg) covalently linked to their 5′ termini and are polyadenylated. The VPg is linked to the viral RNA via the β-hydroxyl group of its N-terminal serine residue. The VPg is not required for the viral RNAs to be infectious.

By the end of 1997, the complete nucleotide sequences of both RNAs of four comoviruses, CPMV, RCMV, CPSMV and BPMV, had been determined. An almost complete sequence of RNA2 of APMV is also available. Where both RNAs of a given comovirus have been examined it has been found that the two viral RNAs have little sequence homology apart from at the 5′ and 3′ termini. All comovirus RNAs examined to date share the common 5′-terminal sequence, VPg-pUAUUAAAAU-. Full-length infectious cDNA clones of CPMV and CPSMV have been constructed, allowing the genomes of these viruses to be manipulated.

Expression of the Viral Genome

All comovirus RNAs sequenced so far contain a single long open reading frame that occupies over 80% of the length of the RNA. A combination of *in vitro* translation and protoplast studies has unravelled the basic mechanism of expression of the genomic RNAs of the type member of the group, CPMV. More limited studies on other members of the group such as CPSMV, BPMV, RCMV and SqMV suggest that the mode of gene expression deduced for CPMV is applicable to all members of the group.

Both RNAs of CPMV are expressed through the synthesis and subsequent cleavage of large precursor polyproteins. Translation occurs directly off the genomic RNAs, with no subgenomic RNAs being produced in infected cells. On RNA1, initiation of translation occurs at the first AUG encountered on the sequence (at position 207) and results in the synthesis of a protein of approximately 200 kDa (the 200K protein). This initial product undergoes rapid co-translational autoproteolysis to give proteins with apparent sizes of 32 and 170 kDa (the 32 and 170K proteins). The 170K protein undergoes further cleavages to give the range of virus-specific proteins shown in **Fig. 3**. *In vitro* translation studies using mutant RNA1 molecules have shown that all the cleavages occur most efficiently in *cis*. The 170K product can initially be cleaved at three different sites to give three different combinations of secondary cleavage products, 58K + 112K, 60K + 110K and 84K + 87K. *In vitro*, and probably also *in vivo*, the 60K and 110K products are stable and do not undergo further cleavage reactions, at least not at an appreciable rate. This is particularly curious in the case of the 110K protein as it contains both the 24K proteinase domain and a cleavage site. By contrast the 112K and 84K proteins do undergo further cleavages. The endproducts of the cleavage pathway of the 170K

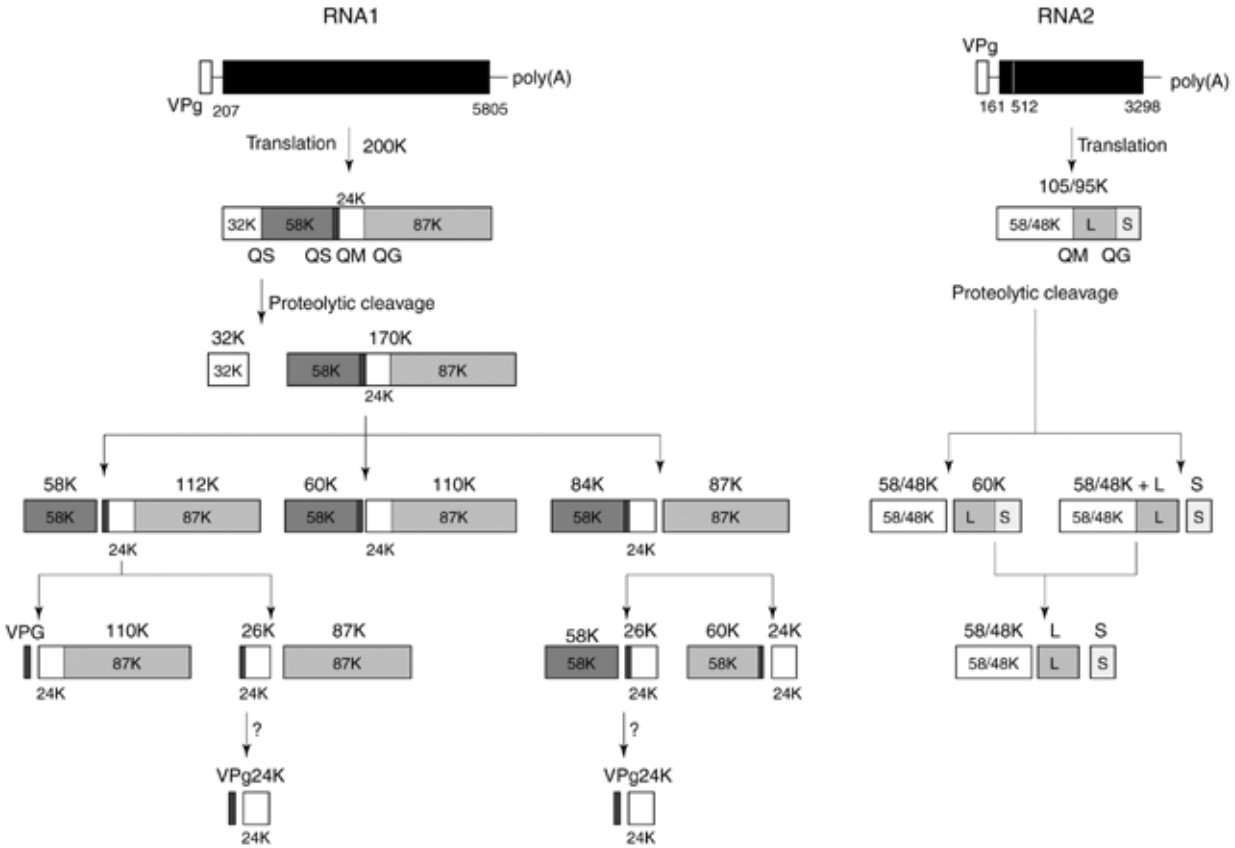

Figure 3 Expression of comoviral RNA1 and RNA2. Both RNAs contain a single long open reading frame. The details, such as the positions of the initiation and termination codons and the dipeptides at the proteolytic processing sites, are correct for CPMV; however, the overall processing scheme is probably applicable to all comoviruses.

protein are, from N- to C-terminus, the 58K protein, the VPg, the 24K proteinase and the 87K protein.

Initiation of translation of RNA2 occurs at two different positions on the RNA and results in the synthesis of two carboxy-coterminal proteins, the 105 and 95K proteins (**Fig. 3**). This double initiation phenomenon is found with the RNA2 molecules of all comoviruses. In the case of CPMV, synthesis of the 105K protein is initiated from an AUG at position 161, while initiation from an AUG at position 512 directs the synthesis of the 95K protein. CPMV RNA2 has an additional AUG (position 115) upstream of both these initiation sites but this feature is not conserved in the RNA2 molecules of other comoviruses. There has been some dispute as to whether initiation to give the 95K protein is a result of internal initiation or leaky scanning, and this has not, as yet, been fully resolved. Both RNA2-encoded primary translation products are cleaved by the RNA1-encoded proteolytic activity to give either the 58 or the 48K protein (depending on whether it is the 105 or 95K protein being processed) and the two viral coat proteins. Processing of the RNA2-encoded polyproteins, at least at the site between the 48K and L coat protein, has been shown to require the presence of the 32K protein as well as the 24K proteinase. For many years it was believed that the 60K protein (**Fig. 3**), containing the sequences of both the L and S coat proteins, was the direct precursor of the two mature capsid proteins; however, recent experiments involving the transient expression of the separate L and S proteins in protoplasts have cast doubt on this interpretation, and the role, if any, of the 60K protein in the virus replication cycle is unclear.

Functions of the Viral Proteins

Functions have been ascribed to most of the regions of the polyproteins encoded by both RNA1 and RNA2 of CPMV. In most cases, however, it is not certain at what stage(s) in the cleavage pathway they manifest their activity.

In the case of RNA1, the 32K protein, which is rapidly cleaved from the N-terminus of the 200K primary translation product, appears to be a cofactor which modulates the activity of the virus-encoded

protease. As described earlier, the presence of the 32K protein appears to be required for the cleavage of the RNA2-encoded 105 and 95K proteins but is not essential for the cleavage of the RNA1-encoded 170K protein. It does, however, seem to play a role in determining the rate at which cleavage of the 170K protein occurs. When mutant RNA1 molecules carrying deletions in the region encoding the 32K protein are translated *in vitro*, the rate of processing of the 170K protein is greatly increased, indicating that the 32K protein acts as an inhibitor of processing. This inhibition may be achieved through the interaction of the 32K with the 58K domain of the 170K protein. The mechanism by which the 32K protein enables the 24K proteinase to cleave *in trans* is unclear. It could be due to a direct association between the 32K protein and the 24K proteinase (or an intermediate containing the proteinase domain) or it could be an indirect result of the 32K protein modulating the cleavage of the 170K protein, thereby allowing a 24K-containing intermediate with *in trans* cleavage activity to accumulate.

The RNA1-encoded 58K protein is associated with cell membranes and contains a nucleotide-binding motif. For a long time it was believed that the 60K protein (**Fig. 3**), containing the amino acid sequence of the 58K protein linked to VPg, was the immediate precursor of the VPg *in vivo*. However, more recent studies have indicated that processing of the 60K protein *in trans* is extremely inefficient, casting doubt on its role as a precursor. It now seems more likely that it is the 112K protein, containing the sequence of the VPg linked to 24K and 87K proteins, which is the immediate precursor of the VPg. The 24K protein is the virus-encoded proteinase which carries out all the cleavages on both the RNA1- and RNA2-encoded polyproteins. Its proteolytic activity has been shown to be expressed in a number of the processing intermediates that contain its sequence. Indeed, it is not known whether the free form of the protein has any biological significance. Although the proteinase contains a cysteine at its active site, it is structurally related to serine proteases, such as trypsin, rather than cellular thiol proteases, such as papain. In this regard it is similar to the 3C proteinases of picornaviruses. All comoviral cleavage sites identified so far have a glutamine (Q) residue at the −1 position. The enzyme encoded by a given comovirus is specific for the polyproteins encoded by that virus and cannot cleave the polyproteins from other comoviruses either in *cis* or in *trans*.

The 87K protein is believed to contain the virus-encoded RNA-dependent RNA polymerase (RDRP) activity as it contains the G-D-D sequence motif found in all such enzymes. It also has amino acid sequence homology to the 3D polymerases encoded by picornaviruses. However, when replication complexes capable of elongating nascent RNA chains were isolated from CPMV-infected cowpea plants they were found to contain the 110K protein (**Fig. 3**), consisting of the sequence of 87K protein linked to the 24K proteinase, rather than the free 87K protein.

In the case of RNA2, the 48K protein, derived from processing of the 95K protein, is involved in potentiating the spread of the virus from cell to cell. This protein has been found in tubular structures that are formed in the plasmodesmata of cells infected with either CPMV or RCMV. Tubules extending into the culture medium can also be seen in protoplasts either infected with CPMV or transiently expressing the 48K protein. Virus particles can be seen within these tubules when protoplasts are infected with CPMV but not when only the 48K protein is expressed. At present, no definite role has been assigned to the 58K protein, which is produced by processing of the 105K protein. Mutants in which translation of the 105K protein is disrupted replicate poorly, if at all. In the light of these observations it has been suggested that the 105K protein may play a role in the replication of RNA2. Apart from containing many hydrophobic and aromatic amino acids, the approximately 10 kDa of protein present in the 58K but not the 48K protein is not conserved between comoviruses. The viral coat proteins are required to enable capsids to be formed. As well as protecting the genomic RNAs, capsid formation is essential for the virus to be able to spread from cell to cell through modified plasmodesmata. Long-distance movement, probably through the xylem, also requires capsid formation.

Replication

Comoviruses generally replicate to high level in infected cells. Replication is believed to involve the initial transcription of the incoming positive-sense RNA into minus-strands, followed by initiation and synthesis of new plus-strands from the recently formed minus-strands. For CPMV, it has been shown that the 5′ ends of both the plus- and minus-strands are covalently linked to the VPg, suggesting that this protein has an essential role in the initiation of RNA synthesis. There also appears to be a tight linkage between the translation of the viral RNAs and their replication.

In the case of CPMV, replication of the viral RNAs has been shown to occur in the membranous cytopathological structures which are formed in the cytoplasm of cells during infection. Both CPMV-specific double-stranded replicative form (RF) RNA and an enzyme activity capable of completing nascent

RNA strands can be isolated from such structures. Purified preparations of the enzyme activity contain the RNA1-encoded 110K protein and two host-encoded proteins of 68 and 57 kDa. However, at present no enzymatic activity capable of initiating RNA synthesis *in vitro* has been described.

Relationships with Other Virus Groups

There is a high degree of similarity between the comoviruses and the fabavirus, broad bean wilt virus (BBWV). For example, the L and S proteins of BBWV are the same size as those of CPMV, as are the respective RNA1 and RNA2. Indeed, some authors have considered BBWV to be a member of the comovirus group. However, BBWV shows no serological relatedness to any comovirus, reaches only moderate concentrations in plant sap, has a very wide host range and is transmitted by aphids rather than by beetles. For these reasons, BBWV is generally considered to be a member of a distinct group of plant viruses.

Consideration of genome structure and organization, translational strategy and amino acid homologies between the virus-encoded proteins has led to comoviruses being grouped with the nepo-, poty- and picornaviruses as members of the picorna-like supergroup of viruses. Members of this group are all nonenveloped positive-strand RNA viruses with 3′-polyadenylated genomic RNAs which have a protein (VPg) covalently linked to their 5′ ends. All members of the supergroup have a similar mode of gene expression which involves the synthesis of large precursor polyproteins and their subsequent cleavage by a virus-encoded proteinase. The members of the supergroup all contain the similar gene order, membrane-bound protein–VPg–proteinase–polymerase (**Fig. 3**), there being significant amino acid sequence homology between the membrane-bound proteins, the proteinases and polymerases. Comovirus capsids are also clearly structurally related to those of picornaviruses (**Fig. 2**) and probably also to those of nepoviruses.

Geographic Distribution

Individual comoviruses tend to have a somewhat restricted distribution. Clearly, the apparent distribution of a virus is governed, at least in part, by whether or not infection is diagnosed and reported. The following list, therefore, contains only those geographical areas where the presence of the virus has, to date, been confirmed.

- CPMV: Nigeria, Kenya, Tanzania, Japan, Surinam and Cuba.
- APMV: Central and South America.
- BPMV: USA.
- BRMV: Central America.
- BBSV: Europe and Africa.
- BBTMV: Europe and Northwest Africa.
- CPSMV: North, Central and South America.
- GMV: Australia.
- PMiMV: New Zealand.
- QPMV: North and Central America.
- RaMV: USA, Japan and Europe.
- RCMV: Europe.
- SqMV: North Africa, Israel, China, Japan, Australia and North, Central and South America.
- UCV: Peru and Bolivia.

Host Range

The host ranges of individual comoviruses tend to be rather narrow. Of the 14 members of the group, 10 (CPMV, BPMV, BRMV, BBSV, BBTMV, CPSMV, GMV, PMiMV, QPMV and RCMV) infect predominantly, if not exclusively, legumes. The other four members of the group, APMV, RaMV, SqMV and UCV, infect predominantly members of the *Solanaceae, Cruciferae, Cucurbitaceae* and *Basellaceae*, respectively.

Transmission

In nature, comoviruses are usually transmitted by leaf-feeding beetles, especially by members of the Chrysomelidae. However, CPMV has been shown also to be transmitted by thrips and grasshoppers. The beetle vectors can acquire the virus by feeding for as little as 1 min and can retain and transmit the virus for a period of days or weeks. The virus does not, however, multiply in the insect vector. Experimentally, all comoviruses are mechanically transmissible. In the case of BBSV, BBTV, CPMV, CPSMV and virus SqMV, transmission through seed has been reported.

Epidemiology

The primary sources for infection of crop plants with comoviruses are transmission through seed and infection from wild hosts which act as reservoirs of the viruses. It is also possible that virus which has overwintered in the beetle vector can act as a primary source of infection. Within-field spread is by the beetle vectors.

Symptomatology and Cytopathology

Generally, each member of the group has certain hosts in which the virus can spread systemically, causing mosaic or mottling symptoms, and other hosts in which the infection is confined to local lesions. Stunting of the host plant is sometimes observed, as is occasional systemic wilting and seed discoloration.

Infection of plant cells with comoviruses results in a number of characteristic cytological changes. These include the appearance of viral particles, either individually or as crystalline arrays, in the cytoplasm, a proliferation of cell membranes and vesicles in the cytoplasm, the appearance of amorphous inclusion bodies near or surrounding the nucleus and a variety of modifications to plasmodesmata. In the case of CPMV, the ability to cause membrane proliferation has been shown to be associated with RNA1.

Economic Importance

At present, BPMV, CPMV, CPSMV and RCMV are considered to be significant pathogens of legumes. Infection of soybeans with BPMV alone can cause yields to be reduced by 10–17%; however, this figure can rise to 60% in plants doubly infected with BPMV and the potyvirus, soybean mosaic virus. In Nigeria, infection of cowpeas with CPMV causes a great reduction in leaf area, flower production and yield. Infection of cowpeas with CPSMV has been shown to cause a 50% reduction in plant fresh weight and in the number and weight of pods. RCMV is of economic importance in forage production as it sometimes heavily invests clover. SqMV is a significant pathogen of cucurbits, problems associated with it being exacerbated by its high rate of seed transmission.

CORONAVIRUSES (*CORONAVIRIDAE*)

Kathryn V. Holmes, Department of Microbiology, University of Colorado HSC, Denver, Colorado, USA

Classification

The *Coronaviridae* were recognized as a new virus family in 1968 because their virion morphology and intracellular budding site distinguished them from other RNA viruses. Characteristic features of their genome, replication strategy, structural proteins and polymerase later supported this classification. The toroviruses and coronaviruses were recognized as separate genera within the *Coronaviridae* family in 1993. The *Coronaviridae* and *Arteriviridae* are now classified as members of the *Nidovirales* order, viruses with monopartite plus-strand RNA genomes that are transcribed to yield a nested set of overlapping subgenomic mRNAs that have a common 3′ end.

Virion Structure and Proteins

A model of coronavirus virions is shown in **Fig. 1.** The enveloped virions are approximately 100 nm in diameter, and are characterized by large, petal-shaped spikes. The spikes are oligomers of the 180–200 kDa S

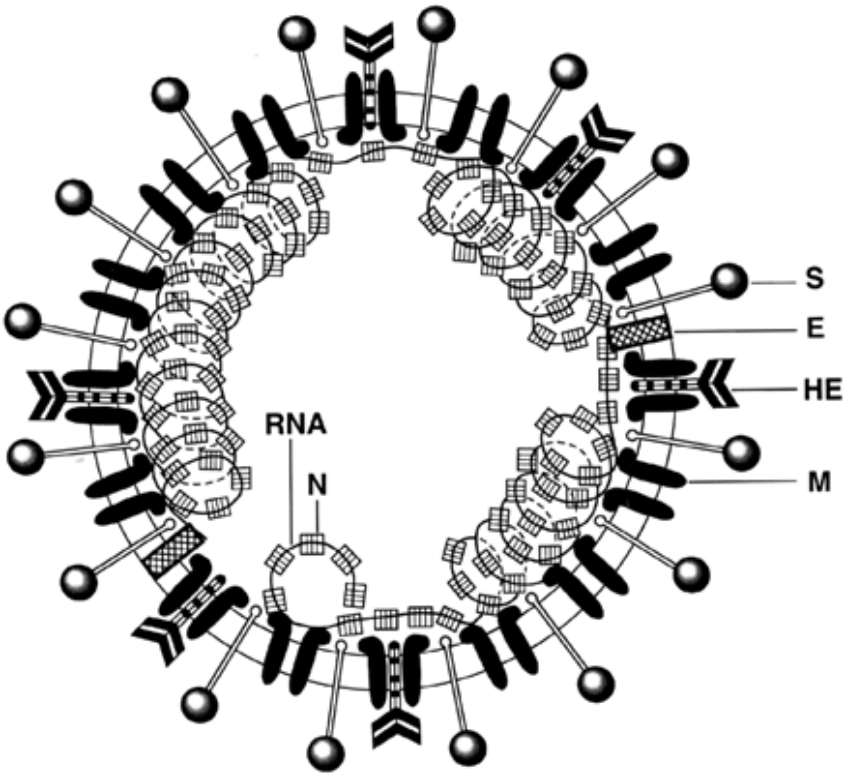

Figure 1 Model of coronavirus virion. The helical nucleocapsid containing the 30 kb, plus-sense RNA genome is coiled within an envelope that contains the S, M and E glycoproteins. Some coronaviruses related to MHV also express the HE glycoprotein. (Modified and published with permission from Fields BN, Knipe DM, Howley PM *et al* (eds) (1996) *Fields Virology*, 3rd edn. Philadelphia: Lippincott-Raven).

glycoprotein that binds to receptor glycoproteins and induces fusion of the viral envelope with cell membranes and, sometimes, cell–cell fusion. S proteins of several coronaviruses also bind to 9-*O*-acetylated sialic acid. A small envelope glycoprotein, M, traverses the lipid bilayer three times and interacts with the nucleocapsid in the virion. Intracellular transport of the M glycoprotein is arrested in the Golgi, which may determine the intracellular budding site of coronaviruses. The small E glycoprotein, originally believed to be a nonstructural protein, is present in small amounts in virions, and is essential for virus budding. Envelopes of some coronaviruses also contain a hemagglutinin-esterase glycoprotein, HE, which forms short spikes that bind *N*-acetyl-9-*O*-acetylneuraminic acid or *N*-glycolylneuraminic acid and have esterase activity. The nucleocapsid protein, N, encapsidates the monopartite, linear, single-stranded genomic RNA. The internal structure of coronaviruses was originally believed to be a helical nucleocapsid as shown in **Fig. 1**. Recently, however, cores that appear to have cubic symmetry were observed in detergent-treated virus preparations. Thus, the internal structure of coronaviruses is not yet understood.

Genome Structure

The 27–32 kb, plus-strand RNA genomes of coronaviruses are capped and polyadenylated. Transfection of genomic RNA into cells leads to production of infectious virions. The genomes of several coronaviruses have been sequenced, although no infectious coronavirus cDNA has yet been obtained. A map of the genome of murine coronavirus MHV (**Fig. 2**) illustrates the characteristic features of coronavirus genomic RNA. At the 5′ end of the genome is a cap with a leader RNA of approximately 70 bp. The order of the genes encoding the polymerase and structural proteins is the same in genomes of all coronaviruses (Pol, S, E, M, N), but several additional open reading frames (ORFs) are interspersed among these genes. These ORFs encode nonstructural (NS) proteins of unknown functions, and they differ in number, position and sequence among different coronaviruses.

For both *Coronaviridae* and *Arteriviridae*, the RNA-dependent RNA polymerase gene at the 5′ end of the genome consists of two ORFs in different reading frames, joined by a pseudoknot at a ribosomal frame shift site. The 5′ and 3′ ends of the genome contain predicted complex stem loop structures, and

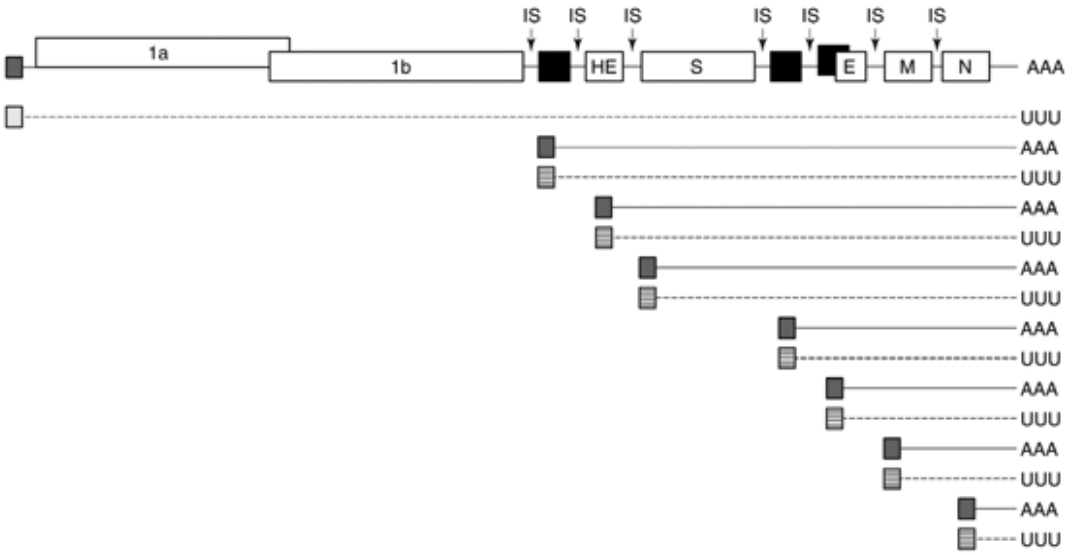

Figure 2 Map of the genome of murine coronavirus MHV and intracellular coronavirus RNAs. The polyadenylated plus-strand RNA genome is approximately 32 kb long. ORFs that encode structural proteins are shown in open boxes with the protein encoded by the gene inside. This gene order is the same in all coronaviruses. The RNA polymerase gene at the 5′ end of all coronavirus genomes consists of two ORFs, 1a and 1b, with a pseudoknot and a slippery sequence in the overlapping region. ORFs encoding putative nonstructural proteins (shown in filled boxes) vary in number and position among different coronaviruses. The conserved intergenic sequence on all plus-strand RNAs is shown by IS. The cap and approximately 70 bp leader RNA at the 5′ ends of each plus-strand RNA are indicated by a shaded box. Minus-strand templates are shown by dashed lines with a sequence complementary to the leader at the 3′ end indicated by a barred box, and a poly(U) tract at the 5′ end. Each subgenomic mRNA is translated to yield only the protein encoded by the 5′ end of the plus-strand RNA.

additional stem loops are predicted within some ORFs. Preceding every ORF in the genome is an intergenic sequence (IS) consisting of one or more UCUAAAC sequences for MHV or related sequences for other coronaviruses. The IS is included in a promoter that regulates the transcription of different viral genes. The location on the genome of packaging signals for the initiation of encapsidation of genomic RNA by the N protein appears to differ among coronaviruses.

Transcription, Replication, Translation and Genetics

Upon infection, the two large ORFs in the 20 kb polymerase gene of the genomic RNA are translated, via ribosomal frameshift, as a single, very large polyprotein that is cleaved during translation by 3-C-like and papain-like proteases within the nascent protein to yield a variety of peptides. The processing of the large polyprotein and the functions of the resulting peptides in RNA-dependent RNA polymerase activity are being analyzed in many laboratories.

Using the genomic RNA as template, the polymerase generates a full-length, minus-strand RNA with a 5′ poly(U) sequence. Infected cells also contain a 3′ coterminal nested set of polyadenylated subgenomic plus-strand mRNAs that have a cap and the approximately 70 bp leader sequence at their 5′ ends (**Fig. 2**). A negative-strand RNA template corresponding to each subgenomic mRNA is also found in infected cells (**Fig. 2**). A nonprocessive, leader-primed polymerase activity was postulated to account for the presence of the leader on each mRNA. A complex of polymerase and leader transcribed from the 3′ end of the full-length negative-strand template would bind to an IS on the template and act as a primer for synthesis of the subgenomic mRNA. This hypothesis does not explain the presence of the negative-strand templates for each subgenomic RNA. An alternative hypothesis suggests that polymerase jumping occurs during negative-strand synthesis, generating the subgenomic negative-strand templates for subsequent mRNA synthesis. Mutations in the IS preceding an ORF can prevent transcription of the mRNA with that ORF at its 5′ end. Although virus strains differ in the relative amounts of various mRNAs in infected cells, there is little temporal regulation of transcription.

Coronavirus replication is associated with a high frequency of mutations that arise by two mechanisms. First, during the replication of each approximately 30 kb RNA genome, several point mutations would

be expected to occur, based upon the known error frequency of RNA polymerases. Second, coronavirus genomes undergo a very high frequency of RNA recombination. Small or large deletions at the sites of recombination can produce mutant viruses, or defective interfering (DI) RNAs and subgenomic replicons. Large deletions in certain sites of the gene encoding the S glycoprotein and mutations in the N gene yield viruses with altered virulence, tissue tropism, or thermal stability. Thus, even after sequential single plaque isolations, coronavirus stocks always contain a mixture of quasispecies. Different virus variants may be selected during passage in different cell lines or under a variety of culture conditions. Therefore it is important to document the passage history of coronavirus strains or mutants. Rarely, recombination may occur between coronavirus genomic RNA and mRNAs of cells or unrelated viruses. Such an illegitimate RNA recombination event may have resulted in the incorporation of the mRNA that encodes the HE glycoprotein of influenza C into the genome of a coronavirus ancestral to the MHV group. Similarly, some of the NS ORFs may have been acquired through recombination with foreign mRNAs.

Genetic analysis of coronaviruses is somewhat limited because no full-length, infectious cDNA clones of coronavirus genomes are yet available. DI RNAs transfected into cells infected with wild-type virus can be replicated and have been used to study encapsidation and transcription initiation signals. Site-specific mutations have been introduced into several coronavirus genomes by targeted RNA recombination in infected cells transfected with a mutagenized subgenomic cDNA.

Coronavirus replication occurs in the cytoplasm and does not require the nucleus. Only the ORF at the 5′ end of each of the coronavirus mRNAs is translated within the infected cell or *in vitro*. The phosphorylated N protein, which is translated from one of the smallest mRNAs, is the most abundant viral protein in infected cells. It assembles with genomic plus-strand RNA in the cytoplasm to form helical nucleocapsids. Viral glycoproteins are translated on the rough endoplasmic reticulum, where S oligomerizes, then they are transported to the Golgi, where S proteins of some coronaviruses are cleaved by a trypsin-like host cell protease to yield S1 and S2 peptides. The S and HE glycoproteins are expressed on the plasma membrane. The viral S, HE, M and E glycoproteins and the nucleocapsid assemble by budding at a special pre-Golgi compartment, and the virions are apparently transported to the cell surface in large vesicles that fuse with the plasma membrane to release virions from the intact cell by exocytosis. Infected cells are characteristically coated with a thick layer of adsorbed virions.

Host Range, Tissue Tropism and Virus Propagation

Most coronaviruses cause epidemic disease in only one species, although limited replication, usually without disease, may result from experimental inoculation of other species. Coronaviruses typically cause respiratory or enteric diseases, although several can also cause hepatitis, infectious peritonitis, nephritis, myocarditis, sialodacryadenitis, or neurological, reproductive or immunological disorders. The viruses were named for their natural host and sometimes for the associated disease: for example, avian infectious bronchitis virus (IBV); mouse hepatitis virus (MHV); sialodacryadenitis virus of rats (SDAV); bovine coronavirus (BCoV); porcine hemagglutinating encephalomyelitis virus (HEV); turkey bluecomb coronavirus (TCoV); human respiratory coronaviruses (HCoV); transmissible gastroenteritis virus of swine (TGEV); porcine respiratory coronavirus (PRCV); canine coronavirus (CCoV); feline infectious peritonitis virus (FIPV) and feline enteric coronavirus (FeCoV); and rabbit coronavirus (RbCoV).

In vivo, coronaviruses bind to receptors expressed on the apical membranes of enteric and respiratory epithelial cells, and are released either from the apical or basolateral borders or both, depending upon the virus. Although strains of many coronaviruses have been adapted to growth in continuous cell lines, isolation of human coronaviruses from infected patients may require human fetal tracheal organ cultures. Some coronaviruses, such as rabbit coronavirus or enterotropic strains of MHV, cannot be propagated in cell culture, but require animal passage. Coronavirus-like particles seen in electron micrographs of human feces (human enteric coronaviruses, HECV) have not been adapted to serial passage in cell culture. IBV and TCoV can be propagated in embryonated eggs, and some strains grow in avian cell lines. Although cells of the natural host species are generally required for infection by virions, purified coronavirus genomic RNA can infect cells across species barriers. Receptors have been identified for several coronaviruses: MHV uses murine biliary glycoproteins in the immunoglobulin superfamily; HCoV-229E and TGEV use human and porcine aminopeptidase N (APN), respectively; FIPV and FeCoV use feline APN, which can also be utilized by HCoV-229E and TGEV; and BCoV and HCoV-OC43 use *N*-acetyl-9-*O*-acetyl neuraminic acid moieties. Expression of the cloned receptor glycoproteins

in cells of a foreign species can render them susceptible to infection with coronavirus virions. Thus, coronavirus–receptor interactions are an important determinant of the species specificity of coronavirus infection.

Coronavirus infection of cells may be inapparent or cause cell fusion, vacuolization, rounding and/or cell death. Cytopathic effects are minimized, and virus yield and stability are increased at acid pH. Some strains of MHV infect cells by receptor-dependent fusion of the viral envelope with the plasma membrane, but other strains of MHV and other coronaviruses appear to enter via fusion with endosomal membranes. For some coronaviruses, cleavage near the middle of the S glycoprotein at a sequence of basic amino acids yields the noncovalently linked S_1 and S_2 peptides and enhances viral infectivity and/or cell fusion. S glycoproteins of many other coronaviruses, such as FIPV, lack the protease target sequence and do not require protease activation for infectivity or cell fusion.

Serologic and Evolutionary Relationships

There are three coronavirus serogroups. One group includes HCoV-229E, TGEV, PRCoV, CCoV, FCoV, and others. A second group includes MHV, BCoV, SDAV, HEV, HCoV-OC43 and others. Avian IBV strains make up the third serogroup. Phylogenetic analysis of coronavirus N and S genes correlate well with the division of coronaviruses into these three groups. Nucleic acid sequence analysis also shows that certain pairs of coronaviruses that cause different syndromes in the same host should probably be considered strains of a single virus. Thus, PRCoV and TGEV of swine, which cause epizootic respiratory and enteric disease, respectively, are highly homologous, except for a deletion of more than 675 nucleotides in the S gene of PRCoV. The feline coronavirus FeCoV causes epizootic enteric disease in cats, and mutant FIPV viruses that arise within FeCoV-infected animals cause fatal systemic disease.

The HE glycoprotein is encoded by a gene found in the MHV group of coronaviruses, but not in the HCoV-229E or IBV groups. Phylogenetic analysis of coronavirus HE gene suggests that BCoV and HCoV-OC43 are more closely related to each other than to MHV. The organization of the polymerase gene with two large slightly overlapping ORFs in different reading frames joined by a pseudoknot is conserved among all coronaviruses and shared by toroviruses such as Berne virus (BEV) and *Arteriviridae*. In addition, BEV encodes a protein with significant homology to HE of coronaviruses and influenza C virus.

Recombination between genomes of related coronaviruses can occur in experimentally inoculated cell cultures or animals, and also during natural outbreaks of disease in the natural host. Recombinants between IBV strains have been isolated from infected birds. Nucleotide sequencing shows that one biotype of feline coronavirus that causes epizootic disease is a recombinant between canine coronavirus and the other biotype of feline coronavirus. Mutants of MHV derived from persistently infected murine cell lines have acquired the ability to infect nonmurine cells. These observations indicate that there may be naturally occurring interactions between the genomes of coronaviruses from different species.

Epidemiology

Most coronaviruses cause epidemic or epizootic disease in only one species. Because of the great antigenic variability among coronavirus strains and because many coronaviruses replicate only in epithelia where protective immunity is relatively short-lived, reinfection is common. Infection is often inapparent, and virus particles or antigens and subsequent seroconversion are observed in healthy individuals. The viruses are enzootic or endemic in their host species, causing sporadic disease and seasonal outbreaks when enough susceptibles are available. Adults with acute, self-limited, inapparent infection transmit virus to neonates that develop clinical disease. Coronavirus diseases are more severe in neonatal animals than adults, either because preexisting immunity to related virus strains moderates infections in adults, or because the immature immune system permits higher levels of virus replication. In immunocompromised hosts, infection may be inapparent but virus shedding may be prolonged. Such individuals serve as reservoirs of virus. For example, enterotropic MHV strains are endemic in colonies of laboratory mice, sustained both by persistent infection of immunocompromised nude mice and by the continuous availability of new susceptibles due to birth or importation.

Outbreaks of coronavirus diseases are often seasonal. In humans, coronaviruses cause 15–30% of colds, predominantly during the winter months, and outbreaks of different human coronaviruses alternate at 2–3 year intervals. Outbreaks of BCoV-induced dysentery in cattle also occur in the winter. Severe enteritis due to TGEV or BCoV infection of suckling pigs or calves, respectively, occurs seasonally in correlation with breeding cycles. Outbreaks of IBV-induced respiratory disease in chickens can occur at

any time, but are most common during the winter. Stress can exacerbate coronavirus-induced diseases. Mice with inapparent MHV infection can develop hepatitis if they are subjected to immunosuppression, thymectomy, transplanted tumors or infection with unrelated organisms. Cattle with inapparent BCoV infection may develop respiratory disease during shipping.

Coronaviruses have broad geographic distribution. Human infections with viruses related to HCoV-229E or to HCoV-OC43 occur worldwide, as do IBV, TGEV, BCoV, FCoV and CCoV infections. Occasionally, strains of these viruses that cause unusual manifestations of disease arise and spread locally, and some of these viruses become very widely distributed. For example, IBV strains that cause severe nephropathy arise and spread locally. PRCoV, which causes a mild epizootic respiratory infection in swine, has arisen several times in Europe and in the USA from TGEV by means of a very large deletion in the S glycoprotein. The epizootic spread of PRCoV in European pigs has apparently acted as a natural vaccine that has decreased the incidence of serious TGEV-induced enteric disease in piglets.

Pathology

Most coronaviruses cause only respiratory or enteric disease in one host species. These viruses generally replicate only in respiratory or enteric epithelial cells, where the apical membranes express specific glycoprotein receptors for the viruses. Coronaviruses are shed in respiratory secretions and/or feces. Some coronaviruses, such as some MHV strains, FIPV and rabbit coronavirus, cause disseminated disease and can replicate in macrophages, hepatocytes, neurons, glial cells, endothelial cells, kidney epithelium, lymphocytes, urogenital tract and/or myocardium. In general, coronavirus titers in the respiratory or enteric tract rise during the first 3–5 days postinoculation, and recovery of infectious virus from an immunocompetent host is usually not possible after 10–14 days, although viral antigens and RNA may continue to be detectable for several weeks. Infectious coronavirus can be shed for months by immunocompromised hosts. Although most coronaviruses do not persist in immunocompetent hosts, coronaviruses such as the neurotropic MHV-JHM strain can sometimes be detected in the brain months or years after inoculation. Reverse transcriptase–polymerase chain reaction (RT-PCR) can detect HCoV-229E and/or HCoV-OC43 RNA in up to 40% of brains from patients with neurological diseases and from healthy individuals, but the significance of this observation for human disease is unknown.

Coronavirus-induced lesions vary markedly depending upon the virus strain, dose and tissue tropism and the genetic background of the host. Intestinal infections with BCoV, MHV, TGEV, FeCoV, TCoV and CCoV cause loss of apical epithelial cells of the intestinal villi and shortening and broadening of the villi. Some enterotropic coronaviruses cause necrotizing enterocolitis, particularly in young animals, while others cause only watery diarrhea or inapparent enteric infection. Diarrhea is probably due to altered transport of fluids and electrolytes by the immature epithelial cells that cover the blunted villi. Intestinal absorption of certain sugars in TGEV-infected pigs remains altered for several days after the diarrhea has ceased. Mononuclear inflammatory cells infiltrate the lamina propria. Reinfection with a different strain of the virus generally causes more moderate disease than primary infection. However, kittens are more likely to develop FIP following their second infection with feline coronavirus, than after their first infection. Thus, an immunological response to the primary infection may somehow facilitate the later development of disseminated disease.

Human respiratory coronaviruses related to HCoV-229E or HCoV-OC43 infect the epithelial cells in the upper respiratory tract and cause colds. Infection of young asthmatic children can exacerbate wheezing, and lower respiratory tract coronavirus infection has occasionally been observed in adults. Reinfection is frequent, even in volunteers inoculated with the same strain of human coronavirus. Infection is usually demonstrated by RT-PCR or by rising serum antibody titers because primary isolation of these viruses from respiratory washings is difficult. It is not yet clear how many coronavirus strains cause human respiratory disease or whether coronaviruses may play a role in other human diseases.

IBV-induced respiratory diseases in chickens is of great economic importance. In addition, some IBV strains are nephrotropic and cause kidney disease, while others infect the oviduct and reduce egg laying. Recombinants between several IBV strains have been isolated from infected flocks.

Neurological disease and hepatitis can result from coronavirus infections. MHV strains cause local and/or systemic infections via respiratory or fecal/oral routes. While some MHV strains are strictly enterotropic, most strains infect both the respiratory and enteric tracts. Some MHV strains causes focal hepatitis, acute encephalitis, and subacute or chronic focal demyelinating disease in the murine brain and spinal cord. Cell fusion, necrosis and infiltration with mononuclear cells are observed in acutely infected tissues, depending upon the strain of virus and strain of mice. Susceptibility to MHV is affected by at least

three murine genes that determine the virus receptor isoforms expressed, the yield of infectious virus and the ability to generate monocyte procoagulant activity, a prothrombinase in the coagulation pathway, in response to MHV infection. Mutations in the MHV and TGEV S glycoproteins can alter tissue tropism, virulence and persistence. HEV causes respiratory infection and outbreaks of encephalomyelitis in suckling pigs, and virus infection of neurons that innervate the stomach causes vomiting and wasting syndrome.

Unusual syndromes associated with coronaviruses include feline infectious peritonitis, rabbit myocarditis and rat sialodacryadenitis. FECV causes enteritis in kittens and inapparent infection in adult cats, while the closely related FIPV can cause infectious peritonitis, with ascites, wasting and death in a small percentage of infected cats. A cardiotropic rabbit coronavirus causes dilated myocardiopathy and death within 7–12 days after intravenous inoculation of rabbits with serum from an infected rabbit. Rat coronaviruses infect the respiratory tract, salivary and lacrimal glands, causing sialodacryadenitis, and can also infect the urogenital tract, interfering with breeding.

Immune Responses

Infection of respiratory or enteric tracts of adults results in antiviral antibodies in the serum, secretory antibody in the respiratory and enteric tracts, colostrum and milk, and development of virus-specific T cells. These immune responses are useful for diagnostic purposes, terminate infection, and probably ameliorate subsequent infections, but they do not necessarily prevent reinfection. In newborns, passive oral immunization with neutralizing antibody can sometimes prevent fatal coronavirus enteritis. Because coronavirus diseases are generally most severe in newborns that do not respond well to active immunization, an attractive strategy to protect these newborn animals that is being explored is to vaccinate pregnant dams in order to maximize antiviral antibodies in the colostrum and milk.

Coronaviruses can sometimes infect cells of the immune system and may modulate cytokines and immune responses to unrelated immunogens. Infected macrophages can spread infection to distant tissues. Mononuclear cell infiltrates in infected tissues consist of macrophages, plasma cells, and CD4+ and CD8+ lymphocytes. Infection of glial cells with MHV can upregulate expression of major histocompatibility complex (MHC) class I or II antigens, making these cells potential targets for cytotoxic T cells. MHV infection causes thymic atrophy, and the virus can also infect B lymphocytes. Polyclonal B cell activation and hypergammaglobulinemia are associated with FIPV infection. Cheetahs, which have little polymorphism in their MHC genes, have a much higher fatality rate after feline coronavirus infection than cats.

Prevention and Control of Coronavirus Diseases

Because of the economic importance of coronavirus diseases of domestic animals, modified live vaccines against IBV, TGEV, BCV, CCV and FIPV have been developed. However, they do not provide solid protection from infection with wild-type coronaviruses. Other approaches to protection or control of coronavirus diseases include use of recombinant S proteins, synthetic peptides that mimic neutralization epitopes, passive immunization with antibody against S glycoproteins, and treatment with interferon α or monoclonal antireceptor antibody. Improvement of vaccines will require understanding of coronavirus virulence factors, strain variation and mechanisms of immunopathology.

Future Perspectives

Full-length cDNA copies of coronavirus genomes and a way to express them to obtain infectious virions are needed to investigate coronavirus replication and pathogenesis. Analysis of the complex synthesis, processing and functions of the coronavirus polymerase peptides will provide unique insight into mechanisms of RNA recombination, tools for coronavirus genetics, and possibly new targets for drugs to inhibit coronavirus replication. Improvements in diagnostic tests to identify coronavirus infections in humans and animals will elucidate the epidemiology of these viruses and may implicate coronaviruses in the etiology of additional diseases. The characterization of coronavirus–host interactions during persistent infection *in vitro* and *in vivo* will provide additional insight into coronavirus epidemiology and pathogenesis. Further understanding of virus variants and host responses to coronavirus infections of the respiratory and enteric tracts may lead to improved coronavirus vaccines.

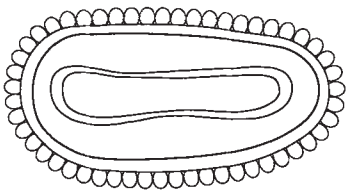
COWPOX VIRUS (*POXVIRIDAE*)



D Baxby and **M Bennett**, Departments of Medical Microbiology and Veterinary Pathology, University of Liverpool, Liverpool, UK

History

The first published account of human and bovine cowpox is Edward Jenner's 'Inquiry' of 1798. He described the clinical signs of cowpox in both species, and how infection in humans with *Variolae vaccinae* ('known by the name of the cowpox') provided protection against smallpox. At that time smallpox killed 200 000–600 000 people each year in Europe and caused up to 30% of all deaths in city children. Jenner's observations, despite the concern of some over the consequences of inoculating bovine material into humans, soon led to the use of smallpox vaccine around the world. However, not until Pasteur's work nearly 100 years later was the principle of immunization used again, and it was Pasteur who suggested that all such immunizations be called 'vaccines' to honour Jenner.

Although Jenner's first vaccines came from cattle, later material was sometimes derived from horses, and the origins of modern vaccinia virus (smallpox vaccine), are unknown. Differences between cowpox and vaccinia viruses were first reported in 1939, since when further biological and genetic studies have confirmed that vaccinia virus is a separate species and not simply a mutant of cowpox virus or a recombinant of smallpox and cowpox viruses.

Even Jenner had difficulty finding cowpox, and cowpox virus is certainly not now endemic in cattle. It is now accepted that cowpox virus is endemic in rodents, with cattle and humans acting as accidental hosts. However since the 1970s, the domestic cat has been the animal most frequently seen with cowpox.

Taxonomy and Classification

Cowpox virus is a member of the genus *Orthopoxvirus* in the subfamily *Chordopoxvirinae* of the *Poxviridae* family; the international reference strain, Brighton, was isolated in 1937 from farm workers in contact with cattle. Cowpox virus can be differentiated from other orthopoxviruses by a combination of biological tests, including the ability to produce hemorrhagic pocks on chorioallantoic membranes, the production of A-type inclusions (ATI) in infected cells, and its 'ceiling temperature' (40°C, the highest temperature at which it will replicate), by minor antigenic differences, and by a variety of molecular assays including restriction enzyme digestion, particularly with Hind III, and sequencing or restriction endonuclease digestion of polymerase chain reaction (PCR) products from, for example, the ATI and fusion protein genes.

Not all strains of cowpox virus are identical and some, isolated from unusual hosts, have been referred to in the past as 'cowpox-like' viruses. However, they are clearly strains of cowpox virus, and probably represent geographic or host-range variants.

Properties of the Virion

Cowpox virus has a typical orthopoxvirus morphology, and is indistinguishable from vaccinia virus by electron microscopy. Virions are brick shaped, approximately 300 × 200 × 200 nm in size, and may be enveloped. The virion consists of a biconcave core, and within each concavity lies a lateral body (**Fig. 1**).

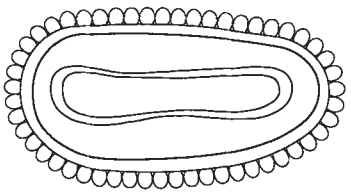
COWPOX VIRUS (*POXVIRIDAE*)



D Baxby and **M Bennett**, Departments of Medical Microbiology and Veterinary Pathology, University of Liverpool, Liverpool, UK

History

The first published account of human and bovine cowpox is Edward Jenner's 'Inquiry' of 1798. He described the clinical signs of cowpox in both species, and how infection in humans with *Variolae vaccinae* ('known by the name of the cowpox') provided protection against smallpox. At that time smallpox killed 200 000–600 000 people each year in Europe and caused up to 30% of all deaths in city children. Jenner's observations, despite the concern of some over the consequences of inoculating bovine material into humans, soon led to the use of smallpox vaccine around the world. However, not until Pasteur's work nearly 100 years later was the principle of immunization used again, and it was Pasteur who suggested that all such immunizations be called 'vaccines' to honour Jenner.

Although Jenner's first vaccines came from cattle, later material was sometimes derived from horses, and the origins of modern vaccinia virus (smallpox vaccine), are unknown. Differences between cowpox and vaccinia viruses were first reported in 1939, since when further biological and genetic studies have confirmed that vaccinia virus is a separate species and not simply a mutant of cowpox virus or a recombinant of smallpox and cowpox viruses.

Even Jenner had difficulty finding cowpox, and cowpox virus is certainly not now endemic in cattle. It is now accepted that cowpox virus is endemic in rodents, with cattle and humans acting as accidental hosts. However since the 1970s, the domestic cat has been the animal most frequently seen with cowpox.

Taxonomy and Classification

Cowpox virus is a member of the genus *Orthopoxvirus* in the subfamily *Chordopoxvirinae* of the *Poxviridae* family; the international reference strain, Brighton, was isolated in 1937 from farm workers in contact with cattle. Cowpox virus can be differentiated from other orthopoxviruses by a combination of biological tests, including the ability to produce hemorrhagic pocks on chorioallantoic membranes, the production of A-type inclusions (ATI) in infected cells, and its 'ceiling temperature' (40°C, the highest temperature at which it will replicate), by minor antigenic differences, and by a variety of molecular assays including restriction enzyme digestion, particularly with Hind III, and sequencing or restriction endonuclease digestion of polymerase chain reaction (PCR) products from, for example, the ATI and fusion protein genes.

Not all strains of cowpox virus are identical and some, isolated from unusual hosts, have been referred to in the past as 'cowpox-like' viruses. However, they are clearly strains of cowpox virus, and probably represent geographic or host-range variants.

Properties of the Virion

Cowpox virus has a typical orthopoxvirus morphology, and is indistinguishable from vaccinia virus by electron microscopy. Virions are brick shaped, approximately 300 × 200 × 200 nm in size, and may be enveloped. The virion consists of a biconcave core, and within each concavity lies a lateral body (**Fig. 1**).

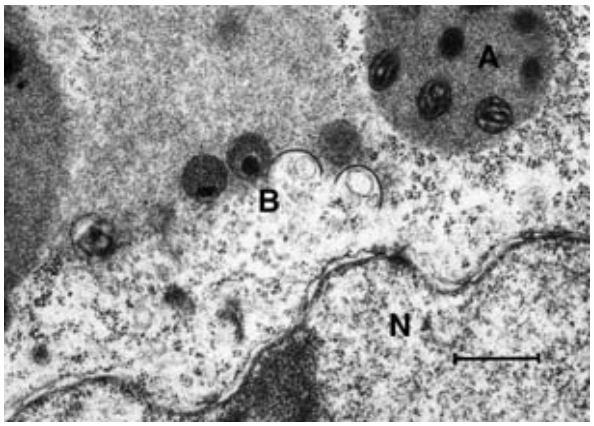


Figure 1 Thin section of a chick chorioallantois cell infected with cowpox virus. A, A-type inclusion containing mature virions; B, B-type inclusion showing virions in various stages of assembly; N, nucleus. Bar = 500 nm.

The whole is surrounded by an outer membrane covered in short spicules. The core contains DNA and virus-encoded enzymes.

Virions released naturally from the cell are wrapped in an envelope derived from the host cell's Golgi membranes. This envelope is very labile and often lost during manipulation. Most virions involved in cell-to-cell spread within an infected animal are probably enveloped (extracellular enveloped virus; EEV), but virus released by cell lysis (intracellular naked virus; INV) is also infectious, and INV, particularly within protective A-type inclusions, is probably important in spread from animal to animal. Because most laboratory stocks of cowpox are prepared by cell disruption, they consist almost entirely of INV, and the biology of EEV has been less well studied.

Negatively stained preparations of INV usually show two types of particle, an M (mulberry) form, the surface of which is covered in randomly arranged tubules, and a C (capsule) form which has a capsule and a dark, homogenous center. Both forms are infectious and their different appearances are due to different degrees of dehydration during preparation.

Properties of the Genome

The genome consists of linear double-stranded (ds) DNA with covalently linked inverted repeats at the termini. The cowpox virus genome is the largest of all the orthopoxviruses with a total of approximately 220 kbp (140 MDa). The central portions are highly conserved, but more variation occurs towards either end. Digestion with Hind III clearly differentiates cowpox viruses from other known orthopoxviruses, but isolates, particularly geographically distinct strains, do vary, and digestion of genomic DNA with other enzymes often reveals much greater differences between strains. However, the genome is fundamentally very stable and no changes in restriction enzyme profile have been seen over numerous passages and many years. Differences in the restriction enzyme profiles of different strains can therefore be used in epidemiological studies to help determine the source of an outbreak.

The main exception to this genomic stability is the frequent mutations which give rise to the 1% white pocks on chorioallantoic membranes. In the Brighton strain this mutation involves the deletion of 32–39 kbp DNA from the right hand end of the genome and its replacement by a nonhomologous copy of DNA from the left hand end. The size of the transposed fragment varies (5–50 kbp) but the net effect maintains the general symmetry of the termini, which is probably important for replication.

Several portions of the cowpox virus genome have been sequenced including the extreme termini, the hemagglutinin gene, a gene responsible for the major protein in A-type inclusions, a putative serine protease inhibitor, and a gene involved in host cell range.

Properties of Proteins

The size of the cowpox virus genome, and comparison with vaccinia virus, suggest that it could encode up to 200 proteins, although not all, for example hemagglutinin and thymidine kinase, are essential for replication. General comparison of proteins from different orthopoxviruses has helped to establish the separate identity of cowpox virus. However, many proteins are shared, and the many enzymes encoded by vaccinia virus have their homologues in cowpox virus.

Interest has recently focused on (1) proteins concerned with attributes possessed by cowpox but not vaccinia virus, such as the ability to grow on Chinese hamster ovary (CHO) cells, to produce A type inclusions (ATI) and in analysis of white pock mutation, and (2) proteins involved in evasion of the host's immune response.

Growth of cowpox virus in CHO cells is dependent on production of a 77 kDa protein, which inhibits apoptosis. These cells rapidly undergo apoptosis when infected with wild-type vaccinia virus, but not with a recombinant expressing this protein. Formation of ATI involves the production of two late proteins. One, of 160 kDa, is the major component of the inclusion itself. The other, probably a virus surface component, is required for occlusion of virions into the inclusion. Mutation to the white

pock character is associated with loss of a gene (*CmrA*), homologous to the *B13R* of vaccinia virus, which encodes a 38 kDa protein, one of the most abundant early gene products. The CmrA predicted amino acid sequence is similar to that of inhibitors of serine proteases (SERPIN) which are involved in blood clotting, and has *in vitro* serine protease inhibitor activity causing inhibition of both apoptosis and production of interleukin 1β (through inhibition of caspase 1) and inhibition of granzyme B, a serine protease released by cytotoxic T lymphocytes. Other cowpox proteins which may be involved in inhibition of aspects of the host's immune response include soluble tumor necrosis factor receptors (CmrB and CrmC), interferon receptors, and a complement-binding protein.

Physical Properties

Little work has been done directly on the physical properties of cowpox virus which are usually assumed to be similar to those of vaccinia virus and infectious ectromelia virus. The lipid envelope of cowpox virus is labile and readily lost by mechanical stress, but is not essential for virus infectivity. The virus is generally very hardy, and can survive for months in dry scab material at room temperature, and indefinitely at −70°C. It is readily inactivated by moist heat at 65°C, and by hypochlorites, phenolics and detergents, but less effectively by alcohols.

Replication

The mechanisms of DNA replication and temporally regulated transcription and translation of cowpox virus mRNA are largely similar to those of vaccinia virus (*see also:* **Vaccinia virus**). Virus replication takes place in the cytoplasm, and virus assembly occurs in areas known as B-type inclusions (**Fig. 1**). Like vaccinia virus, cowpox virions can leave the cell as individual naked (unenveloped) particles by lysis of the cell membrane or as enveloped particles by fusion with Golgi and the outer cell membranes. Cowpox differs from vaccinia virus in that its genome also encodes for large proteinaceous inclusions known as A-type inclusions, into which virions are incorporated (**Fig. 1**). These inclusions are released by cell lysis, and are thought to act as protective packets which aid survival of the virus outside the animal and therefore increase the chance of spread to another host on fomites.

Geographic and Seasonal Distribution

Confirmed isolations of cowpox virus have been made only in Europe and adjoining regions of Asia. Cowpox in domestic cats and humans is mostly seen in the late summer and autumn. This seasonal variation probably reflects the increased prevalence of infection in the reservoir hosts at this time of year. Bovine cowpox is so rare that no data exist to assess any seasonal effects on incidence.

Host Range and Virus Propagation

Cowpox virus has a wide host range both *in vivo* and *in vitro*. It is important to distinguish between reservoir hosts in which the virus is maintained, and accidental (indicator) hosts (**Table 1**; see Epidemiology). Cowpox virus causes natural infections in cattle, humans, domestic cats and dogs, and a variety of zoo animals. During an outbreak at Moscow Zoo, virus was also isolated from laboratory rats used to feed the big cats. Surveys of wildlife have demonstrated infection in ground squirrels and gerbils in Turkmenia, and voles and mice in Western Europe (see Epidemiology.) Mice, guinea pigs and rabbits have been experimentally infected.

Cowpox virus can be isolated and propagated on the chorioallantoic membrane of hens' eggs, but, unlike vaccinia virus, does not grow in feather follicles of adult chickens. It can be propagated in a variety of cell cultures derived from human, simian, bovine, feline, murine and rabbit tissues. Cowpox virus, unlike vaccinia virus, grows in CHO cells.

Genetics

Cowpox virus produces red, hemorrhagic pocks on the chorioallantoic membrane with about 1% white pock mutants. These breed true and the change in pock character reflects deletion and transposition events near the termini of the genome. White pock mutants also lack an antigen, designated 'd', and are better able to grow on arginine-deprived cells than is the parent virus. Other properties which are independently inherited, and vary between individual strains include relative haemagglutinin production, presence of virions in A-type inclusions, resistance to heat, minor differences in ceiling temperature for growth, and pathogenicity for new-born mice and chick embryos. These properties have been used to identify individual isolates of cowpox virus, and may be useful in epidemiological studies. Orthopoxviruses undergo genetic recombination, for example producing hybrids of cowpox and smallpox viruses.

Evolution

Little is known of the evolution of cowpox virus or orthopoxviruses as a whole. Serologic and cross-hybridization studies show that all orthopoxviruses

Table 1 Animals in which natural cowpox has been reported

Probable reservoir hosts	*Distribution*
Ground squirrel (*Citellus fulvus*)	Continental Europe and adjoining states of CIS (former USSR)

[a]Infection recognized in captive species in zoos etc. in areas where cowpox is endemic. Infection has not been reported in the animals' natural habitats, where cowpox does not circulate.
[b]Including cheetah, lion, puma, ocelot, panther and lynx.

are closely related, but each species can be readily differentiated by biological properties and genome structure. Cowpox virus isolates are genetically stable. Recent isolates often have near-identical restriction enzyme profiles to strains isolated many years ago, and the Brighton strain behaves the same now as when first isolated over 60 years ago. However, isolates of cowpox virus do differ in restriction enzyme pattern and minor biological characteristics, and generally greater differences occur between geographically distinct isolates (for example, the Brighton and Moscow Zoo strains). Furthermore, whereas British isolates are all very similar, greater variation exists among Continental isolates and this may reflect a central European origin for cowpox virus, and divergence as individual strains spread out into different host reservoirs and geographical areas.

Serologic Relationships and Variability

There is extensive antigenic crossreactivity within the genus *Orthopoxvirus* although minor differences may allow differentiation of some species. No serological differences have been reported among cowpox virus strains apart from the loss of 'd' antigen from white pock mutants.

Epidemiology

Cowpox virus is rarely isolated from cattle, which serologic surveys show not to be the reservoir host. Most human infection cannot be traced to contact with infected cattle, and over half the recent human cases seen in Britain have been traced to contact with infected cats. The domestic cat, although the species in which cowpox is most frequently diagnosed in Britain, is not the reservoir host because although cat-to-cat transmission can occur, antibody to cowpox virus is rare in cats. There is no evidence that cowpox virus can become endemic in any of the zoo animals which have been infected, but with increasing reliance on zoo populations for the survival of many species, these outbreaks may cause conservation problems.

Cowpox virus has been isolated from and antibody detected in ground squirrels and gerbils (*Rhombomys, Citellus* and *Meriones*) in Eurasia, voles (*Microtus*) in the Russo-Finnish border; antibody and virus DNA has been detected in wild voles and mice (*Apodemus* and *Microtus*) in Britain (**Table 1**). This, together with the restricted geographic range of the virus, the seasonal incidence of feline cowpox and several reports of human cowpox at the site of a rodent bite, all support the theory that cowpox virus is endemic in local rodent populations. **Figure 2**

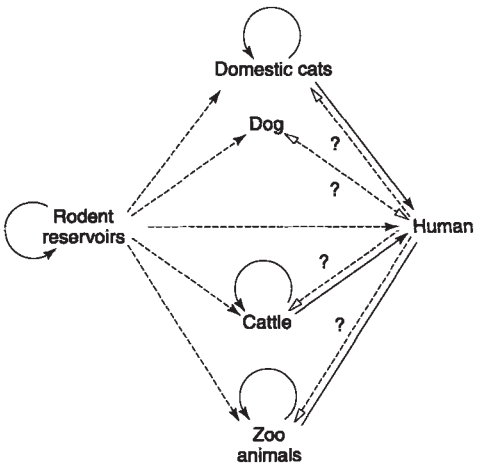

Figure 2 The probable epidemiology of cowpox. Solid lines indicate known routes of transmission, dotted lines indicate probable transmission, and dotted lines with ? indicate possible transmission. In all cases transmission might be direct or via fomites.

summarizes the probable epidemiology of cowpox virus.

Transmission and Tissue Tropism

Little is known about the routes of transmission of cowpox in endemic rodent populations. Voles and mice can be infected experimentally by both skin and oronasal inoculation, and arthropod vectors may play a role in mechanical transmission in wild colonies. Inoculation by either route can cause viremia and systemic infection, with virus detected particularly at the sites of inoculation, in lymphoid tissue and in lung. Rodent infections may persist for several weeks, although the role of possible persistent infection in the epidemiology of cowpox is unknown.

Among the occasional, or 'accidental', hosts of cowpox virus, the most frequent route of infection appears to be through the skin, probably through a cut or abrasion. Domestic cats, however, can be infected experimentally by oronasal inoculation, and respiratory spread may have been involved in some outbreaks of cowpox in big cat collections. Virus replication in cattle and humans is mainly limited to the epidermis at the site of entry, and possibly also to draining lymph nodes. In cats, virus can be isolated not only from skin lesions but also from lymphoid, lung and turbinate tissue. Skin inoculation of cats is followed by virus replication both at the site of entry and in draining lymph nodes, there is development of a viremia, and virus can be isolated from the white cell fraction of blood, from the spleen and other lymphoid organs. After about 7–10 days, virus can be detected in the epidermis leading to the development of secondary skin lesions. The viremia in cats appears to last 1–8 days, and no virus has been isolated from cats after the skin lesions have healed, which may take 5–6 weeks.

Pathogenicity

It is not known if different strains of cowpox virus vary in pathogenicity for cattle or humans. In a small-scale experiment, no differences in infectivity or ability to cause a primary lesion in domestic cats could be detected between the Brighton strain, and isolates from a cheetah and a domestic cat. Differences in pathogenicity of different strains do exist for newborn laboratory mice and chick embryos, but these differences are not associated with ability to infect various accidental hosts and it is not known if they have any significance in the maintenance of different strains of cowpox virus in different reservoir hosts.

Wild-type virus outgrows the white pock mutants and is more pathogenic for laboratory animals. Other virulence factors are discussed above. Given the large number of virulence genes encoded by cowpox virus, the large differences in pathogenicity (see Clinical Features, below) of the virus in different hosts, and particularly its apparently low pathogenicity in wild rodents are noteworthy.

Clinical Features of Infection

In cattle, cowpox virus causes teat lesions, but little apparent systemic disease. Human infection is also characterized by a single skin lesion, usually on a hand or the face, but is often accompanied by systemic signs such as nausea, fever and lymphadenopathy, and children may be hospitalized (**Fig. 3**). Spread of skin lesions in humans is usually the result of direct transmission, for example from hand to face, but multiple lesions may also occur if there is a pre-existing skin condition. Death is rare, but has been associated with underlying immunosuppression.

Cowpox in domestic cats is a more severe disease than in cattle or humans. There is usually a history of a single primary lesion, generally on the head or a forelimb, but by the time the cat is presented for veterinary attention widespread skin lesions have usually developed. The primary lesions vary enormously in character and secondary bacterial infection is common. The widespread secondary lesions first appear as small erythematous macules, which develop into papules and ulcers over several days. These scab over, and the cat usually recovers within 6–8 weeks. Cats may be slightly pyrexic in the early stages of the

Figure 3 Human cowpox. Although most patients have only one lesion which is seen when it has developed to a hard black eschar, this illustration shows a primary lesion at the early eschar stage (right) and a secondary lesion at the earlier vesicular stage. (Reproduced from Baxby D *et al.* (1994) *Br. J. Dermatol.* 131: 598, with permission of Blackwell Science Publishers.)

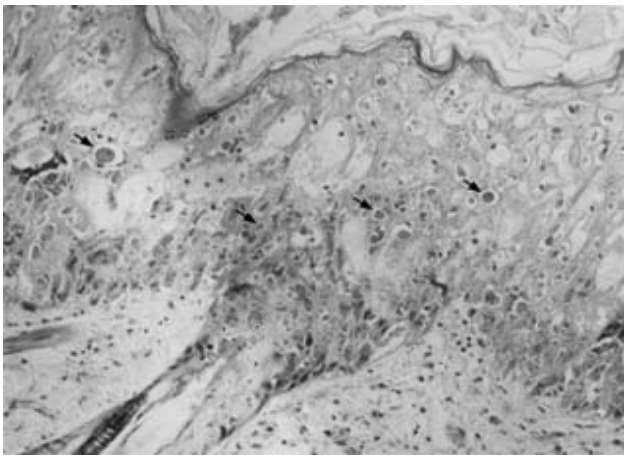

Figure 4 Microscopic section of a cowpox lesion in the skin of a cat, showing hypertrophy, hyperplasia, leukocyte infiltration and A-type inclusions (some indicated). (Reproduced from Baxby D *et al.* (1994) *Br. J. Dermatol.* 131: 598, with permission of Blackwell Science Publishers.)

disease, and some show signs of mild upper respiratory disease. More severe illness such as large non-healing lesions or pneumonia usually, but not always, results from secondary bacterial infection or immunosuppression (for example by concurrent feline leukaemia virus or feline immunodeficiency virus infection). In cheetahs, viral pneumonia is common, and cowpox has a higher mortality rate in most nondomestic felids.

Pathology and Histopathology

The skin lesions associated with human and feline cowpox are generally typical of those expected of an orthopoxvirus infection, developing through papule, vesicle, pustule, ulcer and healing stages, although macroscopic vesicles often quickly ulcerate because of abrasion or, in the case of domestic cats, because the epidermis is too thin in most areas to support a vesicle. Microscopic examination shows hypertrophy and hyperplasia of infected cells, multilocular vesicle formation, large, intracytoplasmic eosinophilic inclusion bodies (A-type inclusions) (**Figs. 1** and **4**) in epithelial cells and a vigorous polymorph infiltration of the dermis. In rodents, similar microscopic changes can be seen, although gross lesions may be limited to mild swelling. Immunostaining demonstrates virus antigen in epithelial cells of the skin, hair follicles and sebaceous glands, and in dermal macrophages.

Even in the lungs and turbinates of cats from which large amounts of virus can be isolated, there are often no gross lesions, and microscopic lesions may not be found. In cats showing clinical signs of pneumonia there is often an interstitial pneumonia, and, again, eosinophilic inclusions can be seen in infected cells. The tonsils and lymph nodes of infected cats and rodents contain many large reactive follicles, and immunostaining may demonstrate antigen in macrophage-like cells. Some follicles may have large necrotic centers suggesting that virus replication is occurring here.

After 3 days growth on the chorioallantoic membrane of 12-day chick embryos, cowpox virus causes hemorrhagic pocks approximately 2 mm in diameter, with a few (usually 1%) white pocks. Microscopically, the red pocks consist of ectodermal proliferation and hypertrophy with many cells containing A-type inclusions, and extensive edema and hemorrhage into the mesoderm. The histopathology of white pocks is similar but consists of more inflammatory infiltration and no hemorrhage.

Immune Response

Relatively little work has been done on the immune response to cowpox virus. Antibody can be detected by ELISA, immunofluorescence, virus neutralization (VN) with or without complement, complement fixation, and hemagglutination–inhibition (HAI) tests. HAI antibody can be detected before VN antibody, and in cattle begins to decline after about six months. HAI antibody is therefore more useful for

the diagnosis of acute infections than VN antibody, and in epidemiological studies indicates more recent infection than VN antibody alone.

Virus neutralizing antibody to EEV is detectable before VN antibody against INV, as has been described for vaccinia virus in mice. VN antibody to EEV is particularly important in protection as most cell-to-cell spread is by EEV. Thus an animal vaccinated with inactivated INV may have high INV-neutralizing antibody levels, which is what most VN assays measure, but little antibody to EEV, and may succumb to live virus challenge.

As in vaccinia and ectromelia virus infections, cell-mediated immunity must also play an important role in protection against cowpox virus, but very little work has been published specifically on the cell-mediated immunity to cowpox. A possible delayed-hypersensitivity response has been reported in cats.

Prevention and Control

As the source of infection is not usually known, and infection in humans or domestic animals is uncommon, measures to prevent infection are generally not warranted. Vaccination against smallpox is no longer routine, but in any case would probably not protect against the development of a skin lesion, although it might reduce the severity of systemic illness. Vaccinia virus infection of cattle and humans often causes lesions and disease similar to cowpox. Vaccination is not recommended for laboratory workers in the UK. Vaccinia virus does not grow well in cats, and its efficacy as vaccine in felids is therefore doubtful.

Although cowpox virus can cause quite severe human disease, it does not appear to be very infectious. Human-to-human spread of cowpox has not been reported (unlike for vaccinia virus). Most recent human cases of cowpox have been traced to contact with infected cats, but we have found no cases of cat-to-human transmission when cowpox has been first diagnosed in the cat. Simple hygiene – washing hands after handling the cat, keeping the cat or scab material away from cuts and the eyes – seems adequate to prevent transmission to humans, although special measures might be taken for the very young, elderly or immunosuppressed. Similarly, if an outbreak occurs in cattle, the main route of spread among the cows is on milking equipment, and simple hygiene should suffice to control spread.

Future Perspectives

Cowpox virus is one of several orthopoxviruses which have wildlife reservoirs. For example, monkeypox virus is endemic in squirrels, and raccoonpox and Californian volepox viruses each circulate in their eponymous hosts. Buffalopox virus is now regarded as a variant of vaccinia virus and may also have a wild animal reservoir in India. Occasionally these and other orthopoxviruses may infect other, accidental, hosts, such as domestic animals – there are reports of uncharacterized orthopoxviruses being isolated from horses, for example, in Africa, North America and Australia – or humans, for example in China. Study of the epidemiology of cowpox virus is therefore useful as a model for orthopoxvirus maintenance in a wildlife reservoir host and the mechanisms of transmission from animals to humans, especially in light of the proposed use of recombinant vaccinia viruses in wildlife.

COXSACKIEVIRUSES (*PICORNAVIRIDAE*)

Bruno Pozzetto and **Odette G. Gaudin**, Laboratory of Virology, Faculty of Medicine Jacques Lisfranc, University of Saint-Etienne, Saint-Etienne, France

History

Descriptions of a disease resembling epidemic myalgia presumably caused by viruses of the coxsackie group have been reported in different Scandinavian areas since the second half of the 19th century. The first coxsackievirus was isolated only in 1948 in New York state (USA) by Dalldorf *et al*, who were investigating an outbreak of paralytic poliomyelitis in the village of Coxsackie. They discovered a new group of viruses pathogenic for suckling mice. The observation led to the widespread use of suckling mice in the investigation of the viral etiology of poliomyelitis-like illnesses. The conditions of their isolation led some investigators to believe that the new viruses were only 'common fellow travellers of poliovirus'. But it rapidly became clear that these viruses had a full range of morbidity.

Taxonomy and Classification

Coxsackieviruses belong to the *Picornaviridae* family, genus *Enterovirus*, group of human enteroviruses. They contain a single plus-strand of RNA protected by an icosahedral capsid exclusively constituted of proteins. The viral particule contains no enzyme and no envelope. Its size is 22–30 nm. Coxsackieviruses are divided into two subgroups: coxsackievirus A (CA) with 23 serotypes 1–24 (23 is missing) and coxsackievirus B (CB) with six serotypes 1–6. This classification is based on the histopathologic lesions in suckling mice (see under Pathology and Histopathology below).

It was noticed early on that pathogenic features for suckling mice are not a definite characteristic. For instance, strains of CA23 have been recognized as being variants of echovirus 9 and some strains of CA24 have been temporarily classified as echovirus 34. Recent developments in molecular biology have contributed to the remodeling of the currently admitted classification. According to RNA analysis, four clusters have been proposed for human enteroviruses among which CA are scattered over three of them (**Table 1**).

Geographic and Seasonal Distribution

Coxsackieviruses are present worldwide, each serotype being found in a given area. More information has been gathered on CB than CA, owing to the somewhat tedious procedure for isolating the latter. Climate has a major role in the epidemiological pattern. In temperate countries, the circulation of coxsackievirus culminates in summer and autumn. In tropical regions, they occur all the year round in an endemic mode. In so-called 'Mediterranean' climates, they are distributed at a low endemic level with a summer–fall increase. They circulate together with other enteroviruses.

Host Range and Virus Propagation

Coxsackieviruses commonly cause diseases in humans. A virus very similar to CB5 has been recovered from pigs. Chimpanzees can also be infected by coxsackieviruses. They usually develop a subclinical infection, but CA7 can produce paralysis in monkeys.

Suckling mice can be experimentally infected by several parenteral routes: 1-day-old newborn mice are required for maximum pathogenic expression for CB. For CA, the susceptibility of the suckling mice extends to the first 4 days of life. Weaning mice can be infected by mutants of CB causing pancreatitis or myocarditis. Suckling merions are also susceptible.

Coxsackievirus can be grown in a number of primary tissue culture systems or continuous cell lines derived from primate (human or monkey) tissue: primary monkey kidney or embryonic human kidney, human heteroploid cells such as KB, HeLa and Hep2, or monkey kidney cell lines such as Vero and BGM. Replication results in a typical cytopathic effect with cell ballooning associated with a dendritic aspect. The virus cycle is completed within 7–8 h and takes place exclusively in the cytoplasm. Rapid cell lysis occurs.

CB induces a chronic infection in human embryonic lung fibroblasts. Some CA serotypes cannot be grown on cells, especially CA1–6. Primary or cell lines originated from mice are not susceptible *in vitro*. Cell susceptibility is linked to the presence of cell membrane receptors for the virus. It has been shown recently that the major cell receptor for CB is a 46 kDa protein that also mediates the attachment of adenoviruses 2 and 5 and has been called coxsackievirus and adenovirus receptor (CAR). The gene coding for this protein is located on chromosome 21. Some CA and CB strains are also able to bind to another receptor – the complement regulatory protein

Table 1 Classification of coxsackieviruses within the *Enterovirus* genus (according to Puli *et al* (1995) *Virology* 212: 30 and Pöyry *et al* (1996) *J. Gen. Virol.* 77: 1699

Clusters	*Coxsackieviruses*	*Other enteroviruses*
A	A2, 3, 5, 7, 8, 10, 12, 14, 16	Enterovirus 71
B	A9	Enterovirus 69
	B1, 2, 3, 4, 5, 6	All echoviruses except types 22 and 23
C	A1, 11, 13, 15, 17–22, 24	Poliovirus 1–3
D	None	Enteroviruses 68 and 70
Undetermined	A4, 6	—

Table 2 Identified cellular receptors of coxsackieviruses

Cell receptor	*Coxsackieviruses*	*Other viruses competing with the same receptor*
CAR	Coxsackieviruses B	Adenoviruses 2 and 5
DAF (CD55)	CB-3, CA-21	Echoviruses 6, 7 and 12
ICAM-1	CA-13, 15, 18, 20, 21	Major group rhinoviruses
$\alpha_v\beta_3$ integrin	CA-9	—

decay accelerating factor (DAF) – that has been shown to be the major receptor of echoviruses types 6, 7 and 12. The $\alpha_v\beta_3$ integrin (vitronectin receptor) is involved in the entry of CA9 in host cells whereas CA types 13, 15, 18, 20 and 21 use ICAM-1 as cellular receptor (**Table 2**). These data suggest that many coxsackieviruses use multiple receptor molecules for their cell entry mechanisms.

Strains of CB agglutinate human cord blood type 0 erythrocytes. The structure and location of the hemagglutinins are unknown.

Genetics

The coxsackieviruses whose full-length sequence is available (CB1, 3, 4, 5, CA9, 21) show a genomic structure similar to that of the other members of the genus *Enterovirus*, especially poliovirus, the most extensively studied. Briefly, the genome is about 7500 bases and is flanked by two nontranslating poly(A) regions (NTR) 5′ and 3′. A small protein, VPg, is linked to the 5′-NTR (**Fig. 1**). In contrast with most eukaryotic messenger RNA molecules, the 5′ NTRs of enteroviruses contain internal ribosomal entry sequences (IRES) so that ribosomes may bind in the absence of a free 5′ capped terminus. The RNA acts as an mRNA which encodes directly a high-molecular-weight polyprotein, p220, consisting of three segments coding for the three precursor proteins, namely P1, P2 and P3. A cascade of cleavages carried out by virus-encoded serine proteases (2A and 3C) leads to 11 polypeptides among which are the final structural proteins of the capsid. These structural proteins are derived from the P1 segment (mol. wt 97 000) of p220 (**Fig. 1**).

The capsid surface of the dense virion is a combination of 60 protomers of four viral proteins (VP) each, numbered from 1 to 4. In coreless particles (empty capsids), only three proteins are present: VP0, 1 and 3. The incorporation of the RNA genome to the empty capsid leads to the provirion. VP0 is the precursor protein for VP2 and 4. The autolytic cleavage of VP0 into VP2 and VP4 stabilizes the capsid structure and leads to the infectious virion. VP4 is an internal protein linked to the genome. The epitopes which bind neutralizing antibodies are mainly present on VP1. Nevertheless, minor epitopes are also present on VP2 and VP3. The structures responsible for adsorption of the virus to the cell receptor (see above)

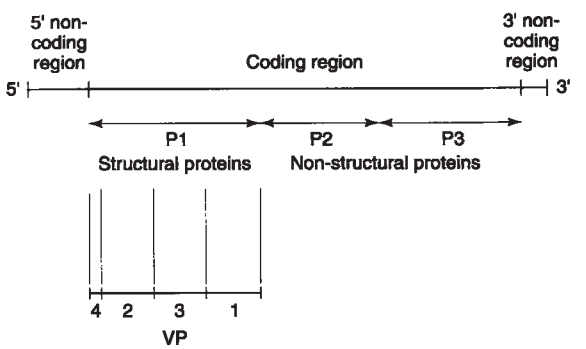

Figure 1 General organization of the genomic RNA of coxsackieviruses.

are buried within a kind of 'canyon' with VP1 on its edges. Defects in the RNA are frequent in the so-called 'defective particles'. Therefore the population of viral particles that finally burst out of the lysed cell is heterogeneous. It contains a mixture of at least the four types described above.

Evolution, Serologic Relationships and Variability

Minor antigenic drifts are currently observed in laboratory isolates and virions can exist as quasi-species in the same organism, as generally happens with other RNA viruses. Although no antigenic shifts comparable with the influenza A virus have been observed, the appearance of a variant of CA24 causing a 'new' disease consisting of a hemorrhagic conjunctivitis (see under Clinical Features of Infection below) may question this.

As a general rule, the 23 serotypes of CA and the six serotypes of CB are antigenically unrelated. The neutralization test is the reference procedure for identification of isolates: serum raised against one serotype does not crossneutralize the others. But limited neutralization sometimes occurs between related serotypes. For instance, CA3 and CA8 show antigenic crossing, as do CA13 and CA18.

Epidemiology

Coxsackieviruses demonstrate the same epidemiological pattern as the other enteroviruses. Each year, whatever the climate or geographic area, a human community experiences at least one, and often several, coxsackievirus infections.

Age is an important risk factor. Young children are the reservoir of the virus. In low socioeconomic conditions babies become infected during the first months of life. As economic development increases, the first contact with the virus may occur later during childhood or even later.

Coxsackieviruses are present in the environment. Many reports regarding isolation of CB from surface or waste waters, soils, raw vegetables and shellfish have shown that these viruses are a major public health problem. The spread of the virus from infected members in a community is due to the feces which contaminate the environment. As children with silent infections excrete the virus in their feces for several weeks, they play the role of an incessant source of virus. The poorer the sanitation, the higher the contamination level of the environment.

Transmission and Tissue Tropism

Coxsackieviruses have the same routes of transmission as polioviruses: the oral route via dirty hands and polluted water and food. Transmission by aerosol is possible when pulmonary syndromes are present, during an outbreak of conjunctivitis, or merely from subjects with subclinical infection when the virus is present in the throat during the incubation period.

Coxsackieviruses affect a wide range of susceptible tissues and organs: striated muscles, myocardium, brain and spinal cord, pancreatic islets, lung, skin and conjunctivae. Mutants with special pathogenic properties have been reported, for example cardiotropic and pancreatropic CB for mice. Much effort has been devoted to the characterization of the genetic determinants responsible for this virulence.

Pathogenicity

After entry by the oral route, the virus is thought to follow the same path as poliovirus: multiplication in the throat and small intestine and in the lymph nodes draining the primary sites of multiplication. Then, via the bloodstream or lymphatic drainage system, the virus reaches the target organs. In the lower intestine, the virus enters the Peyer patches through the M cells. Its multiplication in the absorptive cells has been shown in animal tissues *in vitro* but evidence in humans is lacking.

Most infections are clinically silent. The reason why some individuals exhibit a higher susceptibility to the virus than others is still largely a mystery. Several factors may increase susceptibility: previous immune status, immune deficiency restricted to some strains, higher pathogenic potency of mutants, genetic HLA constitution and/or hormonal interactions with viral multiplication. The last factor would explain the sex ratio of 1.5–2 males for every female when clinical expression of the infection is considered.

Clinical Features of Infection

A large panel of acute diseases are due to coxsackieviruses and there is much evidence for their causative role. The relationship between a serotype and a disease is generally not clear to the clinician, except under epidemic circumstances. Moreover it is difficult to distinguish between coxsackievirus infections and other nonpolio enterovirus infections when clinical symptoms only are considered. Another common clinical characteristic of enterovirus infections is the frequency of featureless diseases (febrile illness, resolutive rash, flu-like syndrome). During the last two decades, persistent pathologic disorders have been attributed to these viruses; their actual role in

such processes is still disputed although more and more evidence tends to accredit this concept, as is discussed below.

Much more information is available for CB than CA viruses, owing to the easier isolation of the former. For the latter, attention has been focused on those CA serotypes that multiply easily in cultured cells, such as CA7, 9, 16, 21 and 24. Coxsackieviruses induce protean clinical pictures depending on the target organ.

Nervous system

CA7 and 9 and CB1–6 have been infrequently involved in polio-like paralysis. Encephalitis, ataxis and paralysis of the cranial nerves are rare. Both CA and CB are responsible for aseptic meningitis, although echoviruses are more frequently the cause of meningitis than are coxsackieviruses.

Skin and mucosa

Herpangina is common in school age children. Clear reddish vesicles are distributed on the moderately inflamed mucosa of the throat, tonsils, soft palate and tongue. It appears as a self-limited stomatitis. CA1–6, 8, 10 and 22 have been isolated from the vesicles. Hand-foot-and-mouth disease consists of vesicles on the palms of the hand and soles of the foot, but also on the limbs and trunk, sometimes associated with stomatitis. The main serotypes involved are CA4, 5, 9, 10 and 16 and CB2 and 5. CA16 is responsible for the majority of outbreaks. Herpes-like vesicular rashes have been described, and CB1 has been isolated from the vesicular fluid. Rubella-like rashes are often associated with other more typical clinical symptoms.

Striated muscles

Pleurodynia, also known as 'epidemic myalgia' or 'Bornholm disease' (from the name of a Danish island where an outbreak gave the opportunity for a well-documented clinical description in 1933) consists of a sudden pain in the chest (due mostly to the involvement of the diaphragm) and a general malaise associated with headache, sore throat and fever. It is common in summer camps for children and teenagers.

CB are also associated with acute myositis and rhabdomyolysis. A mouse model of myositis with CB1 has been described.

Prolonged myalgia was described several decades ago in patients during convalescence from CA infections. A new concept has recently arisen, the 'post-viral fatigue syndrome' (or 'myalgic encephalomyelitis'), which consists of prolonged muscular fatigability (>6 months) often associated with other functional and/or psychological symptoms. The causative role of CB is still largely disputed and some herpetoviruses are also candidates.

Heart

CB are one of the main etiologic agents of acute myocarditis, pericarditis and myopericarditis. The association has been strengthened by the finding, by *in situ* hybridization, of viral RNA sequences in the myocardium of patients who had died from acute heart failure. In neonates, the disease is often fatal whereas the prognosis is usually milder in adolescents and adults.

Dilated cardiomyopathy (DCM), a chronic heart disease characterized by ventricular congestion leading to heart failure and for which the only remedy may be heart transplantation, has also been tentatively linked to a persistent CB infection. A mouse model using CB3 supports this hypothesis. In humans, the role of CB in DCM is suggested by high antibody titers (IgM included) against CB and by the detection of CB RNA by hybridization or polymerase chain reaction (PCR) in the myocardium of patients. The pathogenesis of the disease involves genetic, virological and autoimmune factors. The viral persistence might be related to an impaired replication of the virus illustrated by production of positive and negative RNA genomic strands in equal amount.

Alimentary tract and liver

Acute abdominal pains have been associated with CB, mimicking appendicitis in childhood. A few cases of hepatitis associated with CB have also been described, especially in neonates. Gastroenteritis is a frequent prodromic symptom of coxsackievirus infections. However, these viruses cannot be considered as main etiologic agents of viral diarrhea, owing to their low level of multiplication in the intestinal tract.

Pancreas

There are strong arguments in favor of the involvement of CB in type I insulin-dependent diabetes mellitus, including a mouse model using CB1 and 4. The disease is thought to result from several factors acting together: a genetic predisposition, the multiplication of a diabetogenic strain of CB in the islets of Langerhans and antigen mimicry between CB proteins and cell components of the pancreas, both of them resulting in cell lysis. Rather than a persistent infection, it may be the summation of repeated enteroviral infections, some of which occurred during intrauterine life, which leads to the last event responsible for the chronic insulin deficiency.

Respiratory tract

Coxsackieviruses may be responsible for infections of the respiratory tract: CA9 and 16 have been associated with pneumonia, CA21 and 24 with the common cold and CB2, 3, 4 and 5 with upper and lower respiratory tract infections. They mimic respiratory infections due to myxo-, rhino- and coronaviruses. Although occurring all through the year, the enteroviral origin of these infections may be evoked when observed during the warm season ('summer grippe').

Eye

A new nosological entity which arose in 1969–1970 and consisted of conjunctivitis was first described in South West Asia and was introduced into the Americas in 1981. A variant of CA24 was recognized as the etiologic agent of this acute conjunctivitis. It is clinically less severe than acute hemorrhagic conjunctivitis due to enterovirus 70, the subconjunctival hemorrhages being moderate. No paralysis has been reported from the areas where the main outbreaks occurred, a clinical pattern distinctive of the enterovirus 70 disease.

Coxsackievirus, pregnancy and the neonatal period

The risk of abnormalities in the fetus of pregnant women exposed to coxsackieviruses seems low, although the long-term consequences of such infections are difficult to evaluate. When the disease develops in an infant within the first 2 or 3 weeks of life, the virus is generally transmitted during or immediately after delivery. Infection in the infant ranges from mild to severe, even fatal. Meningitis, myocarditis, pneumonia, encephalitis, hepatitis and pancreatitis may be encountered. It should be noted that severe nosocomial outbreaks of coxsackieviruses have been reported in the neonatal period.

Pathology and Histopathology

The incubation period varies from 2 days (conjunctivitis) to 1 month or more, the mean time being 10–14 days. Information on the histopathological lesions comes mainly from animal models which have been extensively described (**Fig. 2**). A review of histopathological lesions observed in more than 400 isolations from patients in a UK hospital reports a wide range of lesions. The classical distinction between CA and CB is somewhat confused by the fact that a wide range of lesions can be found regardless of the subgroup. However, there are significant variations in the frequency of the main types of lesions.

With CA, polymyositis is found predominantly, as expected from previous data, with the thoracic, abdominal and thigh muscles being the most severely affected. Encephalitis and poliomyelitis are also found, as well as brown fat necrosis and myocarditis, but in a much smaller proportion than in animals infected with CB. In contrast, encephalitis, poliomyelitis, brown fat necrosis, endomyopericarditis and pancreatitis are the main lesions observed in animals infected with CB. Myositis is rare and, when present, it is much more limited. These considerations may explain the finding that the usual signs of CB infection in mice are spasticity and fine tremors rather than the flaccid paralysis commonly observed with CA infection. Wherever the sites of histological lesions are, inflammatory foci are invaded by numerous mononuclear cells.

In experimentally infected susceptible mice using a cardiotropic strain of CB3 by the intraperitoneal route, the virus can be detected in the myocardium as soon as two days postinfection; foci of necrosis associated to calcifications and to infiltrates of lymphocytic cells are present within one week. Inflammation and necrosis peak during the second week; then, these lesions decrease and are progressively replaced by fibrosis. During the acute phase of myocarditis, infectious virions can be recovered from the heart. At the end of the first month, a chronic myocarditis, characterized by an interstitial fibrosis and a mild infiltrate of mononuclear cells, can occur in some strains of mice; at this stage, no infectious virus can be cultured but RNA genome is detected by *in situ* hybridization in a small proportion of myocytes around the foci of fibrosis. Specific cytotoxic T cells and autoantibodies seem to play a leading part in the constitution of both acute and chronic lesions. Similar findings have been described in other experimental murine models using CB strains infecting peripheral muscles or pancreas.

Immune Response

Half a century of investigations has brought definite evidence that the control of and protection against viral infection is mainly related to neutralizing antibodies. Such antibodies mainly result from silent infections. They are considered to be lifelong, although the conditions for this may vary largely in space and time. Naturally acquired immunity declines when the current circulation of the virus decreases within a community.

Specific mucosal immunoglobulin A plays a protective role, especially in the gut. The presence of specific immunoglobulin M has been demonstrated by various technical approaches. However, their signifi-

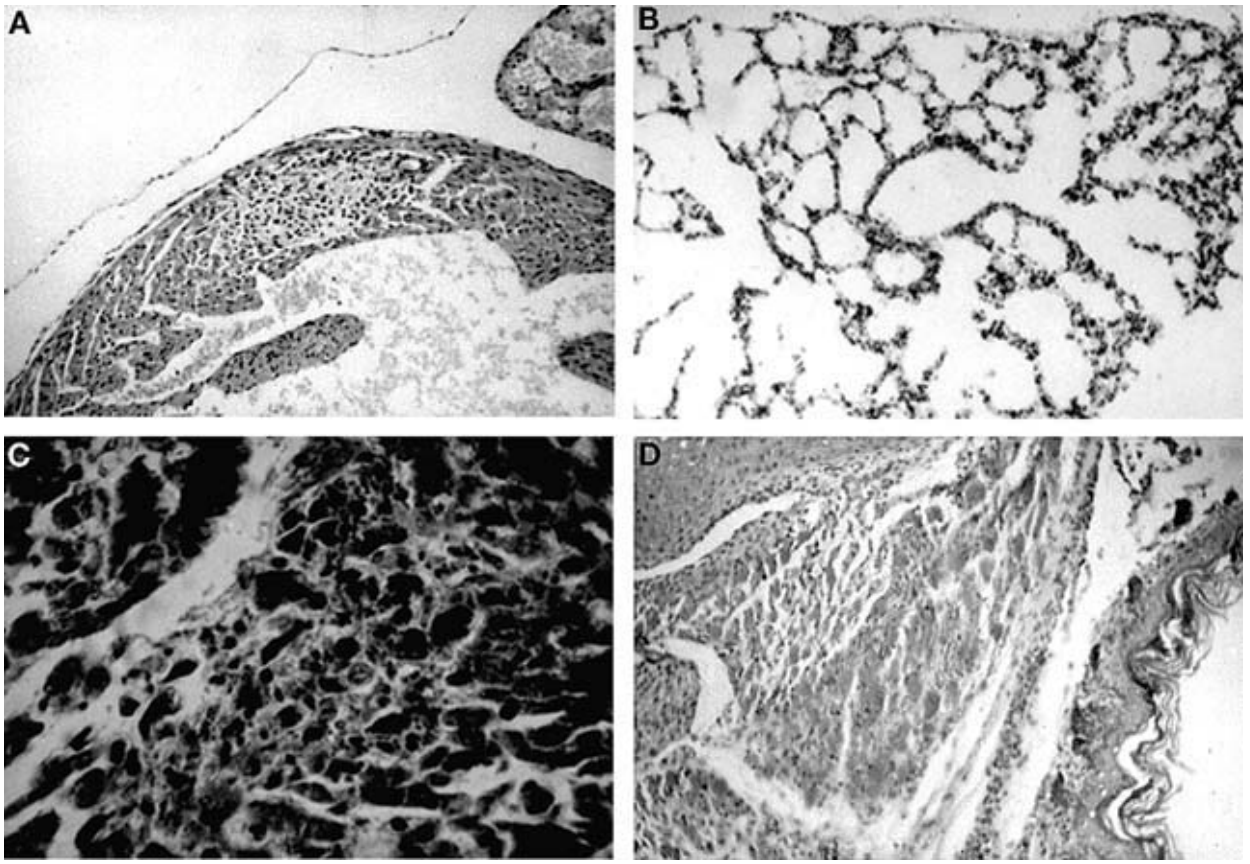

Figure 2 Tissue damage caused in baby mice by a freshly isolated strain of coxsackievirus B (**A–C**) or coxsackievirus A (**D**). (**A**) A large necrotic focus in the atrial myocardium (×100); (**B**) steatitis in the interscapular brown fat pad (×250); (**C**) a ventricular focus of necrotic cardiomyocytes (×450): note the dense mononuclear infiltrate in the infected area. (**D**) Intercostal muscles with diffuse hyalinization of myocytes and mild inflammatory infiltrate (×250).

cance as signs of a current or recent infection is still disputed, owing to the lack of data on their duration in different clinical situations.

Other aspects of immunity are still debated. The target of neutralizing antibodies is limited to epitopes on the surface of the virus. The total constitutive proteins of the capsid represent less than 50% of the total proteins encoded by the genome. Is there a host reaction against the nonstructural proteins? In the inflammatory foci seen in infected tissue in human and murine diseases, mononuclear cells are predominant; specific cytotoxic T cells probably play a key role in the control of infection. As discussed above, autoimmunity is probably involved in the genesis of tissue damage observed in chronic infections.

The immune response to coxsackieviruses is thought to be mostly type specific. However, frequent antigenic crossings of neutralizing, precipitating, complement-fixing antibodies are encountered when sera from infected patients are investigated, which evokes the possibility of common epitopes for subgroups or serotypes. Previous studies have identified a group-specific epitope located on VP1 which is common to most of the members of the enterovirus genus, including CA and CB. Similarly, T cells primed with a given serotype are able to proliferate *in vitro* in the presence of other serotypes of enterovirus.

Prevention and Control

No specific prevention by vaccines is presently available or planned for the near future. Preventive measures include a general hygiene policy, but this cannot avoid transmission through a community, especially among children. As the virus is mainly transmitted by dirty hands or contact with contaminated water or food, particular attention must be paid to individual hand washing and sanitary control of swimming pools and meals. Bathing in natural surface waters (rivers, ponds) should be avoided. Sea resorts may be at risk when waste waters are admitted into the sea at the shoreline without previous treatment. Eating raw shellfish collected in such places is a great risk.

Disinfectants have to be chosen carefully for institutions for children (hospitals, kindergartens, camps) because coxsackieviruses are resistant to many common ones, such as alcohols, quaternary ammonium compounds and chlorhexidine. They are stable at pH values ranging from 3.0 to 10.0. Chlorine is recommended for cleaning bathrooms and other surfaces. For hand disinfection, chlorinated or iodinated disinfectants should be used. For instruments, disinfectants containing aldehydes (formaldehyde or glutaraldehyde) are adequate, provided that the instruments have been cleaned before immersion in the decontaminating bath and the contact is for over 30 min.

Exposure to temperatures above 50°C destroys coxsackieviruses in a few minutes, but the presence of Ca^{2+} or Mg^{2+} can protect against heat inactivation. Viruses are highly resistant in feces, where adventitious substances reduce the efficiency of the disinfectant which does not easily penetrate the fecal material. Feces can remain at room temperature for weeks without substantial loss of infectivity.

No antiviral agent is available for therapy. γ-Globulins have proven useful in a limited number of cases.

Future Perspectives

The role of coxsackievirus has been well established in acute diseases, especially in communities of children. However, the concept of persistent infection, which is essentially related to adults, has been introduced more recently. It has been developed thanks to the tools of molecular biology. The demonstration of RNA sequences in tissues may provide a valuable argument for persistence, but will not elucidate the immunological mechanisms that allow this persistence. Increased knowledge of all facets of immunity is needed to understand these mechanisms. The wide use of PCR in the routine diagnosis of enterovirus infections will also help to identify the pathological role of those CA that cannot be cultivated in cell culture.

As development of vaccines is improbable, owing to the numerous serotypes of coxsackievirus, total control of the infection is not a realistic aim. However, if the role of CB in chronic infection of the heart was fully confirmed, a vaccine directed against the main serotypes of this subgroup could be designed. Two kinds of antiviral agents have been proposed: components acting on the initial phases of the lytic cycle (Win compounds) and protease inhibitors active against the two serine proteases 2A and 3C. They have still to prove their efficiency *in vivo/e2>*.

CRYPTOVIRUSES (*PARTITIVIRIDAE*)

Robert G Milne and **Cristina Marzachi**, Istituto di Fitovirologia Applicata, CNR, Torino, Italy

History

In 1968 and 1969, Pullen at Rothamsted in England showed that all apparently healthy plants examined of seven species of beet (*Beta*) contained small isometric virus-like particles (VLPs) which were inherited through the seed. The particles could not be horizontally transmitted, and the carrier plants could not be freed from the VLPs by heat therapy; therefore they were suspected of being obligatory constituents of all beet plants. However, Kassanis, White and Woods in 1977 found a few beets not containing VLPs, and this stimulated them to purify the virus, study some of its properties, and name it beet cryptic virus (BCV). During this period, in the same laboratory, two other kinds of VLP were found with similar properties. They were named vicia cryptic virus (VCV) and ryegrass spherical virus (later renamed ryegrass cryptic virus, RGCV).

In 1981 members of the Turin plant virus group showed that a further VLP with 'cryptic' properties, named carnation cryptic virus (CCV), contained double-stranded (ds) RNA – at this time novel for small plant viruses. Soon they reported that alfalfa, red clover, white clover and *Festuca pratensis* also contained small isometric dsRNA-containing VLPs, and that RGCV likewise contained dsRNA.

Working independently in Japan, Natsuaki and colleagues at Utsunomiya discovered 'temperate' VLPs containing dsRNA, in several hosts including alfalfa, white clover, beet, radish and spinach. Collaborating, in 1984, the Torino and Utsunomiya groups found that they had been describing similar or identical viruses, and it became clear that cryptic viruses (now more correctly designated cryptoviruses) were a coherent group with some remarkable properties, which are or appear to be the following.

The particles are isometric, approximately 30 or 38 nm in diameter, and the genome consists of dsRNA in two, possibly three linear segments, each of about 1.3–2.3 kbp (mol.wt $0.9–1.5 \times 10^6$). At least in WCCV1 these segments are encapsidated together. Virus concentration in plants is low to very low and there are no obvious signs of disease. There is no mechanical, vector or graft transmission, but transmission through ovules and pollen to the seed is very high. There is no movement from cell to cell except to daughter cells during cell division.

Subsequent work in the UK, Germany, Italy and Japan has shown that cryptoviruses are widespread among both dicotyledonous and monocotyledonous plant species. Some plants are host to several apparently unrelated cryptoviruses; for example, white clover contains three, beet three, hop trefoil three, red pepper two, carrot five, radish three, ryegrass probably three, and carnation probably two. These numbers are conservative.

In 1990, Flachmann, Beuther and Wiese in Germany found small isometric VLPs associated with dsRNAs in fir trees (*Abies*) of six different species. In *A. alba* and *A. homolepis*, there were three dsRNAs in the range 1.5–1.65 kbp. The particles appeared to be seed-transmitted to a high degree but not associated with any symptoms, and not, in preliminary tests, mechanically transmitted, so they were probably also cryptoviruses. Funding for this interesting work was discontinued when it became clear that forest die-back was not attributable to these agents.

In 1992, four major dsRNAs, each about 2 kbp in length, encapsidated in isometric VLPs 25 nm in diameter and located in the chloroplasts of the marine green alga *Bryopsis*, were reported, together with less stable 40 nm particles containing dsRNAs of about 4.5 kbp in size constantly located in the mitochondria of the same organism. These particles appeared to be cryptic-like viruses; dsRNAs of various sizes (but unknown significance) were found in most green, red and brown algae examined.

Taxonomy and Nomenclature

Until recently, these viruses were placed in the genus *Cryptovirus*, comprising subgroups I and II; these categories were then recast as the family *Cryptoviridae*, and the genera *Alphacryptovirus* and *Betacryptovirus*, respectively. Now, *Alphacryptovirus* and *Betacryptovirus* are recognized as two genera within the family *Partitiviridae*, which also includes certain fungal viruses with similar properties in the genera *Partitivirus* and *Chrysovirus*.

Alphacryptovirus, type species, white clover cryptic virus 1 (WCCV1)

The segmented dsRNA genome (two RNAs of about 2.0 and 1.7 kbp, and possibly a third RNA in some cases) is contained in capsids about 30 nm in diameter, rounded and without visible subunits, and built of one polypeptide of about 55 kDa. An RNA-dependent RNA polymerase (replicase) is associated

Table 1 Species and possible species of the genus *Alphacryptovirus*

Species	*Possible species*
Alfalfa cryptic 1	Carnation cryptic 2
Beet cryptic 1, 2, 3	Fescue cryptic
Carnation cryptic 1	Garland chrysanthemum temperate
Carrot temperate 1, 3, 4	Mibuna (*Brassica rapa* var. *laciniifolia*) temperate
Cucumber cryptic	Red pepper cryptic 1, 2
Hop trefoil cryptic 1, 3	Rhubarb temperate
Radish yellow edge	Santosai (*B. rapa* var. *amplexicaulis*) temperate
Ryegrass cryptic 1	White mustard cryptic
Spinach temperate	Amaryllis cryptic
Vicia cryptic	
White clover cryptic 1, 3

White clover cryptic 2	

with the capsid. Particles of WCCV1 have a buoyant density in CsCl of 1.392 g ml^{-1}.

Betacryptovirus, type species, white clover cryptic virus 2 (WCCV2)

The segmented dsRNA genome (two RNAs of about 2.25 and 2.1 kbp) is contained in capsids about 38 nm in diameter, rounded, and with prominent morphological subunits, whose precise arrangement is unknown. An RNA-dependent RNA polymerase (replicase) is associated with the capsid. The particles have a buoyant density in CsCl of 1.375 g ml^{-1}.

A few *Alphacryptovirus* (WCCV1, CCV1, the three BCVs) have been examined in some detail, but no *Betacryptovirus* has yet received much attention. The presumed cryptoviruses of conifers have yet to be studied, classified and named. **Tables 1** and **2** list some cryptoviruses and place them provisionally in one of the two genera.

The fungal viruses in the genera *Partitivirus* and *Chrysovirus*, also members of the family *Partitiviridae*, have affinities with the *Cryptoviridae*, possess two dsRNA genome segments each of about 3.3–2.25 kbp, encapsidated separately within isometric particles 30–35 nm in diameter, with a single coat protein of 50–70 kDa. In both virus families, the RNA polymerase also behaves as a replicase.

Virus–Host Relationships

No cryptic virus has been found to infect more than one species of host plant, although the leguminous genera *Trifolium*, *Medicago* and *Vicia* have been found to harbor related viruses. The one known exception is BCV1 (or a closely similar virus) which has been found in both *Beta vulgaris* and *B. maritima* by the Rothamsted group of Antoniw and White. In Aschersleben, Germany, the group of Thomas Kühne and Andreas Stanarius found that BCV1 and BCV2 occur differentially in different cultivars of fodder beet, red beet and chard, all varieties of the *B. vulgaris* complex.

Cryptoviruses have been detected in all organs and tissues of their hosts, and there is no tissue specificity. VLPs, apparently cryptovirus particles, have been seen in thin sections of cells in both the cytoplasm and the nucleus. With radish yellow edge virus, cytoplasmic viroplasms have been reported.

Cryptoviruses have experimentally been found not to pass across grafts between carrier and noncarrier plants, even though other 'normal' viruses in a mixed infection did pass, and though graft transmissibility is one of the cardinal properties of conventional plant viruses. In other experiments using white clover, some plants originally carrying either WCCV1 or WCCV2 were found, after some months, to have sectored with respect to the virus: some sectors of the plants and their stolons were virus-free, while the rest contained undiminished amounts of virus. These results, and the fact that no means of experimental or natural horizontal transmission are known, suggest that the viruses lack a transport function that would carry them from cell to cell. In this model, the only way for the viruses to spread is for the pollen and/or ovule to infect the zygote, and for the virus to pass to both daughter cells at cell division. Sectoring would be the result of occasional passage of the virus to only one of two daughter cells in a meristem.

The Rothamsted group in England examined rates of transmission through pollen and ovule of a mixture of BCVs in beet and of VCV in *Vicia faba*. In both cases they found that when pollen from carrier plants fertilized flowers of noncarrier plants, about 40% of the progeny were carriers; in the reverse situation, about 80% of progeny were carriers, and when both parents were carriers, the transmission rate was 100%. Computer modeling showed that such transmission rates could result in almost the entire

population being carriers after 80 generations, and that no other means of spread need be postulated.

The great majority of cryptoviruses produce neither symptoms nor cytopathology in their hosts, but there are reports of some mild effects, probably not of commercial significance.

Serologic Relationships and Variability

Although cryptic viruses occur in very low concentration, their particles are rather robust and not, in principle, difficult to purify. Antigenicity of the capsid is high, and several antisera are available. It is to be noted, however, that the genomic dsRNA can also react with any anti-dsRNA antibody present in antisera. Unequivocal identification of the genomic dsRNA can always be achieved by combining temperature-gradient gel electrophoresis and immunoblotting using an anti-dsRNA serum.

No serological relationship has been found with a range of fungal viruses. Using immunoelectron microscopy and gel immunodiffusion tests, the following crossrelationships have been found between cryptoviruses.

- *Alphacryptovirus*. Hop trefoil cryptic virus 1 (HTCV1; from *Medicago lupulina*) is related, but not identical, to alfalfa cryptic virus 1 (ACV1; from *M. sativa*). WCCV1 (from *Trifolium repens*) is related to a morphologically similar unnamed cryptic virus in red clover (*T. pratense*). HTCV3 is related, but not identical, to VCV (from *Vicia faba*).
- *Betacryptovirus*. HTCV2 (from *M. lupulina*) is related to but not identical with WCCV2 (from *T. repens*) and also red clover cryptic virus 2 (from *T. pratense*); these last two viruses are also related to each other.

No serological relationship has been found between cryptoviruses in different genera, nor has relationship been detected between viruses hosted by unrelated plant species.

Molecular Biology

With WCCV1, BCV1, BCV2, BCV3 and ACV1, Northern hybridization has revealed no sequence homology between the different segments of each virus or between the genomes of the different viruses. Some sequence homology has been found between ACV1 and HTCV1, both alphacryptoviruses.

With both ACV1 and BCV1, the two genomic RNAs, translated in an *in vitro* wheat germ system after heat denaturation, produce two major polypeptides of about 67 and 52 kDa. In each case, the smaller peptide, product of RNA2, is precipitated by an antiserum raised against the viral particles and is believed to be the coat protein. The 67 kDa polypeptide, product of RNA1, is thought to be the replicase. With these two viruses, the proteins synthesized represent 82–95% of the coding capacity of the respective RNAs, suggesting that the genome segments are monocistronic.

Nucleotide sequences have been analyzed for BCV3, WCCV1, carrot temperate virus 1 (CTeV1) and radish yellow edge virus 1 (RYEV1). BCV3 RNA1 and RNA2 share the same 5′-terminal sequences, suggesting that, as described for reoviruses, these might play an important role during the replication/packaging process. Terminal sequences for WWCV1, CTeV1 and RYEV1 are not definitive and therefore this possibility cannot be generalized. BCV RNA2 is monocistronic, encoding a peptide of 54.9 kDa which accounts for about 90% of its total coding capacity. The peptides encoded by BCV3 RNA2 and WCCV1 RNA1 are not immunoprecipitated by the respective coat protein antisera, and contain polymerase consensus sequences; they probably represent the viral replicases. Thus with BCV3, RNA2 appears to encode the replicase, not the coat protein, whereas with ACV1, BCV1 and WCCV1 the replicase seems to be encoded by RNA1. Polymerase motifs are indeed found in RNA1 of WCCV1, CTeV1 and RYEV1.

Sequence homology at the amino acid level between the RNA-dependent RNA polymerases (RDRPs), as well as coat proteins, is relatively close (79% and 58%, respectively) between WCCV1 and CTeV1 and there is some homology (19% and 28%, respectively) between WCCV1 and RYEV1, while homology between any of these viruses and BCV3 is not significant.

RDRP activity has been detected in all cryptic viruses examined (WCCV1, WCCV2, CCV (probably a 1 + 2 mixture) and ACV1). The *in vitro* products of these polymerases are dsRNAs of genomic size; they react, in hybridization experiments, with the respective denatured genome segments. Thus the polymerases resemble those of some *Partitiviridae*, and their *in vitro* behavior suggests they are better defined as replicases rather than transcriptases. Of course *in vivo* activity must also include synthesis of mRNA.

Perspectives

Little work has been done on cryptoviruses because they are not of pressing practical importance. However, they are of some theoretical interest as they appear to represent the minimal 'self-sufficient' virus, able to operate using only two cistrons, those of the replicase and the coat protein. There is as yet no evidence for a specifically encoded transport function,

and there is apparently no movement from cell to cell; despite this, the viruses are obviously very successful, being encountered frequently where they are sought. Notably, however, they have not been found in some commonly used plant virus host plants such as *Chenopodium quinoa, Nicotiana tabacum* or *N. clevelandii*.

If indeed these viruses have no routine means to exit from their host species and infect another (sexually incompatible) species, they are also of evolutionary interest, as they may then represent cases of strict coevolution of the virus and its host. However, if it is confirmed that similar cryptoviruses are found in both conifers and angiosperms, then it would appear more likely that, at least on occasion, the viruses have been able to jump wide interspecies barriers. Their genomes, although incompletely characterized, are known to encode some of the amino acid sequence motifs conserved in other well-known virus families, suggesting that cryptic viruses have a common origin with these.

Cryptoviruses are of little direct economic importance and appear never to cause significant diseases. However, in mixed infections, the damage caused by a second (pathogenic) virus might be aggravated by the presence of one or more cryptic viruses. No such case is reliably reported. The unsuspected presence of cryptic viruses could (and sometimes has) confused the interpretation of serological or molecular assays designed to detect other viruses.

History

Cucumber mosaic virus (CMV), is the type member of the *Cucumovirus* genus. The first report of CMV was in 1916, as the causal agent of a mosaic disease in cucumber and muskmelon in Michigan, and in cucumber in New York. Before the advent of modern identification techniques such as nucleic acid hybridization or serology, plant viruses were named by disease type and host plant. More than 40 plant viruses of other names, most notably southern celery mosaic virus, were later proven to be CMV. Over the last 80 years, CMV has been identified as the causal agent of over 100 plant diseases, ranging from mild mosaic to severe necrosis and death.

Robinia mosaic virus (RoMV) was first described in 1935 as the causal agent of a mosaic disease in black locust. Peanut stunt virus (PSV) was identified in 1966 after a widespread epidemic of stunting in peanuts in the southeastern United States, and was recognized as a separate cucumovirus. Recent molecular analyses, as well as indications from earlier serology, clearly show that RoMV and PSV are the same species, and even though it was described first, RoMV is now designated the Robinia strain of PSV.

and there is apparently no movement from cell to cell; despite this, the viruses are obviously very successful, being encountered frequently where they are sought. Notably, however, they have not been found in some commonly used plant virus host plants such as *Chenopodium quinoa, Nicotiana tabacum* or *N. clevelandii*.

CUCUMOVIRUSES (*BROMOVIRIDAE*)

Contents

General Features

Marilyn J. Roossinck, Plant Biology Division, The Samuel Roberts Noble Foundation, Ardmore, Oklahoma, USA

History

Cucumber mosaic virus (CMV), is the type member of the *Cucumovirus* genus. The first report of CMV was in 1916, as the causal agent of a mosaic disease in cucumber and muskmelon in Michigan, and in cucumber in New York. Before the advent of modern identification techniques such as nucleic acid hybridization or serology, plant viruses were named by disease type and host plant. More than 40 plant viruses of other names, most notably southern celery mosaic virus, were later proven to be CMV. Over the last 80 years, CMV has been identified as the causal agent of over 100 plant diseases, ranging from mild mosaic to severe necrosis and death.

Robinia mosaic virus (RoMV) was first described in 1935 as the causal agent of a mosaic disease in black locust. Peanut stunt virus (PSV) was identified in 1966 after a widespread epidemic of stunting in peanuts in the southeastern United States, and was recognized as a separate cucumovirus. Recent molecular analyses, as well as indications from earlier serology, clearly show that RoMV and PSV are the same species, and even though it was described first, RoMV is now designated the Robinia strain of PSV.

Tomato aspermy virus (TAV), the third member of the *Cucumovirus* genus, was first described in 1946. TAV is a common virus of chrysanthemums, and historically it was also known as chrysanthemum aspermy virus.

The cucumoviruses were among the first plant viruses to be purified, in the early 1960s, and a structural analysis of the virions was published in 1963. The RNA nature of the genome was described in the early 1970s, as well as the occasional incidence of satellite RNAs associated with CMV and PSV. Satellite RNAs were isolated from a strain of CMV causing an epidemic of severe necrosis and death in tomato in France in the early 1970s.

CMV was one of the earliest plant viruses for which cDNA clones capable of producing infectious transcripts were generated, in the late 1980s, and the molecular genetic analysis of the virus has progressed rapidly since then.

Taxonomy and Classification

The genus *Cucumovirus* is in the family *Bromoviridae*. All members of the family have a tripartite genome that is packaged in separate virions. The *Cucumovirus* genus consists of three species, CMV, PSV and TAV. The initial classification was based on serological data, but the species have also been distinguished by compatibility of RNAs 1 and 2. The RNA 3 of all members of the genus can be interchanged and still produce infection, whereas RNAs 1 and 2 must be from the same species. CMV is further divided into two subgroups (designated subgroup I and subgroup II) based on serology and nucleotide sequence similarity. PSV has been less thoroughly studied, but appears to have several subgroups, based on the same criteria as the CMV subgroup designations, and is more heterogeneous as a species in nucleotide sequence than the other cucumoviruses. TAV does not have any subgroup divisions, although only a few strains have been thoroughly studied.

Geographic and Seasonal Distribution

All three species of *Cucumovirus* are distributed worldwide. CMV, one of the most common plant viruses known, and by far the most thoroughly studied of the cucumoviruses, has been reported from temperate, subtropical and tropical climates. In temperate zones the virus apparently overwinters in trees or other perennial hosts. PSV has been predominantly isolated from temperate zones in the United States, eastern Europe, South America, and Japan, Korea and China. It has also been found in warmer climates in northern Africa. It has not been reported in Australia. The perennial host of PSV in many parts of the world is white clover, which it often infects asymptomatically. Most PSV epidemics in peanut in the southeastern United States were attributed to a common practice of planting white clover along the borders of peanut fields, providing a constant source of the virus. TAV is found in most places where chrysanthemums are grown. In general, the cucumoviruses do not replicate well at very high temperatures, and so may be less problematic in very hot weather.

Host Range and Virus Propagation

CMV has the broadest host range of any known virus, infecting about 1000 species of plants in 85 families, including herbaceous plants, shrubs and trees, and both monocots and dicots. Individual strains have a more limited host range, but they can be readily propagated experimentally in tobacco or cucurbits. PSV predominantly infects legumes, including leguminous trees such as black locust. Most strains can be propagated in tobacco, but a few strains do not infect tobacco, so cowpea is the preferred host for propagation. TAV is most commonly found in chrysanthemum and tomato, but has also been reported in other hosts, such as zinnia, pepper, chrysanthemum, hyacinth, and *Amaranthus* spp. It is dificult to mechanically transmit to chrysanthemum, but infects most tobacco experimentally, and *Nicotiana* spp. are good propagation hosts. Virus titers for all of the cucumoviruses generally peak about 2 weeks after initial infection, and propagations are usually done for 2–3 weeks. The virions are readily purified from homogenized and clarified infected plant material by high speed centrifugation, usually through a sucrose cushion. The virus can also be concentrated from clarified homogenate by precipitation with polyethylene glycol. Yields range from about 100 mg kg^{-1} to 2 g kg^{-1} of fresh tissue. The purified virus or purified viral RNA of all the cucumoviruses is readily transmitted by mechanical inoculation to experimental plants.

Genetics

The divided genome of the cucumoviruses allowed for substantial genetic analysis even before cDNA clones of the virus were obtained. The three genomic RNAs were isolated by gel electrophoresis separation and reassorted to determine various functions, and symptom and host range determinants were mapped to all three RNAs in this manner. *In vitro* translations of viral RNAs also helped elucidate functions. RNAs 1 and 2 were shown to encode the viral replication

components (the 1a and 2a proteins), and RNA 3 to encode two proteins, the 5′ open reading frame (ORF) encoding a protein (3a) of M_r about 30 000, and the 3′ ORF encoding the coat protein, translated from the subgenomic RNA 4. The 3a protein was later shown to be the movement protein, although other components of the virus are also involved in movement. Reassortants (or pseudorecombinants) also confirmed the species divisions.

RNA 3 could be exchanged between all the viruses, whereas RNAs 1 and 2 could not be exchanged between the species, implying a complex interaction between the 1a and 2a proteins. The construction of cDNA clones of all three genomic RNAs of several strains of CMV, PSV and TAV has allowed for more detailed genetic analyses.

Satellite RNAs

CMV and PSV can both harbor satellite RNAs. These small molecular parasites of the virus do not encode any proteins, but exert their (sometimes dramatic) biological effects with their RNA. They do not contain any regions of sequence similarity with the helper virus that are greater than about 10 nucleotides. The cucumovirus satellite RNAs are linear, highly structured RNAs ranging from about 330 to 400 nucleotides in length. There is no significant sequence similarity between the CMV satellite RNAs and the PSV satellite RNAs. They cannot be replicated by the heterologous helper virus, but the CMV satellite RNAs can be supported by TAV.

Evolution

The *Cucumovirus* genus, family *Bromoviridae* is a member of the alphavirus 'supergroup', that includes both plant and animal viruses. Two domains in the 1a protein are highly similar to methyltransferase- and helicase-like domains within the group. A third domain, in the 2a protein, is highly similar to the RNA-dependent RNA polymerases of the alphaviruses. Hence these viruses are believed to have a common ancestor, and it is postulated that they originated from an insect virus, and were transmitted and adapted to both plants and animals.

All of the cucumoviruses contain a second ORF in RNA 2, encoding the 2b protein. This ORF is not found in most of the other members of the *Bromoviridae* but it was recently described in one other member, tobacco streak virus, a member of the *Ilarvirus* genus, although it is not known if the 2b ORF is functional in tobacco streak virus. The 2b ORF presumably evolved by overprinting of the 2a ORF. The deduced amino acid sequences are much more divergent than those of other cucumoviral proteins. There is conservation of amino acid sequence of the 2b between strains and subgroups of CMV, and between PSV and TAV. However, there is virtually no similarity between CMV and PSV or TAV 2b, or between any of the cucumovirus 2b proteins and the tobacco streak 2b protein.

Table 1 Nucleotide sequence similarity between CMV subgroups, and the *Cucumovirus* species for each RNA

Virus[a]	*CMV (I)*	*CMV (II)*	*PSV*	*TAV*
RNA 1				
CMV (I)	100	78	68	70
CMV (II)		100	70	69
PSV			100	68
TAV				100
RNA 2				
CMV (I)	100	74	65	64
CMV (II)		100	66	66
PSV			100	64
TAV				100
RNA 3				
CMV (I)	100	78	64	65
CMV (II)		100	65	66
PSV			100	72
TAV				100

[a]Comparison were made between Fny-CMV (subgroup I), Q-CMV (subgroup II), J-PSV, and V-TAV (RNAs 1 and 2) or C-TAV (RNA 3).

Nucleotide sequence similarity of the *Cucumovirus* species varies for the different RNAs (**Table 1**). For RNA 1, there is about 78% identity between CMV subgroups, and 68–70% identity between species. For RNA 2, there is about 74% identity between CMV subgroups, and 64–66% between species. For RNA 3 there is 78% identity between CMV subgroups, and 64–72% between species. Hence, the RNA 1 sequences are somewhat more conserved than other portions of the genome, which could reflect less flexibility in the function of the 1a protein. Sequence similarity can be a good approximation of evolutionary relationships, but clearly a rule about levels of divergence necessary for species parameters is not easy to determine.

The ability of *Cucumovirus* species to exchange their RNAs 3 led to the speculation that reassortment may have been important in their evolution. Phylogeny estimations of individual ORFs show different topologies for each RNA, supporting this hypothesis (**Fig. 1**). The characterization of a naturally occurring reassortant, having RNAs 1 and 2 derived from PSV and RNA 3 derived from CMV is further evidence

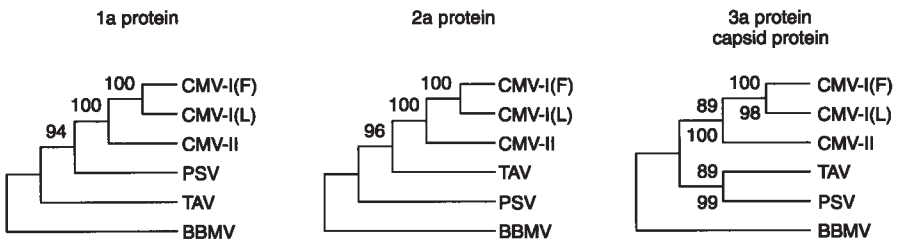

Figure 1 Phylogeny estimation of *Cucumovirus* spp, based on cladistic analysis of aligned amino acid sequences. Bootstrap values are given above the branch points. F, Fny strain of CMV; L, legume strain of CMV; BBMV, broad bean mottle virus, genus *Bromovirus*, family *Bromoviridae*, used as an outgroup.

that reassortment has probably played a pivotal role in the evolution of the cucumoviruses. The very broad host range and numerous strains of CMV indicate that it is a highly adaptable virus. The other members of the *Cucumovirus* genus have more narrow host ranges, but PSV probably has even greater sequence diversity than does CMV. This makes the *Cucumovirus* genus very attractive for studies on virus evolution, and recently it has been exploited as a model system for such studies.

The origin of the satellite RNAs has been the source of much speculation, but no concrete data have emerged to elucidate their evolutionary history. They often appear in experimental plants inoculated with virus alone, and hence appear to have mechanisms of transmission that are different from helper virus transmission. They have even been found in plants inoculated with *in vitro* generated transcript from cDNA clones, but only in greenhouse settings where wild-type virus was also present in nearby plants. They have not been found in transcript-inoculated plants kept under sterile conditions. A phylogeny estimation of satellite RNAs from numerous sources around the world shows essentially no branching, suggesting that they have arisen many times from a common or related source. The longevity of satellite RNA in plants in the absence of virus (25 days in one study with tomato) has added to the difficulty in determining their origins. Hybridization analysis of host nucleic acids has not detected any related sequences, but the sensitivity of these studies may have been too low to detect a single copy gene of the size of the satellite RNAs.

Due to their small size and ease of molecular manipulation, the satellite RNAs have provided a very useful model system to study RNA virus evolution. These studies have shown that selection for specific satellite RNAs in mixed infections is very strong, and that even though satellite RNAs may evolve to become more pathogenic, the selection for these pathogenic variants is at the level of other functions, and not pathology.

Serological Relationships and Variability

There is only very weak or no serological cross-reactivity between the *Cucumovirus* species. Within species, there are also considerable serological differences for CMV and PSV, especially when monoclonal antibodies are used, leading to the original subgroup designations for these viruses. Serological tests have been used in diagnosis of cucumoviruses, and enzyme-linked immunosorbent assay (ELISA) and immunodiffusion tests have been used most widely. The instability of the virions requires that they be fixed with formaldehyde before they can act as good immunogens. This instability also requires careful handling of samples prior to detection of virus, and nucleotide hybridization techniques are sometimes more reliable than serology for diagnostic detection.

There is a large amount of sequence variation among strains of CMV and PSV as assessed by nucleotide sequence analysis. In the case of CMV this is reflected in the variation of host range and symptoms induced by different strains. Sequence similarity between subgroups of CMV is about 75–80%, whereas within subgroups it is 95–99%. Not enough strains of PSV have undergone sequence analysis to determine variation with subgroups, but between major groups the sequence similarity is 78–80%. TAV strain variation has not been studied in any detail. Only RNA 3 has had more than one isolate that has been sequenced, and these are 99% similar.

Epidemiology

Strains of CMV isolated from different parts of the world have proven to be very similar, showing a somewhat uniform worldwide distribution of strains. The only exceptions are the IB strains, a subset of subgroup I strains found only in Asia. This suggests that CMV has been spread on numerous occasions, and may be due to a combination of the enormous host range of CMV, and the frequent worldwide transport of humans and their cultivated plants. PSV

isolates on the other hand, appear to be unique in distinct geographic locations, as assessed by serology and nucleotide sequence analysis, with the exception of the strains found in the eastern United States and in Japan. Hence, most of the worldwide distribution of PSV may have occurred some time ago and the strains have evolved further in their present locations.

Transmission and Tissue Tropism

The cucumoviruses are transmitted by aphid, grafting, dodder, seed and mechanical transmission. CMV is transmitted by more than 75 species of aphids. The specificity of aphid transmission for PSV and TAV has been less thoroughly studied. The viruses are not replicated in the insect vector, and are transmitted in a nonpersistent manner, although all instars of aphids can transmit virus. The transmission rate varies with the virus strain, aphid species, and host plant. The mechanism of aphid transmission and the number of particles transmitted are poorly understood. The coat protein is apparently the only viral component involved in aphid transmission. Recent studies with CMV have identified key amino acids in the coat protein that are essential in aphid transmission and the specificity of transmission by different aphid species.

Graft transmission of CMV has been reported in fruit trees; transmission by dodder (a parasitic plant) is common. Seed transmission varies from 0 to 100%, depending on the virus and the host plant. CMV can also be transmitted vertically from infected corms to new suckers in banana. Mechanical transmission is the most common method used experimentally. The infectivity of purified viral RNA by mechanical inoculation has greatly aided genetic studies of the virus.

The viruses replicate in the epidermal and mesophyllic cells of leaf tissue. They move systemically through the phloem, but it is not thought that they replicate in phloem tissue. Although the coat protein is required for both cell-to-cell and systemic movement, it is not known if the virus moves as a packaged virion or as some other RNA–protein complex. Once a plant is infected, newly formed leaves show symptoms of virus as they emerge, indicating meristematic infection. Mosaic patterns could be due to variable infection of meristematic cells.

Pathogenicity and Cytopathology

The symptoms induced by CMV vary from very mild mosaic to severe necrosis and death. Virus symptoms can appear on the leaves, stems, fruits, and flowers of infected plants. Distortions of leaf morphology are common, including rugosity, stunting, and curling. There is no convincing evidence to correlate severity of symptoms with virus titer. Many wild host plants do not show any symptoms. The presence of a satellite RNA can dramatically alter the symptoms induced by CMV. In most instances satellite RNA attenuates symptoms, but in some cases, most notably in tomato, a satellite RNA can result in chlorosis or systemic necrosis. Tomato necrosis has been cause for great concern in parts of southern Europe, where severe crop losses have resulted. PSV also induces a range of symptoms, from stunting to mosaic. It has also been implicated in decline of year-to-year persistence in white clover. In most cases the PSV satellite RNAs have little effect on the helper virus symptoms, but a few satellite RNAs can attenuate symptoms. TAV infection induces malformation of flowers in chrysanthemum and production of seedless fruit in tomato.

In experimentally infected plants, the cucumoviruses induce several cytoplasmic modifications. Cytoplasmic membranes, thought to be derived from the plasma membrane, proliferate. There is an increase in secondary vacuoles. Vesicles are formed along the tonoplast membrane. The chloroplast structure can be severely altered, through impairment of plastid differentiation. In some strains that induce chlorosis, chloroplasts are smaller and the grana are poorly developed. Mitochondrial structures also may be altered. Effects on chloroplasts and mitochondria appear to be host- and viral strain-specific. The nucleus does not appear to be affected by cucumovirus infection, although one report using tobacco protoplasts described a loss of heterochromatin and vacuolation of the nucleolus.

Inclusion bodies are sometimes seen in cucumovirus-infected plant cells. These are either amorphous or crystalline, and are apparently composed of viral particles. The crystalline structures are generally seen in the vacuoles, and can take a variety of shapes, whereas the amorphous inclusion bodies are usually found in the cytoplasm.

Prevention and Control

The most common means of control of the cucumoviruses are by using virus-free stocks for propagation, eradicating infected plants, and controlling the aphid vectors of the virus. Resistant plants have also been used, but they are not available for many hosts of CMV. Transgenic plants expressing the coat protein of CMV show resistance, and plants expressing portions of the 2a protein are sometimes immune to the virus, but this resistance is generally restricted to similar strains. The attenuating satellite RNAs of

CMV have also been used as biocontrol agents. These have been introduced both as inoculum and as transgenes. This has proven effective in the case of tomato, but the high degree of nucleotide sequence similarity between attenuating and pathogenic strains of satellite RNAs, along with their propensity to mutate, indicates that this method should be used with caution. Transgenic plants expressing viral genes or satellite RNAs have not been used commercially in the United States, but they have been used in other parts of the world. It remains to be seen how long this type of control will hold up under the strong selection pressure of field situations.

Future

The past decade has produced detailed information about the molecular biology of cucumoviruses, and the sequence analysis of numerous strains has allowed conclusions to be drawn about the evolutionary history of these viruses. A lot of experimental work has allowed for the identification of viral components involved in pathogenesis, and many symptom determinants have been mapped to specific amino acids or nucleotides. However, much of the work has focused only on CMV, and many intriguing questions remain. Almost nothing is known about the processes in the plants that allow the viruses to cause disease, or why disease is present in some hosts and not others. Very little is known about the distribution of these and other plant viruses in hosts other than crop plants. These are more difficult questions to answer experimentally, but they are crucial for long-term understanding and control of virus disease. Most control measures seek to reduce or eliminate the virus, and hence exert strong selection pressure on the virus to change to overcome the resistance. In the final analysis, as with all viruses, we may have to learn to live with them rather than try to get rid of them.

Properties of the Virion

Cucumoviruses are icosahedral viruses ($T = 3$) of about 29 nm diameter. They consist of RNA (about 18%) and protein, with 180 copies of the coat protein per capsid. They do not contain any lipids or glycoproteins. The internal diameter of the virion is approximately 16.5 nm. The integrity of the capsid is maintained by electrostatic RNA–protein interactions, and digestion of the encapsidated RNA by ribonuclease results in complete degradation of the particle. The virions contain the genomic RNAs, encapsidated separately, as well as at least one subgenomic RNA, and more than one in some species. In addition, the satellite RNAs, when present, are encapsidated in the virion. Based on the molar ratio of viral RNA to satellite RNA, it is likely that some virions contain only multiple copies of satellite RNA. All of the particles have similar sedimentation properties, and hence it is not possible to separate them by physical means. The virion has not been amenable to detailed structural analysis by x-ray crystallography. This may be due to the mixture of particles of similar but not identical size, resulting in the formation of imperfect crystals. The particles of the three species of *Cucumovirus* cannot be distinguished by electron microscopy.

The virions can be readily dissociated into their component proteins and RNA by using high ionic strength buffers. These associations can be re-established by lowering the ionic strength, and the viral coat protein can encapsidate a number of other RNA species *in vitro*.

Properties of the Genome

The viral genome consists of three single-stranded, messenger sense RNAs, designated RNAs 1, 2 and 3, by diminishing size (**Fig. 1**). All the RNAs have a cap structure at the 5′ terminus, that is similar to host

CMV have also been used as biocontrol agents. These have been introduced both as inoculum and as transgenes. This has proven effective in the case of tomato, but the high degree of nucleotide sequence similarity between attenuating and pathogenic strains of satellite RNAs, along with their propensity to mutate, indicates that this method should be used with caution. Transgenic plants expressing viral genes or satellite RNAs have not been used commercially in the United States, but they have been used in other parts of the world. It remains to be seen how long this type of control will hold up under the strong selection pressure of field situations.

Properties of the Virion

Cucumoviruses are icosahedral viruses ($T = 3$) of about 29 nm diameter. They consist of RNA (about 18%) and protein, with 180 copies of the coat protein per capsid. They do not contain any lipids or glycoproteins. The internal diameter of the virion is approximately 16.5 nm. The integrity of the capsid is maintained by electrostatic RNA–protein interactions, and digestion of the encapsidated RNA by ribonuclease results in complete degradation of the particle. The virions contain the genomic RNAs, encapsidated separately, as well as at least one subgenomic RNA, and more than one in some species. In addition, the satellite RNAs, when present, are encapsidated in the virion. Based on the molar ratio of viral RNA to satellite RNA, it is likely that some virions contain only multiple copies of satellite RNA. All of the particles have similar sedimentation properties, and hence it is not possible to separate them by physical means. The virion has not been amenable to detailed structural analysis by x-ray crystallography. This may be due to the mixture of particles of similar but not identical size, resulting in the formation of imperfect crystals. The particles of the three species of *Cucumovirus* cannot be distinguished by electron microscopy.

The virions can be readily dissociated into their component proteins and RNA by using high ionic strength buffers. These associations can be re-established by lowering the ionic strength, and the viral coat protein can encapsidate a number of other RNA species *in vitro*.

Properties of the Genome

The viral genome consists of three single-stranded, messenger sense RNAs, designated RNAs 1, 2 and 3, by diminishing size (**Fig. 1**). All the RNAs have a cap structure at the 5′ terminus, that is similar to host

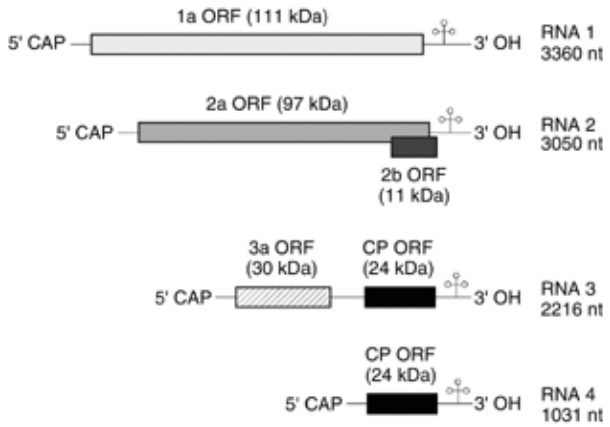

Figure 1 Viral genome of three single-stranded message-sense RNAs designated RNAs 1, 2 and 3 by diminishing size. RNA 4 is not required for infection.

messenger RNA cap structures. The 5′ noncoding regions of RNAs 1 and 2 are highly similar within a strain. The 3′ portion of all the RNAs is also highly similar within a strain, and can form a tRNA-like structure that can be aminoacylated with tyrosine. The sizes of the genomic RNAs and encoded proteins vary between species. Representative members of each species are listed in **Table 1**. RNA 1 is about 3400 nucleotides (nt) in length, and encodes a single protein (the 1a protein) of M_r 112 000. RNA 2 (about 3000 nt) encodes two open reading frames (ORFs) of about M_r 97 000 (2a) and M_r 11 000 – 17 000 (2b). The 2b protein is translated from a subgenomic RNA (RNA 4a) that may be encapsidated. The 2b ORF is found in all *Cucumovirus* members, but not in most of the other *Bromoviridae*. RNA 3 (2200 nt) encodes the M_r 30 000 3a protein, and the M_r 24 000 coat protein, that is translated from the subgenomic RNA 4. RNAs 3 and 4 are coencapsidated, but RNA 4 is not required to establish infection.

Defective RNAs have been isolated from cucumber mosaic virus (CMV) after high multiplicity of infection passage in tobacco plants. These do not appear to interfere with virus symptoms or titer, and hence are not really interfering RNAs. They are not supported by all hosts of the parent virus. They are generated by deletions of portions of the 3a protein coding region. An additional virus-derived RNA, known as RNA 5, is found in infected tissue and is encapsidated in some strains of CMV and TAV. RNA 5 is derived from the genomic RNA 3. Other smaller RNAs are also often seen in agarose gel electrophoresis of peanut stunt virus (PSV) and tomato aspermy virus (TAV) viral RNAs, but for the most part these have not been characterized.

Table 1 Sizes and M_r of *Cucumovirus* RNAs and proteins

Species/strain	*Fny-CMV (I)*	*Q-CMV (II)*	*J-PSV*	*TAV*[a]
RNA 1 (nt)	3360	3389	3355	3410
1a protein (M_r)	111 432	110 917	112 016	112 061
RNA 2 (nt)	3050	3035	2946	3074
2a protein (M_r)	96 709	94 439	93 520	93 509
2b protein (M_r)	12 749	11 579	17 946	15 277
RNA 3 (nt)	2216	2197	2186	2214
3a protein (M_r)	30 461	30 348	31 636	30 532
Coat protein (M_r)	24 243	24 243	24 179	25 753

[a]RNAs 1 and 2 and encoded proteins are given for V-TAV; RNA 3 and encoded proteins are given for C-TAV.

Satellite RNAs

Molecular parasites known as satellite RNAs are also found associated with CMV and PSV. These small RNAs range in size from about 330 to 400 nt. They do not encode any proteins, but can affect both virus titer and symptoms. Analysis of the secondary structure of a CMV satellite RNA responsible for necrosis in tomato (the D satellite RNA) demonstrated that a stem-loop in the 3′ portion of the RNA was highly conserved in the necrosis-inducing satellite RNAs, and contained the three nucleotides previously shown to be critical for necrosis (**Fig. 2**). Another domain in

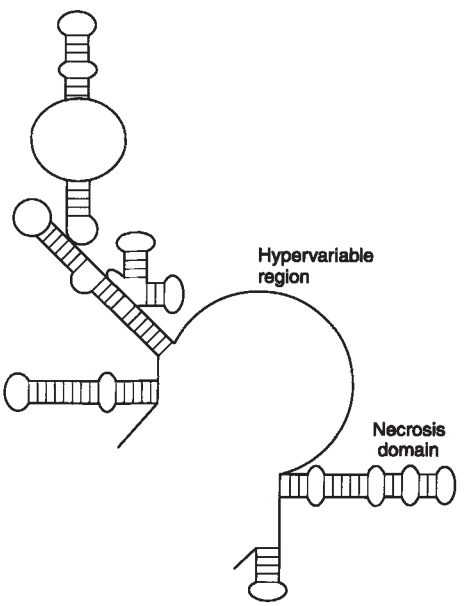

Figure 2 Secondary structure of CMV satellite RNAD *in planta*.

the D4 satellite, identified as the hypervariable domain because of the amount of variation both in wild-type isolates and in progeny of cDNA clones, is found in a nonstructured region of the RNA. The nucleotides responsible for other pathogenic phenotypes of satellite RNAs have also been identified, but structural analysis of these satellite RNAs *in planta* has not been done. The satellite RNAs have provided a model system for studying both the structure of biologically active RNAs and RNA evolution.

Properties of the Proteins

The 1a and 2a proteins are the only viral components required for replication. By analogy to related viruses, the 1a protein apparently encodes the methyltransferase and other activities responsible for capping the viral RNAs, in the amino portion of the protein. In the related animal alphavirus, Sindbis virus, this region is also required for initiation of (−) strand synthesis. There is a central domain in the 1a protein that is not well conserved, but that contains a large number of acidic amino acid residues in the cucumoviruses and in other related viruses. A nucleotide-binding domain is found adjacent to the acidic domain, and the carboxy-terminal portion contains the conserved elements of a helicase. The precise role of the helicase is not known. It may be required to resolve the secondary structure inherent in RNA molecules, or it may be involved in synthesis of (+) strand from a double-stranded replicative intermediate. The 2a protein contains the Gly-Asp-Asp domain conserved in many viral polymerases, but it too may have additional undefined functions. In the closely related brome mosaic virus (BMV), the amino-terminal domain is involved in interactions with the 1a protein. Antibodies to the methyltransferase, helicase and polymerase domains can all inhibit replication *in vitro*.

The 2b protein is the most recently described viral protein, although the open reading frame for the 2b protein was observed when the first strains were sequenced. It has been implicated in long distance movement and host range of the virus, but may have other unidentified functions.

The 3a protein potentiates the cell-to-cell movement of the virus. Like other plant viral movement proteins, the 3a protein presumably alters the plasmodesmata, allowing passage of molecules that are larger than the normal size exclusion limit. The CMV 3a protein produced in *Escherichia coli* has a cooperative single-stranded DNA and RNA binding activity, as well as GTP binding activity. However, all of the viral proteins have been implicated in either long distance or cell-to-cell movement of CMV in various hosts.

The coat protein is involved in encapsidation, movement and aphid transmission of the virus. In protoplast studies it also stabilizes the (+) sense viral RNA, perhaps by encapsidation. In addition, all the viral proteins have been implicated in the host range of various strains, and in pathogenicity.

Physical Properties

The purified virions have a relatively short half-life when stored at 4°C. For CMV, the virus titer drops by one half in about two weeks. This is probably due to the virion permeability to ribonucleases. The virion is unstable to freezing, but can be stored in 50% glycerol at −20°C. The virus is stable to short exposure to chloroform, and nonionic detergents such as Triton X-100, but not to phenol or ionic detergents such as sodium dodecyl sulfate (SDS). The viral RNA is readily purified from virions in the presence of SDS, ethylene diamine tetra-acetic acid (EDTA), and phenol, without the use of protease. The particles are negatively charged, with a pI of 4.75. They sediment as a single component with $s = 98.6$. The extinction coefficient at 260 nm is 5.

Replication

The viral replication complex consists of the 1a and 2a proteins, and host factors. Interactions between the 1a and 2a proteins, as well as 1a–1a interactions have been demonstrated using a yeast two-hybrid system. In the closely related bromoviruses a 1a–2a fusion, resembling the replication protein of tobacco mosaic virus, was only functional when additional 1a protein was added, indicating that the 1a–2a interacting complex was not sufficient for replication. Hence the replicase complex may contain a ratio of 1a to 2a of greater than 1:1, along with necessary host components. Replication occurs on cytoplasmic membranes, and may be associated with the rough ER, as replicase activity can be readily demonstrated in the membrane-bound polysome fraction of infected cells.

The cucumoviruses replicate by first synthesizing a (−) strand from the (+) strand template. Double-stranded (ds) RNA can be readily isolated from infected tissue, and this is presumably the replicative intermediate, although it is possible that (+) and (−) strand RNAs exist separately in the cell, and anneal upon purification. The 3′ terminus of the (−) strand contains an unpaired nontemplate G residue. In the satellite RNA the unpaired G is required for synthesis of (+) strand *in vitro*, suggesting that (+) strand synthesis begins internally with the second nucleotide

of the (−) strand. The 3′ terminus of the (+) strand of viral RNAs also contains a nontemplate nucleotide, an A residue, resulting in a CCA 3′ terminus that is similar to tRNA 3′ ends. The 3′ terminus of all of the cucumoviral satellite RNAs consists of 3 C residues. Deletion of the CCC in the (+) strand of a CMV satellite RNA resulted in repair *in vivo* and restoration of the wild-type sequence, indicating that nontemplated nucleotides can be added to the 3′ end of the (+) sense satellite RNAs as well. Hence both (+) and (−) strand synthesis may initiate internally, rather than at the precise 3′ end of the template.

The CMV and PSV satellite RNAs are found in large quantities as double-stranded RNA in infected cells, and were assumed to replicate in a similar manner to the viral RNAs. However, there have been some reports of multimeric forms of CMV satellite RNAs in infected cells, and it is possible that they utilize other replication strategies such as rolling circle replication.

The 5′ termini of the (+) strands of the genomic and subgenomic RNAs, as well as the satellite RNAs are modified by a 7MeGppp structure. Sindbis virus performs this function with the nsp1 protein. Nsp1 is analogous to the 1a protein of cucumoviruses, although details of the capping reactions may differ.

CMV was the first eukaryotic virus for which an RNA dependent RNA polymerase was isolated that was functional *in vitro*. This complex contained the viral 1a and 2a proteins, and only one apparent host protein. However, the viral replication by this complex *in vitro* did not duplicate the *in vivo* replication in quantities of (+) and (−) synthesis, and it now seems likely that other host factors are involved *in vivo*. Other purification schemes isolated a replicase complex that could only synthesize (−) strand from (+) strand template. These complexes could also use related viral RNAs as templates, but not cellular RNAs, suggesting that much of the specificity of replication may be in the (+) strand synthesis.

Characterization of Transcription and Translation

Transcription of subgenomic RNA 4 from the (−) strand of RNA 3 occurs from a promoter located in the intercistronic region. The minimal core promoter is also found upstream of the start of the 4a transcript, on RNA 2, but additional sequences in the intercistronic region affect levels of RNA 4 transcription in CMV. Most of the intercistronic region is also essential for accumulation of the (+) but not (−) strand of RNA 3 of CMV. RNA 4 is synthesized very efficiently, and accumulates to levels similar to the genomic RNAs. RNA 4a, the subgenomic RNA for the 2b protein, is found in much lower abundance in infected cells. The details of *cis*-acting sequences for transcription of the 4a RNA, as well as for transcription of subgenomic RNAs of other cucumoviruses have not been elucidated.

The level of viral proteins that can be detected in infected cells does not correlate with the steady-state level of the corresponding viral RNAs. In many hosts the genomic RNAs and RNA 4 are found in similar molar ratios, but the coat protein is the most abundant protein, usually easily detected by Coomassie blue staining of total cell extracts separated by gel electrophoresis. The 3a protein is much less abundant, and the 1a and 2a proteins can be difficult to detect at all in infected cells. Hence there appears to be a translational control of viral proteins. Since each virion requires 180 coat protein units, the coat protein is needed in much greater quantities than the other viral proteins. The replicase and movement proteins are needed in much smaller quantities, and higher concentrations of these proteins may actually prove toxic to the host cell. In viruses that produce polyproteins and hence equimolar levels of all proteins, the excess replicase proteins are often sequestered in inclusion bodies. The divided genome of the cucumoviruses has allowed them to evolve more efficient strategies for their protein synthesis.

Although a number of short open reading frames (ORFs) are found in the satellite RNAs, that can be translated *in vitro*, none of them are conserved among satellite RNA strains, and mutation of the AUGs of these ORFs does not affect satellite RNA infectivity or function. Hence they do not appear to be functional in plants.

No specific proteolysis of the viral proteins has been demonstrated, but western blot analyses of protein extracts from infected cells sometimes contain discreet bands not found in uninfected cell extracts, that react strongly with polyclonal antibody to the 1a protein. It is possible that a cleaved form of the 1a protein, along with intact 1a, is involved in the replication complex.

Genetic Mapping of Symptom Determinants

Before the availability of cDNA clones of the viral RNAs that were capable of producing infectious transcripts, numerous symptom determinants were mapped to specific viral RNAs by reassortment of gel-purified RNAs from strains exhibiting different phenotypes. These included determinants for chlorosis, which mapped to RNAs 2 and 3 in different virus strain/host combinations, determinants for necrotic

lesions in legumes, which also mapped to RNAs 2 and 3, and determinants for severe systemic infection, which mapped to RNA 1. In recent years, many of these determinants have been more precisely mapped using recombinant and mutant cDNA clones, and in several cases the precise amino acid responsible for symptom type has been identified. For example, the determinant for eliciting the hypersensitive response (necrosis) in cowpea was identified as a single amino acid in the 2a protein, whereas the determinant for chlorosis in tobacco was mapped to an amino acid in the coat protein. These studies have been useful, but they have not provided a clear picture of how the viral proteins and/or RNAs are interacting with the host to cause disease. This will require more work with the hosts, whose genetic systems are much more complicated. Over the next few years more information about the host's role in disease will undoubtedly become available, and a thorough understanding of virus–host interactions on a molecular level will allow for many practical applications.

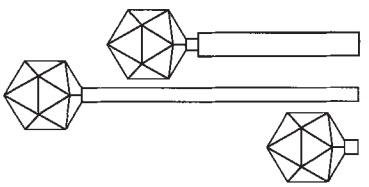
CYANOPHAGES



Eugene L Martin and **Tyler A Kokjohn**, Department of Biological Sciences, University of Nebraska, Lincoln, USA

Introduction

The cyanophages are a group of DNA viruses that attack host organisms found within the cyanobacteria or blue-green algae, a group of oxygenic photosynthetic procaryotes. A continuing dichotomy has occurred as to the nomenclature and taxonomy of these microorganisms. Many of the existing genera and species were mainly described on the basis of morphological characteristics obtained from field-collected samples, and not from axenic cultures. It has been argued that in cell size and morphological complexity the blue-green algae more closely resemble the green algae and other microalgae than the other bacteria and that their dual photosystems are almost identical with that of the eucaryotic algae and higher green plants rather than with anything known in the anoxygenic photosynthetic bacteria.

Detailed physiological and genetic studies have been used to delineate this group of microorganisms more completely. Their multilayered cell wall closely resembles the cell wall structure of Gram-negative eubacteria. On the basis of 16S and 5S rRNA nucleotide base sequence data, the blue-green algal procaryotes have been assigned to the eubacteria, a group distinct from eucaryotes (e.g. algae) and the archaebacteria. Other characteristics that have been analyzed include analysis of pigments (chlorophyll *a* and phytobilins), chemoheterotrophic/photoheterotrophic capabilities, nitrogen-fixation ability, DNA base composition, DNA/DNA hybridization and modes of asexual and sexual reproduction. Of considerable importance is the fact that the basic cell structure of this group is procaryotic, which is synonymous with bacteria. Therefore, while blue-green algae and the cyanobacteria are reasonably compatible terms, cyanobacteria will be used here. In Volume 3 of *Bergey's Manual of Systematic Bacteriology*, Castenholz and Waterbury have divided the cyanobacteria into five morphological groups, which are summarized in **Table 1**. This is the classification scheme that will be used for this article.

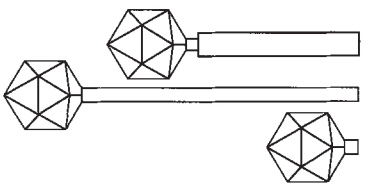
CYANOPHAGES



Eugene L Martin and **Tyler A Kokjohn**, Department of Biological Sciences, University of Nebraska, Lincoln, USA

Introduction

The cyanophages are a group of DNA viruses that attack host organisms found within the cyanobacteria or blue-green algae, a group of oxygenic photosynthetic procaryotes. A continuing dichotomy has occurred as to the nomenclature and taxonomy of these microorganisms. Many of the existing genera and species were mainly described on the basis of morphological characteristics obtained from field-collected samples, and not from axenic cultures. It has been argued that in cell size and morphological complexity the blue-green algae more closely resemble the green algae and other microalgae than the other bacteria and that their dual photosystems are almost identical with that of the eucaryotic algae and higher green plants rather than with anything known in the anoxygenic photosynthetic bacteria.

Detailed physiological and genetic studies have been used to delineate this group of microorganisms more completely. Their multilayered cell wall closely resembles the cell wall structure of Gram-negative eubacteria. On the basis of 16S and 5S rRNA nucleotide base sequence data, the blue-green algal procaryotes have been assigned to the eubacteria, a group distinct from eucaryotes (e.g. algae) and the archaebacteria. Other characteristics that have been analyzed include analysis of pigments (chlorophyll *a* and phytobilins), chemoheterotrophic/photoheterotrophic capabilities, nitrogen-fixation ability, DNA base composition, DNA/DNA hybridization and modes of asexual and sexual reproduction. Of considerable importance is the fact that the basic cell structure of this group is procaryotic, which is synonymous with bacteria. Therefore, while blue-green algae and the cyanobacteria are reasonably compatible terms, cyanobacteria will be used here. In Volume 3 of *Bergey's Manual of Systematic Bacteriology*, Castenholz and Waterbury have divided the cyanobacteria into five morphological groups, which are summarized in **Table 1**. This is the classification scheme that will be used for this article.

Table 1 Taxa of the cyanobacteria

Order	*Distinguishing characteristics*	*Representative genera*
Chroococcales	Unicellular, reproduce by binary fission in one, two or three planes or by budding. Cells are coccoid to rod-shaped	*Chamaesiphon, Gloeobacter, Synechococcus, Synechocystis, (Microcystis), (Anacystis)*
Pleurocapsales	Reproduce by the formation of small spherical cells (baeocytes) produced through multiple fission, often colonial	*Dermocarpa, Xenococcus, Myxosarcina, Pleurocapsa*
Oscillatoriales	All filamentous forms which undergo binary fission in a single plane and produce 'vegetative' cells only. Heterocysts and akinetes do not occur	*Spirulina, Oscillatoria, Lyngbya, (Phormidium), (Plectonoma)*
Nostocales	Filamentous organisms dividing exclusively by binary fission in one plane only. Have the potential to produce heterocysts. Some possibility of false branching	*Anabaena, Aphanizomenon, Nostoc, Nodularia*
Stigonematales	Exhibit the highest degree of morphological complexity and differentiation. Filamentous with branching and heterocysts	*Fischerella, Chlorogloeopsis*

Summarized from Castenholz RW and Waterbury JG (1989) Cyanobacteria. In: Staley JT (ed.) *Bergey's Manual of Systematic Bacteriology*, vol. 3, p. 1710. Baltimore: Williams and Wilkins.

Types and Classification

The cyanophages that have been characterized possess a single piece of double-stranded DNA and the various types of head–tail morphology found for bacteriophages. Many of the cyanophages listed in **Tables 2** and **3** have been placed in the family *Myoviridae* (which includes phages with a central tube and a contractile sheath separated from the head by a neck), in the family *Siphoviridae* (which comprises phages with long, noncontractile tails) and in the family *Podoviridae* (which contains phages with short tails). The cyanophages that are specific for unicellular cyanobacteria (**Table 2**) all attack host organisms found in the order *Chroococcales*, whereas cyanophages that are specific for filamentous cyanobacteria attack host organisms found in the orders *Oscillatoriales* and *Nostocales* (**Table 3**). There appear to be minimal or no reports of cyanophages found for the unicellular order *Pleurocapsales* and the multicellular order *Stigonematales*. Within the last few years Kim and Choi isolated a new virus similar to AS-1. Recently, many new marine cyanophages have been characterized and will be described in the Ecology section.

Because the cyanobacteria occupy such a unique position among living organisms, a wide diversity of research has been pursued. In the 1990s the role cyanophages occupy in marine ecosystems has been thoroughly investigated. In addition to a survey of the ecological research, recent results will be examined in the areas of physiology–genetics and metabolism.

Ecology

Cyanobacteria are clearly of singular importance in many freshwater and marine ecosystems as both primary producers and nitrogen-fixing organisms. From the early 1960s through the 1980s extensive characterization of freshwater cyanophages which infect both unicellular and filamentous cyanobacteria occurred (**Tables 2** and **3**). A role for cyanophages as a major controlling agent of microbial community structure was hypothesized. As a result many early studies focused on using cyanophages as a means to control nuisance cyanobacterial (e.g. blue-green algal) blooms. Limited success has been achieved in this endeavor. Recent research has been directed toward the understanding of cyanophage distribution and dynamics in marine systems.

Suttle and Chan have noted that cyanobacteria of the genus *Synechococcus* are important primary producers that are responsible for considerable carbon fixation in the world's oceans. Three recent lines of research have determined that infective cyanophages for *Synechococcus* are extremely numerous in various coastal and offshore marine environments. The important aspects of each of these research groups will be described.

Using liquid dilution cultures Waterbury and Valois isolated a collection of 75 *Synechococcus* cyanophages from both coastal and offshore waters. From both types of samples, phage titers seasonably reached 10^3 and 10^4 viruses per ml. Representatives were found in each of the three families of tailed

Table 2 Cyanophages specific for unicellular cyanobacteria

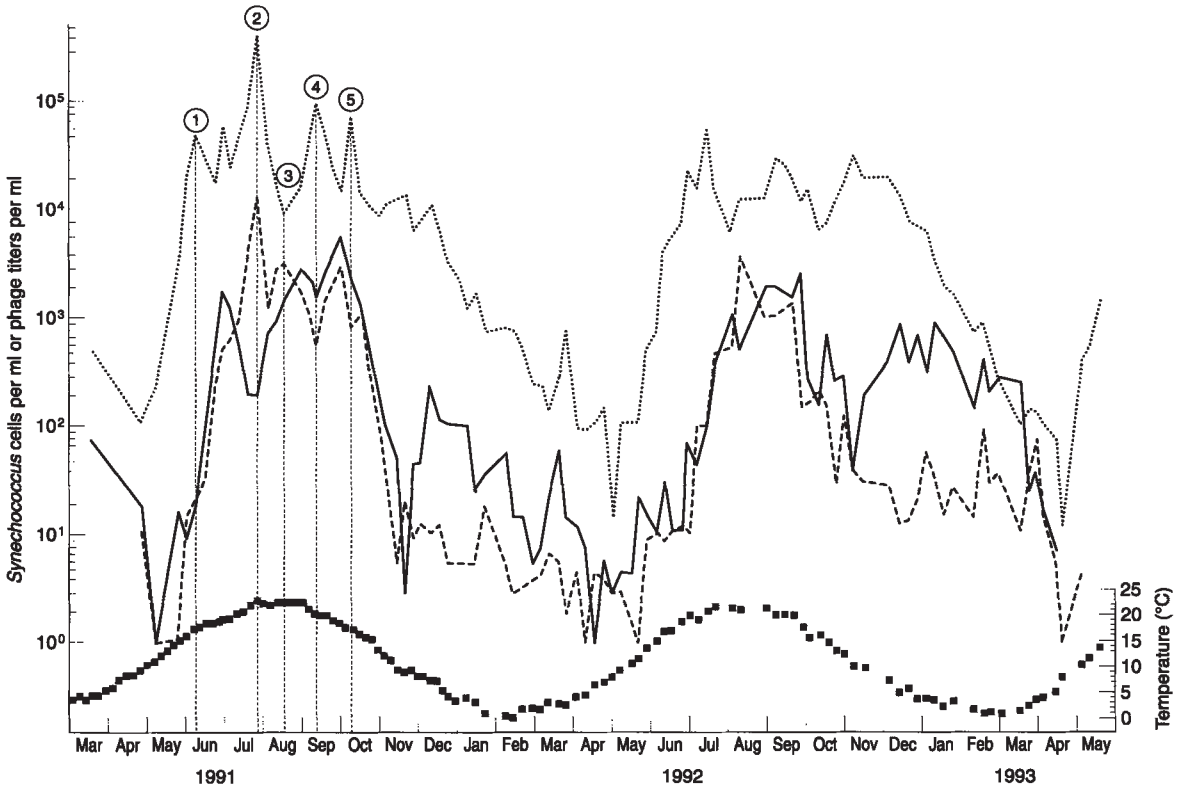

Figure 1 Annual cycle of *Synechococcus* spp. and *Synechococcus* phages in Woods Hole Harbor. Cell counts were determined by epifluorescence microscopy. Phage titers were determined by the most-probable-number technique in tissue culture wells with the host strains WH8018, isolated from Woods Hole in 1980, and WH8012, isolated from the Sargasso Sea in 1980. These strains were chosen because of their sensitivity to a broad spectrum of *Synechococcus* phages. ....., Natural *Synechococcus;* ——, phage titer using host 8018; -----, phage titer using host 8012; ■, temperature (°C). (From Waterbury and Valois (1993).)

phages, with the majority being in *Myoviridae*. Whereas some phage isolates only infected the host strain used for isolation, other phages infected as many as 10 of the 14 host strains. Preliminary characterization indicated that the isolates are virulent phages. Attempts to induce lysogeny in *Synechococcus* strains by using temperature shock, light shifts, ultraviolet and X-radiation, and mitomycin were not successful. The annual cycle of natural *Synechococcus* in Woods Hole Harbor waters is related to water temperature and is very repeatable (**Fig. 1.**). Over the 3 year period examined, cyanophages were present at concentrations approximately one order of magnitude less than the natural *Synechococcus* levels. At Points 1 to 5 in **Fig. 1** the percentage of the natural population that might be lysed by viral infection was measured and this ranged from 0.005% per day at the end of the spring 1991 bloom to 3.2% per day during a *Synechococcus* peak in July 1991.

Similar results were obtained from offshore samples collected from Slope Water south of Cape Cod and from the Gulf Stream: ranging from 0.6 to 2.0% per day. It was then determined that from the Woods Hole Harbor location that the majority of the *Synechococcus* population at the time of sampling was resistant to its co-occurring cyanophages. Waterbury and Valois summarized their results by stating that the acquisition and maintenance of this resistance enables marine *Synechococcus* communities to coexist with cyanophages abundant in seawater: 'As a consequence of this stable coexistence, *Synechococcus* cyanophages have little effect on the overall population densities of marine *Synechococcus* cells but should be important in determining and enhancing the clonal composition of these populations.' Apparently, cyanophages are maintained by infecting the small proportion of *Synechococcus* cells that are still sensitive to viral infection.

Suttle and Chan reported that cyanophages infecting marine *Synechococcus* cells were often very abundant and were found in every seawater sample across an inshore-to-offshore transect in the western Gulf of Mexico and during a 28 month study of

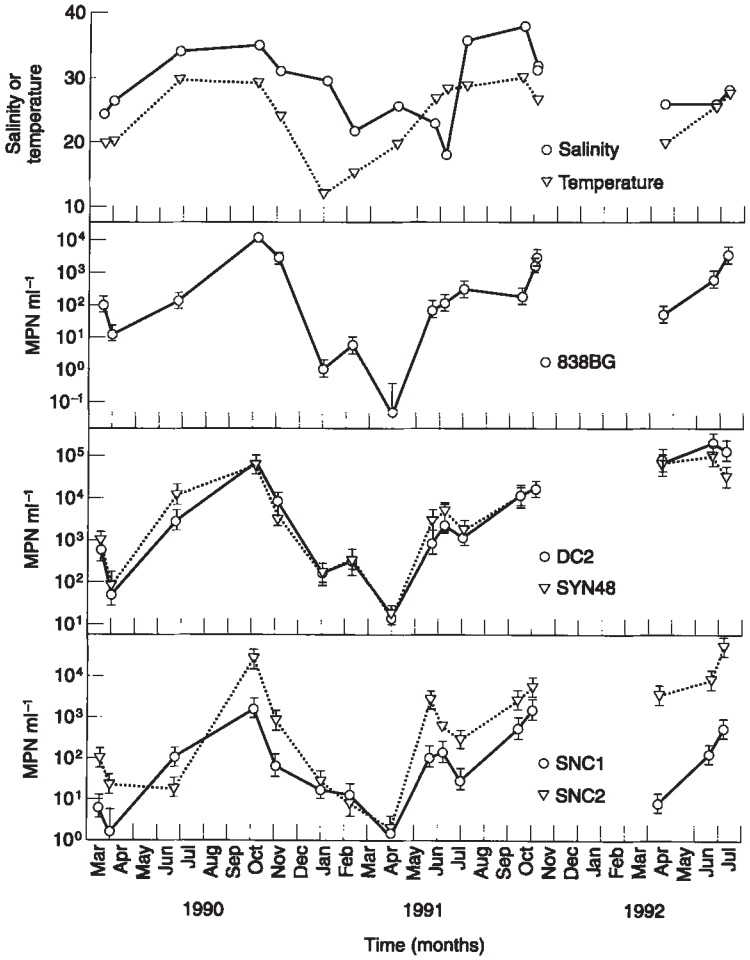

Figure 2 Temperature, salinity and most probable number (MPN) of cyanophages infecting five marine *Synechococcus* strains (838BG, DC2, SNC1, SNC2 and SYN48) in coastal sea water collected from the pier of the Marine Science Institute, Port Aransas, Texas. (From Suttle and Chan (1994).)

coastal seawater collected off the pier of the Marine Science Institute, Port Aransas, Texas. In the coastal seawater study (**Fig. 2**), cyanophages reached a level of 10^3 and 10^4 viruses per ml seasonably during the warmer months of the year, with the lowest concentrations occurring in the cooler water of the winter months. These results were very similar to the Woods Hole Harbor study of Waterbury and Valois (**Fig. 1**). Along the transect viruses infecting two strains of *Synechococcus* (DC2 and SYN48) ranged from a few hundred per ml at 97 m deep and 83 km offshore to 4×10^5 per ml near the surface within 18 km of the coast. Generally when the concentration of *Synechococcus* cells exceeded 10^3 per ml, the concentration of cyanophages increased markedly from 10^2 to $>10^5$ per ml. This suggested for these offshore samples a minimum host density was necessary for efficient viral replication. For most offshore samples the numbers of *Synechococcus* cells and infectious cyanophages were much lower than those found in coastal seawater samples. Therefore, the rate at which viruses contact host cells is less frequent, which in turn results in less selection for cyanophage-resistant strains.

Suttle and Chan further summarized their results in that 'balancing estimates of virus production with contact rates for the furthest offshore station required that most *Synechococcus* cells be susceptible to infection, and that the burst size be about 324 viruses per lytic event'. Therefore, the transport theory of Murray and Jackson used to calculate contact rates for the offshore *Synechococcus* cyanophage can not rely on a small subset of the host cell community being responsible for viral proliferation. For coastal or inshore marine *Synechococcus* populations, a different conclusion is projected. Because rates of viral decay from solar radiation are substantially reduced in the more turbid water, only about 1% of *Synechococcus* cyanophage contacts would result in

infection. This would coincide with the aforementioned work of Waterbury and Valois where they found the majority of inshore host cells isolated were resistant to the most abundant cyanophages. Suttle and coworkers have also used fluorescently stained cyanophages as probes to label, identify and enumerate specific strains of cyanobacteria in marine microbial communities.

The results of these two research groups indicate that cyanophages play an important role in carbon cycling in aquatic ecosystems by causing the lysis of key producer organisms. In effect, a portion of the system carbon held as biomass is converted to dissolved organic carbon in a short-circuiting of the flow from producers to higher trophic level consumers. While heterotrophic bacteria may recapture some of the dissolved organic carbon released by viral lysis, the precise fate of carbon and the effects on the microbial loop as a result of cyanophage activity is not known.

As previously mentioned, in many environments cyanobacteria and cyanophages will be exposed to very substantial levels of solar radiation. Experimental investigation has demonstrated that sunlight exposure rapidly inactivates cyanophages, suggesting that rates of production must be extremely rapid or that the viruses are capable of reactivation after infection of the host cell. Numerous studies have demonstrated that many bacteriophages are able to use host repair systems to eliminate DNA damage and resume replication, and these observations may explain the ability of cyanophages to persist in high-insolation environments. It is at present an open question as to whether cyanophages possess unique host-independent DNA repair genes analogous to those described for bacteriophage T4 and phycovirus PBCV-1.

Wilson and coworkers have also made substantial contributions to the study of cyanobacteria–cyanophage interactions in marine ecosystems. Five marine cyanophages from the *Myoviridae* and *Siphoviridae* families were isolated from three oceanographic sites. These sites included coastal water from the Sargasso Sea, Bermuda, Woods Hole Harbor and coastal water off Plymouth Sound, UK. While measurement of cyanophage numbers was not the primary objective of this study, the cyanophage titers were of same order of magnitude as for previous reports in the same oceanographic sites. All five cyanophages were propagated on *Synechococcus* sp. WH7803, the viral DNA extracted and purified, and restriction endonuclease digestion run. The *Myoviridae* isolates from Bermuda and the English Channel had highly related restriction patterns, as did the DNA from the *Styloviridae* isolates from Bermuda and the English Channel. The DNA of the *Myoviridae* Woods Hole isolate had a unique restriction pattern. The three *Myoviridae* isolates had a genome size of 80–85 kb and the genome size of *Siphoviridae* was in the range of 90–100 kb. The authors remarked that they were surprised to find such highly related DNA profiles from two cyanophage families obtained from the subtropical waters off Bermuda and the more temperate waters of the English Channel. This suggested that certain types of marine cyanophages have a wide distribution pattern comparable to those observed for certain freshwater cyanophages. The *Myoviridae* and *Styloviridae* revealed a clear difference in polypeptide profiles. However, all of the five cyanophages had a major (probably structural) protein in the 53–54 kDa range.

Wilson, Carr and Mann next turned their focus to the effect that phosphate status had on cyanophage infection in the marine *Synechococcus* sp. WH 7803. This cyanobacterial strain contains phycoerythrin and is considered to be a major primary producer in oligotrophic subtropical and tropical oceanic ecosystems. One contributing factor in the control of primary productivity is the availability and flux of nitrogen and phosphate. Other researchers working with viruses that replicated in a marine coccolithophorid found that phosphate limitation but not nitrate limitation affected viral propagation. It was suggested that this was due to the high nucleic acid:protein ratio found for viruses. Wilson, Carr and Mann examined the effects phosphate limitation has on the infection kinetics of a *Myoviridae* cyanophage S-PM2 that was isolated from coastal waters near Plymouth. S-PM2 was propagated on *Synechococcus* sp. WH 7803 under either phosphate-deplete or phosphate-replete conditions. When the growth of the host cells in phosphate-deplete medium was followed after cyanophage infection, an 18 h delay in cell lysis was observed when compared with a phosphate-replete control. Host cultures grown at two different rates with the same nutritional conditions both lysed 24 h postinfection, ruling out growth rate as the factor in the delay of cell lysis.

While phage adsorption kinetics showed no differences under phosphate-deplete and phosphate-replete conditions, there was an apparent 80% decrease in burst size under the phosphate-deplete growth conditions. When the proportion of infected cells that lysed was determined, 9.3% of phosphate-deplete infected cells lysed, in contrast to 100% of the phosphate-replete cells. This suggested that the majority of the cyanophages established lysogeny in response to the phosphate-deplete conditions. Kokjohn and coworkers supported these findings when they observed that a natural phage isolate exposed to

starved cells developed a pseudolysogenic relationship with a naturally occurring aquatic host strain *Pseudomonas aeruginosa*. Wilson and his coworkers concluded: 'These data strongly support the concept that the phosphate status of the *Synechococcus* cell will have a profound effect on the eventual outcome of phage–host interactions and therefore exert a similarly extensive effect on the dynamics of carbon flow in the marine environment.'

Physiology–Genetics

Khudyakov and Wolk have studied *Anabaena* sp. strain PCC 7120, which is a filamentous cyanobacterium that fixes nitrogen under aerobic conditions. In the presence of oxygen the cells are deprived of fixed nitrogen, heterocysts are formed at semiregular intervals along the filaments and in turn provide a microaerobic environment, ATP and reductant for nitrogenase. It was found that the highly pleiotropic, transposon-generated mutant AB22 of the aforementioned host cell exhibited slow growth, the inability to differentiate heterocysts and resistance to cyanophage A-4 (L). Sequencing of the flanking DNA showed that the transposon had disrupted the *hanA* gene which encodes the *Anabaena* HU protein. Therefore, the histone-like HU protein was essential for cyanophage A-4 (L) sensitivity of *Anabaena* sp. strain PCC 7120. Subsequently, Wolk and coworkers found that a modified lipopolysaccharide (LPS) may prevent cyanophage infection of *Anabaena* vegetative cells and the formation of a functional heterocyst envelope. LPS is a major component of the outer membrane of Gram-negative bacteria and consists of a core polysaccharide, an O polysaccharide and lipid A. The O polysaccharide (e.g. O antigen) was the LPS portion that, when altered via mutation, determined the susceptibility of *Anabaena* sp. strain PCC 7120 to infection by cyanophages A-1 (L) and A-4 (L).

Sarma and Singh, working with cyanophage N-1 and the nitrogen-fixing cyanobacterium *Nostoc muscorum* ISU (ATCC 27893), have isolated and characterized temperature-sensitive (ts) mutants of N-1. Treatment with *N*-methyl-*N'*-nitro-*N*-nitrosoguanidine (MNNG) was used to generate the mutants. These ts-mutants constitute a class of conditional lethal mutants which behave as lethal at the 40°C restrictive temperature but, when shifted to a permissive 28–30°C temperature, replicate as normal wild-type phages. All the ts-mutants were more sensitive to germicidal ultraviolet light (emission peak at 253.7 nm) and to ethylenediaminetetraacetic acid (EDTA) than was the wild type.

Some other recent work with *Nostoc muscorum* ISU and cyanophage N-1 has followed host–phage interactions under osmotic stress. Osmotic stress (0.1 mol l^{-1} NaCl for 2–8 h) extended the latent period and significantly reduced the burst size. The deployment of an osmotolerant host and betaine improved the virus yield. Additionally, it has been shown for a strain of *Anacystis nidulans* resistant to cyanophage AS-1, that the resistant strain had some degree of protection from ultraviolet B light (at a wavelength of 290–320 nm). Finally, the activity of a temperate marine cyanophage, ms-1 of *Synechococcus* sp. NKBG 042902, was induced by copper. Chromium, lead, cobalt and zinc were not effective as inducers. The results suggested that copper could be a potential trigger for changes in the cyanobacterial population in the marine environment.

Metabolism

Mendzhul and coworkers have published a series of papers which determine the effect that the replication of cyanophage LPP-3 in the filamentous cyanobacterium *Plectonema boryanum* has on the activity of various host enzymes. The activity of glutamate dehydrogenase and glutamate synthetase was intensified in viral infected cells by 135 and 220%, respectively. Isozymes of glutamate synthetase were purified from both infected and noninfected cells. The chemical and physical properties of these isozymes were different, indicating cyanophage development could cause specific modifications of cell enzymes. In a comparable study of proteinases, new proteinases were found to appear immediately after cyanophage adsorption. The level of alanine hydrogenase fell by 50% after viral infection. It was found that this enzyme also varied in its physicochemical properties from a comparable enzyme found for noninfected host cells. Using the host filamentous cyanobacterium *Anabaena variabilis* and cyanophage A-1, the dynamics of the amino acid pool in the host was studied. Two peaks in the amino acid pool occurred after 0 and 2 h of infection. These were postulated to result not only from proteolysis and degradation of cytoplasmic membranes but also from the enhancement of virus-determined processes of amino acid biosynthesis. Many other aspects of changes in metabolism upon viral infection were also studied by this research group.

Concluding Remarks

The cyanobacteria with their procaryotic structure and oxygenic photosynthesis occupy a unique position among living organisms. These characteristics closely relate them not only to the eubacteria, but also to eucaryotic algae and plants. Over the last 5 or 6

years research has continued to investigate the genetics, physiology and metabolism, primarily for cyanophages which replicate in both unicellular and filamentous freshwater cyanobacteria; however, the major impetus of the latest research has shifted to the role cyanophages occupy in marine ecosystems. Cyanophages are of critical importance in that they can cause substantial lysis of primary producer organisms. This in turn can exert an extensive effect on the dynamics of carbon flow in many of the marine environments studied. It is hoped that many of the aspects of the research described here can continue to come together to give a more interconnected and complete understanding of the interactions between cyanophages and cyanobacteria.

CYPOVIRUSES (*REOVIRIDAE*)

Serge Belloncik, University of Quebec, Armand-Frappier Institute, Laval, Quebec, Canada

History

The observation of abnormal presence of dense inclusion bodies in the midgut of the silkworm *Bombyx mori* led a Japanese scientist, in 1938, to the first diagnosis of cytoplasmic polyhedrosis viruses (CPVs). Later, it was demonstrated that several economically important insects collected in nature or reared in the laboratory, could be infected by different CPVs. Historically, the prevention of CPV infections was the main research objective. Later, however, important fundamental data in virology as well as in molecular and cell biology, such as on the CAP structure of messenger RNA, host–virus relationship, viral persistence and crystallization of proteins were obtained from researches on CPVs. Recently, the potential of these viruses for insect pest control was also demonstrated.

Geographic and Seasonal Distributions

No particular geographic and seasonal distribution has been noted. CPVs are isolated from insects in various climatic and ecological conditions in different geographical areas and all through the year as long as the insect is physiologically active.

Taxonomy and Classification

The cytoplasmic polyhedrosis viruses (CPVs) have double-stranded (ds) RNA and are members of the *Cypovirus* genus within the *Reoviridae* family. Classification of these viruses is determined according to the electrophoretic pattern of the ten viral dsRNA segments on a 3% polyacrylamide gel. Twelve types of CPVs were originally classified, and more recently, two additional types have been reported. Intra-type virus differentiation can be detected by modification of polyacrylamide concentrations of migration gels. Cypoviruses are named according to the type and the insect host, e.g. *Bombyx mori* CPV1 (BmCPV-1), *Euxoa scandens* CPV5 (EsCPV-5), *Spodoptera exempta* cypovirus 12 (SexmCPV-12) etc.

Properties of the Virion

Occluded and non-occluded virions are identical (**Fig. 1**). The icosahedral virus particle has a diameter of

years research has continued to investigate the genetics, physiology and metabolism, primarily for cyanophages which replicate in both unicellular and filamentous freshwater cyanobacteria; however, the major impetus of the latest research has shifted to the role cyanophages occupy in marine ecosystems. Cyanophages are of critical importance in that they can cause substantial lysis of primary producer organisms. This in turn can exert an extensive effect on the dynamics of carbon flow in many of the marine environments studied. It is hoped that many of the aspects of the research described here can continue to come together to give a more interconnected and complete understanding of the interactions between cyanophages and cyanobacteria.

CYPOVIRUSES (*REOVIRIDAE*)

Serge Belloncik, University of Quebec, Armand-Frappier Institute, Laval, Quebec, Canada

History

The observation of abnormal presence of dense inclusion bodies in the midgut of the silkworm *Bombyx mori* led a Japanese scientist, in 1938, to the first diagnosis of cytoplasmic polyhedrosis viruses (CPVs). Later, it was demonstrated that several economically important insects collected in nature or reared in the laboratory, could be infected by different CPVs. Historically, the prevention of CPV infections was the main research objective. Later, however, important fundamental data in virology as well as in molecular and cell biology, such as on the CAP structure of messenger RNA, host–virus relationship, viral persistence and crystallization of proteins were obtained from researches on CPVs. Recently, the potential of these viruses for insect pest control was also demonstrated.

Geographic and Seasonal Distributions

No particular geographic and seasonal distribution has been noted. CPVs are isolated from insects in various climatic and ecological conditions in different geographical areas and all through the year as long as the insect is physiologically active.

Taxonomy and Classification

The cytoplasmic polyhedrosis viruses (CPVs) have double-stranded (ds) RNA and are members of the *Cypovirus* genus within the *Reoviridae* family. Classification of these viruses is determined according to the electrophoretic pattern of the ten viral dsRNA segments on a 3% polyacrylamide gel. Twelve types of CPVs were originally classified, and more recently, two additional types have been reported. Intra-type virus differentiation can be detected by modification of polyacrylamide concentrations of migration gels. Cypoviruses are named according to the type and the insect host, e.g. *Bombyx mori* CPV1 (BmCPV-1), *Euxoa scandens* CPV5 (EsCPV-5), *Spodoptera exempta* cypovirus 12 (SexmCPV-12) etc.

Properties of the Virion

Occluded and non-occluded virions are identical (**Fig. 1**). The icosahedral virus particle has a diameter of

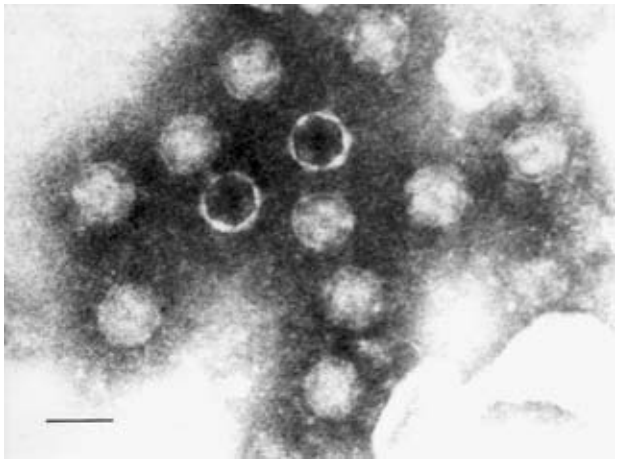

Figure 1 Electron micrographs of negatively stained cytoplasmic polyhedrosis virus particles. Bar = 70 nm.

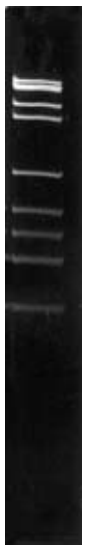

Figure 2 Electrophoretic pattern of *B. mori* CPV (type 1) RNA (7.5% polyacrylamide gel).

50–70 nm and one hollow spike located on each of the 12 vertices of the shell. The absence of a double-shelled structure differentiates the capsid of CPV from other *Reoviridae*. The molecular weight of the virus particles is approximately 50×10^6. The buoyant density in CsCl is 1.44 and 1.30 g cm^{-3} for the virion and empty viruses, respectively. The $s_{20,w}$ is approximately 420 (virions) and 260 (empty particles). Between 25 and 30% by weight of the virion is composed of three to five proteins (mol.wts 27×10^3 – 151×10^3). A transcriptase not requiring activation with proteolytic enzyme, capping enzymes, nucleotide phosphohydrolase, exonuclease and hemagglutinin are also components of the virus particles.

Properties of the Genome

Ten segments of dsRNA characterize the CPV genome (**Fig. 2**) and represent 25–30% of the weight of the virus. The molecular weights of the segments are from 0.3×10^6 to 2.7×10^6 making a total of 15×10^6. Reassortant between CPVs has not yet been isolated. The genome of different CPVs is stable. However, some others present a high degree of predictable or unpredictable genome variability and instability. A viable 11th 'dwarf gene' which is a deletion of gene 10 has been reported.

The coding assignment of each segment has been studied. Gene 10 codes for the polyhedrin, gene 1 for polymerase and methyltransferase, segments 2, 3, 4 and 6 for structural proteins and segments 5, 7, 8 and 9 for nonstructural proteins.

Results published in recent years have demonstrated that mutations at the N-terminal region of the polyhedrin gene are responsible for changing the shape of polyhedra whereas mutations around the C-terminal portion are related to modification of the crystallization pattern and the intracellular localization of the polyhedra.

The genome content of G+C is 36–42%. The plus strand (mRNA) of each strand is methylated and capped at the 5′terminus. Each segment is transcribed independently having a separate transcription enzyme system. The CPV genome and dsRNA–protein complex were visualized by electron microscopy after disruption of viral particles by physical and chemical treatments.

Properties of Polyhedra

A crystalline matrix protein (polyhedrin) constituting the polyhedra is mainly synthesized late during the viral infection. The spacing of the cubic lattice ranges between 4.1 to 7.4. The molecular weight of the polyhedrin is in the range 25 000–37 000. An alkaline protease associated with polyhedra produced in larvae was reported in cell cultures. The polyhedrin is glycosylated. The polyhedra has a buoyant density in CsCl of 1.28 g cm^{-3} and may occlude from one to several thousand virions. The size and shape (cubic, icosahedral) of the polyhedron varies according to virus strain and the insect cell (**Fig. 3**).

Physical Properties

Ultraviolet radiation inactivates virus infectivity and disrupts the structure of virus particles. The infectivity of CPVs is retained for weeks at 25°C. However, treatment of virions at 80°C or 60°C for 10–15 min or 140–160 min, respectively, inactivates this infectivity. The viral polyhedra as well as virions are resistant to

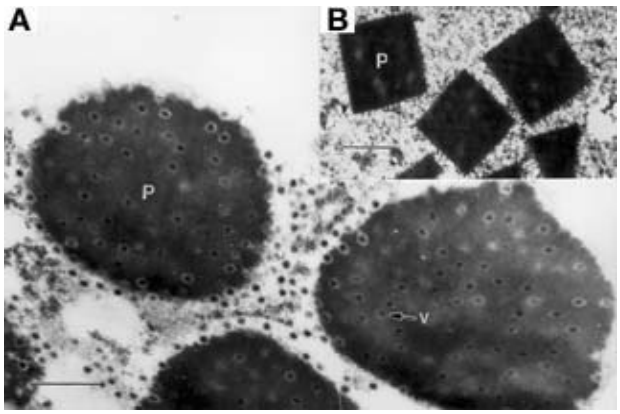

Figure 3 Electron micrgraphs of inclusion bodies of *B. mori* (**A**) and *E. scandens* (**B**) CPVs. V, virion; P, polyhedra. Bar = 2 μm.

low temperatures. The infectivity of polyhedra and virions is retained for many years at −20°C. The enzymatic activity is not affected by repeated freezing and thawing. The virus particles are resistant to ether, trypsin, chymotrypsin, RNase A, DNase, phospholipase C and deoxycholate and are disrupted by treatment with sodium dodecyl sulfate.

It is important to note that several physical as well as chemical factors which reduce the viral infectivity by acting on the integrity of the virus particles could promote and activate CPV infection in insects.

Evolution

No systematic studies have been conducted on the evolution of cytoplasmic polyhedrosis viruses. As stated here, the structure of the CPV virus particle differs from those of vertebrate or other insect reoviruses. According to some speculation on the evolution of viruses, the polyhedrin could be equivalent to the second capsid of reovirus particles or the second reovirus capsid could be a residue of CPV polyhedrin after evolution. Numerous CPVs are noted in nature and several strains of one CPV such as *B. mori* CPV are documented. Some CPV genomes are stable but others demonstrate predictable and arbitrary genomic deletions as well as the appearance of a viable dwarf gene after passages in the insect of some other CPVs. Mutations may explain the evolution of CPVs. The isolation of more than 10 dsRNA segments from insects demonstrates that mixed infections of larvae with several CPV types are frequent in nature. Genetic re-assortment of viral RNA segments between CPVs could be as for other reoviruses a plausible mechanism but it has not been demonstrated during the evolution of cytoplasmic polyhedrosis viruses.

Serologic Relationship

No serological classification of CPVs is available. The classification of cytoplasmic polyhedrosis viruses into types and intratypes is based on the electrophoretic pattern of the RNA segments. No antigenic relationship has been demonstrated between viruses belonging to distinct types using polyclonal and monoclonal antibodies and different serological techniques, but crossreactions between CPVs from a same intratype can occur.

Host Range, Virus Propagation and Epidemiology

Cytoplasmic polyhedrosis viruses have a wide host range and have been isolated from more than 250 species of insects, such as Lepidoptera, Diptera, Hymenoptera and Coleoptera. A CPV of one insect can replicate in other insect species. One CPV strain may therefore be propagated by different hosts. Mixed infections of larvae with several CPV types or strains have been noted in nature. Moreover, insect infection with an exogenous CPV could activate replication of an endogenous CPV strain. However, no crossinfection between insect genera has been documented. CPV infection of invertebrates other than insects and the crustacean *Simocephalus expinosus* has not be noted. Vertebrates, plants or prokaryote organisms are also not susceptible to CPV infection.

The transmission of the viral infection from one larva to another occurs mainly through contaminated food plants. The viral polyhedra are excreted in soil or on plants with the feces or cadavers of the infected larvae. Another mode of transmission of virus infection in nature is by spoilage of the egg surface laid by contaminated females. The polyhedra are ingested by larvae when feeding on contaminated plants or when hatching from spoiled eggs. On some occasions, the dissemination of the viral polyhedra could be achieved by birds, wind, running water or parasites. Latency of CPV in insects and vertical transmission of CPV through the eggs are suspected in the transmission from one generation to another and the persistence of the viral infection in insect populations (see later in this entry).

Morphogenesis and Cytopathology

The liberation of the virions from the polyhedra occurs in the insect midgut by the action of alkaline juice. Approximately 3 h after adsorption of the virus to the gut epithelium and penetration in the cell, new virions are observed in the cytoplasm. Small micronet structures represent the virogenic stroma or viro-

plasms and are the first sign of viral infection. Many viroplasms fuse in structures where the RNA, thin filaments of proteins and granules represent the site of assemblage of capsids, core and virions. It is assumed that the dsRNA is associated with subviral cores. Similar evolution is noted if the virions are injected intraperitoneally into the insect. Crystallization of the polyhedrin occurs about 15 h post-infection when a certain amount of this protein is synthesized. No incorporation of material other than homologous virus particle is noted. The signal that controls the start of polyhedrin crystallization is still unknown. Antigenic modification of the polyhedrin, as earlier reported, or a critical quantity of polyhedrin may be the signal. The insect cell could be involved in the initiation of the crystal formation since abnormal crystallization of expressed polyhedrin in *Escherichia coli* has been obtained. The presence of virions is not essential for normal formation of polyhedra, in contrast with previous assumptions, since no virus is present in the nuclear polyhedra of the A strain of *B. mori* CPV. Moreover, normal crystallization of CPV polyhedrin and formation in the nucleus of polyhedra containing no virus are obtained following the expression of *E. scandens* CPV polyhedrin gene by the *B. mori* baculovirus expression vector.

The shape of the polyhedra depends on different factors. Polyhedra of some CPVs, such as those of *E. scandens* and *Trichoplusia ni* are 99% spherical in larvae but 100% cubical in cell culture. The polyhedra of the A strain of *B. mori* CPV are cubical in shape in both the midgut and cell culture, whereas those of strain H of *B. mori* and *H. armigera* are spherical and, on rare occasions, cubical in any cell system *in vivo* or *in vitro*. Several reports describe the presence of a proportion of malformed polyhedra and fragmentation of inclusion bodies during a normal viral infection. In addition, several polyhedra shapes were obtained when abnormal crystallization of polyhedrin occurred in CPV-infected cells that had been gamma irradiated or treated with fungal toxin.

Therefore, it is strongly believed that the structure and shape of the inclusion body crystal as well as the crystallization of the polyhedrin could in some cases be controlled by the virus and in some others by the cell or some unknown interaction mechanism between the virus and the cell. There is a close interrelationship between the host cell and the CPV strain. Different cell culture conditions that influence the cell metabolism and other cellular factors are crucial for normal crystallization of the polyhedrin. A comparison of results obtained from *in vivo* and *in vitro* viral infections leads to the conclusion that the cubical-shaped polyhedra represent the final stage of maturation of the inclusion bodies when optimal conditions are met and no external and internal factors interrupt the crystallization process. The other shapes observed can be considered as intermediate forms between the mature polyhedra and the pro-polyhedron stage.

At an advanced stage of CPV infection, the midgut is hypertrophied and milky-white in color. The cytoplasm is filled with polyhedra, 0.5–10 μm, containing one to more than thousands of virions. Usually, the inclusion bodies of the posterior part of the midgut are smaller than those of the anterior part. The size and the shape of the polyhedra are also variable according to the location and the CPV strain. Icosahedral, hexahedral, pyramidal, hexahedral, acicular/hexahedral, acicular/conglomerate, acicular and amorphous shapes were described for the strains I, H, P, A, B, B_1, B_2, C_1 and C_2 respectively. Locations of the polyhedrin are strictly cytoplasmic for I, H and P strains, strictly nuclear for A strain and both cytoplasmic and nuclear for the remaining strains. The complete viral morphogenesis is noted only in the midgut cells of the insect and almost exclusively in cylindrical cells. Goblet and differentiated cells are sometimes infected. Variable amounts of non-occluded virions are also noted in the cell cytoplasm at the end of the viral morphogenesis. The infected cells are released in the feces and contaminate by means of the food other larvae. Concomitant passage of non-occluded virus particles to newly generated cells contribute to persistence of the CPV infection in the larva and the amplification of the virus. If the larvae and pupae survived from infection, viral particles can be detected in these insects. Despite the restriction of complete viral infection to the midgut cells, the virions can be detected in the hemolymph of the larvae. However, the cytopathology is limited to the midgut cells where, except for the A, B and C strains, changes are not detected in the nuclei. In the cytoplasm, abundant endoplasmic reticulum and microvilli are degraded.

More information on the CPV morphogenesis was obtained in infected cell cultures of different origins. In particular CPV infection is characterized by no shut-off of cellular protein synthesis and no lysis of cells. Moreover, it has been demonstrated that interactions between the viral genome and the cell culture conditions could influence the crystal formation and shape of the polyhedra.

Transmission and Persistence of CPV Infection

The posterior portion of the midgut is infected first followed by the anterior part and at an advanced stage of infection, the cytoplasm of epithelial midgut

cells. When the cells are filled with polyhedra, diarrhea occurs. Infected cells desquame and viral polyhedra are excreted in insect feces and in this way the viral infection is propagated among the larvae. In the meantime non-occluded virus particles pass through plasma membrane, from infected to newly differentiated regenerated cells. This mechanism allows the persistence and amplification of the virus in insects. CPV are also transmitted from one generation to another. This vertical transmission is partially understood. Infected adults can propagate the viral polyhedra and contaminate the eggs. However, numerous data suggest trans-ovum transmission as well as latency of the CPV. Several physical (temperature, UV), chemical (formalin, diet components), stress or genetic factors which promote outbreaks of cytoplasmic polyhedrosis virus infections have permitted the further investigation of more mechanisms of viral propagation and persistence.

In insect tissue culture no lytic effect of CPV replication has been noted. Infected cell lines can be maintained *in vitro* for several months without lysis of the cells. Foci of CPV-infected cells are often noted as the result of non-occluded virus propagation from one cell to an adjacent cell and multiplication of infected cells. Persistence of viral infection in a cell line has been proved for some CPVs. *Heliothis armigera* CPV infection was detected for more than 100 passages during which time polyhedrin was continuously expressed and polyhedra were formed.

Replication

The complete replication cycle of CPVs can be demonstrated in susceptible insects and various insect cell cultures. Virions contain transcriptase which is not sensitive to actinomycin D. This enzyme acts on the viral dsRNA and no proteolytic or heat treatment of the virions is required. No replication is noted in vertebrates. Other information on the biochemistry of CPV replication has also been obtained from *in vitro* experiments.

When nucleic acid replication is investigated in infected larvae, single-stranded (ss) RNA (15 and 22S) related to the mRNA transcripts of the viral genome is synthesized. CPV transcriptase is active only in intact virions. When mRNA synthesis occurs, it has been suggested that the genome strand moves to the spike during which the mRNA is produced and excreted through the spike. The virion is able to synthesize several segments of RNA simultaneously. Control of the quantity of each polypeptide is achieved by a higher transcription rate of the smaller segments. Transcription is stimulated by a methyl-group donor, *S*-adenosylmethionine (SAM), and 'cap' formation requiring other enzymes present in CPV particles is mandatory for further synthesis of CPV mRNA. Limitation of replication and mRNA synthesis are therefore independent of the cellular enzymes. However, CPV replication may somehow be limited and controlled by the availability of nucleotide triphosphate and SAM in the cell.

The mechanism of genomic RNA synthesis and assembly of dsRNA with proteins is not known in detail. mRNA could, as found for other *Reoviridae*, serve as a template for the synthesis of the complementary strand. Active synthesis of viral dsRNA (15 and 22S) is detected in infected midgut and some reports have stated that viral RNA synthesis takes place in the nucleus. These latter observations have still to be confirmed.

Kinetic studies of protein and antigen synthesis conducted in either larvae or cell cultures give similar results. Viral antigens are detected as early as 4–8 h after infection and the polyhedrin is synthesized 9 h after infection. In a cell culture system, seven viral polypeptides are present after 24 h of CPV infection. Polyhedrin is produced later than the other proteins and increases from 8 to 96 h after infection and this production rate remains high even if the infected cells are subcultured. It is suggested that regulation of polyhedrin viral mRNA synthesis may occur. However, it has also been demonstrated that infected cells are constantly reinfected by the virus and that a number of viral amplification cycles occur. This could also contribute to the constant and persistent increase in polyhedrin synthesis. Nucleic acid and protein metabolism of CPV-infected larvae is affected. However, no shut-off of host protein synthesis occurs in the cell culture system during viral replication despite excessive viral protein synthesis in the cells.

Results of experiments using cell culture systems complement our knowledge on CPV replication and demonstrated the complexity of the multiplication of these viruses. To conclude this section, it is important therefore to point out that CPV replication is dependent on several external and cellular factors which have different enhancing or inhibitory effects on viral synthesis. CPV replication is optimal between 25° and 28°C, and temperatures above 31°C are detrimental. For instance, a temperature of 37°C inhibits all viral synthesis and this is most probably due to inactivation of the transcriptase. Interesting features are observed at the low incubation temperature of 4°C: viral infectivity is not affected and, moreover, dsRNA is synthesized but without any expression of polyhedrin and viral proteins.

Mixed infection by different types of CPV or insect viruses is a frequent phenomenon. Interference between the replication of two CPV types is observed

but co-infection of a single cell by two types of CPV is also found. On the other hand, a large increase in polyhedrin synthesis is the result of simultaneous replication of CPV and the chilo iridescent virus (CIV). Therefore more investigations are needed for a better understanding of interactions at the molecular level between CPV and other insect virus replication steps.

Several lepidopteran cell lines support the entire replication cycle of different CPVs. Internalization of CPV particles was demonstrated in different insect or vertebrate cell lines. Abortive viral replications were also demonstrated. We must, in the light of the new information on CPV replication, reconsider the criteria for detecting CPV infection. The manifestation of different viral synthesis and replication steps rather than the presence of polyhedra may be a more appropriate approach to the assessment of the viral host range and specificity.

Pathogenicity: Virus–Host Interactions

The pathogenicity for an insect of CPVs depends on different factors. Among these factors, the virus strain and the insect are the most important. In addition, other environmental factors influence the viral pathogenicity and the nature of the virus–host interactions. Several CPVs are extremely and more infectious than other insect viruses, such as the baculoviruses. The lethality of CPVs is also variable and depends on the virus strain. Some strains are highly lethal. However, it is a characteristic of CPV infection to be chronic rather than lethal. It is important to point out that the lethality of a particular CPV may be different in laboratory conditions from that in nature where the insect is subjected to numerous environmental stresses.

In the insect, antagonism between infective CPV strains either of the same type or one inactivated and one infective have been demonstrated. Furthermore, during mixed CPV infection the polyhedra of each strain are located in different cells. However, in cell culture infection of a single cell by two different CPVs has been reported. It is not clear how the interaction between CPV strains occurs. Competition at the cell receptors or metabolic pathway level could explain the antagonism effects.

If the virions (non-occluded or alkali-liberated from the polyhedra) are injected into the hemocele of the larvae, the pathogenicity of CPV is the same as for the ingested polyhedra. Despite the presence of the virion in the hemolymph, the complete infection is located in the columnar cells and on rare occasions in the goblet cells. After differentiation of the regenerative cells located in the basal region, these cells are susceptible to complete CPV. Pathogenicity of CPV for the embryo has also been demonstrated.

Insect resistance to CPVs has been documented. As for baculoviruses, old larvae are less susceptibile to CPVs. Molting has also been demonstrated to have an inhibitory effect on the development of CPV. Research using the silkworm showed that two strains of the silkworm could be resistant or susceptible to a CPV infection. The resistance was demonstrated to be under either a multifactorial genetic or a dominant major gene control system. In some rare instances resistance to CPV infection was acquired following repeated application of the virus. Several exogenous factors can affect the pathogenicity and the virus–host relationship. Among these factors treatment of larvae with different chemicals (formalin, chemical insecticides, H_2O_2, disodium salts, dietary components), radiations and low temperatures enhance the susceptibility of the insects to CPV. However, microbial toxins and high temperature reduce the incidence of the virus in insect colonies.

Typical features commonly related to CPV pathogenicity are the alterations of insect functions. Among the metabolic alterations, are decreases in the amounts of proteins and nucleic acid of CPV-infected hemolymph. Amino acid levels decrease except for the glycine. In infected midgut, uric acid and ammonia increase. A reduction of midgut pH was also noted.

Nucleic acid, mostly RNA synthesis in infected cells has been studied by several authors. No major modification of nucleic acid DNA synthesis in infected and healthy midgut cells was demonstrated. Mitochondrial and ribosomal RNA are decreased.

The integrity of the midgut is crucial for the absorption of nutrients. Therefore, the metabolic functions of different organs and tissues may be affected, as a consequence of nutritional deficiency although complete normal viral replication occurs only in the midgut.

Physiological alterations occurring in CPV-infected insects are the consequence of the metabolic modifications. Higher virus concentrations combined with early larval stage result in greater effects. Extended instar duration, decrease of length of the larvae and the weight of the pupae as well as less lipid and proteins are common. Even though the larval stages are extended the damages caused by the infected insects are lower. The breakdown of lipid reserves of CPV-infected larvae results in an increase in oxygen uptake. Adult and larval pigmentations are reduced either because of tyrosine deficiency resulting from less amino acid being available in infected hemolymph or because of hormonal imbalance which affects tyrosinase activity. Moreover, numerous pupae are deformed and the surviving adults have difficulty in

emerging. Malformation of adults reduces the mating ability. Poorly developed oocytes have been noted, and fecundity and the viability of the offspring are reduced.

Interestingly, a consequence of the metabolic and physiologic alterations is the reaction of CPV-infected insects to other pathogens and detrimental environmental conditions. It was demonstrated by several authors that CPV-infected larvae, compared to healthy populations, are less resistant to hibernation which results in a high larval mortality rate during the winter.

Furthermore, synergistic interactions between CPV and chemical insecticide (permethrin) as well as CPV and baculoviruses are the result of a decrease of the resistance of CPV-infected insects to these chemicals and pathogens. When bacteria such as *Pseudomonas maltophilia, Bacillus subtilis, E. coli, Staphylococcus epidermis* are present as contaminants the physiological alterations and mortalities noted when insects are infected by CPV are enhanced significantly. Synergistic interactions have also been shown in relation to insect mortality between CPV and *Bacillus thuringiensis* treatments both in the laboratory and in the field.

Prevention, Control and Practical Applications

The cytoplasmic polyhedrosis viruses have been studied intensively mainly because they were considered as noxious microorganisms and contaminants of reared insect colonies. Therefore, most efforts were first given toward the prevention and control of CPV infections. Cross-protection of insects with inactivated CPVs and the exposure of larvae at high temperature have been shown successfully to control the viral infection. Moreover, the provision of optimal nutritional and environmental conditions contribute to maintaining healthy colonies by controlling the CPV expression in insects. However, despite these demonstrations and the possibility of a vertical transmission, the systematic disinfection of eggs and the equipment with chemicals such as hypochloride and formalin solutions are to date the only techniques used to prevent CPV propagation in reared insect colonies.

On another hand, development of viral insecticides has been based on several characteristics of the cytoplasmic polyhedrosis viruses. Numerous virus particles are protected inside the polyhedra from detrimental conditions of the environment. The CPVs could be lethal, are highly infectious, persistent and induce physiological and metabolic alterations in insects. Furthermore, combinations of CPV with other microbial pathogens or chemicals and environmental factors contribute to a decrease of insect populations over one to several generations. However, CPVs are slow-acting viruses and most of the field applications were conducted in forests where a certain level of damage is tolerable. Considering the viral persistence their use in stable ecosystems such as the forests is the more suitable stable ecosystem to be protected.

The taxonomic relatedness of CPVs to vertebrate viruses, such as reoviruses, could represent a handicap for their use as viral insecticides. Therefore, biosafety testing of CPVs has been conducted in several laboratories. Numerous vertebrate hosts, such as mice, rabbits, avian embryos, fish etc., as well as on vertebrate and mosquito cell lines demonstrated no viral pathogenicity or replication of CPVs for these nontarget organisms.

The *Dendrolimus spectabilis* (DsCPV) has been commercialized, as Matsukemin product, in Japan and the efficacy of several other CPVs such as those of *Lymantria dispar* and *fumida, Thaumetopoea pityocampa, Choristoneura fumiferana, Dendrolimus pini* and *Trichoplusia ni* have been shown to have promise as viral insecticides when used alone or combined with *B. thuringiensis*.

Future

Since the first isolation of cytoplasmic polyhedrosis viruses as contaminants of beneficial insects their importance has been demonstrated in fundamental research in the fields of biology, virology, biochemistry and molecular biology as well as in a variety of applied research programs. The virulence of CPV combined with important physiological and metabolic disturbances produced in the insect as a consequence of CPV infection has renewed interest in CPVs as biological control agents. Furthermore, the peculiar interactions between the insect cell and the CPV, the interaction of the viral infection and different endogenous as well as exogenous factors for an insect cell host and latency phenomena could serve in the future as important and interesting models for the study of other microbial pathogenesis.

CYTOKINES AND CHEMOKINES

Diane E. Griffin, Department of Molecular Microbiology and Immunology, Johns Hopkins University School of Hygiene and Public Health, Baltimore, Maryland, USA

Introduction

Cytokines are small soluble proteins produced by a wide variety of cells and are important mediators of cell-to-cell communication. Production of these biologically potent proteins is particularly associated with generation of the innate and acquired immune responses. Cytokines regulate both the initiation and maintenance of immune responses and some also have direct antiviral effects. Chemokines (*chemo*tactic cyto*kines*) regulate infiltration of leukocytes into infected tissues. Both cytokines and chemokines share the properties of pleiotropy and redundancy. Each cytokine and chemokine has more than one function and any one function can be performed by more than one of these soluble factors.

Cytokines can act at a distance, but usually act in the areas in which they are produced and mediate their effects by binding to small numbers of high affinity receptors on responding cells. Cytokine receptors have a modular design consisting of two or more chains, each with a single transmembrane-spanning domain. Individual components may participate in formation of the receptor for more than one cytokine. Chemokine receptors are single G-protein-coupled molecules with seven transmembrane domains. The biologic function of many cytokines and chemokines is regulated in part by a short half-life for both the protein and the mRNA, but also by the production of circulating cytokine inhibitors such as soluble forms of the cytokine receptor or biologically inactive forms of the cytokine itself. A number of viruses, particularly in the herpesvirus and poxvirus families, encode inhibitory homologues of cytokines, chemokines or their receptors, attesting to their importance for antiviral immunity.

Overview of Cytokine Networks (Fig. 1)

Cytokines associated with the innate immune response are those induced early after infection by virus replication *per se*. One of the most important of these early components of the immunologically nonspecific response are type 1 (α and β) interferons (IFNs) which are generally synthesized and released by infected cells. IFN-α/β can induce an antiviral state in surrounding cells and can also influence the characteristics of the subsequent immune response. In addition, phagocytic cells, responsible for processing and presentation of viral antigens to initiate the antigen-specific immune response, produce a variety of cytokines, including IFN-α/β. These antigen-presenting cells, generally dendritic cells and monocyte/macrophages, may or may not be infected or produce infectious virus. Important cytokines and chemokines produced by antigen-presenting cells in the initial phases of the response to many viral infections are tumor necrosis factor (TNF), monocyte chemotatic proteins (MCP), interleukin (IL)-1, IL-6, IL-12 and IL-18. These soluble factors promote the activation of T cells and recruitment of inflammatory cells into areas of virus replication. IL-12 stimulates natural killer (NK) cells to produce IFN-γ, promotes differentiation of CD8+ cells to cytotoxic T lymphocytes, and influences the early development and differentiation of CD4 T cells toward a delayed type hypersensitivity cellular immune response (type 1).

CD4 and CD8 T lymphocytes are the effectors of the specific cellular immune response and function primarily through synthesis of cytokines. T cells do not produce cytokines constitutively, but upregulate expression in response to stimulation through the T cell receptor. CD8 T cells are stimulated by viral

CYTOKINES AND CHEMOKINES

Diane E. Griffin, Department of Molecular Microbiology and Immunology, Johns Hopkins University School of Hygiene and Public Health, Baltimore, Maryland, USA

Introduction

Cytokines are small soluble proteins produced by a wide variety of cells and are important mediators of cell-to-cell communication. Production of these biologically potent proteins is particularly associated with generation of the innate and acquired immune responses. Cytokines regulate both the initiation and maintenance of immune responses and some also have direct antiviral effects. Chemokines (*chemo*tactic cyto*kines*) regulate infiltration of leukocytes into infected tissues. Both cytokines and chemokines share the properties of pleiotropy and redundancy. Each cytokine and chemokine has more than one function and any one function can be performed by more than one of these soluble factors.

Cytokines can act at a distance, but usually act in the areas in which they are produced and mediate their effects by binding to small numbers of high affinity receptors on responding cells. Cytokine receptors have a modular design consisting of two or more chains, each with a single transmembrane-spanning domain. Individual components may participate in formation of the receptor for more than one cytokine. Chemokine receptors are single G-protein-coupled molecules with seven transmembrane domains. The biologic function of many cytokines and chemokines is regulated in part by a short half-life for both the protein and the mRNA, but also by the production of circulating cytokine inhibitors such as soluble forms of the cytokine receptor or biologically inactive forms of the cytokine itself. A number of viruses, particularly in the herpesvirus and poxvirus families, encode inhibitory homologues of cytokines, chemokines or their receptors, attesting to their importance for antiviral immunity.

Overview of Cytokine Networks (Fig. 1)

Cytokines associated with the innate immune response are those induced early after infection by virus replication *per se*. One of the most important of these early components of the immunologically nonspecific response are type 1 (α and β) interferons (IFNs) which are generally synthesized and released by infected cells. IFN-α/β can induce an antiviral state in surrounding cells and can also influence the characteristics of the subsequent immune response. In addition, phagocytic cells, responsible for processing and presentation of viral antigens to initiate the antigen-specific immune response, produce a variety of cytokines, including IFN-α/β. These antigen-presenting cells, generally dendritic cells and monocyte/macrophages, may or may not be infected or produce infectious virus. Important cytokines and chemokines produced by antigen-presenting cells in the initial phases of the response to many viral infections are tumor necrosis factor (TNF), monocyte chemotatic proteins (MCP), interleukin (IL)-1, IL-6, IL-12 and IL-18. These soluble factors promote the activation of T cells and recruitment of inflammatory cells into areas of virus replication. IL-12 stimulates natural killer (NK) cells to produce IFN-γ, promotes differentiation of CD8+ cells to cytotoxic T lymphocytes, and influences the early development and differentiation of CD4 T cells toward a delayed type hypersensitivity cellular immune response (type 1).

CD4 and CD8 T lymphocytes are the effectors of the specific cellular immune response and function primarily through synthesis of cytokines. T cells do not produce cytokines constitutively, but upregulate expression in response to stimulation through the T cell receptor. CD8 T cells are stimulated by viral

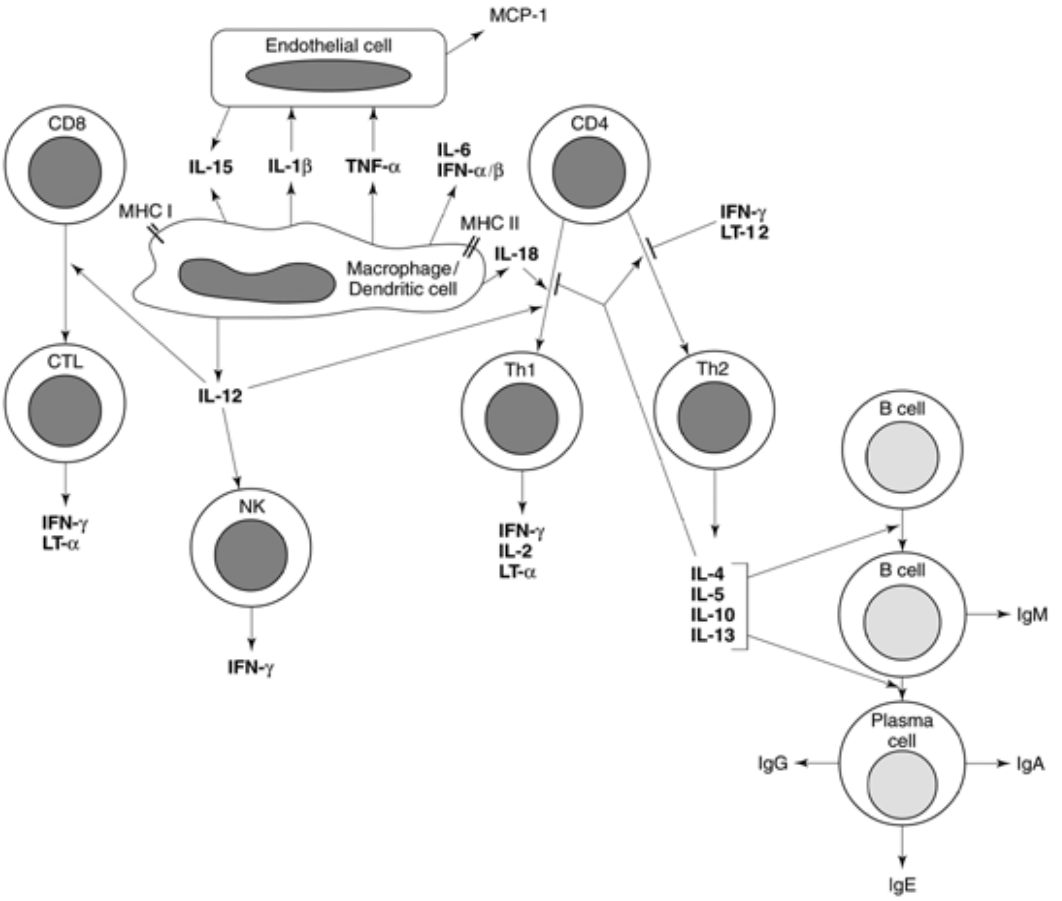

Figure 1 Overview of cytokine networks important for innate and acquired antiviral immune responses.

antigens presented in association with class I major histocompatibility (MHC) antigens. This type of stimulation is most likely to occur if the virus replicates in the antigen presenting cell since antigens presented in association with MHC class I must be processed by proteasomes in the cytosol. CD8 T cells often have cytotoxic activity, but also produce substantial amounts of IFN-γ and lymphotoxin (LT). CD4 T cells are stimulated by viral antigens presented in association with class II MHC antigens. Processing of antigens for presentation in association with MHC class II occurs through an endosomal pathway, therefore, virus replication is not required. Activated CD4 T cells produce IL-2, a T cell growth factor which supports proliferation of both CD4 and CD8 T cells.

With further development of the virus-specific immune response, CD4 T cells tend to differentiate into type 1 or type 2 helper T (Th) cells. Type 1 CD4 T (Th1) cells develop under the influence of IL-12 and produce primarily IFN-γ and TNF-β (LT-α) and are associated with classic delayed type hypersensitivity or cellular immune responses. Type 2 CD4 T cells develop under the influence of IL-4 and produce primarily IL-4, IL-5, IL-10 and IL-13 and are associated with strong antibody responses to viral antigens. Cytokines produced by T cells are necessary for B cell development and for the switch from B cells producing IgM to plasma cells producing more mature forms of immunoglobulin (Ig) such as IgG, IgA and IgE. Both Th1 and Th2 responses are associated with mononuclear cell infiltrates into areas of virus replication, but the cytokines being produced in those sites are distinct.

Brief Description of Cytokine Families

TNF

The TNF family has three members: TNF-α, TNF-β/LT-α and LT-β. These cytokines have approximately 30% homology and share the same cellular receptors. Activated macrophages are the major source of TNF-α and T cells are the major source of lymphotoxin.

TNF-α is synthesized as a proprotein (26 kDa) which is membrane-bound and cleaved by a specific multi-domain cell-surface metalloprotease to yield a 17 kDa protein. The active form of the soluble protein is a cone-shaped trimer which can bind to either of two TNF receptors (TNFR1, p55 and TNFR2, p75). Binding of TNF to TNFR1 induces NFκB and can trigger apoptosis. Homotrimers of LT-α also bind to TNFR1 and TNFR2, but LT-β reacts with a separate member of the TNF receptor family, the LT-β receptor. TNF interacts with a wide variety of cells systemically and locally and induces proinflammatory cellular responses such as expression of adhesion molecules, release of cytokines, chemokines and procoagulatory substances, synthesis of acute phase proteins and production of fever. TNF also has some antiviral activity and is an important early participant in the immune response to infection. In bacterial infections, TNF is one of the mediators of endotoxin-induced (septic) shock. TNF and LT also play an important role in development of lymphoid tissues since mice with deletions of these genes do not have the normal lymphoid architecture.

IFN-γ

IFN-γ is a glycosylated protein of 25 kDa that is produced by NK cells and by type 1 CD4 and CD8 T cells (immune IFN). Although IFN-γ has some antiviral activity it is structurally unrelated to IFN-α/β and uses a distinct receptor. However, IFN-γ shares some components of the intracellular signaling pathways for type 1 IFN. The biologically active form of IFN-γ is a dimer. A primary role for IFN-γ is the activation of macrophages increasing phagocytosis, tumoricidal properties and intracellular killing of pathogens, particularly bacteria and fungi. IFN-γ induces macrophage production of a variety of inflammatory mediators and reactive oxygen and nitrogen intermediates. IFN-γ increases expression of high-affinity immunoglobulin F_c receptors on phagocytes, which increases recognition of opsonized microorganisms by these cells. IFN-γ also increases expression of MHC antigens by macrophages and this facilitates antigen presentation to T cells. The IFN-γ cell surface receptor is composed of two chains, IFN-γR1 (α) and IFN-γR2 (β). The α (R1) chain is sufficient for binding, but the β (R2) chain is required for signaling and receptor complex formation. T cell responsiveness is regulated by receptor expression. Both Th1 and Th2 cells express IFN-γR1, but only Th2 cells express IFN-γR2. Therefore, Th1 cells produce, but do not respond to, IFN-γ whereas Th2 cells respond to, but do not produce this cytokine. Macrophages express both receptor chains and are a primary target of IFN-γ activity.

IL-1

The IL-1 family has three members: IL-1α, IL-1β and IL-1 receptor antagonist (IL-1Ra). IL-1α and IL-1β have only distantly related amino acid sequences, but similar structure, and recognize the same receptors. IL-1Ra binds the IL-1 receptor without transducing a signal and this binding blocks the activities of IL-1α and IL-1β. Activated monocytes and macrophages are the major source of IL-1, although many other cells can produce this cytokine. IL-1β is synthesized as a precursor protein of 31 kDa that is processed by the caspase interleukin-1β-converting enzyme (ICE, caspase-1) to the active secreted 17 kDa form. IL-1 acts systemically, as well as locally, and can produce fever, sleep and anorexia, frequent symptoms of viral infection. Hepatocytes are among the cells that produce IL-1Ra as a part of the acute-phase response to inflammation and infection, presumably to control the effects of IL-1. There are two IL-1 receptors but only IL-1RI transduces an activation signal to responding cells. IL-1RII appears to function as a decoy receptor that regulates IL-1 activity by binding the cytokine without transducing a signal.

IL-2

IL-2 is a unique 15 kDa cytokine produced primarily by activated type 1 CD4 T cells. IL-2 plays an important role in supporting proliferation of activated helper T cells, cytotoxic T cells, B cells, macrophages and NK cells. For stimulated CD4 cells IL-2 acts in an autocrine fashion since Th1 cells can both produce IL-2 and upregulate high affinity IL-2 receptors. The high affinity IL-2R consists of three chains, IL-2Rα, β and γ, which are expressed on the surface of activated T cells. IL-2Rα is a unique protein whereas IL-2Rβ and IL-2Rγ are members of the hematopoietic growth factor receptor superfamily. Members of this superfamily share a 210 amino acid domain in the extracellular region of the molecule. This domain contains a distinct cysteine and tryptophan motif at the N-terminus and a Trp-Ser-X-Trp-Ser motif at the C-terminus. The whole domain is folded into two barrel-like structures with the ligand-binding region between. In addition to the IL-2 receptor this receptor superfamily includes components of receptors for cytokines IL-3, IL-4, IL-5, IL-6, IL-7, IL-9, granulocyte macrophage–colony stimulating factor (GM-CSF), and granulocyte–colony stimulating factor (G-CSF). Signal transduction is through the IL-2Rβ chain. Intermediate affinity IL-2R$\beta\gamma$ receptors are expressed on monocytes and NK cells. IL-2Rγ (γ

constant) also participates in the formation of the multichain IL-4, IL-7, IL-9 and IL-15 receptors. Defects in expression of this molecule lead to severe combined immunodeficiency in humans. Binding of IL-2 to the high affinity receptor leads to T cell proliferation.

IL-4

There are five members of the IL-4 family of cytokines: IL-3, IL-4, IL-5, IL-13 and GM-CSF. These cytokines have approximately 30% protein sequence homology, have similar α-helical structure, are linked in the same chromosomal region and are produced by type 2 CD4 T cells. IL-3 and GM-CSF are two of the four major human myeloid growth factors which also include G-CSF and M-CSF. IL-3 is produced by activated T cells and binds to a heterodimeric receptor. The β subunit of the IL-3R is shared with the receptors for IL-5 and GM-CSF.

IL-4 and IL-13 have similar effects on B cells and monocytes. Both serve as a costimulating factor for B cell proliferation, drive activated B cells into immunoglobulin secretion and, in human B cells, induce class switching to IgG_4 and IgE. IL-4 is regarded as an anti-inflammatory cytokine because it antagonizes the effects of IFN-γ on macrophages and downregulates type 1 CD4 T cell responses. IL-13 induces monocyte proliferation and monocytosis *in vivo*. IL-4 is important for promoting the differentiation of CD4 T cells to type 2 cytokine production. IL-4 and IL-13 are produced by type 2 CD4 T cells. IL-4 is also produced by a subset of CD4 T cells that are $NK1.1^+$, by type 2 CD8 T cells and by mast cells, basophils and eosinophils.

IL-5

IL-5, along with IL-3 and GM-CSF, acts as an eosinophil stimulating factor and its receptor shares a common β chain with these cytokines. The high affinity IL-5R has a unique α chain. IL-5 induces proliferation and differentiation of eosinophil progenitors whereas IL-3 and GM-CSF probably act at earlier stages of development. IL-5 is produced by type 2 CD4 and CD8 T cells and NK cells. IL-5 also induces antigen-stimulated B cells to differentiate into immunoglobulin-secreting plasma cells and enhances secretion of IgA.

IL-6

IL-6 is a member of a family of cytokines and neuronal differentiation factors that includes leukemia inhibitory factor, oncostatin M, IL-11 and ciliary neurotrophic factor. The receptors for these cytokines share the transmembrane protein gp130 which transduces the cytokine signal. IL-6 is a functionally diverse cytokine produced by macrophages and monocytes early in the response to infection. It is an important inducer of hepatic synthesis of acute phase proteins, supports proliferation of B cells and has an important role in production of IgA.

IL-7

IL-7 is a 15 kDa protein that is produced primarily by epithelial cells and supports the growth and development of immature B and T cells, but is unnecessary for the development of NK cells. IL-7 is produced by bone marrow stromal cells, thymic epithelial cells, keratinocytes and intestinal epthelial cells and supports lymphocyte development in these locations. In the thymus IL-7 induces rearrangement of germline T cell receptor genes by upregulating expression of the RAG-1 and RAG-2 recombinases. The α chain of the IL-7 receptor is a member of the hematopoietic growth factor family and associates with the IL-2Rγ chain to form a functional high affinity IL-7R.

IL-10

IL-10 is an 18 kDa polypeptide that forms homodimers. It is predicted, on the basis of sequence, to be a member of the 4α-helix bundle family of cytokines. It is produced by a wide variety of cells including type 2 CD4 and CD8 cells, B cells, mast cells, macrophages and keratinocytes. Epstein–Barr virus encodes a viral homologue of IL-10 that is functionally active. The activities of IL-10 are diverse. IL-10 inhibits cytokine production by Th1 cells, NK cells and macrophages. In macrophages it suppresses the synthesis of TNF-α, IL-1α, IL-6, IL-8, GM-CSF and G-CSF while increasing the production of IL-1Ra. In contrast, IL-10 stimulates proliferation and differentiation of activated B cells and T cells and of mast cells. The IL-10R is structurally related to the IFN-γR.

IL-12

IL-12 is a structurally unique heterodimeric cytokine composed of two disulfide-linked 35 kDa and 40 kDa polypeptides. The 40 kDa protein conveys receptor binding activity and is constitutively produced by many cells. Only the heterodimer is biologically active so regulation of synthesis of the 35 kDa chain controls IL-12 activity. IL-12 is produced by macrophages and dendritic cells and stimulates the production of IFN-γ by NK and T cells. It is essential for differentiation of CD4 T cells into Th1 cells. At least two classes of the IL-12 receptor exist. The IL-12R β1 chain is expressed in both Th1 and Th2 cells whereas the β2 chain is expressed only in Th1 cells. Both β1 and β2 are necessary for IL-12 responsiveness and for T cell

differentiation so only potential Th1 cells respond to this cytokine. Both IL-12R β1 and β2 subunits are related to the gp130 group of cytokine receptors. Homodimers of p40 bind with high affinity to the IL-12R, transduce no signal and block the effect of the heterodimer.

IL-15

IL-15 is a novel cytokine functionally related to IL-2, but without significant IL-2 sequence homology. It binds to a receptor with the β and γ chains of the IL-2R, but has its own unique α chain. IL-15 induces T cell proliferation, enhances NK cell function, is a potent T lymphocyte chemoattractant and stimulates production of IL-5. Unlike IL-2 it is produced primarily by monocyte/macrophages and endothelial cells.

IL-18

IL-18, also known as IFN-γ-inducing factor, is an 18 kDa cytokine produced by macrophages. IL-18 shares structural features with the IL-1 family of proteins and functional properties with IL-12. It is synthesized as a proprotein that, like IL-1β, is cleaved by caspase 1 (ICE) to its biologically active form. Like IL-12, IL-18 stimulates IFN-γ production by T cells, NK cytotoxicity and T cell proliferation.

Chemokines and Chemokine Families

The chemokine superfamily includes a large number of structurally related, basic, heparin-binding, small-molecular-weight (8–10 kDa) proteins that have potent chemotactic and immunoregulatory functions. Chemokines attract specific, but overlapping, populations of inflammatory cells and can be divided into subfamilies based on the spacing of the first two of four conserved disulfide-forming cysteine residues. The subfamilies have different biologic activities. CXC or α-chemokines are the primary attractants for neutrophils. CC or β-chemokines modulate responses of monocytes, macrophages, lymphocytes, basophils and eosinophils. Some variations on these two chemokine themes have been reported. For instance, lymphotactin, a γ chemokine, has only one set of cysteines and is chemotactic for lymphocytes. Neurotactin is a CXXXC or δ-chemokine and is unique in that it is a type 1 transmembrane protein with the chemokine domain on top of an extended mucin-like stalk.

α-chemokines

The first CXC chemokine to be identified was platelet factor 4 (PF4). PF4 is stored in the granules of platelets which contain two additional α-chemokines, platelet basic protein and the related connective tissue activating peptide III. The best characterized α-chemokine is IL-8 which is chemotactic for neutrophils. Other α-chemokines with chemotactic activity for neutrophils include macrophage inflammatory protein (MIP)-2, neutrophil activating protein-2, GRO-α, GRO-β, GRO-γ, epithelial cell-derived neutrophil activating protein and granulocyte chemotactic protein-2. Sequence identities between these various family members range from 24% to 46%. Interferon inducible protein (IP)-10 is a structurally similar, but functionally distinct CXC chemokine since it is an attractant for monocytes and T cells rather than granulocytes.

β-chemokines

The first of the monocyte/lymphocyte chemotactic factors to be identified were MIP-1α and MIP-1β. However, the best characterized chemokine is monocyte chemoattractant protein (MCP)-1. MCP-1 is produced by endothelial cells in response to IL-1β and TNF-α and functions as a dimer. MCP-1 attracts and activates monocytes, NK cells, CD4 and CD8 T cells and is a potent histamine-releasing factor for basophils. MCP-2 and MCP-3 are structurally and functionally related chemokines. Other CC chemokines include monocyte chemotactic and activating factor, RANTES and I309. Sequence identities between family members are 29–71%. These chemokines activate adhesion molecules in the integrin family thereby inducing or increasing adhesion to endothelial cells or extracellular matrix proteins further promoting development of an inflammatory response. Two novel, related β chemokines, MCP-4 and eotaxin, are preferential chemoattractants for eosinophils. Eotaxin is produced by epithelial and endothelial cells, often in concert with IL-5.

Chemokine receptors

Chemokine receptors are 7-transmembrane, G protein-coupled molecules that transduce intracellular signals resulting in upregulation and activation of adhesion molecules. In general, the α-chemokine receptors (CXCR) are distinct from the β receptors (CCR). Each receptor can bind multiple chemokines within its class and each chemokine can bind multiple receptors. Therefore, the specificity of cellular attraction to a site and subsequent activation is probably achieved by selective mixtures of chemokines and cellular receptors. These molecules serve as secondary

receptors for entry of human immunodeficiency virus into T cells and monocytes.

CYTOMEGALOVIRUSES (*HERPESVIRIDAE*)

Contents

General Features (Human)

Edward S. Mocarski Jr., Department of Microbiology and Immunology, Stanford University School of Medicine, Stanford, California, USA

History

Cytomegaloviruses, the prototype members of the *Betaherpesvirinae* subfamily of the *Herpesviridae* family, are widely distributed in nature. All animal species have an associated cytomegalovirus (CMV) which exhibits exquisite species-specificity. These viruses infect for life and are readily isolated from saliva or salivary gland explants, a feature that resulted in the assignments of their earlier name, salivary gland viruses. Intermittent, lifelong shedding in saliva and urine have long revealed a persistent/latent lifestyle typical of all herpesviruses, although CMV recurrence and shedding is not associated with any sort of recurrent disease. CMV infection is typically of little consequence to the host, despite sporadic shedding throughout life: it is only in immunocompromised hosts that the virus is recognized as a major opportunist and a significant cause of disease. The impact of human CMV in allogeneic organ and bone marrow transplant recipients and in patients with acquired immune deficiency syndrome (AIDS) has made this virus the subject of intense study. Immune surveillance plays a critical role in maintaining viral latency and suppressing viral replication. Although reactivation in the immunocompromised host is important, this virus was first recognized because of its etiologic role in congenital disease, and it remains the major infectious cause of deafness in the USA. Infection of the fetus is a consequence of primary infection of the mother and occurs in 0.5–1% of all live births. Neurological damage due to congenital CMV ranges from mild learning or hearing disabilities to a catastrophic central nervous system damage. The involvement in cytomegalic inclusion disease along with the cytomegalic (enlarged cell) cytopathology caused by the virus led to the adoption of the current name for this virus. Although a medically important virus, human CMV is a classic opportunist, with almost all infections remaining subclinical even in highly susceptible populations.

Cytomegaloviruses infecting animal species, such as mice, rats, guinea pigs and rhesus macaques, have been used as surrogates for experimental investigation of viral pathogenesis and the virus–host interaction. They were first recognized early in the twentieth century when guinea pigs were experimentally infected with a filterable agent that caused cytopathol-

Animal Cytomegaloviruses

Donald J Alcendor and **Gary S Hayward**, Departments of Pharmacology and Oncology, Johns Hopkins School of Medicine, Baltimore, USA

History

In addition to human cytomegalovirus or salivary gland virus (HCMV or HHV-5) and the equivalent mouse virus (MCMV), closely related species with typical cytomegalovirus-like characteristics have been described from rats (RCMV), guinea pigs (GpCMV) and other rodents, and from both Old and New World monkeys (SCMV). GpCMV was originally recognized in 1920 and served as a model system for the biology and pathogenicity of HCMV disease for many years. Host-specific SCMV isolates have been reported from almost all major nonhuman primate groups, including gorilla, chimpanzee, bonobo, baboon, rhesus and other macaques, African green monkey, spider monkey, owl monkey, capuchin and marmoset.

Classification and Evolution

All of the animal CMVs described to date are members of the family *Herpesviridae* and belong to the *Betaherpesvirinae* subfamily of herpesviruses. Based on the relatively high (G+C) content of their DNA molecules and their adaptability to grow in fibroblasts in cell culture, most if not all of the traditionally recognized animal CMVs are likely to be evolutionarily more similar to the beta-1 subgroup that includes HCMV and MCMV than to the (A+T)-rich beta-2 subgroup exemplified by HHV-6. The International Committe on Taxonomy of Viruses has now classified betaherpesviruses into three distinct genera, *Cytomegalovirus* (HCMV-like), *Muromegalovirus* (MCMV-like) and *Roseolovirus* (HHV-6, HHV-7), but it is likely that distinctions between the first two taxons at least will become murky when molecular genetic criteria (i.e. gene content and DNA and protein sequence similarities) are applied to those CMV species that infect other mammalian and primate hosts. The genomes of prototype species of all three taxons, including HCMV (1989; 229354 bp; X17403), MCMV (1996; 230278 bp; U68299) and HHV-6 (1995; 159321 bp; X83413) as well as HHV-7 (1996; 144861 bp; U43400), have all been completely sequenced.

All formally recognized betaherpesviruses are listed in **Table 1**. However, it should be noted that there are two very different viruses (with somewhat different gene content) that are both known as rat cytomegalovirus (RCMV). Two CMV-like viruses have also been recently reported to be associated with fatal hemorrhagic disease in young African and Asian elephants, but current genetic analysis suggests that these two viruses are distinct in the two groups of animals and from all three of the currently recognized taxons. Another CMV-like virus, sometimes referred to as 'Stealth virus', has been reported to have been isolated from a human patient with central nervous system neuropathy, but genetic analysis has revealed that this virus contains UL34, UL35 and SSB genes that are virtually identical to those of several characterized SCMV isolates from African green and Vervet monkeys (AgCMV). The AgCMV isolate 'Colburn' was also originally thought to have been of human origin, but whether either is truly a human isolate rather than a contaminant from primary monkey cell cultures is subject to some doubt. Based on genome analyses, both the bovine herpesvirus BHV-4 and the two equine herpesviruses EHV-2 and EHV-5, which were all originally thought to be

Table 1 Known betaherpesviruses

Host group	*Host species*	*Common name*	*Classification*
Old World primates	Human	HCMV	Human herpesvirus 5
	Human	HHV-6A, 6B	Human herpesvirus 6A, 6B
	Human	HHV-7	Human herpesvirus 7
	Bonobo	BoCMV	
	Chimpanzee	ChCMV	
	Baboon	BbCMV	
	Rhesus	RhCMV	Cercopithecine herpesvirus 8
	African Green	AgCMV	Cercopithecine herpesvirus 5
	Vervet	SA6	Cercopithecine herpesvirus 3
	Vervet	SA15	Cercopithecine herpesvirus 4
New World primates	Marmoset	MsCMV	Callitrichine herpesvirus 2
	Owl monkey	HV Aotus type 1	Aotine herpesvirus 1
	Owl monkey	HV Aotus type 3	Aotine herpesvirus 3
	Cebus	CeCMV	
	Capuchin	AI-5, AP18	Cebine herpesvirus
Rodent	Mouse	MCMV	Murid herpesvirus 1
	Rat	RCMV-1	Murid herpesvirus 2
	Rat	RCMV-2	
	Guinea pig	GpCMV	Caviid herpesvirus 2
	Squirrel	SqCMV	Sciurid herpesvirus
Other	Pig	PCMV	Suid herpesvirus 2
	African elephant	HV Loxodonta	Elephantid herpesvirus 1

The betaherpesvirus family contains three formally defined taxons at present: namely, 3.1.21, *Cytomegalovirus* (e.g. HCMV); 3.1.2.2. *Muromegalovirus* (e.g. MCMV); and 3.1.2.3 *Roseolovirus* (e.g. HHV-6, HHV-7)

cytomegaloviruses, have had to be reclassified into the gamma-2 (rhadinovirus) class of herpesviruses. No animal equivalents of HHV-6 or HHV-7 have yet been identified, but they are expected to exist.

Typically, betaherpesviruses have no more than 45 of their 110–180 genes in common with the alpha (HSV, VZV) and gamma (EBV) classes of herpesviruses. Another 35 genes appear to be beta-specific and are likely to be shared by all CMVs and the HHV-6-like viruses, whereas most of the remaining genes are unique to the different species of CMV. As judged by the presence of several large families of related genes in HCMV and MCMV, it appears that the beta-1 group viruses, which possess by far the largest of all herpesvirus genomes, underwent a rapid genomic expansion in the early stages of mammalian evolutionary radiation. In contrast, the beta-2 herpesviruses (HHV-6 and HHV-7) can be considered to be mini-CMVs that lack most of the repeated gene families and the S-segment of the genome. Unlike other herpesviruses, none of the betaherpesviruses is known to encode either a thymidine kinase enzyme or the A-subunit of ribonucleotide reductase, although they do encode uracil DNA gylcosylase and a dUTPase, and HCMV encodes a novel phosphotransferase (UL97) activity that is the target for the effective anti-CMV agent ganciclovir and its derivatives. Like all herpesviruses, the animal CMVs are expected to encode the typical six core DNA replication proteins of herpesviruses: DNA polymerase (POL), DNA primase (PRI), helicase (HEL), single-stranded DNA-binding protein (SSB), polymerase processivity factor (PPF) and primase accessory factor (PAF).

Virion Structure

Animal CMVs are structurally similar to other members of the *Herpesviridae*, as described elsewhere in this volume, and are essentially indistinguishable from HCMV at the electron microscopic level. However, many of the virion proteins of each species display characteristic size variations after PAGE analysis. Large nuclear and cytoplasmic inclusion bodies detectable in lytically infected cells by light microscopy are a hallmark of the group.

Genome Structure

The intact genome size of all known CMV DNA molecules lies between 210 and 240 kb and most have a (G+C) content of around 58%, in contrast to the

much smaller genome size of 145 to 166 kb and 46% (G+C) content of HHV-6 and HHV-7. Structurally, two distinct CMV genome types can be discerned. The New World monkey SCMV genomes (HVaotus types 1 and 3) and HCMV represent one type, with both having large internal inverted repeats that generate four isomeric arrangements of the L (long) and S (short) unique segments similar to the pattern observed in HSV. On the other hand, at least one Old World monkey SCMV studied namely AgCMV (Colburn), and several rodent CMVs (MCMV, RCMV and GpCMV) have essentially linear non-inverting DNA molecules. HHV-6 and HHV-7 both lack the entire 40 kb S-segment region of HCMV and the L-segment is bounded by large (8 kb) direct terminal repeats containing telomere-like motifs. MCMV has a similar sized gene block in place of the S-segment, but this region has very little organizational resemblance or homology to that of HCMV. Large blocks of genes at the left and right ends of the L-segment of each genome are also unique to each of the three taxons. Current evidence also suggests that the gene segments mapping to the right of and adjacent to the major immediate-early (MIE) region of several Old World SCMV genomes differ dramatically both from each other and from the equivalent regions in HCMV.

Both DNA sequence and amino acid analysis indicates that individual species of beta-1 CMVs from different animal hosts are highly diverged in accordance with their host phylogeny, although different genes diverge at very different rates. For example, in a highly conserved region between HCMV and the African green monkey AgCMV, the major single-stranded DNA binding proteins (UL57, SSB) have 72% overall amino acid identity, whereas a group of four adjacent betaherpesvirus-specific glycoproteins mapping to the left of the major immediate early (MIE) region (UL118–UL121) vary from as much as 35% identity overall to as little as 15% at one end only. Similarly, the betaherpesvirus-specific IE2 (UL122) immediate early regulatory proteins of HCMV and AgCMV have 58% amino acid identity, but only over the C-terminal half of the protein. This is a commonly observed level of variation in herpesviruses, with the two primate gamma-1 class viruses EBV (human) and HVpapio (baboon), for example, showing 37% and 68% overall amino acid identity between their EBNA-2 and the Bcl2-like proteins, which are both unique to that subgroup of herpesviruses. Nucleotide sequence differences between homologous CMV genes frequently reach the 20–30% level, even in closely related species such as African green monkey and rhesus, or human and chimpanzee, etc. In fact the DNA molecules of individual isolates of each CMV species are almost always distinguishable on the basis of multiple restriction fragment length polymorphisms stemming from overall intraspecies nucleotide variations of up to 3–4%.

The three prototype betaherpesviruses contain several interesting and in some cases taxon-specific genes related to known cellular genes that appear to be used primarily for evasion of immune responses. For example, HCMV encodes four GDP-coupled seven-membrane spanning receptors (GCR), at least one of which (US28) functions as a broad spectrum chemokine receptor, and three glycoproteins (US3, 10 and 11) that together function to destabilize or inhibit cellular HLA-mediated responses. HHV-6 and MCMV each encode one GCR protein. Both HCMV and MCMV also each encode diverged homologues of an HLA-I protein (inserted at different loci in their genomes) and MCMV also encodes a functional β-chemokine protein. HHV-6 (but not HHV-7) encodes an REP (name of an early protein required for replication) protein apparently captured from adeno-associated virus (AAV), and HHV-6, HHV-7 and RCMV, but not MCMV, encode OX-2 related proteins.

Epidemiology and Physical Properties

Features of host range, virus propagation, virus transmission, tissue tropism, pathogenicity, histopathology and immune responses, together with the physical properties and assembly pathways of the virions, and a number of biochemical properties of their structural proteins, closely resemble those described elsewhere in this volume for HCMV and MCMV.

Replication Strategies

All herpesviruses have enveloped icosahedral capsids and replicate in the nucleus, with expression of several immediate early regulatory proteins preceding expression of the early proteins, including the biochemical functions, viral DNA and late structural proteins. In cell culture, fully permissive host cell types for HCMV are restricted almost exclusively to diploid human fibroblasts (plus some astrocytomas and perhaps smooth muscle cells and differentiated macrophages), although even in fibroblasts fresh clinical isolates usually need to be adapted for efficient growth by multiple rounds of successive passaging (which is accompanied by gene losses at the L-segment unique-repeat boundaries). Laboratory strains of HCMV replicate their DNA efficiently by 72 h in human fibroblasts, but express only the MIE

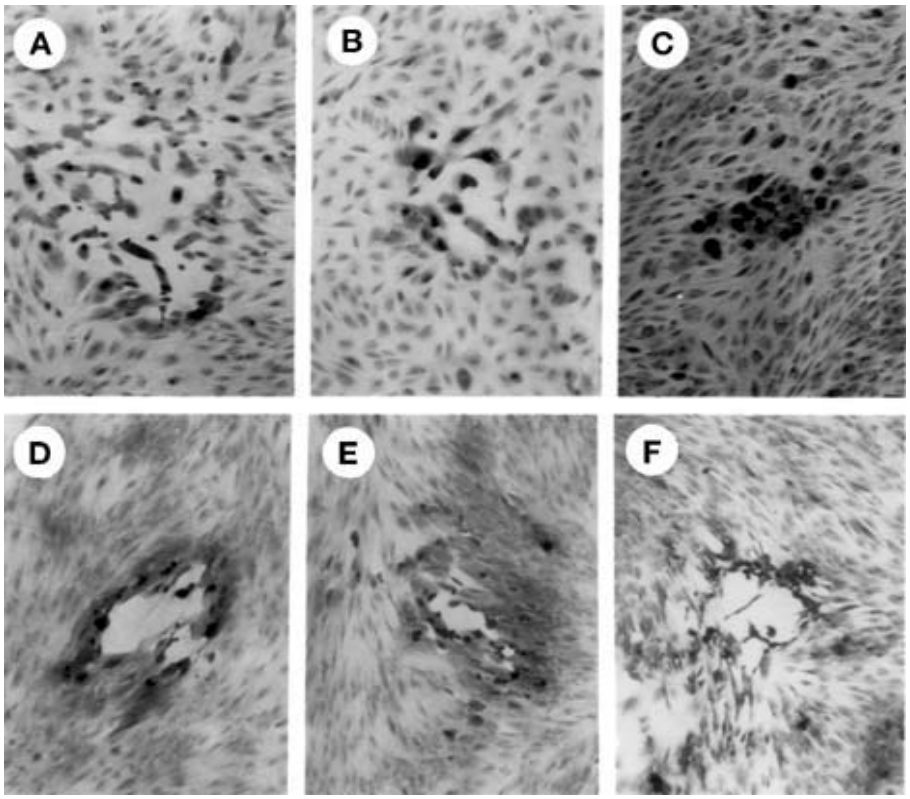

Figure 1 Infection of human diploid fibroblasts (HF cells) with both human and nonhuman primate cytomegaloviruses. HF cells at passage level 15 were infected and examined daily for cytopathic effects. All infections produced characteristic cytomegalic cells in culture. (**A**) HCMV Towne strain, plaque at 7 days after infection; (**B**) African green monkey CMV (AgCMV), plaque at 8 days after infection; (**C**) baboon CMV (BbCMV), plaque at 11 days after infection; (**D**) chimpanzee CMV (ChCMV), plaque at 14 days after infection; (**E**) rhesus CMV (RhCMV), plaque at 14 days after infection; (**F**) Cebus CMV (CeCMV), plaque at 8 days after infection.

proteins and fail to synthesize any viral DNA in rodent or monkey fibroblasts, whereas AgCMV, RhCMV, BaCMV, ChCMV and CeCMV all replicate their DNA and form plaques in both human and simian fibroblasts (**Fig. 1**). In contrast, MCMV successfully carries out viral DNA synthesis in human, monkey and rodent fibroblasts in cell culture. Most transformed human cell types are nonpermissive for HCMV replication, with the block being between DNA entry and synthesis of MIE mRNA. However, some differences between HCMV and African green monkey SCMV have been observed here. For example, HCMV fails to synthesize its MIE proteins in infected human (NTera) or mouse (F9) teratocarcinoma stem cells, in human 293 or NBE cells or in mouse L-cells. In contrast, AgCMV does produce its MIE proteins in infected NTera, 293 and NBE cells, but not in F9 or L-cells. The NTera stem cells can become permissive for both HCMV MIE expression and infectious virus production after differentiation with retinoic acid (RA). Similarly, the F9 cells treated with RA induce AgCMV but not HCMV MIE expression. These biological differences appear to coincide with structural differences in the organization of *cis*-acting transcriptional control elements and adjacent accessory domains located both upstream of, and in the large first intron of, the MIE genes among the different species of old world primate CMVs. While a major *in vivo* site for quiescent inactive infection for both HCMV and MCMV is believed to involve monocytes, many other sites of inapparent noncytopathic infection occur *in vivo* (especially in vascular tissue) and in salivary gland stromal cells for rodent CMVs, but the true site of reactivatable latent state infection has not yet been deciphered for any CMV species.

Control of Gene Expression

The lytic cycle pathway of gene expression for animal CMVs follows the typical herpesvirus cascade of immediate early mRNA and proteins followed by activation of delayed early then late class genes. Similarly organized MIE transcription units, which

encode regulatory proteins that trigger the lytic cycle, have been characterized in HCMV, ChCMV, AgCMV, RhCMV, BaCMV, GpCMV, RCMV, MCMV, and HHV-6 and HHV-7. In each case, these transcription units are oriented leftwards at genome map position 0.7 and produce several multiply-spliced mRNAs whose expression is controlled by powerful upstream *cis*-acting enhancer control regions. By far the most predominant viral mRNAs synthesized after infection of permissive cells in the presence of cycloheximide are these MIE mRNAs, which are also the only HCMV or AgCMV mRNAs and proteins produced after infection of nonpermissive rodent fibroblasts. At least two types of phosphorylated nuclear regulatory proteins are encoded by the MIE transcription unit. These include the highly abundant 72 kDa acidic IE1 (UL123) nuclear protein and the less abundant 86 kDa IE2 (UL122) DNA-binding trans-activator-repressor protein. Not only do the IE2 proteins stimulate transcription of downstream HCMV, SCMV and MCMV promoters and non-specifically transactivate heterologous promoters, but they also specifically downregulate their own MIE promoters (negative autoregulation). The IE1 proteins of AgCMV and MCMV are much larger than in HCMV (94 kDa and 97 kDa, respectively) because of expanded C-terminal glutamic acid-rich domains.

Interestingly, in contrast to the rest of the viral genome, the IE1 and the IE2 coding regions of the MIE transcription units in HCMV, AgCMV, MCMV, RCMV, HHV-6 and HHV-7 (and probably all other betaherpesviruses) are highly CpG suppressed, which suggests that they are accessible to cellular methylation events at some stage of the viral life cycle in which all other viral genes are transcriptionally silent. The 490 amino acid IE1 proteins have barely detectable amino acid homology (15% identity) between HCMV and AgCMV or RhCMV and much less between the primate and MCMV and RCMV versions, although all of the betaherpesvirus IE1 proteins (except for HHV-6 or HHV-7) have a highly acidic glutamic acid-rich C-terminus. In contrast, the 570 amino acid IE2 proteins of HCMV, AgCMV, RhCMV, MCMV, RCMV, and their much larger counterparts in HHV-6 and HHV-7, all exhibit between 25 and 58% amino acid identity over the C-terminal 270 amino acid conserved DNA-binding domain.

The upstream MIE promoter-enhancer regions that serve to sense the intranuclear environment and control entry into or out of the lytic cycle, are large and complex noncoding DNA sequence domains that consist of often multicopy, high-affinity binding sites for numerous constitutive or inducible cellular transcription factors. In HCMV, ChCMV, AgCMV, RhCMV, BaCMV, GpCMV and MCMV these sites include response elements for cyclic AMP (CRE, PKA), phorbol esters (TPA, PKC) and retinoic acid (RA), together with recognition motifs for SRF, ETS, CREB, SP-1, AP-1 and NFκB. Even among the five Old World primate CMVs that have been examined, the organization of these sites differs significantly and the number and pattern of the adjacent tandemly-repeated 15 and 30 bp high-affinity overlapping NFI plus YY1 motifs also differ greatly. A diagram illustrating differences in the organization of BENT DNA, NF1, enhancer (ENH), minimal promoter (MIN) and intron (INT) domains from the upstream control regions of the MIE genes of two Great Ape and three Circopithecine CMVs is presented in **Fig. 2.** Curiously, the organization of the MIE enhancer in RCMV seems to be quite different from and simpler than that in MCMV. The existence or function of other specific regulatory proteins that are common to HCMV and HHV-6, such as the UL36-37 proteins, the US22 family and the UL82-83 matrix phosphoproteins, the UL84 replication-associated protein, and also the HCMV-specific US3 protein and its novel complex NFκB containing IES enhancer, have not yet been evaluated in any of the animal CMVs.

The lytic cycle DNA replication origins (ORI-LYT) are all located to the right of and adjacent to the single-stranded DNA-binding protein gene (SSB, UL57) near the center of the HCMV, AgCMV and MCMV genomes, but again they differ significantly in structural organization and apparently cannot be complemented by each other's replication protein machinery. Although the lytic origin in HHV-6 and HHV-7 is located at the equivalent site in the genome, its structure and the UL9-dependent mode of DNA replication appear to be quite different from that in the CMVs. It is still unknown whether betaherpesviruses also use or need a latency-state plasmid DNA replication mode like that of Epstein–Barr virus.

Future Perspectives

Persistent and inapparent infection with members of the CMV family is probably virtually ubiquitous in most individuals of all mammalian species. The biological and pathological properties of animal CMVs have attracted the interest of herpesvirologists and clinicians interested in CMV disease in patients with acquired immune deficiency syndrome (AIDS) and those who have had organ transplants, probably not so much because of serious morbidity or economic consequences of these infections in their own hosts, but more often as models for latency and pathogenesis or immunological responses in HCMV. Mouse, rat, rhesus and baboon CMVs have all been

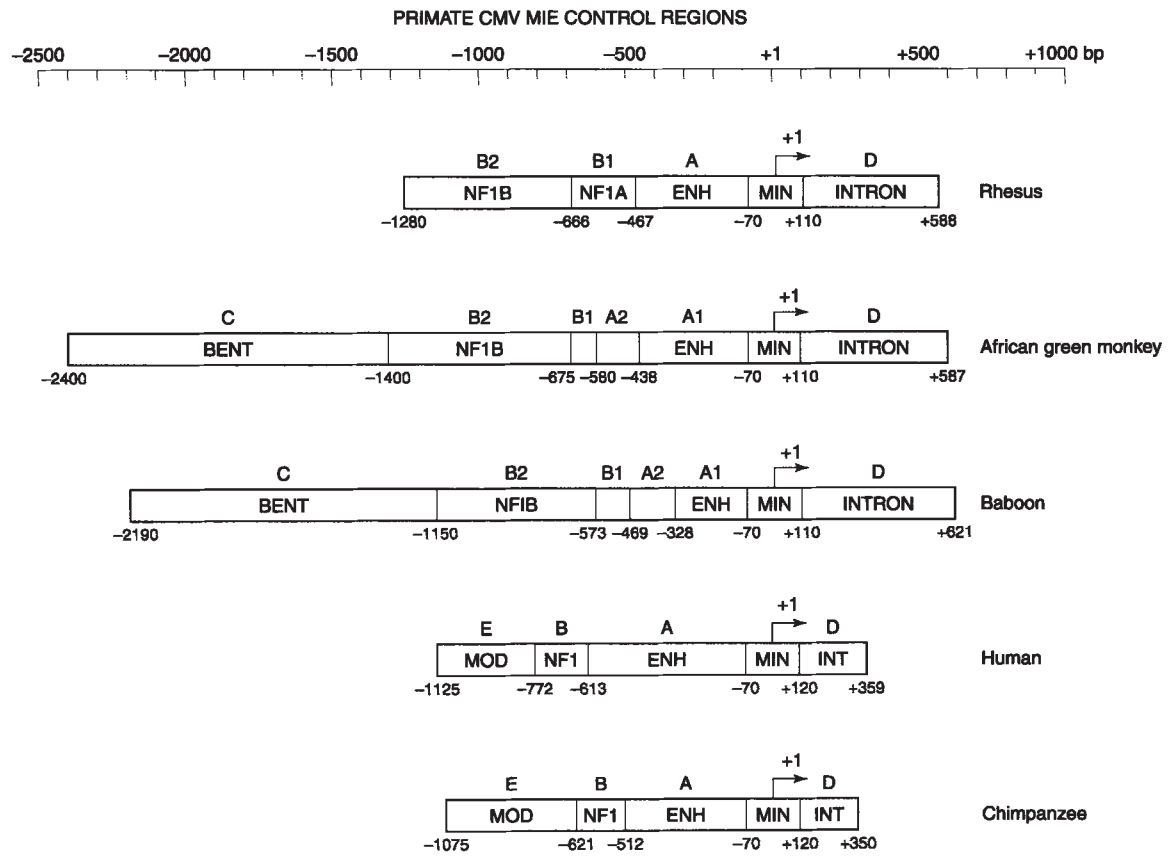

Figure 2 Upstream control regions in the major immediate early genes of five human and nonhuman primate cytomegaloviruses. The diagram illustrates the respective size and organization of domains containing specific transcription factor-binding motif patterns. These include clusters of nuclear factor 1 (NF1) and YY1 sites, the distal enhancer containing multiple CRE, SRE and NFκB-sites (ENH), the proximal promoter and TATATAA box region that includes the start site of transcription +1 (arrowed), and the 5′ half of the large first intron (INTRON). Where appropriate additional upstream AT-rich (BENT) and modulatory (MOD) regions are also included. Domain boundaries are designated as + or − nucleotide positions with reference to the start site of transcription (+1) and given in base pairs. The domains have also been designated A through E with subcategories 1 or 2 in the case of the NF1 and ENH blocks. investigated as models for virus reactivation, and for control of acute and chronic disease by anti-CMV agents (such as ganciclovir) in association with allografted organ transplants or immunosuppression. There is also an expanding interest in questions related to whether, or how extensively, different CMVs can cross host species barriers with possible pathological consequences, which is likely to raise concerns and place some additional focus on baboon and pig CMV, for example, as the prospects of xenografted organ transplants grow. Recently, animal CMVs have also had comparative value in molecular genetics, and biochemical analysis of both their similarities to and differences from HCMV. Current basic scientific interest in genomic evolution (made possible by large-scale DNA sequencing), as well as the role of transcriptional gene regulation mechanisms in determining cell tropism and the switching between latent and lytic cycle virus–cell interactions pathways, may lead to an expansion of these types of studies with animal CMVs in the next few years.

Murine Cytomegaloviruses

John Staczek, Louisiana State University Medical Center, Shreveport, Louisiana, USA

History

Cytomegalia refers to the enlargement of a cell. The discovery of the viral etiology of cytomegalia in the mouse salivary gland preceded the isolation of the virus by 19 years. The mouse salivary gland virus, commonly called mouse (or murine) cytomegalovirus (MCMV), is a surrogate for studying human cytomegalovirus (HCMV)-associated pathogenesis.

Classification

Classification by the International Committee on Taxonomy of Viruses (ICTV) places MCMV in the family *Herpesviridae,* subfamily *Betaherpesvirinae,* genus *Muromegalovirus,* type species mouse cytomegalovirus 1. Herpesviruses are designated by serial arabic number and the family or subfamily of the natural host. Thus, MCMV is designated Murid herpesvirus 1, but its most commonly used synonym is mouse cytomegalovirus.

Properties of Virion

MCMV virions have typical herpesvirus morphology. The virions have a buoyant density of 1.20 g cm^{-3}. Their nuclear membrane-derived envelope is sensitive to denaturation by detergents, pH, heat and desiccation. Viral glycoprotein spikes extending through the envelope are linked to the nucleocapsid via tegument proteins. The icosahedral nucleocapsid, containing 162 capsomeres, surrounds an ultraviolet radiation-sensitive, linear, double-stranded DNA.

Properties and Organization of Genome

General comments concerning the DNA sequence and genomic organization of the Smith strain of MCMV are presented. It is suggested that the reader refer to Rawlinson *et al* for a more detailed description of the DNA sequence and compilation of open reading frames (ORFs).

DNA sequencing of the Smith strain genome reveals 230 278 bp. Buoyant density and sequence analyses denote an overall 58.7% G+C content distributed with areas of major (155–163 kb) and minor (1–17 kb and 204–221 kb) G+C content. Coding regions have a higher G+C content than noncoding regions. CpG dinucleotides occur throughout the genome at frequencies expected for random associations between mononucleotides, except for a CpG deficiency that is evident in the major immediate early (MIE) gene region.

DNA isolated from purified virions contains a single 3′ nucleotide extension that may facilitate circularization to a prereplicative intermediate. Herpesvirus genomes are grouped (A–F) according to sequence reiterations greater than 100 base pairs. Based on this scheme, the MCMV genome, consisting primarily of unique sequences, is catalogued with the group F genomes. However, clusters of 31-bp direct repeats delimit each terminus of the genome, and additional, nonhomologous, intra- and intergenic direct repeats punctuate the centralized unique region. Inverted repeats, present in the origin of replication and upstream of several ORFs, do not mediate isomerization.

Families of homologous genes are a general feature of betaherpesviruses. MCMV has six gene families, two of which (m02 and m145) are unique and four of which are homologous to HCMV families US22, UL25, UL82 and to the G protein-coupled receptors (GCRs). The functions of the gene families are generally unknown. However, the M25 protein has homology to eukaryotic nucleolins and, therefore, may interact with chromatin.

Genetics

Restriction length fragment polymorphisms among MCMVs isolated from wild-type mice indicate widespread heterogeneity in genomic composition which is reflected in peptide analyses using polyclonal sera recovered from infected wild mice. Strain variation influences disease presentation and recovery. Variation in the nonapeptide of the immunodominant

receptors for entry of human immunodeficiency virus into T cells and monocytes.

CYTOMEGALOVIRUSES (*HERPESVIRIDAE*)

Contents

General Features (Human)

Edward S. Mocarski Jr., Department of Microbiology and Immunology, Stanford University School of Medicine, Stanford, California, USA

History

Cytomegaloviruses, the prototype members of the *Betaherpesvirinae* subfamily of the *Herpesviridae* family, are widely distributed in nature. All animal species have an associated cytomegalovirus (CMV) which exhibits exquisite species-specificity. These viruses infect for life and are readily isolated from saliva or salivary gland explants, a feature that resulted in the assignments of their earlier name, salivary gland viruses. Intermittent, lifelong shedding in saliva and urine have long revealed a persistent/latent lifestyle typical of all herpesviruses, although CMV recurrence and shedding is not associated with any sort of recurrent disease. CMV infection is typically of little consequence to the host, despite sporadic shedding throughout life: it is only in immunocompromised hosts that the virus is recognized as a major opportunist and a significant cause of disease. The impact of human CMV in allogeneic organ and bone marrow transplant recipients and in patients with acquired immune deficiency syndrome (AIDS) has made this virus the subject of intense study. Immune surveillance plays a critical role in maintaining viral latency and suppressing viral replication. Although reactivation in the immunocompromised host is important, this virus was first recognized because of its etiologic role in congenital disease, and it remains the major infectious cause of deafness in the USA. Infection of the fetus is a consequence of primary infection of the mother and occurs in 0.5–1% of all live births. Neurological damage due to congenital CMV ranges from mild learning or hearing disabilities to a catastrophic central nervous system damage. The involvement in cytomegalic inclusion disease along with the cytomegalic (enlarged cell) cytopathology caused by the virus led to the adoption of the current name for this virus. Although a medically important virus, human CMV is a classic opportunist, with almost all infections remaining subclinical even in highly susceptible populations.

Cytomegaloviruses infecting animal species, such as mice, rats, guinea pigs and rhesus macaques, have been used as surrogates for experimental investigation of viral pathogenesis and the virus–host interaction. They were first recognized early in the twentieth century when guinea pigs were experimentally infected with a filterable agent that caused cytopathol-

ogy in salivary glands. Many cytomegaloviruses, including human and murine CMV, were isolated in the 1950s when cell culture became widely available. Due to the ease of culture, congenital disease was quickly associated with *in utero* infection in humans. The importance of CMV as a human pathogen increased as immunosuppressive post-transplant therapies and AIDS, as well as other immunodeficiency states, have come to the forefront of medicine. These conditions predispose individuals to disease during primary infection or, once primary infection has resolved, to disease following reactivation of latent infection. CMV is known to be transmitted by direct contact with bodily secretions, including saliva, urine, breast milk and semen, as well as by blood transfusion and organ transplantation. The large reservoir of seropositive, latently infected individuals, which range from 40 to 100% of the population depending on age and geographic location, contributes to the medical importance of the virus. The replication, biology and pathogenesis of CMV have been covered in several reviews listed at the end of this article.

Taxonomy and Classification

The formal designation given by the International Committee on Taxonomy of Viruses to human CMV is human herpesvirus 5 (HHV-5), a name that is not in common usage. Human CMV is the prototype of the genus *Cytomegalovirus*. Cytomegaloviruses share many characteristics with other herpesviruses, including typical virion morphology and large, linear DNA genome, as well as common biological properties such as persistence and latency in the host. These viruses have distinguishing characteristics as well, such as their well-established tropism for salivary glands, restriction to the host species of origin and slow growth in culture. These differentiating characteristics define the *Betaherpesvirinae* subfamily. In addition to the cytomegaloviruses, genome sequence analysis established that the betaherpesviruses include two lymphotropic human herpesviruses, HHV-6 (genus *Roseolovirus*) and HHV-7. Large-scale nucleotide sequence analysis of human CMV, murine CMV, HHV-6 and HHV-7 demonstrated a collinear arrangement of genes on the viral genomes and a significant level of similarity. Human CMV carries over 200 genes, of which 60–70 are similar among betaherpesviruses and 35–40 are common to all mammalian herpesviruses. Cytomegaloviruses, but not HHV-6 or HHV-7, share common growth characteristics and cytomegalic cytopathology. The distribution of this type of virus in nature is very broad, and examples have been found in every mammalian species in which an example has been sought.

Human CMV does not share significant genome nucleotide sequence homology with any of the other human herpesviruses or with animal cytomegaloviruses. The host serologic response does not detect significant differences between human CMV strains. Strains have been differentiated by several nucleic acid-based methods including polymorphism in DNA restriction enzyme fragments as well as sequence variation in DNA polymerase chain reaction (PCR) products from known variable viral genes, such as that encoding envelope glycoprotein (g) B (UL55). Both of these methods reveal the presence of numerous strains circulating in all human populations. Reports have suggested that certain gB genotypes might be associated with more severe disease in immunocompromised individuals, raising the possibility that some strains of CMV are more virulent than others; however, this suggestion has not been generally confirmed. Early evidence based on DNA–DNA reassociation kinetics, suggesting that strains of CMV exhibit only 80–90% sequence homology, has been explained by more recent genome sequencing efforts. Significant sequence variation due to deletions of up to 15 000 bp has been found in some laboratory strains of virus, such as AD169 and Towne vaccine strain (passage 125) relative to clinical strains. It has recently become clear that AD169 and Towne that have been propagated in different locations for extended periods may vary considerably in their growth and genome properties. These have been thought to have accumulated in the course of serial high multiplicity passage of laboratory strains as they were developed to be used as live-attenuated vaccines. Individual low passage or fresh isolates of CMV seem to retain a much higher level of similarity to each other and have not been observed to change following limited passage in cell culture. Currently, isolates of CMV are commonly differentiated either by restriction fragment polymorphism or by direct DNA sequence analysis of DNA PCR products from gB or other highly variable genetic loci.

Geographic and Seasonal Distribution

Geographic, but not seasonal, variation in CMV transmission is known to occur. As is the case with other herpesviruses spread by direct contact and without much morbidity, the virus is distributed worldwide and appears in even the most remote populations. In urban environments, some regions of developed countries and all less developed countries, a high proportion (80–100%) of the population is infected early in life, whereas in rural and suburban

settings of North America, Australia and Europe a smaller proportion (40–60%) of the population is infected, with significant transmission occurring in young adults. Infection rates are clearly related to close contact amongst individuals. There is little evidence for point sources in the epidemiology of CMV infections. Transmission of CMV between young children or from young children to adults is efficient, reaching rates of 25–50% per year in some child homecare or daycare settings. Daycare providers and parents of young children have an increased risk of CMV infection, although good personal hygiene clearly reduces this risk. Very high levels of virus in urine and saliva of young children may play an important role in these transmission patterns. Simply informing individuals of the usefulness of good hygiene can have a dramatic impact on transmission rates in young adults.

Host Range and Virus Propagation

The only natural host for human CMV is humans, and human fibroblasts are used to propagate this virus. Chimpanzee fibroblasts are also permissive for CMV replication, but cells from other primates or animal species are not. As a result of host restriction, little experimental work with human CMV has been undertaken in a host animal and most work relies on surrogate studies of animal CMVs, such as those infecting mice, rats, guinea pigs or rhesus macaques. In addition to a strict host species restriction, only certain types of human cells are permissive for CMV. The virus exhibits a cell type and differentiation requirement and replicates in differentiated, but not undifferentiated or malignant, cell types. In laboratory practice, human CMV is isolated and propagated using secondary cultures of human fibroblasts derived from fetal lung or newborn foreskin. Fibroblasts and stromal cells from any tissue source appear to be permissive. Prolonged (3–4 weeks) culture may be required to isolate virus from infected tissues or fluids, although, once isolated, infectivity of strains that grow in culture may be directly quantified by plaque assay on human fibroblast cell monolayers. Other primary cell types of epithelial, endothelial and monocyte/macrophage origin exhibit more limited permissiveness for viral replication *in vitro*, despite evidence that these cell types are permissive and are involved in the host. During infection of cultured cells, which is prolonged even with laboratory strains, infected cells enlarge and develop both nuclear and cytoplasmic inclusions that confer an 'owl's eye' appearance typical of cytopathology used for histopathological identification of virus-infected tissues in the host. Virus maturation begins with the encapsidation of DNA in the nucleus followed by acquisition of an envelope and release into the culture fluid of infected fibroblasts by 3–4 days after infection. Undifferentiated, malignant and almost all tested immortal human cell lines are nonpermissive for CMV replication. For unknown reasons, human fibroblasts immortalized by the human papillomavirus E6/E7 oncogenes are fully permissive and certain glioblastoma and astrocytoma tumor cell lines are semipermissive for virus replication. Replication of human CMV in differentiated monocyte/macrophages is thought to be important in virus dissemination and persistence in the host, but these cells exhibit striking variations in permissiveness, depending upon the conditions which are used to support their growth and differentiation.

Genetics

Based on genome sequence polymorphisms, a large number of CMV strains circulate worldwide. The difficulty in propagating recent isolates in human fibroblasts led to the dependence on selected laboratory strains for studies of virus biology and genetics. Although the genotype of a virus isolate is stable over short-term passage in culture, as well as during transmission from person to person, high multiplicity passage in fibroblasts appears to drive the generation of nucleotide sequence deletions and duplications such that dramatic sequence differences are obvious in laboratory strains as compared to fresh isolates. Efficient growth in fibroblasts is one common characteristic of laboratory strains. Strains of CMV exhibiting more efficient growth on cultured endothelial cells or fibroblasts have been derived from single isolates, suggesting that there may be a genetic basis for adaption to certain cell types. The significance of adaption in cell culture to the biology of CMV in the host remains unclear.

The only human CMV genome to have been completely sequenced is strain AD169, and this strain has a 230 283 bp genome with over 200 predicted genes. An additional 13 000–15 000 bp are present in fresh isolates but are apparently replaced by duplication within the AD169 or Towne (passage 125) genomes during serial propagation in culture. The original isolate of AD169 dates to the 1950s but was not preserved. Towne (passage 125) and Towne (passage 36) were noted to have different restriction maps when analyzed but the extent of genome rearrangement that characterizes the high passage virus only became evident when regions were sequenced. Significantly, 70 out of over 200 genes in the human CMV genome are already known to be dispensable for growth in cultured fibroblasts. These

genes may carry out functions that are important for growth, dissemination, tissue tropism or pathogenesis in the host. Such functions have now been unambiguously demonstrated to occur through studies comparing the growth of murine CMV mutants in cultured cells and mice.

Several CMV gene functions have been predicted based on their sequence similarity to genes of other herpesviruses or of mammals. The 35–40 genes that exhibit a significant level of predicted amino acid similarity to genes in all herpesviruses of mammals play roles in viral DNA replication and virion structure. The genes in human CMV that bear resemblance to host genes include homologues of a major histocompatibility class I antigen, α chemokines, a β chemokine receptor and other G-protein coupled receptors, a T cell receptor δ chain and a soluble tumor necrosis factor/nerve growth factor receptor.

Evolution

All mammalian herpesviruses apparently share a common progenitor because of limited shared protein sequence similarity. Based on comparisons of 16 mammalian herpesvirus genomes that have been completely sequenced, betaherpesviruses appear to represent the oldest type of herpesvirus. The evolution of herpesviruses has proceeded along with speciation of vertebrates, but with some substantial and abrupt substitutions such that ongoing exchange of genetic information with the host is likely to have contributed substantially over time to the genome complement in any particular virus. CMV has certainly acquired genes from the host after it came into existence as a virus. While a systematic study of evolution continues due to the availability of rapid DNA sequencing methods, the large size of CMV genomes continues to make this a difficult undertaking.

Epidemiology

ased on the facts that humans are the only known reservoir of this virus, that efficient person-to-person transmission results in widespread distribution in the population, and that disease is a relatively rare outcome of infection, human CMV has achieved the status of a successful pathogen. The epidemiology of human CMV disease follows the pattern of an endemic infectious disease agent, although medically significant disease only occurs in the face of diminished host immune surveillance. The occurrence of a significant number of long-term serologically disparate couples suggests that virus transmission is not always assured and may require either large amounts of virus or some breech of epithelium. Virus infection certainly reaches all strata of society. Although hygiene is important, the age of acquisition and the overall percentage of individuals who are infected are influenced by as yet incompletely characterized social behavioral patterns. Crowded living conditions, breast feeding and certain sexual practices are all known to be important components of transmission via infectious bodily secretions. Modern medical practices such as blood transfusion and organ transplantation have clearly brought notoriety to CMV. Importantly, CMV is very unstable in the environment, suggesting that all transmission is via direct contact or very recently contaminated fomites. Following primary infection, CMV replicates at the site of infection as well as in leukocytes, which are likely to be responsible for dissemination of virus to other tissues, including salivary glands and kidneys. Cell-free virus shedding from epithelial cells into saliva and urine may go on for months to years and, once controlled, reactivation results in sporadic shedding throughout life. Congenital or neonatal acquisition of CMV results in a longer time course and greater levels of shedding compared with acquisition later in life. During pregnancy, where primary infection remains a major medical concern because of congenital disease, an estimated 2–2.5% of all women become infected during each gestation, and those who care for young, CMV-shedding infants or toddlers may encounter a tenfold greater risk of infection. Spread to toddlers can occur in any setting where another infected child is present, particularly in any daycare setting. While 0.5 and 1% of all newborns are infected *in utero*, less than 10% of these show any symptoms of CMV disease and very few suffer the severe consequences of cytomegalic inclusion disease. Another 10–60% of newborns, depending on undetermined factors, become infected within the first 6 months of life but only premature infants may be at risk of disease. Although neonatal infection occurs, medically significant sequela, such as hearing or learning disabilities, are uncommon in this population. Congenital infection and perinatal infection of premature infants remain the most important childhood diseases associated with CMV and account for the importance of CMV as the major infectious cause of hearing loss.

From puberty to about 30 years of age, increased sexual activity as well as direct contact with young infants correlate strongly with increasing infection levels. Virus is found free in saliva and urine as well as in cells shed with cervical secretions, breast milk and semen. Individuals at any age are susceptible to infection via blood transfusion or organ transplantation, where seropositive blood and solid organs are of

greatest risk to seronegative recipients. Seroconversion rates in transfusion recipients suggest that 3–15% of seropositive units of blood may transmit and all seropositive solid organs are likely to transmit. Individuals receiving multiple units or large volumes of blood are most likely to become infected. Reactivation of latent virus and reinfection with additional strains are both important in the epidemiology of CMV disease in immunocompromised hosts; however, disease in these situations is typically less severe than following primary infection.

Primary infection with CMV results in lifelong latency in a population of mononuclear leukocytes. There is little chance that any individual ever clears this virus completely. Thus, all individuals who have been infected at any time are potential sources of virus in a wide range of settings for the remainder of their lives.

Transmission and Tissue Tropism

Human CMV may be transmitted by direct person-to-person contact at any time shedding is occurring, but immune status dictates the likelihood of disease following transmission. There is no seasonal variation in infection rates. Primary infection of an immunocompetent host results in a viremia which disseminates virus to organs, including the salivary glands and kidneys. The more immunocompromised a host, the greater the likelihood of spread to additional organs, with or without disease. Congenital transmission may occur throughout gestation following primary maternal infection, although some believe disease risk is greatest during the first half of pregnancy. Seropositive mothers who reactivate virus during pregnancy are less likely to transmit virus because their own adaptive immune response probably reduces the virus load. Congenital infection is a consequence of CMV crossing the placenta, possibly via carriage in maternal leukocytes or replication in trophoblasts. Virus is also shed in cervical secretions and this site can contribute to neonatal infection during natural childbirth.

Direct contact, blood transfusion and organ transplantation may be responsible for transmission at all other ages. Transfusion of whole blood to premature infants and immunocompromised children is restricted because of the high level of risk. Once infected, these children shed for longer periods and at higher levels than immunocompetent children. CMV-seronegative and leukocyte-depleted blood products are widely used to prevent infection in highly risky situations. Virus infection of either immunocompetent or immunocompromised individuals leads to prolonged replication in ductal cells of salivary glands and kidney tubules without any indication of organ dysfunction. Direct histology, antigen detection, *in situ* hybridization and cytopathology have shown that CMV infection proceeds progressivly to infect additional tissues, depending on the immune status of the host.

CMV remains latent in all immunocompetent hosts following primary infection and for this reason transmission via organ transplantation or blood transfusion can occur throughout life. Owing to the fact that only a small proportion of healthy seropositive individuals are able to transmit virus at any particular time, sporadic reactivation in the donor may be a factor in transmission patterns. Although polymorphonuclear leukocytes, endothelial cells and monocytes are all important sites contributing to viremia in immunocompromised individuals, only monocytes and their progenitors have been implicated as sites of long-term persistence and latency. The numbers of CMV positive, latently infected cells in peripheral blood or bone marrow have been estimated to be of the order of 0.01% of total mononuclear cells.

Pathogenicity

The widespread prevalence of CMV in the absence of significant disease is evidence that this virus is an effective pathogen exhibiting low virulence for a host with an intact immune system. Life-threatening diseases follow infection in the fetus or reactivation in individuals with compromised cellular immunity, and define the spectrum of this opportunistic pathogen. Damage to the fetus or immunocompromised host ranges from focal damage in a single site, such as retinitis in patients with AIDS, or pneumonitis in bone marrow allograft recipients, to disseminated multiorgan disease. Disease caused by CMV is a complicated process that may include some contribution by the immune response itself. The demonstration of CMV histopathology and replication at a site are not always indicative of an ongoing disease process. The interplay between the virus and host, both with regards to tissues and immunity, is intricate and little is known about the role of particular viral gene products as virulence determinants. How much each virus strain differs in virulence remains an important question. As is the difficulty with many human pathogens, CMV cannot be readily studied in any experimental animal and the similarity between the pathogenesis of human CMV and animal CMVs remains difficult to qualify.

Clinical Features of Infection

Infection of the normal host is rarely associated with disease. Most children and adults do not appear to

suffer any disease. An infectious mononucleosis-like syndrome, characterized by fever, malaise, myalgia, liver dysfunction and heterophil antibody-negative lymphocytosis, may follow several weeks after exposure in a small proportion of individuals and may last for several weeks. This disease occurs and was first noticed in transfusion recipients and denoted post-perfusion syndrome. It transpires in the face of an aggressive humoral response but a decrease in CD4+ T cells. Cell-mediated immunity appears to be depressed by CMV infection. Chronic diseases that have been associated with long-term CMV infection include atherosclerosis and restenosis that follows coronary angioplasty, but the role of any ubiquitous virus such as CMV in such diseases remains conjectural.

Congenital CMV disease typically follows a subclinical primary infection of an expectant mother. Disease is much less likely to follow reactivated maternal infection, although virus transmission occurs. Perinatal infection can result in a similar disease pattern, but at a much lower frequency. While 0.5–1% of infants are infected *in utero*, fewer than 10% suffer disease. Cytomegalic inclusion disease is the worst manifestation of congenital CMV, representing an extremely broad spectrum of different syndromes, including petechia, hepatosplenomegaly, jaundice, microencephaly and other serious neurological damage. A majority of symptomatic infants suffer subclinical disease with slowly developing hearing loss and mental retardation. Cytomegalic inclusion disease is the most significant disease caused by CMV, and seems to be a manifestation of widespread viral growth before the immune system has had a chance to develop. Congenitally infected neonates may present with rashes, hepatitis, pneumonitis and gastroenteritis, in addition to long-term neurological damage affecting hearing and IQ. The risk of a similar generalized disease in premature, low birth weight infants who are transfused with CMV-contaminated blood products has led to the use of screened products in this population.

CMV poses a great risk to the immunocompromised host. Primary infection results from transfer of CMV-positive transplants or blood and reactivated infection results when latent virus reactivates due to immunosuppression. In solid organ transplant settings, the transplanted organ is likely to be a target of viral disease and a CMV seronegative individual who receives a seropositive organ is at greatest risk. In bone marrow allografting, the serological status of the recipient seems to be the primary determinant of disease, with seropositive recipients being more likely to suffer the consequences of disease. Disease is often targeted to the transplanted solid organ, and may include pneumonitis, hepatitis, gastroenteritis and other organ-specific diseases. Although prophylaxis for CMV with antiviral drugs and antibodies prevents serious disease in many solid organ transplant settings, CMV remains a serious consequence in other settings. Interstitial pneumonia remains a prominent disease in both bone marrow allograft and heart–lung recipients, despite efforts to control CMV infection with antivirals. In many of the situations where CMV is a major problem, viral immunity is either severely depressed or nonexistent. Adoptive transfer of autologous cytotoxic T cell lines into bone marrow allograft recipients can prevent disease. The humoral response is often intact, and even elevated, in immunocompromised hosts, but to little avail. The experience with immunocompromised hosts reinforces the importance of the cellular immune response in preventing virus reactivation and systemic dissemination in normal hosts.

CMV is one of the most common opportunistic infections in individuals with T cell deficiency and patients with AIDS, where the likelihood of CMV disease correlates with a decrease in CD4+ helper T cell function. Prior to the advent of highly active antiretroviral therapy to control human immunodeficiency virus (HIV) infection, CMV was one of the most common AIDS-defining pathogens. Retinitis, with progressive blindness, and gastroenteritis were the two most common diseases. It remains to be seen what will happen in individuals as HIV resistance to these therapies develops.

Serological diagnosis is widely used to assess past infection, and detection of viral antigen in leukocytes, bronchial lavage, semen or infected tissue is used to assess the level of active infection. The presence of high levels of viral DNA in peripheral blood cells or plasma has also been used to detect active infection. There are no reliable serological assays to assess recent infections, although all classes of antibodies rise during primary infection. Histopathology and virus isolation are used to detect CMV in tissues of bodily fluids, but the presence of virus does not always indicate an ongoing disease process.

Pathology and Histopathology

Historically, diagnosis of CMV infections has focused on identifying cells in infected tissues with obvious CMV cytopathology where the combination of nuclear and cytoplasmic inclusions confers an 'owl's eye' appearance on infected cells. Similar inclusions occur in cultured cells late in productive infection and define sites of viral capsid and virion maturation. CMV-infected cells are many times larger than uninfected cells. In most organs, the virus infects

and causes cytopathology in epithelial, endothelial and reticular cells.

The widespread application of monoclonal antibody and nucleic acid probe technologies has expanded our understanding of the distribution of virus in an infected host and has revealed many cells that become infected with CMV but do not become enlarged or show outward cytopathology. Infection, particularly in an immunocompromised host, is more widespread and involves a greater spectrum of organs than originally anticipated based on histopathology. Virus cytopathology is limited to the salivary glands and kidney tubules, where ductal epithelium is infected and is responsible for the production of virus in saliva and urine. The disseminated infection that occurs in an immunocompromised host results in virus cytopathology in a wide range of tissues in addition to those that are the target of disease, including blood cells, intestines, liver, lungs, pancreas, ovaries, skin and bone. While the brain is the primary site of severe cytomegalic inclusion disease, and a range of mild to severe disruption of brain function may accompany infection, many other organs may be infected in this setting as well. Infection of the inner ear is a common sequel of congenital infection, and direct destruction of cochlear duct cells is related to hearing loss. In AIDS patients, CMV and CMV plus HIV can be found in brain as well as broadly distributed throughout vascularized organs.

Immune Response

Little is known about the innate immune response to CMV, although natural killer cells can recognize and destroy virus-infected cells and the virus encodes a function that modulates this response. The adaptive cellular immune response has long been recognized as critical for clearance of viral infection and resolution of disease. T cell-deficient individuals are predisposed to CMV disease. CMV has provided one indication of the importance of the cytotoxic T cell response because virus-encoded functions directly reduce major histocompatibility class I-mediated antigen presentation. A key piece of evidence supporting the role of CMV-specific T cells that have cytotoxic T cell function has to do with their successful transfer and therapeutic efficacy in humans. A role for humoral antibody is less clear, although passive antibody has been associated with better control of CMV in a number of settings, such as neonatal infection and solid organ transplantation. The neutralizing antibody response to a major envelope glycoprotein, gB, has been correlated with protection in some settings.

Humoral and cellular immunity persists for years after primary infection. The long-term response to certain viral antigens may be favored and may be a better choice for detection of immunity. Antibodies to certain structural antigens such as tegument proteins and nonstructural proteins are excellent markers of past infection in the population, although they have little role in protective immunity. Certain viral tegument proteins appear to be very important targets of the cell-mediated immune response and to mediate protective immunity by cytotoxic T cells.

The immune response does not completely protect from reinfection with different virus strains, a situation that is well documented in sexually active homosexual men and recipients of solid organ transplants or of high volume blood transfusions. In these cases reinfection clearly occurs in the presence of respectable levels of humoral and cellular immunity.

The contribution of the immune response or immunopathology to CMV has been widely suspected but poorly documented. Pathogenesis of important diseases such as pneumonitis may involve an immune component that leaves the host manifesting a damage-inducing response to virus or viral antigens. The modulation of the immune response by CMV is also a widely acknowledged characteristic, particularly in relation to mononucleosis; however, a mechanism remains to be identified. Immunocompromised patients supporting high levels of CMV infection also have circulating immune complexes that may contribute to diseases such as glomerulonephritis.

Prevention and Control

Neither treatment nor prophylaxis has eliminated the risk of CMV disease in susceptible individuals, although the medical importance of this virus continues to stimulate identification and development of new strategies for control. Latency complicates prophylaxis and provides an almost ubiquitous reservoir. The major population of patients that benefit from therapy include immunosuppressed and immunodeficient patients. These individuals have difficulty with drug toxicity due to the numbers of other therapeutics they encounter. Nucleoside, nucleotide and pyrophosphate analogues that inhibit the viral DNA polymerase have been the most widely used therapeutics to date. Several other viral gene products have been targeted with other antiviral candidates in preclinical and clinical development.

CMV is not susceptible to the nucleoside analogue acyclovir except at very high concentrations (100 μm) because it does not encode a thymidine kinase necessary for drug phosphorylation, but is highly

sensitive to a compound, ganciclovir (9-[2-hydroxy-1-(hydroxymethyl)ethoxymethyl]guanine, DHPG), that is structurally related to acyclovir but acts via a poorly understood process whereby another viral kinase (UL97) is responsible for its phosphorylation. Ganciclovir is administered parenterally or, at very high doses, orally and can control CMV infections. Because of the chronic immunocompromised settings where CMV emerges as a pathogen, prolonged treatment is often necessary and this leads to the emergence of drug-resistant mutants due to mutations in the UL97 kinase or the DNA polymerase. Another parenterally administered nucleotide analogue, cidofovir ((S)-1-[3-hydroxy-2-(phosphonylmethoxy)propyl]cytosine), has also been licensed for use against CMV, but it shows a very similar tendency towards resistance. Foscarnate (phosphonoformate, PFA), a pyrophosphate analogue that is also administered parenterally, is used as an alternative to ganciclovir or cidofovir when resistance emerges. Due to the prolonged time of treatment and emergence of resistant strains, effective nontoxic treatments are still greatly needed to treat CMV disease.

Pooled human γ globulin, which has a respectable titer of antibodies to CMV, has been in use as a prophylactic therapy in transplant settings to reduce the incidence of CMV disease alone and in combination with antiviral compounds. Monoclonal antibodies that have a strong neutralizing capability have been tested but have thus far failed to show the benefit ascribed to human γ globulin. Vaccines for CMV were initially developed in the 1970s, and one, Towne 125, has undergone almost continuous evaluation since its initial characterization. This vaccine induces cell-mediated and humoral immunity to CMV, and, when evaluated in a solid organ transplant setting, was attributed with reduction in disease severity. Due to the fact that immunity induced by Towne 125 is not as strong as that induced by natural infection, recombinant chimeric viruses that combine segments of the Towne vaccine genome and a low passage strain, Toledo, have been made to test for immunogenicity. Vaccines consisting of the envelope gB subunit have also been produced by recombinant DNA methods and have been shown to induce strong humoral immunity in preclinical evaluation. Universal vaccination before the child-bearing years is the only way to control congenital disease and other diseases that are caused by this virus.

Future Perspectives

Despite the reduced impact of CMV in AIDS due to combination antiretroviral therapies, this virus remains one of the most important opportunist pathogens. The virulence determinants that create the pathogenic signature of CMV will be better understood, as will the role of the host immune response as a contributor to disease. Additional viral targets for antiviral intervention will continue to be described, and latency and reactivation should continue to be better understood. The contribution of CMV to any of a number of chronic diseases, such as atherosclerosis, will hopefully continue to be evaluated on a firmer scientific basis. Finally, the components of the cellular immune response that provide protective immunity against CMV disease and the viral functions that modulate host immune clearance will continue to be better understood.

Properties of the Virion

Typical of the herpesvirus group, the virion of human cytomegalovirus (HCMV, human herpesvirus 5) is approximately 230 nm in diameter and is composed of a DNA-containing nucleocapsid, surrounded by a less structured tegument layer, and bounded by a trilaminate membrane envelope. The nucleocapsid is icosahedral; has an outside diameter of approximately

110 nm; and is made up of four principal protein species that are organized into 162 capsomeres (150 hexamers + 12 pentamers) and 320 'triplexes'. The capsomers are approximately 20 nm in length and 15 nm in diameter; have a channel about 3 nm in diameter that is open at the exterior end; possess favored cleavage planes along the longitudinal axis; and have short spicule-like protrusions, probably representing the triplexes, extending out symmetrically and resulting in a pinwheel appearance of the capsomere viewed end on. The tegument region is approximately 50 nm thick and contains six highly abundant protein species, five of which are phosphorylated. The virion envelope is estimated to be 10 nm thick and contains at least ten protein species, nine of which are known to be glycosylated. The nature of the virion DNA and proteins is described below. In addition to these molecules, the virion is reported to contain the phospholipids phosphatidylcholine, phosphatidylethanolamine, phosphatidylserine and phosphatidylinositol; the polyamines spermidine and spermine; several enzymatic activities, including protein kinase, DNA polymerase, DNase, and topoisomerase II; and several host cell proteins, including PP1 and PP2A phosphatases, and a 45 kDa cellular-actin-related protein.

Properties of the Genome

The genome of HCMV is composed of a linear, double-stranded DNA molecule whose M_r of $\approx 150 \times 10^6$ is 50% larger than that of herpes simplex virus (HSV), and the largest of the characterized herpes group viruses. It is a class E isomerizing genome, like that of HSV, consisting of a long unique (U_L) and a short unique (U_S) sequence, both of which are flanked by much shorter inverted repeat sequences that enable U_L and U_S to invert relative to each other and give rise to the four structural isomers of the genome found in virions. The origin of DNA replication (*ori*-Lyt) has been localized to a 3–4 kb region near the center of U_L. Like *ori*-L, one of three duplicated origin sequences in the HSV genome, the HCMV *ori*-Lyt region is located adjacent to the promoter for the early, single-strand DNA-binding protein, DB140 (UL57). HCMV *ori*-Lyt includes a 2.4 kb sequence which has no homology with other described viral DNA replication origins and contains duplications, inversions, consensus binding sequences for the cyclic-AMP response element and other transcription factors, and 23 copies of the sequence AAAACACCGT that is conserved near the homologous *ori*-Lyt of simian CMV. The complete nucleotide sequence of the HCMV strain AD169 genome has been determined (EMBL data base accession number X17403), analyzed and reviewed. It is 229 354 bp in length, has a G + C content of 57.2 moles percent, and contains approximately 200 open reading frames (ORFs) at least 300 bp in length. Lower-passage strains (e.g. Toledo) contain additional ORFs (see Gene Bank accession numbers U33331 and U33332) and are ≈15 kb larger than strain AD169. Sequence analyses have revealed that the HCMV genome has the comparatively unusual feature of containing nine families of closely related genes that tend to be clustered as homologous blocks of ORFs. Most of these encode known (e.g. RL11, US6 and US27 families) or predicted (e.g. US2) glycoproteins. Taken together these gene families represent 26% (59 728 bp) of the AD169 DNA sequence and may, in part, account for the comparatively large size of the HCMV genome. It is also notable that the HCMV genome contains homologues of at least three cellular genes that code for surface receptors: class I major histocompatibility (MHC) antigens, T cell receptor gamma chains (TCR_γ), and G protein-coupled receptors (GCRs).

Properties of the Proteins

HCMV proteins share the general pattern of expression characteristic of the herpesvirus group. Immediate early (α), early (β) and late (γ) proteins are synthesized sequentially from corresponding mRNAs whose transcription is regulated in a temporal cascade (see Characterization of Transcription below). Immediate early proteins are required to regulate transcription from their own promoters and those of subsequently expressed genes. Early proteins include many of the enzymes and regulatory factors needed to carry out the synthesis of progeny DNA and proteins. Late proteins include most of the virion structural proteins. Members of all three classes have been described for HCMV, but only a small number of its more than 200 potential proteins have been identified. Those that have been reported include both nonvirion and virion species and their properties are briefly described below.

Nonvirion Proteins

Many of the recognized nonvirion proteins are made at early times after infection and localize to the nucleus. The first of these to appear is the major immediate early protein (MIEP or IE1, UL123), a 72 kDa phosphoprotein that together with products of a second immediate early gene, IE2 (UL122), can transactivate CMV early promoters. The IE2 gene gives rise to a family of proteins, ranging in size from 23 to 86 kDa, that are generated by differential RNA

splicing and translational start sites. IE2 proteins can repress the immediate early promoter by acting on a sequence immediately upstream of the transcription initiation site. Other immediate early proteins are encoded by ORFs IRS1, TRS1 and UL36–38 and can act synergistically with IE1 and the US3 protein to regulate both cellular and virus gene transcription.

The early proteins include the 140 kDa viral DNA polymerase (UL54), a 140 kDa nuclear DNA-binding protein referred to as DB140 or CMV ICP8 (UL57), and a set of closely related nuclear phosphoproteins (UL112). The DNA polymerase, like its homologue in other herpesviruses, has an associated 3′-specific exonuclease activity. DB140 is the HCMV homologue of HSV ICP8, one of seven HSV proteins essential for viral DNA replication. Like HSV ICP8, the DB140 gene is located adjacent to the origin of viral DNA replication, and the protein localizes to discrete foci within the nucleus of infected cells and accumulates in the cytoplasm under conditions of inhibited viral DNA synthesis. There is also a set of four early, nuclear, DNA-binding phosphoproteins (34, 43, 50 and 84 kDa) that are related to each other by their common N-terminal sequence; appear to be produced by alternate splicing; have expression regulated at both the transcriptional and post-transcriptional level; and are differentially phosphorylated. Some similarity between these proteins and Epstein–Barr virus nuclear antigen (EBNA-1) suggests that they may have a role in DNA replication or gene regulation.

Another nonvirion nuclear DNA-binding phosphoprotein is distinguished by its high abundance and its kinetics of synthesis. This ≈52 kDa species, referred to as DB52 or ICP36, is the product of ORF UL44. On the basis of its reduced but not eliminated synthesis under conditions of inhibited viral DNA replication, DB52 is a delayed-early or γ_1 protein. Expression of this gene is under different promoter control at early and late times of infection, and there is evidence that its expression is also post-transcriptionally regulated. DB52 and its simian CMV homologue DB51 bind to DNA *in vitro* and *in vivo* and associate with the viral DNA polymerase to enhance its activity, analogous to the HSV UL42 protein. Two other proteins that appear to function in viral DNA replication or processing are a phosphotransferase (UL97 protein) and an apparent homologue of the bacteriophage DNA cleavage/packaging enzyme, terminase (UL89 protein).

Several other nonvirion HCMV proteins have recently been shown to interfere with the class I MHC antigen presentation system (i.e. US11 and US6 proteins). These proteins are thought to help the virus-infected cell escape recognition and destruction by immune surveillance, and provide a mechanism for virus persistance in the immune-competent host.

Virion Proteins

HCMV virions contain a minimum of 23 protein species that differ somewhat in size and relative amount from strain to strain. Characteristics of these proteins, including size, charge, carbohydrate and phosphate content, and deduced location in the particle, are summarized in **Table 1**, along with a descriptive name and the ORF encoding each.

The capsid shell is composed of four abundant protein species referred to as the major capsid protein (MCP), the minor capsid protein (mCP), the mCP-binding protein (mC-BP) and the smallest capsid protein (SCP). Formation of the capsid shell is coordinated by precursors of an internally located maturational proteinase (assemblin) and assembly protein (pAP), which serve a scaffolding role and are present in nascent intranuclear capsids (e.g. B-capsid) and in noninfectious enveloped particles (NIEPs, see below), but not in virions. These internal scaffolding proteins are the only abundant capsid proteins known to be post-translationally modified (**Table 1**).

There are seven proteins provisionally designated as virion tegument constituents. The largest of these, called the high molecular weight protein (HMWP), forms a heterotrimer with another tegument protein called the HMWP-binding protein (hmw-BP), and is thought to be the HCMV homologue of the HSV UL36 protein, VP1,2, which binds to the cleavage/packaging sequence of HSV DNA. Neither the HMWP nor its binding protein is detectably phosphorylated or glycosylated. The basic phosphoprotein (BPP or pp150) and the upper matrix (UM or pp71) and lower matrix (LM or pp65) proteins account for the greatest protein mass of the tegument constituents and are highly phosphorylated, both *in vivo* and *in vitro*, by the virion-associated protein kinase. The BPP is distinguished among the virion proteins by having the highest density of *O*-linked *N*-acetylglucosamine residues, which are attached at a single site or tight cluster of sites. The upper matrix protein is a transacting inducer of immediate early gene transcription that may be functionally analogous to the *α-trans*-induction factor of HSV; the lower matrix protein appears to be an important component in cellular immunity and there are reports that it has an associated protein kinase activity. Several much lower-abundance species have also been found associated with HCMV capsid/tegument structures, including the UL56 protein.

The virion envelope contains at least ten protein species, of which nine are known to be glycosylated.

Table 1 Proteins of the virion

Descriptive name	M_r[a]	*Modification*[b]	*Charge*[c]	*ORF*[d]
Capsid				
Major capsid protein (MCP)	153	—	N	UL86
(Assembly protein) (AP)[e]	(36)	P, C	B	UL80.5
mCP-binding protein (mC-BP)	35	—	N	UL46
Minor capsid protein (mCP)	34	—	B	UL85
Proteinase assemblin (A, An, Ac)[f]	28	—	A	UL80a
Smallest capsid protein (SCP)	8	—	B	UL48/49
Tegument				
High mol. wt protein (HMWP)	212	—	N	UL48
Basic phosphoprotein (BPP; pp150)	149	G, P	B	UL32
HMWP-binding protein (hmw-BP)	115	—	N	UL47
80K	80	P		
Upper matrix protein (UM; pp71)	74	P	N	UL82
Lower matrix protein (LM; pp65)	69	P	B	UL83
24K (pp28)	24	P	B	UL99
Envelope				
gB (gcI)	102	G, P, C	N	UL55
Acidic glycoprotein (AGP)	145	G	A	
gB_N (gcI)	130	G	A	UL55
gH (gcIII)	84	G	N	UL75
gp70	70	G	A	
gB_C	62	G, P	A	UL55
gp57 (gcII)	57	G	A	
Integral membrane protein (IMP)	43			UL100
GCR33	44	G	B	UL33
GCR27	42	G	B	US27

[a] Values given determined by SDS-PAGE and are $\times 10^3$.
[b] G, glycosylation; P, phosphorylation; C, proteolytic cleavage.
[c] Relative net charges were determined by 2-D PAGE (charge/size). N, neutral with respect to the major capsid protein, which is approximately neutral in such separations; A, acidic with respect to the major capsid protein; B, basic with respect to the major capsid protein.
[d] Open reading frame, where known.
[e] Present as a component of immature capsids and noninfectious enveloped particles (NIEPs), but absent from virions.
[f] Assemblin (A) is autoproteolytically concerted to an amino (A_n) and carboxyl (A_c) half.

The high degree of size and charge heterogeneity among this group has complicated their analysis. Three of the HCMV envelope glycoproteins are homologues of HSV glycoprotein B (gB). HCMV gB is synthesized as a 130–160 kDa, cotranslationally *N*-glycosylated precursor that undergoes at least four further modifications: (1) its 17–19 predicted *N*-linked oligosaccharides are converted from nontrimmed to trimmed high mannose forms, and then a portion are further modified to complex structures; (2) *O*-linked carbohydrates are added; (3) the C-end of the molecule is phosphorylated; and (4) the protein is cleaved between Arg460 and Ser461 to yield an intramolecularly disulfide-linked heterodimer composed of a highly glycosylated 115–130 kDa N-terminal fragment (gB_N), and a less extensively modified 52–62-kDa C fragment (gB_C). This gB_N–gB_C heterodimer can form intermolecular disulfide crosslinks, yielding a complex with the composition $(gB_N–gB_C)_2$. A fourth HCMV envelope glycoprotein is the homologue of HSV gH. HCMV gH is an 86 kDa species that is less extensively *N*-glycosylated than gB and its oligosaccharides are not processed beyond the high mannose structure, gH has been proposed to mediate virus–host membrane fusion during the initial steps of virus infection, and its intracellular trafficking associates covalently with another HCMV glycoprotein (gL, UL115 protein).

Two other envelope proteins and two disulfide-linked glycoprotein complexes have been described.

Glycoprotein complex II (gcII) is composed of proteins with M_rs of 50–52 kDa and >200 kDa. These proteins have similar peptide maps indicating that they are closely related, and the 52 kDa component is comparatively highly *O*-glycosylated and sialylated. Glycoprotein complex III (gcIII) is composed of two glycoproteins, 145 and 86 kDa. An additional highly sialylated, *O*-glycosylated virion glycoprotein, gp145, differs from the 145 kDa gcIII protein in that it is not disulfide linked. The relative amount of this protein is more strain-dependent than those of gB and gH. Another envelope protein that may be a component of the gcII complex is referred to as the integral membrane protein (IMP, gM, UL100 protein). It is the homologue of HSV UL10, has an M_r of approximately 45 kDa, five potential *N*-glycosylation sites and eight possible membrane-spanning domains.

Physical Properties

Infectivity of HCMV is eliminated by exposure to 20% ether for 2 h, by heating at 65°C for 30 min, by exposure to ultraviolet light (4000 ergs s^{-1} cm^{-2}; 400 μJ s^{-1} cm^{-2}) for 4 min, by acidic pH (<5) and by treatment with low concentrations of either ionic or nonionic detergents. Infectivity is also reduced following sonication, pelleting by ultracentrifugation, and repeated cycles of freezing and thawing.

Replication

General features of the HCMV replication cycle are typical of the herpesvirus group. Following virus adsorption and entry into the cell, the DNA is transported to the nucleus where it is replicated and packaged into preformed capsids. Maturation of the nucleocapsid involves acquisition of the tegument constituents followed by envelopment, which has been observed at both nuclear and cytoplasmic membranes.

DNA Replication

HCMV DNA is replicated in the nucleus. Parental DNA appears to circularize soon after entering the cell, but maximal rates of progeny DNA synthesis do not occur until approximately 3 days after infection. The 'endless' concatameric nature of progeny DNA is consistent with a rolling circle mechanism of DNA replication. However, the finding that viral DNA synthesis proceeds bidirectionally from *ori*-Lyt under conditions of ganciclovir [9-(1,3-dihydroxy-2-propoxymethyl) guanine, (DHPG)]-inhibited replication is not easily reconciled with this model. Unit length genomic DNA is released from the concatamers by cleavage at a specific site located in the 'a' repeat elements, 30–35 bp from a herpesvirus group-common cleavage/packaging region referred to as the 'herpes pac homology' sequence.

Characterization of Transcription

Transcription of the HCMV genome is temporally regulated and the pattern and control of gene expression shares many features with that of HSV. The first class of mRNAs made are transcribed from input DNA and are referred to as immediate early (IE) or αRNAs. Their expression requires no preceding viral protein or DNA synthesis, and they are operationally defined as those RNAs made in the presence of inhibitors of protein synthesis. The most abundant IE RNAs are transcribed from a region between 0.732 and 0.751 map units, which contains ORF UL122 and exons UL123EX2–4. These transcripts are related to each other by alternate splicing patterns and encode IE1 and multiple forms of IE2. The promoter region for this transcription unit is one of the strongest known, presumably due to its high content of consensus binding sequences for host cell transcription factors such as nuclear factor 1, CAAT-binding protein, and SP1; and the large number of repeat sequences that contain cyclic-AMP response elements and which may interact with additional DNA-binding proteins. Transcription from this region is enhanced by a virion tegument phosphoprotein, referred to as the upper matrix protein or pp71 (UL82), whose function appears to be analogous to that of the HSV *α-trans*-induction factor. Lower abundance IE RNAs arise from ORFs IRS1, TRS1 and UL36–38.

Expression of early or βRNAs requires the preceding synthesis of immediate early proteins, but does not require viral DNA synthesis. Thus, early RNAs are made in the presence of inhibitors of viral DNA synthesis, but not in the presence of inhibitors of protein synthesis. Both immediate early and early genes appear to be transcribed by host cell RNA polymerase II. Expression of late or γRNAs requires the preceding synthesis of both immediate early and early viral proteins, as well as synthesis of viral DNA. The possibility that post-transcriptional events may be involved in controlling HCMV RNA processing and translation, is suggested by the presence of some 'early' RNAs that are not translated until 'late' times of infection.

Characterization of Translation

HCMV RNAs are translated by the host cell protein synthesizing system. Virus-specific proteins that may

augment the host system (e.g. initiation or elongation factors) have not yet been identified. Each viral protein species appears to be encoded by a unique mRNA. Cells infected with HCMV do not show the generalized early shutoff of cell protein synthesis that occurs in HSV-1 infected cells. There are, nevertheless, very early changes in the metabolism of HCMV-infected cells that include: stimulated transcription of the genes for heat shock protein 70, ornithine decarboxylase, thymidine kinase, and creatine kinase; decreased transcription of the fibronectin gene; and changes similar to those induced by the G protein signaling pathway, such as decreased intracellular Ca^{2+} stores and increased levels of intracellular cAMP.

Post-translational Modifications

Modifications of HCMV proteins include phosphorylation, glycosylation and proteolytic cleavage. Phosphorylation has been detected on immediate early (e.g. IE1 and IE2), early (e.g. UL112) and late (e.g. γ_1 nonvirion UL44 protein; γ_2 virion tegument (UL32, UL82, UL83) and capsid (UL80.5)) proteins, all of which localize to the infected-cell nucleus. At least some of these phosphorylations are likely to be catalyzed by reported virus-coded protein kinases. Glycosylation typifies many of the virion envelope glycoproteins and includes both *N*-linked (high mannose and complex structures) and *O*-linked oligosaccharides. The only nonenvelope virion protein that has been demonstrated to be glycosylated is the tegument basic phosphoprotein, which has *O*-linked *N*-acetylglucosamine. Glycosylation of HCMV proteins is most likely carried out by host cell systems. The third modification that has been described for HCMV proteins is proteolytic cleavage. There are two maturational endoproteolytic cleavages, in addition to glycoprotein signal sequence cleavages. The first of these cuts between Arg460 and Ser461 in the envelope glycoprotein gB and is catalyzed by a calcium-dependent cellular, furin-like proteinase. The other is a cleavage between residues Ala308 and Ser309 of the capsid assembly protein precursor (UL80.5 protein). This later cleavage is catalyzed by a genetically related, virus-encoded proteinase, assemblin (UL80a protein), and is essential for the production of infectious virus.

Cytopathology

The mechanisms of cell recognition, binding and penetration by HCMV are not yet understood, but there are at least four proteins that may be involved: (1) β_2-microglobulin is present on virions and may interact with cell surface major histocompatibility proteins; (2) virion envelope glycoprotein B binds to a 30 kDa cell protein that may be a receptor; (3) virion envelope glycoprotein H interacts with a 90 kDa cell protein that may also be involved in binding or penetration; and (4) a highly *O*-glycosylated envelope glycoprotein complex (gC-II) is able to bind heparin, and this interaction could promote early virus-cell interaction as proposed for cellular heparin sulfate and HSV-1.

Assembly of the capsid and DNA replication and packaging take place in the nucleus. As with HSV, the tegument constituents are presumed to be added to the maturing nucleocapsid in the nucleus, and envelopment to occur as the tegument-coated capsid passes through the inner nuclear membrane. The presence of nonenveloped capsids appearing to bud through tubule or vesicle membranes in the infected-cell cytoplasm suggests the possibility of additional or alternate envelopment mechanisms for HCMV.

The cytopathic effects of HCMV are distinctive. Early after infection a transient cell rounding occurs, followed by overall enlargement (cytomegalia) and by the appearance of basophilic intranuclear inclusions, which gradually enlarge to fill and distort the nucleus into an elongated or kidney-shaped form late in infection. These intranuclear inclusions contain viral DNA, proteins and capsids and are thought to be nucleocapsid assembly sites. Late in infection the cytoplasm contains numerous enveloped and nonenveloped capsids, large (>500 nm 'black holes') and smaller (250–500 nm 'dense bodies') electron-dense aggregates, and a large eosinophilic spherical region adjacent to the nucleus that exhibits strong F_C binding.

Although the mechanism by which HCMV is released from the infected cell is not known, the process results in three kinds of enveloped particles being freed into the growth medium of cultured fibroblasts: (1) virions, and two aberrant particles referred to as (2) noninfectious enveloped particles (NIEPs), which closely resemble virions in structure and composition, but have no DNA and contain the capsid assembly protein (UL80.5 protein) that is absent from virions, and (3) dense bodies, which are solid, 250–600 nm spherical aggregates of lower matrix protein (pp65 or UL83 protein) that contain no DNA and are surrounded by an envelope layer.

Animal Cytomegaloviruses

Donald J Alcendor and **Gary S Hayward**, Departments of Pharmacology and Oncology, Johns Hopkins School of Medicine, Baltimore, USA

History

In addition to human cytomegalovirus or salivary gland virus (HCMV or HHV-5) and the equivalent mouse virus (MCMV), closely related species with typical cytomegalovirus-like characteristics have been described from rats (RCMV), guinea pigs (GpCMV) and other rodents, and from both Old and New World monkeys (SCMV). GpCMV was originally recognized in 1920 and served as a model system for the biology and pathogenicity of HCMV disease for many years. Host-specific SCMV isolates have been reported from almost all major nonhuman primate groups, including gorilla, chimpanzee, bonobo, baboon, rhesus and other macaques, African green monkey, spider monkey, owl monkey, capuchin and marmoset.

Classification and Evolution

All of the animal CMVs described to date are members of the family *Herpesviridae* and belong to the *Betaherpesvirinae* subfamily of herpesviruses. Based on the relatively high (G+C) content of their DNA molecules and their adaptability to grow in fibroblasts in cell culture, most if not all of the traditionally recognized animal CMVs are likely to be evolutionarily more similar to the beta-1 subgroup that includes HCMV and MCMV than to the (A+T)-rich beta-2 subgroup exemplified by HHV-6. The International Committe on Taxonomy of Viruses has now classified betaherpesviruses into three distinct genera, *Cytomegalovirus* (HCMV-like), *Muromegalovirus* (MCMV-like) and *Roseolovirus* (HHV-6, HHV-7), but it is likely that distinctions between the first two taxons at least will become murky when molecular genetic criteria (i.e. gene content and DNA and protein sequence similarities) are applied to those CMV species that infect other mammalian and primate hosts. The genomes of prototype species of all three taxons, including HCMV (1989; 229354 bp; X17403), MCMV (1996; 230278 bp; U68299) and HHV-6 (1995; 159321 bp; X83413) as well as HHV-7 (1996; 144861 bp; U43400), have all been completely sequenced.

All formally recognized betaherpesviruses are listed in **Table 1**. However, it should be noted that there are two very different viruses (with somewhat different gene content) that are both known as rat cytomegalovirus (RCMV). Two CMV-like viruses have also been recently reported to be associated with fatal hemorrhagic disease in young African and Asian elephants, but current genetic analysis suggests that these two viruses are distinct in the two groups of animals and from all three of the currently recognized taxons. Another CMV-like virus, sometimes referred to as 'Stealth virus', has been reported to have been isolated from a human patient with central nervous system neuropathy, but genetic analysis has revealed that this virus contains UL34, UL35 and SSB genes that are virtually identical to those of several characterized SCMV isolates from African green and Vervet monkeys (AgCMV). The AgCMV isolate 'Colburn' was also originally thought to have been of human origin, but whether either is truly a human isolate rather than a contaminant from primary monkey cell cultures is subject to some doubt. Based on genome analyses, both the bovine herpesvirus BHV-4 and the two equine herpesviruses EHV-2 and EHV-5, which were all originally thought to be

Murine Cytomegaloviruses

John Staczek, Louisiana State University Medical Center, Shreveport, Louisiana, USA

History

Cytomegalia refers to the enlargement of a cell. The discovery of the viral etiology of cytomegalia in the mouse salivary gland preceded the isolation of the virus by 19 years. The mouse salivary gland virus, commonly called mouse (or murine) cytomegalovirus (MCMV), is a surrogate for studying human cytomegalovirus (HCMV)-associated pathogenesis.

Classification

Classification by the International Committee on Taxonomy of Viruses (ICTV) places MCMV in the family *Herpesviridae,* subfamily *Betaherpesvirinae,* genus *Muromegalovirus,* type species mouse cytomegalovirus 1. Herpesviruses are designated by serial arabic number and the family or subfamily of the natural host. Thus, MCMV is designated Murid herpesvirus 1, but its most commonly used synonym is mouse cytomegalovirus.

Properties of Virion

MCMV virions have typical herpesvirus morphology. The virions have a buoyant density of 1.20 g cm^{-3}. Their nuclear membrane-derived envelope is sensitive to denaturation by detergents, pH, heat and desiccation. Viral glycoprotein spikes extending through the envelope are linked to the nucleocapsid via tegument proteins. The icosahedral nucleocapsid, containing 162 capsomeres, surrounds an ultraviolet radiation-sensitive, linear, double-stranded DNA.

Properties and Organization of Genome

General comments concerning the DNA sequence and genomic organization of the Smith strain of MCMV are presented. It is suggested that the reader refer to Rawlinson *et al* for a more detailed description of the DNA sequence and compilation of open reading frames (ORFs).

DNA sequencing of the Smith strain genome reveals 230 278 bp. Buoyant density and sequence analyses denote an overall 58.7% G+C content distributed with areas of major (155–163 kb) and minor (1–17 kb and 204–221 kb) G+C content. Coding regions have a higher G+C content than noncoding regions. CpG dinucleotides occur throughout the genome at frequencies expected for random associations between mononucleotides, except for a CpG deficiency that is evident in the major immediate early (MIE) gene region.

DNA isolated from purified virions contains a single 3′ nucleotide extension that may facilitate circularization to a prereplicative intermediate. Herpesvirus genomes are grouped (A–F) according to sequence reiterations greater than 100 base pairs. Based on this scheme, the MCMV genome, consisting primarily of unique sequences, is catalogued with the group F genomes. However, clusters of 31-bp direct repeats delimit each terminus of the genome, and additional, nonhomologous, intra- and intergenic direct repeats punctuate the centralized unique region. Inverted repeats, present in the origin of replication and upstream of several ORFs, do not mediate isomerization.

Families of homologous genes are a general feature of betaherpesviruses. MCMV has six gene families, two of which (m02 and m145) are unique and four of which are homologous to HCMV families US22, UL25, UL82 and to the G protein-coupled receptors (GCRs). The functions of the gene families are generally unknown. However, the M25 protein has homology to eukaryotic nucleolins and, therefore, may interact with chromatin.

Genetics

Restriction length fragment polymorphisms among MCMVs isolated from wild-type mice indicate widespread heterogeneity in genomic composition which is reflected in peptide analyses using polyclonal sera recovered from infected wild mice. Strain variation influences disease presentation and recovery. Variation in the nonapeptide of the immunodominant

immediate early protein, pp89, presented by major histocompatability complex (MHC) class I molecules confers escape from antigen-specific cytotoxic T lymphocytes (CTLs). The Cmv1 locus located on chromosome 6 of the mouse determines the host's susceptibility/resistance phenotype.

Replication

Strategy of replication of nucleic acid

The presence of a singular, unpaired 3′ nucleotide extension on the linear DNA molecule provides an opportunity for the formation of a circular prereplicative intermediate. Semiconservative replication occurs by way of a rolling-circle model. The MCMV replicator region (oriLyt) contains 1.7 kbp and is analogous to (but not identical to and cannot substitute for) its HCMV counterpart. The oriLyt is composed of AT- and GC-rich regions, many repeat sequence elements and arrays of closely spaced direct repeats.

Characterization of transcription

MCMV transcription is temporally ordered and regulated in a cascade fashion. The time-dependent appearance of transcripts relative to the initiation of infection and replication of genomic DNA, and the use of inhibitors of transcription, translation and DNA replication, allow division of the transcription into immediate early (IE), early (E) and late (L) phases.

IE transcripts are made from three regions which are similar to three of the four IE regions of HCMV. The most abundant IE mRNAs originate from the MCMV MIE region (0.769–0.818 map units). Transcription from the MCMV MIE is similar to that found in HCMV MIE transcription: transcripts from both viral genomes are colinear, have matching splicing patterns and are under the influence of a strong enhancer. The MIE contains three transcriptional units. The *ie1* gene contains four exons and is transcribed from right to left from the very strong MIE enhancer. The *ie2* gene is located on the opposite side of the enhancer and is transcribed in the opposite direction from *ie1*. The *ie3* gene contains exons 1, 2, and 3 of *ie1* spliced to a fifth exon located downstream of exon 4; thus, this transcript is a hybrid (*ie1/ie3*). The IE1 and IE2 regions are CpG-suppressed and possibly accessible to cellular methylation enzymes during the replication cycle. The enhancer associated with the MIE is composed of five 94-bp tandem repeats containing many viral and cellular transcriptional regulator binding sites responsive to p21ras, NF kappa B, AP1, SP1, ATF and p53. Expression from the MCMV MIE promoter appears to be less species-specific than its HCMV counterpart. The other IE transcription regions in MCMV include ORFs M36–M38 and m143. In contrast to the HCMV *UL37* gene, the M37 ORF does not contain consensus splice donor or acceptor sites. The m143 ORF is similar to the HCMV TRS1 region.

Early and late phase transcripts originate from transcription units located throughout the genome. In general, these transcripts are not spliced. The exceptions are transcripts originating from ORFs m133/m132, which encode the *sgg1* gene required for virus replication in the salivary glands, and M33, which encodes the MCMV homologue to the cellular G protein-coupled receptors (GCR). However, all transcripts are modified post-transcriptionally by capping and polyadenylation.

Characterization of translation

After the transcription of viral genes, the translation of viral messenger RNAs occurs on cellular ribosomes. Currently, much effort is focused on the identification of viral polypeptides, post-transcriptional modifications, and sequence homology to other cytomegalovirus proteins.

Properties of Proteins

Many MCMV structural and nonstructural proteins are functionally homologous to those in other herpesviruses. Most of these proteins contain significant sequence similarity with HCMV.

Proteins with regulatory functions

Several MCMV regulatory genes are homologous to HCMV and HSV-1 genes. MCMV M69 is homologous to HCMV UL69 and HSV-1 ICP27. MCMV ORFs M121 and M116 have sequence similarity to HSV-1 transactivator ICP0. The MIE phosphoprotein (pp89) transactivates heterologous promoters, including the NF-kappa B p105/p50 promoter, the proto-oncogene c-*fos*, and the SV40 early promoter, and interacts synergistically with MCMV IE3 to transactivate the early gene, *e1*. The 88-kDa IE3 protein is homologous to HCMV UL122, autoregulates the *ie3* promoter, and is a major transactivator of early and late genes.

Proteins involved with genome replication and repair

MCMV has homologues for six of seven HSV-1 origin-dependent replication proteins. These proteins are the DNA polymerase, the polymerase accessory protein, the helicase complex (containing three proteins) and the alkaline nuclease. Homologous en-

zymes involved in nucleotide metabolism and repair include ribonucleotide reductase (M45), uracil-DNA glycosylase (M114), dUTPase (M27), pyruvoyl decarboxylase (M77), and phosphotransferase (M97). MCMV does not encode a thymidine kinase or an origin-binding protein.

Structural proteins

It is predicted that MCMV encodes 33–35 structural proteins including the major capsid protein (M86), the large tegument protein (M48), a minor capsid protein (M46), the upper (M82) and lower (M83) matrix proteins, large (M32) and small (M99) phosphoproteins, and a fused protease-capsid assembly protein precursor (M80). The 28-kDa matrix phosphoprotein induces a strong humoral immune response during MCMV infection of mice.

Other proteins

The M84 ORF encodes a nonstructural protein with homology to HCMV UL83 and UL84. M44 ORF encodes a DNA-binding protein. The M103 gene product is an immunoreactive protein that is homologous to HCMV UL103. The M97 protein is a phosphotransferase.

Glycoproteins

There are 64 genes that potentially encode glycoproteins. MCMV glycoproteins with homology to HCMV glycoproteins have been identified by sequence similarity, potential transmembrane hydrophobic sequences, and potential N-linked glycosylation sites. MCMV homologues to HSV-1 glycoproteins include gB (M55), gH (M75), gM (M100) and gL (M115). Antibodies to MCMV gL or gH do not exhibit neutralizing activity in a plaque reduction assay.

Assembly Site, Uptake, Release, Cytopathology

Nucleocapsid self-assembly occurs in the nucleus. Concatemeric viral DNA is cleaved and packaged into preassembled capsids. The association of the nucleocapsids with the nuclear membrane is facilitated by the viral tegument proteins. Viral glycoproteins are targeted to the nuclear membrane and aid in virion assembly. The virion buds out into the cisternae of the Golgi apparatus where further modifications of the glycoproteins may occur.

Infected cells display a cytopathology that is characterized by the enlargement (cytomegaly) of the cell. The enlarged cells have characteristic intranuclear inclusion bodies, marginated chromatin, and large cytoplasmic vacuoles.

Evolution

Comparisons between MCMV sequences and nucleotide sequences of herpes simplex type 1 (HSV-1), equine herpesvirus type 1 (EHV-1), Epstein–Barr virus (EBV), and channel catfish virus (CCV) reveal significant differences in the overall arrangement of genes and nucleotide composition. Yet, MCMV has similarity at the nucleotide level with HCMV. MCMV and HCMV homologues are encoded in the central portion of both genomes and possess either regulatory or structural functions.

Host Range and Virus Propagation

MCMV infects wild or commercially-raised mice. In Australia 80–90% of wild mice (*Mus domesticus*) are seropositive for MCMV. Seroprevalence varies significantly with time and host density. Multiple strains of MCMV coexist in individuals or populations. The incidence of infection in field mice is higher than among commercially available strains. Successful infection of commercially bred mice depends on virus strain, dosage site of inoculation and genetic susceptibility of the mouse.

Most laboratory strains of MCMV are descendants from the original Smith strain isolated in 1934. Initially serially propagated in mice as a homogenate of infected salivary gland tissue, these strains replicate efficiently in cultures of 13–16-day mouse embryos, in epithelial cells of tracheal ring explant cultures, or in continuous murine cell lines. MCMV also replicates in hamster, rabbit, monkey, and sheep cell cultures. Passage of MCMV in mouse tissue culture quickly attenuates its virulence, which may be restored following *in vivo* passage.

Transmission

MCMV is recovered from saliva, urine and sperm of infected mice. Caged weanling mice are infected through contact. Therefore, environmental and sexual contact are probable routes for MCMV transmission.

Pathogenicity

The virus is not highly pathogenic in the immunocompetent host. Experimental pathogenicity of MCMV depends on several factors including dosage, virus strain, genetic susceptibility of the mouse, site of inoculation, and age of the mouse. Immunocompetent mice manifest minor illness when inoculated with a

sublethal LD50. Virus continually passaged in tissue culture loses virulence. Commercially available mice may be genetically susceptible, moderately resistant, or resistant.

Virus titers following an intraperitoneal infection peak between days 5 and 7. Initial virus replication occurs in peritoneal macrophages and mesothelial cells and virus is subsequently disseminated by mononuclear cells to the liver and the spleen. Virus amplification in the reticuloendothelial organs precedes secondary viremia. Infected mononuclear cells infiltrate organs to initiate organ-specific infection. Resolution of the productive infection need not clear virus from organs which become chronically infected. Chronic infections may be persistent or latent. Persistently infected mice shed virus from saliva and urine, and virus may be recovered from explants of organ tissues in a time-dependent manner. The persistent infection wanes, and virus proliferation segues into a state of molecular latency in which the copy number of viral genomes per organ reflects the initial viral burden. In latent infection, viral footprints are detected by molecular analyses, or infectious virus is recovered after immunosuppression or by explantation/cocultivation/transplantation of infected tissues on permissive cell lines or into severe combined immunodeficient (SCID) mice. Primary infections in younger mice are more likely to establish latent infections than in older mice. In germ-free and specific pathogen-free mice, the indigenous bacterial flora influences the establishment of organ-specific latency. The extent of organ-specific, latent MCMV burden in immunocompetent, but not immunocompromised, mice reflects virus amplification during primary infection and augurs reactivation.

Pathology and Histopathology

During a generalized infection, MCMV infects many organs and tissues including the salivary glands, lungs, pancreas, liver, spleen, adrenal glands, cardiac muscle, striated muscle, and, to a lesser extent, lymphoid tissue and kidney. Thymic involution occurs as a result of infection, but the thymus does not support virus replication. Pathologic changes occur in the central nervous system only after intracerebral inoculation. The acinar cells of the salivary gland are the site for persistent MCMV infection. Whether a clear distinction between low level persistence and true molecular latency has been made in published reports is problematic. Organs suspected of harboring latent, but not lytic (persistent), virus include the spleen, kidneys, heart, liver, brain, salivary glands and lungs. Organ-specific endothelial cells, infiltrating T lymphocytes, macrophages and/or peripheral blood mononuclear leukocytes are candidates for the reservoirs of latent virus.

MCMV Infections as Models of Human Infection

There is no specific disease associated with MCMV infection of wild mice. Sublethal dosages of virus inoculated intraperitoneally into commercial mice cause a variety of generalized and organ-specific symptoms. MCMV infections of mice are used as models for HCMV disease. A variety of mouse tissues and organs can be selectively inoculated and the pathology of the resulting infection can be studied with respect to histology and immune responses.

Embryonic development

MCMV infection of pregnant mice causes a decrease in litter size and an increase in stillborn fetuses. Since virus is not recovered from stillborn or newborn mice, it is presumed that the virus cannot pass the placental barrier and that infection of pregnant mice indirectly influences fetal development. Microinjection directly into the endometrial lumina, or the transplantation of blastocyst stage embryos infected *in vitro*, increases the incidence of fetal wastage; however, the embryos are not infected. After day 7.5 of gestation, embryos support infection. Infecting the conceptus at mid- or late-gestation causes microphthalmia, cortical atrophy and cystic lesions in a time-dependent manner. Embryonic mesenchymal, neuronal and endothelial cells support MCMV replication. Mesenchymal cells are the primary target of infection and subsequent spreading to the eyes and brain induces disrupted organogenesis.

Lung infections

Intranasal inoculation of immunocompetent mice with small doses of MCMV produces a generalized, subclinical infection without pneumonitis, whereas larger dosages effect a fatal, interstitial pneumonitis characterized by macrophage infiltration and accumulation of proteinaceous material in pulmonary lesions. When administered intraperitoneally, virus is not recovered from the lungs unless mice are treated with cytokines. Athymic mice develop severe pneumonitis following intranasal inoculation.

Inner ear infection

Experimental inoculation of MCMV through the anterior coronal suture results in perilabyrinthitis in the cochlea.

Eye infections

Intraperitoneal inoculation is not necessarily associated with overt ocular disease, but virus is recovered from explanted tissues of the eye or optic nerve. In natural killer cell-depleted BALB/c mice inoculated intraperitoneally, virus is recovered from blood lymphocytes, macrophages, granulocytes and plasma, but not the optic nerves or trigeminal ganglia. Recovery of virus from the eyes of mice inoculated intravenously requires immunosuppression prior to infection. In normal mice, direct intraocular inoculation of MCMV produces pathology on the eyelid, conjunctiva and cornea. The virus spreads to the ocular muscles and chorioretinal layer before establishing a generalized infection. Supraciliary or subretinal inoculation of mice immunosuppressed by methylprednisolone administration, radiation treatment, or retrovirus-induced immunodeficiency (MAIDS) results in virus replication and destruction of the retina. Systemic administration of interleukin 2 (IL-2), but not IL-12, mitigates MCMV-associated retinitis in mice with MAIDS, and the adoptive transfer of MCMV-immune lymph node cells confers protection from retinitis. Upon immunosuppression, latent virus is reactivated and recovered from ocular and nonocular tissues.

Cardiac infections

Myopericarditis and dystrophic cardiac calcification are associated with MCMV inoculation of the heart. Uninfected recipients of hearts heterotropically transplanted from infected donors develop a fatal, generalized infection.

Arteritis

Genetically resistant or susceptible mice feeding on commercial or atherogenic diets develop MCMV-associated inflammatory lesions in the aorta and pulmonary artery after MCMV exposure.

Cerebral infections

Severe ependymitis, encephalitis and cerebral malformation are sequelae to intracerebral inoculation of MCMV into suckling mice. Inoculation of virus into the cerebral ventricles of embryos disrupts neuronal migration and causes neuronal loss. In tissue culture, interferon γ (INF-γ) treatment of permissive MCMV-infected-microglial cells suppresses virus infection.

Lethal hepatitis

Intraperitoneal inoculation with a lethal dose of MCMV is followed by a marked increase in serum transaminase levels and severe liver pathology.

Skin infections

Following intravenous inoculation, lesions on the mouth, ears, tail and feet are associated with vascular damage, edema, cellular infiltration, and swollen endothelial cells. Upon histologic examination, infected cells are detected in the dermis, but not the epidermis. However, antibodies against the MCMV 98-kDa structural protein are cross-reactive with the stratum spinosum and the outer sheath of hair follicles.

Response to Infection

Host immune response

In general, mice are genetically susceptible, moderately resistant, or resistant to MCMV infection. The genetic resistance locus (Cmv1) spans 0.4 map units on chromosome 6 of the mouse and is tightly linked to genes *Ly49* and *Nkrp1* of the natural killer complex. Some strains of mice primarily use CD8+ T cells to control MCMV replication, whereas others use natural killer cells. In mice moderately resistant (C57BL/10) or resistant (CAB/CaH) to MCMV infection, natural killer cells mediate viral clearance without a requirement for CD4+ or CD8+ T cells, although increased numbers of CD4+ T cells and activated macrophages are detected. Natural killer cells in SCID mice devoid of functional T and B cells mediate MCMV-associated pathology. In susceptible mice (BALB/c or A/J), CD8+ T cells primarily limit viral replication. CD4+ T cells expressing mRNAs for IFN-γ, IL-2 and IL-4 are required for antibody responses and delayed type hypersensitivity in all mice regardless of genetic background. Viral clearance is also influenced by organ-specific mechanisms. For example, clearance of virus from salivary glands requires a subset of CD4+ T cells, but not CD8+ T cells. MCMV resistance in the spleen of C57BL/6 mice is natural killer-cell perforin-mediated, whereas natural killer cell-associated IFN-γ regulates MCMV synthesis in the liver.

Initial MCMV infection induces IFNs, IL-12 and tumor necrosis factor (TNF), followed by increased levels of IL-1α, IL-6 and glucocorticoid early in infection. IFN-α induces natural killer cell blastogenesis and cytotoxicity, but not IFN-γ production by natural killer cells. IL-12 induces natural killer cell-associated IFN-γ production. Pretreatment of mice with IFN-α and IFN-γ significantly reduces mortality. IFN-α- and IFN-γ-associated reduction of MCMV replication in tissue culture correlates with the decreased availability of NF-κ B, which, in turn, leads to a cascade of reduced (via unused NF-κ B elements located in the MIE enhancer) IE mRNA,

pp89 production, E transcription, viral DNA synthesis, and nucleocapsid formation.

MCMV immune modulation

MCMV infection induces a generalized immune suppression, but enhances autoimmunity and exacerbates graft-versus-host disease. Immune suppression correlates with the mouse's genetic phenotype (susceptibility). Sublethal infection of susceptible mice reduces the number of myeloid and erythroid progenitor cells in the bone marrow, decreases leukocyte counts in the peripheral blood, and reduces (by 80–90%) the number of thymocytes recovered from the thymus. The bone marrow atrophy and loss of cortical thymocytes is not due to lytic infection of bone marrow cells or thymocytes, but may be associated with increased maturation and migration of bone marrow cells to the sites of virus infection or Fas-mediated apoptosis (in thymocytes or bone marrow cells). Thymic involution coincides with bone marrow hypoplasia, but the two appear to be independent events. Myelosuppression is restored after treatment with the immunomodulator AS101 [ammonium trichloro (dioxyethylene *O-O'*)tellurate].

Autoimmunity is a common manifestation of cytomegalovirus infections. Thymic involution may impair the elimination of autoreactive T cells, thus promoting autoimmunity. CD4+-dependent antibody profiles are altered showing increases in serum immunoglobulin (reactive with autologous tissues and ovalbumin) levels in general and 6–20-fold increases in IgG_3 and IgG_{2b} levels specifically. Antibodies with specificity toward the 98-kDa structural protein are neutralizing, but are also cross-reactive with mouse neurofilament protein (NFP), which is a component of the central and peripheral nervous systems, and to a lesser extent to the stratum spinosum of the skin and the outer sheath of hair follicles. Concurrent MCMV infection in bone marrow transplants exacerbates the host-versus-graft reaction.

MCMV encodes genes whose proteins are immune modulators. The nonapeptide YPHFMPTNL from the immunodominant immediate early protein (pp89) elicits a protective MHC class I H-$2L^d$-restricted CD8+ T-lymphocyte response. During a permissive infection, several MCMV early-gene functions from a 6.8-kb region within the *HindIII* E restriction fragment prevent transport of the trimolecular complex of H-$2D^b$ from the endoplasmic reticulum-*cis* Golgi compartment and independently prevent maturation of the class I heavy chains to the fully glycosylated forms. Degradation of class I molecules is not affected. The decrease in MHC class I expression on the surface of the infected cell prevents priming of the antigen-specific helper and cytotoxic T cells, thereby protecting the infected cell from the effects of cytotoxic T cells. Treatment with IFN-γ causes a 25-fold increase in the presentation of MHC class I molecules containing the pp89-derived nonapeptide; the excess molecules apparently become surface-exposed, thereby restoring susceptibility to primed T-cells. In viruses recovered from wild mice populations, variation in the immediate early-CTL epitope in 19 of 27 virus isolates potentially explains why CTLs primed against some isolates did not react with cells infected by heterologous MCMV isolates.

Additional immune modulators include a MHC class I homologue (m144), which potentially disrupts the presentation of peptides by native MHC class I molecules to cytotoxic T cells, and MCMV gp34, which binds to MHC class I complexes, thereby counteracting the retention of the complex in the endoplasmic reticulum-*cis* Golgi compartment. It is thought that presentation of the m144 homologue and the gp34–MHC class I complex on the surface of the infected cell is necessary for defense against attack by natural killer cells. MCMV also encodes a Fc receptor homologue which is expressed and glycosylated into 86–88-kDa and 105-kDa forms. And, lastly, several MCMV genes have homology to the beta class of chemotactic cytokines.

Prevention and Control

Immunization with vaccines remains the mainstay for prophylactic prevention of virus-associated diseases. As a model for HCMV vaccines, MCMV vaccines are readily available as one passage in tissue culture is sufficient to attenuate the virus. However, reversion occurs after passage *in vivo*. Sodium periodate-inactivated virus is innocuous, elicits a strong humoral response and protects mice from a lethal challenge for a three-week period. The administration of the CTL-specific nonapeptide from the immediate early pp89 protects mice; however, variability in this sequence in wild-type virus may render this strategy ineffectual. Intradermal DNA immunization with pp89 provides variable protection from lethal challenge and interferes with virus replication.

Combination immunotherapy with IFN-γ/TNF-α increases infected mouse survival rates and decreases virus replication *in vitro*, but not *in vivo*. Systemic immunotherapy with IL-2, but not IL-12, reduces the frequency of MCMV-induced retinitis in mice with MAIDS. Administration of the octapeptide thymic humoral factor (THF-γ 2) enhances the immunocompetence of spleen cells and restores MCMV-suppression of T cell mitogenic responses and IL-2 secretion.

Immunotoxins containing MCMV-specific IgG linked to deglycosylated ricin A chain or gelonin (ribosome-inactivating enzyme) inhibit MCMV replication. Immunomodulators such as BCH-527 (the hydrochloride salt of D-alanyl L-glutamine), lactoferrin, polyinosinic:polycytidylic acid (poly(I:C)), GLA-60 (synthetic lipid A subunit analogue), and iota-carrageenan (i-CAR) mediate viral spread by modulating the immune response.

Several antiviral drugs, including ganciclovir (GCV and its derivatives SR3772 and SR3773), BMS-180194, HPMPA, HPMPC and cidofovir are effective at reducing MCMV replication and extending the survival of MCMV-infected immunodeficient mice. Virus cross-resistance to the antivirals correlates with mutated viral DNA polymerase and not the phosphorylation of the drug (MCMV does not encode a thymidine kinase). Drug-resistant viruses are often markedly attenuated in their ability to kill SCID mice. Combined GCV/THF-γ 2 therapy significantly reduces MCMV in the salivary glands of intraperitoneally infected mice. GCV and immunotoxin synergistically extend survival time of infected SCID mice.

Future

The most striking advantage of the murine cytomegalovirus system is its potential for answering questions concerning the molecular biology of cytomegalovirus infection while simultaneously providing an *in vivo* system for testing molecular hypotheses in a naturally occurring biological context. Numerous homologies to HCMV bespeak the usefulness of *in vivo* MCMV infections as a surrogate for HCMV infections.

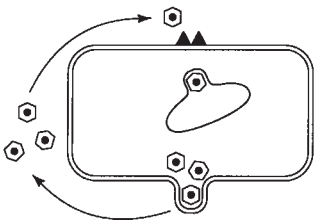
D

DEFECTIVE INTERFERING VIRUSES



Laurent Roux, Department of Genetics and Microbiology, University of Geneva Medical School, Geneva, Switzerland

History

In 1943, Henle and Henle reported the decreased infectivity for mice of influenza virus stocks obtained after a series of undiluted passages in embryonated chicken eggs. In the early 1950s, von Magnus showed that such undiluted passages generate incomplete virus particles capable of limiting the growth of infectious virus (hence exhibiting interference). This first characterization was soon followed by similar reports by Mims, on the one hand, and Cooper and Bellet, on the other, dealing respectively with Rift Valley fever virus and vesicular stomatitis virus (VSV). In the late 1950s, Cooper and Bellet went so far as to assign interference to sedimentable particles, but failed to identify them as antigenically related to VSV. From the mid-1960s on, the characterization of other positive- and negative-stranded RNA virus defective particles continued. In 1970, a review by A. Huang and D. Baltimore set the basic definition of defective interfering (DI) particles and emphasized their widespread occurrence. Since then, DI particles have been described for almost all the known DNA and RNA viruses, including plant and even fungal viruses.

Structure

DI particles have the same protein composition as their homologous nondefective 'parents', often called (St). However, they differ from the St particles in the primary structure of their genome. As emphasized later, DI genomes lack part of the genetic information. They may or may not serve as coding sequences. However, they always conserve the *cis*-sequences needed for replication initiation (origins of replication), sometimes present in more than one copy, and sequences involved in encapsidation. Foreign sequences can also be inserted. DI particles can sometimes be separated from St particles on the basis of size, when the size of the particle closely corresponds to the size of the genome (for instance rhabdovirus), or on the basis of particle density differences (changes in nucleic acid to protein ratios). Often, however, only viral stocks enriched in DI particles are available owing to the size heterogeneity of the virus particles.

Generation of DI Genomes

DI DNAs very likely arise from various recombinational events not necessarily linked to genome replication, and which result in deletion, tandem duplication, insertion of host DNA and polymerization of small monomer sequences. DI RNAs have been proposed to arise almost exclusively during genome replication by a mechanism of 'leaping polymerase' consisting of polymerase stop/fall off or slippage/reinitiation events (**Fig. 1**). In this model the replicase complex moves with the nascent RNA still attached to it. Depending on where reinitiation takes place, and on the number and the direction of the leaps, the resulting molecules can be of the copy-back type, with more or less intramolecular inverted complementary sequences (A), of the internal deletion type (B), and of the duplication type (C). Multisteps (B) or (C) and combinations of steps (B) and (C) can, moreover, lead to various mosaic types. Insertion of host RNA is also observed, especially in plant DI RNA. The frequency at which the polymerase leaps and resumes its synthesis is unknown. The probability for this exercise to be successful in producing a viable DI genome has been estimated for VSV to range in the order of 10^{-7} to 10^{-8} per genome replication.

Defectiveness

The DI genomes contain interrupted or rearranged open reading frames. They partly or completely lack the full coding capacity of the viral genome. They are

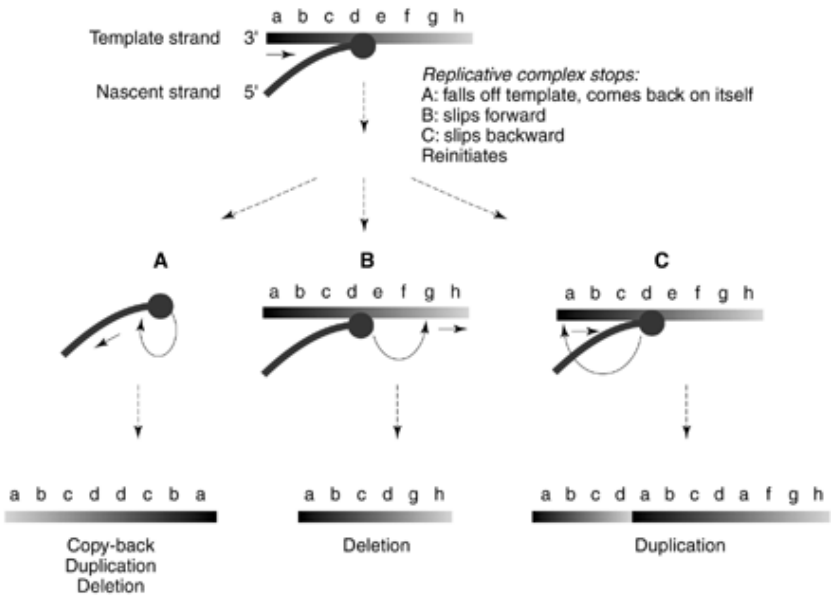


Figure 1 Defective RNA genome generation.

therefore defective, and depend for their replication and for their propagation (formation of virus particles) on the functions provided by the homologous standard virus (helper). Co-infection of cells with DI and standard particles is therefore essential for DI particle multiplication. Consequently, low-multiplicity infections, and particularly plaque purification, represent conditions which decrease, and potentially eliminate, DI particles from a viral preparation.

Interference

As stated earlier, the generation of a defective genome is likely to represent a rare event. This event would never be seen unless it was successfully amplified. During this amplification step the defective genome is preferentially replicated over the nondefective genome. This ability to replicate efficiently at the expense of the nondefective genome is called interference. The mechanisms of interference are not completely understood. They obviously change depending on the specificity of the viruses, and appear to be also affected by the host cell types. In general, interference involves an early step in genome replication, and can be pictured as a competition for limiting replication 'factors' (viral replicase, encapsidation proteins, host cell factors). Reiterated origins of replication or encapsidation sites on DI DNAs, presence of higher affinity sites for the replicase or for the encapsidation on both positive and negative polarity DI RNAs, and shorter length of the replicating units, higher availability for replication of molecules not involved in transcription, have been shown or postulated as taking part in the interference mechanism.

Defective Interfering versus Defective Viruses

Based on the outcome of experimental co-infections of defective with nondefective viruses, a distinction has been made between defective interfering or defective noninterfering particles, according to the ability of the defective viruses to selectively restrict nondefective virus replication. This distinction may not apply during the first events following the generation of a defective genome. As this is bound to be a rare event, then an interference mechanism has to be invoked any time this defective genome is amplified to the point it can be detected, or become predominant.

Cyclic Variations of Defective Interference

The dependence of DI genome replication on functions provided by the nondefective genome on the one hand, and the interference exhibited by DI genome on the other hand, result in out-of-phase cyclic variations of both DI and St genome replication. As illustrated in **Fig. 2**, efficient St genome replication must precede extensive DI genome replication. This in turn establishes conditions of high interference which results in

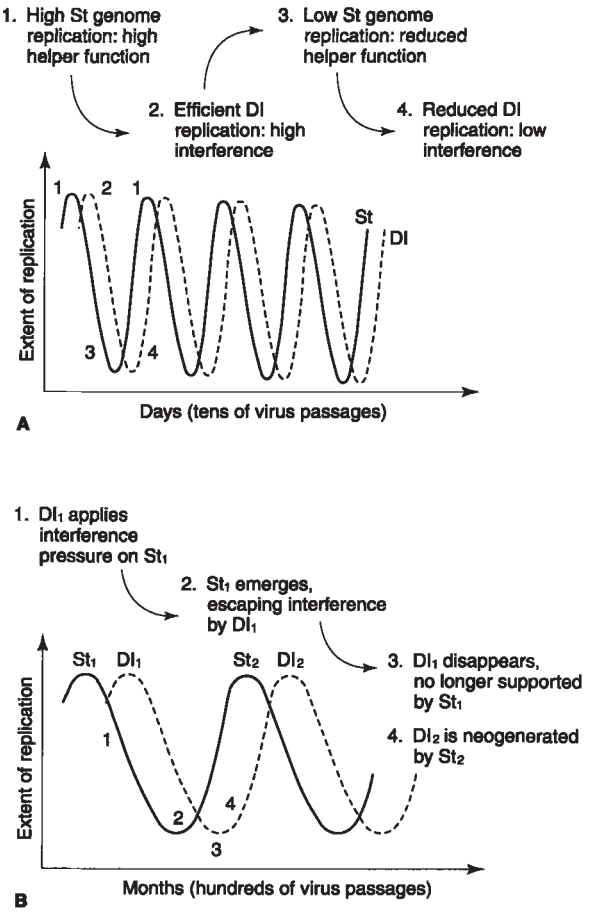

Figure 2 Cyclic variation of DI replication in (**A**) days, and (**B**) months.

inhibition of St genome replication. Decrease of helper function availability leads to DI genome replication dampening, and therefore to release from interference, allowing efficient St genome replication to resume. These cyclic variations have been observed in serial passages of St and DI viruses in cell culture as well as in persistent infections. The periodicity of a complete cycle is generally a matter of days or of a few serial passages.

Assay for DI Particles

DI particles can be detected by physical separation on velocity or density gradients when applicable (see above, Structure). The presence of subgenomic nucleic acids in viral stocks or in infected cells (distinct from viral messengers) can also be diagnostic. The ability to decrease the infectivity of a viral stock or to protect infected cells from the lytic infectious virus (see below, Biological Effects) are used in various biological assays to estimate quantitatively and qualitatively the DI particle composition of a viral stock. These assays, although appropriate to characterize DI particle preparations, are generally not sensitive enough to exclude, when negative, the presence of DI particles in a viral preparation. The test that still remains the most dependable to assess presence or absence of DI particles consists of multiple independent serial undiluted passages. It is based on the observation that a viral stock contaminated with an undetectable amount of DI particles will, on subsequent independent serial passages, promote in each series amplification of the same contaminating DI particles. A DI particle-free stock, on the other hand, will yield in each series different DI particles or different sets of DI particles.

Biological Effects

DI particles have been shown to modulate the course of an infection. In cell culture, attenuation of the cytopathic effects is the most frequently described, and DI particles can promote cell survival and establishment of persistent infections. As far as negative-stranded RNA viruses are concerned, copy-back DI RNAs appear to prevent induction of apoptosis through a mechanism which has still to be unravelled, in which a certain category of small leader RNAs may participate. A possible role of the matrix M protein, the concentration of which is decreased to the point where viral assembly and budding at the cell surface is highly diminished in the presence of DI genomes, has also been considered. DI interfering ability selectively allows emergence of St virus (St2) which escapes interference (**Fig. 2B**). St2, resistant to interference, is selectively amplified over St1, still sensitive to interference, and soon becomes predominant. It loses its ability to support DI1, which therefore disappears. St2 will generate its own DI2, which in turn will favor emergence of a new St variant. Thus, DI viruses serve as mutational drivers favoring virus evolution, through cycles of high and low interference whose periodicity is this time measured in months or in hundreds of viral passages (compare **Fig. 2A** and **2B**).

DI Particles in Experimental Animals

DI particles are generated and amplified in the whole animal as well as in cell culture. They can change the symptoms of viral infection from rapid death to slow, progressing paralysis. They can sometimes fully protect the animals from an otherwise lethal infection. Interference is likely to be involved in this modulation of symptoms, but other phenomena like

increased interferon induction and immune response modulation are reported.

DI Particles in Natural Infections

Involvement of DI particles in natural infections is still poorly documented. This is partly because the experimental results supporting the strong potential for infection modulation of DI particles have not been fully recognized, as detection of DI particles in natural infections is not straightforward. Unpredictable cyclic variations in DI replication, efficiency of DI replication changing with the types of infected tissues, and potent interfering ability associated with poor DI particle replication are all factors which undoubtedly make DI particle detection difficult *in vivo*. Last but not least, virus isolation, which is used to characterize the infectious agent associated with a disease, often represents conditions (low multiplicity of infection) known to impair drastically DI particle replication.

Nevertheless, association of a chicken influenza virus strain, efficiently producing DI particles, with an epidemic of low morbidity and low mortality, and conversely, a high-mortality epidemic associated with a strain free of DI particles, have been reported. Murine and feline leukemia virus strains causing immunedeficiency syndromes are shown to contain predominantly replication-defective viral genomes before onset and during the development of the disease. The pathogenicity of some bovine and swine pestiviruses has clearly been associated with presence of DI RNAs in the animals. For the bovine viral diarrhea virus (BVDV), a pestivirus of the same family as hepatitis C virus, the presence of a particular DI RNA can turn noncytopathic virus into a fatal infectious agent. In plants, at least three examples of DI RNAs are described to be involved in infection modulation. Interestingly, depending on the types of viruses, DI RNAs can either attenuate or exacerbate the symptoms.

DI RNAs are identified in stool and blood samples of humans suffering from hepatitis A virus, an infection known to be rather moderate and prolonged. DI particles are identified in measles virus-attenuated vaccine preparations which have been, and are being, widely and successfully used (raising the question of DI particle participation in vaccine attenuation). Measles viruses defective in viral assembly are currently found associated with human subacute sclerosing panencephalitis (SSPE). The brain cells of SSPE patients were, moreover, shown to harbor many species of measles virus copy-back DI RNAs. Direct amplification of a portion of the HIV *tat* gene from infected patients demonstrates that about a third of the sequences correspond to defective *tat* function. Moreover, human immunodeficiency virus (HIV)-1 sequences isolated from a cohort of six blood or blood product recipients infected with one donor all contained a similar deletion in the *nef* gene. Remarkably, all the patients harboring this deleted viral genome remained free of HIV-related diseases 12–16 years after infection, suggesting that this defective species of HIV genome is responsible for this decreased pathology. Epstein–Barr virus (EBV) replicative infections developing in human epithelial lesions involve a deleted rearranged form of EBV DNA (het DNA). This het DNA is associated, in experimental infections, with disruption of latency and persistent productive infections. Specific identification of viral hepatitis B (HBV) genomes containing an interrupted precore antigen (HBeAg) coding sequence in patients dying from fulminant hepatitis suggests that such defective genomes may be responsible for the exacerbation of the disease. This contrasts with more recent data reporting experimental evidence for the existence of DI-like viruses in HBV human chronic carriers; fluctuations between these naturally occurring core internal deletion variants and helper HBV in three chronic carriers were reminiscent of the cycling phenomenon in other DI viral systems.

Future Perspectives

Defective interfering particles are ubiquitous in the realm of animal and plant viruses. In experimental conditions they appear as necessary companions of their nondefective homologues. Capable of affecting the extent of viral growth, the course of viral infections, and serving as selective pressure to drive mutational changes, they can be seen as natural regulators of virus evolution. The demonstration of their participation in natural infections, and of their ability to affect the course of diseases, constitutes a challenge for the years to come. As pointed out by the few examples listed earlier, their direct detection in infected tissues will certainly be needed to assert their involvement in natural infections. The availability of sensitive detection techniques (like polymerase chain reactions), allowing direct observation of viral genomes without the possible distortion of virus isolation, bears great hope. More than giving increased insights into the physiopathology of viral infections, in times where the modifications of the viral genomes represent an imperative step in the generation of viral recombinant vaccines or of appropriate vectors for gene targeting, DI viral genomes represent natural versions of defective genomes that can serve as model tools for creation of more adapted vectors.

DENGUE VIRUSES *(FLAVIVIRIDAE)*

Duane J Gubler, Division of Vector-Borne Infectious Diseases, Fort Collins, Colorado, USA

History

Dengue fever is a very old disease; the earliest record of a dengue-like illness found to date is in a Chinese encyclopedia of disease symptoms and remedies, first published during the Chin Dynasty (265–420 AD) and formally edited in 610 AD (Tang Dynasty) and again in 992 during the Northern Sung Dynasty. There are reports of epidemics of dengue-like illnesses in the French West Indies in 1635 and in Panama in 1699. By the late 1700s, the disease had a worldwide distribution in the tropics, with epidemics of a clinically compatible disease occurring in 1779 in Batavia (Jakarta), Indonesia and Cairo, Egypt, and in 1780 in Philadelphia, Pennsylvania, USA. From the late 1700s to World War II, repeated epidemics of dengue-like illness occurred in most tropical and subtropical regions of the world at 10- to 30-year intervals. There is no documentation, however, that dengue viruses were responsible for all of these epidemics because diagnosis was based only on clinical reports. Clinical descriptions of some early epidemics were compatible with chikungunya virus infection, which has a transmission cycle similar to dengue. It is likely that epidemic chikungunya did occur, but recent data show that the dengue viruses, not chikungunya, were responsible for the majority of epidemics in the past 50 years.

The virus etiology of dengue fever was not documented until 1943–1944, when Japanese and American scientists simultaneously isolated the viruses from soldiers in the Pacific and Asian theaters during World War II. Albert Sabin isolated dengue viruses from soldiers who became ill in Calcutta, India, New Guinea and Hawaii. The viruses from India, Hawaii and one strain from New Guinea were antigenically similar, whereas three other strains from New Guinea appeared to be different. These viruses were called dengue 1 (DEN-1) and dengue 2 (DEN-2) and designated as prototype viruses (DEN-1, Hawaii, and DEN-2, New Guinea C). The Japanese virus, isolated by Susumu Hotta, was later shown to be DEN-1. Two more serotypes, called dengue 3 (DEN-3) and dengue 4 (DEN-4), were subsequently isolated by William Mcd. Hammon and his colleagues from children with hemorrhagic disease during an epidemic in Manila, Philippines, in 1956. Although thousands of dengue viruses have been isolated from different parts of the world since that time, all fit antigenically into the four serotype classification.

Many early workers suspected that dengue viruses were transmitted by mosquitoes, but actual transmission was first documented by H. Graham in 1903. In 1906, T. L. Bancroft demonstrated transmission by *Aedes aegypti,* later known to be the principal urban mosquito vector of dengue viruses. Subsequent studies in the Philippines, Indonesia, Japan and the Pacific showed that *Aedes albopictus* and *Aedes polynesiensis* were also efficient secondary vectors for dengue viruses.

During and following World War II, *Ae. aegypti* greatly expanded its distribution in Asia, becoming the dominant day-biting mosquito in most Asian cities. A dramatic increase in urbanization in the postwar years, created ideal conditions for increased transmission of urban mosquito-borne diseases. These changes, plus an increased movement of people within and between countries of the region via air-

It is likely that epidemic chikungunya did occur, but recent data show that the dengue viruses, not chikungunya, were responsible for the majority of epidemics in the past 50 years.

The virus etiology of dengue fever was not documented until 1943–1944, when Japanese and American scientists simultaneously isolated the viruses from soldiers in the Pacific and Asian theaters during World War II. Albert Sabin isolated dengue viruses from soldiers who became ill in Calcutta, India, New Guinea and Hawaii. The viruses from India, Hawaii and one strain from New Guinea were antigenically similar, whereas three other strains from New Guinea appeared to be different. These viruses were called dengue 1 (DEN-1) and dengue 2 (DEN-2) and designated as prototype viruses (DEN-1, Hawaii, and DEN-2, New Guinea C). The Japanese virus, isolated by Susumu Hotta, was later shown to be DEN-1. Two more serotypes, called dengue 3 (DEN-3) and dengue 4 (DEN-4), were subsequently isolated by William Mcd. Hammon and his colleagues from children with hemorrhagic disease during an epidemic in Manila, Philippines, in 1956. Although thousands of dengue viruses have been isolated from different parts of the world since that time, all fit antigenically into the four serotype classification.

Many early workers suspected that dengue viruses were transmitted by mosquitoes, but actual transmission was first documented by H. Graham in 1903. In 1906, T. L. Bancroft demonstrated transmission by *Aedes aegypti,* later known to be the principal urban mosquito vector of dengue viruses. Subsequent studies in the Philippines, Indonesia, Japan and the Pacific showed that *Aedes albopictus* and *Aedes polynesiensis* were also efficient secondary vectors for dengue viruses.

During and following World War II, *Ae. aegypti* greatly expanded its distribution in Asia, becoming the dominant day-biting mosquito in most Asian cities. A dramatic increase in urbanization in the postwar years, created ideal conditions for increased transmission of urban mosquito-borne diseases. These changes, plus an increased movement of people within and between countries of the region via air-

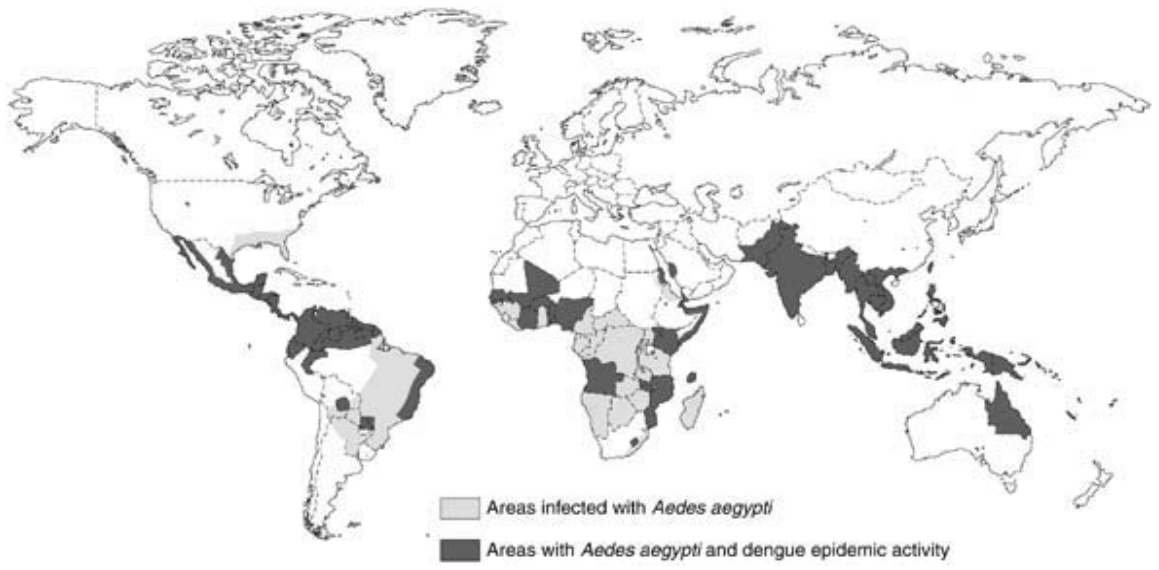

Figure 1 Global distribution of dengue fever and the principal epidemic mosquito vector, *Aedes aegypti*.

plane, resulted in increased movement of dengue viruses between population centers, increased frequency of epidemic activity, the development of hyperendemicity (co-circulation of multiple serotypes) and the emergence of dengue hemorrhagic fever/dengue shock syndrome (DHF/DSS) in many countries of southeast Asia during the 1960s. By 1975, DHF/DSS was a leading cause of hospitalization and death among children in the region. During the 1980s and 1990s, epidemic DHF/DSS continued to expand geographically in Asia. DHF/DSS moved into the Pacific islands in the 1970s. In the Americas, where *Ae. aegypti* had been eradicated from many countries to control yellow fever, increased epidemic dengue fever closely followed the reinfestation of countries by the mosquito in the 1970s, 1980s and 1990s. With the development of hyperendemicity, DHF/DSS has emerged as a global public health problem in the past 20 years. In 1997, dengue fever is the most important arbovirus disease of humans with over 2.5 billion people living in areas at risk for dengue in a belt around the tropics of the world (**Fig. 1**). An estimated 100 million cases of dengue fever, and over 500 thousand cases of DHF/DSS occur each year. The average case fatality rate for DHF/DSS is 5%.

Classification

Dengue viruses belong to the family *Flaviviridae*, genus *Flavivirus*. There are four serotypes: DEN-1, DEN-2, DEN-3 and DEN-4. They belong to a larger, heterogeneous group of viruses called arboviruses. This is an ecological classification, which implies that transmission between vertebrate hosts including humans is dependent on hematophagous arthropod vectors.

Dengue viruses, like other flaviviruses, consist of a single-stranded RNA genome surrounded by an icosahedral nucleocapsid. The latter is covered by a lipid envelope, which is apparently derived from the host cell membrane from which the virus buds. The complete virion is about 50 nm in diameter. The mature virion contains three structural proteins as follows: the nucleocapsid core protein (C), a membrane associated protein (M) and the envelope protein (E). Functional domains responsible for virus neutralization, hemagglutination, fusion and interaction with virus receptors are associated with the E protein. Epitope mapping has demonstrated three to four major antigenic sites.

Antigenically, the four dengue viruses make up a unique complex within the genus *Flavivirus*. Although the four dengue serotypes are antigenically distinct, there is evidence that serologic subcomplexes may exist within the group. For example, a close genetic relationship has been demonstrated between DEN-1 and DEN-4 using cDNA hybridization probes. Also, surprisingly, DEN-2 shows a high sequence homology (71%) with Edge Hill virus, an ecologically distinct flavivirus from Australia. There are over 70 antigenically related flaviviruses, including the genus prototype, yellow fever, Japanese encephalitis, Murray Valley encephalitis, St Louis encephalitis, West Nile, Kunjin, Zika and others, which are transmitted by mosquitoes. Another group of flaviviruses are tick-borne and include tick-borne ence-

phalitis, Omsk hemorrhagic fever and Kyasanur Forest disease. A small number of flaviviruses have no known anthropod vector.

Geographic and Seasonal Distribution

Dengue viruses have a worldwide distribution in the tropics (**Fig. 1**). The viruses are endemic in most urban centers of the tropics with transmission occurring year around. Epidemic transmission occurs periodically in most virus-endemic areas, usually at 3- to 5-year intervals. Because surveillance in most endemic countries is poor, cases usually are not reported during interepidemic years, thus misleading tourist and other agencies about the risk of infection. It is well documented, however, that dengue viruses are maintained during interepidemic periods in most tropical areas and, although risk of infection is lower than during epidemic periods, it is still substantial to unsuspecting visitors.

Peak transmission of dengue viruses is usually associated with periods of higher rainfall in most endemic countries. Factors influencing seasonal transmission patterns of dengue viruses are not well understood, but obviously include mosquito density, which may increase during the rainy season, especially in those areas where water level in larval habitats is dependent on rainfall. In areas where water storage containers are not influenced by rainfall, however, other factors such as higher humidity and moderate ambient temperatures associated with the rainy season increase survival of infected mosquitoes, thus increasing the chances of secondary transmission to other persons.

Host Range and Virus Propagation

There are only three known natural hosts for dengue viruses: *Aedes* mosquitoes, humans and lower primates. Viremia in humans may last 2–12 days (average, 4–5 days) with titers ranging from undetectable to over 10^8 mosquito infectious doses 50 (MID_{50}) ml^{-1}. Experimental evidence shows that several species of lower primates (chimpanzees, gibbons and macaques) become infected and develop viremia titers high enough to infect mosquitoes, but do not develop illness. Viremia levels in lower primates are more transient, often lasting only 1–2 days if detectable, with titers seldom reaching 10^6 MID_{50} ml^{-1}.

Dengue viruses are known to cause clinical illness and disease only in humans. Baby mice, which are used for the isolation and assay of many other arboviruses, generally show no signs of illness after intracerebral inoculation with most unpassaged strains of dengue viruses. Experimentally, however, some strains can be adapted to produce illness and death in baby mice.

Only species of the genus *Aedes* appear to be natural mosquito hosts for dengue viruses. Species of the subgenus *Stegomyia* are the most important vectors in terms of human transmission, and include *Ae. (S.) aegypti,* the principal urban vector worldwide, *Ae. (S.) albopictus* (Asia–Americas), *Ae. (S.) scutellaris* spp. (Pacific), *Ae. (S.) africanus* and *Ae. (S.) luteocephalus* (Africa). Species of the subgenus *Finlaya* (Asia) and *Diceromyia* (Africa) appear to be important mosquito hosts involved in dengue forest maintenance cycles. Two other species, *Ae. (Gymnometopa) mediovittatus* (Caribbean) and *Ae. (Protomacleaya)triseriatus* (North America) have been shown to be excellent experimental hosts for dengue viruses.

Low passage or unpassaged dengue viruses can only be propagated with consistent results in laboratory-reared mosquitoes and in mosquito cell lines. Mosquito species most commonly used for *in vivo* propagation include *Ae. aegypti, Ae. albopictus* and *Toxorhynchites* spp., all of which can be reared with ease in the laboratory. Only three mosquito cell lines show high susceptibility to dengue viruses: C6/36 from *Ae. albopictus,* AP-61 from *Ae. pseudoscutellaris* and TRA-284 from *Tx. amboinensis.*

Dengue viruses can also be propagated in baby mice (see above) and in several vertebrate cell lines. These all have lower susceptibility to infection than mosquito cells, however, and dengue viruses must be adapted to each system by serial passage before consistent results can be obtained. Mammalian cell lines commonly used include LLC-MK2 and VERO (monkey kidney), BHK-21 (baby hamster kidney), FRhL (fetal rhesus lung) and PDK (primary dog kidney).

Genetics

Laboratory studies have documented that genetic variants of dengue viruses occur in nature. DEN-3 viruses isolated during epidemics in Puerto Rico in 1963 and in Tahiti in 1965 are antigenically and biologically very similar to each other, but very different from Asian strains of the same serotype. Similar antigenic differences were observed between Caribbean and Asian strains of DEN-4.

Oligonucleotide fingerprinting, restriction enzymes, primer extension sequencing and limited nucleotide sequence comparison using polymerase chain reaction have all been used to study genetic variation among dengue viruses. In general, viruses circulating in the same geographic region during the

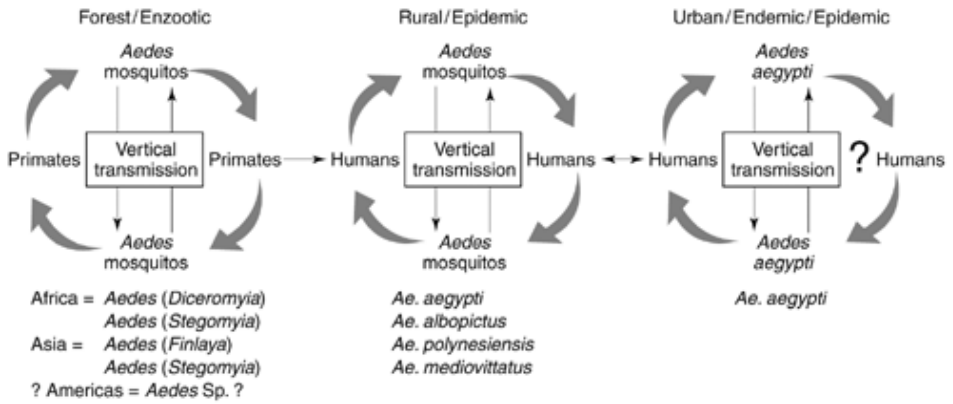

Figure 2 Natural transmission and maintenance cycles of dengue viruses.

same general time frame show genetic homogeneity, while differing from viruses of the same serotype from other regions. Oligonucleotide fingerprint analysis of DEN-2 viruses collected from the same area over a period of over 20 years suggests that the rate of change is very low (1.4% per year).

The number of genetic subtypes identified in each serotype varies with the method used, but more viruses have now been studied by partial nucleotide sequencing. Based on sequencing a 600 bp region of the envelope protein, which correlates well with sequencing the entire envelope protein, there are two distinct genotypes of DEN-1, five of DEN-2, four of DEN-3 and two of DEN-4. Of considerable epidemiologic interest is that there are currently two genotypes of DEN-2 circulating in the American region. One, designated Puerto Rico, has been in the Americas since at least 1952, whereas the second, designated Jamaica, was isolated for the first time from dengue patients in Jamaica during the Cuban epidemic of DHF/DSS in 1981. Analysis by restriction enzymes and primer extension sequencing has shown that the Jamaica virus is nearly identical to strains of DEN-2 isolated in Vietnam in 1987, suggesting that the DEN-2 virus causing the Cuban epidemic was introduced from Vietnam. This conclusion is supported by the fact that many Cubans were working in Vietnam on various aid projects during the late 1970s and early 1980s. The Jamaican genotype has subsequently become the predominant and most widespread strain of DEN-2 virus in the American region. There is no evidence that genetic reassortment or recombination of dengue viruses occur in nature, but this has not been fully studied. In recent years, with increased occurrence of the cocirculation of multiple serotypes in an area (hyperendemicity), there have been increased reports of concurrent infections with two serotypes. This will increase the probability that recombination might occur.

Evolution

The origin of dengue viruses is unknown. Their natural history, however, suggests that they were most likely mosquito viruses prior to becoming adapted to lower primates and humans. Biologically, dengue viruses are highly adapted to their mosquito hosts, being maintained by vertical transmission (from female mosquito to her offspring) in those species responsible for the forest maintenance cycle, with periodic amplification in lower primates (**Fig. 2**). Such forest cycles have been documented in southeast Asia and Africa. At some point in the past, probably with the clearing of the forests and development of human settlements in Asia, these viruses moved out of the jungle and into a rural environment where they were, and still are, transmitted to humans by peridomestic mosquitoes such as *Ae. albopictus*. Migration of people ultimately moved the viruses into the cities of the tropics where they became 'urbanized' and transmitted by the highly domesticated, urban *Ae. aegypti* mosquito.

Because of the rather slow rate of change (genetic drift) of the dengue virus genome, viruses isolated over long periods of time in the same geographic region still show striking homogeneity. The greatest genetic difference between dengue virus strains was observed between DEN-2 isolated from forest mosquitoes in Africa and viruses of the same serotype isolated from humans or mosquitoes in a nearby urban area. This would suggest that there is little gene flow between the forest and urban cycles. On the

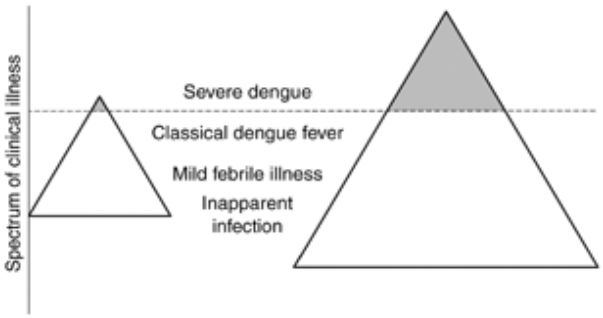

Figure 3 The iceberg concept of dengue/dengue hemorrhagic fever. The severe form of disease represents only the tip that protrudes from the water. As the incidence of infection increases, so too does the severe and fatal form of disease (see also Fig. 4).

other hand, both laboratory and field evidence suggests that significant genetic changes that influence epidemic potential do occur in nature (see below).

Serologic Relationships and Variability

Dengue viruses share common morphology, genomic structure and antigenic determinants with over 70 other flaviviruses. Serologic tests most frequently used to determine antigenic relationships have included the hemagglutination–inhibition (HI), complement fixation (CF) and the plaque reduction neutralization (PRNT) tests. Because all flaviviruses share common antigenic determinants, identification of individual family members using these tests is difficult. The dengue viruses make up one of eight complexes within the family *Flaviviridae*. They share complex-specific antigenic determinants on both structural and nonstructural proteins. Serotypes within the dengue virus complex are most accurately and easily identified with an indirect immunofluorescent antibody (IFA) assay using serotype-specific monoclonal antibodies which react to epitopes on the structural protein. They can also be readily identified using polymerase chain reaction (PCR).

Both antigenic and biologic variation among dengue viruses have been documented. As noted above, DEN-3 viruses isolated in the Caribbean and the South Pacific in the 1960s were found to be antigenically distinct from the prototype and Asian strains of DEN-3 using PRNT. They were also biologically unique in that they did not grow as well as Asian strains in baby mice and mosquitoes. DEN-4 viruses isolated in the Caribbean after the introduction of this serotype into that region in 1981 were antigenically distinct from DEN-4 viruses from Asia.

Field and epidemiologic evidence for natural strain variation among dengue viruses is more circumstantial. When dengue was introduced into the South and Central Pacific islands in 1971 after an absence of over 25 years, epidemics occurred on numerous islands. Marked variation was observed in disease severity, viremia levels and epidemic potential between epidemics. This variation was observed with both DEN-1 and DEN-2 in the Pacific and with DEN-3 in Indonesia. Some DEN virus strains appeared naturally attenuated, causing mild illness with low viremia levels of short duration, whereas others caused explosive epidemics with severe hemorrhagic disease and high viremia levels. Factors that could influence epidemic transmission and disease severity, other than differences in the virus strain, were ruled out as a cause of this variation.

Epidemiology

Dengue viruses exist in nature in three basic maintenance cycles (**Fig. 2**). The primitive forest cycle involves canopy dwelling mosquitoes and lower primates. A rural cycle, primarily in Asia and the Pacific, involves peridomestic mosquitoes (*Ae. albopictus* and *Ae. scutellaris* spp.) and humans. The urban cycle, which is the most important epidemiologically and in public health impact, involves the highly domesticated *Ae. aegypti*, mosquito and humans. The viruses are maintained in most large urban centers of the tropics with epidemics occurring at periodic intervals.

A combination of increased urbanization in the tropics, changing life styles and lack of effective mosquito control has made most tropical cities highly permissive for dengue transmission by *Ae. aegypti*. Increased air travel by humans provides the ideal mechanism for the transport of dengue viruses between population centers. As a result, in the past 20 years there has been a dramatic increase in the movement of dengue viruses within and between regions, resulting in increased epidemic activity, development of hyperendemicity (the cocirculation of multiple serotypes) and the geographic spread and increased incidence of the severe and fatal form of disease, DHF/DSS. Once observed only in southeast Asia, DHF/DSS has spread in epidemic form to west Asia, the Peoples Republic of China, the Pacific islands and the Americas in the past 18 years.

The factors responsible for the emergence and spread of epidemic DHF/DSS are not fully understood. The changing disease pattern described above provides support for both principal hypotheses on the pathogenesis of DHF/DSS, secondary infection and virus virulence. Thus, increased movement of viruses between population centers, increases transmission, and the development of hyperendemicity increases

both the chance of a secondary infection and the chance of a virulent virus emerging via natural selection or being introduced to an area. Increased transmission of multiple dengue serotypes increases the iceberg and thus the probability that severe disease will occur, regardless of whether the underlying cause is due to increased virulence, immune enhancement or, more likely, a combination of both (**Fig. 3**).

Dengue is primarily an urban disease. Most major epidemics of DHF/DSS occur in tropical urban centers where large and crowded human populations live in intimate contact with the principal mosquito vector, *Ae. aegypti*. This mosquito is a highly domesticated, day biting species that lives and breeds in and around the home. High mosquito densities often occur in tropical cities because of water storage practices and domestic trash. Primary larval habitats for *Ae. aegypti* include a variety of domestic water storage containers such as clay jars and pots, metal drums, cement cisterns and many other artificial containers found in the domestic environment that collect and hold rain water. The latter include, but are not limited to flower vases and pots, used automobile tires, buckets, bottles, cans, old machinery, etc.

Transmission and Tissue Tropism

Dengue viruses are only transmitted by the bite of an infective mosquito vector. All four serotypes may cause high levels of viremia in humans ($\geq 10^8$ MID_{50}/ml) that lasts an average of 4–5 days (range, 2–12 days). If a competent mosquito vector takes a blood meal from a person during this viremic phase, virus is ingested with the blood and infects the cells of the mosquito mesenteron. After 8–12 days, depending on ambient temperatures and the virus strain, the virus will disseminate and infect other tissues, including the mosquito salivary glands. When the mosquito takes a subsequent blood meal, virus is injected into the person along with the salivary fluids. Dengue virus infection has no apparent effect on the mosquito, which is infected for life.

Ae. aegypti is a highly competent epidemic vector of dengue viruses. It lives in close association with humans because of its preference to lay eggs in artificial water-holding containers in the domestic environment, and to rest inside houses and feed on humans versus other animals. It has a nearly undetectable bite and is very restless in the sense that the slightest movement will make them interrupt feeding and fly away. It is not uncommon, therefore, to have a single mosquito bite several persons in the same room or general vicinity over a short period of time.

In addition to transmitting the virus to humans or lower primates, the female mosquito may also transmit the virus vertically through the eggs to her offspring. Although the implications of vertical transmission are not fully understood, it is thought to be an important mechanism in the natural maintenance cycles of dengue viruses, especially in rural and forest settings.

The primary site of dengue virus replication after injection into humans by the feeding mosquito is believed to be phagocytic monocytes. Other tissues from which the viruses have been isolated include the liver, lungs, kidneys, lymph nodes, stomach, intestine and brain, but it is not known to what extent the virus replicates in these tissues. Pathological changes similar to those observed in yellow fever, with focal central neurosis, have been observed in the livers of some patients who died of dengue virus infection. There is some evidence that the viruses also replicate in endothelial cells and possibly in bone marrow cells. Although encephalopathy has been documented in dengue infection, evidence to date does not suggest that dengue viruses cross the blood–brain barrier and replicates in the central nervous system.

Pathogenicity

There is still considerable controversy about the pathogenesis of DHF/DSS. Evidence suggests that at least two pathogenetic mechanisms are associated with severe dengue infection. Classical DHF/DSS is characterized by a vascular leak syndrome, which if not corrected, may lead to hypovolemic shock and death. The underlying pathogenetic mechanism for this syndrome is thought to be an immune enhancement phenomenon whereby the infecting virus complexes with nonneutralizing dengue antibody, thus enhancing infection of mononuclear phagocytes which produce a vasoactive mediator responsible for increased vascular permeability. Loss of plasma from the vascular compartment may be mild and transient or severe and prolonged, the latter resulting in severe shock and death. Although classical DSS is most commonly associated with secondary dengue infections, it has also been documented in primary infections, which suggests that subneutralizing levels of homologous antibody or other substances may also cause immune enhancement.

In vitro studies have shown that not all dengue viruses can be enhanced and that there are qualitative differences in the enhancing ability of dengue antibody. This raises the question of whether dengue virus strains vary in their pathogenicity and, if so, how this influences the immune enhancement hypothesis. Because an animal model is not available, no good data exist that demonstrate variation in virulence among dengue viruses. However, an accumulat-

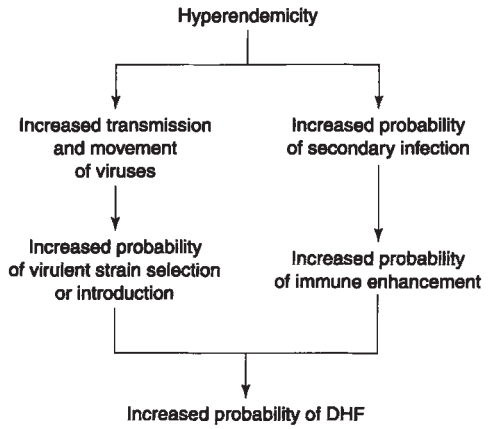

Figure 4 The cocirculation of multiple virus serotypes in a community (hyperendemicity) is the most important risk factor for the occurrence of dengue hemorrhagic fever and is compatible with the two principal hypotheses of pathogenesis, immune enhancement and virus strain variation.

ing mass of both experimental and field data suggest that dengue viruses, like most other animal viruses, do vary in their pathogenicity and their epidemic potential. When DEN-1 and DEN-2 viruses were introduced into the Pacific in the early 1970s after an absence of over 25 years, some islands experienced explosive epidemics with severe and fatal hemorrhagic disease whereas others with similar ecology experienced only low-level, sporadic and even silent transmission with mild illness. Virus strain variation was the only logical explanation for these differences. Recent laboratory evidence suggests that a major Cuban epidemic of DHF/DSS in 1981, the first of its kind in the American Region, was caused by a DEN-2 virus strain introduced from Vietnam, which was genetically distinct from the original American DEN-2 virus. This epidemic is often cited to support both immune enhancement and virus virulence hypotheses, which are not mutually exclusive. The most constant feature associated with the emergence of DHF/DSS in an area is the development of hyperendemicity (the cocirculation of multiple virus serotypes in the same community). This increases the probability of secondary infection, which has been shown to be associated with DHF/DSS, but hyperendemicity is also associated with increased movement of viruses between population centers, which increases the probability of introduction or of genetic selection of virus strains that have greater epidemic potential or virulence (**Fig. 4**).

Patients infected with dengue viruses who do not have classical DHF/DSS, may experience severe and uncontrolled bleeding, usually from the upper gastrointestinal tract. This severe hemorrhagic disease is often more difficult to manage than classical DHF/DSS. The underlying pathogenetic mechanism for this type of bleeding is clearly different from that of the vascular leak syndrome and involves disseminated intravascular coagulation and thrombocytopenia.

A third type of severe and fatal dengue infection, which may or may not involve overt hemorrhagic disease, is encephalopathy. Although many of these latter patients present clinically as viral encephalitis, conclusive evidence that dengue viruses infect the central nervous system has not yet been found. Available data suggest that neurologic symptoms may be secondary to cerebral hemorrhage, edema or other indirect effects of dengue virus infection.

Clinical Features of Infection

Dengue infection causes a spectrum of illness in humans ranging from clinically inapparent to severe and fatal hemorrhagic disease with the latter representing only the tip of the iceberg (**Fig. 3**). The incubation period may be as short as 3 days and as long as 14 days, but most often is 4–7 days. The majority of patients present with mild, nonspecific febrile illness or with classical dengue fever. The latter is generally observed in older children and adults, and is characterized by sudden onset of fever, frontal headache, retroocular pain and myalgias. Rash, joint pains, nausea and vomiting and lymphadenopathy are common. The acute illness, which lasts for 3–7 days, is usually benign and self-limiting, but it can be very debilitating, and convalescence may be prolonged for several weeks.

The hemorrhagic form of disease, DHF/DSS, is most commonly observed in children under the age of 15 years, but it also occurs in adults. It is characterized by acute onset of fever and a variety of nonspecific signs and symptoms that may last 2–7 days. During this stage of illness, DHF/DSS is difficult to distinguish from any number of other viral, bacterial and protozoal infections. In children, upper respiratory symptoms caused by concurrent infection with other viruses or bacteria are not uncommon. The differential diagnosis should include other hemorrhagic fevers, hepatitis, leptospirosis, typhoid, malaria, measles, influenza, etc.

The critical stage in DHF/DSS occurs when the fever subsides to or below normal. At that time, the patient's condition may deteriorate rapidly with signs of circulatory failure, neurologic manifestations, shock and death if proper management is not implemented. Skin hemorrhages such as petechiae, easy bruising, bleeding at the sites of venepuncture and purpura/ecchymoses are the most common hemorrhagic manifestations; gastrointestinal (GI) hemor-

Table 1 World Health Organization classification of dengue hemorrhagic fever

Grade I	Fever accompanied by nonspecific constitutional symptoms, with a positive tourniquet test and/or scattered petechiae as the only hemorrhagic manifestation
Grade II	The same as grade I, but with spontaneous hemorrhagic manifestations
Grade III	Circulatory failure manifested by rapid, weak pulse, narrowing of pulse pressure (20 mmHg or less), or hypotension
Grade IV	Profound shock with undetectable pulse and blood pressure

Source: Anon (1986) *Dengue Hemorrhagic Fever: Diagnosis, Treatment and Control.* Geneva: World Health Organization.

rhage may also occur, usually after, but in some cases before, onset of shock.

The World Health Organization (WHO) has defined strict criteria for diagnosis of DHF/DSS, with four major clinical manifestations: high fever, hemorrhagic manifestations, hepatomegaly and circulatory failure. WHO has classified DHF/DSS into four grades according to severity of illness: grades I and II represent the milder form of DHF and grades III and IV represent the more severe form, DSS (**Table 1**). Thrombocytopenia and hemoconcentration are constant features. However, there is some disagreement with the WHO case definition in that some patients may present with severe and uncontrollable upper GI bleeding with shock and death in the absence of hemoconcentration or other evidence of the vascular leak syndrome. These patients by the WHO criteria, cannot be categorized as having DHF/DSS. Additionally, hepatomegaly may not be a constant feature in all epidemics of DHF/DSS.

Dengue virus infection is associated with a variety of neurologic disorders, including headache, dizziness, hysteria and depression. In addition, some patients present with clinical symptoms of viral encephalitis, but as noted above, there is no conclusive evidence that actual CNS infection occurs.

Treatment for DHF/DSS is symptomatic, and the prognosis of the disease depends on early recognition, initiation of corrective fluid replacement and management of shock. Definitive diagnosis can only be made in the laboratory by serologic and/or virologic methods.

Pathology and Histopathology

The pathology of dengue virus infection is not well understood because systematic post-mortem studies have not been done on patients representing all types of clinical expression. The major pathophysiologic abnormality in classical DHF/DSS is an increase in vascular permeability which leads to leakage of plasma. Patients may have serous effusion in the pleural and abdominal cavities and a variable amount of hemorrhaging in most major organs. Studies have not revealed destructive inflammatory vascular lesions, but some swelling and occasional necrosis have been observed in endothelial cells, as well as some perivascular edema.

Limited studies on patients with a fatal outcome have demonstrated focal necrosis of the hepatic cells, Councilman bodies and hyaline necrosis of Kupffer cells in the liver. Changes in the kidney are suggestive of an immune-complex type of glomerulonephritis. There is depression of bone marrow elements which improve when the patient becomes afebrile. Biopsy studies of the skin rash have demonstrated perivascular edema with infiltration of lymphocytes and monocytes.

Immune Response

Persons infected with dengue viruses produce specific immunoglobulin (Ig)M and IgG antibodies, both of which appear in 5–7 days after onset of illness in primary infections. The highest titers of IgM antibody are produced in primary dengue infections, but it is also produced in secondary and tertiary infections. IgM antibody is transient and disappears in 30–90 days after onset of illness in primary infections and after shorter periods in secondary and tertiary infections. IgG antibody, by contrast, persists for at least 50 years and probably for the life of the patient. In persons experiencing their first dengue or flavivirus infection, peak IgG titers are reached 14–21 days after onset of illness and seldom exceed 1:640 to 1:1280, although there are exceptions. In secondary infections, on the other hand, there is an immediate anamnestic IgG immune response to dengue complex- and/or flavivirus-specific antigenic determinants. In these patients, IgG antibody titers may exceed 1:20 480. Both IgM and IgG antibodies neutralize dengue viruses, and infection provides life-long immunity to that specific dengue virus serotype.

Both IgM and IgG dengue antibodies crossreact with other flavivirus antigens, including yellow fever, Japanese encephalitis and St Louis encephalitis viruses. Crossing with viruses in the dengue complex is more extensive than with other flaviviruses, and

crossreactions make interpretation of serologic results difficult. In patients with second and third flavivirus infections, original antigenic sin reactions are not uncommon. In geographic areas where several flaviviruses are endemic, therefore, definitive laboratory diagnosis can only be made by virus isolation, and in patients with primary infection, by PRNT. Normally, a combination of laboratory (serologic and virologic) clinical and epidemiologic data are used to make a diagnosis of dengue and other flavivirus infection.

Because IgG antibody persists for many years, its presence in a single serum sample is not diagnostic unless it occurs at high titer ($\geq$1:1280 by HI and PRNT, $\geq$1:256 by CF or $\geq$1:163 840 by IgG ELISA), which is considered presumptive evidence of a recent infection. Lower IgG titers simply indicate that the person has had a previous infection at some time in the past. Paired serum samples are thus required to demonstrate a fourfold or greater rise in specific IgG antibody. The presence of detectable IgM antibody in a single serum sample, however, is considered to be diagnostic because this isotype does not persist for long periods. The diagnosis is considered presumptive, however, because IgM antibody does persist for up to 90 or more days.

There is some evidence that cell-mediated immunity may also play a role in terminating dengue infection. Thus, T-cell clones that kill dengue virus-infected cells have been identified.

Prevention and Control of Dengue

The options available for prevention and control of DEN/DHF are limited. Although currently not available, considerable progress has been made in recent years in development of a vaccine for dengue/DHF. Effective vaccination to prevent DHF will require a tetravalent, live attenuated vaccine. Promising candidate attenuated vaccine viruses have been developed and have been evaluated in phase I and II trials in Thailand. A commercialization contract has been signed and the tetravalent vaccine formulation is currently undergoing repeat phase I and II trials.

Promising progress has also been made on developing second-generation, recombinant dengue vaccines by using cDNA infectious clone technology. An infectious clone of the DEN-2, PDK-53 vaccine candidate virus has been constructed, and work is currently in progress to construct chimeric viruses by inserting the capsid, premembrane (PrM) and envelope genes of DEN-1, DEN-3 and DEN-4 into the DEN-2 PDK-53 backbone. These recombinants, through genetic manipulation, may be made to grow better, be more immunogenic and safer.

The development of other new technology such as DNA vaccines is in its infancy. Despite the promising progress, it is unlikely that an effective, safe and economical dengue vaccine will be available in the near future. It will likely be 10 or more years before an effective, safe, economical vaccine is commercially available. Currently, the only way to prevent dengue infection is to control the mosquito vector that transmits the virus.

Unfortunately, our ability to control *Ae. aegypti* is limited. For over 25 years, the recommended method of control was the use of ultra low volume (ULV) application of insecticides to kill adult mosquitoes. Field trials in Puerto Rico, Jamaica and Venezuela, however, showed that this method was not effective in significantly reducing natural mosquito populations for any length of time. This supports epidemiologic observations that ULV has little or no impact on epidemic transmission of dengue viruses.

The only truly effective method of controlling *Ae. aegypti* is source reduction, that is to eliminate or control the larval habitats where the mosquitoes lay their eggs. Most important larval habitats are found in the domestic environment, where most transmission occurs. To have sustainability of prevention and control programs, some responsibility for mosquito control must be transferred from government to citizen homeowners. Mosquito control programs, therefore, must be community-based and integrated. Persons living in *Ae. aegypti* infested communities must be educated to accept responsibility for their own health destiny by helping government agencies control the vector mosquitoes, and thus prevent epidemic dengue/DHF/DSS.

Countries with endemic dengue should develop active, laboratory-based surveillance systems that can provide some degree of epidemic prediction. Finally, prevention of excess mortality associated with DHF/DSS can be achieved by educating physicians in endemic areas on clinical diagnosis and management of DHF/DSS. As demonstrated in countries such as Thailand, early recognition and proper management are the key to keeping DHF/DSS fatality rates low.

Future

Continued population growth and urbanization of the tropics, changing lifestyles, increased air travel and lack of effective mosquito control have been the most important factors responsible for the dramatic increased incidence and geographic expansion of DHF/DSS in the 1980s and 1990s. DEN/DHF/DSS has become a global public health problem in the tropics and it is anticipated that this trend will continue unless something is done to reverse it. More

effective integrated prevention and control strategies must be developed and implemented worldwide in the tropics. Ultimately, development of an economical tetravalent vaccine holds the greatest promise for prevention and control.

DENSONUCLEOSIS VIRUSES (*PARVOVIRIDAE*)

Jacov Tal, Department of Virology, Ben-Gurion University of the Negev, Beer-Sheva, Israel

Introduction

Densonucleosis viruses (DNVs) belong to the subfamily *Densovirinae* within the *Parvoviridae* family. The other subfamily, the *Parvovirinae*, includes parvoviruses that infect a wide range of vertebrates, including humans. The DNV name (commonly shortened to densoviruses) is derived from the characteristic appearance of densely stained nuclei in the infected cells. The first DNV was isolated in 1964 from larvae of the greater wax moth *Galleria mellonella*. Over 25 additional DNVs have been isolated since from a variety of Lepidoptera, Diptera, Orthoptera and Odonata.

The criteria for the classification of densoviruses as parvoviruses are the physicochemical properties of the virion and the single-stranded DNA (ssDNA) genome with terminal palindromic structures. *Densovirinae*, however, constitute a highly diverse group of viruses with respect to genome structure and transcriptional patterns. However, the continued discovery of new DNVs with different properties dictates periodic updating of the taxonomy of these viruses.

Virion Composition and Genome Structure and Expression

The DNV virion is icosahedral, 19–24 nm in diameter, and composed of 12 capsomers. Typically, three density classes of 1.32, 1.40 and 1.44 g ml^{-1} are obtained in aqueous CsCl. The 1.32 density class contains 'empty' particles which are devoid of viral DNA and are not infectious. The other two density classes are both DNA-containing, infectious particles, having similar physicochemical properties. The DNV virion is composed of four structural proteins (VP1–VP4) with molecular weights of 76 000–110 000, 64 000–72 000, 52 000–62 000 and 42 000–49 000, respectively. The viral genome is a single-stranded DNA molecule of negative orientation. The 3′ and 5′ ends of the viral DNA can fold to form terminal hairpin structures which are utilized for self-primed DNA replication by the host DNA replication machinery, but these terminal sequences vary in size and in their internal architecture.

The current classification of members within the subfamily *Densovirinae* of the *Parvoviridae* family is

effective integrated prevention and control strategies must be developed and implemented worldwide in the tropics. Ultimately, development of an economical tetravalent vaccine holds the greatest promise for prevention and control.

The 3′ and 5′ ends of the viral DNA can fold to form terminal hairpin structures which are utilized for self-primed DNA replication by the host DNA replication machinery, but these terminal sequences vary in size and in their internal architecture.

The current classification of members within the subfamily *Densovirinae* of the *Parvoviridae* family is

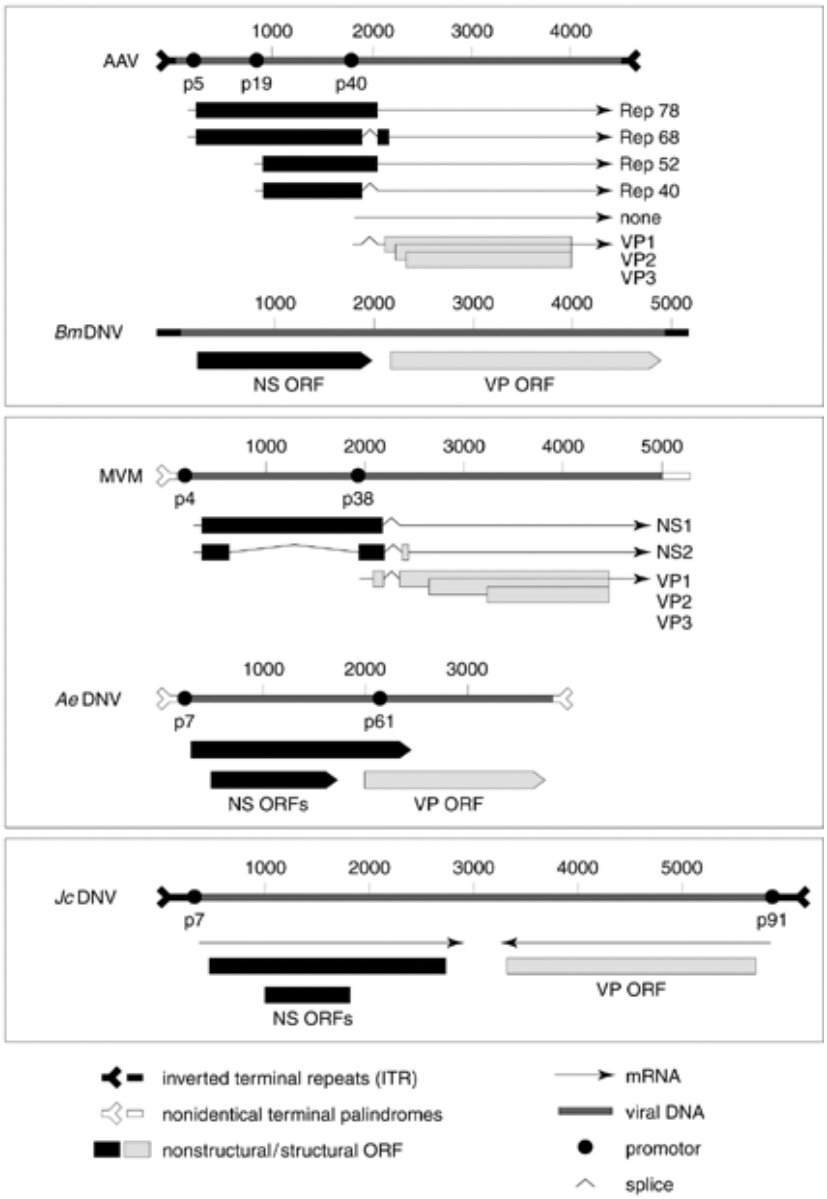

Figure 1 Organization of densovirus genomes compared with selected vertebrate parvoviruses. See text for details.

based primarily on their expression strategies. Genus *Iteravirus* [type species *Bm*DNV-1 (the Ina isolate)] bear the highest resemblance to the AAV (*Dependovirus* in the subfamily *Parvovirinae*). Like AAV, the 5048 nucleotide (nt) genome contains an inverted terminal repeat (ITR) on either end, the first 153 bases of which are palindromic, but the terminal T-shaped conformation, which is characteristic of AAV, is missing. The ITRs flank the coding sequences of the virus, all of which are clustered within the same strand, organized in two ORFs. Another similarity to AAV is that both encapsidate (+) and (−) DNA strands in separate virion particles in equal amounts (**Fig. 1**).

Genus *Brevidensovirus* (type species *Ae*DNV) bears resemblance to the vertebrate, autonomously replicating parvoviruses (genus *Parvovirus*) such as the minute virus of mice (MVM). Their DNA is the smallest among the parvoviruses: 4009 nt in *Ae*DNV and 4176 nt in *Aa*DNV). The hairpin structures on both ends differ in length (146 and 164 nt in *Ae*DNV; 134 and 182 nt in *Aa*DNV, at the 3′ and 5′ ends, respectively) and contain predominantly different nucleotide sequences, as in most autonomously replicating parvoviruses. Both termini can assume a T-shaped structure. Similar to autonomously replicating parvoviruses, the entire coding capacity of the viral DNA, located on one DNA strand, contains

partially overlapping ORFs, and the DNA (−) and (+) strands are encapsidated into separate virus particles. The encapsidation of the (−) strand is preferred and thus (−) strand-containing virions constitute about 90% of the progeny virions.

Genus *Densovirus* (type species *Gm*DNV and *Jc*DNV) form a third group with properties unique to invertebrate parvoviruses. They are characterized by long genomic DNAs (about 6 kb) and a considerably long ITR (440 nt) which, unlike AAV and *Bm*DNV, are all engaged in the terminal hairpin structure. They are the only group of parvoviruses in which both DNA strands encode viral proteins. Two TATA boxes are located within the ITRs at both ends at the junctions with the unique sequence (map positions 9 and 93), and a number of consensus sequences for polyadenylation are clustered in the middle of the genome, between the two ORFs. Both transcripts are polyadenylated and unspliced, approximately 2.5 kb in length. The right ORF encodes four viral structural proteins, and the left ORF encodes at least three nonstructural proteins: a prominent 30 kDa and two minor ones 55 kDa and 60 kDa in size. Hence, the basic organization of the right and left ORFs which encode structural and nonstructural proteins, respectively, is conserved albeit on separate strands.

The wide diversity of *Densovirinae* is only partially known to date and new genomic structures and expression mechanisms are being revealed as new DNVs are discovered. Recently, a new taxonomy has been proposed for DNVs with the suggested names *Densovirus, Brevidensovirus* and *Iteravirus* for genus A, B and C, respectively. A fourth genus, *Bidensovirus*, has also been proposed, based on the molecular structure of *Bm*DNV-2 shown to have a bipartite genome.

As in vertebrate parvoviruses, the cumulative size of these proteins exceeds the coding capacity of the viral DNA. To express all their proteins, vertebrate parvoviruses are therefore making use of a variety of mechanisms including multiple promoters, alternative splicing, the use of unusual initiation codon and proteolytic cleavage. To expand the use of their genomes, some DNVs (e.g. *Gm*DNV, *Jc*DNV) were so far shown to utilize multiple internal initiations of protein synthesis within their nonstructural and structural mRNA molecules. The peptide mapping of *Gm*DNV proteins has demonstrated that all four structural proteins contain extensive sequence homologies.

Host Range and Viral Propagation

The most extensively studied DNVs are those which infect the greater wax moth, *Galleria mellonella* (*Gm*DNV), the Buckeye caterpillar *Junonia coenia* (*Jc*DNV), the silkworm, *Bombyx mori* (*Bm*DNV), and the mosquitoes *Aedes aegypti* (*Ae*DNV) and *Aedes albopictus* (*Aa*DNV). Other DNVs include isolates from the cutworm, *Euxoa auxiliaris*, the cricket, *Acheta domestica*, the sugarcane pest, *Diatraea saccharalis*, the lepidopteran pest of palm, *Sibine fusca*, the black fly, *Similium vittatum*, the smoky-brown cockroach, *Periplaneta fuliginosa*, the Swedish dragonfly, *Leucorrhinia dubia*, the butterfly, *Agraulis vanillae*, the cabbage worm, *Pieris rapae*, the soybean looper, *Pseudoplusia includens* and the crab, *Carcinus mediterraneus*.

Some DNV have a wide host range whereas others exhibit species specificity so narrow as to infect one host only. Thus, *Jc*DNV infects a wide spectrum of insect larvae including *Spodoptera littoralis, B. mori*, but not *G. mellonella*, and the *Ae*DNV is infectious to a number of *Aedes* and *Culex* mosquito species. In contrast, the host range of *Gm*DNV (which is closely related to *Jc*DNV by serological and nucleotide sequence homology criteria) is confined to *G. mellonella*. The two viruses also vary widely in their tissue specificities and histopathological effects in their respective hosts. Infectivity of all three isolates of *Bm*DNV (the Japanese isolates *Bm*DNV-1 and *Bm*DNV-2, and the China isolate *Bm*DNV-3) is restricted to silkworm strains, but most silkworm strains are susceptible to one of the three isolates only. Genetic studies revealed that the resistance to *Bm*DNV-1 and BmDNV-2 is controlled by a recessive gene which is not sex linked, hence strains homozygous strains for the resistance gene are the preferred ones for silkworm rearing.

A major impediment to DNV research is the absence of a tissue culture host system for most of these viruses (although there are some exceptions: *Jc*DNV, for example, can grow in two *Spodoptera* cell lines following virus infection and also after transfection with an infectious DNA clone). As a result, the cultivation of the virus is mostly done *in vivo*; genetics studies are made complicated, and *in vitro* infectivity assays cannot be established. At present, there are only partial solutions to this technical problem. First, it was shown that following the injection of viral DNA in the form of calcium phosphate or DEAE dextran precipitates, replication and expression take place. Second, when tissue cultures from a variety of insect sources (e.g. *S. littoralis, Trichoplusia ni* and *Galleria*) are infected with *Gm*DNV, viral DNA replication can be readily demonstrated. Hence, the nonpermissiveness of insect cell lines is manifested at later stages in the virus replication cycle. In contrast, recent, extensive studies have shown conclusively that *Gm*DNV is unable to

replicate in vertebrate cell lines and viral DNA replication was not detected in mouse, hamster and human cell lines, even after infection with 10^4 virus input in excess of that used to demonstrate DNA replication in insect cell lines.

DNV Disease and Ecology

There have been a number of reports of DNV diseases of economically important insects in Japan and the Peoples' Republic of China. A disease of the silkworm *B. mori* in the vicinity of Ina City, Japan, in 1968 has led to the discovery of *Bm*DNV. At least two other isolates of DNV from diseased silkworms were later discovered in Japan and in China. Epizootic spread of DNV was observed in Japan in silkworm sericulture farms and in mulberry pyralids in mulberry plantations. The virus isolated from the mulberry pyralid was serologically indistinguishable from *Bm*DNV-1 and was infectious to *Bm*DNV-1-susceptible silkworm strains, suggesting that they are either identical or have a common origin. DNV antigen was detected in the dust collected from several silkworm-rearing farms in Japan, in which *Bm*DNV-resistant silkworm strains are being used. These findings are interpreted to suggest that enzootic distribution of *Bm*DNV is widespread, and probably demonstrate that epizootics are prevented by the use of nonsusceptible silkworm strains.

Some evidence suggests that immunity to infection may play a role in the spread of disease by DNVs. Primarily, extracts from uninfected *Galleria* larvae were found to contain substances with affinity to, or associated with *Gm*DNV. There is no evidence for acquired immunity.

Although some DNVs inflict economical damage, others are considered as potential biological control agents. Some success has been reported using the virus as an insecticide. In Columbia, extracts of DNV-infected larvae were used to control the disease of palm trees caused by *Sibine fusca*, and in the Ivory Coast DNV has been highly successful in the eradication of *Casphalia extranea*, a pest of oil palm and coconut trees. The advantages of DNV as pest control agents are the high resistance of the virions to environmental conditions such as heat and organic solvents and their high infectivity ratios to susceptible insects. The major disadvantage is that the extreme sensitivity of these ssDNA-containing, nonenveloped virions to UV radiation imposes limitations on their use as insecticides.

Densoviruses differ in their pathology and tissue specificity; some (e.g. *Gm*, *Jc*DNVs) can cause an extensive viremia in most or all tissues, whereas the replication of others, such as *Sibine* DNV, is restricted primarily to the midgut. *Bm*DNV multiplies only in the nuclei of the columnar cells of the midgut epithelium columnar cells.

DNV-caused disease is lethal, and is characterized by the accumulation of DNV particles in the nuclei of infected cells. The nuclei degenerate gradually and vacuoles and inclusion bodies appear in the cytoplasm. In the nucleus, the virus forms multilayer crystalline-like structures which occupy the majority of the nucleoplasm volume. The infected larvae become anorexic, sluggish and flaccid, and are progressively paralyzed. Death occurs within 5–10 days, depending on the larval stage, multiplicity of infection and environmental conditions.

DNV histopathology can assume many forms. In *Ae*DNV infected *Aedes aegypti* larvae, the nuclei of the infected cells (hypodermis, imaginal disk, endocrine glands, trachea, hypodermis, etc.) become double in size of those of normal cells and intranuclear structures are disrupted. In *Gm*DNV infection the nuclei of the midgut cells become hypertrophied and eosinophilic, and dense bodies accumulate in the nucleoplasm. *S. fusca* DNV produces distinct pathological changes: the digestive tracts of the infected larvae become thickened, opaque and whitish.

DNV infections of last instar larvae often result in inhibition of pupation. Infection at lower concentrations results in partial metamorphosis, but larval tissues in the pupae are affected. Silk production and cocoon spin are also inhibited.

DNV Gene Vectors

Mammalian parvoviruses, especially AAV, are being studied extensively as transducing and expression vectors. The growing understanding of DNV molecular biology is accompanied by similar attempts to exploit these viruses as vectors for the expression of foreign genes in larvae. Success has been reported in some cases, especially with the lepidopteran *Jc*DNV and the mosquito DNVs. However, the possible application of these vectors to other insects is not clear since these studies were so far confined to their own natural hosts. Both promoters were shown to be capable of driving the expression of heterologous genes such as β-galactosidase and chloramphenicol acetyltransferase, and of allowing the selection of G418 resistant cells using neo^R gene. Success has also been reported in the construction of infectious clones and in packaging them into infectious particles. DNVs are similar to vertebrate parvoviruses in that their major nonstructural protein, NS1, is essential for viral DNA replication and for transactivating transcription from the structural promoter. Finally,

*Jc*DNV has been reported to integrate into the DNA of *Spodoptera* cell lines.

DIAGNOSTIC TECHNIQUES

Contents

Detection of viral antigens, nucleic acids and specific antibodies

Aloys CM Kroes and **Linda FF Kox**, Department of Virology, Leiden University Medical Center, Leiden, The Netherlands

Introduction

Today, *in vitro* virus isolation techniques are still widely used and these constitute perhaps the most convincing diagnostic method available. The identification of complete infectious viruses in clinical specimens is considered the gold standard of diagnostic virology; however, other approaches are becoming increasingly important, for several reasons. First, the maintenance of tissue cultures is labor intensive and time consuming. Furthermore, even with some technical improvements, diagnosis based on virus isolation is relatively slow, taking one to several days. But most important in this respect is the simple fact that many important viruses cannot be cultured *in vitro* at all, e.g. many gastroenteritis viruses, hepatitis viruses and papilloma viruses. This has stimulated diagnostic approaches aimed not at isolation of the virus but just at the identification of viral proteins, of antibodies in the host against viral antigens, or of viral nucleic acids. The techniques employed for these purposes are developing rapidly, leading to impressive increases in sensitivity and also to reduced demands for time and cost. Although these approaches have in common the fact that they do not formally demonstrate the presence of biologically active, complete virus, they are of great practical importance in diagnostic virology. It is to be expected that the increasing demand for rapid and efficient large-scale testing in virology will continue to stimulate the use of these techniques. In particular, the detection of viral nucleic acids, which benefits most fully from biotechnological advances, will probably be the primary approach in diagnostic virology of the twenty-first century.

Viral Antigens

Immunological techniques are usually employed to demonstrate the presence of a viral protein in a clinical specimen; therefore, this viral protein is then referred to as a viral antigen, recognized by the specific antibodies used in the test. Assays of this kind have benefited greatly from the improved availability of antibodies of any desired specificity, by the continuous stable *in vitro* production of monoclonal antibodies, which can recognize single epitopes of viral proteins. This has led to increased specificity and sensitivity of this category of tests.

The principal limitation of this approach is the concentration of viral antigens in the specimens. Antigens are not always present in sufficient concentrations for even the most sensitive assays, and there is no additional technique available to increase this target concentration, in contrast to the detection of viral nucleic acids. The signal obtained after the binding of an antigen can be detected with increasing sensitivity, although still not comparable to the thresholds of culture and viral nucleic acid amplification.

The main advantage of antigen detection is its speed, often producing results after one simple

DIAGNOSTIC TECHNIQUES

Contents

Detection of viral antigens, nucleic acids and specific antibodies

Aloys CM Kroes and **Linda FF Kox**, Department of Virology, Leiden University Medical Center, Leiden, The Netherlands

Introduction

Today, *in vitro* virus isolation techniques are still widely used and these constitute perhaps the most convincing diagnostic method available. The identification of complete infectious viruses in clinical specimens is considered the gold standard of diagnostic virology; however, other approaches are becoming increasingly important, for several reasons. First, the maintenance of tissue cultures is labor intensive and time consuming. Furthermore, even with some technical improvements, diagnosis based on virus isolation is relatively slow, taking one to several days. But most important in this respect is the simple fact that many important viruses cannot be cultured *in vitro* at all, e.g. many gastroenteritis viruses, hepatitis viruses and papilloma viruses. This has stimulated diagnostic approaches aimed not at isolation of the virus but just at the identification of viral proteins, of antibodies in the host against viral antigens, or of viral nucleic acids. The techniques employed for these purposes are developing rapidly, leading to impressive increases in sensitivity and also to reduced demands for time and cost. Although these approaches have in common the fact that they do not formally demonstrate the presence of biologically active, complete virus, they are of great practical importance in diagnostic virology. It is to be expected that the increasing demand for rapid and efficient large-scale testing in virology will continue to stimulate the use of these techniques. In particular, the detection of viral nucleic acids, which benefits most fully from biotechnological advances, will probably be the primary approach in diagnostic virology of the twenty-first century.

Viral Antigens

Immunological techniques are usually employed to demonstrate the presence of a viral protein in a clinical specimen; therefore, this viral protein is then referred to as a viral antigen, recognized by the specific antibodies used in the test. Assays of this kind have benefited greatly from the improved availability of antibodies of any desired specificity, by the continuous stable *in vitro* production of monoclonal antibodies, which can recognize single epitopes of viral proteins. This has led to increased specificity and sensitivity of this category of tests.

The principal limitation of this approach is the concentration of viral antigens in the specimens. Antigens are not always present in sufficient concentrations for even the most sensitive assays, and there is no additional technique available to increase this target concentration, in contrast to the detection of viral nucleic acids. The signal obtained after the binding of an antigen can be detected with increasing sensitivity, although still not comparable to the thresholds of culture and viral nucleic acid amplification.

The main advantage of antigen detection is its speed, often producing results after one simple

reaction. This had led to widespread use of antigen detection in several areas of diagnostic virology, to trace those infections leading to the release of relatively large amounts of viral antigens, in particular when a rapid diagnosis is important.

In addition, it is possible to detect viral antigens in infections in which viral culture is difficult or impossible.

The following techniques are in use for the detection of viral antigens in clinical specimens.

Immunofluorescence If specific antibodies against viral antigens are used, and are conjugated with fluorochrome dyes (usually fluorescein isothiocyanate or FITC), this is termed direct immunofluorescence. If an unconjugated antiviral antibody is used, a second incubation is necessary with an appropriate fluorochrome-labeled anti-immunoglobulin, which is known as indirect immunofluorescence. After the incubations, the clinical specimen is examined microscopically in ultraviolet light and typical staining patterns of virally infected cells can be observed if the test is positive.

This approach is feasible when virally infected cells can be easily obtained. It has been particularly successful for rapid diagnosis of respiratory infections, as caused by respiratory syncytial virus (RSV) and others. The same principle is also used extensively to detect viral antigens in virus isolation procedures.

Immunoenzyme staining This approach is identical to immunofluorescence, except for the label used, which is an enzyme, usually peroxidase or phosphatase. Local color change is observed microscopically if a suitable substrate is added after the antibody incubation. The technique is widely used to demonstrate viral antigens in tissue sections but has many applications. It is used to demonstrate cytomegalovirus antigen in peripheral blood cells, enabling a rapid diagnosis of active infections without viral culture.

Enzyme immunoassays (EIA, or ELISA) The viral antigen again is recognized by a specific antibody, either directly or indirectly through labeling with an enzyme. The reaction catalyzed by the enzyme is usually the production of colored dye, which then is detected by photometry. Recently, the same principle has been applied for several other enzyme-mediated conversions, leading to a product detectable by chemiluminescence or fluorescence. To allow the separation of antibody bound to the antigen from unbound labeled antibody, a 'solid phase' is essential in this type of immunoassay, which means a surface to which a specific antibody is stably bound and immobilized during subsequent washing steps. Many viral antigens are detected with great sensitivity by these techniques. Routine testing for hepatitis B virus (HBV) infection is generally done by EIA detection of the viral surface antigen (HBsAg) in serum. EIA techniques are also used for the detection of gastroenteritis viruses in feces and for respiratory viruses in nasal or throat washings. Some commercial versions are easily carried out in handheld devices with visual detection of color production if a viral antigen is present in the specimen. But, in contrast, EIAs are also widely employed in large-scale fully automated analyzers.

Radioimmunoassay (RIA) The antiviral antibody in this technique is labeled with a radioactive isotope, which can be detected by gamma counters or liquid scintillation counters, depending on the nature of the emission. The traditional advantage of this technique was always its sensitivity. Nowadays, the EIA-based methods are not much different in this respect, and in other respects the RIA technique has a number of important disadvantages, mainly the limited shelf-life of many radiolabels and the extensive regulations for safe handling and waste disposal, which make this technique less suitable for routine viral diagnosis.

Particle agglutination Particles which are coated with antiviral antibodies can produce macroscopic agglutination if mixed with a specimen containing viral antigens. Although this is an elegant technique with a minimal requirement for technical support, its applications are limited owing to its low sensitivity. Erythrocytes, latex, gelatin and other particles can be used. A classical example has been the field test for hepatitis B surface antigen. Nowadays, this technique is still used frequently to detect viruses causing gastroenteritis, mainly rotavirus, as these are excreted in feces in high concentrations.

Specific Antibodies

The detection of antibodies in the host, to demonstrate a viral infection, is extremely successful because of its many practical advantages. These include: the nature of the clinical specimen, which is just a sample of venous blood for all tests; and the simplicity of the techniques involved and therefore the speed and low cost of the procedures. Immunoglobulins are generally produced in high concentrations, easily detectable by several techniques. Antibody testing can also be utilized for most viruses which cannot be recovered by virus culture. With all these benefits in mind, it should be emphasized that the detection of specific

antiviral antibodies in the host, as a diagnostic approach, also has several important weaknesses. The disadvantages of antibody detection for viral diagnosis (sometimes shortly referred to as 'serology') include the following:

- Antibody production by the host inevitably requires time, to allow for a primary or secondary immune response. This precludes a diagnosis in the acute phase of some infections, although other infections at the time of clinical presentation may have given rise to an antibody response.
- The antibody response requires a properly functioning immune system in the host; however, several infections do occur preferentially in patients with decreased immunity (immunocompromised hosts). In these cases, a diagnosis based on antibody detection can be either impossible or, at best, will be delayed. This category of patients is by no means rare in modern medicine (transplant recipients, acquired immune deficiency syndrome (AIDS), tumor chemotherapy, etc.).
- Antibody detection does not discriminate between past and current infections without special precautions. For any infection that is not extremely rare in the population studied, to link the presence of antibodies to an actual clinical problem requires either the demonstration of a rise in antibody titers in the course of the disease or the demonstration of the usually short-lived IgM class of antibody against the virus. Although neither procedure provides absolute proof of a viral infection in the period involved, positive results can be considered strong support for this assumption.
- Special problems are encountered in the diagnosis of congenital infections, as the fetal antibody response may be lacking, transient or masked by the maternal response.

To resolve many of the problems listed above, one should resort to diagnostic techniques demonstrating the virus or viral components directly. Essentially, antibody detection should be considered only indirect proof of the presence or absence of a virus.

All techniques aimed at detection of antiviral antibodies rely heavily on the availability of specific antigens. While in the past these were often obtained from viral cultures or even from infected patients, nowadays recombinant DNA techniques are rapidly becoming the dominant method of producing viral antigens. Increasingly, naturally occurring antigens are even replaced by carefully selected synthetic peptides containing single epitopes of which specificity and immunological recognition have been demonstrated. These developments have greatly improved many serological tests in terms of sensitivity and specificity.

Table 1 Principal techniques for the detection of viral antigens and antiviral antibodies

Immunofluorescence	Antigen and antibody
Immunoenzyme staining	Antigen
Enzyme immunoassay	Antigen and antibody
Radioimmunoassay	Antigen and antibody
Particle agglutination	Antigen and antibody
Neutralization	Antibody
Hemagglutination inhibition	Antibody
Complement fixation	Antibody

Antibodies against viral antigens can be demonstrated by various methods, several of these being similar to those applied to antigen detection as discussed earlier (**Table 1**). The following techniques are relevant in clinical and veterinary medicine.

Neutralization This technique, like the next one, constitutes a classical virological approach to find antiviral antibodies but is infrequently used in routine practice. Serum or preferentially paired serum samples are used to inhibit ('neutralize') the culture of a specific virus. The neutralizing capacity is considered an important biological function of antibodies, but its detection requires culturing the virus involved. It is cumbersome and not applicable to many viruses.

Hemagglutination inhibition Certain viruses cause hemagglutination if a suspension of cultured virus is incubated with erythrocytes. The presence of antiviral antibodies can prevent this macroscopically visible effect. Classically, it is used to detect type-specific antibodies against influenza viruses. Apart from this application, the technique is rarely used.

Complement fixation One of the typical biological effects of antigen–antibody complexes is the binding of complement. Complement is a system of serum enzymes, which on activation may lead to cell lysis. If complement is bound by a complex, in a hemolytic system which relies on the presence of a critical concentration of complement, hemolysis will be suppressed.

In this way, specific antibody is detected if after the incubation phase with a suitable antigen no hemolysis is observed. This technique also allows macroscopical reading of results. It requires technical experience and has low sensitivity. Its main advantage is that all (sub)classes of immunoglobulin able to bind complement are detected simultaneously. It is still widely used in tests for antibodies against respiratory viruses.

Immunofluorescence Antibodies against a virus are detected by incubation of serum with cells expressing viral antigens. These cells are usually obtained from standard viral cultures. Alternatively, cells can be made to express certain antigens by recombinant DNA techniques. In a second incubation step, the bound antiviral antibodies are visualized microscopically by a FITC-labeled anti-immunoglobulin. Appropriate controls should demonstrate a typical staining pattern. The technique is relatively time consuming and the reading of results is subjective to some extent. It is widely used to detect antibodies against viruses that are easily cultured, as the slides for these tests can then be prepared in the laboratory.

Enzyme immunoassays (EIA, or ELISA) The binding of antiviral antibody to a prepared antigen is recognized by the reaction of an enzyme-linked anti-immunoglobulin. As described for the antigen detection by EIA, a solid phase is required to immobilize the antigen–antibody complex. Several technical variations are in use. One of the most important is particularly suitable for detection of IgM antibodies: the capture technique, which binds all IgM to the solid phase by using anti-IgM antibody. Afterwards, viral antigen is added, detected by labeling this protein or by a labeled antibody in a subsequent step. EIA testing for viral antibodies is the most widely used technique and is employed in many different ways, from handheld visually readable tests to sophisticated analyzers. Improvements include kinetic measurements instead of end-point reactions, the use of luminescent or fluorescent reaction products and the increase of solid-phase surfaces, for example by using microparticles.

Radioimmunoassay (RIA) Like its application in the detection of viral antigens, the principle of using antibodies or antigens labeled with a radioactive isotope can provide very sensitive assays but its practical applications are increasingly limited by the typical disadvantages, which were discussed before.

Particle agglutination Particles coated with viral antigens are used, which will produce agglutination if antiviral antibody is present. Sensitivity is limited and the tests are used exclusively in some rapid test procedures, usually with single specimens.

Immunoblot techniques These constitute an important approach in antibody diagnosis which is used extensively when tests with maximal specificity are required. Essentially, a number of viral antigens derived from the same virus are separated and transferred to an immobile matrix. The antibody reactivity of a specimen against each of the antigens is visualized by a secondary incubation with enzyme-labelled anti-immunoglobulin. The observed patterns can provide a high degree of confidence that a response is directed at the virus. Originally, antigens were prepared from lysates of viral cultures; recombinant proteins or synthetic peptides are now often used. The test is frequently used for confirmation of screening test results by EIA, routinely for human immunodeficiency virus (HIV) and hepatitis C virus (HCV), for example.

Typical pitfalls in diagnostic use of antibody detection include:

- cross-reacting antibodies directed against related viruses;
- false-positive IgM assays due to the presence of rheumatoid factor (RF) in samples, an autoreactive IgM antibody binding to IgG, which can produce a positive signal with any labelled anti-IgM if IgG is present;
- false-negative IgM assays, due to the competing presence of IgG.

The described IgM-capture technique can resolve the last problems, otherwise IgG should be selectively removed before IgM detection.

Nucleic Acids

An overview is presented of techniques currently in use for detection and identification of viral nucleic acids in routine medical or veterinary laboratories, with the exception of *in situ* techniques. Since only in a few cases clinical specimens contain sufficient virus to allow identification of their genomes directly by physical methods (e.g. gel electrophoresis of feces samples containing rotavirus), these tests are usually based on hybridization or amplification reactions.

Hybridization

Nucleic acids are able to form a double-stranded structure with a complementary nucleotide sequence and this reaction is highly specific as a result of the base pairing between nucleic acid molecules.

By using a probe, a DNA or RNA molecule with a complementary sequence to the genome to be detected, the presence of viral DNA or RNA can be demonstrated by hybrid formation. This hybrid formation or hybridization is detected by a suitable label which is incorporated in the probe: radioisotopes, enzymes or fluorochromes.

The use of non-isotopic labeled probes is preferred in diagnostic laboratories. In addition, a number of indirect detection systems have been developed, for

example probes labeled with biotin, detected with enzyme-labeled avidin or streptavidin, and probes labeled with digoxigenin, detected with an enzyme-labeled antibody. Another recently developed indirect detection system employs enzyme-labeled antibodies directed against DNA:RNA hybrids. In all these cases, final detection takes place by colored or chemiluminescent products.

Viral nucleic acids can be detected by hybridization in a wide range of clinical specimens like blood, cerebrospinal fluid, urine, bronchoalveolar lavage and others. Before the identification with a probe is possible, viral nucleic acids have to be isolated from the specimens and separated to single strands if the genome is double stranded. Hybridizations can be performed as solid-phase assays or in solution. In solid-phase hybridizations nucleic acids are fixed in a single-stranded form on a nitrocellulose or nylon filter. In solution-phase hybridizations both the nucleic acid and the probe are free to interact in the reaction mixture. Specific procedures to enhance the hybridization signals can be employed (see also below).

Amplification

Although hybridization assays are able to detect minuscule amounts of DNA and RNA, the sensitivity is too limited for many applications. Amplification of nucleic acids and amplification of hybridization signals have realized a considerable increase in sensitivity. In recent years, much progress has been made in the development of several amplification techniques for the detection of specific viral nucleic acids.

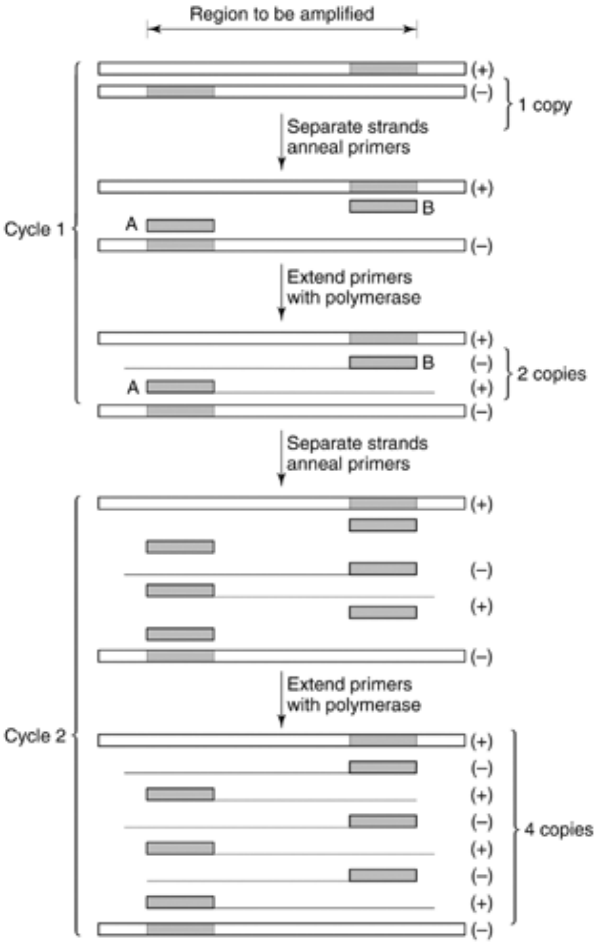

Figure 1 PCR. (+), Sense or coding strand; (−) antisense or noncoding strand; hatched (A) bar, sense primer; stippled (B) bar, antisense primer; empty bar, DNA.

The first nucleic acid amplification technique to be used was the polymerase chain reaction (PCR). Several other methods are currently in use for the detection of specific viral nucleic acids, as summarized in **Table 2.** The transcription-based amplification systems (TAS) include nucleic acid sequence-based amplification (NASBA), self-sustaining sequence replication (3SR) and transcription-mediated amplification (TMA). Other amplification strategies are: ligase chain reaction (LCR), strand displacement amplification (SDA), branched DNA (bDNA) signal amplification and Q-β replicase (QBR). These techniques can be subdivided in target, probe and signal amplification techniques, as indicated.

Target amplification *PCR* With the PCR technique (**Fig. 1**), target DNA sequences are exponentially replicated in repeated cycles of DNA synthesis driven by specific primers (short stretches of nucleotides, complementary to a DNA strand). At a high

temperature (94°C), the double-stranded viral target DNA is separated to single strands. Subsequently the primers are hybridized at a temperature of 40–60°C to both single strands of the target DNA and the primers are extended by the action of a heat-stable DNA polymerase (*Thermus aquaticus (Taq)* DNA polymerase, *Thermus thermophilus (Tth)* DNA polymerase) at a temperature of 72°C, resulting in the synthesis of new complementary strands. These three incubation steps, denaturation, annealing and extension, give a doubling of the target DNA and the new strands serve as a template in the next cycle. By repeating the cycle several (20–40) times, a large amount of viral DNA with fixed ends, determined by the distance of the two primers on the target DNA, is generated. If viral RNA is the target it is first converted into copy DNA (cDNA) by the action of the enzyme reverse transcriptase (RT) before the amplification reaction. This modification is known as RT-PCR.

The specificity of the PCR is dependent on the nucleotide sequence of the primers, which has to be virus specific, and the temperature and salt conditions used during the incubations. Both specificity and sensitivity of the PCR can be increased by performing a nested PCR: a second round of amplification, using a second pair of primers that is specific for the internal sequence amplified by the first primer pair. The strength of PCR is that it can be applied to relatively crude samples containing only small numbers of viral fragments. Using PCR it is possible to amplify any target DNA or RNA molecule to a detectable level. The amplified DNA can be detected by electrophoresis in ethidium bromide-stained agarose gels. However, this only provides information on the size of the PCR product. For diagnostic purposes, further confirmation of the result is usually required. This can be done by subsequent hybridization with a specific probe. When a suitable restriction site is present, the PCR product can be cut in defined fragments. PCR products can also be analyzed by sequencing, but this approach is not practical for routine diagnosis.

TAS The transcription-based methods NASBA, 3SR and TMA are very similar. NASBA is a continuous, isothermal process, which can amplify RNA (**Fig. 2**). Target RNA is first converted into cDNA by RT using a virus-specific primer, containing a promoter sequence that is recognized by T7 RNA polymerase (P1). After removal of the RNA from the DNA:RNA hybrid by RNase H and synthesis of the complementary DNA strand with a second virus-specific primer (P2), about 1000 RNA copies from the DNA template are transcribed by incubation with T7 RNA polymerase. Each RNA copy now serves again as a template for a new round of amplification. 3SR differs from NASBA in that both primers contain T7 promoter sequences. In TMA, only an RT and an RNA polymerase are used. These methods are increasingly employed, mainly in complete commercial systems.

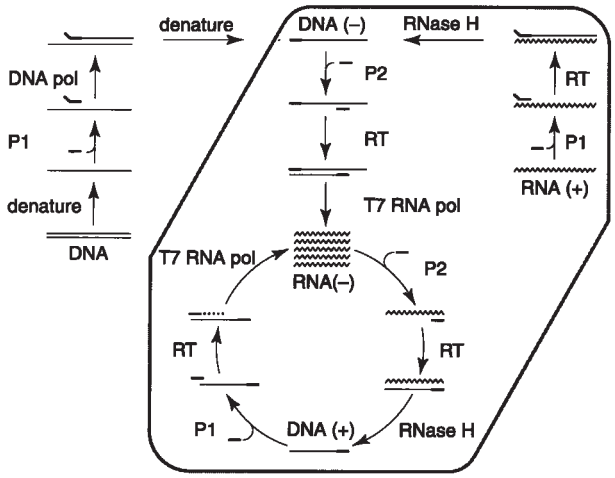

Figure 2 NASBA. RT, reverse transcriptase; P1, antisense primer; P2, antisense primer; pol, polymerase; (+), sense or coding strand; (–) antisense or noncoding strand; bold lines, primers; light lines, DNA; wavy lines, RNA; dotted line, incomplete DNA strand.

SDA This is an isothermal method of amplifying target DNA which requires two enzymes, a DNA polymerase and a restriction enzyme. It uses two primer sets, one to define the target sequence and a second to introduce a restriction site. Extending upstream and downstream primers displace each other from the template on both strands simultaneously. The first SDA assays used the exonuclease deficient (exo$^-$) Klenow fragment of *Escherichia coli* DNA polymerase and *HincIII* as restriction enzyme. It produces a 10^8-fold amplification during a single 2 h incubation at 40°C. The second generation SDA assays use exo$^-$ *Bst* or exo$^-$ *Bca* DNA polymerase and *Bso*BI and produces a 10^{10}-fold amplification in 15 min at 50–60°C.

Probe amplification *LCR* This method utilizes four oligonucleotide primers (instead of two used in PCR) and a thermostable DNA ligase to ligate the contiguous primers and cycles between the denaturation temperature (94°C) and the ligation temperature (72°C). A variation of LCR called gapped LCR employs *Taq* polymerase to fill in one nucleotide prior to the ligation of adjacent primers.

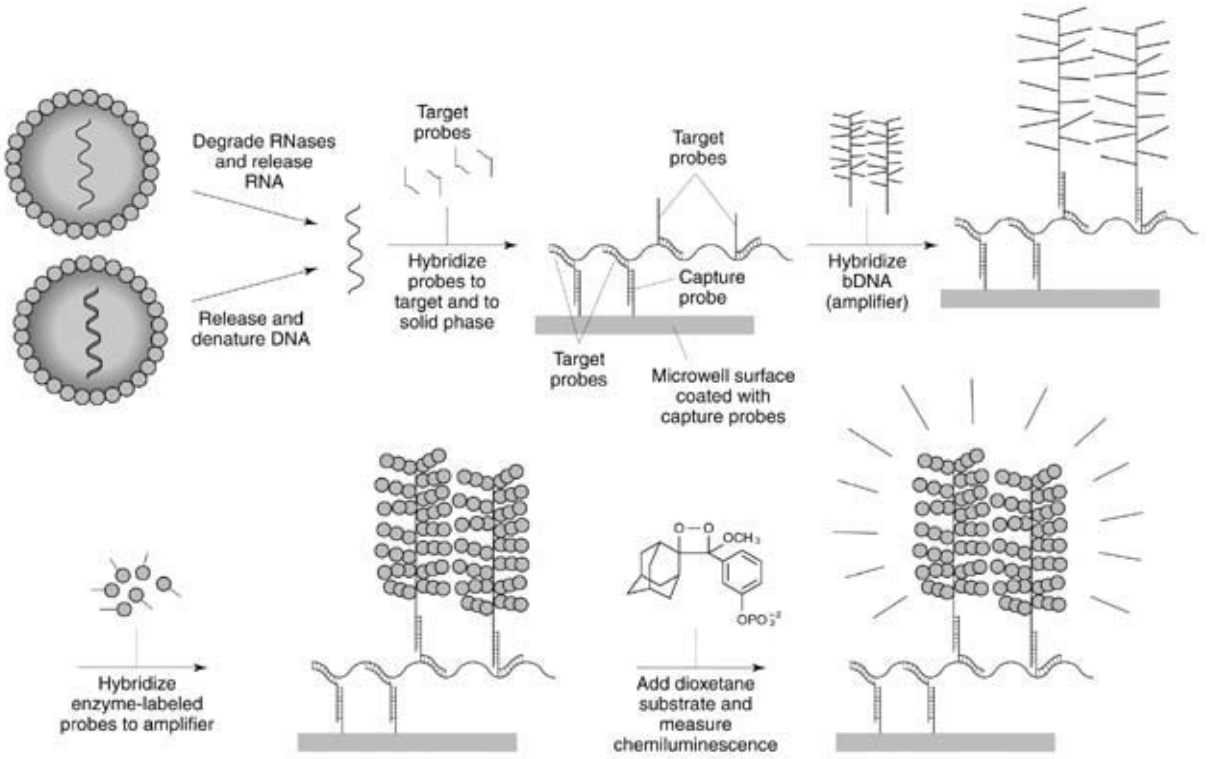

Figure 3 bDNA signal amplification.

QBR This amplification is named for the enzyme carrying out amplification, Q-β replicase, a RNA-directed RNA polymerase produced by the Q-β bacteriophage. The enzyme recognizes and produces copies of a 'reporter' RNA molecule, midivariant 1 (MDV-1) which can incorporate a short foreign RNA probe. The presence of target DNA leads to hybrid formation with subsequent activation of the Q-β replicase, generating many new RNA molecules. The RNA molecules serve as probes in the following rounds. So far, this system has not been extensively used.

Signal amplification *bDNA signal amplification* This is a sandwich hybridization assay performed in the wells of a microtiter plate in which lysis, hybridization, capture and signal amplification occur (**Fig. 3**). A mixture of capture probes and target probes hybridizes to highly conserved regions of the nucleic acid, thereby capturing the nucleic acid molecules on to the surface of a microtiter plate. After hybridizing the target to synthetic bDNA molecules added to the well, multiple copies of an alkaline phosphatase-linked synthetic probe hybridize to the immobilized complex, thereby amplifying the target signal. Detection is achieved by incubating the complex with a chemiluminescent substrate and measuring light emission, which is proportional to the concentration of target nucleic acid in the specimen.

Potential problems

Although amplification assays are rapidly becoming 'routine' tests in diagnostic laboratories there are some pitfalls to be aware of. A summary of these will focus on PCR, as it is the most widely used amplification technique.

A major problem with diagnostic assays based on amplification is the occurrence of false-positive results due to nucleic acid contamination. This can be either viral nucleic acid or products from previous amplifications (amplicons). The amplicons are particularly likely to cause contamination because of the large number of molecules produced. To perform different steps of the PCR procedures at different locations is a first step in the prevention of contamination. In addition, amplicon contamination can be prevented by using uracil DNA glycosylase (UDG) together with dUTP, instead of dTTP. In the incubation step prior to amplification, UDG is allowed to excise uracil from any contaminating dU-containing PCR product. At the high cycling temperatures during amplification the UDG is inactivated and any possible contaminants are

broken into small fragments. An alternative to this pre-PCR enzymatic amplicon degradation method is the post-PCR photochemical method. In this method high concentrations of isopsoralen inactivate the amplicons. This method has the disadvantage that an excess of isopsoralen can inactivate the DNA polymerase. Furthermore isopsoralens are mutagenic.

Another problem with the diagnostic use of PCR can be the occurrence of false-negative results due to inhibition of the *Taq* DNA polymerase. Most inhibitors are poorly characterized and occur rather unpredictably in clinical materials. Inhibition can be detected by testing specimens in duplicate, with and without exogenously added DNA or RNA (or virus) that can be amplified with the same or different primers. This external inhibition control increases the number of PCR tests necessary for each sample. Therefore internal controls, included in the same reaction, are preferred, although these require a careful design.

The extraction of nucleic acid from the clinical samples is a critical process. Different procedures are needed depending on the nature of the sample and it is important to identify the optimal procedure for a specific assay. Inhibitors of the PCR must be removed effectively while minimizing the loss of nucleic acid.

Amplification procedures demand strict quality control of the reaction mixtures, standardization of the procedures and a dependable thermocycler. The use of multiple positive and negative controls to monitor each step of the assay is mandatory for diagnostic purposes. With this approach, amplification assays are reliable diagnostic tests and can be employed in any routine diagnostic laboratory. The commercial availability of complete test systems theoretically could make quality control easier. However, several studies have shown that the use of commercial test systems is not a guarantee for reliable results. All nucleic acid amplification methods, as a category of diagnostic tests, require strict quality control measures.

Significance in diagnostic virology

Nucleic acid amplification techniques will be increasingly used for the diagnosis of viral infections, as they combine sensitivity, specificity and speed and are universally applicable. Amplification techniques are therefore well suited for the detection of viruses that cannot be recovered by culture. This has been effective for detection of hepatitis C virus (HCV), human parvovirus B19, papilloma viruses and many others. In addition to detecting this category of viruses, molecular methods can be used in quantitative assays to determine viral concentrations ('viral load') in several chronic infections, such as those of HIV, HCV, HBV and cytomegalovirus. These quantitative assays are particularly important to monitor the response to new antiviral drug therapies.

antigens and/or viral products. In addition, recent advances in the development of molecular biologic techniques have been applied to the detection of viral genomes with a sensitivity that approaches that of culture. The four basic methods are illustrated in the flow chart in **Fig. 1**. This chapter discusses the isolation of animal viruses in cell culture and their identification by electron and light microscopy. Techniques for detecting viral antigens, specific antibodies and viral nucleic acids are discussed in the preceding chapter (*see also* **Diagnostic Techniques: Detection of Viral Antigens, Nucleic Acids and Specific Antibodies**).

Primary Virus Isolation and Identification

Viruses are obligate intracellular parasites. Thus, isolation of a virus requires inoculation of either cell culture, suckling mice, embryonated eggs or other host systems. The host system selected depends on the virus sought. When attempting to isolate virus from a clinical specimen and the identity of the virus is uncertain, the use of multiple systems may be necessary for maximum sensitivity.

Use of cell culture monolayers for virus isolation

Isolation of virus in cell culture monolayers is the most convenient method available and is the sole culture system used in most diagnostic laboratories. A variety of cell cultures in flasks or roller tubes are available from commercial suppliers or can be prepared in the laboratory. Cell cultures are categorized as either primary, passaged or continuous. Primary cells, such as monkey kidney or rabbit kidney, are obtained directly from a tissue or organ and cannot be serially passaged. Embryonic tissues such as human embryonic fibroblasts can be passaged a finite number of times. Continuous cell lines, such as HEp-2 cells, are transformed cells and can be passaged indefinitely. Representative primary cultures and passaged cell lines are essential in a diagnostic laboratory to isolate a broad spectrum of viruses.

Conventional methods

Cytopathic effects (CPE) in tube culture For conventional virus isolation, specimens are inoculated into susceptible cell cultures in roller tubes which are incubated at 35–37°C in either stationary racks or roller drums. For many viruses, rotation of the tubes in a roller drum provides for more rapid onset and easier recognition of cytopathic effects (CPE). The cell cultures are examined serially under the light microscope for the development of viral-induced CPE, which is often characteristic for different virus groups (**Fig. 2**). For example, clusters of swollen cells, diffuse rounding, syncytium formation, or foci of refractile cells may be observed. The characteristics of the cellular changes, the rapidity of both onset and

progression of CPE, and the cell culture exhibiting the changes all lead to a presumptive diagnosis of the causative virus.

Differential cell susceptibility Although a virus may be able to infect and replicate in several cell systems, some cell cultures will be more sensitive than others. When the virus concentration in the inoculum is high, the differences in sensitivity will not be apparent. However, when the concentration is low, less-sensitive cell systems may give false negative results or the onset of CPE may be delayed.

Hemadsorption For some viruses, such as influenza or parainfluenza viruses, cellular changes may not be evident. To detect the presence of these viruses, the hemadsorption test is commonly used. Influenza and parainfluenza viruses express a viral hemagglutinin on the surface of infected cells. By the hemadsorption test, the culture medium is removed and replaced with a 0.5% dilute solution of guinea-pig red blood cells. After an incubation of 20–30 min either at room temperature or 4°C, the monolayer is washed to remove the red cells. If a viral hemagglutinin is present in the cells, the red blood cells will adhere in a specific pattern. If the culture is placed at 37°C, the viral neuraminidase will cleave the hemagglutinin and the red cells can be removed.

Plaque formation Viruses may induce plaque formation when infected cell monolayers are overlaid with a semisolid medium. The virus infection spreads from cell to cell resulting in a localized plaque. After an appropriate incubation period, the overlay medium is removed and the monolayers are fixed and stained with crystal violet. Uninfected cells take up the dye. Areas of cell destruction represent viral plaques and are enumerated as plaque forming units (PFU). Plaque formation is useful to identify a virus, determine the infectivity titer of a virus stock, or perform antiviral susceptibility testing.

Centrifugation culture in shell vials

Detection of CPE in conventional cell cultures may require one day for viruses such as herpes simplex virus (HSV) or 3–4 weeks for other viruses, such as cytomegalovirus (CMV). As antiviral therapy has become available, obtaining a rapid diagnosis has assumed increasing importance. For many years it has been recognized that centrifugation of viruses and chlamydia onto cell monolayers enhances infectivity. In fact, the standard method for isolating chlamydia has been centrifugation culture in shell vials followed by incubation for 24–48 h then staining for inclusion bodies in infected cells. This methodology has been applied to the diagnosis of CMV with significant enhancement of both the speed and sensitivity of virus detection. Samples are inoculated into shell vials containing coverslips with cell monolayers. Following low-speed centrifugation for 30–60 min, shell vial cultures are incubated at 37°C for 24–48 h. Then monolayers are fixed and stained with a fluorescein or peroxidase labeled monoclonal antibody to CMV early antigens, which are expressed in the nuclei of infected cells (**Fig. 3**). Thus viral antigens can be detected in infected cells as early as 16 h postinoculation, whereas days to weeks may be required before viral CPE can be observed by light microscopy. This technique can also be used for the rapid detection of other viruses that replicate in cell culture for which a specific antibody is available. Its greatest benefit is for

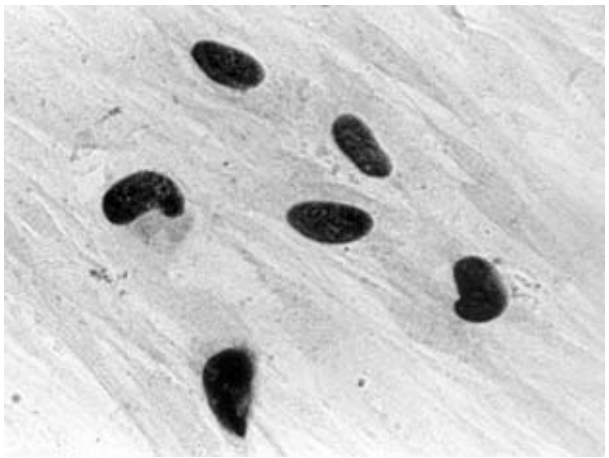

Figure 3 Shell vial centrifugation culture: 24 h after specimen inoculation, CMV immediate early antigen can be detected in infected HDF nuclei (immunoperoxidase staining method).

those viruses with a long replication cycle for which monoclonal antibody to early antigens is available. For maximum sensitivity, conventional cultures should be performed in parallel with centrifugation cultures.

Use of genetically modified cell lines

The use of genetically modified cell lines is an emerging technology with great potential for the diagnostic laboratory. By this method, genetic elements derived from viral, bacterial or cellular sources are stably introduced into a cell. When a particular virus subsequently enters the cell, a specific event in the viral replication cycle triggers the production of an easily measurable enzyme. This approach has been given the acronym enzyme-linked inducible system (ELVIS) and has been shown to be feasible for both DNA and RNA viruses, although different strategies are necessary for enzyme induction. In contrast to CPE, ELVIS can be read by an untrained observer and the earliest stages of infection reliably detected.

However, both the cell line and the reporter gene chosen can have significant effects on the sensitivity and specificity of the system. *Escherichia coli* β-galactosidase is a commonly used reporter gene, but many cell types have high background due to endogenous enzyme activity. Firefly luciferase may offer greater sensitivity since it is absent in mammalian cell lines.

Recently, a baby hamster kidney cell line (BHK ICP6Laz-5) has been genetically modified to contain an HSV-inducible promoter gene linked to an *E. coli* *Lac Z* reporter gene. When these cells are infected with HSV, the β-galactosidase gene is expressed, leading to intracellular accumulation of the enzyme. HSV-infected cells then stain blue in a simple histochemical assay. The ELVIS method for detection of HSV appears to be simple, sensitive and rapid, and is an attractive assay especially for laboratories processing large numbers of specimens. However, ELVIS remains somewhat less sensitive than the most sensitive of conventional cell culture systems when specimens contain only a few infectious HSV particles.

ELVIS culture methodology is amenable to automation with some advantages over standard immunological methods, such as ELISA: it can provide more sensitive results and can detect infectious virus. Lastly, genetically modified cell lines can also facilitate antiviral susceptibility testing.

Use of lymphocyte cultures

Although not available in routine diagnostic laboratories, human lymphocyte cell cultures are used in the research laboratory to isolate several human herpesviruses, Epstein–Barr virus (EBV), human herpes virus type 6 (HHV-6) and type 7 (HHV-7) and retroviruses, human immunodeficiency viruses (HIV) 1 and 2 and human T cell leukemia viruses (HTLV) I and II. Human leukocytes for cocultivation can be obtained from seronegative donors or from cord blood of uninfected newborn infants.

EBV is able to transform uninfected human leukocytes into continuous cell lines and EBV nuclear antigen can be detected in the nuclei of transformed cells. Throat washings are filtered, added to leukocytes and placed on placental fibroblast feeder layers. Transformation by EBV is heralded by a sudden increase in cell numbers, cell clumping and ability to be subcultured indefinitely. Unfortunately transformation usually requires 30–90 days of incubation.

HTLV I and II, HHV-6 and HHV-7 can be isolated by cocultivating samples with cord blood lymphocytes stimulated with phytohemagglutinin or interleukin 2 (IL-2). Identification is by polymerase chain reaction (PCR) or monoclonal antibodies, as well as by reverse transcriptase assay of supernates for HTLV.

Since HIV lyses CD4 lymphocytes, successful isolation necessitates repeated additions of fresh stimulated, uninfected peripheral blood lymphocytes to cultures. Virus growth is detected by periodically assaying supernatant fluid for reverse transcriptase or viral antigen, or by electron microscopy (EM). Continous mature T cell lines from leukemic patients are useful in propagating HIV laboratory strains but

are not as sensitive for primary isolation of wild-type viruses.

Use of embryonated eggs and infant mice in selected instances

Although most diagnostic laboratories confine their virus isolation techniques to monolayer cell culture, certain virus isolates may be missed without the inoculation of embryonated hens' eggs, in particular some influenza type A strains (e.g. H2N2). Suckling mice remain the universal host for group A coxsackieviruses and toga- and flaviviruses, although a number of virus types can be isolated in specialized cell cultures. Mice are also useful for isolation of rabies and are essential for the recovery of hantaviruses which can be slow to adapt to cell cultures.

Embryonated eggs can be inoculated via the amniotic or allantoic cavities or via the chorioallantoic membrane. For the isolation of influenza, the amniotic and allantoic cavities of 10–13-day-old embryos are inoculated; for mumps, 7–8-day-old embryos are used. Inoculated eggs are incubated 2–4 days for influenza and 5–7 days for mumps. At that time, eggs are chilled for 2–4 h, then amniotic and allantoic fluids are harvested separately under sterile conditions. The fluids are then assayed for the presence of viral hemagglutinin by mixing an aliquot of the fluids with a 0.5% suspension of guinea-pig red blood cells. Virus isolates can be passaged by egg inoculation and can be identified by hemagglutination inhibition with specific antisera.

To inoculate the chorioallantoic membrane (CAM) of hens' eggs (9–12 days old), an artificial air sac is first induced. Then an inoculum is dropped onto the membrane through a hole in the egg shell. The opening is sealed and the egg incubated for 2–3 days, at which time the membrane is harvested and placed in a Petri dish containing saline to facilitate counting of virus-induced pocks. Though rarely performed today, pock formation can still be useful for the biologic characterization of poxvirus isolates.

Most group A coxsackieviruses and many toga- and flaviviruses are best isolated in the newborn mouse. For optimal sensitivity, when these viruses are sought, newborn mice, 24–48 h old, should be inoculated intracerebrally and/or intraperitoneally. For coxsackie A viruses, a characteristic hindlimb paralysis develops in the mice. Mice should be checked twice daily for signs of illness, paralysis or death. The mouse brain or skeletal muscle (coxsackie viruses) should then be harvested, a 20% suspension prepared and inoculated into appropriate cell cultures and/or mice for further study and identification.

Virus Identification

When a virus isolate is obtained in monolayer cultures, a presumptive identification is made based on the type of cell culture exhibiting cytopathic effects, the characteristic CPE observed, and the specimen source. A final identification can be made by the use of virus-specific antiserum to detect viral antigens or to inhibit virus-induced effects in infected cultures. The three tests below are commonly used for virus identification, however other tests such as complement fixation (CF), hemadsorption–inhibition and hemagglutination–inhibition can also be used.

Immunofluorescence test

Immunofluorescence (IF) techniques include the direct fluorescent antibody (DFA) procedure and the indirect fluorescent antibody (IFA) procedure. These tests have long been used in the diagnosis of viral diseases. By this technique, specific antibody is tagged with a fluorescent dye, allowed to react with the viral antigen in infected cells and after an incubation period, the antigen–antibody complex is visualized using a microscope with an ultraviolet light source. With DFA, the virus specific antibody is conjugated with a fluorescent dye, whereas with IFA specific antibody is not labeled. Rather, a second antibody, directed against the animal species in which the virus-specific antibody was prepared, is fluorescein-labeled. The direct method is quicker and simpler, whereas the indirect method requires only one conjugate for the detection of many antigen–antibody reactions, provided all antisera are made in a single animal species.

In the past, only polyclonal antiserum made from animals was available and variation in quality was problematic. At present, a variety of high quality monoclonal antibodies are available commercially and as a result, the use of IF techniques to identify viruses has become routine in many laboratories. For herpes simplex, influenza and parainfluenza viruses, type-specific monoclonal antibodies are also available. Once CPE or hemadsorption is detected and involves 50% or more of the infected cell monolayer, the cells are removed, centrifuged, resuspended in a small volume of buffer and dropped onto welled-slides. The cells are fixed in acetone, then stained with specific antibody. The fluorescent pattern seen in infected cells will vary with the virus, the cell type and the antibody used. Appropriate positive and negative controls should be tested with each assay.

Immunoperoxidase test

Immunoperoxidase (IP) techniques follow the same principles as IF, however, the conjugate is an enzyme, such as horseradish peroxidase. In the direct method,

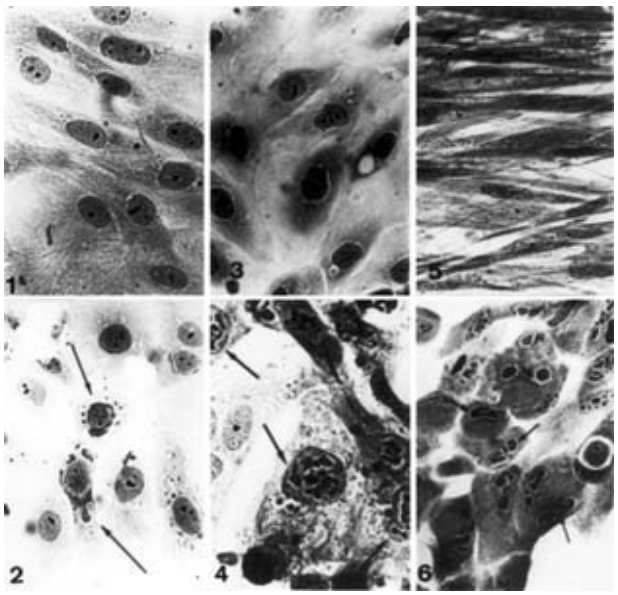

Figure 4 Examples of virus-induced inclusions (arrows) by different viruses (H&E stained preparations) 40 × objectives. 1, Uninfected rhesus monkey kidney cells; 2, intracytoplasmic inclusions induced by reovirus type 1; 3, uninfected human embryonic kidney cells; 4, intranuclear inclusions induced by adenovirus type 2; 5, uninfected human diploid fibroblasts; 6, intranuclear inclusions induced by CMV. Arrows indicate inclusions.

the virus specific antibody is enzyme-labeled, whereas in the indirect method, an anti-animal species antibody is labeled. The presence of the enzyme conjugate bound to the virus-infected cells is detected by adding a substrate, such as diaminobenzidine or aminoethylcarbazole, then oxidizing it in the presence of hydrogen peroxide which results in a reddish-brown color. Although IP staining requires an additional step (the addition of the substrate), it has several advantages over IF. The reaction is read using a light microscope or even the naked eye. The slides are permanent, the reagents are more stable, there are fewer nonspecific reactions and IP has been more successful than IF on processed tissue sections.

Neutralization test

The neutralization test (NT) is arguably the most sensitive and accurate method available to identify a virus isolate. However, it is also very time consuming and labor-intensive. By this technique, virus infectivity is neutralized by the incubation of the virus isolate with specific antiserum, followed by the inoculation of the virus–serum mixture into sensitive cell cultures. The NT is used for the type-specific identification of enteroviruses and rhinoviruses. Unfortunately, these virus groups have no common antigen against which to prepare a monoclonal antibody. The NT is also used for type-specific identification of adenoviruses. For adenovirus-group identification, a monoclonal antibody to the common hexon antigen is available for use in IF and IP assays.

In order to perform the NT, a virus stock must be prepared and the infectivity titer determined. Then a challenge dose of approximately 100 PFU or tissue culture infectious dose ($TCID_{50}$) is prepared. An aliquot of the virus at the selected titer is allowed to react with 20 units of specific antiserum in a test tube for 1–2 h. The virus–antiserum mixture is then inoculated into susceptible cell cultures and observed for virus-induced CPE or plaque formation. Virus mixed with sterile buffer is inoculated as a positive control. Complete inhibition of virus-induced changes by 20 units of antiserum is considered a positive neutralization test.

Direct Observation of Virus-Induced Changes by Light Microscopy

Microscopic examination of fixed and stained cells is a technique that can be used as an additional aid in the diagnostic laboratory. When cultured cells are stained and mounted, these preparations are a distinct aid in recognizing and identifying viruses and can be filed for reference and become part of the permanent record. The most commonly used staining technique is with hematoxylin and eosin (H&E), a technique which every pathology laboratory uses routinely. Zenker's fixing solution is particularly useful for the demonstration of virus-induced intranuclear inclusions and preserves sharp details of virus-infected cells (**Fig. 4**). For determination of DNA viruses by the Feulgen reaction or RNA viruses by the acridine orange stain, infected cells are fixed in freshly prepared Carnoy's fixing fluid followed by Schiff's reagent for DNA viruses or acridine orange for RNA viruses. Good reagents and very meticulous procedures are required.

Direct Observation of Virus Particles by Electron Microscopy

The recognition of virus particles in clinical specimens by means of electron microscopy (EM) has been made for years. However, specimen preparation is a time-consuming and tedious task. In recent years, improved technology has simplified many of the procedures and reduced the time needed for processing specimens.

Essentially, there are two basic techniques available for routine use: negative staining of virus particles (**Fig. 5**, top row) and thin sectioning of virus infected cells (**Fig. 5**, middle row). Negative staining of clinical materials provides the simplest and most rapid method for detection and recognition of virus particles. Thin sectioning, although less rapid, provides a more reliable diagnosis, since the examination of virus infected cells reveals the site of viral replication. In the following sections, the two basic techniques for preparing samples for electron microscopy are briefly described.

Negative staining

The negative staining technique for visualization of virus particles was introduced by Horne and Wildy in 1959. They described how the use of heavy salts may enhance the contrasts in virus particle images. The procedure is simple and needs no special equipment. Generally, viruses in aqueous suspension are mixed with an equal volume of heavy metal salt solution (2–4%), such as phosphotungstic acid (PTA) or 0.5% uranyl acetate. The mixture is then placed on a Formvar or collodion-coated electron microscope grid. Excess fluid is blotted away and the specimen is then air dried. The grid containing the mixture is then examined under an electron microscope. The virus particles are surrounded by heavy metal atoms and are revealed against a dark background, the so-called negative stain because the electron beam can pass through the low electron density of the virus but not through the metallic background.

However, most clinical specimens contain small numbers of virus particles; therefore, additional procedures have been developed for concentration of virus particles and are commonly used in diagnostic laboratories.

In order to facilitate recognition of the relatively small number of virus particles in the specimen, immunoelectron microscopy (IEM) has been used for enhancing concentration of virus particles and for rapid serodiagnosis of virus infection. IEM has been widely used for recognizing rotaviruses and Norwalk agent in stool samples of patients with gastroenteritis and to detect hepatitis B virus antigen in patient's serum.

Thin sectioning

The thin-sectioning method is used to prepare fixed and embedded tissues or cells for electron microscopy. It is, however, more time-consuming and requires personnel with special skills. Examining well-preserved virus-infected cells offers the advantage of direct observation of virus–cell interaction, which in turn reveals the site of virus replication and maturation in the host cell, thus aiding identification of unknown viruses. The conventional procedures consist of primary fixation (with glutaraldehyde or paraformaldehyde), postfixation (osmium tetroxide), *en bloc* staining with uranyl acetate (optional), dehydration (ethanol or acetone), infiltration (propylene oxide or other solvents), embedding (epoxy resin or other embedding media), thin-sectioning and staining. The choice of reagents for fixing and embedding varies from laboratory to laboratory and usually depends on experience.

The various virus morphologies as seen in negative stain or in thin-sectioning with their respective schematic diagrams are illustrated in **Fig. 5**.

Future Perspectives

Over the past decade, significant changes have occurred in diagnostic virology. A plethora of high quality reagents, including monoclonal antibodies, antigen and antibody detection kits, and nucleic acid probes and amplification kits, have become commercially available. The demand for rapid and accurate viral diagnostic testing continues to escalate due to the increasing recognition of serious viral infections and the need to intervene with antiviral therapy.

A variety of test methods are now available, each with advantages and disadvantages. Rapid antigen, nucleic acid and antibody detection assays have provided rapid results and had a favorable impact on patient care. However, only the suspected viral agent is tested for in these assays, and they tend to be less sensitive than isolation in cell culture. With the availability of genetically modified cell lines, new avenues for virus detection are available. Virus isolation is more open minded, since unsuspected viruses, as well as multiple viruses, may be detected. At present, a number of viruses are still not cultivable by methods used in a routine diagnostic laboratory. Thus, for optimal results, a combination of rapid and conventional methods is often required.

DIANTHOVIRUSES (*TOMBUSVIRIDAE*)

Steven A Lommel, Department of Plant Pathology, North Carolina State University, Raleigh, North Carolina, USA

History

Carnation ring spot virus (CRSV) was first isolated and described as a disease of carnations in 1951. Red clover necrotic mosaic virus (RCNMV) was first described in red clover and alfalfa in 1967. Sweet clover necrotic mosaic virus (SCNMV) was first defined as a new *Dianthovirus* in 1986. The International Committee on the Taxonomy of Viruses formed the genus *Dianthovirus* for *Dianthus* the generic name for carnation (*Dianthus caryophyllus*) the major host for the type member of the species, CRSV.

Geographic and Seasonal Distribution

Dianthoviruses, with the possible exception of furcraea nectrotic streak virus (FNSV), which appears to be tropical in range, are widespread throughout the temperate regions of the world. CRSV has been identified wherever carnations are grown on a large scale. The worldwide distribution of CRSV is most likely due to the practice of distributing vegetative propagules within the floral industry. Quite separately, CRSV is also established in stone fruit orchards and grape-growing regions of Eastern and Central Europe. RCNMV has been identified in temperate forage legume growing regions of Canada, Australia, New Zealand, England, and Northern and Central Europe. SCNMV has been found only in Alberta, Canada.

Taxonomy and Classification

The *Dianthovirus* genus in the *Tombusviridae* family is defined by those plant-infecting viruses which have 32–35 nm icosahedral virions composed of 180 copies of a 37 kDa capsid protein and two nonhomologous positive polarity single-stranded RNA species of 4 and 1.5 kb. The key taxonomic feature which distinguishes members of this genus from other genera within the *Tombusviridae* is the segmented nature of their single-stranded RNA genomes. Based on significant viral replicase and capsid protein amino acid sequence similarity, the *Dianthovirus* genus has been placed within the recently established family *Tombusviridae*. The *Dianthovirus* genus is currently composed of three definitive members; carnation ring spot virus (CRSV), the type member; red clover necrotic mosaic virus (RCNMV); and sweet clover necrotic mosaic virus (SCNMV); and one potential member, furcraea necrotic streak virus (FNSV). For each definitive member, several biological and serological strains have been identified.

Properties of Virion

Electron microscopic examination of dianthoviruses show that they are 32–35 nm icosahedral virus particles with a $T=3$ symmetry. The particles have distinctively granular surfaces similar to members of the *Tombusvirus* and *Carmovirus* genera. The virion is composed of 180 copies of the 37 kDa capsid protein. This forms the protein shell that packages the 4 kb and 1.5 kb genomic single stranded RNAs. X-ray crystallographic studies have not been performed on any dianthoviruses. However, several structural features can be inferred as a result of amino acid sequence similarity between RCNMV and both turnip crinkle carmovirus and tomato bushy stunt tombusvirus (TBSV) (**Table 1**), whose structures have

been solved at 3.2 Å resolution. The RCNMV capsid protein is organized into four domains. The N-terminal RNA binding (R) domain, which is basic in nature and extends into the interior of the virion, is truncated relative to the R domains of the carmo- and tombusviruses. The R domain is connected to the shell domain (S) by a short intervening arm (a) (**Fig. 1**). The 160 residue S domain is highly conserved among members of the diantho-, carmo- and tombusviruses, suggesting that the dianthovirus virion shell is composed of the conserved 'jellyroll β barrel' structure found in all spherical viruses of eukaryotes. In addition, clusters of conserved negatively charged residues, including an invariant aspartic acid residue within the S domain, constitute a Ca^{2+} binding site which may be associated with structural integrity and virion assembly. The internal S domain is linked to the C-terminal protruding domain (P), which projects outward from the surface of the virion. The P domain most likely gives dianthoviruses their distinctive granular appearance in the electron microscope. The putative RCNMV P domain possesses only moderate amino acid sequence conservation with the P domains of the tombus- and carmoviruses.

Several different strains of CRSV are distinguished by distinctive aggregation properties. CRSV-A assembles into clusters of 12 particles assuming an

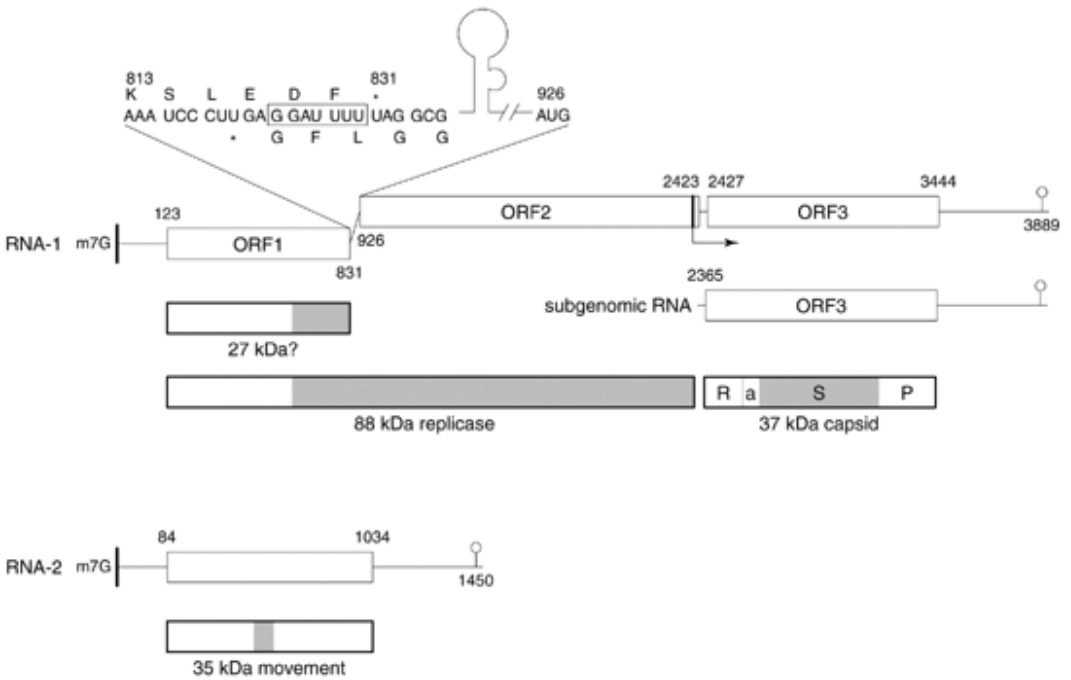

Figure 1 Schematic of the genome organization of RCNMV, illustration of sequences predicted to be involved in replication and gene expression, and identification of conserved protein domains. RCNMV RNA-1 and RNA-2 are depicted as solid lines with ORFs identified as open rectangles. Numbers above or below the borders of the ORFs identify initiation and termination codons defining the ORF. ORFs are labeled with respect to the size of the polypeptide they encode. Solid vertical bars at the 5′ end of RNA-1, RNA-2 and near the C-terminus of the p57 ORF identify a 13 nucleotide conserved sequence. Right angle arrow identifies the location of the beginning of the capsid protein subgenomic RNA. The stem–loop at the 3′ end of both viral RNAs symbolizes the 3′ terminal 27 homologous nucleotides capable of forming a stable stem–loop structure. Above RNA-1 is an expanded region of sequence between RNA-1 nucleotides 813 and 926. The heptanucleotide sequence facilitating ribosomal frameshifting immediately preceding the p27 ORF amber termination codon is boxed. Following this sequence is a schematic of a predicted stable stem–loop structure that may be involved in ribosomal frameshift expression of the 88 kDa fusion polypeptide. Shaded rectangles below the RNAs represent viral encoded polypeptides identified *in vivo*. Shaded areas within RNA-1-encoded polypeptides identify domains with significant amino acid sequence similarity to proteins from the carmo- and tombusviruses. The shaded region in the RNA-2 encoded 35 kDa polypeptide identifies a domain conserved between the *Bromoviridae* movement proteins. The R (RNA binding), a (arm), S (shell) and P (protruding) domains of the RCNMV capsid protein are indicated. Polypeptide functions are stated below the protein, if known.

icosahedral symmetry. This 12 particle unit can form higher order aggregates. CRSV-N and -R strains form alternative two-dimensional net-like aggregates. These aggregation properties appear to be unique to CRSV and have not been observed for the other dianthoviruses.

Properties of Genome

The structure of the dianthovirus genome is based on the complete nucleotide sequence of CRSV, RCNMV and SCNMV. The dianthovirus genome is composed of two, essentially nonhomologous, positive polarity, single-stranded RNAs of approximately 4 kb (RNA-1) and 1.5 kb (RNA-2). The genomic RNAs are infectious as naked nucleic acids. Each RCNMV genomic RNA is capped at the 5′ terminus with m^7GpppA and is not 3′-terminally polyadenylated. Only the 5′ terminal six nucleotides and 3′ terminal 27 nucleotides are identical between RNA-1 and RNA-2. The identical 3′ 27 nucleotides are capable of forming a stem–loop structure which may be involved in viral replicase recognition (**Fig. 1**). RNA-1 contains three open reading frames (ORFs). The first ORF (p27) initiates at the first methionine codon, 123 nucleotides from the 5′ terminus. The p27 ORF is capable of encoding a 27 kDa polypeptide. An internal ORF (p57) could encode a 57 kDa polypeptide. The most 3′ terminal ORF encodes the 37 kDa capsid protein, followed by a 445 nucleotide 3′ terminal noncoding sequence. RNA-2 is monocistronic, containing a single ORF encoding a 35 kDa polypeptide. RNA-1 directs the synthesis of 27, 57, 88 and 37 kDa polypeptides *in vitro*. Only the 88 kDa polypeptide, which is made in small quantities relative to other products, does not correlate in size to one of the three RNA-1 ORFs. The p88 polypeptide is a fusion protein which is serologically related to both the p27 and p57 polypeptides. Immediately preceding the p27 ORF termination codon, a seven-nucleotide element has been identified which facilitates ribosomal frameshifting in accordance with the simultaneous slippage model (**Fig. 1**). Following the frameshift heptanucleotide, a stable stem–loop structure is predicted. These structural features have been shown to facilitate ribosomal frameshift expression of *gag-pol* fusion proteins in retrovirus systems. Mutation of the frameshift element affects the expression of p88 synthesis *in vitro*. Together, this information suggests that p88 is a fusion protein resulting from translational readthrough of the p27 ORF into the p57 ORF by a ribosomal frameshifting mechanism. The 57 kDa polypeptide has not been observed *in vivo* and the independent production of this protein may well be an *in vitro* translation artifact.

Physical Properties

The icosahedral *Dianthovirus* virions sediment as a single species with a sedimentation coefficient ($s_{20,w}$) of 132 S and have an equilibrium density of 1.366 g cm^{-3} in CsCl. The molecular weight of a virion, assuming that each particle possesses one copy of RNA-1 and RNA-2 is 8.2 MDa. It is not known whether a virion contains one copy of both genomic segments or whether a virion contains one copy of RNA-1 and another contains three copies of RNA-2. Dianthovirus particles are stabilized by RNA–protein interactions and pH-dependent protein–protein interactions. Dianthoviruses are generally quite stable with RCNMV being more stable than CRSV. Particles slowly swell when pH is increased from 5.0 to 7.5. EDTA also induces particle swelling whereas Mg^{2+} and Ca^{2+} ions prevent particle swelling. CRSV particles have an isoelectric point of pH 5.1. RCNMV strains A, B and C have isoelectric points of pH 5.0, 4.8 and 4.6, respectively.

Replication

Little is known regarding the specifics of dianthovirus replication. Cytological studies suggest that replication occurs in the cytoplasm of infected cells, although mature virions have been reported in the nucleus. Dianthoviruses replicate by producing a negative sense complementary copy of the viral RNA. The viral replicase most likely recognizes the 3′ terminal stem–loop structure on the viral sense RNA-1 and -2, enabling it to initiate synthesis of the full length complementary strand. After completion of complementary strand synthesis, the viral replicase then recognizes the conserved 3′ termini as an initiation site for the production of progeny genomic RNA-1 and -2. This replication strategy dictates that prior to replication, viral replicase must be expressed from the original infecting genomic RNA-1. Consistent with this assumption, the putative replicase ORFs are located at the 5′ terminus of RNA-1 making them easily accessible to translation. A template-bound RNA replicase has been isolated from RCNMV-infected tissue that upon digestion with micrococcal nuclease became template-dependent. The replicase complex was composed of the RCNMV 27 kDa and 88 kDa polypeptides in addition to several proteins thought to be of host origin. The RNA-1 3′ terminal capsid protein ORF is expressed *in vivo* from a 1.4 kb subgenomic RNA. Presumably the viral replicase recognizes an internal sequence con-

taining a 13 nucleotide element upstream of the capsid protein ORF initiation codon. This sequence element is identical to the 3′ terminus of the full length complementary strand. Once bound, the replicase synthesizes a positive sense copy of the capsid protein subgenomic RNA.

Host Range and Virus Propagation

Dianthoviruses have moderately broad natural and experimental host ranges. CRSV was originally isolated from commercial carnations, but has since been found to infect a wide range of orchard trees, including plum, pear, apple and sour cherry, and also grapevines. CRSV has also been identified in several weed species growing within infected fruit orchards. RCNMV has been isolated from naturally infected alfalfa and red, sweet and white clovers. SCNMV has been identified in sweet clover and alfalfa, as well as in various leguminous weeds. The experimental host range of the dianthoviruses is much broader than that found in nature. The dianthoviruses are easily mechanically transmissible to a wide range of herbaceous species. These viruses can systemically infect a number of members of the *Solanaceae, Leguminosae, Cucurbitaceae* and the *Compositae*. Dianthoviruses infect an even larger number of plants locally (nonsystemically).

CRSV infection in carnations results in diagnostic ring spots, mottling and leaf and flower distortions. The disease symptoms are enhanced when carnations are co-infected with carnation mottle carmovirus. On experimental systemic hosts, CRSV causes concentric ring-spots with necrotic centers on the inoculated leaves and mosaics, necrotic flecks and often veinal necrosis on the systemically infected leaves. RCNMV and SCNMV infections result in necrotic mosaics, and necrotic and chlorotic spots on the inoculated and systemic leaves of naturally infected clover species. Systemically infected leaves of *Nicotiana* and legume species exhibit necrotic mosaics which result in leaf deformation and plant stunting. In general, dianthovirus infections do not kill the host plants, however, necrosis and symptom severity can become quite severe at sustained temperatures between 15 and 20°C versus temperatures above 20°C. In nature, symptoms generally disappear and plants recover when the average mean temperature rises above 20°C for an extended period of time.

Genetics

RCNMV RNA-1 can replicate in plant protoplasts in the absence of RNA-2. This fact allows for the assignment of replication and encapsulation functions to RNA-1 and cell-to-cell movement function to RNA-2. The RNA-1 encoded 88 kDa polypeptide contains the conserved glycine-aspartate-aspartate (GDD) motif present in all RNA-dependent RNA polymerases. In addition, extensive amino acid sequence similarity exists between the RCNMV 27 kDa and 88 kDa polypeptides and the replicases encoded by all of the species within the *Tombusviridae* (**Table 2**). Deletion mutagenesis has shown that RNA-1 is capable of replication in the absence of both the capsid protein gene and RNA-2. From this information it is concluded that the RCNMV RNA-1-encoded 27 and 88 kDa polypeptides are required and sufficient for viral replication. Interestingly, unlike many viral replicase proteins, those encoded by the dianthoviruses and other viruses in the *Tombusviridae* do not contain an identifiable helicase motif.

SCNMV	62/76	91/93	—	18/46
TBSV	19/45	19/45	18/46	—

The 37 kDa polypeptide encoded by the RCNMV RNA-1 3′ proximal ORF is the viral capsid protein. Mutagenesis of this ORF revealed that C-terminal amino acid sequence deletions completely destabilize the protein, such that neither virion formation nor truncated forms of the capsid protein can be detected *in vivo*. These same C-terminal, as well as other internal capsid protein deletions prevent rapid systemic infection from occurring in all hosts, with the exception of *Nicotiana benthamiana* at low temperatures. However, as many as 16 amino acids can be deleted from the N-terminus of the RCNMV capsid protein with no effect on polypeptide stability, virion formation, or ability to rapidly systemically infect host plants.

RCNMV infections, in the absence of RNA-2 or with deletion mutations within the RNA-2 p35 ORF, are restricted to the initially inoculated cell and are incapable of moving to adjacent cells. Consequently, it was concluded that the 35 kDa polypeptide is the viral cell-to-cell movement protein which facilitates movement of the virus from infected to neighboring healthy cells through the plasmodesmata. The RCNMV capsid protein is not necessary for cell-to-cell movement, but is required for rapid systemic

Table 3 Percentage amino acid sequence identity among *Dianthovirus* species movement proteins

infection through the vascular tissue. The RCNMV and CRSV movement proteins contain movement protein motifs conserved among species within the RNA plant virus *Bromoviridae* family (**Fig. 1**)(**Table 3**).

Pseudorecombination studies between various strains, as well as distinct members within the *Dianthovirus* genus, further support the assignment of cell-to-cell movement function to RNA-2. In addition, RNA-2 controls lesion morphology and the ability to systemically invade cowpea. RNA-1 contains host range specificity, serological specificity, and symptom expression determinants.

Serologic Relationships and Variability

The dianthoviruses, like most spherical RNA plant viruses, are good immunogens. Studies using polyclonal antisera have identified three serologically distinct strains of CRSV (A, N and R), four strains of RCNMV (A, B, C and D), and two SCNMV strains (38 and 59). Clover primary leaf necrosis virus was once considered to be a distinct dianthovirus, but upon immunological analysis, has now been determined to be a previously recognized RCNMV serotype. The various SCNMV and RCNMV serotypes weakly crossreact with one another using polyclonal antibodies. In addition, RCNMV polyclonal antibodies react with FNSV virions. No cross-reactivity has been observed between CRSV and RCNMV or SCNMV with polyclonal antibodies. However, a single monoclonal antibody to SCNMV does react with CRSV and RCNMV. This monoclonal antibody most likely recognizes a highly conserved epitope in the capsid protein shell domain.

Epidemiology

CRSV is an established and persistent disease problem in commercial carnation facilities. The virus has diminished as a major problem in recent years due to vigilant and effective control measures. Infected nuclear block plants, from which production cuttings are derived, serve as sources of virus inoculum in commercial glasshouses. Rouging, selection, indexing and meristem tip culture are all effectively employed to insure that these stock plants are free of all viruses, including CRSV. CRSV in carnations spreads by careless propagation and leaf and root contact. In orchard crops, it has been observed that nematode infestation increases the incidence of CRSV. Cultural practices and chemicals which control nematode populations control the spread of CRSV in orchard crops. Little information exists regarding the epidemiology and control of RCNMV and SCNMV.

Transmission and Tissue Tropism

Dianthoviruses are not transmitted through seed, nor by insects or soil-inhabiting fungi. However, confusion exists as to whether dianthoviruses can be transmitted from plant to plant by nematodes. Early reports suggested that CRSV could be transmitted by several species of nematodes. These data tended to confirm observations that CRSV infections were more widely spread in orchards and vineyards when the soil was infested with known virus-vectoring nematodes. However, more recent reports suggest that CRSV, RCNMV and SCNMV particles are released directly from infected roots into the soil. Plant-to-plant transmission can then occur passively through the soil in the absence of a biological vector. Presumably, infection occurs through microscopic sized root wounds. Nematode and soil fungus colonization of roots tends to increase the possibility of soil transmission of dianthoviruses by generating virus entry sites, but transmission is not absolutely dependent on this. Thus, dianthoviruses require no biological vector for soil transmission. Dianthoviruses are readily mechanically transmissible. In nature, dianthoviruses are transmitted from plant-to-plant by physical contact or by contaminated soil. In addition, CRSV spread in carnations is most likely due to vegetative propagation.

RCNMV infects most cell and tissue types in systemic hosts. RCNMV also appears to infect most,

if not all tissues of the roots of systemic hosts. In the systemic host *N. benthamiana* the virus titer in root tissue is twice that of foliar tissues. In hosts of RCNMV that are capable or supporting only a localized infection (*Nicotiana tabacum,* for example), the virus is limited to the epidermal, mesophyll, bundle sheath and phloem parenchyma cells. The infection is incapable of infecting either the companion cells or sieve element.

Pathogenicity

CRSV is an economically significant pathogen of commercial carnations. Extensive indexing and eradication programs are employed to eliminate CRSV from commercial carnation production facilities. Carnations infected with CRSV alone, or in combination with several other viruses, yield low quality unmarketable flowers. In Eastern and Central Europe, CRSV infects a wide range of orchard and vine crops. However, the role of CRSV in economically important diseases of these crops has not been fully established. Diseased orchard trees in addition to having low titers of CRSV are always infected with one or more other viruses. Typically, RCNMV and SCNMV infections of forage legumes result in rather mild diseases which have limited impact on yield. However, infection by either RCNMV or SCNMV can result in economic losses when temperatures remain unusually cool for an extended period of time.

Pathology and Histopathology

Dianthovirus-infected cells contain large amorphous inclusions which can be readily observed with a light microscope after staining. Electron microscopic studies show that these inclusions are composed of large aggregates of virus particles within the cytoplasm. Inclusions form as intracellular virus titer increases and become readily observable when the virus titer reaches a maximum, approximately one week after inoculation. CRSV infections in cowpea result in crystalline arrays composed of virions in the cytoplasm. The nuclei also contain aggregates of virus particles, in addition to tubular inclusions, which frequently have virus particles apparent on the surface. In carnation, spherical inclusion bodies are also observed. Inflated and electron transparent mitochondria, clusters of proliferated endoplasmic reticulum with dilated cisternae are apparent in cells with mature infections. CRSV particles are commonly observed scattered throughout the cytoplasm of mesophyll cells, with necrotic cells having massive aggregates of virions. RCNMV induces pronounced chloroplast vasiculation. FNSV particles are detected in the cytoplasm of both leaf and root cells and are sometimes associated with electron-dense tubular inclusions.

Prevention and Control

CRSV is the most pathologically relevant species within the *Dianthovirus* genus. The most effective control is sanitation during plant propagation. In vegetatively propagated hosts such as carnation and fruit trees, eradication of CRSV in plant shoots or meristems by chemo- and thermotherapy is routinely accomplished to produce certified virus free nuclear stocks which are then commercially propagated under a strict sanitation regime. Production from virus-free nuclear stocks coupled with constant monitoring for CRSV infection by ELISA has ensured the production of CRSV-free commercial carnations.

Control of RCNMV is more problematic. RCNMV is not seed transmitted and legume seedlings probably are infected by plant-to-plant contact or by direct soil transmission. Little if any breeding for resistance to RCNMV has been performed, consequently most commercial cultivars of red clover are fully susceptible to the virus.

Evolution
