History

The highly contagious acute respiratory illness known as influenza has afflicted humans since ancient times. The pattern of outbreaks of respiratory diseases that appear suddenly, persist for a few weeks and then suddenly disappear is sufficiently characteristic to permit the identification of numerous major epidemics in the distant past. One such epidemic was recorded by Hippocrates in 412 BC, and several were described in the Middle Ages. Historical data from 1500–1800 indicate that: (1) epidemics occurred relatively frequently but irregularly, with the disease seeming to disappear for periods of time; (2) epidemics varied in severity but usually caused mortality in the elderly; and (3) some epidemics, such as those in 1781 and 1830, spread across Russia and Asia. There are similarities with our current knowledge of the epidemiology of influenza, including age-related mortality and emergence of epidemics in China.

The 1918 'Spanish influenza' pandemic was particularly severe, killing between 20 and 40 million people worldwide, and partial analysis of the virus genome from a lung sample in a paraffin block of a soldier that died in 1918 supports the belief that the virus originated from swine. In the late 1920s, Richard Shope showed that swine influenza could be transmitted with filtered mucus, suggesting that the causative agent was a virus. Human influenza A virus was first isolated in ferrets in 1933 by Wilson Smith, Sir Christopher Andrewes and Sir Patrick Laidlaw, in the UK. Influenza B was first isolated by Thomas Francis in 1940.

Fowl plague, a lethal form of influenza in chickens, was first reported in Italy in 1878 but it was not until 1955 that Walter Shafer in Germany showed that this disease was actually caused by an influenza virus.

Taxonomy and Classification

Influenza viruses belong to the *Orthomyxoviridae* family of RNA viruses and is constituted of four genera; *Influenzavirus* A, *Influenzavirus* B, *Influenzavirus* C and *Thogovirus*. These viruses have segmented negative-strand RNA genomes enclosed in a lipid envelope derived from the host cell. The particles are covered in a layer of spikes, contained in the envelope, which are of three kinds: a hemagglutinin (HA) which agglutinates erythrocytes, an enzyme neuraminidase (NA) which releases the virus from cells and a small number of copies of the M2 protein that serves as an ion channel. Beneath the lipid envelope is a membrane or matrix (M) protein surrounding a helical complex containing the nucleoproteins (NP) and three poly-

merase proteins. *Influenzavirus* A and B have eight RNA segments whereas *influenzavirus* C and *Thogovirus* have seven, each coding at least one protein. Influenza A viruses are divided into subtypes which are based on the host of origin (pigs, horses, birds), geographic origin, strain number and year of isolation, the subtype is given in parenthesis, e.g. A/swine/Iowa/15/30 (H1N1). By tradition, the host of origin of human strains is not included, e.g. A/Hong Kong/1/68/(H3N2).

Geographic and Seasonal Distribution

Human influenza occurs worldwide, is endemic in tropical regions and occurs year round. In the temperate and subarctic regions, influenza in humans and swine is a 'winter disease'. The occurrence of influenza in winter is not well understood and may be associated with crowding, low humidity, and increased virus survival. Avian influenza viruses are prevalent in the fall of the year in wild ducks when the young congregate prior to migration and in shorebirds in the US in spring.

Equine, swine and avian influenza viruses have a wide geographic distribution; the avian influenza viruses from Europe and Asia can be separated phylogenetically from those in the Americas.

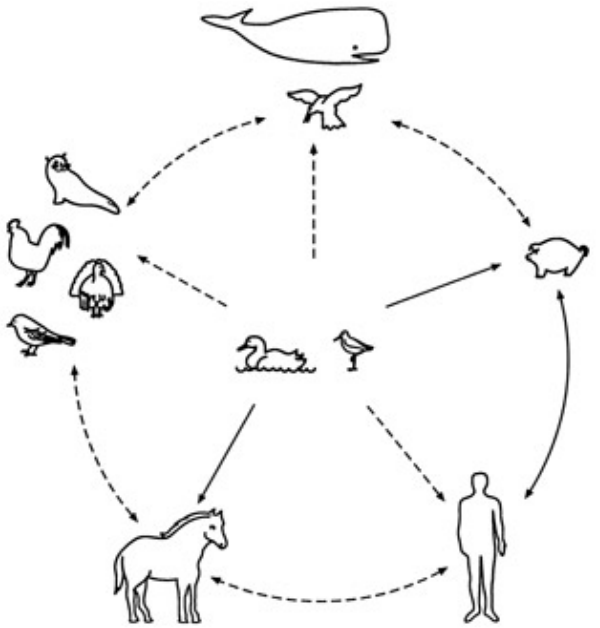

Figure 1 The reservoir of influenza A viruses. The working hypothesis is that wild aquatic birds are the primordial reservoir of all influenza viruses for avian and mammalian species. Transmission of influenza has been demonstrated between pigs and humans (solid lines). There is extensive evidence for transmission between aquatic birds and other species including pigs and horses and indirect transmission to humans through pigs and evidence for direct transmission to humans from chickens.

Host Range and Viral Propagation

Influenza A viruses commonly cause disease in humans, pigs, horses and occasionally in birds. Since 1933, three HA subtypes have been identified in humans, two in pigs, and two in horses. All of the 15 subtypes are found in aquatic birds, mainly in wild ducks and shorebirds; they usually cause no disease in these hosts but serve as reservoirs of influenza A genetic information (**Fig. 1**). Influenza viruses (of avian origin) are occasionally isolated from seals, mink and whales. Influenza B viruses occur only in humans, whereas influenza C has been found in humans and pigs.

Experimental hosts include ferrets, which develop febrile rhinitis after infection with influenza A and B viruses. Ferrets have been used extensively to study the biology of influenza viruses and as a source of reference antisera. Other experimental animals include mice, monkeys and New World primates. Mice are not naturally infected with influenza viruses, but both influenza A and B viruses can be adapted to mice. The virus replicates in the upper and lower respiratory tract and, after adaptation can cause pneumonia and death. Most strains of mice can support influenza virus after adaptation, and inbred strains have been valuable in elucidating cell-mediated immune responses to respiratory viral infection. The A2G mouse is resistant to influenza and carries a dominant allele (*Mx* gene) that specifies a protein which is induced by interferon and inhibits influenza virus.

Influenza viruses can be grown in embryonated hens' eggs or in a number of primary tissue culture systems. Cultivation of influenza viruses in eggs remains the system for production of vaccine and for large quantities of virus used in laboratory studies. The continuous Madin Darby canine kidney cell line and primary monkey, calf, hamster and chicken kidney cell cultures will support influenza viral replication, provided trypsin is added to cleave the HA. Influenza virus replication is detected by hemagglutination of erythrocytes.

Genetics

Influenza viruses show genetic changes by accumulation of point mutations in their RNA segments and by reassorting their segments after two or more influenza viruses infect a single cell. The mutation rate of influenza A is approximately 1.5×10^{-5} mutations per nucleotide per replication cycle. In human influenza A viruses, up to 50% of the nucleotide

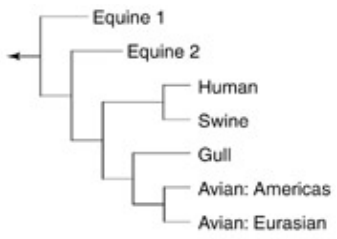

Figure 2 Generalized phylogeny of influenza A virus. Generalized phylogenetic tree of the nucleotide sequences of the nucleoprotein gene of influenza viruses. The most ancient influenza lineage (Equine 1) may have disappeared from horses. Human and swine viruses have a brother–sister relationship. Avian lineages are geographically separable into those from the Americas and those from Eurasia.

changes result in amino acid changes. Amino acid changes are less frequent in influenza B and C and in avian influenza A. Human influenza A viruses are evolving more rapidly than other influenza viruses and also reassort their genomes after mixed infection with another influenza A virus.

Evolution

Results of sequence analysis of each of the genes of influenza A viruses support the idea that there are five host specific lineages, that the avian lineages are in evolutionary stasis and can be separated in American and Eurasian varieties (**Fig. 2**). The influenza A viruses currently circulating in humans probably originated approximately 150 years ago from influenza viruses in avian species. The available information suggests that the catastrophic 1918 'Spanish' influenza originated from swine supporting the notion of the pig as the intermediate host. The highly virulent strains died out but gave rise to the current human influenza A lineage. The influenza A viruses circulating in swine and horses, and occasional isolates from seals and mink, also originate from avian sources.

Serologic Relationships and Variability

Influenza A and B viruses are distinguished antigenically on the basis of their NP and M proteins. The subtypes of influenza A are distinguished by serologic differences between their HA and NA proteins. Influenza A and B viruses of mammals are unique among the respiratory tract viruses in that they undergo continuous variation; thus, vaccines must be changed almost every year. The surface antigens of the influenza A viruses undergo variation by both antigenic drift and antigenic shift; antigenic drift occurs in types B and C virus but shift occurs only in influenza A.

Antigenic drift in the HA and NA occurs by point mutations in the gene, leading to an accumulation of amino acid sequence changes that alter the antigenic sites such that they are no longer recognized by the host's immune system. Antigenic drift can be mimicked in the laboratory by growing influenza viruses in the presence of monoclonal antibodies to the HA or NA.

Antigenic shift occurs only in influenza A viruses and is caused by a more radical change in the HA and/or NA. After antigenic shift, influenza viruses appear in the population with surface antigens unlike those of viruses immediately preceding them. Since the first human influenza virus was isolated in 1933, antigenic shifts have occurred in 1957, when H2N2 subtype (Asian Strain) replaced the H1N1 subtype, in 1968, when the Hong Kong (H3N2) virus appeared, and in 1977, when the H1N1 virus reappeared. All these major antigenic shifts in the virus occurred in China. Serologic evidence suggests that since 1890 there have been six antigenic shifts (**Fig. 3**). There has been a cyclic appearance of three HA subtypes: H2N8 viruses in 1890, H3N8 in 1900, H1N1 in 1918, H2N2 again in 1957, and H3N2 in 1968, and H1N1 in 1977.

Epidemiology

The available evidence indicates that new human influenza strains may result from genetic reassortment between influenza virus in humans and in lower animals and birds and that these viruses originate in China. There is ample evidence for genetic reassortment of the segmented RNA genome, and sequence analysis has established that three of the eight segments of the Asian 57 strain came from avian sources (HA, NA and one polymerase PB1). The 1968 Hong Kong virus obtained an HA and a PB1 gene from an avian source. Pigs are susceptible to infection with avian and human influenza viruses and the possibility has been raised that they may serve as the mixing vessel.

It is about 30 years since a novel influenza subtype emerged in humans and a new pandemic is considered imminent. The direct transmission of an avian H5N1 influenza virus to humans in Hong Kong in 1997 with 18 confirmed cases and six deaths might represent the early stages of development of a pandemic. The H5N1 virus was prevalent in the live bird markets and was highly pathogenic for chickens but nonpathogenic in ducks. This virus failed to transmit efficiently from human to human and transmission to humans from avian sources was interrupted by slaughter of the poultry in Hong Kong. The depopulation of poultry, cleaning of markets and the new policy of marketing

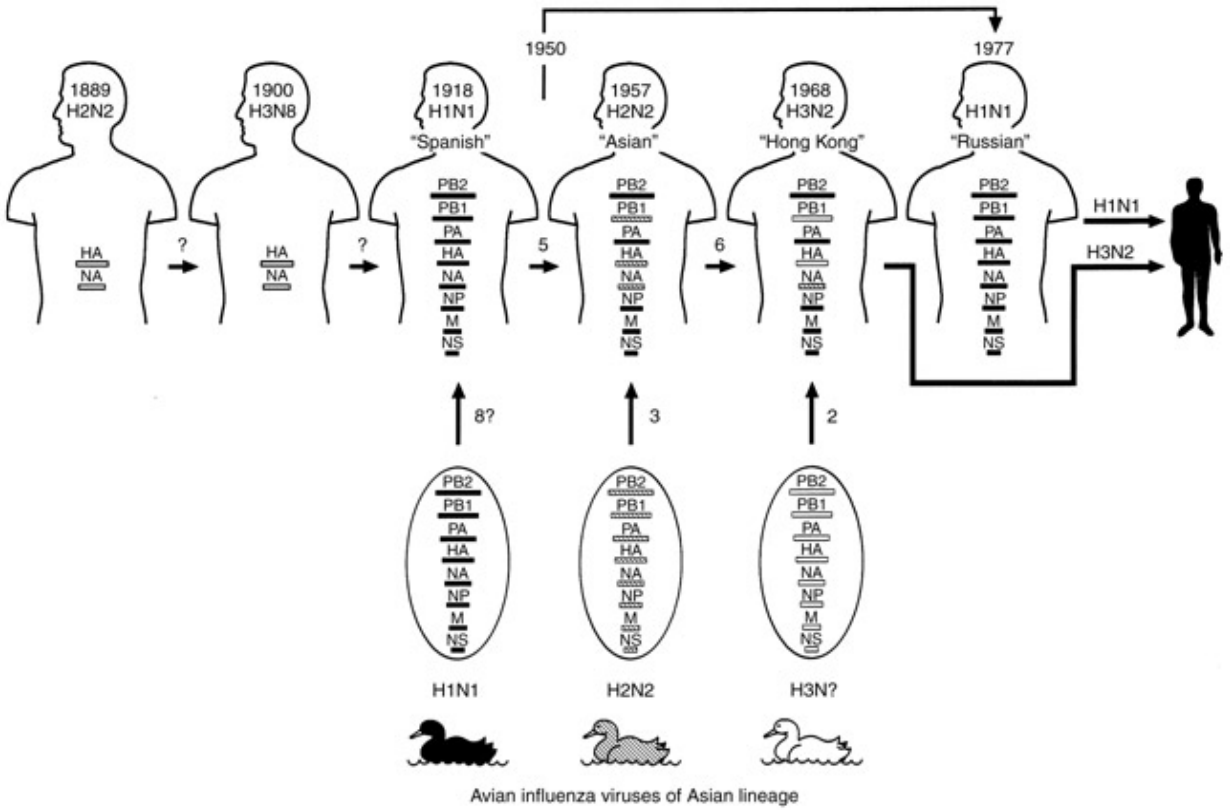

Figure 3 Emergence of influenza A pandemic viruses. Seroarcheology suggests that H2N2 and N3N8 influenza viruses circulated in humans in 1989 and 1990 respectively. Phylogenetic evidence suggests that an influenza virus possessing eight gene segments from avian influenza reservoirs was transmitted to pigs and before 1918 it spread and replaced the 1900 strain. This virus was reportedly carried from North America to Europe by American troops and caused the catastrophic Spanish influenza pandemic of 1918. In 1957 the Asian pandemic virus acquired three genes (*PBI, HA, NA*) from the avian influenza gene pool in wild ducks by genetic reassortment and kept five other genes from the circulating human strain. After the Asian strain appeared, the H1N1 strains disappeared from humans. In 1968 the Hong Kong pandemic virus acquired two genes (*PBI, HA*) from the duck reservior by reassortment and kept six genes from the virus circulating in humans. After the appearance of the Hong Kong strain, the H2N2 Asian strains were no longer detectable in humans. In 1977 the 'Russian' H1N1 influenza virus that had circulated in humans in 1950 reappeared and spread in children and young adults. This virus probably escaped from a laboratory and has continued to cocirculate with the H3N2 influenza viruses in the human population.

live chickens separate from aquatic birds may influence interspecies transmission.

It is unclear how all of the subtypes of influenza A viruses are maintained in aquatic birds from year to year. Influenza viruses are cleared from ducks in approximately 7 days, and there is no evidence of persistence of influenza virus genetic information in any species. The available data support the hypothesis that the viruses are maintained by circulation at low levels in the avian population during migration and overwintering.

Transmission and Tissue Tropism

Influenza viruses of humans and other mammals are spread by aerosols, including sneezing. The virus replicates in the cells of the upper and lower respiratory tract, reaching a peak at 2–3 days after infection, and is usually cleared in 7 days. Children experiencing their first infection can shed virus for up to 13 days.

Influenza viruses of birds are usually spread by fecal contamination of water but can also be spread by aerosols. Unlike mammalian influenza viruses, which combine with receptors in the respiratory tract, avian influenza viruses combine with receptors in both the respiratory and lower intestinal tracts. The HA molecule combines with cell surface sialic acid-bearing glycoproteins and glycolipids. In aquatic birds, viruses are shed in high concentrations in the feces, which probably serve as the main vector for transmission to domestic poultry.

Pathogenicity

Influenza virus strains differ in pathogenicity: some viruses cause substantial mortality in their hosts, whereas others do not. The immune status of the population and the extent of antigenic differences between strains are of key importance. Since 1957, the most serious outbreaks of disease in humans have corresponded to the introduction of 'new' pandemic strains, but interpandemic variants can also be associated with high mortality rates. The disease resulting from influenza viral infection is a complex event involving both the virus and the host. The viral genes responsible for high degrees of pathogenicity are better resolved for influenza viruses in chickens than in humans. The HA is of critical importance, but the correct combination of genes must also be present and usually include the NP, one of the polymerase genes and NA. In avian strains, a series of basic amino acids at the cleavage site between HA1 and HA2 is correlated with the potential for high pathogenicity (*See also:* **Influenza viruses – molecular biology** and **structure of antigens**); avirulent strains have a single arginine at this site. It is not known whether this finding extends to mammalian influenza strains. Equine H7 influenza virus, which possesses such a sequence, is not highly pathogenic in horses.

Clinical Features of Infection

In humans, influenza is characterized by the sudden onset of an acute respiratory illness with headaches, chills and nonproductive cough, followed by high fever, muscle aches, generalized weakness and loss of appetite. The fever declines by the third day and is usually gone by the sixth day, but cough and weakness can persist for an additional 2 weeks. More severe illness can develop if primary influenza pneumonia or secondary bacterial pneumonia occurs. People over 65 years of age and those with health problems, such as heart conditions, emphysema, asthma or acquired immune deficiency syndrome (AIDS), and children and adults receiving cancer chemotherapy are at increased risk for complications from influenza and should receive yearly vaccination. At least 10 000 excess deaths (over expected) have been documented in each of 19 different US epidemics in the period 1957–1986; in three epidemics there were >40 000 excess deaths. Approximately 80–90% of the excess deaths attributed to pneumonia and influenza were in people aged 65 years or older. Reye's syndrome, an often-fatal disorder, may occur in children after influenza infection most often with influenza B with brain and liver damage. Reye's syndrome is associated with the use of aspirin compounds and its incidence has declined with reduced use of these compounds.

Disease signs in pigs and horses are similar to those in humans. Influenza also occurs in birds, mainly aquatic species, with no detectable disease signs. In domestic species such as chickens and turkeys, the symptoms are usually mild with respiratory signs. However, two subtypes, H5 and H7, can cause generalized infection with central nervous system involvement and very high mortality in chickens and turkeys.

Pathology and Histopathology

Human influenza A virus induces pathologic changes throughout the respiratory tract, with the most significant pathology seen in the lower respiratory tract. Bronchoscopy of persons with uncomplicated influenza infections shows a diffuse involvement of the larynx, trachea, and bronchi, with acute mucosal inflammation and edema. Light microscopic studies reveal that within 1 day after the onset of symptoms, there is severe desquamation of the ciliated and mucus-producing epithelial cells, and thickened hyalinized basement membrane is exposed. Submucosal edema and hyperemia occur with an infiltration by neutrophils and mononuclear cells. Viral antigen is present predominantly in the epithelial cells and the mononuclear cells. Complete resolution of the epithelial necrosis probably takes up to a month. Viral pneumonia involves the spread of virus to the lung parenchyma. Combined viral and bacterial pneumonia often occurs in elderly and immunocompromised patients.

Immune Response

Recovery from influenza viral infection involves both humoral and cell-mediated responses. The surface glycoproteins are of the most importance in the humoral response, and internal proteins predominate in the cellular response. Mucosal [immunoglobulin (Ig)A] and serum (IgG) antibodies to the HA molecule neutralize viral infectivity and are primarily responsible for resistance to infection. This is the basis of vaccination against current epidemic strains with killed virus. The Ig response to the HA is subtype specific, but accumulation of point mutations (antigenic drift) permits infectious virus to escape antibody-mediated destruction. Five antigenic sites associated with protection have been identified on the globular head of the H3 molecule. Antibodies to the NA do not prevent infection, but reduce the spread of virus.

Influenza viruses are normally cleared by CD8+T virus-specific T lymphocytes. CD4+T cells do not clear influenza virus as effectively as CD8+T cells; however, their presence is required for antibody production although they can also contribute to the lung consolidation that is characteristic of influenza pneumonia. Infection with any influenza A virus primes for a secondary T cell response to any other influenza A virus because many of the CD8+T cells are specific for peptides of conserved internal viral proteins that are presented in a class I-restricted manner. The NP is particularly prominent in this regard, although the M protein, as well as NS and polymerase proteins may contribute to antigenicity. Macrophages, natural killer cells and immune T lymphocytes all play a role in virus clearance and release interferon, which inhibits influenza viral replication.

Prevention and Control of Influenza

Two options are available for the control of influenza A virus: vaccination or therapy with influenza specific antiviral agents. With increased global surveillance by the World Health Organization, vaccines and epidemic strains are usually well matched and effective at providing protection against influenza A and B.

The available vaccines include purified inactivated egg-grown whole virus or purified surface antigens. Only surface antigens (subvirion vaccines) are recommended for children under 12 years, because the whole-virus vaccine causes febrile responses in children. Persons with known allergies to eggs should not be given egg-grown vaccine. Cold-adapted attenuated live influenza vaccines have been shown to be safe and effective in experimental trials and are currently under review for licensing for general use.

The antiviral agents amantadine and rimantadine that target the M2 ion channel are only efficacious on influenza A viruses and resistant variants arise rapidly. Antiviral agents targeting the NA (Zanamivir, GS4071 and GS4104) are efficacious against influenza A and B viruses and clinical testing shows considerable promise.

Future Perspectives

Continuing antigenic drift and irregular antigenic shift are neither predictable nor preventable. The natural reservoirs of influenza viruses in aquatic birds throughout the world means that influenza is not eradicable. Thus the long-term perspective for influenza is the development of improved control strategies. It is considered inevitable that there will be another human influenza pandemic and as time passes the likelihood increases. Planning for the next human pandemic has been done in many countries and is promoted by the World Health Organization. Pandemic plans include improved ability to respond to antigenic drift on an annual basis with increased surveillance, rapidity of preparing vaccines, and the utilization of available antiviral drugs. Improvements in dealing with antigenic drift will ensure the ability to rapidly implement a pandemic plan.

It is recognized that we are ill equipped to deal with the emergence of a 1918-style pandemic that immediately causes high mortality and transmits rapidly. Increased human surveillance particularly in China and the possibility of an early warning system that involves the detection of novel influenza viruses in pigs may provide additional lead-time for vaccine preparation. There is an urgent need for highly efficacious anti-influenza drugs. The NA inhibitors are showing promise but additional targets need to be investigated. Stockpiling of amantandine and rimantadine must be considered. The preparation of high growth reassortant strains to each influenza A subtype and methods to broaden the immune response with crossreactive determinants including the use of new adjuvants are necessary. Other strategies including live attenuated vaccine strains to all subtypes and DNA vaccine strategies requires additional study and incorporation into a strategic plan that is updated on a regular basis – minimally every 3 years.

Properties of the Virion

Influenza viruses are spherical enveloped viruses of approximately 120 nm in diameter, but large filamentous forms can also be observed in the electron microscope, especially when polarized cells are infected. The viral glycoproteins hemagglutinin (HA) and neuraminidase (NA) are inserted in the external viral envelope and form spike-like structures. The HA protein is the major surface glycoprotein in influenza A and B viruses, and appears as an elongated homotrimer, while the NA protein forms a mushroom-shaped homotetramer. In contrast to influenza A and B viruses, influenza C viruses appear to have only one type of glycoprotein, the hemagglutinin/esterase (HE or HEF), which is anchored in the lipid bilayer membrane. In addition, the envelope of influenza A, B and C viruses contains small amounts of another integral membrane protein, the M2, NB and CM2 proteins, respectively. Just beneath the viral envelope of all influenza viruses is a protein layer made up of the M1 protein. The viral ribonucleoprotein (RNP) core consists of the viral RNAs which are associated with the nucleoprotein (NP) and the polymerase proteins (PB1, PB2 and PA). A scheme of the organization of an influenza A viral particle is shown in **Fig. 1**.

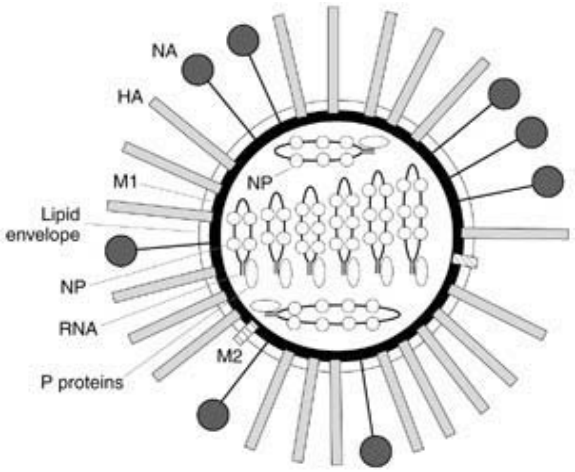

Figure 1 An influenza A viral particle. The virion contains a lipid envelope in which three different types of transmembrane proteins are anchored: the hemagglutinin (HA) and the neuraminidase (NA) form the characteristic viral spikes which can easily be seen by electron microscopy; the M2 protein is a nonabundant short transmembrane polypeptide. Inside the envelope there is a protein layer constituted by the M1 protein (filled ring), which surrounds the viral core or ribonucleoproteins (RNPs). Each RNP consists of one single-stranded RNA segment associated with the nucleoprotein (NP) and the three polymerase (P) proteins. In addition, the NEP(NS2) protein might also be a structural component present in the inside of the viral particle. RNA segments exist in a circular conformation stabilized by base-pairing between their 3′ and 5′ ends. Eight different RNA segments can be found per virion.

Properties of the Genome

The genomes of influenza A and B viruses consist of eight different single-stranded RNA segments of negative polarity; that of influenza C viruses has only seven segments. The coding capacity of these genomes is approximately 13 600, 14 600 and 12 900 nucleotides for A, B and C viruses, respectively, and the sequences of many different strains have been obtained. The RNA segments of influenza A viruses exist in the virion in a circular conformation due to a terminal panhandle/fork/corkscrew structure stabilized by base-pairing between the 3′ and 5′ ends of the RNA segments. Although it has not yet been proven, it is assumed that this is the case for B and C viruses as well.

When influenza viruses are grown at high multiplicity, defective interfering (DI) particles may be produced. These DI particles contain one or more extra RNA segments whose 3′ and 5′ ends are identical to those of normal influenza viral RNAs. The DI RNAs are caused by internal deletion of influenza viral RNA segments, and their presence makes the virus defective. It also appears that the DI RNAs may interfere with viral replication.

Properties of the Proteins

The major surface glycoprotein of the virus is the HA, a polypeptide of approximately 560 amino acids. The HA undergoes various post-translational modifications during its transport to the plasma membrane, including trimerization, glycosylation, disulfide bond formation, palmitoylation, proteolytic cleavage and conformational changes. A diagram of the three-dimensional structure of the mature HA is shown in **Fig. 2A**. After proteolytic cleavage, two polypeptides are produced, the HA1 and the HA2; they remain linked by a cysteine bridge. Two principal functions have been found for the HA protein: (1) it is responsible for attachment of the virus to host-cell receptors, which are believed to be glycoproteins or gangliosides containing sialic acids; and (2) it possesses fusion activity. After attachment, the virus is

Figure 2 (**A**) Diagram of an H3 hemagglutinin kindly provided by Dr D. Wiley. The chain tracing shows a side view of a single monomer. The β chains (broad arrows) and the helices are indicated. (**B**) The four identical subunits of an NA spike viewed from above. The chain tracing has been kindly provided by Dr G. Air and Dr M. Luo and is based on the x-ray diffraction analysis of the crystallized molecule. Each of the four subunits has an unusual array of six β sheets. Each of these β sheets (resembling blades of a propeller) consists of four connected strands (wide arrows).

internalized into a cellular endosome. Acidification of this vesicle provokes a conformational change in the HA. The N-terminal region of the HA2, which is hidden inside the HA molecule, rearranges to form an extended coiled-coil structure, leading to the interaction of the endosome membrane with the hydrophobic N-terminus of the HA2. As a result, the viral envelope and the endosome membranes are fused, and the viral nucleocapsid is released into the cytoplasm of the host cell. The fusion activity of the HA is dependent on its being cleaved, and the susceptibility of cleavage of the HA has been correlated with virulence of virus in tissue culture and animals. In addition to the receptor binding and fusion activities, the HA protein contains the principal antigenic determinants, and it is assumed that antigenic variation of the HA is the major factor which allows the virus to escape the host immune response.

Like the HA, the NA is also a transmembrane glycoprotein. It contains approximately 460 amino acids, distributed along a short internal tail, a transmembrane domain, a stalk and a globular head. The three-dimensional structure of the head is represented in **Fig. 2B**, and consists of six β-sheet structures resembling a propeller with six blades. The NA protein is an integral membrane glycoprotein (of

type II) anchored in the lipid envelope by its N-terminus. It is found in the virion as a homotetramer. Because of its sialidase (neuraminidase) activity, this protein is responsible for the receptor-destroying activity of the virus. It appears that the NA facilitates the release of the new viruses from the host cell. In the absence of this enzyme, viruses remain bound to the cellular receptors by their HA proteins. The NA also removes the sialic acid present on the virus particles, preventing their aggregation to one another.

Influenza C viruses contain only one type of viral spike glycoprotein, the HEF protein, which is responsible for the receptor-binding, receptor-destroying and fusion activities of the virus. The cellular receptor for the influenza C virus is known to be the 9-*O*-acetyl-*N*-acetylneuraminic acid, and its receptor-destroying enzyme is not an NA, but a neuraminate-*O*-acetylesterase. Like the HA protein of A and B viruses, the HEF of influenza C viruses must be cleaved in order to exhibit membrane fusion activity.

The M2 protein of influenza A viruses is a small polypeptide ($M_r \approx 11\,000$) encoded by a spliced form of the mRNA derived from RNA segment 7. It contains a cytoplasmic C-terminus, a transmembrane domain and an external N-terminus and it is relatively abundant as a homotetramer in the plasma membrane of infected cells, but very rare in the virion (20–60 molecules per virus). In order to explain this discrepancy, an exclusion mechanism from the viral envelope could be proposed for the M2 protein. Mutations in the M2 protein have been associated with the resistance of the virus to amantadine and rimantadine, which are chemotherapeutic agents against influenza. It has been found that this polypeptide forms an ion channel, which is important during the uncoating as well as the viral maturation steps. Thus, the M2 protein pumps protons from the endosome to the inside of the virus during viral entry, leading to acidification of the viral cores and to dissociation of the M1 protein (uncoating) from the viral RNP complexes.

The RNA segment 6 of influenza B viruses codes for the NB protein and the NA protein; the latter is coded for via a second open reading frame with an alternative AUG initiation codon. The NB is a small glycosylated transmembrane polypeptide ($M_r \approx 18\,000$), structurally similar to the M2 protein of A viruses. It also serves as an ion channel and it may have functions similar to those of the M2 protein in influenza A viruses. Influenza C viruses also express a small integral homotetrameric membrane glycoprotein (the CM2 protein) from the same RNA segment which encodes the M1 protein. This glycoprotein, as the M2 and NB proteins, seems to be incorporated at low levels into the viral envelope and may also be an ion channel involved in viral uncoating.

The M1 protein is a polypeptide of $M_r \approx 28\,000$ and is encoded by RNA segment 7 of influenza A virus. It is the most abundant protein in the virion, and appears as a peripheral membrane protein surrounded by the viral lipid envelope. During uncoating, the M1 protein must dissociate from the RNPs, which then are transported into the nucleus. During the late period of viral replication, the newly synthesized M1 proteins appear to inhibit viral RNA transcription and they may have an indirect or direct role in promoting the exit of the RNPs from the nucleus into the cytoplasm. In any case, the M1 protein seems to be responsible for preventing the reimport of the RNPs into the nucleus. In addition, it has been postulated that the M1 protein associated with the RNPs interacts with the plasma membrane and possibly with the viral HA, NA and M2 proteins and/or with host membrane proteins, playing a key role in the budding of the virus from the host cell.

The polymerase proteins PB1, PB2 and PA are encoded by the three largest RNA segments. Their molecular weights are each around 80 000–90 000 and together they form a complex which possesses RNA-dependent RNA polymerase activity. Approximately 50 polymerase complexes are found per virion. The P proteins contain karyophilic signals in their sequences and they accumulate readily in the nucleus of infected cells. The PB2 protein seems to be involved in the recognition and cleavage of the type I cap structures of the cellular mRNAs, which then are used as primers for influenza viral RNA transcription. The PB1 protein is the catalytic polymerase subunit and is required for the initiation and elongation of the newly synthesized viral RNA. The PA protein may be involved in viral RNA replication and, in addition, the expression of the PA protein in infected cells has been associated with proteolytic activity. The functional significance of the latter activity is not yet understood.

The NP protein is the major structural protein of the RNPs and it has been found to be associated with the viral RNA segments. The NP is an arginine-rich protein ($M_r \approx 55\,000$) of approximately 500 amino acids. Each NP molecule covers approximately 20 nucleotides of the viral RNAs. The NP mediates the transport of the incoming viral RNPs from the cytoplasm into the nucleus by interacting with the cellular karyopherinα/importinα transport machinery. In addition, the NP plays an important role during viral RNA synthesis, and free NP molecules are required for full-length viral RNA synthesis, but not for viral mRNA transcription. The NP protein is the major antigenic target for cytotoxic T lympho-

cytes. It contains an immunodominant T cell epitope which is recognized in association with class I proteins of the major histocompatibility complex.

The NS1 (M_r between 26 000 and 18 000, depending on the virus strain) and NEP (NS2) ($M_r \approx 11\,000$) proteins are viral proteins derived from RNA segment 8 by alternative splicing of the mRNA. The nonstructural NS1 protein is an RNA binding protein which can be found in the cytoplasm and in the nucleus of infected cells. Several different functions have been proposed for this protein. In the nucleus, it seems to inhibit the processing of the cellular mRNAs at several steps, including polyadenylation, splicing and RNA transport mechanisms. The NS1 also appears to specifically enhance in the cytoplasm the translational rate of the viral mRNAs. Finally, the ability of the NS1 protein to bind double-stranded RNA, which could be formed during viral RNA replication and transcription, might prevent the activation of antiviral (interferon) pathways by these RNA species.

The NS2 or NEP (*n*uclear *e*xport *p*rotein) of influenza A viruses has recently been shown to have a nuclear export signal similar to the Rev protein of HIV. Since, in addition, the NEP is synthesized at late times during viral infection, it has been proposed that it mediates the nuclear export of the viral RNPs which is a prerequisite for viral budding. Interestingly, the NEP and M1 proteins interact in *in vitro* assays, and it is thought that the nuclear export of RNP molecules is facilitated through the association of the M1 protein with the NP (and the NEP). It will be interesting to investigate whether the NS2 proteins of influenza B and C viruses have similar nuclear export activities. In contrast to the previously believed nonstructural character of the NS2/NEP, this protein appears to be incorporated into virus particles via its interaction with the M1.

Another viral polypeptide (BM2), of $M_r \approx 12\,000$, has been identified in influenza B virus-infected cells. This protein has no known counterpart in influenza A and C viruses. It is encoded by a second open reading frame of RNA segment 7 of influenza B virus, and its function has not been determined.

Physical Properties

In general, influenza viruses show a sensitivity to denaturing agents comparable to that of other enveloped viruses. Differences in pH, ionic strength and ionic composition of the surrounding medium influence the viral resistance to physical and chemical agents. The infectivity can be preserved in saline-balanced fluid of neutral pH at low temperatures. Influenza viruses are relatively thermolabile, and are rapidly inactivated at temperatures higher than 50°C. Agents affecting the stability of membranes, proteins or nucleic acids, such as ionizing radiation, detergents, organic solvents, etc., reduce or completely destroy the infectivity of the virus.

Replication

Strategy of replication of nucleic acid

The replication and transcription of the genome of influenza virus takes place in the nuclei of infected cells (**Fig. 3**). In the nucleus, the viral RNP is used as template for the viral RNA polymerase complex (PB1, PB2, PA) to produce two different species of RNA: complementary RNA (cRNA), a full-length copy of viral RNA (vRNA); and mRNA, which is capped at the 5′ end and lacks the 3′ 15–16 nucleotides of the cRNA, having instead a poly(A) tail. The minimal promoter for the synthesis of mRNA and cRNA is formed by both the 5′ and 3′ noncoding regions of the vRNA. The cRNA is used as template to generate new vRNA and it also contains a promoter formed by its 5′ and 3′ ends. Promoter sequences of the cRNA and vRNA are similar but not identical. Both promoters consist of short sequences (12–13 nucleotides) which are highly conserved in all RNA segments of influenza A viruses, and they are localized at the precise 3′ and 5′ ends of the RNA. There is ample experimental evidence showing that these ends adopt a secondary structure (in form of a panhandle, fork or corkscrew) which appears to be required not only for replication, but also for transcription, polyadenylation, and packaging of vRNAs. However, other regions outside the conserved RNA ends also seem to influence these processes. Primers have not yet been identified for full-length replication of influenza virus RNAs *in vivo*, but short primers (such as ApG) are required for an optimal *in vitro* reaction.

Characterization of transcription

The vRNA is not only used as template for replication, but also for the synthesis of mRNA. This process is primed *in vivo* by m^7GpppXm-containing short capped RNAs derived from host-cell mRNAs. The primers are generated by endonuclease activity of the viral PB2 protein, which cleaves the 5′ ends of cellular mRNAs when vRNA specific sequences are also present. Binding of the viral polymerase complex to the 5′ ends of the viral mRNAs might prevent their cleavage by the PB2. Polyadenylation of the viral mRNA requires the panhandle structure of the vRNA and a juxtaposed stretch of five to seven uridines. It has been hypothesized that the panhandle structure and/or proteins bound to this panhandle, such as the

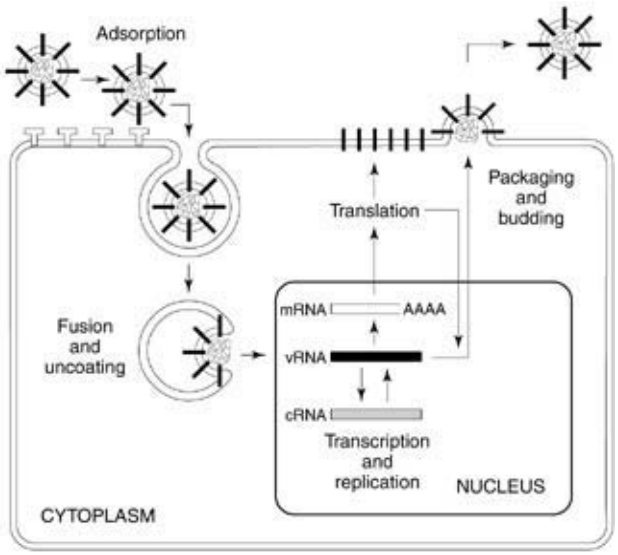

Figure 3 Replicative cycle of influenza virus. (1) Adsorption: the virus interacts with sialic acid-containing cell receptors via its HA protein, and is internalized by endosomes. (2) Fusion and uncoating: the HA undergoes a conformational change mediated by the acid environment of the endosome, which leads to the fusion of viral and cellular membranes. The inside of the virus also gets acidified due to proton trafficking through the M2 ion channel. This acidification is responsible for the separation of the M1 protein from the ribonucleoproteins (RNPs), which are then transported into the nucleus of the host cell thanks to a nuclear localization signal in the NP. (3) Transcription and replication: the viral RNA (vRNA) is transcribed and replicated in the nucleus by the viral polymerase. Two different species of RNA are synthesized from the vRNA template: (a) full-length copies (cRNA), which are used by the polymerase to produce more vRNA molecules; and (b) mRNA. (4) Translation: following export into the cytoplasm the mRNAs are translated to form viral proteins. The membrane proteins (HA, NA and M2) are transported via the rough endoplasmic reticulum and Golgi apparatus to the plasma membrane. The viral proteins possessing nuclear signals (PB1, PB2, PA, NP, M1, NS1 and NEP) are transported into the nucleus. (5) Packaging and budding: the newly synthesized NEP protein appears to facilitate the transport of the RNPs from the nucleus into the cytoplasm by bridging the RNPs with the nuclear export machinery. M1–RNP complexes are formed which interact with viral proteins in the plasma membrane. Newly made viruses bud from the host cell membrane.

viral polymerase complex, provides a physical barrier for transcription, and that the RNA polymerase stutters at the stretch of uridines, thus adding the poly(A) tail. The melting of the panhandle structure in the presence of free viral NP could itself be the *cis* signal for the switch from mRNA to cRNA synthesis.

Characterization of translation

The influenza viral mRNAs use the cellular translation machinery to synthesize the viral proteins. While translation of viral mRNAs is a very efficient process, translation of the host cell mRNAs is inhibited in influenza virus-infected cells. The precise mechanism for this inhibition is not well understood. Interestingly, the virus has evolved several mechanisms by which it can increase its coding capacity. They include: partial splicing of the mRNA, coupled stop–start translation of tandem cistrons and ribosomal choice between two possible initiation codons.

The RNA segment 7 of influenza A virus encodes two proteins, M1 and M2. The M2 protein is produced by translation of an mRNA derived from the M1 mRNA by splicing; it shares only its first eight amino acid residues with the M1 protein. Because of a frameshift resulting from the splicing, the remaining amino acids of the M2 are different from those of the M1. The mRNA coding for the M1 protein of influenza C virus also appears to be spliced. Surprisingly, the spliced mRNA actually encodes for the M1 protein. Recently, a protein product, the CM2 protein, which is translated from the unspliced mRNA has been identified. The CM2 protein is most likely generated by cleavage of the precursor protein.

RNA segment 8 of influenza A and B viruses and RNA 7 of C viruses also have coding capacities for two different proteins, the unspliced forms of their mRNAs code for the NS1 proteins, and the spliced forms for the NS2 (NEP) proteins. The ratio of spliced to unspliced mRNA is about 1:10. The viral splicing sequences share the consensus sequences of eukaryotic mRNAs, which in general undergo complete (efficient) splicing. It has been suggested that both *cis*- and *trans*-acting signals (i.e. the NS1 protein) are involved in the regulation of splicing in influenza viral mRNAs.

Two different polypeptides, the NA and NB proteins, can be translated from the influenza B virus segment 6. If initiation of the translation takes place at the first AUG of the mRNA, the NB protein is synthesized; the second AUG, separated from the first by four nucleotides, initiates the synthesis of the NA protein.

Segment 7 of influenza B viruses is used for the synthesis of the M1 protein. Cellular ribosomes, after the stop codon for the M1 protein, appear to reinitiate translation at an AUG codon overlapping the stop codon UAA in the pentanucleotide sequence UAAUG. This process, which is similar to that observed in multicistronic bacterial genes, leads to the synthesis of the BM2 protein.

Post-translational processing

The viral protein that incurs the largest number of post-translational modifications is the HA protein.

While it is being synthesized, a signal peptide in the N-terminal sequence of the nascent polypeptide mediates its attachment to the membrane of the rough endoplasmic reticulum (RER). The signal peptide is then cleaved and the HA molecule remains attached to the membrane of the RER by its C-terminal sequence. After synthesis is completed, the HA protein follows the exocytic cellular pathway, and in this process it is folded, assembled into trimers, glycosylated in its extracellular domain, and palmitoylated in the cysteine residues of its cytoplasmic tail. Finally, the molecule is cleaved into its two subunits, HA1 and HA2, which remain bound by a disulfide bridge. Cleavage of the HA is essential for its fusogenic activity.

The NA protein also follows the exocytic cellular pathway: it is post-translationally folded, assembled into tetramers and glycosylated. However, in contrast to the HA and the majority of cellular transmembrane proteins, its signal peptide is not cleaved, and the NA is attached to the plasma membrane by its N-terminal sequence. Other viral proteins that undergo post-translational modifications are the M2 protein, which is phosphorylated and palmitoylated at its cytoplasmic tail, the NB and CM2 proteins of influenza B and C viruses, which in addition are glycosylated, and the NP, M1, NS1 and NEP(NS2) proteins, which can be phosphorylated. The precise functional significance of all these modifications is not yet clear.

Packaging of vRNA, assembly and release of virus

At late times in infection, the newly synthesized RNPs move back from the nucleus to the cytoplasm. The precise regulation of this transport is not yet understood. It has been proposed that the late viral protein NEP plays a key role in this process (see above). In addition, the M1 protein and unknown phosphorylation events might be involved. Once in the cytoplasm, the RNPs (in association with the M1 protein) interact with the plasma membrane, where the viral transmembrane proteins HA, NA and M2 are inserted. The M1 protein is probably responsible for the virus budding, selecting the viral envelope proteins via specific interactions. Although the cytoplasmic tails of the HA, NA and M2 proteins are the most likely candidates for these specific interactions with the M1 protein, viable viruses in which the cytoplasmic domains of the HA and the NA were deleted have been generated. In any case, the new viral progeny buds from the infected cell, with the viral envelope derived from the plasma membrane of the infected host cell.

It has been demonstrated that the 3′ and 5′ noncoding regions of the vRNAs contain the *cis* signals required for packaging, as reporter genes containing only these noncoding sequences are packaged into virions. The question then arises as to whether the eight vRNA segments are selectively chosen one by one for packaging into a viral particle or whether they are randomly packaged. The difficulty of elaborating a mechanism of selective packaging that would involve complex and specific interactions among each RNA segment and possibly the nucleocapsid proteins and the M1 protein favors the random packaging hypothesis. In this model, it is assumed that influenza viruses package on average 11–12 RNA segments per particle; these segments are randomly taken from a pool of eight different vRNAs, all of which carry the same packaging signal. Only virus particles with a full complement of the eight different RNA segments (among the 11–12 randomly packaged ones) are infectious. Based on statistical analysis, this model is compatible with the finding that only a small percentage (less than 10%) of influenza virus particles are infectious. Supporting this theory, it was shown directly that influenza viruses can package additional segments. Using genetic engineering methods (see below), a virus was constructed which required nine different RNA segments in order to be infectious. However, observations that DI RNA segments derived from specific influenza virus vRNAs are able to compete for packaging into virus particles with their parental vRNA segment would favor a selective packaging model.

Genetic Manipulation of Influenza Viruses

Unlike the RNA of positive-strand RNA viruses, the RNA of negative-strand RNA viruses is not infectious. As a consequence, it is not possible to obtain recombinant influenza viruses containing site-specific mutations by solely transfecting cDNA-derived viral genomic RNA into cells. However, several systems have been developed which allow the *in vitro* or *in vivo* reconstitution of a biologically active RNP complex and subsequent rescue of infectious virus using plasmid-derived RNA. Briefly, synthetic viral RNA transcribed from plasmid cDNA *in vitro* is incubated with purified viral NP and polymerase proteins and the reconstituted RNPs are transfected into cells. Subsequent infection with a helper virus allows the introduced RNP to be replicated, transcribed and packaged (**Fig. 4**). Alternatively, RNPs can be reconstituted *in vivo* by transfecting into cells expression plasmids for vRNA and NP and polymerase proteins. These RNPs then can be packaged into new virions if the cells are

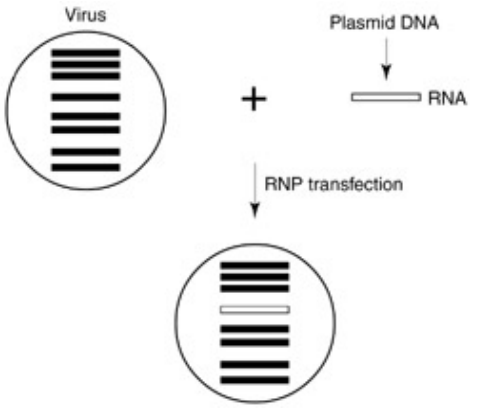

Figure 4 Genetic manipulation of the influenza virus genome via cDNA-derived RNA. Plasmid DNA is used to transcribe viral RNA *in vitro*. This RNA (or RNA derived from a genetically altered plasmid) is mixed *in vitro* with purified influenza viral NP and polymerase complex. The resulting ribonucleoproteins (RNP) are transfected into cells which have been infected with helper virus. Genetically altered transfectant viruses can then be rescued from the infected cell.

also infected with a helper virus. These powerful systems now permit mutations to be introduced into the viral genome so that the *cis*-acting sequences required for RNA transcription, replication and packaging may be studied. In addition, the function and properties of the individual viral proteins can be studied using this methodology. Finally, genetically altered influenza viruses are now being made in the laboratory to display specific biological features, such as attenuation properties or expression of foreign genes and antigens. Such an approach may ultimately lead to the development of greatly improved vaccines against influenza and/or other diseases.

Introduction

Influenza viruses are classified into three types, A, B and C, on the basis of their type-specific nucleoprotein and matrix protein antigens. Type A influenza viruses are further classified into subtypes based on the antigenic characteristics of their surface antigens, hemagglutinin (HA) and neuraminidase (NA). Fourteen distinct HA subtypes and nine NA subtypes are now recognized in the nomenclature system of the influenza A viruses recommended by the World Health Organization. This section will describe those structures recognized by the antigen specific receptors of B lymphocytes (antibodies; Ab) and T lymphocytes (T cell receptor; TCR).

Structure of the Hemagglutinin (HA)

In type A influenza virus, the HA accounts for about 25% of the viral protein. It is responsible for the attachment of virus to cells and for the penetration of the virus into the cell during the initial stages of infection. Antibodies to the HA neutralize the infectivity of the virus. Variation in the HA glycoprotein is mainly responsible for the continually occurring outbreaks of influenza and for our inability to control these by vaccination.

The HA of the 1968 influenza virus strain A/Aichi/2/68 (H3N2) is synthesized as a single polypeptide chain of 550 amino acids (**Fig. 1**), which is shortened by removal of a single peptide and subsequently cleaved by removal of Arg329 into two chains, HA1 (36.3 kDa) and HA2 (25.7 kDa). These chains are covalently attached by a disulfide bond from HA1 position 14 to HA2 position 137, and the two-chain monomers are associated noncovalently to form trimers on the surface of membranes. Bromelain treatment of virus yields a soluble trimer, BHA of the extracellular regions, containing all of HA1 and the first 175 to 221 amino acids of HA2 but missing the hydrophobic membrane-anchoring peptide.

Three-dimensional structure of the HA

Bromelain-released HA from some influenza A viruses can be crystallized, and from X-ray diffraction

Introduction

Influenza viruses are classified into three types, A, B and C, on the basis of their type-specific nucleoprotein and matrix protein antigens. Type A influenza viruses are further classified into subtypes based on the antigenic characteristics of their surface antigens, hemagglutinin (HA) and neuraminidase (NA). Fourteen distinct HA subtypes and nine NA subtypes are now recognized in the nomenclature system of the influenza A viruses recommended by the World Health Organization. This section will describe those structures recognized by the antigen specific receptors of B lymphocytes (antibodies; Ab) and T lymphocytes (T cell receptor; TCR).

Structure of the Hemagglutinin (HA)

In type A influenza virus, the HA accounts for about 25% of the viral protein. It is responsible for the attachment of virus to cells and for the penetration of the virus into the cell during the initial stages of infection. Antibodies to the HA neutralize the infectivity of the virus. Variation in the HA glycoprotein is mainly responsible for the continually occurring outbreaks of influenza and for our inability to control these by vaccination.

The HA of the 1968 influenza virus strain A/Aichi/2/68 (H3N2) is synthesized as a single polypeptide chain of 550 amino acids (**Fig. 1**), which is shortened by removal of a single peptide and subsequently cleaved by removal of Arg329 into two chains, HA1 (36.3 kDa) and HA2 (25.7 kDa). These chains are covalently attached by a disulfide bond from HA1 position 14 to HA2 position 137, and the two-chain monomers are associated noncovalently to form trimers on the surface of membranes. Bromelain treatment of virus yields a soluble trimer, BHA of the extracellular regions, containing all of HA1 and the first 175 to 221 amino acids of HA2 but missing the hydrophobic membrane-anchoring peptide.

Three-dimensional structure of the HA

Bromelain-released HA from some influenza A viruses can be crystallized, and from X-ray diffraction

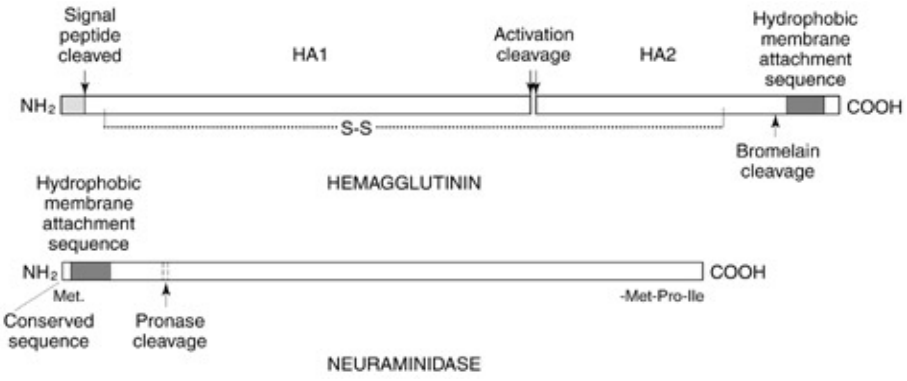

Figure 1 Some features of the HA and NA polypeptides. The HA is synthesized as a single polypeptide. Following its synthesis, an N-terminal signal peptide is cleaved off and the molecule is cleaved further into HA1 and HA2 with the removal of one or more intervening amino acids. This latter cleavage is necessary for the virus to be infectious. HA1 and HA2 remain linked by a single disulfide bond, and each HA spike contains three of these dimers. A sequence of hydrophobic amino acids near the C-terminus of HA2 serves to anchor the HA in the lipid of the viral membrane. Treatment with bromelain removes this hydrophobic region without damaging the rest of the molecule which, in some cases, can be crystallized. The NA is oriented in the viral membrane in the opposite way to the HA. No post-translational cleavage of the NA polypeptide occurs, no signal peptide is split off and even the initiating methionine is retained. No processing at the C-terminus takes place; the C-terminal sequence, Met-Pro-Ile, predicted from the gene sequence, is of N_2NA found in intact NA molecules isolated from virus and in the pronase-released NA heads. A sequence of six polar amino acids at the N-terminus of the NA polypeptide, which is totally conserved in at least eight different NA subtypes, is followed by a sequence of hydrophobic amino acids which probably represents the transmembrane region of the NA stalk. This sequence is not conserved at all between subtypes (apart from conservation of hydrophobicity). Pronase cleaves the polypeptide in the positions shown, removing the stalk and releasing the enzymatically and antigenically active head of the NA which, in some cases, can be crystallized.

data the three-dimensional structure of Hong Kong (H3N2) HA has been determined (**Fig. 2**). Conservation of the structural features such as disulfide bonds suggests that HA molecules from other subtypes will have highly similar structures. The HA glycoprotein of influenza virus is a trimer built of two structurally distinct regions: a triple-stranded coiled-coil of α helices that extends 7.6 nm from the membrane and a globular region of antiparallel β sheet which contains the receptor-binding site. The variable antigenic determinants are located on the globular domain. Each subunit has an unusual loop-like topology; it begins at the membrane, extends 13.5 nm distally, and folds back to enter the membrane (**Fig. 2**).

Structure of the Neuraminidase (NA)

The NA is the second subtype-specific glycoprotein on the influenza virion and is composed of a single polypeptide chain. It exists as a mushroom-shaped spike with a box-like head made out of four coplanar and roughly spherical subunits and a centrally attached stalk containing a hydrophobic region by which it is embedded in the viral membrane. The role of the NA in the life cycle of the virus is still unclear. Mutants of influenza virus lacking NA activity form aggregates at the surface of infected cells, suggesting that one function of the NA is the removal of receptors from the HA, from itself and from the

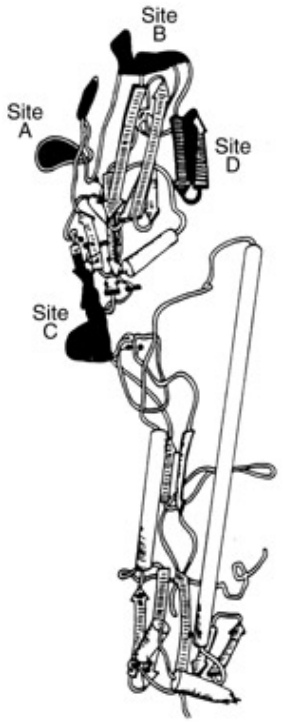

Figure 2 The Hong Kong HA monomer, showing folding of the HA1 and HA2 polypeptides. The four shaded areas show where four independent antigenic areas may be located. Note that in the HA spike, which is composed of three of the monomers, side D is buried and may not be involved in antibody binding.

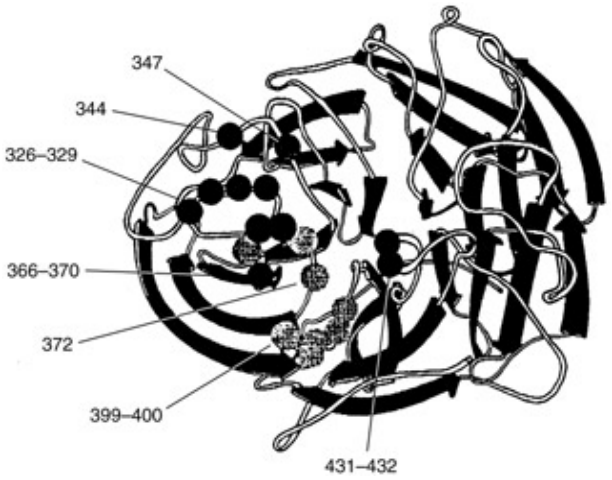

Figure 3 The NC41 epitope on N8 NA. The chain fold in the monomer is viewed down the fourfold axis. The 19 amino acid residues on the NA in contact with antibody are shown as circles: ●, contact to L chain; ◍, contact to H chain; ●, contact to H and L chains.

infected cell surface. This prevents self-aggregation, promotes virus release from the infected cell, and enables the virus to escape from nonproductive interactions, e.g. binding to noncellular sialic acid containing substances such as mucus.

The NA is oriented in the viral membrane in the opposite way to the HA, i.e. the transmembrane portion is at the N terminus (**Fig. 1**). No post-translational cleavage of the NA polypeptide occurs, a signal peptide is not split off and even the initiating methionine is retained. Processing at the C-terminus does not take place, i.e. the C-terminal sequence predicted from the gene sequence is found in intact NA molecules isolated from virus and in the pronase-released NA heads. A sequence of six polar amino acids at the N-terminus of the NA polypeptide, which is totally conserved in at least eight different NA subtypes, is followed by a sequence of hydrophobic amino acids that probably represents the transmembrane region of the NA stalk. Apart from conservation of hydrophobicity, this sequence is not conserved between subtypes. Pronase cleaves the polypeptide, removing the stalk and releasing the enzymatically and antigenically active head of the NA which, in some cases, can be crystallized. The influenza C virus does not have NA activity.

Three-dimensional structure of the NA

Pronase-released NAs have been crystallized, and from X-ray diffraction data the three-dimensional structure has been determined. Influenza viral NA provides the first known example of a tetrameric protein with circular fourfold symmetry. The polypeptide chain folds into six topologically identical four-stranded antiparallel β sheets which are themselves arranged like the blades of a propeller (**Fig. 3**).

The product of catalysis, sialic acid, is observed to bind in a large pocket on the distal surface, flanked and surrounded by nine acidic residues, six basic residues and three hydrophobic residues, all of which are strictly conserved in all known influenza viral NA sequences. The conservation of amino acids around the catalytic site suggests that antibodies cannot exert pressure on that site for its modification or that mutations in this site are lethal.

Structure of Antigenic Determinants (Epitopes) on Proteins

Of an almost infinite variety of B cell epitopes (or antigenic determinants) on protein molecules, the complete structures of very few are known. The single method that can determine the complete structure of an epitope is preparation of a complex of a monoclonal antibody Fab fragment with its antigen, crystallization of this complex and determination of its structure using X-ray diffraction methods.

The term epitope was coined by Niels Jerne in 1960, when he proposed that 'an antigen particle carries several epitopes' (= surface configurations, single determinants, structural themes, immunogenic elements, haptenic groups, antigenic patterns, specific areas). Hidden epitopes which become immunologically available only after breakage, decomposition or denaturation of the antigen are cryptotopes. Inherent in this definition is the concept that an epitope occurs on the surface of a native protein, whereas a linear peptide sequence seen after protein unfolding could occur on the inside or the outside of the folded polypeptide. Processed peptides that would be recognized by T cells in association with major histocompatibility complex (MHC) molecules would actually be included in the latter category and are more appropriately considered cryptotopes than T cell epitopes, as they are now known.

The term T cell epitope is in common usage to describe the peptide sequence on the original protein, although it is not in this native form that it is recognized by the T cell. In contrast, antibodies do recognize epitopes on native proteins, and the complementary paratope on the antibody is exquisitely specific for the native conformation.

The epitopes so far characterized by X-ray crystallography are of the discontinuous type, encompassing 2–5 surface loops. The highly complementary interface between antigen and antibody is absolutely dependent on the folding of the native protein. The

antibody-combining site is seen to be an irregular, rather flat surface with protrusions and valleys formed by amino acid side chains. The epitopes each contain between 15 and 22 residues on the antigen in contact with a similar number of residues on the antibody paratope. Although the interpretation of contacts is somewhat arbitrary (and may differ between laboratories) and the contribution of each to the binding energy (both positively and negatively) is unknown, these provide the best descriptions of epitopes on native proteins so far available.

Despite the consensus that X-ray crystallography has provided of the structure of protein epitopes, there still is a widely held misconception that epitopes on native proteins consist of segments of about seven amino acid residues that can be mimicked or mapped utilizing synthetic peptides of a similar length. In fact, numerous studies claimed to have localized epitopes on native proteins by studying synthetic peptides corresponding to short linear sequences within the protein. However, the success of such approaches with well-defined antibodies has been limited, and most of the crossreactivity seen in these experiments represents binding to denatured protein present in the antigen preparation. Conversely, those cases in which free peptides appear to give good crossreactivity with antiprotein antibodies in solution assays probably represent antibodies originally elicited by denatured protein.

Epitopes on Influenza Viral HA and NA and the Mechanism of Antigenic Drift

The location of epitopes on the HA of influenza viruses is known, but crystals of the complexes of HA and antibody Fab fragments have not yet been reported, so the three-dimensional structure of epitopes on the HA remains to be determined. Escape mutants, isolated by growing virus in the presence of neutralizing monoclonal antibodies to the HA, have single amino acid sequence changes in the HA1 polypeptide that cluster in four regions on the top of the HA globular domain (**Fig. 2**). The crystal structure of these escape mutants (which do not bind the antibody used for their selection) shows that the changes in structure of the HA are restricted to the side chains of the amino acid residues involved, indicating, first, that these residues form part of the epitope recognized by that particular monoclonal antibody, and, second, that conformational alterations in the HA are not required to greatly reduce antibody affinity.

Crystals of influenza viral NA complexed with monoclonal antibody Fab fragments have been obtained, and the three-dimensional structure of one epitope on the NA recognized by monoclonal antibody NC41 has been determined to high resolution, and structures of other antibody–NA complexes are underway. This antibody-binding site (epitope) on NA of the N9 subtype is discontinuous and comprises five chain segments and 19 residues in contact, while 33 NA residues in eight segments have 8.99 nm^2 of surface area buried by the interaction (to a 0.17 nm probe), including two hexose units. Seventeen residues in the NC41 Fab fragment lying in five of the six complementarity-determining regions (CDRs) make contact with the NA, and 36 antibody residues in seven segments have 9.16 nm^2 of buried surface area (**Fig. 3**).

Why B and T Cell Determinants Differ

As alluded to above, influenza virus-specific T cells, unlike most antibodies induced by influenza viral infection, recognize sequential/continuous types of determinants in influenza viral proteins. The different nature of B and T cell determinants reflects a fundamental difference in how antigens are presented to antigen receptors expressed on the surface of B and T cells. Antibody secretion by B cells is triggered by antigen crosslinking of surface antibody. Although there are probably peptides or larger fragments of viral proteins that are either released from virus-infected cells or created by the action of extracellular proteases, these fragments are poorly immunogenic, possibly because their monovalent nature prevents them from crosslinking B cell receptors. By contrast, native influenza viral glycoproteins are highly immunogenic, as they form repeating structures by virtue of their assembly into homo-oligomeric structures that themselves are incorporated in macromolecular assemblies in virions.

T cell activation is similar to B cell activation in requiring antigen–receptor crosslinking. Unlike B cells, however, T cells recognize antigens in a complex with MHC (in humans termed HLA) class I or class II glycoproteins. These proteins are encoded by highly polymorphic genes: indeed, these are the most polymorphic human genes known. For each HLA class I or II locus there are hundreds of alleles present in appreciable frequencies among various populations. Individuals usually express 4–6 different class I molecules and a similar number of distinct class II molecules. The sequential nature of T cell determinants reflects the properties of the antigen-binding sites on MHC molecules. Solution of the structure of class I molecules by X-ray crystallography reveals the antigen-binding site to be a groove comprised of two parallel α helices separated by 1.8 nm, laying atop a platform of eight antiparallel β sheets to form a

2.5 nm long cleft, 1 nm deep. This groove accommodates peptides of 8–9 residues in a fairly extended form. Although longer peptides are capable of binding to class I molecules, they do so with lower affinity, at least in part because the N- and C-termini of the optimally sized peptides form important contacts with residues near the ends of the binding site. Most peptides directly isolated from MHC class I molecules are 8–10 residues in length, although longer peptides are occasionally isolated. The binding of peptides to class I molecules is governed by the highly specific interaction of one or two critical residues in the peptide ('dominant anchors'), with several other residues interacting in a less critical manner with the binding site. The exact type and position of these critical residues differs for interaction with the various class I alleles. In this way, the host is able to sample 4–6 distinct sets of peptides. By pool sequencing peptides recovered from different class I molecules, the dominant anchor residues recognized by numerous human class I molecules have been determined. Using this information, it is often possible to identify peptides in viral proteins that bind the respective class I molecule. Mere binding of the peptide to the class I molecule, however, does not guarantee that the peptide will be immunogenic. Binding is just one factor in an equation that includes the efficiency of antigen processing (see below) and the presence of T cells with TCRs able to recognize the class I–peptide complex.

The three-dimensional structure of a TCR interacting with class I molecules complexed with peptide has been determined. The TCR interacts with the class I molecule over a broad surface, much like the interaction of antibodies with globular proteins. The TCR contacts both the side chains of the 3–4 residues in the peptide that point out of the binding site, as well as residues present in the α helices that form the side walls of the antigen-binding groove.

Despite a limited amount of amino acid homology, the structure of class II molecules is uncannily similar to that of class I molecules. Indeed, in side-by-side representations it is difficult to distinguish them at a glance. There are subtle differences, however, in the nature of the binding pocket that enables class II molecules to bind peptides that extend beyond the binding groove with little or no cost in binding energy compared to binding of smaller peptides. Consequently, there is much greater heterogeneity in the sizes of peptides bound by class II molecules. As a rule, peptides bound to class II molecules are generally around 15 residues in length, although peptides are represented in a continuum ranging from eight residues to full length proteins. As with class I molecules, peptide binding is due largely to the interactions of a few side chains with pockets in the binding groove. Due to the heterogeneity in length, however, rules governing the interactions of peptides with class II molecules are in more primitive state.

Two T Cells

The activation of T cells often requires more than the simple binding of the T cell antigen receptor to a foreign protein bound to MHC molecules. A number of other cell surface molecules on T cells and antigen-presenting cells are usually actively involved in T cell activation. Of particular importance functionally are the interactions of two cell surface glycoproteins, termed CD4 and CD8, the expression of which on almost all mature T cells is mutually exclusive. These molecules function to target the T cell antigen receptor to class II or class I molecules. This is achieved by the direct interaction of peptide-bearing class II and I molecules with CD4 and CD8 molecules, respectively.

The expression of CD4 or CD8 molecules on T cells is coordinately regulated with T cell function. The primary function of T_{CD8+} is to limit the replication of influenza virus. This is achieved by destroying virus-infected cells, and, possibly, by releasing lymphokines with antiviral activity. The primary function of CD4-expressing cells (T_{CD4+}) is to enhance antibody responses and specific and nonspecific cellular immunity. Consistent with these functions, class I molecules are expressed by virtually all cell types, while class II molecules are expressed largely by B cells and inflammatory cells (monocytes, macrophages). Upon exposure to any of several cytokines (most importantly interferon γ and tumor necrosis factor α), class II molecules are induced in many cell types, enabling T_{CD4+} to participate more directly in exerting antiviral effector functions.

General Characteristics of T cell Determinants Derived from Influenza Viral Proteins

Obviously, the first criterion for a given sequence of influenza viral protein to be recognized by T cells is that it bind class I or II molecules with sufficient affinity. Although strict rules have not been established, it appears that the lower end of the dissociation constant required is in the micromolar range (the highest affinity peptides exhibit dissociation constants in the one-tenth nanomolar range). The second criterion is that the determinant be liberated from the viral protein and find its way to the appropriate intracellular compartment where binding to class I or II molecules occurs. The general term for this series of

events is antigen processing. For most peptides destined to bind class I molecules, antigen processing begins in the cytosol. There are two sources of viral proteins in the cytosol. First, during the process of viral penetration, small amounts of viral proteins are delivered to the cytosol from the incoming virions. Second, viral proteins are synthesized in the cytosol by ribosomes from viral mRNAs produced by the viral polymerases from the negative-stranded genome. The important practical consequence of this feature of class I-associated processing is that infectious virus is required to stimulate T_{CD8+} responses.

Viral proteins in the cytosol are cleaved by cellular proteases, including, but probably not limited to, proteasomes. Proteasomes are extremely abundant macromolecular structures that play the essential role of disposing of damaged or unwanted cellular proteins. They are highly conserved in nature, and even proteasomes from yeast are able to produce peptides cabable of binding to class I molecules. Indeed, T cells may have evolved to take advantage of the ability of proteasomes to produce peptides.

Cleavage products are then transported into the endoplasmic reticulum apparatus by TAP, the transporter associated with antigen processing. TAP is a resident endoplasmic reticulum protein encoded by two genes located in the class II region of the MHC. It transports peptides of between 8 and $\sim$16 residues and demonstrates a preference for C-terminal residues bound by HLA class I molecules (hydrophobic or positively charged residues). Peptides with N-terminal extensions are probably trimmed in the endoplasmic reticulum to the optimal length for binding to class I molecules, possibly as the peptides are tethered to class I molecules by their C-termini. TAP also functions to bind newly synthesized class I molecules, presumably to increase the efficiency of peptide loading. This binding is mediated by a newly discovered protein termed tapasin. Peptide association with class I molecules induces their release from TAP, and the peptide–class I complex is then rapidly transported to the cell surface through the secretory pathway.

At this point, the final criterion for T cell recognition must be met: the immune system must have the capacity to encode a T cell antigen receptor that is able to distinguish the viral peptide–class I complex from class I complexes containing peptides derived from host proteins.

The same three criteria apply to T_{CD4+} recognition of antigens in association with class II molecules. In this case, however, antigen processing occurs not in the cytosol but in an endosomal compartment. Viral proteins or particles that have entered cells by either absorptive endocytosis or, far less efficiently, by pinocytosis, are unfolded and degraded by proteases located in an early endosomal compartment. Peptides generated in this manner then bind to newly synthesized class II molecules, which are specifically targeted to endosomes during their transport to the cell surface. Due to the ability of class II molecules to bind long peptides, class II molecules are also able to bind peptides in unfolded proteins, and for some antigens this step probably occurs prior to liberation of the peptide from the proteins.

As a consequence of the endosomal origin of class II-associated viral peptides, vigorous class II restricted responses are elicited by immunization with viral proteins or noninfectious intact viral preparations. Such responses are not, however, identical to those elicited by infectious virus. There are two general types of determinants that arise only during a viral infection. First, there are determinants derived from viral proteins not present in virions that are synthesized during the infectious cycle ('nonstructural proteins'). Second, there are some determinants within viral structural proteins that, for reasons that are not completely understood, are preferentially derived from proteins that have been synthesized by the antigen-processing cell.

Specific Characteristics of T Cell Determinants Derived from Influenza Viral Proteins

In theory, the special characteristics of a protein could limit the ability of the antigen processing machinery to liberate antigenic determinants contained within it. In practice, the antigen processing machinery does not appear to distinguish between the various influenza viral proteins. All of the viral proteins have been found to be processed for recognition by T_{CD8+}. Although not as extensively examined, it also appears likely that all viral proteins are presented to T_{CD4+}. Importantly, the recognition of proteins from different influenza A virus isolates by a single T cell clone generally reflects the overall degree of amino acid homology exhibited by the proteins. For example, recognition of nucleoproteins derived from any influenza A virus isolate by either class I- or II-restricted T cells is highly crossreactive, in keeping with the greater than 90% amino acid homology exhibited between these proteins. By contrast, the viral glycoproteins, which exhibit antigenic drift and shift, are often recognized in a strain-specific manner. As a practical manner, this means that T cells capable of reacting with an influenza A isolate can be easily elicited by immunization with the highly conserved internal viral structural and nonconstructural proteins.

With the type of criteria that must be met for a given sequence in a protein to act as an antigenic determinant, it is hardly surprising that the number of determinants contained within each protein capable of eliciting a T cell response restricted to a given MHC molecule is limited. Influenza proteins generally have 3–5 or more nonoverlapping sequences capable of eliciting T cells restricted by a given class II allele. By contrast, the same proteins contain much fewer determinants capable of eliciting T cells restricted by a given class I allele, ranging from 2 to 1, or, fairly often, even 0. Thus, while immunization with an isolated protein elicits T_{CD4+} responses among individuals of various HLA types, the same protein, even when delivered in the appropriate manner to elicit class I-restricted responses (i.e. in a way that allows for cytosolic access), can fail to elicit T_{CD8+} responses in an appreciable number of the same individuals. A given peptide determinant is usually recognized in association with a single class I or II allele, but there are some examples in which overlapping sequences have been shown to be recognized by both class II- and class I-restricted T cells.

DNA Vaccination

Great excitement has greeted the possibility of using purified DNA encoding viral proteins to vaccinate against viral infections. The mechanism of presentation of DNA-encoded antigens to the immune system remains to be established but, in principle, DNA vaccination is similar to vaccination with infectious virus. Thus, the synthesis of viral proteins by antigen-presenting cells transfected by the vaccinating DNA will provide peptides to class I molecules, and viral proteins released from transfected cells should be processed and presented with class II molecules by professional antigen-presenting cells. Viral proteins released from transfected cells also stimulate B cells. Indeed, it has been found that neutralizing antibodies, T_{CD4+} and T_{CD8+} responses are induced following immunization in animals with DNA encoding influenza virus proteins. The immune response is, however, less potent than that obtained following immunization with live attenuated influenza virus, and it remains to be seen whether DNA immunization for influenza virus offers any real advantages in efficacy, safety or cost over existing vaccines or new vaccines.

Nonoccluded viruses	dsDNA	Coleoptera, Lepidoptera
Baculoviridae (Nucleopolyhedrovirus, Granulovirus)	dsDNA	Coleoptera, Diptera, Hymenoptera, Lepidoptera, Trichoptera

chemicals on the environment. These problems have led to an upsurge of interest in biological control agents, including the use of insect-specific microorganisms, for pest control. Among these microorganisms are the viral pathogens of insects.

The major virus groups with members that infect insects are shown in **Table 1**; as discussed below, the suitability of members of these groups for use as pest control agents varies considerably.

Desirable attributes of any ideal viral insecticide include an appropriate host range, an ability to cause virulent infections in the field, and a rapid speed of pest kill; in addition, any ideal agent should be easy to produce and apply, and should show stability both in storage and once released into the environment. Finally, such an agent should also have a well-understood biology and ecology. In this entry we discuss each of the virus groups listed in **Table 1** in turn, examining how they compare against these various criteria. It is apparent that many of the groups have little potential as control agents, and these are dealt with briefly. In contrast, most of the entry deals with members of the *Baculoviridae*, on which the majority of development work has been done to date.

RNA Viruses

Nodaviridae

These small RNA viruses have received little consideration as control agents, in part because they seem unable to produce frequent infections with high levels of mortality in the wild, leading to concerns over their ease of transmission to the target species. The other main concern is the documented ability of some of these viruses to replicate in both vertebrate and plant tissue cultures, leading to worries over the safety of nontarget organisms within the environment.

Tetraviridae

Members of the *Tetraviridae* are small nonenveloped RNA viruses that are specific for lepidopteran hosts. Symptoms of infection vary from mild weight loss to severe stunting and death. The viruses can be transmitted horizontally, and it is suspected that vertical transmission between generations is possible; in addition, tetraviruses also demonstrate substantial levels of persistence in the environment. One of the better studied members of this family is the *Heliothis armigera* (cotton bollworm) stunt virus (HaSV) whose relatively simple genome consists of a total of three genes on two RNA segments. Unfortunately, the current lack of cell culture systems for any tetravirus, and, as a consequence, the high costs associated with *in vivo* production have thus far hindered the development of these viruses as pest control agents. Also, the widespread distribution of crossreactivity in vertebrate sera to members of this group is a factor whose basis needs to be resolved before uncontained application could proceed in the field. Nevertheless, the simplicity of the genome of these viruses has been recognized as lending them to genetic manipulation. Thus, in recent work HaSV has been produced from chromasomally-integrated genes in transgenic plants, a route that suggests two possible approaches to circumvent the cost of production problems. In one, it could be envisaged that transgenic plants expressing infectious particles of HaSV could be protected against *Heliothis* larvae; alternatively, the ability to produce the virus in, for example a plant cell culture system might provide an economically feasible alternative to *in vivo* production.

Insect picorna-like viruses

This is a broadly-based group of small RNA viruses that are found in invertebrates and that show physical similarities to picornaviruses. Ultimately, however, many of these viruses are likely to be assigned to

families other than the *Picornaviridae*. Current members include two viruses that have been reasonably well characterized, namely cricket paralysis virus (CrPV) and *Drosophila* C virus (DCV). Although found initially in crickets, CrPV has also been found to infect several species of lepidoptera (moths and butterflies), thus demonstrating a broad host range. This virus has been used on several occasions as a pest control agent, in one instance in olive plantations to suppress populations of *Parasa viridissima* (West African slug caterpillar). In this case a dose-dependent mortality rate of 11–61% was recorded 7 days postapplication, and after 14 days this rose to up to 92%. Another 'picorna-like' virus, *Gonometa* virus, has been used to control *G. podocarpi,* a pest of pine trees in Uganda. Both these examples have, however, been noncommercial in nature, and the commercialization of any picorna-like insect viruses for pest control purposes currently appears unlikely. However, the increased use of molecular biology techniques, together with the possibility of engineering transgenic plants to produce infectious virions, as discussed above, could facilitate the exploitation of specific members of this group, such as aphid viruses, as pest control agents in the future.

Reoviridae

The best-characterized insect-specific members of the *Reoviridae* are assigned to the genus *Cypovirus,* and are more commonly known as cytoplasmic polyhedroviruses (CPVs). Infection with these viruses results in formation of polyhedral occlusion bodies in the cytoplasm of infected cells; these occlusion bodies provide protection for the virions during the process of transmission between hosts. CPVs have been identified in a wide range of insect orders, including dipterans (flies), lepidopterans and coleopterans (beetles). Their ability to produce occlusion bodies, their highly infectious nature, and their collectively wide host range are all viewed as positive attributes with respect to their development as pest control agents. Their speed of kill, however, is slow in comparison to chemical pesticides and some other viruses, so their use is likely to be limited to situations where some crop damage can be tolerated. Only one commercial CPV product (Matsukemin), has been produced to date, for use against *Dendrolimus spectabilis,* a pest of pine trees in Japan. A number of trials have also been carried out in China to assess potential for control of *D. punctatus* (pine caterpillar), a serious defoliating pest of Massonian pine plantations in Southern China. Trials are also being conducted, mainly in Japan and China, using a mixture of the insecticidal bacterium *Bacillus thuringiensis* and *Dendrolimus* CPV.

DNA Viruses

Densovirinae

Comprising a subfamily of the *Parvoviridae*, the *Densovirinae* contains members (DNVs) that are invertebrate-specific viruses, and that have a single-stranded linear DNA genome. Densonucleosis viruses (DNVs) have been shown to cause lethal infections in hosts from the orders Lepidoptera, Diptera and Orthoptera (locusts and crickets). The virions are relatively stable in the environment, but are apparently highly susceptible to ultraviolet (UV) light. Horizontal transmission is either via excretion of infected cells, as documented in, for example, a virus from *Sibine fusca* (SfDNV), or by cannibalistic ingestion of infected insects as is the case for, for example, *Galleria mellonella* (greater wax moth) densovirus (GmDNV).

Although not an extensively studied virus group, several examples of successful pest control using DNV have been documented. For example, SfDNV has been successfully used to control *S. fusca* on Colombian palm oil trees. In one trial, a dose of 1–5 infected larval equivalents per hectare was sprayed from the air, resulting in a dose dependent mortality rate of 73–97% at 15 days postapplication. A similar result was achieved in the control of *Casphalia extranea* in Ivory Coast palm oil and coconut plantations, using between 50 and 100 infected *C. extranea* larval equivalents per hectare. To date, the reported broad host range of DNVs for insects, together with their extreme sensitivity to UV light, has limited the development of these viruses as control agents.

Ascoviridae

Ascoviruses contain a linear double-stranded DNA genome, and to date have been identified only as pathogens of the Noctuid family of Lepidoptera. The viruses cause a chronic infection, taking between 2 and 6 weeks to kill the host. This slow speed of kill, together with apparently poor levels of transmission between hosts, and the absence of examples of natural epizootics, suggest that they have little to offer as biological control agents. At this time there is no record of attempts to use these viruses for insect control. However, it has been noted that ascovirus infection is associated with impairment of larval development and feeding. This fact, together with the specificity of their host range, which includes several

economically important pests, suggests that they may merit more detailed study.

Iridoviridae

This family contains viruses that infect both vertebrates and invertebrates, but members of two genera, *Iridovirus* and *Chloriridovirus,* are insect specific. The prefix 'irido' is derived from the characteristic iridescent appearance that can occur in infected insects; recently, however, it has been shown that the incidence of the virus within natural populations is far greater than suggested by the number of iridescent insects. This group of viruses has been found in coleopteran, lepidopteran and dipteran hosts, including important crop pests such as *Heliothis* spp., and blackflies (*Simulium* spp.), which are vectors of human disease.

Unfortunately, little is known about the transmission route or life cycle of these viruses and this, together with their apparent lack of virulence, has discouraged their serious consideration as pest control agents. However, their ability to infect dipteran hosts, a group from which relatively few other insect viruses are recorded, as well as their potential amenability to genetic engineering, is likely to encourage the further investigation of these viruses as potential pesticides.

Entomopoxvirinae

The *Entomopoxvirinae* (EPV) are a subfamily of the *Poxviridae* that are specific to insect hosts. EPV infections have been documented in four major orders of insect pests: the Lepidoptera, Coleoptera, Orthoptera and Diptera. The EPVs resemble the baculoviruses in a number of ways, including their production of occlusion bodies and their amenability to genetic modification. In addition, however, EPVs are capable of infecting a number of economically important pest species not affected by the *Baculoviridae,* including the desert locust (*Schistocerca gregaria*), possibly the most destructive pest species worldwide, and a variety of scarab beetle pests. To date the EPVs have received little attention as potential pest control agents, due largely to their slow speed of kill. However, several EPVs are capable of replicating in insect cells in culture, and this has enabled researchers to investigate the possibility of genetically modifying EPVs to enhance their speed of kill. One EPV showing particular promise in this respect is the *H. armigera* EPV (HaEPV). This virus infects several different economically important lepidopteran pests, grows readily in tissue culture, and can be genetically modified. Work is currently underway to increase the speed of kill of this virus in the same manner as for baculoviruses (see below).

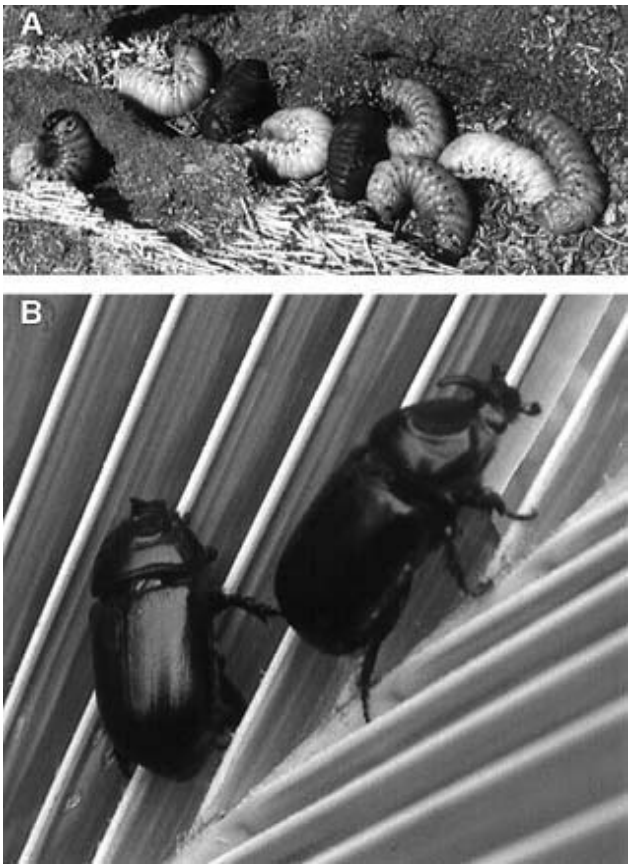

Figure 1 (**A**) *Oryctes rhinoceros* (coconut rhinocerus beetle) larvae and pupae at a breeding site. (**B**) *Oryctes rhinocerous* adults. (Courtesy of Dr D F Waterhouse, CSIRO, Australia.)

Non-occluded DNA viruses

This now unclassified group of viruses was formerly considered to be a subfamily of baculoviruses, with which they share many physical characteristics. Unlike members of that group, however, they do not produce occlusion bodies, and can infect both adult and larval insect hosts. Three viruses with large double-stranded DNA genomes have been assigned to this group, and all are apparently specific to insects. The first of these to be discovered was the *Oryctes* virus (Or-1V) which infects *O. rhinoceros* (the coconut rhinoceros beetle). The other two members of the group (Hz-1V and Hz-2V) have both been found in *Helicoverpa zea* (corn ear worm). Both Ov-1V and Hz-1V are able to replicate in tissue culture and so have been relatively well characterized. Hz-2V infects the reproductive tissue of adult *H. zea,* causing atrophy of the reproductive organs. Symptoms of

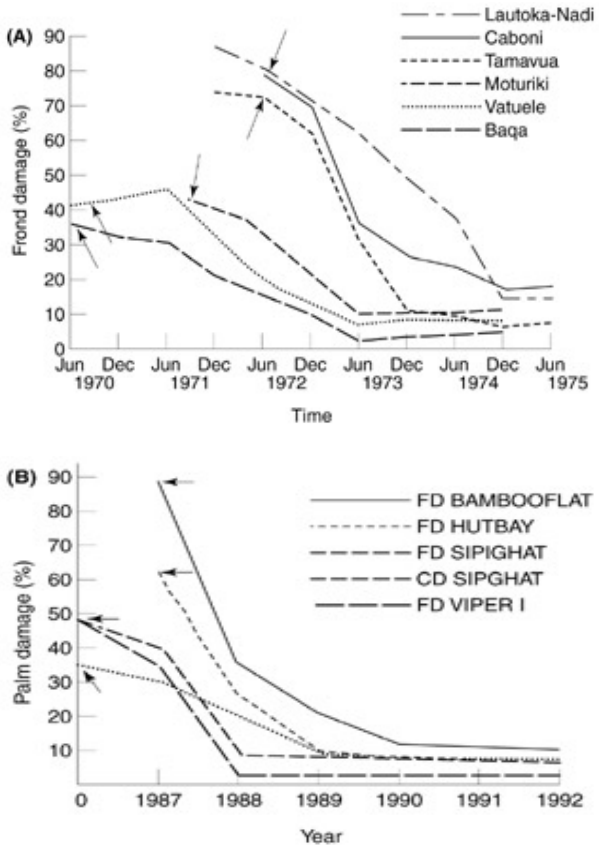

Figure 2 (**A**) Effect of *Oryctes rhinocerous* virus on palm damage by *O. rhinoceros* in the Fiji Islands. Arrows indicate time of virus introduction; virus spread naturally into Lautoka-Nadi area by mid-1973. (Modified from Bedford GO (1980) with permission from the *Annual Review of Entomology*, Volume 25 1980 by Annual Reviews.) (**B**) Decline in palm damage in the Indian Andaman Islands 1987–1992. Arrows indicate date of *O. rhinocerous* virus release; FD, frond damage; CD, crown damage. (Modified with permission from Jakob TK (1996) *Bull. Entomol. Res.* 86: 257–262.)

infection include shrunken testes in males and possible absence of ovaries in females. Infected adults that are not sterilized by the disease have been shown to produce apparently healthy larvae, but adults that develop in turn from these larvae can also show the characteristic atrophy of the reproductive organs. This effect of host sterilization, together with the capacity for vertical transmission and the importance of the host as a pest species, indicate a possible future for Hz-2V as a pest control agent.

Or-1V is currently the most successful example of the use of a viral biological control agent for insect pest control. This virus was isolated from *O. rhinoceros* (**Fig. 1**) in Malaysia in 1963 and was subsequently found throughout southeast Asia. However, it was found to be absent from the South Pacific countries where *O. rhinoceros* was a serious pest of palm trees. As a consequence, a program to introduce the virus into Western Samoa was started in 1967. The virus was initially introduced into the natural breeding sites for the beetle using logs or sawdust infected with Or-1V. Later, artificial breeding sites contaminated with the virus were set up, and, in addition, adult males were infected in the laboratory and returned to the breeding areas. Adult beetles infected with the virus can transmit it to other adults during mating, by accidental contact or via infected excreta at the breeding site; larvae that ingest this infected excreta may also become infected, and subsequently fail to reach adulthood. The initial trial on Western Samoa was so successful that a control program was introduced throughout the South Pacific. Results throughout this region indicated dramatic reductions in palm damage (**Fig. 2A**). In Fiji, damage was reduced from 75–90% in the worst affected areas in 1970 to around 10% by late 1974. Similar results were seen on Mauritius, where in 1978 palm damage was reduced by 60–95% from previrus release levels in 1970. The success of this program led to the use of Or-1V in the Indian Andaman Islands, with similar results (**Fig. 2B**). Both these programs have now resulted in long term economic control of this important pest, and the only maintenance required for continued control has been the sporadic reintroduction of the virus on some islands.

Baculoviridae

General biology The baculoviruses are a well-characterized group of invertebrate-specific viruses that are divided into the genera *Nucleopolyhedrovirus* (containing the NPVs) and *Granulovirus* (containing the GVs). NPVs are found mainly in insect hosts, and have been widely recorded from larvae of lepidopteran species, as well as in members of the Hymenoptera, Diptera, Coleoptera and Trichoptera. There are also reports of NPV infections in crustaceans. In contrast, the GVs are apparently restricted to lepidopteran hosts. Like CPVs and EPVs (see above), baculoviruses produce large proteinaceous occlusion bodies which serve to protect the virions during periods of transmission between hosts. NPV occlusion bodies always contain multiple virus particles, whereas in GVs only one virus particle is occluded in each occlusion body.

Most baculovirus isolates have a narrow host range, and many are highly virulent (**Fig. 3**), causing widespread epizootics in the natural environment, and playing a significant role in natural regulation of insect populations. This combination of characters has led to baculoviruses being perceived as the best

Figure 3 *Heliothis armigera* (cotton bollworm) cadaver after infection by HaNPV.

suited of the insect viruses for development as commercial pest control agents.

Past and current uses of baculoviruses Baculoviruses have been used for many years as pest control agents, being exploited both commercially (**Table 2**) and noncommercially. Early reports of use include the Chinese army using mortars to fire infected larvae into the canopy of forests infested with caterpillars. Nevertheless, until recently the relatively slow speed of action of baculoviruses has meant that most commercial use of the viruses has been directed towards forestry, or other production systems where commodities can tolerate levels of damage typically suffered in the time between infection and death of a pest. Examples of semicommercial use include the US Forestry Service products Gypcheck (*Lymantria dispar* NPV) used against *L. dispar* (gypsy moth) and Neocheck-S (*Neodiprion sertifer* NPV) used to control *N. sertifer* (pine sawfly). There are relatively few examples of natural baculoviruses being used to protect field crops. The most successful example is the use of *Anticarsia gemmatalis* NPV (AgNPV) to control *A. gemmatalis*, the velvetbean caterpillar, in soybean crops in Brazil. A long-term program there has now led to establishment of a large *in vivo* production industry, and the annual spraying of over two million hectares with the virus. Other notable examples of baculovirus use include GemStar™, a wild-type *H. zea* NPV being evaluated for use in a US Department of Agriculture bollworm/budworm suppression program and control of *H. armigera* in grain crops in Australia, and SPOD-X LC™, a commercial formulation of the wild-type baculovirus *Spodoptera exigua* (beet armyworm) NPV (SeNPV). Since 1994 SPOD-X LC™ has been marketed in the USA, Thailand and Holland for the control of *S. exigua* on ornamental, vegetable and field crops. Results of use reported so far have indicated that it can achieve a level of control equivalent to that of commercial chemical products, demonstrating that commercial use of natural baculoviruses can be a successful strategy on high-value crops.

Advantages and disadvantages of baculoviruses as pest control agents In natural settings, baculoviruses are known to cause large-scale epizootic events that are responsible, in part, for the regulation of populations of many insect species. Under artificial circumstances (e.g. when used as a pest control agent) baculoviruses also have a significant number of advantageous characteristics. Thus, when administered *per os* they are extremely virulent, and usually cause lethal infections. Their invertebrate specificity and limited host range means that a baculovirus-based pesticide is unlikely to cause problems to beneficial insects and other nontarget organisms. Despite their individually narrow host range, baculoviruses are collectively capable of infecting a wide range of

economically important pests, so that it is likely that technology developed for one virus–pest combination will also be applicable to the development of other viral pesticide products. Finally, development of pest resistance to these complex agents seems less likely to occur – at least in the short term – than has frequently been the case with simple chemical compounds.

Baculoviruses do, however, also have a number of limitations that have prevented their widespread use as biological insect control agents. Thus they are currently rather expensive to produce, either *in vitro* (in cell culture systems) or *in vivo* (in insect larvae). Similarly, while their narrow host range is an advantage from a safety perspective (see above), it can also be a disadvantage when more than one pest species occurs on a crop. Further, these viruses are also highly susceptible to inactivation by UV light in sunlight, so that complex formulation strategies must be used. However, perhaps their principal disadvantage is their relatively slow speed of action. Most baculoviruses take 7–10 days to kill an infected host, and substantial damage can thus be caused to a crop between the time of virus application and the eventual death of the target pest.

In recent years considerable efforts have been made on several fronts to decrease these limitations. One strategy being pursued to reduce production costs is the development of efficient cell culture systems. Continual progress is being made in increasing the size and capacity of fermentation vessels for growth of large and high-density cell cultures, as well as in optimizing cheap culture media and the highly productive cell lines necessary for commercial-scale virus production. Work is also being done with respect to characterization of the genetic basis of baculovirus host range/specificity, and a number of genes have now been demonstrated to play a role in this phenomenon. A detailed understanding of the mechanism of host range determination at a molecular level should provide an ability to modify virus host range, thus making these engineered baculoviruses more attractive as pest control agents.

It seems likely that the problem of UV sensitivity will be solved by the development of appropriate formulations containing effective UV protectants that can be applied to the crop with the viral pesticide. Finally, substantial progress has been made in increasing the speed of action of baculoviruses by genetic manipulation, as reviewed in the following section.

Genetic manipulation of baculoviruses Two broad and complementary approaches have been taken to improve the insecticidal properties of NPV baculoviruses by genetic manipulation; namely, the insertion of genes from other sources into the viral genome, and the manipulation/deletion of normally occurring viral genes. The types of foreign genes inserted into the virus genome can be subdivided into those that encode insect-specific toxins, and those that encode hormones or enzymes designed to disrupt host homeostasis (**Table 3**). Genes encoding insect-specific toxins have been isolated from sources ranging from scorpions and spiders to mites, bacteria and sea anemones. The effects of these toxins, when expressed by a recombinant virus, on the insecticidal properties of that virus have been mixed. Of those for which published data are available, the AaHIT toxin of the North African scorpion (*Androctonus australis*), and a toxin from *Pyemotes tritici* (straw itch mite) have proved most effective, resulting in demonstrated pest kill times of 48–72 hours.

Table 3 Genes used in attempts to improve insecticidal activity of baculoviruses

Foreign gene inserted	*Target*
Lesser Asian scorpion toxin	Sodium channels
North African scorpion toxin	Sodium channels
LQH scorpion toxin	Sodium channels
Straw itch mite toxin	Nervous system
Funnel web spider toxin	Sodium channels
Sea anemone toxin	Sodium channels
Bacillus thuringiensis toxin	Cell membranes
Wasp antigen 5	?
Maize mitochondrial toxin (URF13)	?
Insect diuretic hormone	Water balance
Prothoracicotropic hormone	Ecdysteroid levels
Juvenile hormone esterase (JHE)	JH levels
Eclosion hormone	Insect development

The insertion of genes designed to disrupt insect homeostasis has proved less effective, although overexpression of a mutant form of the *H. virescens* juvenile hormone esterase has been reported to improve the insecticidal properties of NPVs under some circumstances.

The other approach taken to enhancing the insecticidal activity of baculoviruses is to delete genes from the viral genome. One viral protein which baculoviruses use to control host development is ecdysteroid UDP-glucosyl transferase (EGT); this protein inactivates the host hormones that trigger molting, initiating a virally-induced developmental arrest. This molting arrest is thought to be advantageous to the virus in prolonging the duration of the feeding stage of host larvae, and ultimately leading to a higher level of virus production. Deletion of the *egt* gene has produced viruses that kill their hosts up to 30% more quickly than the wild-type parental virus,

in the process reducing overall host feeding levels by 20–30%.

Field trials of genetically modified baculoviruses A number of field trials of recombinant baculoviruses have now been done. Trials in Oxford (UK) involved the release, under controlled conditions, of a recombinant *Autographa californica* NPV (rAcMNPV) containing the AaHIT gene on cabbage infested with *Tricoplusia ni* larvae. These trials demonstrated that the enhanced speed of kill of the virus led to a 25% reduction in crop damage. Larger scale trials have been carried out in the USA by the agrochemical company American Cyanamid. These involved the use of both an *egt*-minus AcMNPV and an *egt*-minus AcMNPV containing the AaHIT gene. Trials in 1993–1995 demonstrated that under field conditions the *egt*-minus virus killed target species up to 20% faster than wild-type virus, and trials using *egt*-minus rAcMNPV containing the AaHIT gene showed still further improvement in insecticidal activity. A trial on cotton in Louisiana demonstrated that control of *H. virescens* by this *egt*-minus AaHIT-expressing virus was comparable with that of a commercial insecticide and a *B. thuringiensis* bacterial biopesticide.

Conclusions

The advent of powerful techniques of molecular biology together with increasing environmental concerns over chemical pesticides have led to a resurgence of interest in the use of insect viruses in pest control regimens. The possibility of using EPVs, CPVs and tetraviruses has been greatly enhanced by advances in genetic engineering. However, it is the baculoviruses, and in particular the NPVs, that have been the subject of most dramatic progress. Recombinant baculoviruses with significantly enhanced speed of action are now available, and field trials using these have produced encouraging results.

None the less, some issues remain to be resolved before such viruses are taken through to full commercial development. One area of concern is the possible effects of toxins produced in infected insects on nontarget organisms. Work done so far has shown that the amount of AaHIT produced by rAcMNPV is not sufficient to harm either mammals or predatory/scavenging insects feeding on infected caterpillars or their cadavers. Thus it seems that this issue will not present any problem. Another area of concern is the possibility of genetic exchange between the virus and other organisms. It is conceivable that a toxin gene for instance, could become inserted in the genome of another organism, possibly upsetting the natural balance between that organism and those others it interacts with in the environment. Present research indicates that such an event is unlikely, but further research of the risk associated with that phenomenon is required. Currently, it seems likely that the first recombinant baculovirus pesticides will be available on a commercial basis within the next few years.

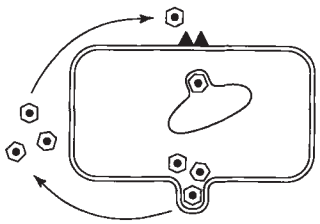
INTERFERENCE

Julius S Youngner and **Patricia Whitaker-Dowling**, University of Pittsburgh School of Medicine, Pittsburgh, Pennsylvania, USA



History

From the earliest days of quantitative virology it was recognized that when two different viruses infect the same cell one virus frequently affects the growth of the other. When interference between the two viruses occurs it is traditionally subdivided into two categories: homologous and heterologous interference, depending on the closeness of the relation of the two viruses. For many years the mechanisms involved in these phenomena remained obscure and subject to much speculation. The discovery of interferon in 1957 offered a potential mechanism for virus interference and many of the examples that had been observed in the past were explained by the action of this antiviral protein. The revival of interest in virus interference led to increasing recognition that in many cases the interferon mechanism is not involved and that other factors play a role in the inhibitory interactions between viruses.

Types of Virus Interference

There are several mechanisms that can be invoked to explain the interference that is observed between related and unrelated viruses. It should be noted that two of the types of interference referred to below have been extensively investigated and are covered in more depth in other entries in this volume.

Interferons

As mentioned above, the discovery of interferon by Isaacs and Lindenmann led to the clarification of the mechanism involved in a number of the interference models that had been studied. The interferon system is composed of a family of proteins (designated α-, β-, and γ-interferons) which are induced in cells infected by a variety of RNA and DNA viruses. The ability to induce interferon can vary widely with different viruses and has even been shown to vary with different mutants of the same virus. Furthermore, the antiviral effects of interferon are not virus-specific; the inhibitor will act against the virus that induced it as well as against heterologous viruses. Co-infection of cells with two viruses with different interferon-inducing abilities can result in a situation in which the growth of one of the viruses is hindered by the interferon induced by the other virus. A detailed summary of the characteristics of interferon and the mechanisms of its antiviral action are described elsewhere in this volume.

Incompatibility of heterologous viruses

Interference between heterologous viruses usually is produced by one virus inactivating or inhibiting a host cell function required by the other virus. A prime example of this type of incompatibility is seen in cells infected with poliovirus and an unrelated RNA virus, vesicular stomatitis virus (VSV). Infection with poliovirus results in the inactivation of the cap-binding protein complex of the infected cell, an action that blocks the translation of capped mRNAs. Since VSV produces capped mRNAs, VSV protein synthesis is inhibited in poliovirus-infected cells.

Another example of heterologous interference is the inhibition of the growth of influenza A virus in cells doubly infected with this virus and VSV. Influenza virus requires continuous host mRNA synthesis during its replicative cycle because it 'steals' the 5′ end of host mRNAs and uses these oligonucleotides as primers for the synthesis of its own mRNAs. Since VSV infection produces an efficient and early shutdown of host RNA transcription, in doubly infected cells there are no newly synthesized host mRNAs from which influenza virus can obtain the cap sequences necessary for its own mRNA; its replication is thus blocked.

Heterologous interference also can occur when one virus has a faster replication cycle and rapidly shuts down a host function that is needed by a second virus that is replicating with a slower growth cycle. For example, VSV inhibits the growth of a herpesvirus, pseudorabies, in doubly infected cells by shutting off the host protein synthesis machinery before the herpesvirus has the opportunity to express all of its proteins.

An alternative mechanism which can cause incompatibility of heterologous viruses is based on the interaction of their gene products. This type of interference occurs when two different viruses encode proteins that are similar enough to form heterologous multimeric complexes. If these multimeric complexes are nonfunctional, interference results. Such a mech-

anism may explain the interference observed between two VSV serotypes (Indiana and New Jersey).

Superinfection exclusion

Several families of viruses have evolved strategies to block the invasion of a cell that has been previously infected. This block can occur at the level of adsorption, penetration, or later in the replicative cycle. For example, certain retroviruses inhibit the expression of their cell surface receptor following infection, thus blocking the adsorption of superinfecting virus. Members of the orthomyxovirus and paramyxovirus families encode a transmembrane glycoprotein with receptor-destroying activity which blocks virus binding. This activity not only allows the efficient escape of newly formed progeny virus but also prevents superinfection by related viruses.

VSV is also capable of preventing superinfection at the level of penetration; this block is caused by a VSV-induced inhibition of endocytosis, a pathway used by many viruses to enter cells.

The term 'intrinsic interference' is used to describe a phenomenon in which cells infected with a noncytopathic RNA virus, such as rubella, are resistant to superinfection with an unrelated RNA virus, Newcastle disease virus. This resistance is not due to interferon induction since the only cells in the culture that are resistant are those that are actually infected with rubella. Indirect studies suggest this interference is due to the synthesis of protein(s) of the rubella virus rather than some host protein, but the mechanism is not understood.

Defective interfering (DI) particles

Serial high-multiplicity passages of most viruses produce mutant viruses that have part of their genome deleted or rearranged. Because these mutants are defective for replication, they require a helper function that is provided in *trans* by the parental virus. However, in the course of this co-infection the replication of the defective virus is favored and the production of the parental virus is reduced significantly. A detailed description of the generation of DI particles and their inhibiting effect on the replication of parental virus is given elsewhere in this volume.

Dominant-negative mutants

A sizable body of information has accumulated reporting instances in which viruses with mutations that produce *ts*, host range, small plaque, or nonsense mutants behave in a dominant manner and can inhibit the growth of the standard wild-type virus in mixed infections. These mutants differ from DI particles in that there is no absolute requirement for a helper virus in order for them to grow, and they interfere by mechanisms that differ from those used by DI particles.

The documentation of interference by dominant-negative mutants covers a wide range of RNA and DNA animal viruses, as well as plant viruses and bacteriophage. In the case of plant viruses, this phenomenon has been a subject of interest for decades. It was originally investigated in connection with its effect on viral pathogenesis in plants. The term 'cross-protection' is used to describe the resistance afforded against a virulent strain of virus by prior infection with an attenuated strain of the same virus. Since plants do not mount an antiviral response analogous to the interferon system or have any known counterpart to the immune system, it is thought that cross-protection arises from virus interference.

Detailed Consideration of Dominant-negative Mutants

Dominant-negative mutants have been derived spontaneously or by mutagenesis from nearly every family of animal viruses. In fact, viral mutants with the ability to interfere have proved relatively easy to obtain and for some viruses, such as VSV, have been identified in every complementation group. The ease with which this phenotype arises may be due to the fact that the majority of virus gene products function as components of multimeric complexes; only a small proportion of viral gene products function as single-subunit, soluble proteins. Dominant mutants may also have a selective advantage and may prevent the successful growth of revertants by virtue of their dominant phenotype. Mutant viruses that evolve in long-term persistent infections in cell culture model systems are of particular interest.

Such viruses frequently express two phenotypes that are crucial to the maintenance of the persistent state. First, the viruses derived from persistent infections have a reduced capacity to kill cells; second, these mutant viruses are also dominant over the parental wild-type virus in mixed infections. Both phenotypes would be expected in viruses that are selected in long-term persistence. In fact, establishing persistent infections may provide an effective selection technique for obtaining viruses that are attenuated, dominant-negative mutants.

It is important to distinguish the ways in which dominance can be manifested. In the case of some dominant-negative mutants, only their phenotypes are dominant in mixed infection with wild-type virus.

Although co-infection with these mutants can significantly affect the ability of the wild-type virus to grow, the reduced yield from these limited replication cycles reflects the same ratio of the two viruses as in the input inoculum. This can be termed 'phenotypic dominance'. For example, double infection at the nonpermissive temperature with equal amounts of a dominant-negative, temperature-sensitive mutant and a wild-type virus may reduce the yield of the wild-type virus by several orders of magnitude, but the composition of the total yield will be 50% mutant and 50% wild-type virus. This type of dominance prevents the overgrowth of revertants which may arise within the population, but since it provides no reproductive advantage to the dominant mutant, this virus will be unable to establish predominance within a mixed virus population. An alternate manifestation of a dominant-negative phenotype occurs when the mutant dominates at the level of phenotypic expression and also suppresses the growth of wild-type virus relative to its own. In this instance the yield from the mixed infection is predominantly mutant virus. This variety of dominance can be termed 'genotypic dominance'. Any mutants with this trait will have a strong selective advantage in a mixed virus population and thus be able to both establish and maintain predominance within a mixed virus population.

Possible mechanisms of interference by dominant-negative viruses

Despite the large number of instances in which dominant-negative viruses have been described, there is a paucity of direct biochemical data dealing with the mechanism of interference. There has been a good deal of speculation based on observations of reductions in virus yield, genome replication, or viral gene expression. Out of this speculation some recurrent themes have emerged concerning mechanisms that may be involved in this type of interference but the authors do not intend to imply that this is an exhaustive list. Of the five suggested mechanisms described next, the first three would be expected to show phenotypic dominance whilst the last two would be predicted to result in genotypic dominance. It should be noted that some of these mechanisms also may apply to cases of heterologous interference or interference by superinfection exclusion.

The 'rotten apple' hypothesis Perhaps the most common hypothesis to explain the mechanism of interference by a mutant virus is that a defective polypeptide enters into a multimeric complex and thereby inactivates or inhibits the activity of all the components of that complex. The formation of such hybrid structures has been suggested in the case of certain bacterial and animal viruses. A possible example of this mechanism is seen with a *ts* mutant of VSV that encodes a lesion in the nucleocapsid protein (N). In mixed infections of cell cultures with wild-type and mutant viruses, the pool of N protein in the cell would consist of a mixture of both normal and defective N polypeptides. Should the defective product participate in the polymerization of N protein on the viral RNA, a premature termination of assembly or defective nucleocapsids might result. Either of these outcomes would effectively incapacitate both the viral RNA molecule and all normal N protein in the complex. If this mechanism were operating, relatively small amounts of the defective polypeptide would cause significant levels of interference.

The 'road block' hypothesis In this model the defective function of the mutant virus irreversibly sequesters the pool of a factor or site required for the replication of both viruses. A possible example of this mechanism is the ability of a mutant of VSV that contains a lesion in the RNA polymerase protein (L) to interfere with wild-type virus in mixed infections. This defective polymerase may bind preferentially to RNA synthesis initiation sites on the wild-type genome and thus prevent access by the functional wild-type enzyme. Such a mechanism is particularly applicable in the case of mutated *trans*-activating elements. Viral proteins which function to activate enhancer regions on viral genomes could mutate in a manner that retains their binding activity but loses their activating function. In some instances involving DNA viruses, it is proposed that the dominant-negative phenotype may be mediated by binding of the mutant protein to the replication origin, thus inhibiting the initiation of viral DNA synthesis.

The 'all things in moderation' hypothesis It has been demonstrated in several bacteriophage and plant virus systems that gene dosage is another mechanism that may explain interference. In these instances, an imbalance in the relative amounts of certain structural proteins leads to the improper or inhibited assembly of virus particles or affects gene expression. In this case a termination mutation at any site on a particular gene may be sufficient to cause the dominant phenotype.

The 'direct competition' hypothesis In double infections with two viruses, competition for some limiting factor or site of either viral or host origin may play a role in interference. One of the interacting viruses may have the advantage of a higher binding

affinity for such a specific site or factor, and thus outcompete the other virus in a mixed infection. From this model it would be expected that as the degree of interference with the wild-type virus increases, the amount of the mutant progeny would also increase since the total yield of virus is dependent on the limiting factor in the growth cycle. Such an outcome has been reported in a double infection involving wild-type and mutant Sendai virus. In this case, despite significant reduction in wild-type virus progeny, net yield of virus is unchanged.

The 'attractive genome' hypothesis A mechanism for interference may operate that is similar to what has been proposed for the action of defective-interfering particles. Extensive studies with VSV have suggested that DI particles interfere by successfully competing with the parental genome for the available RNA polymerase complex. In a similar manner, the genomes of dominant-negative viruses may possess binding sites for the viral replication machinery, or its components, that are more attractive or in greater abundance than the binding sites of the wild-type virus.

Complementation and reassortment inhibition

That a detrimental mutation results in the phenotypic absence of that particular function and that phenotypic rescue can be accomplished by supplying that function in *trans* are commonly held tenets of genetics. Complementation analysis is based on these assumptions. Interference by dominant-negative mutants may explain some of the difficulties encountered in demonstrating significant complementation. Examples are cited in the literature for several families of DNA and RNA viruses, e.g. herpesvirus HSV-1 and VSV, where co-infection of cells with complementation incompetent mutants interferes with the successful growth of wild-type virus. This test can be used to differentiate dominant-negative mutants from mutants that are complementation incompetent due to alteration in *cis*-acting functions. In addition to an inhibition of complementation, reassortment of viral genes of segmented RNA viruses can also be affected when one of the two parental viruses is able to dominate the other. Such an inhibition of reassortment has been shown to occur with both influenza and reoviruses.

Dominant-negative mutants as antiviral agents

The potential for using dominant-negative mutants to prevent or treat disease in humans or animals is being increasingly recognized. Two approaches are being pursued. One approach involves the performance of what is essentially gene therapy, i.e. the use of expression vectors carrying naturally occurring or genetically engineered dominant-negative viral genes. Akin to antisense messenger RNAs, which are genetically engineered products whose design is directed at blocking the expression of a specific gene, dominant-negative mutants function by blocking the activity of a specific gene product. When introduced into cells susceptible to, or infected with, a virulent wild-type virus, expression of the mutant gene would produce a protein that would act as a dominant-negative inhibitor.

There are several examples of the effective use of dominant-negative mutant proteins derived from viral genes and delivered by expression vectors in cell culture model systems. The growth of wild-type virus is suppressed in these transfected cells. It has been reported that in the case of human immunodeficiency virus type 1 (HIV-1), expression of mutant *tat*, *gag* or *rev* proteins in transfected cells results in dominant-negative inhibition of the replication of wild-type HIV-1. The replication of a herpesvirus, HSV-1, is inhibited in transfected cells expressing a mutated form of a structural protein, glycoprotein B, or expressing a mutated viral *trans*-activator necessary for early gene expression. The expression of dominant-negative mutant genes in cells has been termed 'intracellular immunization'. The transfection of dominant-negative genes also offers the possibility for the creation of transgenic animals carrying genes which confer on the animals a genetic resistance to infection with specific viral pathogens. The application of these cell culture models to disease states in humans is fraught with the problems associated with gene therapy in general, foremost among them the delivery to and appropriate expression of the dominant-negative genes in the correct target cells in the body.

An alternate approach, and one which might be achievable in the near future, is the use of attenuated, dominant-negative mutant viruses to modify disease processes prophylactically or therapeutically by interfering with their virulent counterpart. The use of attentuated intact viruses carrying dominant-negative mutations circumvents the problem of delivery since the mutant virus is already targeted to the appropriate cell population. Furthermore, the proper expression of the mutant protein is assured since the gene appears in its natural context. The feasibility of this approach has been demonstrated in experimental animals in the case of an attenuated influenza A strain that is a dominant-negative mutant. Simultaneous co-infection of animals with this attentuated virus and wild-type influenza virus results in the complete suppression of the disease symptoms seen in animals infected

with the same amount of wild-type virus alone. The advantages of the use of attenuated viruses are that the effective dominant gene(s) are delivered in the intact animal directly to the appropriate target cells and their expression is transient and does not cause the permanent alteration of the host genome.

Live virus vaccines should contain dominant negative mutations

In this connection it should be noted that the ability to interfere with the growth of wild-type virus would be a particularly desirable trait in the case of live virus vaccines. The use of vaccine viruses with attenuating mutations that also confer a dominant-negative phenotype would add a significant degree of protection against virulent revertants that may arise during the immunizing infection or against epidemic viruses that may be circulating concurrently in the population. In addition to their immunizing potential, dominant-negative vaccine viruses could offer short-term antiviral protection until the immune response to the virus is firmly established.

INTERFERONS

IF

Philip I Marcus, University of Connecticut, Storrs, Connecticut, USA

History

Interferons (IFNs) represent the prototype of a family of cytokines with an extraordinary wide range of biological effects including their action as antiviral agents – the basis of their discovery. Interferons have emerged as some of the most active biological substances known. Their study reveals myriad effects on cells, contributing to our understanding of basic cellular, immuno- and developmental biology. The IFN system, both its induction and action, represents the first line of defense against viral diseases, and possibly other infections agents, and has attained official sanction as an acceptable therapeutic agent, fulfilling the dreams of its early investigators.

Virologists long recognized that exposure of cells to one kind of virus often rendered the cells refractory to infection by another virus, even of heterologous origin. The simultaneous occurrence of two different childhood virus diseases is unprecedented. The shroud of mystery surrounding these examples of 'viral interference' was lifted with a seminal discovery by Isaacs and Lindenmann in 1957. They found that chicken cells exposed to heat-inactivated influenza virus released a factor which, when added to fresh cells, reduced their capacity to produce new virus. Based on this ability to interfere with virus replication the factor aptly was termed 'interferon'. During the first decade after its discovery, IFN was viewed as a curiosity, the research object of a small number of virologists; yet some had visions of its use therapeutically as an antiviral agent. Initial attempts to purify interferon, a prerequisite for clinical use, were unsuccessful because cells produced only a few molecules following its induction. However, these molecules were extremely potent biological response

with the same amount of wild-type virus alone. The advantages of the use of attenuated viruses are that the effective dominant gene(s) are delivered in the intact animal directly to the appropriate target cells and their expression is transient and does not cause the permanent alteration of the host genome.

Philip I Marcus, University of Connecticut, Storrs, Connecticut, USA

History

Interferons (IFNs) represent the prototype of a family of cytokines with an extraordinary wide range of biological effects including their action as antiviral agents – the basis of their discovery. Interferons have emerged as some of the most active biological substances known. Their study reveals myriad effects on cells, contributing to our understanding of basic cellular, immuno- and developmental biology. The IFN system, both its induction and action, represents the first line of defense against viral diseases, and possibly other infections agents, and has attained official sanction as an acceptable therapeutic agent, fulfilling the dreams of its early investigators.

Virologists long recognized that exposure of cells to one kind of virus often rendered the cells refractory to infection by another virus, even of heterologous origin. The simultaneous occurrence of two different childhood virus diseases is unprecedented. The shroud of mystery surrounding these examples of 'viral interference' was lifted with a seminal discovery by Isaacs and Lindenmann in 1957. They found that chicken cells exposed to heat-inactivated influenza virus released a factor which, when added to fresh cells, reduced their capacity to produce new virus. Based on this ability to interfere with virus replication the factor aptly was termed 'interferon'. During the first decade after its discovery, IFN was viewed as a curiosity, the research object of a small number of virologists; yet some had visions of its use therapeutically as an antiviral agent. Initial attempts to purify interferon, a prerequisite for clinical use, were unsuccessful because cells produced only a few molecules following its induction. However, these molecules were extremely potent biological response

modifiers as measured during the action phase; detectable at about 10 molecules per cell, or 10^{-15} M.

Recognition of the full spectrum of the actions of IFNs came slowly, hampered by difficulties inherent in purifying a protein produced so sparingly by cells. As IFNs became available through recombinant DNA technology, the scope and magnitude of research broadened and the pace quickened. As part of a complex network of cytokines, IFNs display attributes beyond those of an antiviral agent. They function as negative cell growth regulators, immunomodulators, regulators of differentiation and development, inhibitors of some nonviral pathogens, and a reproductive hormone in ruminant ungulate species.

The small number of IFN molecules produced per cell initially limited human IFN for clinical use. For many years the Finnish Red Cross was the sole source of IFN, obtaining it from white blood cells infected with Sendai virus as the inducer. Its production limited clinical studies. In contrast, *Escherichia coli* that express human IFN can produce more than 10^9 units l^{-1}, representing over 10% of the bacterial mass, whereas clinical doses are on the order of 10^6 units per patient per day. Although IFN made by bacteria is not glycosylated, it is biologically active. All of the human IFN genes and many of animal origin, along with avian IFN genes, have been cloned and their respective IFNs produced in large quantity. Cloning and expression of chicken IFN completed the cycle of research started by the discovery of IFN in that species some 40 years ago. IFN molecules altered and produced by genetic engineering have enhanced specific activity, broadened species specificity and increased stability. Ingenuity, not amount, now limits the use of IFN.

Interferon Genes and Molecules

Cells produce two distinct types of IFNs, types I and II. These are distinguished by several biological and molecular attributes: the types of cells that express them, antigenicity, the 5′ regulatory regions of their respective genes, structural coding sequences, three-dimensional structure, the specific cellular receptors to which they bind and initiate signaling, and the signal transduction pathways (shared in part) that lead to activation of IFN action genes. IFNs collectively termed type I consist of four major family members, IFN-α, -β, -ω, -τ, and a new member, IFN-δ. Type II IFNs contain a single member, IFN-γ.

Type I interferons (α, β, ω, τ, δ) While antigenically distinct, these share a common ancestry and biological and biochemical properties, including their hallmark stability to heat ($\approx$ 70°C, 30 min) and acid (pH 2). Type I IFNs compete to varying degrees for common receptors on the cell surface ubiquitously distributed among virtually all cell types. Although many attributes are shared, each family displays distinct characteristics.

IFNs-α are produced primarily from leukocytes upon stimulation by double-stranded RNA (dsRNA) or viruses because of dsRNA formed during their replication. The human IFN-α family consists of 14 intronless genes and four pseudogenes located on chromosome 9. The 5′-flanking regions of the IFN-α genes contain sequences responsible for the inducible transcription that characterizes all IFN genes. Sequences in the 3′-flanking region contain polyadenylation sites and a motif common to genes that are characteristically expressed transiently due to an instability conferred on that class of mRNA. The primary proteins of the IFN-α family contain signal and mature protein sequences of 23 and 166 amino acids, respectively, and produce a molecule of $\approx$19.5 kDa. The biologically active molecules of human (Hu)IFN-α contain two intramolecular disulfide bonds, of which only one is essential (Cys29–Cys138), contributing to the heat and pH 2 stability that characterize type I IFNs.

IFN-β molecules are produced primarily by fibroblasts and epithelial cells following induction by dsRNA or viruses, and, in contrast to the HuIFN-α family, constitute the product of a single intronless gene. This gene also is located on chromosome 9, and shares about 30% homology with HuIFN-α genes. The HuIFN-α/β genes appear to have diverged about 250 million years ago, and are expressed in mammals, birds, reptiles and fish. All members of these families possess the IFN system, but those of mammals are best characterized. The fully processed, glycosylated and secreted molecule of HuIFN-β contains 166 amino acids and has a molecular weight of $\approx$23 kDa. The nonglycosylated molecule produced in *E. coli* has a molecular weight of 20 kDa and is fully active. HuIFN-β contains three cysteine residues. When Cys17 is replaced by serine, dysfunctional intramolecular sulfide bonds are precluded and the specific biological activity of this IFN-β_{ser} is increased. Murine IFN-β consists of five α helices, a structure shared by other cytokines. There is extensive sequence homology between the 5′-flanking regions of HuIFN-α and -β genes upstream from the TATA box, often resulting in the coordinate induction of both. In avian cells a dsRNase is coordinately induced with type I IFN.

IFN-ω (omega) is an antigenically distinct type I IFN that shares several attributes with IFN-α/β, including common receptors. The mature proteins of IFN-ω contain 172 residues, six amino acids longer

than IFN-α/β. IFN-ω makes up to 30% of the IFN produced by virus-induced peripheral blood mononuclear cells. IFN-ω, like IFN-α/β, induces an antiviral state, downregulates cell growth and modulates the immune response. The expression of IFN-stimulated genes may be sustained longer in IFN-ω-treated cells and hence this cytokine may prove to be more effective in the clinic. There are at least six HuIFN-ω genes, five of which are pseudogenes. IFN-ω is widely distributed among mammals, dogs being the exception, and likely diverged from IFN-α some 200 million years ago.

IFNs-τ (trophoblast) constitute type I IFNs induced by an unknown means in massive amounts from embryonic trophectoderm during maternal recognition of the conceptus and are the major product of the preimplantation embryo of ruminant ungulates. Like IFN-ω, the mature protein of IFN-τ contains 172 amino acids. Trophoblast IFNs are thought to have evolved from IFN-ω some 50 million years ago. Though IFN-τ and -ω share up to 75% sequence identity they are immunologically different and are derived from genes with distinctive promoter sequences. The unique action of IFN-τ as a reproductive hormone suggests that other novel IFNs may exist.

IFN-δ (delta) is a novel truncated type I IFN that is transiently expressed in porcine trophoblast during implantation in the uterus. The mature protein contains 149 amino acids following loss of a 21 amino acid signal peptide. IFN-δ is produced from an intronless gene, contains distinct regulatory sequences, and is antigenically distinguishable from other porcine IFNs. IFN-δ, like IFN-τ, represents a class of IFNs induced under physiological conditions and not significantly by viruses.

Type II interferon (IFN-γ, or immune IFN) This is produced by T lymphocytes following their exposure to mitogens, specific antigens or various cytokines. HuIFN-γ is encoded by a single gene on chromosome 12 which transcribes RNA containing three introns. The mRNA from the four exons produces a primary and signal-processed mature protein of 166 and 143 amino acids, respectively. The 16.8 kDa mature protein is glycosylated at one or two sites, to produce molecules of 20 kDa or 25 kDa. The active molecule does not contain cysteine residues, but functions biologically as a homodimer. The acid and heat lability of IFN-γ distinguish it from type I IFNs. The 5′-flanking region of the HuIFN-γ gene functions as an inducible transcriptional enhancer and contains sequences in regions comparable with those of other cytokines expressed in lymphocytes.

Induction of Interferons

Probably all cell types are capable of producing IFN when appropriately induced by viruses, dsRNA, mitogens or other cytokines. Most RNA viruses are good inducers of IFN because they generate dsRNA during replication and complete the induction process before host cell macromolecular synthesis is compromised. RNA viruses that fail to induce IFN invariably suppress its induction, even in cells already programmed to produce it. Some DNA viruses induce IFN because they generate dsRNA through convergent transcription of their genome. Even organisms as diverse as mycoplasmas, rickettsia, bacteria and protozoa can induce IFN, albeit less efficiently.

Once dsRNA appears in the cytoplasm it is recognized by a cellular protein with high binding affinity for helical RNA, an endogenous protein kinase (PKR) that is activated by dsRNA. For HuIFN-β this activation leads to phosphorylation and subsequent proteolysis of IκB, the inhibitor of the ubiquitous transcription factor NFκB. NFκB freed of its inhibitor is translocated to the nucleus where it functions as one of several positive regulatory factors for transcription.

In the fully competent but uninduced cell, expression of the HuIFN-β gene is tightly repressed by several protein factors bound to the 5′-promoter region of the genes that act cooperatively as negative regulators (HMGI/Y, OCT, IRF2, PRDI-BFI, PRDII-BFI, NRE-BP). IFN induction leads to activation of transcription factors that act positively (ATF2/CREB, HMGI/Y, IRF1, NFκB/Rel). These displace and/or rearrange extant negative regulators on the DNA sequence which contains four positive regulatory domains (PRDI-IV) and one overlapping negative regulatory element (NRE) upstream from the TATA box that precedes the transcription start site. This chain of events begins within minutes after a cell is exposed to an IFN inducer. Most RNA viruses are excellent inducers of IFN because they form dsRNA during replication or contain it as genome. The cell is exquisitely responsive to dsRNA – a single molecule constitutes the threshold for IFN induction. Helical RNA with as few as 40 base pairs suffice to activate dsRNA-dependent enzymes, albeit not as efficiently as longer sequences. Some chemicals, like imiquimod, an imidazoquinolinamine, induce IFN following oral administration.

IFN mRNA appears in the cell within an hour after virus infection/induction, reaches peak rates of synthesis by 5–10 h, and declines rapidly thereafter. Downregulation of transcription of positive regulatory factors, coupled with the programmed short half-life of IFN mRNA, contribute to the character-

istic pulse-like yield of IFN observed over 24 h. This highly regulated process results in a quantum, or finite, yield of IFN, the absolute value of which varies with both inducer and cell.

IFN production can be enhanced by 'priming' cells, i.e. pretreating them with IFN, or by superinduction. Priming induces higher levels of transcription factors, like IRF-1 (*IFN regulatory factor*), thus shortening the period to new IFN production and enhancing its yield. Superinduction is achieved through the sequential use of inhibitors of translation and transcription, and can enhance the yield of IFN several hundred-fold, by blocking production of repressor molecules and thereby prolonging transcription of IFN mRNA, and in some cases by extending its half-life.

The acquisition of IFN inducibility is linked to development. Embryonic cells of murine or avian origin cannot be induced to make IFN until after 5–7 days of gestation. Thereafter, the cells' capacity to produce IFN increases with embryonic age. Undifferentiated embryonal teratoma cells do not acquire IFN inducibility until they differentiate. The absence of *trans*-acting factors or IFN-stimulated response elements (ISRE)-binding proteins in the undifferentiated cell indicates developmental events regulate the process, as does the failure of viruses to activate NFκB and IRF-1 in young chicken embryo cells.

The Antiviral State

Within hours after virus infection, newly produced and released IFN is circulating in the body. Cells most proximal to the initially infected cell, and hence most vulnerable to infection, receive IFN first and in the highest concentrations. The binding of as few as ten molecules of IFN to specific receptors on the cell surface starts the action phase of the IFN system, where a broad spectrum antiviral state develops within hours. IFN is comparable in its action against viruses with that of broad-spectrum antibiotics against bacteria.

Receptor–IFN binding This initiates a cascade of events that terminate in an antiviral state. Receptors on the cell surface constitute specific sites to which IFNs bind with high affinity ($K_D \approx 10^{-10}$ M). Receptors number in the thousands per cell, and are transmembrane proteins molecularly distinct for types I and II IFN. Cellular receptors are responsible for species specificity. Thus, chicken IFN does not act on human cells, and vice versa; there are some exceptions. Human type I IFN receptors (IFNAR) are encoded by genes on chromosome 21 that express three subunits: IFNAR-1, IFNAR-2.1 and IFNAR-2.2. Both IFN-α/β bind to these IFNAR as monomeric ligands. Cells trisomic for chromosome 21 contain more receptors than diploid cells and consequently display an enhanced sensitivity to the action of type I IFN. HuIFN-γ binds as a homodimer to a specific transmembrane receptor, IFNGR, that contains two subunits: IFNGR-1, a high binding affinity molecule encoded on chromosome 6, and IFNGR-2, an accessory protein required for signaling that is encoded on chromosome 21. IFN-γ functioning as a homodimeric ligand may in turn dimerize two sets of IFNGR subunits to initiate the signaling that culminates in the expression of IFN action genes.

Signal transduction pathways Development of the antiviral state starts with IFN binding to specific cell receptors and ends with the expression of a coterie of rapid response genes, some of whose products confer an antiviral state. Between these two events lies a complex signal transduction pathway. Within minutes after the ligand IFN binds to its receptors a series of signal-responsive events convert latent cytoplasmic transcription factors into active proteins, IFN stimulated gene factors (ISGF), including a family of IFN-regulatory factors (IRF) that when properly assembled bind to specific DNA sequences: the IFN stimulated response elements (ISRE) for type I IFNs, and the gamma activated sequences (GAS) for type II IFN. There follows transcription of the myriad IFN-stimulated genes (ISG) whose products result in the broad range of antiviral and other effects that characterize IFN action. IFNs share parts of the signaling pathways with other cytokines and growth factors. The pathway for type I IFN induced action includes TYK2 (tyrosine kinase), JAK1 (Janus kinase), STAT1/STAT2 (signal transducer and activator of transcription) and p48 (a DNA binding protein). Upon ligand binding, the two kinases, located on the cytoplasmic side of IFN receptors, become activated through phosphorylation, and in turn phosphorylate and thus activate STATs, which complex with p48 to form ISGF-3. ISGF-3 translocates to the nucleus where, along with other transcription factors, it binds to ISRE for activation of type I IFN genes. In the type II IFN signaling pathway ligand binding activates by phosphorylation, JAK1/JAK2 which in turn phosphorylate and thus activate STAT1. The homodimer STAT1/STAT1 translocates to the nucleus and along with other transcription factors bind to GAS to initiate type II IFN gene activation. This receptor–JAK/STAT pathway distinguishes between the two types of IFN through extracellular binding and by selective use and activation of JAK/STAT members intracellularly. This results in selective activation of action genes of the two IFN families, with some overlap. In this way

events at the outer cell membrane are converted into DNA transcription signals and the selective expression of IFN action genes.

Antiviral systems activated by IFN action Following binding of IFN to cellular receptors and the resultant transduction signaling cascade, there is enhanced or new expression of over 100 genes. Gene activation generally does not require *de novo* protein synthesis, enabling cells to respond rapidly to IFN. Some genes are induced by either type I or II IFNs, others exclusively by one or the other. Only a few of these newly expressed proteins thus far have been linked to the antiviral state. These are considered below.

2–5 Oligoadenylate synthetase/2–5 (A)/RNase L system

2–5 Oligoadenylate synthetase (2–5 (A) synthetase) is constitutively present in a latent state at low basal levels in cells, and increases 10- to 1000-fold in response to IFN.

The latent enzyme is activated in a novel manner, namely through the high affinity binding ($K_D \approx 10^{-10}$ M) of dsRNA – a signature molecule of virus infection. Once activated by dsRNA the 2–5 (A) synthetase polymerizes ATP into a series of 2′–5′ linked oligomers. The trimer [(2′–5′)pppA(pA)$_n$], called 2–5A, often the most abundant species, activates a latent cellular endoribonuclease (RNase L), itself inducible by IFN, which cleaves single-stranded (ss) RNA and hence blocks protein synthesis through degradation of mRNA. The highest concentration of 2–5 A accumulates near the site of 2–5 (A) synthetase activation by viral dsRNA and hence activates first RNase L molecules closest to viral RNA synthesis. This results in a localized and preferential degradation of viral ssRNA or mRNA, often allowing the IFN-treated cell to survive virus infection. In subsequent rounds of infection in adjacent cells, IFN production and action continue to compromise the yield of virus and spare cells from its lethal action. Expression of the dsRNA-dependent 2–5 (A) synthetase/2–5A/RNase L system is transient, with a 2′–5′-phosphodiesterase regulating the level of 2–5A. Not all viruses are blocked by its action, but picornaviruses are particularly vulnerable. Normal regulation of cell growth, differentiation and development may require this enzyme system.

PKR, a dsRNA-dependent protein kinase

PKR (protein kinase RNA), a serine-threonine kinase found at low basal levels in cells, is another enzyme induced to high levels by IFN and activated by dsRNA. PKR has emerged as an important regulator of cellular processes. Due to its effects on both transcription and translation, PKR plays a key role in the development of an antiviral state against several different virus families, and in the regulation of cell growth, differentiation and transformation. When PKR is activated by dsRNA in the course of virus infection it autophosphorylates and in turn phosphorylates and thereby inactivates the translation initiation factor eIF-2α. This mechanism is not intrinsically specific for viral protein synthesis; none the less, when transient global inhibition of protein synthesis occurs, inhibition of translation of viral mRNA is particularly vulnerable, but the cell may recover. PKR plays a key role in both IFN induction, with IκB as its substrate, and in IFN action, where eIF2α serves as a major substrate. The importance of PKR in establishing an antiviral state is gleaned from the myriad reactions that viruses have evolved to circumvent its activation (see below). The 2–5 (A) synthetase/2–5 A/RNase L and PKR systems account for many, but not all, antiviral states induced by IFN.

Mx proteins

The type I IFN-inducible Mx proteins were first thought to be unique in their action against influenza viruses (*Orthomyxoviridae*). Indeed, transgenic mice expressing the *Mx* gene constitutively are resistant to influenza virus, but not to other viruses. In certain cell systems Mx proteins are active against viruses in the *Paramyxo-*, *Rhabdo-*, and *Bunyaviridae* families. The *Mx* gene is highly conserved in mammals, birds and fish, and responds to IFN through the ISRE and produces proteins that are distributed in the cytoplasm or nucleoplasm, depending upon the species of cell. Not all Mx proteins produce an antiviral state, as for example in chicken cells. Mx proteins are GTPases that belong to the dynamin family of GTP-binding proteins, a microtubule-associated enzyme with ATP- and GTP-hydrolyzing activity. The Mx protein is thought to block influenza virus replication because it forms a tight complex that encircles viral nucleoprotein and functionally impairs primary transcription of genomic RNA. Understanding the molecular basis of Mx protein action with its dependence on compartmentalization in the cell may lead to targeting treatments for specific viruses. Since mice lacking functional *Mx* genes appear healthy, no obvious function for this gene has been found beyond its role in the antiviral state.

The Mx system provides an example of what poetically may be termed Koch's postulates at the

molecular level. Cells lacking the *Mx* gene do not develop an antiviral state against influenza virus when treated with type I IFN. However, cells that naturally contain the *Mx* gene express its product when exposed to IFN and develop an antiviral state. When the *Mx* gene is isolated from these cells and expressed constitutively in cells otherwise lacking it, they become intrinsically resistant to influenza virus without exposure to IFN.

Other proteins associated with antiviral states induced by IFN

Many other IFN-induced proteins are being characterized to determine their contribution, if any, to the generalized antiviral state. For example, dsRNA-specific adenosine deaminase (dsRAD) induced by type I IFN catalyzes deamination of adenosine to inosine in dsRNA, but not in ssRNA. These changes might destabilize an RNA helix during virus replication and impart unwindase activity, or target the dsRNA for degradation. Neither possibility has yet been demonstrated as an antiviral mechanism.

Another type I IFN-induced protein, ISG-15, may adversely affect processing of human immunodeficiency virus (HIV) RNA, whereas p202 protein may reduce the activity of NFκB and other transcription factors, thereby adversely affecting the replication of viruses dependent on them. A family of IFN-induced IFN-regulatory factors (IRF-1 to -7, ICSBP, ISGF3λ, Pip) share binding affinity for ISRE/ISRE-like elements and function as transcription factors that may positively (IRF-1) or negatively (IRF-2) regulate ISRE-containing genes. To the extent that these genes may function to induce an antiviral state they are important in the global regulation of that state. One IFN-γ induced gene, IP-10, encoding a chemokine, may assume importance in the control of HIV infection because of the newly assigned role of the chemokine family as a coreceptor for HIV infection of CD4 cells. IFN-γ also activates macrophages. These produce a variety of toxic products and immune system reactants that may contribute to an antiviral state. One such product, an inducible nitric oxide (NO) synthase is reported to inhibit the replication of herpes- and poxviruses. Genes encoding the major histocompatibility antigens also are activated by IFNs, and may contribute to the killing of virus-infected cells by cytotoxic T lymphocytes. Another IFN-γ-induced protein illustrates IFN action directed at a higher organism. Human IFN-γ induces in fibroblasts high levels of indoleamine 2,3-dioxygenase. This tryptophan-degrading enzyme reduces intracellular tryptophan levels, thus compromising the growth of *Toxoplasma gondii*, an obligate intracellular protozoon.

Mechanisms of Interferon Action

Interferon is the only natural product known that can block the replication of viruses once they have entered the cell. Considering the myriad genes activated by IFN and the diverse nature of the viruses affected, it is not surprising that IFN may exert its antiviral action at different steps in the replication of different viruses, and by a range of means in different cells. Alterations occur in the physical and biochemical nature of the plasma membrane following exposure to IFN; however, inhibition of the early steps in virus replication, i.e. viral attachment, entry and uncoating, are not usually affected. In some cell types, entry of the virus is slowed, and in others, IFN action may block a late step in the maturation or release of virus. In cells treated with IFN and infected with transcriptase-containing [−]strand RNA viruses, the first synthetic step in replication, primary transcription from the input genome, is often compromised. Transcripts escaping this early block may succumb to an inhibition of translation. The combination in sequence provides a formidable barrier to viral replication. For [+]strand RNA viruses the inhibition of viral protein synthesis is the dominant mechanism of IFN action. The 2–5 (A) synthetase and PKR systems both provide mechanisms for inhibiting protein synthesis, and, along with the Mx system, are likely to be responsible for much of the antiviral action of IFN.

The plethora of other gene products induced by IFN provides the potential for other mechanisms, some quite specific in their action for a particular combination of host cell and virus. DNA viruses sensitive to the action of IFN are known to form dsRNA during replication, enabling them to activate any of the dsRNA-dependent systems and mimic RNA viruses in sensitivity.

Some IFN inducible genes can be activated directly by dsRNA, presumed to form during virus replication, through common sequences in the ISRE. Activation by dsRNA may involve phosphorylation events regulated by PKR, and in some cases involve activation of NFκB. Although several transcription factors may not be involved, IRF-1 is needed. IFN is not an intermediate in these inductions, nor is ISGF-3 required. This means that particular genes may be activated by novel transcription factors during infection without the necessity of awaiting the production and release of IFN and its mandatory feedback action through receptors on the cell surface. Direct activation of certain IFN-inducible genes by dsRNA provides a unique early warning/response to virus infection.

When cells are treated simultaneously with types I and II IFN the antiviral state that develops may be 10- to 40-fold greater than that produced by either type of IFN acting singly, or expected from additive effects. Type I IFN by itself induces ISGF-3α (STAT1/STAT2) which when complexed with the DNA binding protein p48 (ISGF-3γ) to form ISGF-3 (STAT1/STAT2/p48) translocates to the nucleus where it binds to ISRE with high affinity to cooperate in the transcription of IFN-stimulated genes (ISGs). The amount of ISGF-3 formed after type I IFN treatment may be limited by the basal levels of p48 intrinsic to the cell, and hence limit the magnitude of ISGs activated and the antiviral state. However, IFN-γ induces p48 (ISGF-3γ) so that in cells exposed to both types of IFN p48 is no longer limiting and elevated amounts of ISGF-3 are produced. From this view, the two types of IFN act in concert to produce maximal activation of IFN-stimulated genes and the enhanced antiviral state that follows. The production of both types of IFN at the site of virus infection and the ensuing synergy may mirror the situation in nature where the IFN system is presumed to abort most virus infections or ameliorate the disease.

In summary, to generate an antiviral state IFN must first bind to specific high affinity cellular receptors in the plasma membrane. The extent of this binding and/or basal or induced levels of transcription factors may constitute rate limiting steps in the spectrum of genes activated and the magnitude of the transcriptional response to IFN.

Antiantiviral Mechanisms

Viruses have evolved elaborate means of evading the action of interferon. Many simply turn off cellular macromolecular synthesis so rapidly that IFN is never produced, or leave little time for it to act. PKR, with its capacity to inactivate eIF2 and thus inhibit protein synthesis, emerges as a common target for many viruses that have developed antiantiviral mechanisms, a tribute to the important role this kinase plays in body defenses in addition to its central role as a regulator of cell proliferation. Adeno-, Epstein–Barr and human immunodeficiency viruses block activation (autophosphorylation) of the dsRNA-dependent PKR through production of small RNAs with secondary structure. The helical portions of these small viral RNAs bind to, but do not activate, PKR; however, they prevent activation by larger dsRNA that the virus may produce. Vaccinia and reoviruses synthesize dsRNA-binding proteins that preferentially sequester dsRNA, making it unavailable for activation of dsRNA-dependent enzymes. In addition, vaccinia virus synthesizes a decoy of eIF2 and thus blocks PKR-mediated phosphorylation inactivation of this translation initiation factor. Herpes simplex virus produces a protein that blocks the phosphorylation of eIF2 by PKR. All the anti-PKR mechanisms are designed to preserve cellular protein synthesis so that virus protein synthesis will not be compromised. Poliovirus and influenza virus use two other anti-antiviral mechanisms. The former produces a protease which degrades the PKR, and the latter activates a cellular protein, p58, which, in concert with some stress proteins, binds to PKR and prevents its activation. Adenovirus EIA protein competes with STATs for binding to ISRE and hence blocks transcriptional activation of ISGs. Hepatitis C virus (*Flaviviridae*) encodes a nonstructural protein that binds to, and inhibits, PKR. Other viruses employ different mechanisms. Poxviruses encode IFNGR-like molecules, which as decoys bind to IFN-γ, aborting its action. Equally inventive from the IFN induction view is hepatitis B virus: its core protein, and/or a terminal portion of its polymerase, prevents the induction of IFN. Undoubtedly other antiantiviral mechanisms will be revealed.

Clinical Use against Infections

In spite of their discovery as antiviral agents, the major impetus to develop IFNs as products of biotechnology and move them into the clinics came from their antitumor activity. The first therapeutic use of IFN by physicians was sanctioned by the Food and Drug Administration, based on its effectiveness against hairy cell leukemia, probably of viral origin (HTLV-II). Approval soon followed for the clinical use of IFN against hepatitis B virus (HBV, *Hepadnaviridae*), where IFN is the therapeutic agent of choice. With over 200 million carriers of HBV in the world, and the strong causal relationship between HBV infection and hepatocellular carcinoma, IFN could have a formidable impact on a serious virus-mediated disease leading to malignancy. IFN-α also emerges as the only available treatment for hepatitis C virus (*Flaviviridae*).

Infections (genital warts) caused by human papilloma viruses have been treated successfully by intralesional, topical and parenteral therapy with IFN. It also is used as adjunctive therapy in the reoccurrence of juvenile laryngeal papillomas following surgery.

Recombinant human IFN-α (rHuIFN-α) and IFN-β_{ser} have shown significant activity against rhinovirus infections in volunteers in both therapeutic and prophylactic situations, yet in natural infection in a family environment rIFN-α was not effective against

other respiratory viruses (influenza, parainfluenza or corona).

Synergistic effects have been reported between IFN and viral-specific antibody both *in vitro* and *in vivo*. Ocular infections with the picornavirus, causing acute hemorrhagic conjunctivitis, and with herpes simplex virus suggest that the combination of endogenously produced IFN and antibody may be more efficacious than either agent alone. A shared time during infection with these two antiviral agents, as the concentration of IFN wanes and that of antibody waxes, may represent the time for this synergistic action.

The progression of lesions from activated latent herpesviruses can be ameliorated, or their initiation prevented, by IFN treatment – an important consideration given the widespread distribution of this family of viruses and its propensity to break from latency in the stressed or immunocompromised host. The intrinsic sensitivity of herpes viruses to IFN portends its use in treating the most recently discovered human herpes virus HHV8 as the likely etiologic agent of Kaposi's sarcoma.

Successes with IFN as a clinically effective antiviral generally have not paralleled the dramatic effects observed *in vitro*. Once IFN enters the body it becomes but one actor in a large company of cytokines, some of which IFN can induce. Much remains to be learned about the optimal use of this potent cytokine *in vivo* before its full potential as an antiviral agent can be realized. For example, studies indicate that IFN may be more effective when used in combination with chemical antiviral agents, antibodies, dsRNA, or other IFNs – as in synergy.

Polyribonucleotides, in the form of a complex of polylysine and carboxymethylcellulose with poly(rI)·poly(rC) [poly ICLC], have been used clinically as inducers of IFN with the potential to activate the antiviral state they may illicit. This drug is resistant to serum dsRNases, and may mimic IFN induction and its action following natural infection. In a mouse model system poly ICLC enhances the antimalarial activity of chloroquine. Clinical results from these biological response modifiers that both induce and activate the IFN system should be enlightening.

Some bacterial infections result in the production of IFN, and are themselves adversely affected by its action through mechanisms not well understood but thought to involve the immune defense system, including enhanced phagocytic activity. Several protozoan parasites induce IFN in their mammalian host, and exogenously added IFN-γ, but not IFN-α/β, appears to alter the course of infection. The induction of a tryptophan-degrading enzyme by IFN may be involved. Further studies are needed to clarify the role of IFN-γ in resistance to infection by protozoa like *Toxoplasma* or *Leishmania*.

A note of caution must accompany the use of IFN as an antiviral agent. In some virus diseases in which IFN is induced to extremely high titers, the prognosis for recovery is inversely related to the titer of circulating IFN. Infection with the arenavirus causing Argentine hemorrhagic fever is an example. Also, prolonged therapy with IFN may induce neutralizing antibodies against some forms of the protein. However, new evidence indicates that proper preparation and storage of IFN will eliminate IFN–IFN and IFN–human serum albumin aggregates that appear to be antigenic.

Future Perspectives

The use of IFN as an antiviral agent *in vivo* has yet to live up to expectations based on *in vitro* studies. Perhaps we have not yet mastered the optimal means of inserting a potent biological response modifier like IFN into a system where perturbations to cytokine crosstalk must be carefully regulated. None the less, the IFN system has served as a prototype cytokine and continues to reveal new facets of gene regulation. The future seems bright for fine-tuning the use of IFN for clinical use. Several areas warrant further study. A more comprehensive understanding of the IFN system is needed at the molecular level to define the functions of most of the genes activated by IFN, dsRNA directly, or by drugs, and at the biological level to expand its role as an antiviral agent and biological response modifier. Subtle differences in the action of members of the IFN-α family need to be resolved. This may lead to molecular tailoring for the activation of specific IFN-stimulated genes and the design of IFNs for specific virus infections. A full appreciation of the extent to which synergy between types I and II IFNs functions in natural infection is needed for prudent application in the clinic. The three-dimensional structure/function analysis of IFNs and their receptors should provide further insight into the first step in IFN action and allow for designer IFNs. Continued progress in elucidating genetic-based defects in IFN-mediated signal transduction should serve as a guide for intervention through gene therapy. Mounting evidence points to significant antiviral and immunomodulatory effects from the administration of IFN at low doses (10–1000 units) to oral/mucosal systems. Thus, low doses of IFN-α administered orally to children who had measles, significantly ameliorated all symptoms of the disease. This seemingly novel means of stimulating the mucosal immune system may actually represent a natural pathway used to amplify and disseminate the action of IFN, and presages increased use of this mode

of administration. The production of IFN by the administration of chemical inducers of IFN orally or topically provides other novel means of activating the IFN system *in vivo*, as does its expression through the introduction into tissues of plasmid DNA encoding IFN genes.

The future calls for further study on the molecular subtleties of IFN structure/function, ligand–receptor interaction, signal transduction participants and pathways, expression of IFN-stimulated genes and their spectrum of actions, and the optimization of IFN use as one of many cytokines that function together. New avenues of research portend a bright future for the use of IFNs in the clinic and as the antiviral agents their discoverers envisioned over four decades ago.

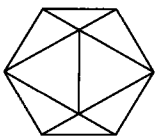
IRIDOVIRIDAE – INVERTEBRATE



Richard Webby and **James Kalmakoff**, University of Otago, Dunedin, New Zealand

Introduction

Iridoviruses are icosahedral, double-stranded (ds) DNA viruses belonging to the family *Iridoviridae*. Members of this family are able to infect protozoa, algae, invertebrates and vertebrates. The viruses are ubiquitous in nature and have been found on all continents of the world and have been isolated from a variety of insect species. The genus *Iridovirus* consists of the small insect viruses (120–140 nm) with blue to purple iridescence, whereas the genus *Chloriridovirus* consists of the large insect virus group (>180 nm) with a yellow–green iridescence. The type species for the *Iridovirus* and Chloriridovirus groups are *Chilo* iridescent virus (CIV) (type 6) and IV3, respectively. Two other genera infecting vertebrates in the *Iridoviridae* family are *Ranavirus* and *Lymphocystivirus*.

Taxonomy and Classification

The first iridovirus (IV) to be described was isolated from the larvae of the crane fly *Tipula paludosa*, discovered by Claude Rivers in 1954. The systemic infection conferred a blue coloration to the larvae and the term iridescent virus was coined. Since then similar viruses have been isolated from different parts of the world and different invertebrate species. Iridoviruses have been isolated from invertebrates indigenous to all the major continents. The nomenclature of these viruses can be confusing as they were sometimes referred to by their historical designation, based on host of isolation, or by their type number. In the interim typing scheme viruses were assigned type numbers depending on the chronological order of their isolation. Since *Tipula* iridescent virus (TIV) was the first discovered it has been designated iridovirus type 1 (IV1), whereas CIV, being the sixth to be reported, was iridovirus type 6 (IV6). The problems associated with both these nomenclature systems have led to the suggestion that they should be replaced with geographical descriptors. TIV would thus become Plowden IV, Plowden being the nearest major town to the site of isolation. This system is analogous to that used for many virus families,

of administration. The production of IFN by the administration of chemical inducers of IFN orally or topically provides other novel means of activating the IFN system *in vivo*, as does its expression through the introduction into tissues of plasmid DNA encoding IFN genes.

The future calls for further study on the molecular subtleties of IFN structure/function, ligand–receptor interaction, signal transduction participants and pathways, expression of IFN-stimulated genes and their spectrum of actions, and the optimization of IFN use as one of many cytokines that function together. New avenues of research portend a bright future for the use of IFNs in the clinic and as the antiviral agents their discoverers envisioned over four decades ago.

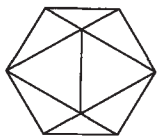
IRIDOVIRIDAE – INVERTEBRATE



Richard Webby and **James Kalmakoff**, University of Otago, Dunedin, New Zealand

Introduction

Iridoviruses are icosahedral, double-stranded (ds) DNA viruses belonging to the family *Iridoviridae*. Members of this family are able to infect protozoa, algae, invertebrates and vertebrates. The viruses are ubiquitous in nature and have been found on all continents of the world and have been isolated from a variety of insect species. The genus *Iridovirus* consists of the small insect viruses (120–140 nm) with blue to purple iridescence, whereas the genus *Chloriridovirus* consists of the large insect virus group (>180 nm) with a yellow–green iridescence. The type species for the *Iridovirus* and Chloriridovirus groups are *Chilo* iridescent virus (CIV) (type 6) and IV3, respectively. Two other genera infecting vertebrates in the *Iridoviridae* family are *Ranavirus* and *Lymphocystivirus*.

Taxonomy and Classification

The first iridovirus (IV) to be described was isolated from the larvae of the crane fly *Tipula paludosa*, discovered by Claude Rivers in 1954. The systemic infection conferred a blue coloration to the larvae and the term iridescent virus was coined. Since then similar viruses have been isolated from different parts of the world and different invertebrate species. Iridoviruses have been isolated from invertebrates indigenous to all the major continents. The nomenclature of these viruses can be confusing as they were sometimes referred to by their historical designation, based on host of isolation, or by their type number. In the interim typing scheme viruses were assigned type numbers depending on the chronological order of their isolation. Since *Tipula* iridescent virus (TIV) was the first discovered it has been designated iridovirus type 1 (IV1), whereas CIV, being the sixth to be reported, was iridovirus type 6 (IV6). The problems associated with both these nomenclature systems have led to the suggestion that they should be replaced with geographical descriptors. TIV would thus become Plowden IV, Plowden being the nearest major town to the site of isolation. This system is analogous to that used for many virus families,

including *Reoviridae, Bunyaviridae, Rhabdoviridae* and *Arenaviridae,* but this scheme offers little in terms of taxonomic relationships.

To date, more than 30 invertebrate iridescent viruses have been recognized and assigned a type (**Table 1**). Not all of the different isolates listed in **Table 1** are distinct viruses. For instance, type 9 was 100% homologous to type 18 by both DNA and serological comparisons, and these two viruses are probably the same. Type 19, which was isolated from the coleopteran host *Odontria striata,* is also very likely to be the same virus as type 16, which was isolated from a similar coleopteran host *Costelytra zealandica*. Both of these examples of redundancies in iridovirus classification are a direct consequence of the wide host range of IVs. In both situations the homologous viruses were isolated from the same location but from different hosts. Taking this into

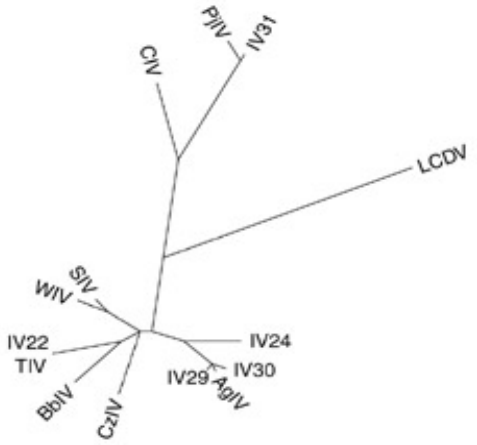

Figure 1 Phylogenetic tree of the genus *Iridovirus*. The tree was constructed from the nucleotide sequence of a 355 bp fragment of the major capsid protein gene using the Neighbor–Joining method. The vertebrate lymphocystis disease virus (LCDV) was used as an outgroup to estimate the tree root.

consideration, and the fact that no material is available for many others, the number of species recognized by the International Committee on Taxonomy of Viruses (ICTV) can be significantly reduced. Recent findings also suggest that current stocks of IV types 21 and 28 (again probably variants of the same species) have become contaminated with CIV and should no longer be recognized as separate species.

The problems associated with the classification of the *Iridovirus* genus have only recently been addressed using molecular approaches. A broad comparative study using restriction endonuclease (REN) profiles, polymerase chain reaction (PCR) and DNA hybridization revealed that the genus can be divided into three further clusters. The high level of sequence homology in the major capsid protein (MCP) gene has also led to the development of a PCR/sequencing approach to classify these viruses. Consensus PCR primers were designed to amplify a 500 bp fragment of the *MCP* gene containing both conserved and variable regions. PCR products from a range of diverse invertebrate IVs were amplified and sequenced and the resulting nucleotide sequence used to construct a phylogenetic tree (**Fig. 1**). These results support the three divisions within the genus *Iridovirus*. A summary of the result of these studies is shown in **Table 2.** The groupings observed in the MCP-derived tree show no correlation to host of isolation, which is not surprising considering the wide host range of the virus family. The tree does, however, reflect the geographical distribution of virus isolates, with a correlation between closely related viruses and the regions of their geographic isolation. The true indication of virus relationships will remain unknown until more genes are compared in this way, or entire genomes sequenced. This PCR/sequencing technique in conjunction with restriction endonuclease profiles offers a simple tool to identify novel isolates. Preliminary results of solution DNA–DNA reassociation reactions indicate that this technique may be of limited taxonomic value for all but the most related of isolates. This is evident from the low homologies observed between related viruses from the same genus group. For example, *Wiseana* iridescent virus (WIV) and TIV, viruses clustered within the same group by molecular techniques, have DNA–DNA homologies of less than 5%. No homology was detected between WIV and CIV, viruses belonging to different genus groups.

Virion and Genome Structure

The first 'spherical' virus shown by shadowing and electron microscopy to have icosahedral symmetry was TIV (**Fig. 2**) in 1958. An icosahedron consists of 20 equilateral triangular faces each of which can consist of smaller subunits called capsomeres. Disruption of TIV gave triangular and pentagonal subunit aggregates. Each pentasymmetron contained 31 subunits and each trisymmetron contained 55 subunits. This suggested a possible triangulation number of $T = 147$ (1472 subunits). Negative staining shows the particle size to be 120 nm.

The genome is a single copy, linear, dsDNA, which varies in size between 150 and 280 kbp depending on viral species. It is cyclically permuted with terminal redundancy and has internal repetitive DNA sequences. CIV has a genome size of 210 kbp with a terminal redundancy (the amount of DNA duplicated

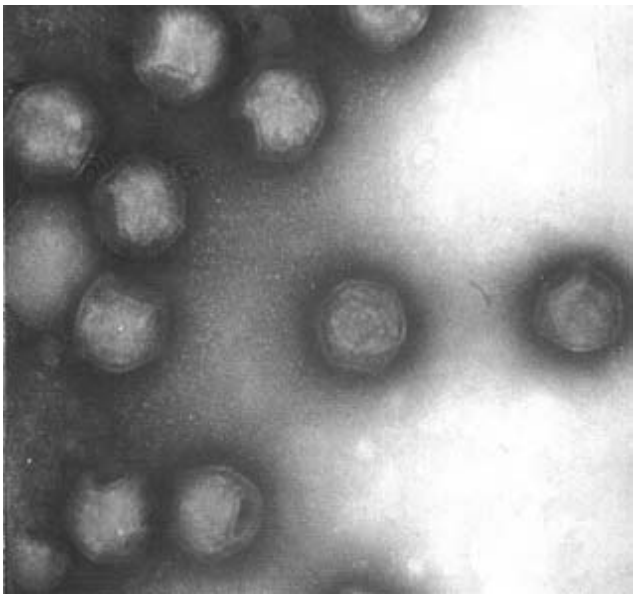

Figure 2 Electron micrographs of negative-stained TIV particles.

at each end of the genome) of 12% and the cyclic permutation (the range of fragments that formed the ends) was 100%, i.e. no unique ends. These genome structures are common to some prokaryotic viruses such as bacteriophage T4, but have not been demonstrated in any other eukaryotic viruses.

Virion Composition

The virions contain 11–18% DNA packed within an electron-dense core in association with six or more DNA binding proteins. The GC content of the DNA is about 30%. This DNA core is surrounded by an internal 4 nm thick lipid membrane (about 4–9% of the virus weight) in which phospholipids are abundant. The composition of this lipid membrane is independent of the host of propagation, but does differ from virus species to virus species. The exact mechanisms of viral lipid sequestering are unknown, although evidence suggests that the membrane is synthesized *de novo* during viral replication rather than by the acquisition of host membranes.

The third outer concentric domain is a proteinaceous icosahedral capsid which makes up 50% of the viral mass. It is intimately associated with the viral core by proteins that span the lipid membrane. Iridoviruses have been shown to have 25–70 structural polypeptides ranging in molecular weight from 12 to 150 kDa depending on the method used. They all have a major protein of 50–55 kDa which has been estimated to comprise 45% of the total proteins. Various enzymes have been found to be associated with virus particles. These include a protein kinase, an alkaline protease, a deoxyribonuclease, an RNA polymerase, a nucleotide phosphorylase and an ATPase. Not all of these enzymes have been shown to be virally encoded. There are reports that the protein kinase phosphorylates the structural proteins. Studies on TIV have shown that none of the virion structural proteins appear to be glycosylated. The DNA of the iridoviruses is not methylated unlike other members of the *Iridoviridae* which infect vertebrates. Some isolates of TIV contain two DNA components L (176–247 kbp) and S1 (10.8 kbp) within the DNA core.

Virus Genes

Sequence data for the family *Iridoviridae*, apart from lymphocystis disease virus (LCDV) which has been completely sequenced, are limited. Excluding the *MCP* gene, the only invertebrate IV species for which genes have been described are CIV and TIV. The complete *MCP* genes have been sequenced from IV22, TIV, CIV, WIV and *Costelytra zealandica* iridescent virus (CzIV). These share significant amino acid similarities with values ranging from 65.4% between CIV and IV22 to 93.7% between TIV and IV22. The only other gene described for TIV codes for a protein of 96 kDa which has homologies to various DNA binding proteins. This, and the presence of a glycosaminoglycan-like proteolytic cleavage site, has led to the speculation it may be involved in TIV structure. Additional genes from CIV code for proteins that share database homologies to zinc finger proteins, a nonhistone chromosomal high-mobility-group (HMG) protein, a GTP phosphohydrolase, a helicase, a DNA-dependent RNA polymerase subunit, a ribonucleoside-diphosphate reductase, and a protein that contains conserved motifs of *Baculoviridae* apoptosis inhibitors (IAP). Sequencing of 60 170 bp of the CIV genome revealed the presence of 112 possible reading frames with similarities in gene arrangements to LCDV. Phylogenetic comparisons of the CIV helicase and RNA polymerase genes suggest that these two genes have been acquired from eukaryotic host cells more recently than those of other cytoplasmic DNA viruses. This does, however, rely on unsubstantiated assumptions concerning evolutionary rates between virus families and host cells.

Virus–Host Interaction

The host range of some iridoviruses such as TIV appears to be wide, since they are able to infect dipteran, lepidopteran and coleopteran hosts, whereas others, e.g. CzIV are more restricted. The mode of transmission for these viruses has not been elucidated.

Many routes of infection have been suggested, including oral ingestion, infection through the spiracles, transovarial transmission and the contamination of eggs. The oral ingestion of virus appears to be one of the most obvious routes, but generally it is thought that these viruses are not very infectious *per os*, the virus being degraded shortly after entering the midgut. In the foregut, the peritrophic membrane is a barrier to infection. Transovarial infection appears to be the method of transmission for the chloriridovirus group. Other possible routes include cannibalism, wounding or infection via other parasites (such as nematodes). Cannibalism of infected cadavers would result in a massive uptake of concentrated virus. Wounding, which is common among aggressive species, would mimic the intrahemocelic injection that is used to infect insects in the laboratory.

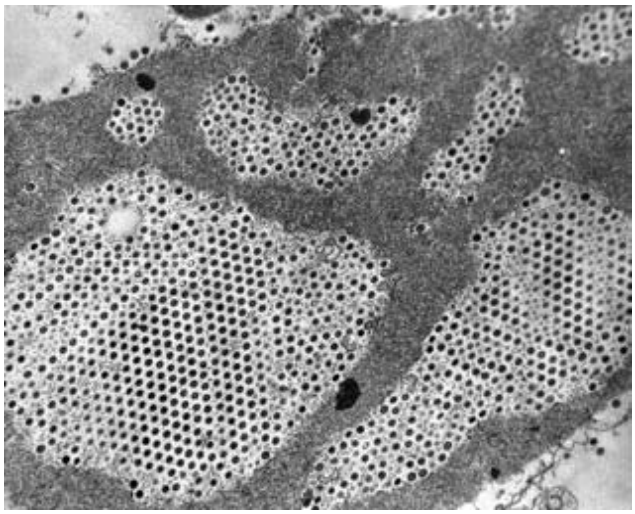

Figure 3 Viral crystalline array of TIV in the cytoplasm of a virus-infected cell.

Serology

Serological methods include serum neutralization, complement fixation, ELISA, latex agglutination, immunoperoxidase staining and radioimmunoassay. In general, serum neutralization is impractical for screening because of bacterial contamination of triturated larvae. Complement fixation is relatively insensitive when larval extracts are used and is not quantitative. Latex agglutination was found to be 50 times less sensitive than ELISA, and radioimmunoassay is technically demanding. The ELISA assay is probably the best serological technique available for virus detection, but has the disadvantage of being only semiquantitative. Moreover, many iridescent viruses were propagated in experimental laboratory hosts such as *Galleria mellonella*, and it is possible that there has been crosscontamination between iridescent viruses. For example, there were antigenic differences in TIV propagated in *Lymantria dispar* or *Tipula paludosa* when compared with TIV propagated in *G. mellonella*. Despite these problems, serology has been used to compare different isolates of iridoviruses and some general conclusions can be made. The members of the chloriridovirus genus (iridescent viruses types 3, 4, 5, 8, 11, 12, 14 and 15) appear to be serologically related to each other, but not to any members of the iridovirus genus. Within the iridovirus genus TIV and SIV have been shown to be virtually identical by most serological tests, including immunodiffusion, immunoprecipitation, and immunoelectron microscopy, although complement fixation and neutralization tests successfully discriminated between them. Other isolates tested showed relatedness to varying degrees with the exception of CIV and iridovirus type 24. Iridoviruses types 1, 2, 9, 10, 16, 18, 21, 22, 23, 24, 25 and 28 all showed common antigens and formed a broad serological group. Three groups of closely related viruses could be distinguished: (1) types 1, 22 and 25, (2) types 21 and 28, and (3) types 9 and 18. Analysis by Western blotting and the purification of individual polypeptides has shown that the antigenic relationships between the iridoviruses is very complex and some of the earlier findings have to be revised. For example CIV was shown not to be as antigenically distinct from the other iridoviruses (type 9 and type 16) as previously reported.

Inclusion Bodies

The major common feature of all iridescent viruses is the iridescent, or opalescent, blue–green coloration of heavily infected larvae or purified pellets of the virus. This coloration is caused by closely packed paracrystalline arrays of virus particles within heavily infected tissues causing Bragg reflections of light. The color of the iridescence is determined by the interparticle spacing. For TIV the virus particles are packed in a face-centered array with an interparticle distance of 250 nm, or about twice the size of virions observed by negative staining. The production of iridescence in infected larvae does not always occur, probably because paracrystalline virus arrays do not always form. This has been shown both *in vivo* and *in vitro* and may be due to the virus budding continuously from infected cells. Massive amounts of virus can result from the infection of larvae with the highest concentration in the fat body and epidermis. It has been suggested that iridescence may be a trivial characteristic of these viruses as it bears no relationship to any functional feature of the virus and is due only to physical structure.

By electron microscopy, viroplasmic centers can be seen as membrane-free pockets of cytoplasm 18–24 h after infection (**Fig. 3**). These contain 'dark matrix' where DNA synthesis is occurring and 'light matrix' where ribosomes are synthesizing viral proteins and where virion assembly occurs.

Pathology

The pathogenesis of these viruses is poorly understood since little is known about how the virus gains access to the initial site of replication. When administered orally these viruses have low infectivity which has led to suggestions that under natural conditions cannibalism, wounding, and parasitism by nematodes may play roles in transmission. The exception may be an iridovirus from *Scapteriscus vicinus* (Southern mole cricket) which has been shown to cause infections *per os*. The primary sites of replication are probably the hemocytes and fat bodies. The rate of pathogenesis is temperature-dependent and at optimum temperatures the virus spreads through the insect to produce a systemic infection. Larvae become blue and flaccid about 5–10 days after infection. The cytopathology has mainly been studied in hemocytes or cells in culture. Virus particles enter cells by pinocytosis or by phagocytic engulfment into membrane-bound vesicles within 1.5 h of inoculation. A general breakdown of the virus occurs within the vesicles where presumably they are uncoated, and viroplasmic centers appear in the cytoplasm after 4 h. Release of virus occurs by cell lysis or exocytosis and the virus is dispersed into the hemolymph. The cytoplasm has been described as the site of virus assembly, morphogenesis and DNA synthesis. However, the necessity for a functional cell nucleus has been proposed for frog virus 3. Infection with CIV rapidly induces the formation of syncytia which is independent of viral replication and due to components of the invading CIV particle.

Replication

The replication of frog virus 3 (FV3), a vertebrate IV, has been used as a model for the replication of other members of the *Iridoviridae*. In this model there are nuclear and cytoplasmic sites of DNA replication. After entry of the virus into the cell, the viral DNA is transported to the nucleus where transcription is initiated by the host RNA polymerase. The parental DNA is then used for DNA synthesis which results in the formation of genomic and greater than genomic length DNA. This DNA is then transported to the cytoplasm where it undergoes further DNA synthesis resulting in large concatemeric complexes. This concatemeric DNA is packaged into larger than genomic lengths by a 'headful' mechanism giving rise to the terminally redundant and cyclically permuted genome.

With CIV infection host cell macromolecular synthesis is rapidly shut down and this appears to be caused by unknown viral structural protein(s). The viral inner membrane proteins, which can be solubilized by octylglucoside, contain all the factors important in the initial stages of infection, including a cell-fusion activity (independent of capsid proteins), an inhibitory protein which switches off host cell synthesis and an activating factor which stimulates the transcription of immediate early viral genes. Cellular DNA polymerase, thymidine kinase and RNA polymerase levels increase during infection. The DNA is then transported to the cytoplasm where further DNA replication occurs producing high-molecular-weight concatemeric complexes. Studies carried out with WIV have shown that genes are transcribed in a temporal cascade that results in the formation of distinct immediate, delayed-early and late mRNA species. Furthermore, it was shown that the early mRNA is shut-off during late phase infection illustrating that the expression of the viral genome is controlled at the transcriptional level in a manner similar to other DNA viruses such as the herpesviruses.

The application of the FV3 replication model to invertebrate IVs may not be entirely correct. There are differences in genome structure that indicate some features of the FV3 model will need to be modified. The genome of FV3 is highly methylated unlike that of TIV and WIV and other invertebrate IVs. The expression of the FV3 genome may involve a methylation-based control mechanism not present in invertebrate IVs. The nature of the terminal redundancy is also different between invertebrate and vertebrate viruses. In CIV and WIV (and other iridoviruses) the ends of the DNA can represent any part of the genome and are therefore 'random' whereas in FV3 the DNA ends are restricted to 30% of the genome. This suggests that either the DNA packaging mechanism or the nature of the complex concatemeric DNA structure is different. The bacteriophage T4 has 'random' ends to its cyclically permuted terminally redundant genome. Furthermore, bacteriophage T4 has been shown to initiate replication from at least seven origins of replication, a similar number being found in CIV. During WIV infection the DNA in the cytoplasm appears to undergo the branched recombination/replication structure proposed for bacteriophage T4. This would suggest that the DNA replication of invertebrate IVs may be more closely related to bacteriophage T4 than that proposed for FV3.

Economic Importance

Conventional wisdom has it that the iridoviruses are not good biological control agents since they do not cause a lethal infection and are difficult to transmit in the field. However, the iridovirus isolated from southern mole crickets, *Scapteriscus vicinus*, operates in an epizootic fashion, killing greater than 70% of the collected mole crickets. When the virus is added to the diet of laboratory-reared nymphs, at least 65% became infected. This virus also infects *Trichoplusia ni* larvae and insect cell cultures and may be a pathogenic strain of iridovirus.

CIV might be of agricultural importance since it has been shown to infect the green rice leafhopper, *Nephtholettix cincticeps*, and is lethal for the leafhopper, *Colladonus montanus*, the vector of a mycoplasma agent of stone fruits. CIV could be used to eliminate insects which act as vectors in transmitting plant diseases.

WIV infects *Wiseana* spp. a major soil-dwelling pasture pest in New Zealand and infection rates can be as high as 30% based on the iridescence of the infected larvae. The actual infection rate could have been much higher since iridescence is a poor indicator of infection. Infection of the larvae results in cessation of feeding and death within 14 days. A similar situation applies to CzIV, a potential pathogen of coleopteran larvae. However, naturally occurring epizootics of WIV have not be reported since 1969.

There is an exciting potential in the field of genetic modification of these viruses. The terminal redundancy and cyclic permutation can be used to introduce toxins or to modify the virus easily. There is no necessity to find nonessential regions to insert genes since the DNA contains at least 112% of the genome and the duplication is at random. Furthermore the promoter for the coat protein gene would seem to be a good candidate site since this gene is highly expressed during virus infection, up to 25% of the weight of an infected insect being virus.

Ecology

Evans and Entwistle have discussed the division of the invertebrate *Iridoviridae* into the large (*Chloriridovirus*) and small (*Iridovirus*) insect iridescent viruses, and their evolution. They suggested that, based on ecologically different routes of evolution, *Iridovirus* with its wider host range is the older genus and *Chloriridovirus*, which has evolved exclusively in association with the aquatic diptera, is a more specialized derivative. The iridoviruses are thought to have only a horizontal route of transmission, whereas the chloriridoviruses have a vertical route of transmission in addition to larval cannibalism. It has been suggested that the internal membrane structure gives these viruses greater stability in aquatic environments. This idea has been extrapolated to suggest that insect viruses were the first viruses and that they later adapted to life in vertebrates which fed on the insects. WIV and CzIV, isolated from indigenous sympatric hosts in New Zealand, are genetically closely related and probably share a common ancestor. The WIV genome is 24 kbp larger than the CzIV genome and the region of nonhomology between the WIV and CzIV genomes is also 24 kbp in size. It is possible that in the course of evolution WIV gained that extra piece of DNA or CzIV lost it. In considering insect viruses in general, it has been postulated that the evolution of the virus group is probably not older than the host taxon itself. Using this assumption one could postulate that since the Coleoptera (late permian) are more ancient than the Lepidoptera (middle cretaceous) then CzIV is probably older than WIV, in which case WIV acquired the extra piece of DNA as it diverged from CzIV. Since CzIV has a limited host range, one could speculate that the piece of DNA which was gained by WIV coded for the host range determinants. This idea can also cover CIV which has a genome of 209 kbp, 17 kbp larger than WIV, and CIV has a larger host range than WIV. It would be worthwhile to return to the sites of the original WIV and CzIV isolations to see whether there have been any changes in these viruses in the years since the original isolation. One iridovirus isolate, TIV, appears to have diverged into two evolutionary lines. The TIV virion comprises two DNA components, L and S1. Recently an isolate from Ireland was found to contain only the L component. Since this isolate was from the same host as the original isolate, one might speculate that time and differences in climate and environmental conditions have enabled a variant TIV strain to evolve. Of interest would be the natural occurrence of the iridoviruses from isopods and nematodes and their relationship with soil insects. Equally interesting is the ecology of the isolates from aquatic environments. For instance, *Corethrella brakeleyi* is a small chaoborid found in Louisiana, a predator of first-instar mosquito larvae which can be infected with an iridovirus, but no transmission occurs to mosquitoes or vice versa. In New Zealand a copepod was found to be infected with an iridovirus and in the same pool an epizootic of an iridovirus was occurring among mosquitoes, yet the two viruses appeared to be unrelated.

A major drawback to the ecological study of IVs is the historical use of iridescence to monitor infected insects. Within an infected population only a small

percentage of individuals will show this phenomenon. Williams found that within a population of blackfly larvae from the River Ystwyth, Wales, external signs of IV infections were extremely rare, whereas infection rates as high as 37% were seen when a PCR-based diagnosis approach was used. This suggests that many earlier studies on the impact of IV infections on insect populations may be misleading and grossly understated. Further studies on the same blackfly populations also indicated distinct patterns of covert (inapparent) and patent (lethal) infections. Although diverse viral isolates were apparent by REN profile polymorphism, it seems that the two patterns of infections are not caused by different IV species, with identical viruses being associated with covert and patent infections. Changes in the ratios of covert and patent infections coincided with changes in population density, water flow, temperature and growth rates. Similarly, seasonal changes and host densities have been shown to be critical to the persistence of IV infections within mixed woodlice populations.

Now that specific and sensitive DNA probes are available to detect iridoviruses from field samples, the ecology offers many Cinderella-like opportunities.

J

JAPANESE ENCEPHALITIS VIRUS (*FLAVIVIRIDAE*)

Akira Igarashi, Nagasaki University, Nagasaki, Japan

History

Acute encephalitis which is different from Von Economo's encephalitis (type A) was described as type B encephalitis as early as 1981 in Japan. A large epidemic occurred in 1924, and the causative agent was isolated from fatal human brain in 1935. The disease sporadically occurred in late summer to early autumn in Japan. Epidemiological studies on the disease clarified the transmission cycle by vector mosquito *Culex tritaeniorhynchus* and virus amplification in swine and avians. The names of the disease and its causative virus, 'Japanese encephalitis (JE)' and 'JE virus', were derived from the first virus isolation in Japan. However, JE and JE virus exist in much wider Asian monsoon areas in the east, through southeast, to south Asia, where rice cultivation and swine raising are common.

Taxonomy and Classification

From its natural transmission cycle and antigenic crossreactivity, JE virus was classified in the group B arboviruses, which contains many human and veterinary pathogens. According to the virion morphology and single-stranded positive-sense RNA genome, group B arboviruses were later classified in the genus *Flavivirus* of the family *Togaviridae*. Because of its unique genomic organization, structural and replication strategy, this genus then became the genus *Flavivirus* of an independent family *Flaviviridae*.

Properties of the Virion

The JE virus is an enveloped spherical particle of 38–50 nm in diameter. Nucleocapsid symmetry is probably cubic, but a report showed helical structure in the virion preparation. Peplomers have not been clearly identified.

Properties of the Genome

The genome of JE virus is single-stranded, positive-sense linear RNA molecule of 45S. Its 3′ end does not carry a poly(A) tract, but is postulated to form a stem–loop secondary structure, to which some cellular regulatory proteins could interact. The entire or partial nucleotide sequence has been analyzed for several strains of JE virus. The total number of nucleotides is 10 976 (95 in the 5′ noncoding region, 10 296 in a long open reading frame (ORF), and 585 in the 3′ noncoding region). Similar to other flavivirus genomes, the ORF codes seven virus specific proteins (C, PreM/M, E, NS1, NS2A, NS2B, NS3, NS4A, NS4B and NS5).

Properties of Virus Proteins

JE virion contains three structural proteins: membrane protein (M), core protein (C), and envelope glycoprotein (E). The M protein consists of 75 amino acids with a calculated molecular weight (mol. wt) of 8329 and is hydrophobic, and inside the lipid envelope. The C protein consists of 136 amino acids of mol. wt 13 859, is rich in basic amino acids (20% Lys and Arg) and interacts with genomic RNA. The E protein consists of 500 amino acids of mol. wt 53 334, contains a single potential *N*-glycosylation site (Asn-X-Ser) at amino acid number 448, and is exposed on the surface of the virion.

Multiple E protein epitopes with various biological properties and crossreactivities have been identified by monoclonal antibodies, such as JE-specific, flavivirus crossreacting and subgroup crossreacting ones. Passive immunization of the neutralizing and JE-specific monoclonal antibody was protective in mice from lethal challenge of JE virus.

Physical Properties of the Virion

The sedimentation coefficient of infective mature virion is around 200S with a density of 1.23 g cm^{-3} in sucrose-D_2O or 1.20 g cm^{-3} in potassium tartrate. Besides mature virion, slowly sedimenting hemagglutinin (SHA) and soluble complement fixing antigen (SCF) are present in infected mouse brain homogenate and infected cell culture fluid. The SHA is associated with the E protein and the SCF with the nonstructural protein NS1, respectively.

JE virus infectivity is readily lost by heat, acid, lipid solvents and detergents. Lipid solvents (ether and chloroform), or ionic detergents (sodium deoxycholate and sodium dodecyl sulfate) inactivate both infectivity and hemagglutinating activity (HA). Although nonionic detergents (Triton X100, or Nonidet P40) destroy virion structure and infectivity, HA is retained.

Replication of Genomic RNA

Replication of JE virus RNA appears to take place in close relationship with membrane structures, particularly the outer nuclear membrane as shown by the localization of radiolabeled virus-specific RNA and viral RNA polymerase. Virus growth was inhibited in cells enucleated before virus infection, but proceeded at reduced level in the cells enucleated after 6 h of infection. Sucrose gradient sedimentation analysis of radiolabeled virus-specific RNA revealed that the 8–12S RNA was labeled earlier than the RNase-resistant 23S replicative form. The implication of this 'intermediate RNA' is not clear. Positive-sense genomic RNA codes virus-specific nonstructural proteins, some of which (probably NS3 and NS5) were found in the membrane and 'nuclear' fractions which are associated with high viral RNA polymerase activity. This enzyme activity was inhibited by antisera against NS3 and NS5, indicating their role in viral RNA replication. By strand-specific probes, progeny positive-sense viral RNA was found primarily in the membrane fraction, in contrast to the negative-sense virus-specific RNA which was present in the supernatant fraction of the infected cells.

A single polyprotein is translated from a long ORF of virion RNA and is cotranslationally processed to the final products. Two forms of the nonstructural glycoprotein, NS1, were found in virus-infected cells, probably arising from different modes of cleavage of the polyprotein. Both forms of the NS1 and E protein were secreted into the medium of infected mosquito cells. The E protein has to be associated with the PreM protein for their proper transport and secretion. The M protein is post-translationally cleaved from its glycosylated precursor (PreM) in the Golgi bodies.

Mature virions accumulate in cytoplasmic vacuoles and lumen of smooth endoplasmic reticulum in the infected cells and tissues.

The cytopathic effect of JE virus infection is generally mild, possibly because of slow growth rate.

Host Range and Virus Propagation

JE virus is transmitted among various vertebrate hosts by vector mosquitoes. A number of mammals (swine, equine, canine), avians and reptiles are infected with JE virus in nature. Horses suffer from fatal encephalitis by JE virus infection, whereas infections in swine are generally inapparent, except for stillbirth or abortion in pregnant swine and aspermia in the boar.

The most important vector mosquito in the epidemic cycle is *C. tritaeniorhynchus* and related species which breed in watered rice fields.

Mice have been used most extensively for animal experiments on JE, and suckling mice are the most sensitive animals to propagate JE virus, particularly by intracerebral inoculation. Persistent infection of JE virus in pregnant mice was reported to result in vertical transmission of the virus into progenies.

A number of primary and continuous cell cultures can support the growth of JE virus, such as hamster, porcine, monkey, chicken, as well as cells of mosquito origin. They have been used for virus infectivity assay by plaque formation or cytopathic effect, and also for virus isolation.

Genetics

Only a single serotype has been identified among JE virus isolates, although variation was recognized by serological and molecular studies. Hemagglutination inhibition (HI) and neutralization (N) tests combined with antigen adsorption procedure could distinguish at least two subtypes, Nakayama and JaGAr-01 (including Beijing-1), among JE virus isolates in Japan. On the other hand, all 12 strains isolated in Thailand and examined so far belonged to other subtypes. By oligonucleotide fingerprint analysis, and recently by nucleotide sequencing of PreM gene, differences among JE virus strains with different isolation histories were demonstrated at the genomic level. The strains isolated in the same geographical areas are generally similar, particularly those isolated in the same year.

Recombination was not definitely demonstrated among different JE virus strains possessing different phenotypes.

Serologic Relationships and Variability

JE virus crossreacts with most of the flaviviruses in the HI and less in the complement fixation (CF) test. A particularly close relationship was observed with Murray Valley encephalitis, West Nile and St Louis encephalitis viruses. This relationship was also shown by the homology of their nucleotide sequence, and these viruses constitute a subgroup or complex in the genus *Flavivirus*, family *Flaviviridae*, although each virus can be differentiated by the N test.

Epidemiology

Because of the mode of transmission cycle in nature, infection of JE virus depends on the activity of vector mosquitoes. The epidemic season is late summer (August) to early autumn (September) in temperate areas like Japan, Korea and China, or the rainy season in tropical or subtropical areas. Only one out of several hundred infected humans manifests apparent encephalitis and the majority remain as inapparent infection. In the areas where human vaccination is not widely performed and JE immunity is conferred by natural infection, the most frequently affected age groups are the children under 14 years old. In contrast, adults (particularly elderly people) are frequently affected in Japan where human vaccination has been performed widely.

After 1966 in Japan, the number of human JE cases decreased dramatically and the low endemicity with less than 100 annual cases has been maintained from 1972 until present. It is generally agreed that this decrease is due to mass vaccination of humans and reduced vector population. The latter was the result of wide spraying of pesticides in watered rice fields by the farmers to protect the crop. Recently, field-caught *C. tritaeniorhynchus* was found to be highly resistant to pesticides, particularly organophosphorus compounds, and the mosquito population is increasing. Still, the number of human JE cases is kept at a low level in Japan probably because of sustained vaccination and spatial dissociation between the *Culex*–swine cycle of JE virus transmission and human dwellings.

In the Republic of Korea, the number of human cases has decreased significantly since 1981, with virtually no officially recognized JE cases after 1983. This change is reported as the result of mass vaccination of humans.

In China, extensive human vaccination with hamster kidney cell culture-derived JE vaccine has been performed. However, more than 10 000 sometimes 20 000 JE cases are sill reported every year, indicating insufficient vaccine supply.

In contrast, the magnitude of JE epidemics has apparently been increased in Vietnam and Thailand after the 1960s, in India and Nepal after 1978, and in Sri Lanka after 1985. It was suggested that this change was the result of economic, particularly agricultural, development to meet the demand of food supply by population explosion.

JE is endemic in tropical Asia like Philippines, Malaysia and Indonesia and spill over of JE in surrounding areas has been reported, for example, in Pakistan, Saipan Island and Badu Island in the Torres Strait between Papua New Guinea and Australia.

Transmission and Tissue Tropism

Infection of JE virus in humans occurs through infective vector mosquitoes. Humans are relatively insensitive to JE virus infection, and dead-end hosts in the natural transmission cycle of JE virus, without significant viremia, and no appreciable transmission from human to human or vectors.

In infected vertebrates, JE virus appears in the blood (viremia) before invasion to its final target organ, the central nervous system (CNS). The viremia level is determined by virus growth in extraneural tissues (initial inoculation site, regional lymph nodes, liver, kidney and muscles). Viremia subsides as humoral antibodies are produced, and further clearance takes place by the reticuloendothelial system.

Pathology

The pathogenicity of JE virus depends on its neuroinvasion, and is determined by both host and viral factors, as well as virus dose and route of infection. Generally, young animals are more susceptible than old ones, and the difference is more pronounced by peripheral than intracerebral inoculation of the virus. Neuroinvasiveness differs from strain to strain and is related to the level of viremia. Analysis by monoclonal antibody-escaped mutants showed that certain amino acid replacements on the E protein result in the loss of neuropathogenicity, indicating that the interaction of the virion surface and host cell membrane is a determinant factor of neuroinvasion. Comparative nucleotide sequence analysis on Chinese attenuated vaccine strain (SA14-14-2) and its parental virulent strain identified multiple nucleotide and amino acid substitutions. Analysis of the progeny virus derived from infectious cDNA showed that a single substitution from Glu to Lys at amino acid position 138 on the E protein is related to the attenuation phenotype.

In the CNS, JE virus grows efficiently in the neurons, and their destruction is directly related to the clinical manifestation of encephalitis.

Clinical Features of Infection

JE is a typical acute encephalitis with sudden onset of high fever and headache after incubation for 1–2 weeks. After a few days of prodromal stage, full symptoms of encephalitis appear with impaired consciousness. Nuchal rigidity is present in all cases, with frequent signs and symptoms of chills, vomiting, malaise, photophobia, pareses and tremors. Cerebrospinal fluid (CSF) findings are moderately elevated pressure and protein content, and lymphocytic pleocytosis with normal sugar level. The peripheral blood picture shows moderate leukocytosis with relative lymphopenia. The case fatality rate is high, around 25–50%, and most of the deaths occur around 5–9 days after onset. Respiratory dysfunction, abnormal reflexes, seizures, prolonged fever, albuminuria, infectious virus and absence of anti-JE antibodies in the CSF are correlated with poor prognosis. There is no specific treatment for JE except supportive care. Grave sequelae with neurological and psychiatric disorders are observed in approximately half of survivors.

Pathology and Histopathology

Three major pathological findings in the CNS have been described: (1) perivascular cuffing (infiltration of small round inflammatory cells around small vessels); (2) neuronophagia (degeneration and necrosis of neurons and their uptake by phagocytes); and (3) foci (accumulation of small round cells probably microglia and lymphocytes). These changes are observed in the gray matter of the brain. Immunofluorescent staining reveals the presence of JE antigen in the neurons but not in glia cells.

Immune Response

IgM class antibodies are found in the acute phase serum and CSF after JE virus infection. Demonstration of these early antibodies, particularly in CSF, is diagnostic and indicative of CNS involvement. Serum IgM antibodies are produced also in systemic inapparent infection.

Because of crossreactions with other flaviviruses, classical serology by the HI test on paired sera sometimes shows a pattern of secondary flavivirus infection. This pattern is characterized by high-titered IgG antibodies which crossreact with almost all flavivirus antigens, and is frequently observed in the areas where multiple flavivirus infections, particularly dengue virus infections, coexist. Such patterns are difficult to interpret and provide the diagnosis of just flavivirus infection. Since IgM class antibodies are produced transiently and are more specific to recently infecting virus type, the HI test was performed on IgM fractions separated by sucrose gradient centrifugation, or on serum specimens before and after 2-mercaptoethanol treatment. The IgM antibody assay was simplified by radioimmunoassay or ELISA.

Prevention and Control

Formalin-inactivated and highly purified vaccine has been developed from infected mouse brain in Japan, and its efficacy and safety have been demonstrated in the field as well as laboratory studies. Sufficient level of N antibodies was produced when two doses of vaccine were given with a one week to one month interval followed by a booster shot in the next year. The protective level of N antibodies gradually declines over 3–4 years but can promptly be augmented by a booster shot. In passively immunized mice, N antibodies detectable at 1:10 serum dilution was protective against the lethal challenge of 10^4 LD_{50} JE virus, which is the maximal amount of the virus inoculated by a single mosquito bite. The present recommendation for JE vaccination in Japan is initial immunization with two doses with 1–2 week intervals followed by a booster shot in the next year. Protective immunity should be maintained by booster immunization every 3–4 years.

Another formalin-inactivated vaccine, prepared from infected hamster kidney cell cultures, has been extensively used in China. An international standard to cover both the Japanese and Chinese inactivated vaccines has been worked out by the Expert Advisory Committee of the World Health Organization (WHO).

To cover various JE virus strains with different antigenic subtypes, bivalent vaccine was prepared by combining the classical Nakayama vaccine and Beijing-1 vaccine. Mice immunized with the bivalent vaccine produced antisera which neutralized almost all strains to similar levels. Since a single strain is preferred for vaccine production and quality control, the National Institute of Health of Japan changed the vaccine strain from Nakayama to Beijing-1 because of a wider range of neutralizing capacity of anti-Beijing-1 sera than anti-Nakayama sera produced in mice.

Swine immunization with live-attenuated vaccines in limited areas in Japan provided apparently successful results with a reduced number of human JE cases in the following years. However, swine immunization has not been extensively used because of the high turnover rate of the swine population and the limited

window period of live-attenuated vaccine administration, which is ineffective in the presence of maternal antibodies.

Several live-attenuated JE vaccine strains were developed in China, and one of them (SA14-14-2) produced anti-JE antibodies in a number of children and horses without adverse reactions.

Overwintering in Temperate Climatic Areas

No definite answer has been obtained for the overwintering mechanism of JE virus in temperate areas. Two alternative possibilities have been postulated: overwintering of the virus locally and reintroduction of the virus from tropical or subtropical areas. It is generally agreed that the epidemic cycle of *Culex*–swine amplification of JE virus is not directly involved in virus survival in nature and some basic cycle must be present. The possibility of virus survival in vertebrate animals was analyzed by serological survey and virus isolation. Bats were shown to be infected with JE virus for a prolonged period and produced sufficient viremia to infect vector mosquitoes. Some viruses (including JE virus) were isolated from bats in nature; however, the connection between bat infection and the *Culex*–swine epidemic cycle has not been demonstrated. Experimental infection of JE virus in some reptiles demonstrated virus survival during the winter season and appearance of viremia the following spring. However, no evidence was obtained that the reptile was involved in the natural transmission of JE virus. Neither has the implication of JE antibodies among turtles been clarified. Also, the attempts to isolate JE virus from overwintering *C. tritaeniorhynchus* turned out to be negative. Under experimental conditions, JE virus was transovarially transmitted from infected female *Aedes* mosquitoes to progenies. This finding should be substantiated by demonstrating that natural *Aedes* mosquitoes are frequently infected with JE virus and connected to the epidemic virus transmission cycle. Attempts to demonstrate JE virus reintroduction by infected migratory birds or vector mosquitoes have also been negative.

A recent survey of swine abortion in the low endemic northern island of Japan (Hokkaido) demonstrated that JE virus infection occurs focally (not continuously) on several separate swine farms. This result supports the possibility that JE virus overwinters in isolated domestic areas. By the reverse transcription polymerase chain reaction (RT-PCR) persisting JE virus genome was detected in peripheral blood or spleen cells on infected swine. The finding should be supported by the facts that such persisting viral genome could lead to the epidemic cycle of JE virus transmission.

Further Perspectives

Control of JE epidemics in developing Asian countries is a high-priority health problem. In order to meet the supply of inexpensive JE vaccine in large quantity, development of the second generation vaccine by molecular technologies has been postulated by WHO. Initial success toward this objective has been the expression of the E gene by the recombinant yeast, *Escherichia coli*, baculovirus and vaccinia virus. However, antigenicities of the gene products were generally low and inappropriate as candidate vaccines. This phenomenon may be related to the fact that most of the E protein epitopes are conformation dependent. The E gene product, with almost similar reactivities with a battery of monoclonal antibodies as authentic E protein, was obtained by a recombinant which possessed not only E but also its upstream PreM and a part of the C gene. This gene product was expressed on the surface of the recombinant virus-infected cells. In the recombinant vaccinia virus-infected cells subviral particles similar to SHA and carrying E and PreM protein was secreted extracellularly. Animals immunized with such recombinant baculovirus-infected cells, recombinant vaccinia virus, or subviral particles produced anti-JE N antibodies and were protected from lethal challenge of the virus. Further studies require purification of the gene products and safety assessment to use live recombinant vaccinia virus for humans in the face of smallpox eradication. Recent immunization of mice with a DNA molecule coding JE virus PreM and E proteins produced anti-JE N antibodies and conferred protection against lethal challenge by JE virus.

The overwintering mechanism (see earlier) of JE virus should be clarified using modern molecular technologies together with the connection to epidemic cycle of JE virus transmission.

The endemicity of JE in tropical Asia should be investigated.

The biological functions of several virus-specific nonstructural proteins should also be investigated in the future.

JC AND BK VIRUSES (*PAPOVAVIRIDAE*)

Richard J Frisque, Department of Biochemistry and Molecular Biology, Penn State University, University Park, Pennsylvania, USA

History

In 1971, two laboratories reported the isolation of a human polyomavirus; subsequent biological and biochemical characterization revealed that the two isolates were previously unrecognized and closely related viruses. Duard Walker's group in Madison, Wisconsin isolated JC virus (JCV) from the brain tissue of a patient with the rare demyelinating disease progressive multifocal leukoencephalopathy (PML). At about the same time, Sylvia Gardner's laboratory in London, UK recovered BK virus (BKV) from the urine of a renal allograft recipient undergoing immunosuppressive therapy. The names of both viruses were derived from the initials of these patients.

JCV has now been isolated from the brain tissue of a large number of PML patients, and it is considered the etiologic agent of this usually fatal disease. BKV has been associated with cystitis and acute respiratory disease in children, ureteral stenosis in renal allograph patients and hemorrhagic cystitis in bone marrow transplant recipients. Both viruses have been detected in human tumors. In most individuals JCV and BKV establish asymptomatic infections in the kidneys and viruria is frequently observed.

The naming of JCV strains has generally relied on their geographic origin followed by a number, e.g. JCV(Mad1) was the first (prototype) strain of JCV isolated in Madison, Wisconsin. Naming of most BKV and some JCV strains has utilized the initials of the person from whom the variant was obtained, e.g. BKV(AS) indicates a BKV isolate from an individual with the initials AS.

Classification

JCV and BKV belong to the genus *Polyomavirus* of the family *Papovaviridae*. Additional members of this group include the closely related monkey virus SV40 and the more distantly related type species, mouse polyomavirus. Initially, these small DNA tumor viruses were classified together on the basis of the size and structure of their capsid, the antigenic similarities of their viral proteins and the site of their multiplication (nucleus) within the infected cell.

Properties of the Virion

The polyomavirus capsid is 38–44 nm in diameter, is made up of 72 capsomers, and has an icosahedral symmetry. The virion lacks an envelope and is resistant to ether and heat treatment. Red blood cells are agglutinated by the JC and BK virus particles.

Properties of the Genome

The JCV and BKV genomes (**Fig. 1**) are double-stranded, covalently closed circular DNA molecules that include approximately 5000 nucleotide pairs (np). Their G + C content of 40–41% is similar to that of the host chromosomes. The two viral DNAs share 75% sequence identity with one another, and 69–70% identity with the SV40 genome. The non-coding regulatory regions of the three viruses span about 400 nucleotides. The *cis*-acting sequences specifying the transcriptional control elements have diverged to the greatest extent, whereas those making up the core origins of DNA replication are highly conserved. It is within these latter sequences that replication initiates and then proceeds bidirectionally around the circle and terminates at a point approximately 180° away.

The coding region of these viral DNAs is divided into two nearly equal parts, based on whether the viral genes are expressed before (early) or after (late) DNA replication. The early and late mRNAs are transcribed from opposite strands of the DNA; their start sites are heterogeneous and are located near the replication origin.

The polyomavirus capsid is 38–44 nm in diameter, is made up of 72 capsomers, and has an icosahedral symmetry. The virion lacks an envelope and is resistant to ether and heat treatment. Red blood cells are agglutinated by the JC and BK virus particles.

Properties of the Genome

The JCV and BKV genomes (**Fig. 1**) are double-stranded, covalently closed circular DNA molecules that include approximately 5000 nucleotide pairs (np). Their G + C content of 40–41% is similar to that of the host chromosomes. The two viral DNAs share 75% sequence identity with one another, and 69–70% identity with the SV40 genome. The non-coding regulatory regions of the three viruses span about 400 nucleotides. The *cis*-acting sequences specifying the transcriptional control elements have diverged to the greatest extent, whereas those making up the core origins of DNA replication are highly conserved. It is within these latter sequences that replication initiates and then proceeds bidirectionally around the circle and terminates at a point approximately 180° away.

The coding region of these viral DNAs is divided into two nearly equal parts, based on whether the viral genes are expressed before (early) or after (late) DNA replication. The early and late mRNAs are transcribed from opposite strands of the DNA; their start sites are heterogeneous and are located near the replication origin.

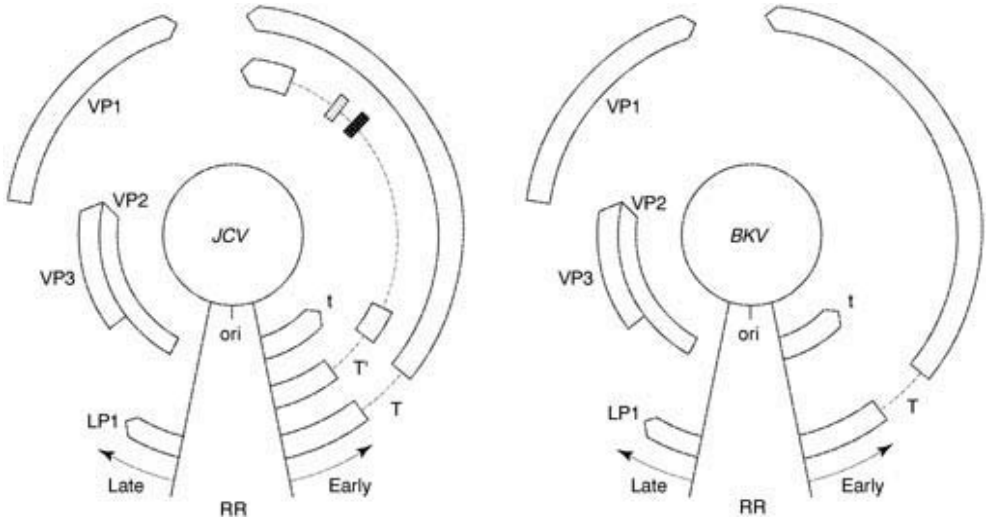

Figure 1 Comparison of the JCV and BKV genomes. The organization of these human polyomavirus genomes is nearly identical. The inner circles represent the double-stranded DNA genomes (~5 kb), the outer arrows denote the encoded viral proteins. The genomes are divided into three parts. The early region specifies five (JCV) or two (BKV) regulatory proteins produced by translation of alternatively spliced early mRNAs. T′ on the JCV map represents three proteins which share their first two exons and have unique carboxy-terminal exons (T'_{165}, open box; T'_{136}, box with lines; T'_{135}, shaded box). The existence of BKV T′ proteins and JCV and BKV early leader peptides (JELP and BELP) is predicted but has not been confirmed. The late region specifies four proteins required for capsid assembly. The regulatory region (RR) contains the *cis*-acting signals which control viral DNA replication (ori) and transcription.

Properties of Virus Proteins

Based on DNA sequence information, mRNA and protein analyses, and comparisons with SV40, the JCV and BKV genomes are predicted to encode seven to ten proteins. The early proteins are translated from mRNAs that are generated by alternative splicing of a single precursor message. In addition to the regulatory large T and small t antigens, three additional JCV early proteins, T'_{165}, T'_{136} and T'_{135}, have recently been detected in lytically infected and transformed human cells. BKV proteins corresponding to these T′ species are predicted based on immunoprecipitation experiments involving BKV-transformed cells. Amino-terminal sequences of all early proteins are shared, and carboxy-terminal sequences are unique. They are first produced early in a lytic infection, and they are the only proteins expressed in cells oncogenically transformed by the viruses. The multifunctional SV40 large T antigen has been studied extensively and is known to play critical roles in viral DNA replication, transcription and oncogenesis. Several of these functions have been assigned to domains within the corresponding JCV (**Fig. 2**) and BKV proteins. The small t and T′ proteins are less well understood, but they appear to augment large T activity under certain conditions. Four late proteins have been identified, three capsid proteins, VP1, VP2 and VP3, and LP1 (or agnoprotein) which may be involved in virion assembly. One additional SV40 protein, SELP (SV40 early leader protein) has been identified, but has no known function. Its expression is the result of a switch in early mRNA start site utilization that occurs during a lytic infection. Expression of the corresponding JCV (JELP) and BKV (BELP) polypeptides is predicted, but has not been demonstrated.

Geographic and Seasonal Distribution

Serological surveys indicate that JCV and BKV are widely distributed in the human population, and that most people are infected before reaching adolescence. Recent sequence analyses have identified predominant strains of JCV excreted in the urine of individuals living in North America, Europe, Africa and Asia. These isolates can be assigned to various types and subtypes based on nucleotide differences found primarily within their VP1 coding regions.

Seasonal variations in incidence rates have not been reported, probably because a primary infection is difficult to detect (due to its subclinical nature and occurrence early in the life of its host), and because it

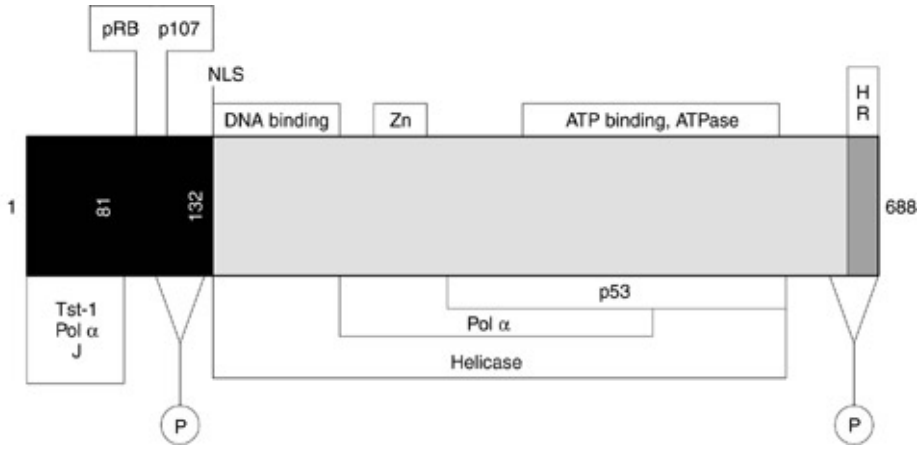

Figure 2 Predicted functional domains of the JCV T antigen. Identification of functional domains of the 688 amino acid (aa) JCV T antigen is based on mutational analyses and sequence comparisons with the SV40 T antigen. Similar domains are expected to be encoded within the BKV T protein. The first 81 aa are shared with the other four JCV early proteins, and the first 132 aa (shaded box) are shared with the three T′ proteins. The carboxy-terminal 33 aa (hatched box) overlap those of T'_{165}. NLS, nuclear localization signal; Zn, metal binding region; HR, host range domain; Polα, binding region for DNA polymerase α-primase; J, sequences homologous to the J domain of DnaJ proteins; P, serine and threonine phosphorylation sites.

often results in viral (and antibody) persistence that may preclude reinfection.

Host Range and Virus Propagation

JCV and BKV are strictly human viruses; there is no evidence to suggest that an animal reservoir exists. Inoculation of rodents (with JCV and BKV) and primates (with JCV) often results in the formation of a variety of tumors; infectious virions are not produced. JCV has a propensity for causing tumors in neural tissue, whereas BKV induces tumors in a variety of tissues.

The host range of the polyomaviruses in culture is restricted to a limited number of cells. This restriction is exaggerated in the case of JCV and has impeded the study of this opportunistic pathogen. JCV multiplies inefficiently in human primary B lymphocytes, embryonic kidney, amnion, transitional epithelial, Schwann and adult brain cells, and in glial and B cell lines. Significant replication of the virus has been demonstrated in tonsillar stromal cells, but propagation is most efficient in primary human fetal glial (PHFG) cells or transformants derived from this heterogeneous cell population. Even in these latter cells, however, the lytic cycle is prolonged and virus yields are generally low. BKV demonstrates a wider host range; virion production occurs in a number of primary and established human and monkey cell types and is most efficient in human fetal glial and kidney cells.

Measurement of virus titers is most readily determined using a rapid and inexpensive hemagglutination assay. A viral plaque assay is also available for BKV, but not for nondefective strains of JCV. Additional means of determining virus titers, such as a fluorescent cell focus assay, are not convenient for routine use.

Evolution and Genetics

Serological investigations have demonstrated that sera collected from individuals prior to the use of SV40-contaminated polio and adenovirus vaccines contained antibodies to JCV and BKV. This finding eliminated any suspicion that the high prevalence of anti-JCV and anti-BKV antibodies in today's population is due to exposure to SV40 in vaccines. Based on the extent to which the human and monkey viruses have diverged, it is evident that the viruses have not recently evolved from one another.

Alterations to the JCV and BKV genomes readily occur during passage of the viruses in their host and/or in cell culture. Sequence hypervariability involves the deletion and amplification of promoter–enhancer signals (**Fig. 3**). In the prototype strain of JCV, these transcriptional control elements are represented by a tandem duplication of 98 nucleotides, which is identical in genomes cloned directly from the PML patient's brain or from Mad1 virus propagated in cell culture. A large number of additional JCV DNAs have been cloned from the brain tissue of other PML patients. Although their promoter–enhancer elements

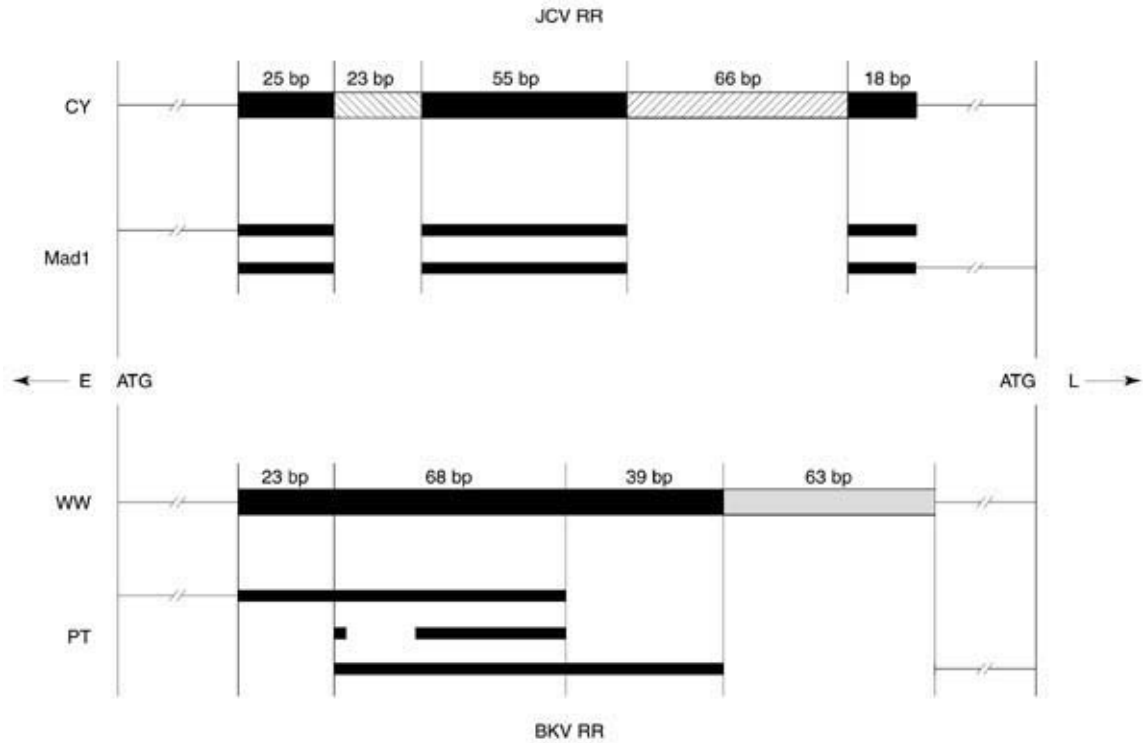

Figure 3 Comparisons of the JCV and BKV archetype and rearranged transcriptional control regions. The transcriptional control region (TCR) within the regulatory region (RR) of the prototype Mad1 strain of JCV contains a 98 bp tandem repeat composed of duplicate copies of 25 (includes TATA box), 55 and 18 bp blocks of DNA. These sequences, and an additional 23 and 66 bp sequence, are present as single copies in the promoter–enhancer of the archetype CY strain of JCV. The TCR of the prototype PT strain of BKV contains a 23 (includes TATA box) and 39 bp block of DNA and a triplication of a 68 bp sequence (the central repeat has a deletion of 18 bp). These sequences, and an additional 63 bp sequence, are present as single copies in the TCR of the archetype WW strain of BKV. The Mad1 and PT sequences are identified by lines below the CY and WW sequences and are read left to right. A gap within these lines represents a deletion relative to the archetype sequence; parallel lines represent multiple copies of that particular region. The initiation codons (ATG) for the early (E) and LP1 (L) proteins are indicated.

differ in size and sequence, the tandem repeats are clearly related to those of Mad1. Passage of these isolates *in vitro* often generates additional regulatory region alterations which may favor the viruses' growth in cell culture. In contrast to these rearranged (or PML) variants, JCV DNA obtained directly from the kidney or urine of normal individuals exhibits little sequence heterogeneity. A representative of this latter type of genome has been called 'archetype', a form from which all known rearranged JCV variants could have evolved. The presence of unique 23 and 66 np sequences, and the absence of a large tandem duplication distinguishes the archetype promoter–enhancer region from those of other JCV DNAs.

An archetype form of BKV DNA is also routinely cloned directly from human urine specimens. Rearrangement of the BKV promoter–enhancer sequences has been demonstrated in DNAs obtained from virus passaged in cell culture. The transcriptional control regions of these isolates contain large tandem duplications or triplications which often involve a 68 np sequence. It now appears that, like JCV, the presence of tandem repeats in the BKV regulatory region may occur in strains that already exist *in vivo* and are not simply the result of passage in culture.

Multiple typing schemes have been developed for JCV and BKV based on sequence differences within specific regions of the viral genomes; naming of these genotypes has been a source of confusion in the literature. Archetype and rearranged types of JCV and BKV are differentiated by alterations within the transcriptional control regions. This scheme has been used to distinguish the proposed circulating form of the virus (archetype) from the forms which evolve anew in each infected host or in cell culture (rearranged). A second typing scheme recognizes nucleotide differences which have accumulated in the VP1

gene during long-term association of the virus with geographically separated human populations. A scheme proposed prior to the discovery of archetype strains which attempted to classify rearranged variants into two groups is outdated and should be discarded.

Serologic Relationships and Variability

Genus- and species-specific antigens have been identified on and within the JCV and BKV capsids. Members of the polyomavirus genus share a cross-reacting antigenic determinant that is not exposed on the virion surface. Antibodies directed against this determinant are produced by immunizing rabbits with disrupted virions or purified VP1. At least one species-specific antigenic determinant is found on the surface of the JCV, BKV and SV40 capsids which allows them to be distinguished from one another by serological means. Antibodies to this antigen are generated during an infection by the viruses of their natural hosts.

Antigenic similarities between the large and small T proteins of these three viruses can be demonstrated by a variety of immunological methods. Polyclonal antiserum raised against the early antigens of one virus generally crossreacts with those of the other two viruses, whereas monoclonal antibodies are less likely to recognize all three sets of proteins. Cytotoxic T lymphocytes (CTL) also have the ability to identify shared and distinct epitopes of T antigen presented on the surface of JCV- and SV40-transformed cells; most CTL clones directed against determinants of the SV40 protein lyse cells expressing the JCV protein.

One major serotype of JCV (represented by Mad1) appears to circulate in the population, although a distinct antigenic variant JCV(Mad11) has been recognized. The Mad1 and Mad11 VP1 proteins only differ at amino acid position 66 (aspartic acid vs. histidine) which lies within a region (amino acids 40–80) predicted to be an antigenic epitope. Recently, two genotypic variants have been identified with deletions in their VP1 gene. It is not known whether these alterations signal the existence of additional JCV serotypes. BKV has been grouped into four serotypes. Sequence differences observed between amino acids 61 and 83 of their VP1 proteins are predicted to have altered a dominant epitope on the capsid surfaces, resulting in antigenic variability.

An important consequence of having multiple JCV and BKV serotypes circulating in the population might be the underestimation of the prevalence of these viruses in their human host if a single viral strain is used as the source of antigen in serological testing.

Epidemiology

Until recently, investigators relied on seroepidemiology as a means of acquiring information about the distribution and natural history of JCV and BKV. Such surveys suggested that humans are the natural reservoir for JCV and BKV. Most people are infected before reaching adolescence, and greater than 70% of adult sera contain antibodies to one or both of these viruses. These studies have been based on the detection of hemagglutination-inhibiting antibodies, because they can be measured easily and quickly, and because their titers correlate well with neutralizing antibody titers. Enzyme-linked immunosorbent assays (ELISA) have also been used to screen human sera for evidence of exposure to these viruses. Concerns remain, however, regarding the specificity of these assays, since crossreactivity of anti-JCV and anti-BKV antibodies may occur when purified viral proteins are used as the source of the antigen. Epidemiological approaches are being extended using molecular techniques such as the polymerase chain reaction (PCR), which greatly increases the ability to detect and analyze JCV and BKV in body fluids and tissue samples.

Transmission and Tissue Tropism

Very little is known about how the human polyomaviruses are transmitted to their host, although it is suspected that virus may enter via a respiratory or oral route. The only recognized release of JCV and BKV is through the urine, and this occurs transiently in many individuals over the age of 20. Studies in urban versus rural areas of Japan indicate that population density and environmental conditions may affect the transmission of JCV. Genotypic analysis suggests that up to 50% of the population may become infected when JCV is transmitted from a family member.

Little information is available regarding the syndrome of the primary infection. The initial infection generally occurs during childhood and is largely asymptomatic. BKV infection has been linked to cystitis and an acute respiratory illness among immunocompetent children; clinical illness has not been clearly associated with a primary JCV infection. Preliminary data indicate that JCV and BKV may infect tonsillar tissue *in vivo*, and tonsillar stromal cells do support JCV replication in culture.

Once virus has multiplied at the primary site of infection, lymphocytes are thought to transport it to the brain, urinary tract and lymphoid tissues. It has also been speculated that lymphocytes might contribute to the rearrangement process which alters the

archetype promoter–enhancer sequences and results in the appearance of variants with new tissue tropic properties. Upon reaching the kidney, archetype virus establishes a persistent infection which is often manifested by transient viruria both in immunocompetent and immunocompromised individuals. Because virus is frequently detected in the urine of pregnant women, attempts have been made to uncover evidence for a transplacental route of transmission for the human polyomavirues; such evidence has not been forthcoming.

After a primary infection or the reactivation of a persistent kidney infection, JCV, and perhaps BKV, may reach the brain where they remain latent or, in the case of JCV, might actively replicate to cause PML. The predominant form of virus detected in normal and diseased brain contains a rearranged transcriptional control region. Recent PCR findings suggest that the Type 2 genotype of JCV is disproportionately represented in the brains of PML patients; no evidence is available to suggest differences in the pathogenic behavior of BKV genotypes.

The influence of the JCV and BKV regulatory signals on cell tropism has been tested *in vitro*, and the results indicate that the BKV signals have a broader range and are more active than those of JCV. In addition, the rearranged transcriptional control elements are more potent than the archetype signals. These studies indicate that the JCV promoter–enhancer elements function best in cells of glial origin, thus leading some investigators to improperly designate JCV as a strictly neurotropic virus.

Pathogenicity

An association between BKV and human disease most frequently involves pathologic changes in the urinary tract following reactivation of a persistent infection in immunodeficient individuals; they rarely represent a life-threatening event. BKV is also detected in lymphocytes and brain, but pathogenic consequences appear to be rare. BKV variants isolated from tissue or urine may have single or multiple copies of the promoter–enhancer sequences. Although these strains vary in their lytic behavior *in vitro*, data supporting differences in their pathogenic potential are lacking.

JCV causes PML, a fatal degenerative disease of the central nervous system (CNS). There is evidence to suggest that PML occasionally results as a consequence of primary infection. Such a possibility is supported by cases involving very young children with innate immune deficiencies. Examination of one such case indicates that promoter–enhancer rearrangements occur early in the infection, that multiple variants are generated and that the virus becomes established in multiple tissues. However, most cases of PML appear to result from the reactivation of a latent or persistent infection during a decline in immune status. Usually only one rearranged variant is detected in these patients.

The following series of events might occur in a reactivation case of PML. After an initial exposure to archetype virus, latent and persistent infections may be established in a healthy individual. It is unclear whether rearranged genomes arise before the initial immune response or only later after some impairment to T cell function. However, both forms are eventually found in most people and they can be detected at different preferred sites in the body. The host–parasite relationship may remain fairly stable during most of an individual's life, with only occasional episodes of viruria to signal the presence of JCV. Disruption of this relationship could occur during periods of prolonged and severe immune deficiency, and JCV might then actively replicate in the CNS to yield PML.

Although once considered an extremely rare disease, PML is now being seen with increasing regularity, due primarily to an increase in the numbers of patients comprising two at-risk groups; people undergoing immunosuppressive therapy and victims of the AIDS pandemic. It is estimated that PML is the cause of death in up to 5% of the individuals in this latter population. The relatively high incidence of PML in AIDS patients may be due to more than just the host's inability to maintain effective immune surveillance. The HIV *tat* protein has been shown to *trans*-activate the JCV late promoter *in vitro*. *In vivo*, *tat* might influence the pathogenic potential of JCV either through a direct interaction with a TAR-like element found in JCV late mRNAs or through indirect effects on specific inflammatory cytokines which might enhance JCV gene expression.

Clinical Features of Infection

PML presents as an insidious, subacute disease and indications of infectious inflammatory disease are often minor or absent. Signs and symptoms depend on the location of the lesions in the CNS, with prominent early manifestations including motor disturbances, mental changes and visual and speech impairment. Over the course of the disease, these neurological problems generally progress and new ones are observed as additional sites are affected. At the time of diagnosis, many patients exhibit partial or complete paralysis. Mental problems may have advanced to dementia and visual defects to cortical blindness. The

survival times of most PML patients following diagnosis is often less than six months.

Pathology and Histopathology

Lesions within the subcortical white matter of the PML brain are seen as multiple foci of demyelination that range in size from 1 mm to several centimeters in diameter. The pathognomonic feature is the altered oligodendrocyte. The nucleus of this cell is two to three times the expected size, and it usually stains deeply basophilic with hematoxylin. The normal chromatin pattern is lost, and the nucleus is filled with virions and viral antigens.

The altered oligodendrocytes are most prominent within small early lesions and near the borders of larger, more advanced lesions. Within the central areas of older PML lesions, the oligodendrocytes are missing and macrophages and reactive astrocytes are common. Giant, bizarre astrocytes with pleomorphic, hyperchromatic nuclei are often found as well, and these cells strongly resemble malignant astrocytes of pleomorphic glioblastomas.

Immune Response

Most people produce antibodies against JCV and BKV; significant antibody titers may persist for life due to the ability of these viruses to establish persistent infections. Reactivation of these infections is not prevented by high levels of antibody, but does occur during conditions that lead to impairment of T-cell function, for example during AIDS, autoimmune diseases, immunosuppressive therapy used for treating malignancy or preventing rejection of transplants, pregnancy and old age. In addition to a general depression of cell-mediated immunity, a severe, more specific deficiency in cellular immune response to JCV may be a determining factor in whether PML becomes the final outcome of reactivation.

Once PML is diagnosed, most patients only survive a few months. In some individuals, however, the disease progresses more slowly, resulting in significantly longer survival times. In such cases, evidence of immunosuppressive therapy or underlying immune deficiency disease may be absent. These long-surviving patients often demonstrate signs of active cellular inflammatory response and perivascular cuffing with plasma cells and lymphocytes. The ability of these individuals to mobilize some cellular immunity against the infection presumably accounts for the slower advance of the disease.

Prevention and Control of Human Polymavirus Infections

Considering the early age at which people are infected by JCV and BKV, the prevalence with which these viruses circulate in the population, and the ability of these viruses to establish persistent infections in immunocompetent hosts, it appears unlikely that we will soon be in a position to prevent or eliminate primary or reactivation infections by the human polyomaviruses. At present, efforts to alter the outcome of severe opportunistic infection through the identification of effective means of diagnosis and treatment should be encouraged.

The most serious polyomavirus infection in humans, PML, is caused by JCV. There is no proven treatment for this disease, and the prognosis for PML patients has generally been poor. If some degree of success in therapy is to be achieved, top priorities must include attempts to make an early diagnosis, to shore up the host immune response and to inhibit viral multiplication with antiviral agents. Although sporadic success has been reported using antiviral agents such as nucleic acid base analogs (e.g. cytosine arabinoside [Ara-C]) and β interferon, a recent study conducted under the auspices of the NIH Neurological AIDS Research Consortium failed to demonstrate significant clinical benefit for patients receiving Ara-C therapy. Given that PML nearly always occurs in severely immunocompromised individuals, there are two groups of patients for which an effective strategy is being developed. Individuals undergoing immunosuppressive therapy to control autoimmune disease or to prevent allograph rejection have demonstrated functional resistance if removed from immunosuppression. In addition, immune reconstitution in HIV-infected patients with PML by combined antiretroviral therapy has resulted in prolonged remission of PML. This host resistance in combination with an agent designed to inhibit viral DNA replication might further improve the prognosis. Potential candidates include camptothecin, a DNA topoisomerase inhibitor, and cidofovir, an acyclic nucleoside phosphonate analogue, which have been shown to block replication of primate polyomaviruses in cultured cells.

Future

A key to the successful treatment of PML will be the ability to make an early diagnosis before extensive damage is done to the CNS. At present the only definitive means of diagnosis is by histopathological examination of diseased tissue obtained by biopsy or at autopsy. Noninvasive procedures, although not specific for PML, are useful in their ability to exclude

other potential causes of the presenting signs and symptoms. These procedures make use of the electroencephalogram, computer tomography and magnetic resonance imaging. Several laboratories have employed PCR to detect JCV in cerebral spinal fluid, and although some questions remain concerning the levels of sensitivity and specificity of this approach, it holds promise as a diagnostic tool.

A number of questions need definitive answers before we have a significant understanding of the pathogenesis of PML. For example, how is the virus transmitted from person to person and what is the site of primary infection? When does JCV make its way to the brain once it is in the body? Are lymphocytes involved in rearrangement of the archetype transcriptional control region. Does the adaptation from a kidney to a brain variant result in a virulent form of JCV and under which conditions might such an event occur? What role does the host immune system play in the establishment and maintenance of a persistent JCV infection?

L

LASSA, JUNIN, MACHUPO AND GUANARITO VIRUSES (*ARENAVIRIDAE*)

Joseph B. McCormick, Epidemiology and Biostatistics Unit, Institute Pasteur, Paris, France

History

Lymphocytic choriomeningitis (LCM) virus, the first identified arenavirus, was isolated by Lillie and Armstrong in 1933 from the cerebrospinal fluid of a patient suspected of having St Louis encephalitis. The virus was again isolated in 1935 from patients with aseptic meningitis, and finally by Traub in 1935 from laboratory mice. More than 20 years passed before Junin virus, the next member of this taxon to be identified, was isolated from patients with Argentine hemorrhagic fever in 1957. Machupo virus from patients with Bolivian hemorrhagic fever was similarly identified in 1964. A third arenavirus from South America which is pathogenic for humans is Guanarito virus, isolated from patients in Venezuela in 1991. Yet another pathogenic arenavirus, Sabia virus, this time from Brazil, was isolated from a fatally ill individual. Several other arenaviruses have also recently been isolated from rodent species in South America, but none of these have yet been associated with human illness. Lassa virus was the first arenavirus isolated from Africa, in 1969, and remains the only arenavirus pathogenic for humans from Africa, although several other arenaviruses have also been identified from Africa. In total, 19 arenaviruses have been identified worldwide, but only six are known to be pathogenic for humans.

Classification

The 19 members in the *Arenavirus* genus of the *Arenaviridae* have traditionally been placed in categories of Old and New World arenaviruses (**Table 1**), based on geographic locations. More recently Tacaribe complex viruses (in the Western hemisphere) have been more completely placed in phylogenetic relationship with each other based on a sequence of about 600+nucleotides in the nucleoprotein. The present information suggests three related groups: lineage A contains Pichinde, Parana, Flexal and Tamiami viruses; lineage B contains Junin, Machupo, Amapari, Guanarito, Sabia and Tacaribe viruses; lineage C contains Latino and Oliveros viruses. More recently still, further genetic analysis has led to the suggestion that Pichinde and Oliveros viruses are most closely associated with Old World arenaviruses. The likelihood that arenaviruses and their rodent hosts have coevolved was suggested some time ago, and now seems a possible hypothesis to begin to test through the parallel use of rodent genetics, alongside the understanding of the genetic relationships between arenaviruses.

The six arenaviruses presently know to be pathogenic for humans (LCM, Lassa, Junin, Machupo, Guanarito and Sabia viruses) will be the primary subjects of this entry.

Properties of the Virion

The arenaviruses are enveloped, pleomorphic, membrane viruses ranging in diameter from 50 to 300 nm, with a mean diameter of 110–130 nm. The virion density in sucrose is 1.17 g ml^{-1}. They contain two segments of single-stranded RNA tightly associated with a nucleocapsid protein. This is enclosed in a membrane consisting of two glycosylated proteins (or in some cases a single glycosylated protein). The genome consists of two segments of single-stranded RNA, both contain two genes encoded in an ambisense structure. The small RNA segments encodes for the glycoprotein precursor (GPC) and for the nucleoprotein (NP). The NP and GPC genes are encoded in nonoverlapping reading frames with origins at the 3′ and 5′ ends of the molecule,

Table 1 Arenaviruses: basic biological information

Virus	*Human disease*	*Geographic distribution*
Lymphocytic choriomeningitis	Lymphocytic choriomeningitis	Europe, Asia, Western Hemisphere
Lassa	Lassa fever	West Africa
Mopeia	Human infection, no disease known	Southern Africa/Mozambique, Zimbabwe, Rep. of South Africa
Mobala	Human infection, no known disease	Central African Republic
Ippy	Unknown	Central African Republic
Lineage B[a]		
Junin	Argentine hemorrhagic fever	Argentina
Machupo	Bolivian hemorrhagic fever	Bolivia
Guanarito	Venezuelan hemorrhagic fever	Venezuela
Sabia	Hemorrhagic fever	Brazil
Amapari	None	Brazil
Tacaribe	None	Trinidad
Lineage A[a]		
Parana	None	Paraguay
Tamiami	None	Florida
Pichinde	None	Colombia
Flexal	None	Brazil
Lineage C[a]		
Latino	None	Bolivia
Oliveros	None known	Argentina
Not yet placed[a]		
Pirital	None known	Venezuela
White Arroyo	None known	North America

[a] In current phylogenetic scheme suggested for Tacaribe complex viruses.

respectively. The N gene is encoded by the 5′ half of the viral complementary RNA sequence corresponding to the 3′ half of the viral RNA molecule. The GPC gene is encoded by the 5′ half of the viral RNA molecule. Similarly, the large strand of RNA codes for the RNA-dependent viral RNA polymerase and a smaller ring-finger protein involved in replication. The arenaviruses are virtually indistinguishable from each other morphologically, and all share the characteristic granules noted in electron micrographs. These granules appear to be the results of the binding of the zinc-binding ring-finger protein of arenaviruses with the nuclear fraction of ribosomal proportion. The nuclear ribosomal protein (PO) appears in the virion, while other ribosomal proteins do not. This suggests that the granules, believed to be nonspecific inclusion of ribosomes into the virion, may rather be a specific process related to virion replication and assembly. These granules give rise to the family name *Arenaviridae*, derived from *arenos*, the Latin word for sand, based on their electron micrographic appearance as grains of sand.

Geographic and Seasonal Distribution

Junin, Machupo and Guanarito viruses occur in Argentina, Bolivia and Venezuela, respectively. Junin and Guanarito are endemic in their respective areas. Junin virus primarily infects workers during the corn harvesting season, by disturbance of the rodent host, *Callomys callosus*, which lives in the corn fields. Guanarito virus infection is endemic, and its epidemiology may resemble that of Lassa virus in Africa, which occurs throughout the year; however, insufficient data presently exist to confirm this impression. Machupo virus occurred in epidemic fashion in the 1960s in a circumscribed area of Bolivia. It was associated with the transient marked increase in the population of *Calomys* rodents, which are normally field rodents but because of overpopulation moved into human dwellings in search of food. Elimination of the rodents in the towns stopped the epidemic, and few further cases have since been reported (though a few cases were reported in 1996). Lassa virus infection is endemic in West Africa from Senegal to Cameroon

and perhaps other areas not yet explored. There are increases in Lassa infection during the dry seasons, perhaps because of increased virus stability in lower humidity, but other, as yet unknown, factors may also be involved.

Host Range and Virus Propagation

All of the New World arenaviruses have rodent reservoir hosts with the exception of Tacaribe virus, which was isolated from bats in Trinidad (**Table 1**). A hallmark of the arenaviruses is their intimate biological relationship with rodents, resulting in lifetime infection and chronic virus excretion. Many arenaviruses have more than one rodent host, although usually a single species will predominate as the reservoir in nature.

The hosts of LCM virus (LCMV) have included *Mus* species and hamsters. Guinea pigs are also capable of transmitting the virus in laboratory settings. Machupo virus often renders its major natural host, *Calomys callosus*, essentially sterile by causing the young to die *in utero*. Machupo virus also induces a hemolytic anemia in its rodent host, with significant splenomegaly, often an important identifier of infected rodents in the field. The major rodent hosts for Junin virus are *Calomys* species. Transmission of Junin virus from rodent to rodent is generally horizontal, and not vertical, and is believed to occur through contaminated saliva and urine. The *Calomys* rodents are affected by the virus, with up to 50% fatality among infected suckling animals, and stunted growth in many others. Both Junin and Machupo viruses induce a humoral immune response when transmitted to their suckling natural rodent hosts, which may have neutralizing antibody in the face of persistent infection. Guanarito virus has been isolated from *Zygodontomys brevicauda*, though its detailed biology remains to be learned.

The only known reservoir of Lassa virus in West Africa is *Mastomys natalensis*, one of the most commonly occurring rodents in Africa. At least two species of *Mastomys* (diploid types with 32 and 38 chromosomes) inhabit West Africa, and both have been found to harbor the virus. All species are equally susceptible to silent persistent infection, as seen when LCMV infects mice. This presumably occurs as in LCM infection, from a selective deletion of the thymic T cell response to the virus. All of the arenaviruses pathogenic for humans will also infect and produce illness in a wide range of primates. However, it is not known whether such infections occur in nature, as is known for Ebola virus for example. In addition human infection plays no biological role in the life cycle and ecology of the arenaviruses.

Virus Propagation

The original isolation of LCMV was made in suckling mice, which have been important in isolation and characterization of several of the arenaviruses. The arenaviruses are, however, easily cultivated in a wide variety of mammalian cell monolayers. The Vero E6 remains the cell of choice for primary isolation and cultivation, but arenaviruses also replicate in baby hamster kidney cells, as well as in a number of specialized cells such as continuous macrophage lines, endothelial cells, fibroblasts and a variety of mouse cell lines, with specific MHC markers used as targets for immunological studies. The infected cells may produce a cytopathic effect (CPE) beginning on days 4–7 of incubation. However, not all arenaviruses produce CPE, especially on primary isolation. For diagnosis, cells may be harvested after 48–72 hours and assayed for antigen by immunofluorescent antibody (IFA) or ELISA. Virus plaquing techniques may also be used for the arenaviruses.

Genetics

While advances have been made in determining the genetic relationship between different arenaviruses (see Classification), the level of genetic variability within species of arenaviruses is not well characterized, though it must be added that little genetic data on field isolates exist on which to make this judgement. It would appear that the frequency of variability at the amino acid level, as judged by B cell epitope variability, is not high. Thus the variability in B cell epitopes among Lassa viruses isolated from humans or rodents over a 10 year period in a circumscribed area was not substantial, suggesting that B cell epitopes are under limited immune pressure in their rodent hosts. No data are available on the variability of T cell epitopes among Lassa viruses. The South American arenaviruses may be under both B and T cell immune pressure in their rodent hosts, though no data are available on this issue. Reassortment, demonstrated only in the laboratory, may also be a means of genetic variability, but its occurrence in nature and therefore its importance is unknown.

Evolution

The *Arenaviridae* are distributed over five continents and can be divided into three 'coevolutionary' groups, Lassa complex in Africa, LCM in North America, Europe and South America, and the Tacaribe complex in South America. Today's arenaviruses probably descended from an ancestral virus which subsequently differentiated in parallel with the evolution of the Cricetid rodents persistently infected by arena-

viruses. It seems likely, therefore, that the present distribution and evolution of these viruses are directly related to the distribution and evolution of the earliest Cricetid rodents and their descendants, which now make up the natural hosts of most of this family of viruses (Tacaribe virus has a bat host). The coevolution of these viruses will undoubtedly continue and depend primarily on mutations, selected by the persistently infected host's immune pressure, and perhaps on reassortment in the rodent host.

Serological Relationships and Variability

Some monoclonal antibodies raised against African arenaviruses react with arenaviruses of broadly separated geographic origins and others only with local strains. However, other data suggest considerable antigenic stability of arenaviruses in a circumscribed area. The most variable antigenic sites are on GP1 and NP proteins. Thus, a monoclonal antibody to the GP1 and to the NP of Lassa Josiah strain from Sierra Leone identified only local isolates from Sierra Leone or from the immediately adjacent countries. On the other hand some epitopes on both NP and GP2 proteins were conserved among the known African arenaviruses. The GP2 proteins revealed two patterns of conservation. One epitope reacted only with West African strain viruses, while a different epitope reacted with all representative arenaviruses, including South American ones. This observation is in agreement with analysis of sequence homology among the GPC precursors of arenaviruses which showed extensive conservation of sequences in GP2 proteins. Other data, such as neutralization tests, are not yet available or sufficiently reliable to assess these relationships further.

Epidemiology

The fundamental determinant of the ecology of hemorrhagic fevers is the occurrence of persistent virus infection in rodents. Who becomes infected, and when, are functions of the behavior of the persistently infected rodent, and the cultural and occupational patterns of human populations. The arenavirus hemorrhagic fevers are primarily rural and semirural diseases; however, some evidence exists that under certain conditions (poverty, overcrowding) their rodent reservoirs may also establish urban habits. The rodents infect the environment via urine, feces and saliva. Interactions between rodents and humans are peridomestic or in agricultural areas. However, details of the rodent population dynamics, behavior and the natural history of the persistent virus infection in the feral rodent hosts are only poorly understood. The Old World arenaviruses, LCM and Lassa, produce persistent infection in their rodent hosts without significant detrimental effects. The South American viruses, in contrast, may cause illness and death in newborn rodents, or may induce persistence. The modes of transmission from rodent to human are not precisely known. Direct contact by humans, with cuts and scratches on hands and feet, with articles and surfaces contaminated by virus may be a more important and consistent mode of transmission. Transmission to mucosal surfaces may also occur under some circumstances.

Lassa fever

Lassa fever occurs in West Africa, but with a wide geographic area from Northern Nigeria to Guinea, encompassing perhaps 100 million population. At least two species of *Mastomys* occupy West Africa, and both have been found to harbor the virus. These rodents, especially the species with 32 chromosomes, are highly commensal with humans. The movement of *Mastomys* within a village is very limited, and their average lifespan is about 6 months, with little seasonal fluctuation in their breeding pattern. From 5% to as many as 70% have been found to be infected with virus in some village houses. Therefore most virus transmission takes place in and around the homes. All age groups and both sexes are affected and antibody prevalence increases with age. Risk factors for human infection include contact with rodents, direct contact with ill persons infected with Lassa virus, presence of a large household rodent population, and human practices such as catching, cooking and eating rodents and indiscriminant storage of food. In many endemic areas Lassa fever is a common cause of hospitalization. The death rate in systematically studied, untreated hospitalized patients with Lassa fever is 16%, very similar to that described for Junin and Machupo infections. Nosocomial transmission occurs in Africa from contact with infected patients, or through improper use or sterilization of needles, sometimes leading to an outbreak. Person-to-person spread of Lassa virus in households is common, a unique characteristic of Lassa virus in relation to other arenaviruses (no data are yet available on Guanarito virus from Venezuela, or Sabia virus from Brazil), and is usually associated with direct contact or care of someone with a febrile illness, or possibly with sexual contact with a spouse during the incubation or convalescent phases of illness. Illness to infection ratios are 10–25% in some endemic areas of West Africa. Antibody prevalence ranges from less than 1% to over 40% in some villages.

Argentine hemorrhagic fever (AHF)

AHF, caused by Junin virus, was recognized in the 1950s in the northwestern part of the Buenos Aires Province in Argentina, an area of very fertile farmland and therefore of great economic importance. The total number of cases reported over a 30 year period is about 21 000. AHF is a seasonal disease with peak yearly incidence in May. The average number of cases from 1981 to 1986 was 360 per year. Although all ages and sexes are susceptible, nevertheless the major group affected is the male working population, explained by the habits of the rodent hosts for Junin virus, *Calomys musculinus* and *Calomys laucha*. These animals are not peridomestic, but rather occupy grain fields, and this is the major reason for the affected population of field workers. Infection also occurs infrequently in other rodents: *Mus musculus, Akodon azarae* and *Oryzomys flavecens*. Transmission from rodent to rodent is horizontal, not vertical, and is thought to occur via contaminated saliva and urine. It is believed that the major routes of virus transmission from humans is through contact with virus-infected dust and grain products and subsequent infection through cuts and abrasions on the skin, or through airborne dust generated primarily by killing and scattering of rodents during mechanized farming. The disease has spread over the 30 years or so since its recognition from an area of 16 000 km^2 and a quarter of a million persons to an area greater than 120 000 km^2 containing a population of over 1 million persons. Furthermore, the incidence in the older affected areas appears to wane after 5–10 years. Overall antibody prevalence is 12%, with a typical predominance in agricultural workers. One-third of the seropositive individuals have no history of typical illness, suggesting that the case:infection ratio is about 2:3.

Bolivian hemorrhagic fever (BHF)

The only known reservoir for the virus is *Callomys callosus*, a Cricetid rodent that is found in the highest density at the borders of tropical grassland and forest. The distribution of this rodent appears to include the eastern Bolivian plains, as well as northern Paraguay and adjacent areas of western Brazil. The disease was recognized in 1959, and by 1962 more than 1000 cases had been identified in a confined area of two provinces, with a 22% case fatality ratio. The largest known epidemic of BHF, involving several hundred cases, occurred in the town of San Joaquin in 1963 and 1964. This outbreak occurred because of a marked increase in the *Callomys* population, and the subsequent invasion of homes in the town by these rodents. Although the *Callomys* appears to be capable of living both in the areas surrounding the towns and in the towns themselves (where the most efficient transmission of virus would appear to occur), they favor a nonperidomestic habitat where contact with humans is much reduced. It appears that the situation in San Joaquin was unusual, and such an event has not been observed again after nearly 25 years. There has not appeared to be any increase in the geographic areas affected by BHF in the last decade, and few cases have been reported.

Venezuelan hemorrhagic fever

The epidemiologic pattern of this disease has not yet been well characterized. In one survey the antibody prevalence in the population in the endemic area in central Venezuela was 2.6%. The virus was isolated from the cane rat *Zygodontomys brevicauda*. The occurrence of person-to-person transmission has not yet been demonstrated. The low frequency of infection in family contacts and lack of disease in hospital workers caring for patients suggest that person-to-person spread is uncommon. The pattern of infection includes all ages and sexes, suggesting that transmission occurs in and around houses, similar to Lassa fever and BHF and unlike AHF.

Transmission and Tissue Tropism

The primary mode of arenavirus transmission is from human contact with rodent urine or blood. This probably occurs primarily when individuals come into contact with surfaces or material recently contaminated by rodent urine, or when they trap a rodent and handle the carcass. Some evidence suggests that rodent blood or urine might be aerosolized by machinery during mechanized harvesting of corn in Argentina, with consequent transmission of Junin virus to people working near the machinery; however, no detailed studies of specific risk factors exist. In Africa, the rodents are highly commensal and probably deposit virus-laden urine in many areas of the houses they inhabit. The people tend to walk barefooted, and, based on the epidemiologic pattern of somewhat sporadic infection in households, it seems likely that contact with infectious urine is the primary source of contamination. In addition, in parts of Africa people catch and eat rodents, putting them in direct contact with rodent tissue, blood and secretions during the preparation. Finally, for some of the viruses, particularly Lassa virus, there is person-to-person transmission primarily through contact with the blood or secretions of an infected, ill person. Whatever the mode of transmission, it would seem that the reticuloendothelial system is probably a primary target of replication of the

arenaviruses, though they replicate well in many organs, including liver, adrenal gland, placenta, lung and many other organs.

Pathogenesis

The most common sites of initiation of human infection by the arenaviruses is not yet known, although they seem likely to be cuts and abrasions in the skin. Following the initiation of infection, all arenaviruses progress to generalized multiorgan infections, especially of the reticuloendothelial system. Thereafter, however, the pathogenesis of the different infections is variable.

Lassa fever

The 1–3 week incubation that follows infection suggests an unknown primary replication site, probably within the reticuloendothelial system. Route and titer of infecting dose may be important determinants of outcome, as may the virus strain. For example, death rates in nosocomial outbreaks where parenteral exposure is substantial are usually higher than community-acquired infections.

The degree of organ damage in fatal human infections is mild, which is sharply at variance with the clinical course and collapse of the patient. Indeed, there are few clues to the pathogenesis of Lassa fever in standard pathological studies. Liver damage is variable, with concomitant cellular injury, necrosis and regeneration. Nevertheless, serum aspartate aminotransferase (AST) levels over 150 iu ml^{-1} are correlated with poor outcome, and an ever-increasing level is also associated with increased risk of death. Alanine aminotransferase (ALT) is only marginally raised, and the ratio of AST:ALT in natural infections and in experimentally infected primates is as high as 11:1. Furthermore, prothrombin times, glucose and bilirubin levels are near normal, excluding biochemical hepatic failure. An increasing Lassa viremia is also associated with increasing case fatality. In addition to the liver, high virus titers occur in many other organs without significant pathologic or functional lesions, perhaps reflecting blood rather than parenchymal levels of virus.

Some patients develop severe pulmonary edema and adult respiratory distress syndrome, gross head and neck edema, pharyngeal stridor and hypovolemic shock. This pattern is consistent with edema due to capillary leakage, rather than cardiac failure and impaired venous return. Endothelial cell dysfunction has been demonstrated in primates experimentally infected by Lassa fever, in that there is apparently a marked decrease in prostacyclin production by endothelial cells. Loss of integrity of the capillary bed presumably causes the leakage of fluids and macromolecules into the extravascular spaces and the subsequent hemoconcentration, hypoalbuminemia and hypovolemic shock. Proteinuria is common, occurring in two-thirds of patients.

Edema and bleeding may occur together or independently. Since there is minimal disturbance of the intrinsic, and almost none of the extrinsic, coagulation system, and there is no increase in fibrinogen breakdown products, disseminated intravascular coagulation (DIC) is excluded. Furthermore, platelet and fibrinogen turnover in experimental primate infections are normal. Though platelet numbers are only moderately depressed, in severe disease platelet aggregation is almost completely abolished by a circulating inhibitor. The origin of this inhibitor is not known; however, it cannot be reproduced with viral material nor can it be blocked by antibodies to Lassa virus. In the platelet it blocks dense granule and ATP release and thus abolishes the secondary wave of *in vitro* aggregation, while sparing the arachidonic acid metabolite-dependent primary wave. The inhibitor of platelet function also interferes with the generation of the FMLP-induced superoxide generation in polymorphonuclear leukoeytes probably through a similar mechanism.

AHF and BHF

Despite the different degrees of bleeding, there are sufficient similarities between the course of disease in AHF, BHF and Lassa fever to speculate that there exists a similar pathophysiologic pathway underlying all of the diseases. Organ function, other than the endothelial system, appears to remain intact, and the critical period of shock is brief, lasting only 24–48 hours. Hepatitis is mild, and renal function is also well maintained. Bleeding is more pronounced with AHF and BHF than Lassa fever, but it is not the cause of shock and death. Capillary leakage is significant, with loss of protein and intravascular volume being much more pronounced than loss of red cells. Proteinuria is significant, and dehydration with hemoconcentration appears to be an important process. The shock is not associated with evidence of disseminated intravascular coagulation, and even though there are petechiae suggesting some direct endothelial damage, no clear evidence of virus replication in, and damage of, endothelium has been demonstrated. Thus clinical observations suggest that vascular endothelial dysfunction may be the basis of subsequent circulatory failure in AHF and BHF. Persistent hypovolemic shock in the face of intravascular volume expanders suggests that it is due to the loss of endothelial function and leakage of fluid into

extravascular spaces. This is supported by the tissue edema frequently observed, and more directly by the pulmonary edema which may result from vigorous fluid therapy of the shock. These events lead to irreversible shock and death in the most severely ill patients. Two other observations have been made in AHF: high levels of interferon in severely/fatally ill patients, and a decrease in complement. These are general phenomena observed in other severe infectious processes and are consistent with the events described above. Neither would dictate a substantially different pathophysiologic explanation of these diseases.

Clinical Features

Lassa fever

Lassa fever begins after 7–18 days of incubation, with fever, headache and malaise. Aching in the large joints, pain in the lower back, a nonproductive cough, severe headache and sore throat are common. Many patients also develop severe retrosternal or epigastric pain. Vomiting and diarrhea occurs in between a half and two-thirds of patients. In more severely ill patients complete prostration may occur by the 6th to 8th day of illness. Patients with Lassa fever appear toxic and anxious, and in the absence of shock, the skin is usually moist from diapheresis. There is an elevated respiratory rate and pulse. The systolic blood pressure may be low. There is no characteristic skin rash; petechiae and ecchymoses are rare, nor is jaundice a feature of Lassa fever. Conjunctivitis is common, but rare conjunctival hemorrhages portend a poor prognosis. Seventy percent of patients have pharyngitis, often exudative, but few if any petechiae, and ulcers are rare. Mucosal bleeding occurs in 15–20% of all patients, and although associated with severe disease it is almost never of a magnitude to produce shock by itself. Edema of the face and neck are commonly seen in severe disease. About 20% of patients have pleural or pericardial rubs heard late in disease at the beginning of convalescence. The abdomen may be diffusely tender. The ECG may be abnormal, primarily with elevated T waves, but without a characteristic pattern. Moderate or severe diffuse encephalopathy with or without general seizures is characteristic in severe disease. Severe Lassa fever can progress rapidly between the 6th and 10th days to respiratory distress with stridor due to laryngeal edema, central cyanosis, hypovolemic shock and clinical signs of encephalopathy, sometimes with coma and seizures. Tremors are often seen in the hours just before death. Acute, focal neurological signs rarely occur, with the exception of VIIIth nerve deafness seen in convalescence. Residual ataxia is common. Lassa fever is also a pediatric disease affecting all ages of children. The disease appears to be even more difficult to diagnose by clinical criteria in children than in adults because its manifestations are so general. In very young babies marked edema may be seen, associated with very severe disease. In older children the disease may manifest as a primary diarrheal disease or as pneumonia or simply as an unexplained prolonged fever. The case fatality in children is 12–14%.

The mean white count in early Lassa fever may be low or normal, with a relative lymphopenia, but late neutrophilia may supervene in severe disease. Proteinuria is very characteristic. A serum AST (SGOT) level of >150 iu ml^{-1} is associated with a case fatality of 50%, and there is a correlation between an ever-increasing level and an increased risk of death. A viremia of $>1 \times 10^3$ $TCID_{50}$ ml^{-1} is associated with an increasing case fatality. Both factors together carry a risk of death of 80%.

Pharyngitis, proteinuria and retrosternal chest pain have a predictive value for Lassa fever in febrile hospitalized patients of 81% and a specificity of 89%. Likewise, a triad of pharyngitis, retrosternal chest pain and proteinuria (in a febrile patient) correctly predicted Lassa fever 80% of the time (in an endemic area). Both triads have sensitivities of 50% for detecting cases of Lassa fever. Significant complications of Lassa fever include a two- to threefold increased risk of maternal death from infection in the third trimester, and a fetal/perinatal loss of 84% that does not seem to vary by trimester. Another significant complication is that of acute VIIIth nerve deafness, with nearly 30% of patients suffering an acute loss of hearing in one or both ears. Other complications which appear to occur much less frequently are uveitis, pericarditis, orchitis, pleural effusion and ascites.

AHF and BHF

These diseases have an insidious onset of malaise, fever, general myalgia and anorexia. Lumbar pain, epigastric pain, retro-orbital pain, often with photophobia, and constipation occur commonly. Nausea and vomiting frequently occur. Temperature is high, reaching 40°C or above. Unlike LCM and Lassa fever, AHF and BHF do not usually lead to respiratory symptoms and sore throat. On physical examination patients appear toxic. Conjunctivitis, erythema of the face, neck and thorax are prominent. Petechiae may be observed in the axillae by the 4th or 5th days of the illness. There may be a pharyngeal enanthem, but pharyngitis is uncommon. Relative bradycardia is

often observed. The disease may begin to subside after 6 days of illness; if not, the second stage of illness supervenes, and most commonly manifests as epistaxis and/or hematemesis or acute neurological disease. The bleeding may be from mucosal surfaces or into the skin, with petechiae and hemorrhagic rash, with preceding increase in packed red cell volume. Pulmonary edema is common in severely ill patients. The appearance of intractable shock is a serious sign which becomes irreversible in some patients, and accounts for the majority of deaths from AHF and BHF. Fifty percent of AHF and BHF patients also have neurologic symptoms during the second stage of illness, such as tremors of the hands and tongue, progressing in some patients to delirium, oculogyrus and strabismus.

A low white blood cell count (under 1000 mm^{-1}) and a platelet count under 100 000 are invariable. Proteinuria is common and microscopic hematuria also occurs. Alterations in clotting functions are minor, and DIC is not a significant part of the diseases. Liver and renal function tests are only mildly abnormal.

Venezuelan hemorrhagic fever

Little information is available on the spectrum of disease caused by Guanarito virus infection. Hospitalized patients with severe diseases are febrile on admission, with prostration, headache, arthralgia, cough, sore throat, nausea/vomiting, diarrhea and hemorrhage. The bleeding includes epistaxis, bleeding gums, menorrhagia and melena. On physical examination, patients with severe disease appear toxic, and usually dehydrated. They are described as having one or more of a series of signs, including pharyngitis, conjunctivitis, cervical lymphadenopathy, facial edema and petechiae. Thrombocytopenia and neutropenia are common at admission. Case fatality of a single group of 15 hospitalized patients was over 60%; however, the single serum survey available suggests that overall mortality:infection ratio is much lower.

Pathology and Histopathology

Lassa fever

The most frequently and consistently observed microscopic lesions in fatal human Lassa fever are focal necrosis of the liver, adrenal glands and spleen. The liver damage is variable in the degree of hepatocytic necrosis. The liver demonstrates cellular injury, necrosis, and regeneration, with any or all present at death. A substantial macrophage response occurs, with little if any lymphocytic inflammatory response. Nevertheless, fatal cases do not exhibit sufficient hepatic damage to implicate hepatic failure as a cause of death. Similarly, moderate splenic necrosis is a consistent finding, primarily involving the marginal zone of the periarteriolar lymphocytic sheath. Diffuse focal adrenocortical cellular necrosis has been less frequently observed. Although high virus titers occur in other organs, such as brain, ovary, pancreas, uterus and placenta, no significant lesions have been found. Thus few clues to the pathogenesis of Lassa fever are found in standard pathological studies. It is clear that the outcome in Lassa fever is associated with the degree of virus replication; nevertheless the effect of replication is not major tissue destruction, but a more subtle biological effect on vascular endothelium, and perhaps other key cells or organs.

AHF and BHF

AHF and BHF are typical hemorrhagic diseases and have very similar pathologic features, some of which differ from Lassa fever. Patients with AHF manifest a skin rash and petechiae, and gross examination of organs at necropsy also show petechiae on the organ surfaces. Ulcerations of the digestive tract have been described, but the bleeding is not massive. Microscopic examination shows a general alteration in endothelial cells, mild edema of the vascular walls, with capillary swelling and perivascular hemorrhage. Large areas of intra-alveolar or bronchial hemorrhage are often seen with no evidence of inflammatory process. Pneumonia with necrotizing bronchitis or pulmonary emboli is observed in half of the fatal necropsied cases. Hemorrhage and a lymphocytic infiltrate have been observed in the pericardium, occasionally with interstitial myocarditis. The lymph nodes are enlarged and congested with reticular cell hyperplasia. Splenic hemorrhage is common. Medullary congestion with pericapsular and pelvic hemorrhages are frequently seen. Acute tubular necrosis occurs in about half of the fatal cases, but adrenal necrosis has not been reported.

Venezuelan hemorrhagic fever

Only a limited number of post-mortem dissections have been performed. Observations included pulmonary edema with diffuse hemorrhages in the parenchyma, and subpleural, focal hepatic hemorrhages with congestion and yellow discoloration, cardiomegally with epicardial hemorrhages, splenic and renal swelling, and bleeding into numerous cavities, including stomach, intestines, bladder and uterus.

Immune Response

There is a brisk B cell response to Lassa virus, with a classic primary IgG and IgM antibody response to virus early in the illness. This event does not, however, coincide with virus clearance, and high viremia and high IgG and IgM titers often coexist in both humans and primates. Indeed virus may persist in the serum and urine of humans for several months after infection, and possibly longer in occult sites, such as renal tissue. Neutralizing antibodies to Lassa virus are absent in the serum of patients at the beginning of convalescence, and in most people they are never detectable. In a minority of patients some low titer serum neutralizing activity may be observed several months after resolution of the disease. Passive protection with antibody to Lassa virus has been demonstrated in animals given selected antiserum at the time or soon after inoculation with virus, but clinical trials of human plasma given after onset of illness have shown little or no protective effect. Thus the clearance of Lassa virus in acute infection appears to be less dependent of antibody formation, and presumably depends more on the cell immune response. This is supported by recent experience with experimental Lassa vaccines in primates. In recent studies of LCM infection there is clearly apoptosis of T cells and probably B cells during acute infection in the mouse model. Such a scenario must be entertained for acute Lassa infection, and could help explain the fulminant course in some patients. Such work will need to be performed in primate models or during studies of human disease in endemic areas. Neutralizing and complement fixing antibody to Junin and Machupo are usually detectable 3–4 weeks after the onset of illness. Indirect fluorescent antibodies may be detected at the end of the second week of illness. The efficacy of convalescent plasma has been demonstrated in the therapy of Junin infection (see Therapy). The effectiveness of the plasma has been demonstrated to be associated with the level of Junin virus-neutralizing antibodies. The IFA test is the most commonly performed test for diagnosis by antibody detection for AHF and BHF. Little data are available on Guanarito virus, which appears to induce an antibody response. However, more like AHF and BHF, antibodies to Guanarito virus seem to appear later in illness.

Prevention and Control

Rodent control

The ideal method of prevention for these rodent-borne diseases is to prevent contact between rodents and humans. The effectiveness of this was shown in the outbreaks of BHF in the 1960s. However, the prospects of rodent control in preventing AHF are not so bright. The human–rodent encounter resulting in AHF occurs during the crop harvests, and with present technology it is difficult to imagine how control of noncommensal feral rodents could be accomplished. The best choice may be better protection of the agricultural worker from contact with rodent secretions and blood. Similarly the control of rodents as a broad approach to preventing Lassa fever is not realistic. The improvement of housing and food storage could reduce the domestic rodent population, but such changes are not easily made. Rodent trapping in an individual village where transmission is high has demonstrated as much as a fivefold reduction in the rate of virus transmission. However, such a program is only applicable in villages with exceptional transmission rates, and would certainly not be applicable to large areas.

Vaccines

The live attenuated Junin vaccine has now been shown to be not only effective, but has had a dramatic effect in reducing the number of cases of AHF seen each year in the endemic area. A vaccine against Lassa fever has been made by cloning and expressing the Lassa virus glycoprotein gene into vaccinia virus. This vaccine has proven highly successful in preventing severe disease and death in challenged monkeys. Only the glycoprotein gene is protective in the two species of monkeys thus far tested, and the basis of protection is not neutralizing antibody, which does not develop, but more likely the cell-mediated immune response.

Drug prophylaxis

In the event of identifiable exposure to Lassa virus (and possibly other pathogenic arenaviruses) in a hospital or laboratory setting, the prophylactic use of orally administered ribavirin is recommended.

Therapy

Significant advances have been made in the therapy of Junin and Lassa virus infections over the last decade. Convalescent plasma is effective in the treatment of Junin virus during the first 8 days of illness, but not Lassa virus. Ribavirin is effective in reducing the viremia and mortality of Lassa fever particularly when given in the first week of illness.

Lassa fever

Ribavirin can prevent death in Lassa fever when given at any point in the illness, but it is more effective when given early, and intravenously. Thus, patients with

risk factors for severe disease who were treated within the first 6 days of illness experienced a 5–9% case fatality. Those with the same risk factors, in whom treatment was initiated more than 6 days after the onset of illness, had a case fatality of 20–47%. Regardless, the case fatality was significantly less for ribavirin-treated patients in all categories than for either nontreated patients or for those treated with plasma alone. As such it seems reasonable to assume that it would also be an effective measure in the event of laboratory or hospital exposure to the disease. The pathogenesis of the infection is less reversible later in illness. Furthermore, patients treated with ribavirin had significant declines in viremia regardless of outcome, whereas patients who were untreated or treated with plasma and who died showed no decrease in viremia, consistent with the observation that outcome, and presumably the result of therapy, is closely related to the inhibition of virus replication. Therefore patients coming late in disease will require more effective clinical management of physiologic dysfunction, and perhaps other drugs which may be used to stabilize the shock state sufficiently long to allow recovery and improve survival (see Pathogenesis).

AHF

A randomized trial of patients with AHF demonstrated that convalescent-phase plasma reduced the mortality from 16% to 1% in the patients who were treated in the first 8 days of illness. The efficacy of the plasma was directly related to the concentration of neutralizing antibodies of the plasma.

The success of this therapy was not without a price, however, which was the development of a late neurological syndrome in about 10% of cases. Thus far there is no correlation between the day of therapy nor the dose of neutralizing antibodies given and the occurrence of late neurological syndrome. Passive antibody therapy depends on collection of plasma from persons known to have had the disease, testing the plasma (or screening the donor) for antibodies to blood-borne agents such as hepatitis, and proper storage until its use. In addition, the advent of the acquired immunodeficiency syndrome (AIDS) and the other diseases transmissible by blood products means that further screening is required before use.

BHF

Recent experience of successful treatment of two patients with intravenous ribavirin suggests that further efforts to evaluate the effectiveness of ribavirin in this disease will be worthwhile.

Future Perspectives

An important area of future research includes a more thorough understanding of the viral and host components of the virus-clearing and protective immune response in humans. A second area of substantial interest is the nature of the persistent infection in the rodent host. A more complete understanding of the pathogenesis of Lassa fever may provide insight not only to that disease, but to basic elements of how the host response may be detrimental as well as beneficial to the host. Finally, a more thorough comprehension of how to control the more widespread arenavirus diseases, either through vaccination, or preferably rodent control, is essential.

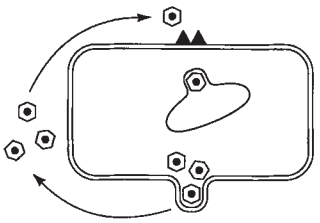
LATENCY

Jack G Stevens, University of California, Los Angeles, California, USA



Introduction

Latent infections, as they relate to animal viruses, represent one of two general mechanisms by which virus exists for extended periods in an infected host. The other mechanism, which involves continued replication of infectious virus, is termed a chronic infection. Latent infections are defined as those in which complete copies of the viral genetic information persist for extended periods by processes not requiring the continued production of infectious virus. Whichever mechanism is employed, it is important to note that unique methods of evading the immune response have evolved. In the case of latent viruses, the mechanism usually involves restrained expression of the viral genome so that immunologically relevant molecules displayed on the viral or cellular surface during the course of productive infection are not synthesized.

In all instances sufficiently documented to date, the phenomenon of latency has been limited to DNA-containing viruses or to RNA-containing viruses employing a DNA intermediate in their replicative cycle. In all these systems, the viral DNAs are conserved either by integration into the host cell chromosome (at random or specific sites) or by maintenance of plasmids (usually, but not always, as multiple copies of individual genomes). In most of the systems studied, when technologies of sufficient sensitivity were employed, the latent viral DNA was found to be transcribed and protein products were often produced. Among these products are the 'transforming proteins' associated with neoplastic alterations of latently infected cells.

There are at least two biologically important consequences of latent infection. The most notable is a later 're-activation' or reappearance of infectious virus within the individual harboring the latent infection. This event may result in the appearance of clinically apparent features, which may or may not resemble those associated with the disease evident during initial infection. The disease resulting from re-activation is often accentuated in immuno-compromised hosts; indeed, immunosuppression may play a role in the re-activation process itself. The second important consequence of the latent infection is neoplastic alteration of the latently infected cell, and the subsequent appearance of tumors. Essentially all latent agents accomplish the former; only some are responsible for the latter. Finally, although the hypothesis that latent infections can alter important functional properties of differentiated cells has been historically an intriguing one, there is no consistent evidence supporting this notion.

Viruses that Establish Latent Infections

A list of viruses capable of existing in the latent state is presented in **Table 1**. Several general statements can be made about this group. First, the kinds of cells involved are many, ranging from immature lymphocytes to terminally differentiated neurons. It should also be stressed that with many viruses, the kinds of cells harboring latent infection are likely to extend beyond those presently appreciated or postulated. Second, features of latent infection now shown only in cell culture systems (for example, integrated sequences of the HIV process) are also likely in the future to be demonstrated in cells taken from infected individuals. Third, in some latent infections, perhaps most notably those involving herpes simplex virus and papillomaviruses, viral-encoded proteins have not been detected in cells harboring the viral DNA. However, transcripts containing potential open reading frames have been found in the former, and transcripts encoding proteins that have been detected in transfected and lytically infected cells have been identified in the latter. Finally, it should be emphasized that in some instances the relative roles played by chronic and latent infection in maintenance of the persistent infection are not clearly defined. For example, even though latent infections are well appreciated in hepadnavirus and cytomegalovirus infections, a persistent viremia is also characteristic of hepadnavirus infection, and cytomegalovirus is often shed from the urine for extended periods.

The Herpesvirus Model

Additional features characteristic of latent infections can be identified through a more detailed consideration of latent infections engendered by the herpes simplex virus and Epstein–Barr virus (EBV). The herpesviruses, particularly herpes simplex virus, are the classic examples of latent agents, and latent infections are basic to their natural history.

Table 1 Latent infection in the intact host by viruses infecting humans

Virus group	*Cell type involved*	*State of DNA*	*Viral proteins present?*
Adenoviruses	B lymphocytes?	Probably integrated	Probably
Hepadnavirus	Hepatocytes, lymphocytes	Integrated	Probably
Herpesviruses			
(a) Herpes simplex 1 and 2	Neurons	Episomal	No
(b) Varicella-Zoster	Satellite cells and neurons reported	?	?
(c) Cytomegalovirus	Lymphocytes? macrophages?	?	?
(d) Epstein–Barr	B lymphocytes, epithelial cells	Usually episomal	Yes
(e) Human herpesviruses 6, 7, 8	Probably T lymphocytes	?	?
Papillomaviruses	Keratinizing epithelial cells	Integrated and episomal	No
Parvoviruses	Epithelial cells	Integrated	No
Polyomaviruses	?	Probably integrated	Probably
Retroviruses			
(a) Human T-cell leukemia viruses	T lymphocytes	Integrated	No
(b) Human immunodeficiency virus (HIV)	CD4+ T lymphocytes, probably macrophages	Episomal and probably integrated	No

Herpes simplex virus

The relevant pathogenesis of herpes simplex virus involves infection and viral replication at the body surface, followed by the passage of the virus (or, more probably, the viral nucleocapsid) to the regional sensory ganglion by fast axonal transport in the associated sensory nerve. At this juncture, two mutually exclusive events occur in the infected neuronal somas. Either (1) the five immediate early regulatory proteins encoded within the viral genome are expressed, thus initiating the 'lytic cascade' of gene expression which results in viral replication and cell death, or (2) the latency-associated transcription unit (see below) is expressed at high copy number and the latent infection is established. In the latter instance, present evidence indicates that no viral proteins are expressed, and the viral DNA does not replicate. In an individual sensory ganglion initially infected by herpes simplex virus, then, some neurons produce infectious virus and are destroyed, while others simultaneously harbor viral DNA, survive and thus become latently infected. The experiments that established these features took two general forms related to the genetic constitution of the virus employed. In one group of experiments, viruses compromised for replication were employed. These viruses were defective in genes expressing thymidine kinase, the virion-associated transcription factor αTIF, the immediate early regulatory protein ICP0, or the immediate early regulatory protein ICP4. In all instances, latent infections were established, indicating that extensive genetic expression and viral replication are not required for establishment of the latent infection. Studies with the ICP4 negative mutants were particularly instructive, since cells infected with these agents do not replicate viral DNA and transcription is qualitatively drastically limited. In the other groups of experiments, replicating viruses were employed. Neurons found to express viral proteins did not transcribe from the latency-associated transcript promoter, and vice versa. In addition, experiments of several designs indicated that viral DNA did not replicate during establishment of the latent infection. In studies of a different design, neurons in ganglia with no evidence of prior acute viral infection were later found to be latently infected. Taken together, these studies indicate that viral DNA replication and expression of viral proteins are not associated with establishment of the latent infection. Thus, the 20 or so viral plasmids known to be present in each latently infected neuron consist of input DNA, and the neuron controls establishment of the latent infection. How this occurs is unknown, but specific transcription factors seem likely to play important roles. Expression of these factors may well be related in some way to the different, mutually exclusive, surface markers that have been identified on sensory neurons destined to become latently infected compared to those that are lytically infected. Thus, most neurons that are latently infected are SSEA-3 antigen positive and LD-2 antigen negative; those lytically infected may be either SSEA-3 or LD-2 antigen positive.

Recent studies of the molecular aspects of herpes simplex virus latency have been based largely on the discovery some 5 years ago of latency-associated transcripts. These transcripts are encoded from the long terminal repeat region of the viral genome, and the principal unit appears to be an 8.5 kb transcript the synthesis of which initiates downstream from, and on the opposite DNA strand to, that encoding the immediate early regulatory protein ICP0. This transcript extends across the ICP0 coding region and terminates in the short terminal repeat region just downstream from the termination of the ICP4 (also an immediate early regulatory gene). Several derivatives of the latency-associated transcription unit are present in latently infected cells, the most prominent being a 2.0 kb stable intron present in more than 10^4 copies per nucleus of each latently infected neuron. The 8.5 kb transcription unit and its derivatives appear to be the only transcripts present in latently infected cells, and genetic experiments involving deletion mutants have shown that these RNAs play no role in either establishment or maintenance of the latent infection in mice or rabbits. Both of these major events can take place with no expression from the viral genome.

To restate and emphasize the important features of herpes simplex virus which have just been presented, establishment and maintenance of the latent infection appear to be neuronal functions. Multiple copies of input viral DNA are maintained in sensory neurons as single-copy episomes which express latency-associated transcripts. There is no evidence that any of these transcripts are translated into proteins, and a principal derivative persists as a stable intron in neuronal nuclei.

The latent infection is maintained for the life of the infected individual, and essentially all persons seropositive for herpes simplex virus 1 harbor latent infection in sensory neurons in trigeminal ganglia. In a subset of these individuals, clinically apparent reactivations occur periodically, and virus, or at least viral genetic information, is thought to pass intraaxonally to neuroepithelial junctions where infection of epithelial cells results in productive infection and, ultimately, lesions. The molecular basis for the reactivation is not understood, but in the rabbit ocular model in which re-activation from trigeminal ganglia

is efficiently induced by iontophoresis of epinephrine through the cornea, some derivative of the 8.5 kb latency-associated transcription unit plays a significant role. Thus, viruses with deletions in the transcription unit do not re-activate following the induction process. Additional viral genes active in this process have yet to be identified. Finally, although it has been known for over 20 years that *in vitro* cultivation of latently infected ganglia would result in 're-activation' of the virus, it is not known whether the same process occurs in latently infected ganglia *in situ*.

Epstein–Barr virus

The process just described is considerably more simple than that undergone by the related EBV. The major biologic difference relates to the fact that while herpes simplex virus latently infects a terminally differentiated cell, EBV establishes this infection in B lymphocytes (and probably pharyngeal epithelial cells) which subsequently divide. Obviously, in this case, a method has to be derived for replicating the approximately 50 single-copy episomes present in these latently infected cells, and distributing them to daughter lymphocytes. In addition, the fact that EBV is oncogenic implies that viral gene products play a role in the neoplastic process. These phenomena would predict that the viral protein products now known to be expressed in latently infected cells would, in fact, be present.

As presently understood, the virus infects via the nasopharynx, productively infecting epithelial cells in this area, and secondarily infecting B lymphocytes, which then harbor latent virus for the life of the individual. Whether or not these cells have the basic properties of 'immortalized' B cells which carry EBV genomes in culture systems is not known. Although virus is shed from the nasopharynx for extended periods, the best evidence indicates that this is not a requirement for maintenance of a latently infected B lymphocyte. However, the converse may well be true. That is, B lymphocytes may re-activate in the nasopharynx, supplying virus that maintains the nasopharyngeal infection. Alternatively, the long-term active infection of the nasopharynx may be a chronic infection not requiring re-infection for maintenance.

The 'classic' latently infected immortalized B cell in culture expresses some nine EBV-encoded proteins six of which [the Epstein–Barr nuclear antigens (EBNA)] are translated from one basic transcript which undergoes very long-range splicing events with some derivatives being bi- or poly-cystronic. Only one of the EBNA proteins, EBNA-1, appears to be crucial to the latent phase, since it is the only one known to be universally present in cells harboring the EBV genome. This molecule binds to the EBV DNA origin of replication employed for plasmid replication by the host-cell-encoded DNA polymerase and enables molecules to replicate and persist as episomes. For completeness, it should be noted that a different origin of DNA replication and the viral-encoded rather than the host-cell-encoded polymerase, are employed for the EBV lytic infection. Other EBNA molecules are known to function in the cellular immortalization process, or possess functions unknown at present. The other three proteins (LMP-1, 2a, 2b) target the cellular cytoplasmic membranes, and LMP-1 is known to be involved in the immortalization process. From all of this it is clear that, unlike the process with herpes simplex virus, EBV viral genetic expression is crucial to establishment and maintenance of the latent infection.

The process of EBV re-activation is better understood than is the process described for herpes simplex virus. As with herpes simplex virus, *in vitro* cultivation of latently infected EBV cells may result in re-activation and replication of infectious virus in some lymphocytes. A number of other stimuli, including *n*-butyrate, the phorbol ester tumor promoter 12-O-tetradecanol phorbol 13-acetate (TPA) and calcium ionophores may increase the number of cells producing virus. Whatever the inducing agent, it seems likely that a common pathway exists involving initial expression of the ZEBRA protein [from the *BamZ* leftward open reading frame number one (BZLF-1)] from the viral genome. Expression of this gene is repressed (by unknown, but obviously very important, mechanisms) in latently infected cells. Induction of the protein is followed by expression of early genes, and the entire viral replicative cycle may then follow. The precise nature of this induction is unknown, but probably involves some mechanism of direct transcriptional activation occurring in conjunction with cellular transcription factors, since ZEBRA is a DNA-binding protein with homologies and binding-site properties similar to the *fos–jun* family of cellular-derived oncogenes.

Summary and Future Perspectives

An overview of latent infections as they relate to virus infection of human beings has been presented. Although, as **Table 1** indicates, viruses comprising several major groups are capable of persisting in this state, in essentially all cases the latent genome persists as DNA. As the discussion of herpesviruses emphasizes, beyond this fundamental property the molecular characteristics of the latent state vary greatly. For

example, genomes may be integrated or exist as episomes, transcripts and proteins may or may not be present, latently infected cells may or may not divide, and the latent state may be accompanied by alterations in basic cellular properties, including the induction of neoplasia.

Increasingly, the general medical significance of latent viral infections is being recognized. For example, latent viral infections are fundamental to the natural history of such major syndromes as AIDS and viral hepatitis. Adequate control of these and other diseases in which latent infections play significant roles can be intelligently planned and achieved when a more precise basic understanding of the latent infection is obtained.

LUTEOVIRUS (*LUTEOVIRIDAE*)

W Allen Miller, Department of Plant Pathology, Iowa State University, Ames, Iowa, USA

Taxonomy

Luteoviridae are spherical, phloem-limited, aphid transmitted plant viruses, containing a positive-sense genomic RNA. In 1998, the International Committee on the Taxonomy of Viruses (ICTV) raised the luteovirus group to the level of family. The new *Luteoviridae* family now contains three genera: the genus *Luteovirus* (formerly known as luteovirus subgroup I), the genus *Polerovirus* (formerly known as luteovirus subgroup II), and the genus *Enamovirus* which consists solely of pea enation mosaic virus-1. This entry refers only to the luteoviruses and poleroviruses. Another entry discusses the genus *Enamovirus*. Members of the *Luteovirus* and *Polerovirus* genera have distinctly different genome organizations, cytopathological effects and serological properties. The differences and similarities between the two genera will become evident throughout this entry.

A list of *Luteoviridae* and their vectors is shown in **Table 1**. Barley yellow dwarf virus (BYDV), beet western yellows virus (BWYV) and potato leafroll virus (PLRV) are the best characterized, so most discussion will focus on these. Several viruses on this list may be strains of a single virus, because *Luteoviridae* (1) are difficult to identify by sympto-

Members of the *Luteovirus* and *Polerovirus* genera have distinctly different genome organizations, cytopathological effects and serological properties. The differences and similarities between the two genera will become evident throughout this entry.

A list of *Luteoviridae* and their vectors is shown in **Table 1**. Barley yellow dwarf virus (BYDV), beet western yellows virus (BWYV) and potato leafroll virus (PLRV) are the best characterized, so most discussion will focus on these. Several viruses on this list may be strains of a single virus, because *Luteoviridae* (1) are difficult to identify by sympto-

Table 1 *Luteoviridae* classification

Virus	*Abbreviation*	*Vector*[a]
Luteovirus genus		
Barley yellow dwarf-PAV	BYDV-PAV	*Rhopalosiphum padi, Sitobion avenae*
Barley yellow dwarf-MAV (rice giallume)	BYDV-MAV	*S. avenae*
Probable *Luteovirus*		
Soybean dwarf[b] (strawberry mild yellow edge)	SBDV	*Aulacorthum solani*
Subterranean clover redleaf	SCRLV	*A. solani*
Polerovirus genus		
Cereal yellow dwarf-RPV (formerly BYDV-RPV)	CYDV-RPV	*R. padi*
Beet western yellows (malva yellows) (turnip mild yellows)	BWYV	*Myzus persicae*
Beet mild yellowing	BMYV	*M. persicae*
Cucurbit aphid-borne yellows	CABYV	*M. persicae, Aphis gossypii*
Potato leaf roll (Solanum yellows) (tomato yellow top)	PLRV	*M. persicae*
Probable *polerovirus*		
Barley yellow dwarf-RMV	BYDV-RMV	*Rhopalosiphum maidis*
Carrot red leaf	CRLV	*Cavariella aegopodii*
Cereal yellow dwarf virus – GPV (formerly BYDV-GPV)	CYDV-GPV	*Schizaphis graminum*
Groundnut rosette assistor	GRAV	*Aphis craccivora*
Genus uncertain (*Luteovirus* or *Polerovirus*)		
Barley yellow dwarf-SGV	BYDV-SGV	*Schizaphis graminum*
Bean leaf roll = pea leaf roll (pea leaf roll) (Michigan alfalfa) (legume yellows)	BLRV	*M. persicae*
Chickpea stunt associated	CpSaV	*M. persicae*[c]
Sweet potato leaf speckling	SPLSV	*Macrosiphum euphorbiae*
Tobacco necrotic dwarf	TNDV	*M. persicae*
Solanum yellows	SYV	*M. persicae*
Indonesian soybean dwarf	ISDV	*Aphis glycines*
Enamovirus genus		
Pea enation mosaic virus-1	PEMV-1	*M. persicae*

Synonyms are in parentheses. Probable members of genera have been assigned by the author, not the ICTV.
[a]For each virus, the best characterized vector is shown. In some cases, several aphid species serve as vectors.
[b]Has been proposed to be in a third subgroup owing to structural genes that are most closely related to those of poleroviruses, and absence of ORF 6.
[c]Less than 10% transmission efficiency.
Modified from D'Arcy *et al* (1999).

matology, (2) are difficult to purify, (3) show varying degrees of serological crossreactivity, and (4) vary in host range, depending on the isolate. For example, soybean dwarf (SBDV) and subterranean clover red leaf (SCRLV) viruses are so closely related serologically that they may be strains of the same virus. However, a Mississippi isolate of SCRLV is unable to infect soybeans.

In contrast to potentially synonymous viruses, BYDV has been split into two viruses. Originally, five serotypes were defined by the different aphid vectors that transmit them (**Table 1**). Furthermore, isolates of a serotype can vary greatly in symptom severity in a given host, and one isolate can cause widely varying symptoms in different hosts. Because of major differences in genome organization and cytopathology, BYDV serotypes have been divided among luteoviruses and poleroviruses. BYDV-PAV and BYDV-MAV are closely related strains of BYDV, the only official luteovirus; while the former BYDV-RPV is now called cereal yellow dwarf virus-RPV and assigned to the *Polerovirus* genus.

Geographic Distribution

BWYV, PLRV, BYDV and carrot red leaf virus (CRLV) have worldwide distributions. BYDV or cereal yellow dwarf virus (CYDV) have been reported virtually wherever wheat, barley or oats are grown. Tobacco necrotic dwarf virus (TNDV) and SBDV are

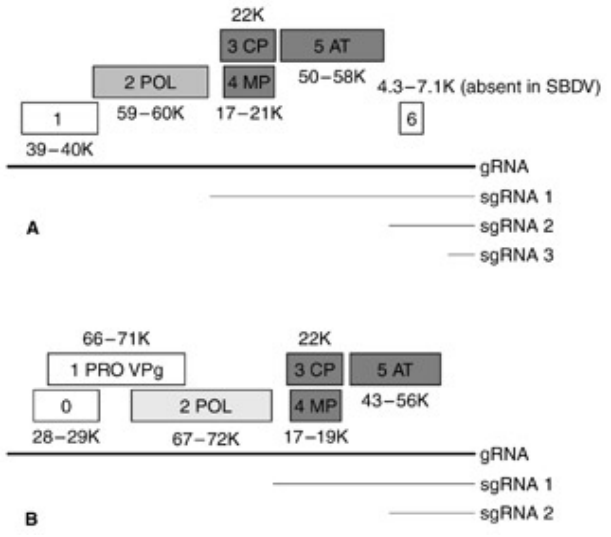

Figure 1 Genome organizations of *Luteoviridae:* (**A**) *Luteovirus*; (**B**) *Polerovirus*. Molecular weights of proteins encoded by each ORF are indicated in kilodaltons (K). Unshaded, no homology to known proteins; checkered, highest homology to diantho- and carmoviruses; light shading, highest homology to sobemoviruses; dark shading, highest homology to other *Luteoviridae*. Functions of proteins are indicated where known: PRO, putative protease; VPg, genome-linked protein; POL, RNA-dependent RNA polymerase; CP, coat protein; AT, aphid transmission; MP, probable movement protein. Positions of subgenomic RNAs (thinner lines) are indicated below genomic RNA (bold line).

limited to Japan. Isolates of SCRLV, which have been considered synonymous to SBDV, occur in Australia and the southern USA, but the American isolate does not infect soybean. Groundnut rosette assistor virus (GRAV) occurs only in Africa.

Host Range

Most luteoviruses have limited host ranges. BWYV stands out with its very wide range of dicotyledonous hosts, although very few isolates actually infect beets. In contrast, the more common beet-infecting luteovirus is beet mild yellowing virus (BMYV). Because PLRV, which is limited to the *Solanaceae*, and BWYV both have the same vector, host range is not determined merely by the host range of the vector. BYDV and CYDV infect most if not all members of the *Graminae*. CRLV is the only luteovirus known to infect the *Umbelliferae*.

Virus Structure and Composition

Luteoviridae particles are icosahedral, $T = 3$, with a diameter of 24–30 nm. They contain 180 subunits of a 22 kDa coat protein. A small, undetermined number of coat protein subunits contain an additional 50–53 kDa polypeptide fused to the C-terminus, produced by translational readthrough of the coat protein gene stop codon. The virion is 28% RNA by weight. It contains a 5.5–6 kb genomic RNA. A genome-linked protein (VPg) with reported molecular weights of either 7 kDa (PLRV) or 17 kDa (CYDV) is attached covalently to the 5′ end of the genomic RNA of poleroviruses. BYDV RNA lacks a VPg or any other known modification. The 3′ end of the genomic RNA contains neither a poly(A) tail nor a tRNA-like structure.

Replication

Genome organization

Luteoviridae have a positive-sense RNA genome encoding 5–6 open reading frames (ORFs) (**Fig. 1**). Different genome organization is a major distinction between the *Luteovirus* and *Polerovirus* genera (**Fig. 1**). Poleroviruses have a gene (ORF 0) at the 5′ end of the genome that encodes a 28–29 kDa protein (P0) which is absent in luteoviruses. Luteoviruses contain an ORF encoding a 4–7 kDa protein (P6) that is absent in poleroviruses. SBDV, while resembling luteoviruses in untranslated sequences, RNA-dependent RNA polymerase (RDRP), and genome organization, lacks ORF 6 and is more homologous to poleroviruses in the structural genes.

Protein functions

The functions of P0 and P6 are unknown. The products of ORFs 0, 3, 4, 5 and 6 are unnecessary for RNA replication in protoplasts, but some of them can increase the accumulation of viral RNA. The product of ORF 2 is expressed only as a C-terminal fusion with ORF 1 (P1–2). ORF 2 encodes the RDRP component of the replicase. P1 of poleroviruses contains the catalytic triad of amino acids conserved among cysteine proteases. Downstream of this region, but upstream of the frameshift site, P1 also contains the VPg amino acid sequence. Thus, the VPg is made available presumably by proteolytic cleavage of P1 and/or P1–2. P3 is the major coat protein (CP). A minor portion of the coat proteins produced in infection consists of a fusion of P3 and P5 made by translational readthrough of the ORF 3 stop codon. P4 is necessary for systemic infection of plants by BYDV, but not by BWYV. Evidence supports a role in cell-to-cell movement for P4 of PLRV: it is associated with plasmodesmata and fragments of this phosphorylatable protein have noncovalent, nonspecific single-stranded nucleic acid binding properties. The P3–5 translational readthrough product is often

found cleaved about midway in the P5 domain. The N-terminal portion of P5 is necessary and sufficient (when fused to coat protein on virions) for aphid transmission. The C-terminal portion of P5 may be involved in virus movement within the plant, at least for BWYV.

Transcription

Although only the genomic RNA is encapsidated, subgenomic (sg) RNAs are produced by RNA-templated transcription in the infected cell. ORFs 3, 4 and 5 are translated from subgenomic mRNA 1 (sgRNA1) (**Fig. 1**). In BYDV, smaller sgRNAs 2 and 3 are also produced. These RNAs may serve a regulatory function. sgRNA2 is predicted to be an efficient message for ORF 6 and functions as such *in vitro*. In cells infected with PLRV or cucurbit aphid-borne yellows virus (CABYV), sgRNA2 may also be a message for small ORFs. Presence of the ST9-associated RNA increases the abundance of sgRNA2 in BWYV-infected cells (below).

All sgRNAs are 3′-coterminal with the genomic RNA and are present in abundance that is roughly inversely proportional to their size. The 5′ termini of sgRNAs and genomic RNA begin with common sequences. In poleroviruses, sobemoviruses and dianthoviruses this sequence is ACAAAA. In luteoviruses the consensus is AGUGAAGA. These sequences or their complements are likely involved in replicase promoters. The ACAAA motif is unusually abundant throughout the genomes of all luteoviruses.

Translation

Luteoviridae employ a plethora of rare translational events to control gene expression. BYDV RNA lacks a 5′ cap (m^7GpppN). A sequence located, surprisingly, in the 3′ end of the genome facilitates efficient cap-independent translation. The polymerase gene (ORF 2) is expressed only via a '−1' ribosomal frameshift that occurs during translation of ORF 1 in the region where the two ORFs overlap. At a low frequency, elongating ribosomes slip back one nucleotide, moving from ORF 1 to ORF 2, resulting in a low abundance fusion protein comprising these two ORFs. Ribosomal frameshifting facilitates synthesis of low levels of polymerase, an enzyme needed in only small quantities, and high levels of its N-terminal region, P1, whose function by itself is unknown. Some of the *cis*-acting signals that mediate this event – a shifty heptanucleotide followed by a highly structured sequence – are similar to those which induce −1 frameshifting in translation of the polymerases of corona viruses and retroviruses. However, in the case of BYDV, sequences located several kilobases downstream in the 3′ untranslated region of the genome, are also necessary for frameshifting. This differs dramatically from other known frameshift signals.

Translation initiates at the start codons of ORFs 3 and 4 by leaky scanning on sgRNA1. This mechanism may also apply to translation of the overlapping ORFs 0 and 1 from genomic RNA of poleroviruses. ORF 5 is expressed by occasional in-frame read-through of the coat protein stop codon, giving rise to the P3–5 fusion protein. A nucleotide tract harboring 8–16 multimeric CCXXXX repeats just downstream of the ORF 3 amber stop codon, as well as a sequence about 750 nt downstream, are necessary for read-through.

Luteoviridae-associated RNAs

A 322 nucleotide satellite RNA (satCYDV RNA, formerly satRPV or sBYDV RNA) was discovered in an Australian isolate of CYDV-RPV. satCYDV RNA replicates by a symmetrical rolling circle mechanism. Hammerhead self-cleavage structures exist in the plus (encapsidated) and minus strands of the RNA. satCYDV RNA reduces CYDV-RPV helper virus levels and ameliorates disease symptoms in infected oat plants. It is not supported by BYDV, but its replication is supported by BWYV in dicotyledonous hosts. Thus, a component provided by poleroviruses is necessary for replication, and the host range of the helper virus may define the satellite's host range.

Additional RNAs have been found associated with a severe isolate of BWYV called ST9 and with CRLV. These 3 kb RNAs encode RDRP sequences that are more similar to luteovirus RDRPs than those of poleroviruses, to which BWYV and CRLV belong. They can replicate independently in protoplasts, but depend on their helper viruses for encapsidation and efficient spread in plants. Both of the associated RNAs enhance accumulation of their helper viruses. This typifies a phenomenon in *Luteoviridae* in which RNAs harboring luteovirus-like and polerovirus-like RDRP genes, enhance each others' accumulation. These cross-enhancing interactions range from mixed infections of BYDV and CYDV viruses, to complete interdependence of two such RNAs in pea enation mosaic virus (PEMV). PEMV, the sole member of the *Enamovirus* genus, consists of two particles. Each PEMV RNA can replicate autonomously in plant cells, but both are required to form a viable agent in the field. PEMV1 has a polerovirus-like RDRP while the PEMV2 RDRP resembles those of luteoviruses and umbraviruses.

Evolution

As discussed above, the 5′ halves of the genomes of the *Luteoviridae* have two separate origins (**Fig. 1**). The RDRP genes of luteoviruses are most similar to the RDRP genes of the umbra- carmo-, tombus- and dianthoviruses. The RDRP genes of poleroviruses are more closely related to those of the sobemoviruses than to those of luteoviruses. In contrast, the genes in the 3′ halves of the genomes of all *Luteoviridae,* are more similar to each other than to genes of any other virus family or genus. Hence, these must be the genes that confer the biological properties that make the *Luteoviridae* a distinct family. Because of the divergent origins of luteoviral genomes it is obvious that *Luteoviridae* do not descend from a common ancestor. Instead, horizontal exchanges of genes must have occurred to generate the two main genera.

Additional divergence between halves of the genome exists within genera. BWYV and BMYV have around 90% amino acid sequence identity in the structural genes, but less in the polymerase genes and only 25% and 34% identity in ORFs 0 and 1, respectively. Yet BMYV and CABYV are 42% and 49% identical in these ORFs but only 63% identical in the CP and 39% identical in the P5 domain. Similarly, Mexican and Californian isolates of CYDV-RPV are 90% identical to the New York CYDV-RPV isolate in structural genes, but show no homology in ORF 0 detectable by northern blot or polymerase chain reaction (PCR).

The sharpest point of divergence in sequence homology both within and between subgroups is at or near the region that separates the RDRP and structural genes. This is also the site of the promoter for sgRNA1. Thus it is possible that recombination occurs by replicase strand-switching at sgRNA promoters.

Comparison of luteovirus sequences with other viruses has revealed striking evolutionary relationships. The genome organization of PEMV1 RNA is similar to that of poleroviruses, except that it lacks ORF 4, and ORF 5 is only 33 kDa. All the ORFs of RNA1 show clear similarity to those of other *Luteoviridae,* which is why it has been placed in this family. In contrast, while ORFs 1 and 2 of PEMV2 RNA resemble those of the luteoviruses, they are most closely related to the umbraviruses which, like PEMV2 RNA, lack structural genes. Thus PEMV2 has been placed in the *Umbravirus* genus. PEMV may have originated as a mixed infection of an umbravirus and a polerovirus, with the former RNA providing a movement protein gene that confers the ability to spread beyond the phloem, allowing mechanical transmission.

Serologic Relationships

Luteoviridae have been compared extensively by ELISA. They can be clustered into the following subsets based on high serological crossreactivity: (1) BYDV-MAV, BYDV-PAV and BYDV-SGV; (2) CYDV-RPV, BYDV-RMV and RGV; (3) SBDV, SCRLV and BLRV; and (4) TNDV, PLRV and TYTV. BWYV reacts at least slightly with antibodies to nearly all *Luteoviridae.* All antibodies to BWYV crossreact with BMYV.

Epidemiology

The spread of *Luteoviridae* depends primarily on the movement of aphids that carry them. The mere presence of a large population of aphids is not sufficient to predict virus spread. The species of aphid and the predominant strain of virus are important factors. For instance, if a large population of *Sitobion avenae* accumulates in an oat field infected only with CYDV-RPV, these aphids are unlikely to spread the virus because *S. avenae* is a poor vector for CYDV-RPV. *Luteoviridae* are spread by aphids that colonize their host, rather than those that exhibit short probing behavior before moving on. The aphid must feed on phloem tissue to acquire and spread the virus. Because the virus must circulate and then accumulate in the accessory salivary gland of the aphid, a latent period of 8–24 h is necessary between the time the virus is acquired and the time it can be transmitted.

Because the virus is persistent, aphids can travel thousands of miles in jet streams over several days, and still transmit the virus. This is important because crops can become infected by a different strain of the virus than is found in the weeds in or near the field. On the other hand, neighboring crops and weeds often serve as reservoirs. Irrigated corn, weeds and nonweedy wild grasses can serve as symptomless hosts of BYDV or CYDV, from which the viruses are transferred to wheat, barley or oat crops by aphids. The timing of aphid infestation is important. A relatively small population of aphids can cause significant damage by infecting a crop when seedlings are young. When older plants are inoculated, the disease causes less damage.

Transmission and Tissue Tropism

Aphid transmission

With the exception of PEMV, *Luteoviridae* are transmitted to plants only via aphid vectors. Protoplasts can be inoculated by electroporation and whole plants have been infected by inoculation with *Agrobacterium* harboring a full-length clone of the BWYV

genome in the Ti plasmid. Thus, the aphid does not supply a factor required for infection, rather its feeding likely serves as a very efficient delivery system. *Luteoviridae* are transmitted in a persistent, circulative manner, i.e. they circulate in the hemocele of the aphid. Once an aphid acquires a luteovirus, that virus can be transmitted throughout the life of the aphid, even after moltings. *Luteoviridae* do not replicate in aphids.

Luteoviridae have highly specialized relationships with their aphid vectors. This allowed differentiation of BYDV/CYDV strains based on their predominant aphid vectors (**Table 1**). Heterologous encapsidation in mixed infections can allow transmission of a genomic RNA of one strain by a vector of another. This phenomenon explains transmission of some virus complexes. CRLV allows the non-*Luteoviridae* carrot mottle umbravirus (CMoV) to be transmitted by *Cavariella aegopodii* in a persistent fashion because some CMoV genomic RNAs are encapsidated in particles containing CRLV coat protein. Similarly, groundnut rosette umbravirus is not transmissible in the absence of groundnut rosette assistor virus (GRAV) which, by itself, causes little damage.

The mechanism of virus transmission and vector specificity has been examined ultrastructurally by Gildow. He showed that the virus is specifically transported across three barriers: the hindgut epithelium, and the basal lamina and plasmalemma of the accessory salivary gland. Particles are then released into the phloem via the salivary duct as the aphid feeds. The particles appear to cross both the hindgut epithelium and the accessory salivary gland plasmalemma via receptor-mediated endocytosis in coated vesicles. *Luteoviridae,* but not other plant viruses, can cross the hindgut into the hemocele even in nonvector aphid species. However, only those virions that can be transmitted by the aphid can cross the plasmalemma of the accessory salivary gland. A highly abundant protein, called symbionin, that is produced by endosymbiotic bacteria (*Buchnera* spp.) in the hemocele, binds the readthrough domain of the virus particle. This protein resembles the chaperonin groEL, and may be involved in maintaining particle stability in the hemolymph.

Tissue tropism

Luteoviridae are generally confined to the phloem, including phloem parenchyma, companion cells and sieve elements. The exception is PEMV which can infect mesophyll cells and spread systemically, allowing it to be transmitted mechanically. The blockage of sieve tubes and degeneration of vascular tissue may account for the disease symptoms, although severity of disease symptoms does not always correlate with the amount of virus accumulating in the plant. Under laboratory conditions, protoplasts derived from mesophyll, epidermis, xylem and undifferentiated tissue can be infected with *Luteoviridae*. Thus, *Luteoviridae* do not require conditions found only in phloem cells, but rather their limitation to the phloem may be a result of their lack of ability to move from cell-to-cell into other tissues. Some evidence indicates that in whole plants, PLRV can be found in low levels in mesophyll cells.

Pathogenicity

Symptomatology

Symptoms caused by *Luteoviridae* are often difficult to identify clearly. In general, *Luteoviridae* cause stunting of plants, yellowing, reddening or 'rolling' of leaves, and an increase in leaf brittleness. Because symptoms may be confined to stunting or a change in leaf color that is not an obvious mosaic or mottle, luteovirus infection can be confused with nutritional deficiencies or other environmental stresses. Environmental factors also affect symptoms. Cool temperatures and high light maximize changes in leaf color. The most common symptom caused by BYDV or CYDV is stunting. As their names imply, they cause yellowing in many lines of barley. They can induce bright reddening of leaf tips in oats, corn and other grasses. This can be confused with the effects of frost. In oats, BYDV causes a marked increase in sterile florets. This, combined with reduced kernel weight caused by BYDV in oats and barley, greatly reduces grain yield. Symptoms can vary between hosts. A BYDV isolate called PAV129 is virtually symptomless in wheat from which it was isolated initially, but it is very severe in oats, including cultivars that are resistant to other isolates. BWYV induces bright yellowing of leaves on sugar beets, lettuce and spinach. In addition to leaf curling, PLRV causes net necrosis, a blackening of the vascular tissue in the tuber. Unlike most plant viruses, TNDV can kill its host in natural infections, as can BYDV under laboratory conditions.

Cytopathology

The cytopathology of *Luteoviridae* has been characterized best for BYDV and BWYV. Cells infected by luteoviruses show: (1) extreme distortion of the nucleus, and aggregation and accumulation of densely staining, heterochromatin-like material; (2) accumulation of new virus particles in the cytoplasm; and (3) single-membraned vesicles containing fibrils in the cytoplasm. Cells infected by poleroviruses show: (1)

relatively normal nuclei at first, until the heterochromatin slowly disintegrates; (2) accumulation of new virus particles around the nucleolus; and (3) cytoplasmic vesicles containing fibrils enclosed in a second membrane.

Prevention and Control

Several strategies have been used to manage *Luteoviridae*. These include: (1) avoidance of aphids through careful monitoring of aphid populations and timing of planting; (2) use of insecticides or parasites to reduce aphid populations; and (3) use of crops that are genetically resistant to *Luteoviridae*. For control of BMYV in England, an equation involving the abundance of vector *Myzus persicae* in the autumn and the number of frost days in the winter is used to predict the arrival of aphids the following spring. If the predicted infestation is high, seeds pretreated with insecticide are recommended. An additional spray warning system is used after aphids have begun to colonize plants. If aphids exceed a threshold, growers are advised to spray insecticides. For BYDV hosts, sowing fall and spring cereals after major aphid migrations will reduce the chances of aphid colonization. However, this strategy reduces the time available for the crop to reach maturity and thus may reduce yield. The use of insecticides to control *Luteoviridae* is cost-effective only in areas of extremely intensive agriculture, such as wheat fields in England and potato fields in the northwestern USA. Parasitic wasps have proved to be effective biological control agents, reducing BYDV spread in South America, but their ability to control aphids is often limited.

A BYDV resistance gene, *Yd2*, from Ethiopian barley has been introduced into some commercial lines of barley. This has greatly reduced losses in California and elsewhere. However, this resistance has broken down in some cases, and is linked to undesirable traits. Tolerance to BYDV in oats is a quantitative trait. Resistance to BYDV has been introduced into wheat from *Thinopyron* species by alien gene introgression. However, the lines obtained to date still carry too many nonagronomic traits from the wild relative to be released as agronomically acceptable seed.

Plants that have been genetically engineered to express the coat protein of PLRV show delayed disease development and reduced symptoms when challenged with PLRV. Highly virus resistant Russet Burbank potatoes and oats have been obtained by transformation with the polymerase genes (ORFs 1 and 2) of PLRV and BYDV, respectively. Owing to the recombinogenic nature of the *Luteoviridae* genome on an evolutionary time scale, and the potential synergistic interactions between genomes, forethought must be used in designing and deploying *Luteoviridae* genes as resistance transgenes.

Economic Significance

The *Luteoviridae* family is one of the more economically significant plant virus families because BYDV, CYDV, PLRV and BWYV are ubiquitous, and cause significant losses in major crops. Because they often occur every year and are often not diagnosed, it is impossible to put an accurate dollar value on the losses due to *Luteoviridae*. Natural BYDV infection can cause average annual losses of 11–33%, and in some areas up to 86%. If BYDV caused 5% losses in 1989, it would have been valued at $US387 million for wheat, $US48 million for barley and $US28 million for oats. BYDV usually causes more obvious damage to oats and barley than to wheat. But due to the extensiveness of wheat production, the reduction in yield caused by BYDV, however slight, probably adds up to a significant monetary loss. The losses to BYDV in wheat are probably greater in North Africa, China and in tropical regions.

Infection of sugar beet with BMYV at an early stage in plant development can decrease root yield by 30%. Losses valued as high as £13 000 000 occur in BMYV epidemics in the UK. BWYV caused increasingly severe damage to sugar beets in California between 1951 and 1968. Beginning in 1968, the use of more resistant varieties of sugar beets and phytosanitary cropping practices greatly reduced the incidence of BWYV infection. The ensuing increase in yield, credited largely to the reduction in BWYV incidence, was estimated at $US167 million for a 5 year period in the state of California alone. Artificial inoculation of oilseed rape with BWYV resulted in 25% yield loss. BWYV has also been reported to cause significant losses in spinach, lettuce, turnips, cabbage, many brassicas, pea and flax at various locations around the world.

Groundnut rosette disease, caused by the complex of groundnut rosette virus and GRAV, is one of the most severe limitations to peanut production in Africa. The net necrosis symptom of PLRV makes potatoes unmarketable. Thus, yield loss in infected plants can be 100%. The value of the losses is so high that growers are anticipated to be willing to pay a premium for commercially produced transgenic potatoes with engineered resistance to PLRV. This, combined with engineered resistance to other viruses and insects in this potato variety, should reduce the need to apply high levels of insecticides that are

currently used to control the aphid vector of PLRV and other insect pests.

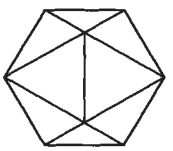
LYMPHOCYSTIS DISEASE VIRUS (*IRIDOVIRIDAE*)



Christian A Tidona and **Gholamreza Darai**, Institute for Medical Virology, University of Heidelberg, Heidelberg, Germany

History

Lymphocystis disease virus (LCDV) is the causative agent of lymphocystis disease (LD), which has been reported to occur in over 100 different fish species in fresh water and salt water worldwide. These include species that are of particular importance for fisheries and fish farming. LCDV infection frequently appears in *Pleuronectidae* (flatfish), such as *Platichthys flesus* (flounder), *Pleuronectes platessa* (plaice), and *Limanda limanda* (dab). LD of fish was first described in 1874 by Lowe. The term lymphocystis cell was used when Woodcock (1904) considered it a life stage of a parasite infecting flatfish. The viral aetiology was proposed by Weissenberg in 1914. The first electron microscopic observation of the virus was made in 1962 by Walker.

Taxonomy and Classification

LCDV is classified in a separate genus (*Lymphocystivirus*) within the family *Iridoviridae*. Iridoviruses are relatively large icosahedral cytoplasmic deoxyriboviruses that have been isolated from insects and vertebrates. LCDV type 1 (LCDV-1) occurs in flounder and plaice; LCDV type 2 (LCDV-2) was isolated from dab.

Properties of the Virion

The nonenveloped LCDV particles accumulate in the cytoplasm of the infected lymphocystis cells (**Fig. 1A**). The virions are characterized by an icosahedral morphology with diameters of 227.5 ± 12.5 nm (flounder; **Fig. 1B**), 198.8 ± 12.9 nm (plaice), and 200.5 ± 12 nm (dab) respectively. The outer capsid of the virion is separated from the electron-dense concentric core by an intermediate lipid layer (**Fig. 1C, D**).

Properties of the Virus Genome

The LCDV particles contain a single linear double-stranded DNA molecule that has been characterized

currently used to control the aphid vector of PLRV and other insect pests.

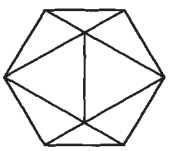
LYMPHOCYSTIS DISEASE VIRUS (*IRIDOVIRIDAE*)



Christian A Tidona and **Gholamreza Darai**, Institute for Medical Virology, University of Heidelberg, Heidelberg, Germany

History

Lymphocystis disease virus (LCDV) is the causative agent of lymphocystis disease (LD), which has been reported to occur in over 100 different fish species in fresh water and salt water worldwide. These include species that are of particular importance for fisheries and fish farming. LCDV infection frequently appears in *Pleuronectidae* (flatfish), such as *Platichthys flesus* (flounder), *Pleuronectes platessa* (plaice), and *Limanda limanda* (dab). LD of fish was first described in 1874 by Lowe. The term lymphocystis cell was used when Woodcock (1904) considered it a life stage of a parasite infecting flatfish. The viral aetiology was proposed by Weissenberg in 1914. The first electron microscopic observation of the virus was made in 1962 by Walker.

Taxonomy and Classification

LCDV is classified in a separate genus (*Lymphocystivirus*) within the family *Iridoviridae*. Iridoviruses are relatively large icosahedral cytoplasmic deoxyriboviruses that have been isolated from insects and vertebrates. LCDV type 1 (LCDV-1) occurs in flounder and plaice; LCDV type 2 (LCDV-2) was isolated from dab.

Properties of the Virion

The nonenveloped LCDV particles accumulate in the cytoplasm of the infected lymphocystis cells (**Fig. 1A**). The virions are characterized by an icosahedral morphology with diameters of 227.5 ± 12.5 nm (flounder; **Fig. 1B**), 198.8 ± 12.9 nm (plaice), and 200.5 ± 12 nm (dab) respectively. The outer capsid of the virion is separated from the electron-dense concentric core by an intermediate lipid layer (**Fig. 1C, D**).

Properties of the Virus Genome

The LCDV particles contain a single linear double-stranded DNA molecule that has been characterized

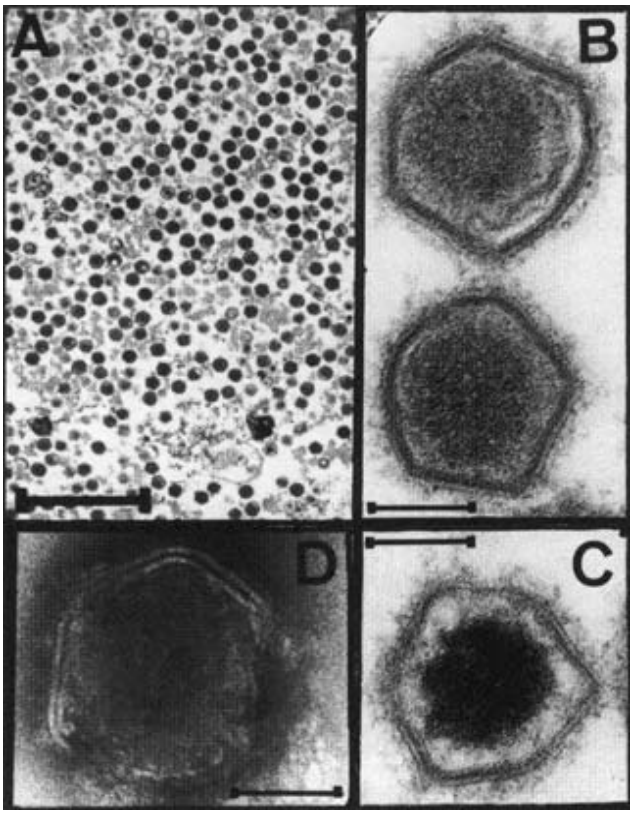


Figure 1 Electron micrographs of lymphocystis disease virus particles. (**A**) Ultrathin section of the cytoplasm of a lymphocystis cell exemplifying the huge amount of virus particles present in infected cells (bar = 1 μm). (**B**) The fine structure of the intact virion is best revealed in ultrathin sections (bar = 100 nm). (**C**) The concentric electron-dense core inside the virion is often separated from the capsid by an electron-translucent region (bar = 100 nm). (**D**) Negative staining of an LCDV virion. Due to osmotic shock the capsid of the virion is broken and partly dissociated into two layers, while the core seems to remain compact and stable (bar = 100 nm).

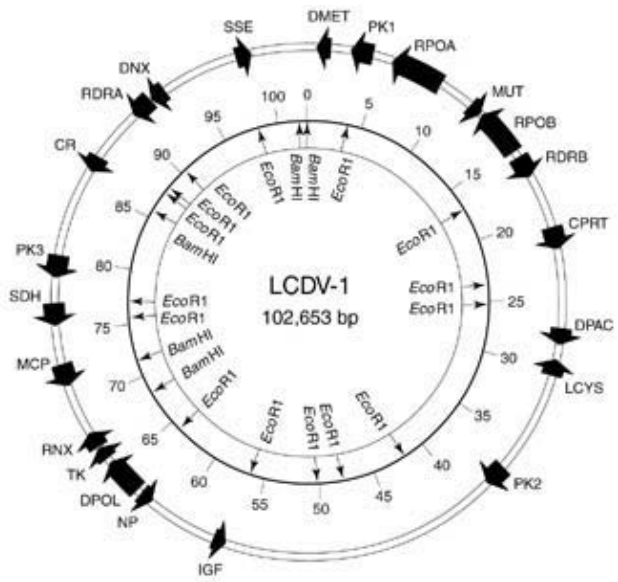

Figure 2 Physical map of the LCDV-1 genome. Inner circle: the arrows indicate target sites for the restriction endonucleases *Eco*RI and *Bam*HI and the figures indicate nucleotide positions given in kilobase pairs (kb). Outer circle: the arrows represent putative genes identified by significant amino acid sequence homology to well-characterized proteins of other species. Abbreviations of putative genes: DMET, DNA methyltransferase; PK1,-2,-3, protein kinases 1–3; RPOA/B, subunits of the DNA-dependent RNA polymerase; MUT, mutT protein homologue; RDRA/B, subunits of the ribonucleoside diphosphate reductase; CPRT, cysteine proteinase; DPAC, putative DNA packaging factor; LCYS, collagen type IX homologue; IGF, insulin-like growth factor homologue; NP, putative nucleoprotein; DPOL, DNA polymerase; TK, thymidine kinase; RNX, putative ribonuclease; MCP, major capsid protein; SDH, steroid dehydrogenase; CR, tumor necrosis factor receptor homologue; DNX, putative restriction endonuclease; SSE, structure-specific endonuclease.

by molecular cloning, physical mapping and nucleotide sequence analysis. The structure of the genome of LCDV was found to be circularly permuted and terminally redundant. LCDV DNA is sensitive to lambda 5′-exonuclease and to *Escherichia coli* 3′-exonuclease III without preference for any specific terminal DNA restriction fragment, indicating the circular permutation of the viral genome. Isolated LCDV DNA molecules appear to be heterogeneous in size and the average terminal redundancy was found to be approximately 50%. Because of the genomic features, the physical map of the viral genome is circular (**Fig. 2**).

The genome of LCDV-1 is 102 653 bp in length and contains 110 largely nonoverlapping putative viral genes. The base composition of the genomic DNA of LCDV-1 was found to be 29.1% G+C and 70.9% A+T.

A characteristic genomic property common to LCDV and frog virus 3 (FV3), which is another vertebrate iridovirus, is the high degree of methylation at cytosine residues. Comparison of cleavage patterns of LCDV DNA after treatment with the restriction endonucleases *Msp*I and *Hpa*II indicated that CCGG sequences are completely methylated at the inner C. The content and distribution of the 5-methylcytosine in the LCDV-1 DNA was determined by high-performance liquid chromatography (HPLC) and nearest neighbor analysis. These studies revealed that 22% of all C residues are methylated, including 74% in CpG, 1% in CpC and 2–5% in CpA dinucleotide sequences.

Replication of the virus genome and assembly into virus particles occurs exclusively in the cytoplasm of the infected cell.

Viral Proteins

LCDV virions contain at least 33 polypeptides with apparent molecular weights ranging from 14 to 220 kDa. LCDV polypeptide patterns are similar when virus isolates from different host species (e.g. flounder and plaice) are compared. However, the polypeptide patterns of the two LCDV strains show significant differences when compared with each other. The predominant structural component of the virus particles, comprising 40–45% of the total particle polypeptide, was shown to be the major capsid protein (MCP) with a molecular weight of about 50 kDa.

Viral Enzymes

Enzymatic activities such as protein kinase, ATPase, RNase, DNase, thymidine kinase and protein phosphatase have been reported to be associated with purified LCDV particles. Putative LCDV-1 gene products with enzymatic activity were identified by amino acid sequence homology analysis. These include the two major subunits of the viral DNA-dependent RNA polymerase, DNA polymerase, at least three different protein kinases, two subunits of the ribonucleoside diphosphate reductase, thymidine kinase and DNA methyltransferase (**Fig. 2**).

Geographic and Seasonal Distribution

LCDV is geographically distributed worldwide. LD epidemics frequently occur in wild flatfish in the North Sea as well as in sea bream (*Sparus aurata*) aquaculture in the Mediterranean and the Red Sea. A high rate (14–17%) of incidence of the disease was observed by Möller, in 1979, in the Gullmarsfjord of the Swedish West coast and in the Irish Sea. Similarly high rates of incidence have been documented in areas of the North Sea such as Öresund and Kattegat. LD epidemics in different fish species have also been reported from the Eastern USA, Florida and Bahamas, South America, Trinidad, Hawaii, South Pacific, Indochina and Singapore.

The occurrence of LD seems to be seasonally dependent. In the North Sea, for example, a significant increase of LD in fish can be observed during summer and autumn. However, other factors such as pollution, stress and changes in salt concentration may increase the susceptibility of fish to LCDV infection.

Host Range and Viral Propagation

The only well-characterized members of the genus *Lymphocystivirus* have been isolated from flatfish, predominantly *Pleuronectes platessa* (plaice), *Platichthys flesus* (flounder), and *Limanda limanda* (dab). LCDV can be experimentally propagated *in vivo* after subdermal inoculation of *Lepomis macrochirus* (bluegill).

Since the discovery of LD in 1874 by Lowe, many attempts have been made to propagate LCDV *in vitro*, with limited success. For example, the LCDV strain Leetown (ATCC VR-342) can be propagated at 21°C in BF-2 cell cultures (ATCC CCL 91) derived from bluegill fry. However, the titer yield at 21–28 days postinfection is usually very low.

Evolution

The amino acid sequence of the MCP was shown to be a suitable target for the study of iridovirus evolution because it contains highly conserved domains but is sufficiently diverse to distinguish closely related iridovirus isolates. Based on the amino acid sequence of the MCP, the iridoviruses were found to be phylogenetically at least distantly related to the family *Phycodnaviridae* and African swine fever virus. Within the iridovirus family the different genera infecting insect and vertebrate hosts appear to have diverged at the basis of iridovirus evolution.

Transmission and Tissue Tropism

The route of transmission of LCDV is not known. LCDV infection usually occurs within the connective tissues of fins and skin. The enhanced susceptibility of fish to LCDV infection in high-density aquaculture suggests that LCDV may be transmitted by direct contact between diseased and healthy individuals. The involvement of ectoparasite vectors has also been postulated.

Clinical Features of Infection

LD rarely causes death; the major impact on the infected animals is the production of unsightly raspberry-like external lesions which appear as disseminated white to grey nodules on fins and skin. There have been reports of ocular lesions and involvement of gills and internal organs associated with a much higher mortality rate. The disease does not usually elicit an inflammatory response. Often the infections are self-limiting and disappear spontaneously.

Pathology and Histopathology

The infected animals develop clusters of extremely hypertrophied fibroblasts or osteoblasts, called lymphocystis cells. Individual cells may undergo a 50 000–

100 000-fold increase in size and reach a diameter of up to 2 mm. Infected cells are characterized by an enlarged nucleus, basophilic cytoplasmic inclusions and a hyaline capsule surrounding the individual cells. As the infection progresses and the virus replicates, the nucleus becomes vacuolated and undergoes necrosis while the virus progeny accumulates in the cytoplasm and the capsule thickens.

Future Perspectives

The major obstacle in the analysis of the molecular mechanisms underlying LCDV infection, replication and pathogenesis is the lack of an efficient cell culture system for virus propagation. However, the knowledge of the complete primary structure of the viral genome now allows the *in vitro* expression and functional analysis of individual viral gene products.

LYMPHOPROLIFERATIVE DISEASE VIRUS OF TURKEYS (*RETROVIRIDAE*)

Arnona Gazit and **Abraham Yaniv**, Department of Human Microbiology, Sackler School of Medicine, Tel-Aviv University, Tel-Aviv, Israel

History

The lymphoproliferative disease (LPD) of turkeys is a naturally occurring lymphotumoral disorder characterized by enlargement of the spleen, thymus and liver, with focal lesions in most organs. The disease was first recognized in the UK, by Biggs *et al* in 1974, as a new disease entity distinct from reticuloendotheliosis (RE), which is also a leukotic condition in turkeys. Subsequently, sporadic outbreaks of LPD were also reported to occur in other European countries and in Israel. In 1978, a retrovirus, designated lymphoproliferative disease virus (LPDV), was isolated from afflicted turkeys.

Etiology

A retroviral etiology for LPD was first suspected based on the finding of C-type particles in plasma pellets and in tissues and lesions of birds with natural or experimentally induced disease, as well as the demonstration that preparations of these materials produced the disease when inoculated into poults. Further evidence for a retroviral etiology was based on the presence of budding C-type particles in tissue sections of LPD tumors and on molecular evidence showing that LPDV information is present and expressed in LPD tumor cells. Transfection of the cloned LPDV provirus into turkey lymphocytes and their injection into autologous turkeys resulted in the induction of LPD symptoms. This indicated that LPDV is a replication-competent virus, capable of inducing the disease in the absence of a defective oncogene-containing retroviral counterpart.

General Features and Classification

The mature LPDV viral particles measure 90–120 nm in diameter and have an electron-dense core with a less dense intermediate layer bounded by an outer envelope. As with a typical retrovirus, LPDV virions possess a buoyant density of 1.17 g ml^{-1} in sucrose gradients. They contain 35S plus-strand viral RNA and an RNA-dependent DNA polymerase (RT) that is preferentially activated by magnesium ions. The virion structural proteins are the two envelope glycoproteins of 76 and 41 kDa, the matrix (MA) protein of 20 kDa and several core proteins, including the capsid (CA) protein of 28 kDa, a core protein of 31 kDa, the nucleocapsid (NC) protein and the protease (PR) of 13–15 kDa each.

liferative disease virus of turkeys represents a distinct class of avian type-C retrovirus. *Gene* 122: 349.

LYMPHOCYTIC CHORIOMENINGITIS VIRUS (*ARENAVIRIDAE*)

Contents

General Features

Raymond M. Welsh, Department of Pathology, University of Massachusetts Medical Center, Worcester, Massachusetts, USA

History

Lymphocytic choriomeningitis virus (LCMV) is an etiological agent for human 'acute aseptic meningitis' and 'grippe-like' infections and is maintained in nature by life-long persistent infections of mice (*Mus musculus*). Three strains still being studied today were initially isolated in North America in the 1930s. During an attempt to recover and passage virus from a suspected human case of St Louis encephalitis, C. Armstrong and R. Lillie isolated LCMV (Armstrong strain) from a monkey that developed a lymphocytic choriomeningitis. E. Traub next reported the isolation of a serologically indistinguishable virus contaminating his mouse colony (Traub strain), and T. Rivers and T. Scott isolated similar viruses from human meningitis patients (one being the WE strain). Subsequently, many other isolations from humans and animals were made, and a clear cause-and-effect relationship between LCMV and about 8% of the North American cases of human nonbacterial meningitis was established.

The LCMV infection of the mouse soon became an important model system for studying viral immunology. A distinguishing feature of the LCMV infection was that it established a long-term persistent infection in mice infected *in utero* or shortly after birth, whereas adult mice inoculated with LCMV either cleared the virus with lasting immunity or, in the case of an intracranial infection, died of a lethal meningoencephalitis. Antiviral antibody was difficult to detect in the persistently infected mice, and this led Burnet and Fenner to postulate that exposure to viral antigen before the maturation of the immune system resulted in mice becoming immunologically tolerant to LCMV and thus unable to clear the infection. It was this system that provided the basis for Burnet's theories of immunological tolerance that have stood the test of time. Subsequent work by Oldstone and Dixon, however, demonstrated that persistently infected mice did make antiviral antibody which was difficult to detect because of excess viral antigen. The antiviral antibody traveled in the circulation complexed to virus and complement, and these circulating as well as tissue-bound 'immune complexes' contributed to a progressive degenerative disease involving glomerulonephritis, arteritis, and chronic inflammatory lesions. In the acute infection both the clearance of the virus and the lethal meningoencephalitis were shown to be due mostly to the cytotoxic T lymphocyte (CTL) response. Antiviral CTL were first demonstrated in the LCMV model, and Zinkernagel and Doherty used this model to demonstrate the important concept of major histocompatibility complex (MHC)-restriction in CTL recognition. Persistently infected mice were eventually shown to have 'split-tolerance' to LCMV, in that although they could mount an antibody response to LCMV they could not generate the LCMV-specific CTLs which were needed to clear the infection.

Classification

LCMV is the prototype virus of the genus *Arenavirus* in the *Arenaviridae* family of RNA viruses, and although it has some homology with all arenaviruses,

it is most closely related to the African virus Lassa and is classified as an Old World arenavirus. Its ambisense genome consists of two single-stranded RNAs each encoding two genes of opposite polarity and separated by a double-stranded hairpin structure. The small S RNA (1.1×10^3 kDa) in the virion encodes in the negative-sense a 63 kDa ribonucleoprotein (NP) and in the positive- or message-sense a 75 kDa cell-associated glycoprotein (GPC), which is cleaved into two virion glycoproteins (GP1 (44 kDa) and GP2 (35 kDa)). The large L RNA (2.1×10^3 kDa) in the virion encodes in the negative-sense a 200 kDa RNA-dependent RNA polymerase (L) and in the positive-sense a smaller 10 kDa zinc-binding protein (Z) which binds to the ribonucleoprotein complex. LCMV replicates in the cytoplasm and buds from the plasma membrane, incorporating host lipids into the viral membrane. It is pleomorphic, with sizes reported from 50 to 300 nm. Some of the virions, which may or may not be infectious, contain ribosome-like structures, giving the virion the characteristic arenavirus appearance.

Geographic and Seasonal Distribution

LCMV infections of mice and man have been well established in Europe and in North and South America, but they are not well documented elsewhere. LCMV is considered an Old World arenavirus brought to the Americas by its host, *Mus musculus*. There is some evidence that human infections occur more commonly in the winter and spring.

Host Range and Virus Propagation

The natural host for LCMV is the mouse, but it can be transmitted to humans, hamsters, guinea pigs, rats, dogs, swine, monkeys, chimpanzees and chick embryos. It commonly causes long-term persistent infections in mice and hamsters, and this has provided a source for human infections. The receptor for LCMV is not yet clearly identified, but it is likely to be ubiquitous, as LCMV grows in a wide variety of tissues *in vivo* and in most tested cells in culture. For instance, LCMV has been propagated and plaque assayed in 3T3, baby hamster kidney (BHK), Detroit-98, HeLa, JLSV-9, L-929, MDBK, MDCK, Vero, and vole cell lines. Vero, L-929, and BHK cells are most commonly used for plaque assays and BHK cells have been the cell of choice for most biochemical analyses because of the relatively high yields of virus (ca 10^8 PFU ml^{-1}) and the lack of secreted endogenous retrovirus contaminants. LCMV also grows in lymphocytes and macrophages, and the latter can be used as stimulator or target cells in T cell proliferation or cytotoxicity assays, respectively.

Genetics

Like other single-stranded RNA viruses, LCMV mutates frequently, and these mutants vary in their tropism and disease-producing potential. A single passage of a cloned LCMV variant into mice will soon segregate into clear neurotropic and turbid viscerotropic plaque variants, which can be recovered from the brain and spleen, respectively. A single amino acid change in the LCMV glycoprotein (residue 260) can convert the immunostimulatory Armstrong strain of LCMV into an immunosuppressive (clone 13) variant, and these genotypes rapidly intraconvert during *in vivo* passage. Several strains of LCMV have been sequenced at least in part, and the highest level of sequence homology is at the 3′ termini of the S and L virion RNA. These are presumed polymerase binding sites which are well conserved throughout the arenavirus family. Different arenaviruses crossinterfere via a defective interfering virus mechanism. The preservation of these polymerase binding sites may allow for this heterotypic interference. The NP and GP of the Armstrong and WE strains share 90% amino acid homology.

The presence of two virion RNAs allows for high frequency 'recombination' due to reassortment of viral genomes. The technique of generating reassortants has led to the assignment of virus-encoded proteins to the appropriate RNA and has facilitated the mapping of genes required for disease-producing potential. The ease of producing reassortants in the laboratory suggests that they also occur in nature and probably play roles in enhancing the genetic diversity of arenaviruses.

Evolution

Arenaviruses do not show substantial sequence homology with any other virus group, but the homology within members of this family suggests a common origin for all arenaviruses. LCMV is most closely related to Lassa virus, which, like LCMV, has its origins in the Eastern hemisphere. Each arenavirus favors a specific rodent host, and selective evolutional pressure on these viruses must have been conferred by their adaption to their respective hosts in forms that established persistent infections. Of interest is that LCMV and other arenaviruses undergo rapid evolution as they form persistent infections. These persistent infections *in vitro* and *in vivo* result in the extensive production of defective interfering virus and of attenuated relatively noncytopathic plaque variants

which may help in the maintenance of persistent infections by preventing virus-induced cell death.

Serological Relationships and Variability

Antisera to Lassa virus and to all members of the Tacaribe complex crossreact to some extent with LCMV by complement fixation and immunofluorescence assays but not at the level of viral neutralization. Few monoclonal antibodies show crossreactivity between LCMV and other Tacaribe complex viruses, but several crossreact with the more closely related Lassa virus. Protective immunity between LCMV and Lassa virus in guinea pigs is reciprocal and may reflect crossreactive T cell responses. Different strains of LCMV are not easily distinguishable by antisera but can be distinguished by some monoclonal antibodies.

Epidemiology

Human LCMV infections occur without sexual bias and at all ages, but most frequently in the 20- to 30-year age group. A longitudinal study in the United States from 1941 to 1958 implicated LCMV infections in about 8% of patients diagnosed with suspected viral meningitis, and serological studies have suggested an incidence of LCMV infection in 5–15% in the general population. Most of these infections are probably mild or subclinical. Laboratory infections with LCMV are relatively common, and several cases have been in laboratories working with the WE strain, which was reisolated from one laboratory worker and identified serologically with monoclonal antibodies.

Transmission and Tissue Tropism

LCMV has been experimentally transferred to humans by intramuscular injection, but the normal route of infection is probably via the respiratory tract after exposure to mouse secretions. LCMV is shed at high titer in mouse feces and urine and is probably not transmitted by arthropod vectors. Another source of infection is the Syrian hamster (*Mesocricetus auratus*), which, like the mouse, can harbor a long-term persistent infection. Several cases of LCMV in different geographic areas have been linked to a colony of persistently infected hamsters distributed throughout the United States. Horizontal person-to-person transmission is rare, but LCMV can cross the placenta and infect the fetus.

Pathogenicity

LCMV strains appear to differ in their pathogenicity in humans, but conclusive analyses of strain virulence differences in humans have not been done. Several human infections have occurred in laboratories working with the WE strain, and the WE strain has been reisolated from a laboratory worker with meningitis and clearly identified. There appear to be fewer anecdotal reports of human infection with the Armstrong strain, but one confirmed laboratory infection did occur in 1995. The WE strain is much more virulent than the Armstrong strain in hamsters and guinea pigs, and reassortant analyses have mapped the ability to cause lethal infections in guinea pigs to the L RNA of the WE strain. The United States Center for Disease Control recommends Biosafety Level 2 practices for most studies with LCMV in mice but Biosafety Level 3 practices for work with hamsters. This is based on the presumption that LCMV becomes more virulent for humans as it passes through hamsters. Although this has not been formally proven, this precaution would appear necessary due to the high number of clinical infections in individuals exposed to persistently infected hamsters.

LCMV has been used in a number of pathogenesis studies in mice and is dependent on age of host, route of infection and virus dose (**Fig. 1**). Viral strain variant differences exist in the encephalitis model, in which 'docile' or viscerotropic variants fail to kill mice, whereas 'aggressive' or more exclusively neurotropic variants do. However, a docile variant for one strain of mouse may be aggressive to another strain of mouse, and the susceptibility of mice to these variants seems to be linked to both major histocompatibility complex (MHC)- and non-MHC genes. One reason for 'docility' is the immunosuppressive nature of some LCMV strains, particularly when inoculated into mice at high dose. Lethal encephalitis does not occur when the T cell response is severely compromised. Immunosuppressive variants of LCMV tend to replicate to very high levels in the visceral organs and may mediate immunosuppression by replicating in leukocytes or simply by inducing a clonal exhaustion of T cells. T cells activated during the LCMV infection become very susceptible to apoptosis on T cell receptor signalling (activation-induced cell death). This is the mechanism for a virus-induced transient immune deficiency associated with the failure of virus-activated T cells to proliferate in response to mitogenic signals and may also be a mechanism for clonal exhaustion, which occurs during a presumed overwhelming T cell receptor stimulation under the conditions of high antigen load.

One noteworthy pathogenic feature of LCMV is its ability to cause a loss in cellular specialized or 'luxury' functions required not for cell survival but for homeostasis of the whole organism. Persistent LCMV infection results in reduced neurotransmitter enzyme activity in cultured neuroblastoma cells *in vitro* and

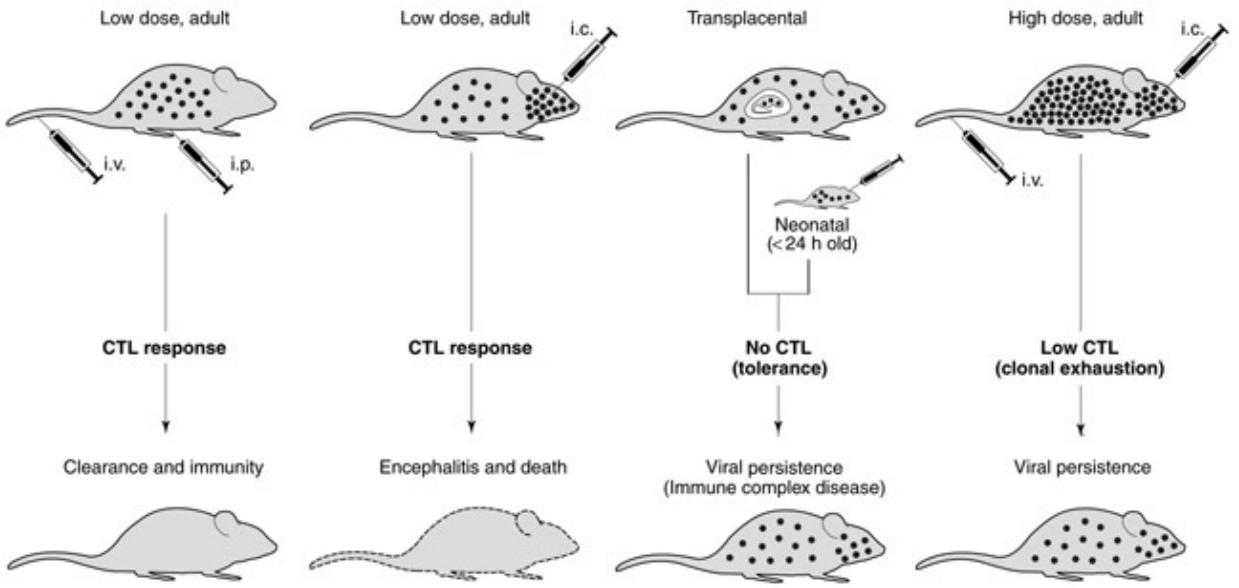

Figure 1 Pathogenesis of the LCMV infection is dependent on the age of the host, the route of infection and the dose of the virus.

reduced levels of growth and thyroid hormones in mice. Reduced growth hormone synthesis is associated with a runting syndrome in young infected mice. LCMV infects *in vivo* the cells which produce growth hormone and thyroid hormone and causes significant reductions in levels of mRNA encoding these hormones but not other hormones and proteins such as thyroid stimulating hormone, actin, and collagen.

Clinical Features of Infection

The LCMV infection of humans can be an inapparent or subclinical infection, or it can present as a non-meningeal grippe-like ailment, an aseptic meningitis, or a more severe meningoencephalitis. The incubation period is 1–2 weeks or longer, and the disease may come in two or three waves. The grippal type is characterized by fever, malaise, lethargy, weakness, myalgia, arthralgia, headache, photophobia, anorexia and nausea. Some patients develop a rash, arthritis, parotitis or orchitis. The grippal type is likely the most common form of disease. The meningeal type is often preceded by the grippal type and presents with stiff neck, vomiting, irritability and Brudzinski's and Kernig's signs. The meningoencephalomyelitic form, which is relatively rare, is associated with confusion, hallucinations, papilledema and weakness progressing to paralysis. Patients usually recover without lasting sequelae. Death is very rare, and there have been only nine fatal cases documented since 1942. There are also some reports of human transplacental infection, resulting in fetal abortion or malformation.

Pathology and Histopathology

Virus can be recovered from the blood, cerebrospinal fluid, urine, and nasopharyngeal secretions during the human LCMV disease. Leukopenia is a common feature of the infection, but there is a pleocytosis in the cerebral spinal fluid in the meningeal stages, and histological analyses of diseased brain tissue in lethal cases of LCMV have revealed meningeal perivascular inflammation and many lymphocytes and monocytes in the arachnoid. This is consistent with studies in the mouse which have demonstrated a lymphocytic infiltration of the meninges. Extensive studies in the mouse model of LCMV-induced acute meningoencephalitis have indicated that virus-specific MHC class 1-restricted CD8+ CTL are the major mediators of the lethal disease, and this may also be the mechanism for the human disease. The mouse model has also shown that antibody–virus–complement immune complexes can be pathological entities, and these could be involved in some of the human arthritic symptoms and the rash, when present.

Immune Response

Human cases of LCMV are characterized by a rise in antibody titer after infection, followed by lasting immunity. Little work has been done on human cellular immunity to infection. However, the LCMV

infection of the mouse has provided the most extensive analyses of the cellular immune response to any virus disease. The infection is characterized by an early stage 1–5 days postinfection and a later stage 6–10 days postinfection. The early stage involves the log-phase replication of the virus and a variety of antigen-nonspecific responses including the liberation of interferon α (IFN-α), IFN-β, tumor necrosis factor α (TNF-α), the activation and proliferation of NK cells and a depression in bone marrow hematopoiesis. The IFN and probably some of the TNF is directly and rapidly induced in cells by the LCMV infection. IFN and possibly other cytokines stimulate the activation and proliferation of NK cells, which substantially increase in number and accumulate in virus-infected tissue. The depressed bone marrow function, which is likely due to the effects of inhibitory cytokines such as IFN and to the ability of activated natural killer (NK) cells to lyse or suppress hematopoietic precursor cells, may be the cause of the leukopenia. Genetic or antibody-mediated depletion of IFN-α/β function enhances the synthesis of LCMV, but antibodies to NK cells do not alter the course of the infection. During this early stage there is a pronounced IFN-induced increase in class 1 MHC antigen expression throughout the body, an increase in the susceptibility of the cells to CTL, and a decrease in their susceptibility to NK cells. IFN-mediated protection of uninfected and LCMV-infected target cells may make them resistant to surveillance by NK cells.

The second phase of the response is associated with the expansion of clones of virus-specific T and B cells, a decrease in the production of virus, an increase in the production of IFN-γ and interleukin 2 (IL-2), and an increase in the activation of macrophages. The major factor in the control of the LCMV infection, in the development of encephalitis, and in the development of immunopathological lesions throughout the body is the generation of CD8+ CTL, which can develop in CD4+ T cell-depleted mice. The IFN-induced upregulation of class 1 MHC antigens conditions cells in the host to be good targets for CD8+ T cells, which recognize viral peptides in the context of class 1 antigens. Some LCMV immunodominant T cell epitopes have been identified, and, in the context of synthetic peptides, vaccinia virus recombinants, or DNA vaccines, they can immunize mice against LCMV. During the peak of the T cell response to LCMV infection, the host becomes transiently immune deficient as the T cells fail to proliferate in response to mitogens but instead undergo apoptosis. Apoptosis is also observed in T cell populations *in vivo* as the immune response silences, but CTL precursors remain both at a high frequency and stable for the lifetime of the animal. The preservation of these memory CD8+ CTL probably does not require the persistence of viral antigen but does require the presence of CD4 cells, which may provide them with growth or survival factors. Very high doses of LCMV can overwhelm the T cell response, causing clonal exhaustion of CTL and resulting in a persistent infection.

Antiviral antibody plays only a minor role in the acute LCMV infection and is not needed to clear the infection. However, in the absence of a CTL response, such as in congenitally infected mice, antibody–virus–complement immune complexes mediate the development of glomerulonephritis, arteritis, and other inflammatory lesions. Usually the LCMV infection *per se* is relatively mild, and it is the immune response to the virus that causes the damage in the infected mouse.

Prevention and Control of LCMV

LCMV has not been a sufficiently significant human pathogen to warrant special public health measures for its control. However, the disease can be reduced in frequency by ridding houses of mice, by ensuring that pet hamsters are not infected, and by adhering at least to Biosafety Level 2 procedures in the laboratory. Supportive therapy without antiviral chemotherapy is recommended for patients experiencing LCMV infection.

Future

Studies with LCMV have in the past provided much of the conceptual basis for viral immunology and pathogenesis, including (1) the theory of immunological tolerance, (2) the concept of virus-induced immunopathology, (3) the analysis of immune complex disease, (4) the discovery of virus-specific CTL and demonstration of their roles in viral clearance and immunopathology, (5) the discovery of MHC-restriction in T cell recognition, (6) the discovery and analysis of NK cell activation and proliferation and (7) the concept that sublethal viral infections can abrogate specialized 'luxury' functions of cells and lead to metabolic disturbances. In the future the LCMV infection will likely continue to be an important model, and it is now being used for the development of vaccines directed against T cell epitopes, for examining the clearance of virus by T cell immunotherapy, for elucidating mechanisms of virus-induced immunosuppression and tolerance, for analyzing the regulatory roles of cytokines in the development of the NK cell and T cell response, for determining the relationships between CD8+ and CD4+ T cell function during infection, and for

determining factors contributing to the development and maintenance of immunological memory. LCMV variants can produce, in mice, syndromes that very closely resemble acquired immunodeficiency syndrome, and it is possible to manipulate this system to get a persistent infection without a CTL response at all, a persistent infection associated with immunosuppression and a low level CTL response, or an acute infection with a strong CTL response which clears the infection. Exploiting the biology of these systems should continue to provide basic concepts fundamental to viral immunology and pathogenesis.

Introduction

Lymphocytic choriomeningitis virus (LCMV) is the prototype of the *Arenaviridae* family and has been studied extensively since the 1930s as a model of both acute and persistent viral infection in laboratory mice. The outcome of infection is determined by both viral and host parameters: the strain and dose of virus, the strain and age of the mouse and the route of infection. Mouse infections are highly reproducible and, in this property, LCMV represents one of the most diverse and accessible systems for the study of *in vivo* infections. Analysis of *in vitro* infections has revealed considerable information on the basic virus life cycle; major contributions have also been derived for the related arenaviruses, Pichinde and Tacaribe. The application of cloning and sequencing techniques has allowed definition of the complete genetic potential and provided invaluable probe reagents for hybridization studies. Comparative sequence analyses for several members of the arenavirus family (Pichinde, LCMV-two strains and one variant, Tacaribe, Lassa and Junin viruses) have created a foundation from which to explore the molecular basis of host and tissue tropism and the pathogenesis of virus-induced diseases.

Properties of the Virion

The virions are enveloped spherical particles with a diameter in the range of 50–300 nm; variability in both size and shape has been observed depending upon the method of virion purification. The surface of the virions is covered with club-shaped spikes that project 5–10 nm beyond the envelope. These spikes are thought to be composed of one or both of the viral glycoproteins. Within virions, viral genomic RNAs are organized in helical nucleocapsid structures that have been visualized as arrays of 'nucleosome-like' subunits in circular configurations ranging between 40° and 1300 nm in length. Virion particles display a grainy interior appearance when viewed in the electron microscope and this gives rise to the name 'arena' which is derived from the Latin *arenosus*, sandy. This appearance is seemingly due to the encapsidation of host ribosomes acquired during budding from the plasma membrane of virus-infected cells; the ribosomes are not required for infectivity.

LCM virions can be readily purified from the supernatant medium of infected tissue culture cells using polyethylene glycol precipitation followed by density gradient centrifugation. Buoyant densities have been reported as follows: in sucrose 1.17–1.18 g cm^{-3}, in cesium chloride 1.19–1.20 g cm^{-3} and in amidotrizoate compounds, which are used most commonly, 1.14 g cm^{-3}. The virions are relatively unstable *in vitro* and are rapidly inactivated outside the pH range of 5.5–8.5 or by heating at 56°C. In addition, the virions are very sensitive to inactivation by either UV or γ irradiation. Solvents or detergents that disrupt the integrity of the virion

determining factors contributing to the development and maintenance of immunological memory. Introduction

Lymphocytic choriomeningitis virus (LCMV) is the prototype of the *Arenaviridae* family and has been studied extensively since the 1930s as a model of both acute and persistent viral infection in laboratory mice. The outcome of infection is determined by both viral and host parameters: the strain and dose of virus, the strain and age of the mouse and the route of infection. Mouse infections are highly reproducible and, in this property, LCMV represents one of the most diverse and accessible systems for the study of *in vivo* infections. Analysis of *in vitro* infections has revealed considerable information on the basic virus life cycle; major contributions have also been derived for the related arenaviruses, Pichinde and Tacaribe. The application of cloning and sequencing techniques has allowed definition of the complete genetic potential and provided invaluable probe reagents for hybridization studies. Comparative sequence analyses for several members of the arenavirus family (Pichinde, LCMV-two strains and one variant, Tacaribe, Lassa and Junin viruses) have created a foundation from which to explore the molecular basis of host and tissue tropism and the pathogenesis of virus-induced diseases.

Properties of the Virion

The virions are enveloped spherical particles with a diameter in the range of 50–300 nm; variability in both size and shape has been observed depending upon the method of virion purification. The surface of the virions is covered with club-shaped spikes that project 5–10 nm beyond the envelope. These spikes are thought to be composed of one or both of the viral glycoproteins. Within virions, viral genomic RNAs are organized in helical nucleocapsid structures that have been visualized as arrays of 'nucleosome-like' subunits in circular configurations ranging between 40° and 1300 nm in length. Virion particles display a grainy interior appearance when viewed in the electron microscope and this gives rise to the name 'arena' which is derived from the Latin *arenosus*, sandy. This appearance is seemingly due to the encapsidation of host ribosomes acquired during budding from the plasma membrane of virus-infected cells; the ribosomes are not required for infectivity.

LCM virions can be readily purified from the supernatant medium of infected tissue culture cells using polyethylene glycol precipitation followed by density gradient centrifugation. Buoyant densities have been reported as follows: in sucrose 1.17–1.18 g cm^{-3}, in cesium chloride 1.19–1.20 g cm^{-3} and in amidotrizoate compounds, which are used most commonly, 1.14 g cm^{-3}. The virions are relatively unstable *in vitro* and are rapidly inactivated outside the pH range of 5.5–8.5 or by heating at 56°C. In addition, the virions are very sensitive to inactivation by either UV or γ irradiation. Solvents or detergents that disrupt the integrity of the virion

envelope rapidly eliminate infectivity in viral preparations.

Several distinct enzymatic activities have been associated with purified virions: poly(A) and poly(U) polymerases thought to be derived from the encapsidated host ribosomes, a serine/threonine protein kinase of unknown origin that can phosphorylate the viral nucleocapsid protein, NP, and a viral-encoded RNA-dependent RNA polymerase which is essential for viral RNA transcription and replication in infected cells. An *in vitro* assay to monitor viral polymerase activity yielded variable and unconvincing results for LCMV whereas parallel incubations with disrupted purified Pichinde virions produced clear evidence of polymerase activity.

Properties of the Genome

The genome of LCMV comprises two single-stranded RNA molecules, designated L and S, that exhibit ambisense coding arrangements. The only significant homology between the genomic RNAs is located at the 3′ termini where there is a highly conserved sequence of approximately 30 nucleotides; the complement of these sequences is found at the 5′ termini. Thus, individual RNAs could form panhandle type structures and intermolecular annealing could generate homodimeric or heterodimeric forms. The L and S RNAs are not present in equimolar amounts and, within virions and infected cell RNA samples, the S RNA is always more abundant. Hybridization studies with strand-specific probes have established that genomic complementary RNA can also be detected in virions. RNA extracted from highly purified virions normally contains host-derived 28S and 18S ribosomal RNAs together with a heterogeneous collection of RNAs in the 4–7S size range. A viral subgenomic mRNA, encoding the Z protein, is a component of this low molecular weight virion RNA fraction but there is no evidence to suggest that Z mRNA should be considered a genomic RNA.

The S RNA (3376 nucleotides) contains the coding sequences for the major structural proteins: the internal nucleocapsid protein, NP, and the surface glycoprotein precursor, GPC. The NP and GPC coding regions are separated by an intergenic non-coding region that has the potential to form a stable stem-loop structure (21 base pairs in the stem and four bases in the loop). The L RNA (7220 nucleotides) contains the coding sequences for the L and Z proteins. There is an intergenic region of almost 200 nucleotides separating the coding regions of the L RNA that can be predicted to assume various complex stem–loop structures. Precise information is still lacking because the intergenic region contains a 30-base C-rich sequence that has proved extremely refractory to direct RNA sequencing and this region is invariably deleted in cDNA clones. The existence of the Z coding region and the ambisense nature of the L RNA segment were completely unknown prior to M. Salvato's sequencing studies of the LCMV genomic L RNA. An equivalent coding region has been detected at the 5′ end of the Tacaribe L segment but there is considerable uncertainty about the role of Z protein in the infectious process.

Properties of the Proteins

The nucleoprotein, NP (558 amino acids, observed molecular weight 63 000), is the first newly synthesized viral protein to be detected in acutely infected cells, and its appearance corresponds to the beginning of the exponential phase of the replicative cycle. NP is complexed with genomic RNAs within cells and virions in the form of ribonucleoprotein (RNP) complexes. By analogy with other viral systems, it is probable that levels of intracellular NP influence the relative rates of transcription and replication and it has been suggested that NP coating of the intergenic regions might serve to disrupt secondary structures and allow synthesis of full-length replication intermediates. The vast majority of mature NP is identical to the primary translation product but there are indications that modified species may also exist. Both virions and infected cell extracts routinely contain small amounts of reproducible NP breakdown fragments. How and why these fragments are generated remain unknown but it is conceivable, given limited coding capacity, that NP-breakdown fragments fulfil the roles played by minor structural proteins in other viral systems. Also, a phosphorylated form of NP has been observed at late times in acute infection raising the possibility that this modification may influence viral gene expression. There is currently no information on whether the kinase detected in purified virions is responsible for intracellular phosphorylation of NP.

The glycoprotein precursor, GPC (498 amino acids, observed molecular weight 70 000–75 000) is cleaved by a trypsin-like protease to release the mature glycoprotein species: GP-1 (40 000–46 000 molecular weight) and GP-2 (molecular weight 35 000). GP-1 constitutes the N-terminal portion of GPC and the actual cleavage site is located between residues 262 and 263 of the precursor. Cleavage apparently occurs in the Golgi or post-Golgi compartment and requires prior glycosylation of GPC. There are five predicted sites for N-linked glycosylation in GP-1 and two sites in GP-2. From deglycosylation studies it appears that all sites can accept carbohydrate but, because GP-1

migrates as a heterogeneous species on sodium dodecyl sulfate (SDS)-denaturing polyacrylamide gels, all sites may not be utilized all the time. Neutralizing antibodies are directed primarily against conformational epitopes within GP-1, and epitope recognition is dependent on both glycosylation and retention of disulfide bonds. Recent protein cross-linking studies in M.J. Buchmeier's laboratory have begun to elucidate the structural organization of the mature glycoproteins in virions. GP-1 is a peripheral membrane protein, whereas GP-2 is an integral membrane protein; both species are assembled as native homotetramers. There is no evidence yet for any interaction between GP-1 and GP-2 and, although such an interaction is anticipated, it is currently unclear how GP-1 remains associated with the membrane. GP-2 can be linked to NP in the interior of virions using a membrane-permeable cross-linker, and this interaction is likely to be important in virion assembly.

There is no evidence for any modification to the L-encoded proteins but reagents necessary for systematic analyses are only now becoming available. The L protein is a minor constituent of virions and reproducible detection was problematic until the development of anti-peptide antibodies specific for sequences predicted from the L open reading frame. Conventional procedures to form hybridomas had failed to produce any antibody with reactivity against the L protein – presumably because of the low relative abundance of L when compared with the major structural proteins. It has been assumed that the L protein (2211 amino acids, predicted molecular weight 254 529 and observed molecular weight approximately 200 000) constitutes part or all of the viral RNA-dependent RNA polymerase. By analogy with the polymerases of negative-strand viruses, the L protein may possess multiple enzymatic activities.

The Z-protein-encoding region contains 90 amino acids and predicts a primary translation product of molecular weight approximately 10 000. Antibodies to examine Z protein accumulation and distribution were first raised against a fusion protein expressed in *Escherichia coli* but subsequent studies have also utilized anti-peptide antibodies. The Z protein has been detected as a relatively abundant component of virions and complexes between Z and NP have been generated in cross-linking studies. Z may therefore be a matrix-like protein. Alternatively/additionally, Z may be involved in transcriptional regulation and, in support of this possibility, the predicted Z protein sequence includes a potential zinc-finger motif, and zinc binding has been formally demonstrated. The presence of Z mRNA within virions would provide a mechanism for Z protein to be present at the earliest stages of infection, much sooner than could be achieved from *de novo* transcription of the genomic complementary L RNA template.

Replication

Transcription and replication are confined to the cytoplasm of virus-infected cells and require the activity of the virus-encoded RNA-dependent RNA polymerase. This enzyme is largely unaffected by addition of actinomycin D or α-amanitin. Viral RNP complexes are known to be associated with the nuclear membrane and there remains an unexplained dependence on the presence of the host cell nucleus for efficient viral replication. The process of RNA replication involves synthesis of full-length genomic complementary RNAs (anti-genomes) that then serve as templates for synthesis of genomic RNAs. The precise mechanism for priming the initiation of replication is currently unclear but D. Kolakofsky and his colleagues, working with Tacaribe, have proposed a mechanism based on primer annealing at the 3′ end of the template RNA followed by slippage backwards so that the 5′ nucleotide of the chain to be synthesized is no longer base-paired. The source of the primer is not known. This model attempts to account for the presence of an extra, nontemplated G residue detected at the 5′ end of genomic S RNA segments. When first observed, the extra G was thought to be a cloning artifact, but independent verifications strengthen the interpretation that the 5′ extra G is a genuine structural feature. There is still some ambiguity about the nature of the 5′-terminal nucleotide present on genomic RNA segments and, because of a clear link with initiation of RNA replication, this problem is now under active investigation.

Transcription

NP mRNA is transcribed from the 3′ end of the genomic S RNA and is therefore of genomic complementary polarity. The GPC mRNA is transcribed from the 3′ end of the genomic complementary S RNA and therefore has the same polarity as the genome. This transcription profile is imposed by the ambisense coding arrangement and suggests a temporal component to transcription regulation that has been supported by experimental observations: NP mRNA is synthesized immediately after infection while GPC mRNA is not synthesized until RNA replication has been initiated. Recent transcription mapping studies have determined that the S-derived subgenomic mRNAs have 5′ cap structures and extend for one to seven nucleotides beyond the ends

of the RNA templates. The origin(s) of the 5′ caps and nontemplated bases are currently unknown. It is possible that LCMV may utilize a cap-snatching mechanism or that primer synthesis and capping can be performed by the viral polymerase. The 3′ termini of the subgenomic mRNAs derived from the S RNA segment are located at heterogeneous positions in the intergenic region. The mRNAs are not polyadenylated so the possible presence of a terminal hairpin structure could provide an alternative mechanism to stabilize the 3′ termini from ribonuclease degradation in the cytoplasm. Essentially identical results have been reported for the related arenavirus, Tacaribe, suggesting that 5′ nontemplated bases and 3′-terminal heterogeneity may be general characteristics of at least the S-derived mRNAs.

The L-protein-encoding region is located at the 3′ end of the genomic L RNA segment and therefore can be transcribed immediately in the infected cell to produce a genomic complementary mRNA. The open reading frame for the L protein spans 6633 nucleotides from the total length of 7220 for the genomic L segment. The 5′ end of the L RNA segment contains the Z-encoding region (Z mRNA is approximately 0.5 kb) and the subgenomic Z mRNA has the same polarity as the genomic L RNA. At present, there is no sequence information relating to the termini of L-derived mRNAs but it is highly likely that the general features observed for S mRNAs will be duplicated for the L mRNAs.

Polymerase Activity

An *in vitro* assay has been developed to monitor the LCMV polymerase activity but, although the enzyme is presumed to be present in virions, the activity was much more readily detectable in cytoplasmic extracts harvested from acutely infected cells. Both genomic and subgenomic mRNAs could be synthesized *in vitro* but the labelled products detected probably represented elongation of preinitiated chains. A short virus-specific RNA was repeatedly synthesized in the polymerase assays and, although unassigned when the experiments were being performed, this product can be retrospectively identified as Z mRNA. A subsequent study of the Tacaribe polymerase demonstrated that addition of short oligonucleotide primers could significantly increase the efficiency of RNA synthesis *in vitro*.

Progression of Acute Infections

LCMV infects and replicates efficiently in a wide variety of cell types from many different species. The viral receptor has not been identified but, based on the known diversity of susceptible cells, the receptor must be a highly conserved and widely distributed molecule. Infections with LCMV are not normally cytolytic. After an initial period of active viral transcription, replication, synthesis of virus-encoded proteins and release of progeny virions, viral gene expression is downregulated and the cells progress towards a state of persistent infection. Production of progeny virions is reduced significantly and the accumulation of viral glycoproteins in the cell membrane is correspondingly diminished. Assuming that the L protein represents part or all of the polymerase protein, the *in vitro* assay for polymerase activity demonstrated that increasing intracellular concentrations of L protein correlated with a significant reduction in the level of enzymatic activity. This could represent part of the regulatory mechanism influencing the progression from acute to persistent infection. The accumulation of L protein observed at late times in an acute infection might lead to the formation of aberrant RNA–L-protein complexes and thereby remove RNA templates from a replicating pool. Similar observations have been made with the vesicular stomatitis virus polymerase to suggest that the intracellular concentration of viral polymerase may have a critical influence on the state and progression of the infection.

In tissue culture cells, the persistent infection is perhaps best viewed as a dynamic state. Cells contain high levels of cytoplasmic viral antigen (NP) and intracellular viral RNAs (both genomic and subgenomic mRNAs) and some degree of viral replication appears necessary to prevent dilution of the persistent infection at cell division. However, uninfected cells can be recovered from persistently infected cultures by single cell cloning and the intracellular viral RNA content of individual cells in the culture has been found to vary widely. Infectious virus is periodically released to reinitiate infection in any susceptible cells in the culture. Viral RNAs with internal deletions [potential defective-interfering (DI) RNAs] have been detected in persistently infected tissue culture cell lines but there is no convincing evidence that these RNAs are causal to the persistent infection. Apparently full-length genomic RNAs are the most abundant viral RNA species detected in total cell RNA preparations from persistently infected cells.

LCMV Strains and Reassortant Viruses

Several different strains of LCMV (Armstrong or Arm, WE, Pasteur, Traub and UBC) have been defined on the basis of distinct biological properties, monoclonal antibody recognition profiles, RNA fingerprinting, nucleic acid cross-hybridization and finally nucleotide

sequencing. Considerable effort has been invested into determining the molecular basis for strain-specific properties, and significant insight has been derived from the creation of reassortant viruses. Using this approach, Oldstone and colleagues were able to map LCMV virulence in adult guinea pigs to the L RNA segment and assign tissue tropism and virulence in mice to the S RNA segment. They also observed, as has been noted in other viral systems with segmented genomes, that reassortment between two nonpathogenic parental strains can generate viruses with novel and unexpected pathogenic potential.

Variant Viruses

Infection of neonatal BALB/c mice with LCMV results in viral replication in multiple tissues and a life-long persistent infection is established (see *In situ* hybridization below). Virus can readily be recovered from such persistently infected mice and it was widely known that the recovered viruses could differ in plaque morphology depending upon the tissue source (for example, predominantly clear plaques were recovered from brain whereas turbid plaques were generally recovered from spleen). Ahmed made a critical observation when he realized that the spleen-derived virus displayed fundamentally different biological properties. All wild-type LCMV strains induce a lethal immune-mediated choriomeningitis when inoculated intracerebrally into adult immunocompetent mice, but an equivalent infection with the spleen-derived virus (Clone 13) resulted in an asymptomatic persistent infection. It was subsequently shown that infection with Clone 13 fails to induce a cytotoxic T-cell (CTL) response in adult mice despite the fact that Clone 13-infected cells are recognized efficiently by CTLs induced by the parental LCMV Arm strain. Comparisons of the genomic RNA sequences for Clone 13 and Arm have revealed remarkably few changes (five differences from a total of 10 600 nucleotides causing two amino acid changes – residue 260 of GPC, Phe in Arm and Leu in Clone 13, and residue 1079 in L, Lys in Arm and Glu in Clone 13). The change in GPC is located in close proximity to the protease cleavage site of GPC but it is by no means clear how CTL induction may be disrupted. Curiously, LCMV strains other than Arm have Leu at residue 260 in GPC and yet are fully proficient at CTL induction. The situation is clearly complex because independent isolation of 'Clone 13-like' viruses from the parental Arm stock has consistently reproduced the Phe to Leu change but Clone 13 revertants that reacquire the ability to induce CTLs all retain Leu at position 260. Thus, perhaps both amino acid differences between Arm and Clone 13 are required for the phenotypic change. This conclusion is reinforced by early reassortant experiments that indicated an involvement for the L segment. It is probable that a critical event must occur immediately after infection with Clone 13 because low-dose infection or infection by intraperitoneal rather than intravenous injection does allow the generation of a Clone 13 CTL response.

Persistent Infections and *in situ* Hybridization

The availability of molecular clones corresponding to the genomic L and S RNA segments has permitted systematic hybridization analyses of viral-encoded RNAs throughout the time course of both tissue culture and mouse infections. Adaptation of conventional techniques to perform *in situ* hybridization on whole-body sections of mice has provided an efficient method to monitor the distribution of viral RNAs in persistently infected mice. Furthermore, this procedure has provided a dramatic illustration of the clearance of viral nucleic acid sequences following syngeneic cell transfer of spleen cells from an LCMV-immune mouse into a persistently infected recipient. In analyzing persistent infections of mice between birth and 6 months of age, there appeared to be a discrepancy between the titer of infectious virus that could be recovered and the intracellular accumulation of viral RNAs. Initially, virus titers are high [10^6 plaque-forming units (PFU) per g of tissue or per ml of serum], and viral nucleic acid is essentially undetectable but, by about 2 weeks after infection, virus titers have fallen (10^2–10^3 PFU per g of tissue or per ml of serum), and nucleic acid sequences have accumulated and are retained at consistently high intracellular levels. This is suggestive of the emergence of DI RNAs but, although LCMV DI particles have been implicated in several different studies, no rigorous correlation has yet been established between biological interference and molecular changes in either the protein and/or RNA components of virions. A complex population of heterogeneously sized viral RNAs has been detected within multiple tissues of persistently infected mice but, although these RNAs are unique to the persistent infection *in vivo*, it is not clear if they are causally linked to the persistent infection. One consistent observation is that the ratio of L-derived to S-derived RNAs is further skewed towards S during persistent infections.

Expression of LCMV Genes in Novel Environments

The construction of cDNA genes corresponding to the NP- and GPC-encoding regions has permitted

expression studies in several different vector systems (plasmids, vaccinia virus and baculovirus). The vaccinia vectors have been used extensively by Whitton and Oldstone to map CTL epitopes within NP and GPC. Each viral structural protein contains a few linear amino acid sequences that represent major CTL determinants, but recognition is profoundly influenced by MHC haplotype.

Several independent lines of transgenic mice expressing LCMV cDNA genes have been produced in the laboratories of Oldstone and Zinkernagel. These mice display a T-cell nonresponsive (tolerant) phenotype towards the viral transgene products. However, infection of these transgenic mice with LCMV appears to overwhelm the non-responsive state leading to 'autoimmune-like' tissue damage in locations where the transgenes are expressed. Many details relating to the induction of the pathogenic immune response still remain to be clarified. The homologous nature of the system (expression of genes from a mouse virus in mice with the possibility to challenge with the original virus) should produce substantial new information on the nature of virus-induced immune responses and pathogenic events in the LCMV-infected LCMV transgenic mice.

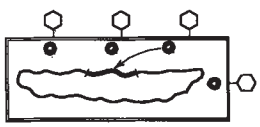
LYSOGENY AND PROPHAGE



Max Gottesman, Institute of Cancer Research, Columbia University College of Physicians and Surgeons, New York, USA

Arnos Oppenheim, Department of Medical Genetics, Hebrew University, Hadassah Medical School, Jerusalem, Israel

Introduction

The phenomenon termed lysogeny is discussed here, mainly through the perspective of the coliphage λ in the family *Siphoviridae*, genus 'λ-like viruses'. Lambda lysogeny was the first to be understood in detail, and remains the best studied example of the process. Furthermore, it is probable that the principles derived from the study of λ lysogeny will be applicable, *mutatis mutandis*, to other lysogenic phage.

General Features

The chromosome of coliphage λ is 48 514 bp, containing about 50 genes, and is fully sequenced. The λ chromosome is present in the virion as double-stranded DNA, with 12 bp 5′ cohesive overhangs. The order of genes in the virion is unique, and the viral DNA is injected through the tail in a polar fashion. The injected DNA is rapidly circularized and negatively supercoiled by the bacterial enzymes DNA ligase and gyrase, respectively.

Unlike the virulent T phages, λ is a temperate phage; a portion of infected cells survive. Most of the survivors become lysogens, and carry the λ as a stable, mostly inert, prophage integrated in the bacterial chromosome. The lysogenic state – the presence of a prophage – can be detected in several ways. Lysogens are immune; they are not killed by superinfecting λ virions. The inert prophage is carried like a set of bacterial genes, and is passed on from generation to generation. However, certain treatments induce, or activate, the prophage. The induced prophage excises from the bacterial chromosome, replicates, packages itself, and lyses its host, releasing several hundred phage particles.

Because of its ability to lysogenize, λ makes a turbid plaque on a lawn of sensitive bacteria growing

100 000-fold increase in size and reach a diameter of up to 2 mm. Infected cells are characterized by an enlarged nucleus, basophilic cytoplasmic inclusions and a hyaline capsule surrounding the individual cells. As the infection progresses and the virus replicates, the nucleus becomes vacuolated and undergoes necrosis while the virus progeny accumulates in the cytoplasm and the capsule thickens.

Future Perspectives

The major obstacle in the analysis of the molecular mechanisms underlying LCDV infection, replication and pathogenesis is the lack of an efficient cell culture system for virus propagation. However, the knowledge of the complete primary structure of the viral genome now allows the *in vitro* expression and functional analysis of individual viral gene products.

LYMPHOPROLIFERATIVE DISEASE VIRUS OF TURKEYS (*RETROVIRIDAE*)

Arnona Gazit and **Abraham Yaniv**, Department of Human Microbiology, Sackler School of Medicine, Tel-Aviv University, Tel-Aviv, Israel

History

The lymphoproliferative disease (LPD) of turkeys is a naturally occurring lymphotumoral disorder characterized by enlargement of the spleen, thymus and liver, with focal lesions in most organs. The disease was first recognized in the UK, by Biggs *et al* in 1974, as a new disease entity distinct from reticuloendotheliosis (RE), which is also a leukotic condition in turkeys. Subsequently, sporadic outbreaks of LPD were also reported to occur in other European countries and in Israel. In 1978, a retrovirus, designated lymphoproliferative disease virus (LPDV), was isolated from afflicted turkeys.

Etiology

A retroviral etiology for LPD was first suspected based on the finding of C-type particles in plasma pellets and in tissues and lesions of birds with natural or experimentally induced disease, as well as the demonstration that preparations of these materials produced the disease when inoculated into poults. Further evidence for a retroviral etiology was based on the presence of budding C-type particles in tissue sections of LPD tumors and on molecular evidence showing that LPDV information is present and expressed in LPD tumor cells. Transfection of the cloned LPDV provirus into turkey lymphocytes and their injection into autologous turkeys resulted in the induction of LPD symptoms. This indicated that LPDV is a replication-competent virus, capable of inducing the disease in the absence of a defective oncogene-containing retroviral counterpart.

General Features and Classification

The mature LPDV viral particles measure 90–120 nm in diameter and have an electron-dense core with a less dense intermediate layer bounded by an outer envelope. As with a typical retrovirus, LPDV virions possess a buoyant density of 1.17 g ml^{-1} in sucrose gradients. They contain 35S plus-strand viral RNA and an RNA-dependent DNA polymerase (RT) that is preferentially activated by magnesium ions. The virion structural proteins are the two envelope glycoproteins of 76 and 41 kDa, the matrix (MA) protein of 20 kDa and several core proteins, including the capsid (CA) protein of 28 kDa, a core protein of 31 kDa, the nucleocapsid (NC) protein and the protease (PR) of 13–15 kDa each.

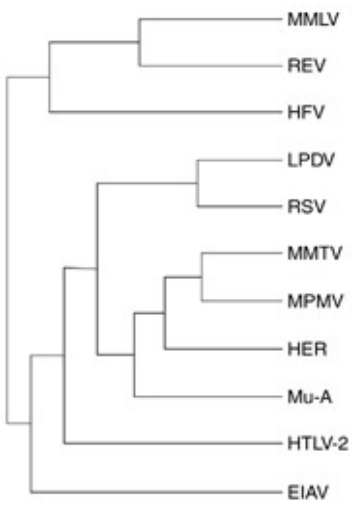

Figure 1 Evolutionary tree of LPDV. The deduced amino acids of the *pol* genes of the following viruses were aligned: Moloney murine leukemia virus (MMLV); reticuloendotheliosis virus (REV); human foamy virus (HFV); lymphoproliferative disease virus, LPDV; Rous sarcoma virus (RSV); mouse mammary tumor virus (MMTV); Mason–Pfizer monkey virus (MPMV); human endogenous virus (HER); mouse intracisternal A particle (Mu-A); human T-cell leukemia virus (HTLV-2); equine infectious anemia virus (EIAV).

According to cross-nucleic acid hybridization assays and nucleic acid sequence analysis, LPDV is a representative of a new and distinct class of avian retroviruses that can be readily distinguishable from the avian sarcoma–leukemia viruses (ASLVs) and the RE viruses. Sequence analysis of the *pol* gene and its comparison to the *pol* genes of other retroviruses established that LPDV is evolutionarily most related to the avian sarcoma–leukemia viruses (**Fig. 1**) and belong in the Alpharetrovirus genus of the *Retroviridae* family.

Viral Genome Organization and Properties of Viral Proteins

The LPDV RNA genome is 7143 bp long. The LPDV provirus is flanked by two host-derived 6 bp direct repeats formed during integration of the viral DNA into the host DNA. The LPDV proviral genome is bordered by two long terminal repeats (LTRs) of 354 bp each, which are bordered by 7 bp imperfect inverted repeats (5′-TGTGTG/CGCTACA-3′). The LTR comprises three sections: U3 of 236 bp, R of 22 bp, and U5 of 96 bp. The U3 region is a potent transcriptional element containing a TATA box, an upstream CAAT box in an inverted position (ATTGG), and two 12 bp imperfect direct repeats which constitute two CArgG motifs, suggesting their role as serum response elements (SREs). In addition, negative regulatory elements were found to reside at the 5′ end of the U3.

The overall structure of the LPDV LTR is similar to that of ASLV genomes. The primer binding site, which serves as the primer for the synthesis of minus-strand DNA, is a 18 bp motif, complementary to the chicken $tRNA^{Trp}$, as is the primer binding site of ASLV. The polypurine tract, which presumably serves as a primer for the synthesis of the plus-strand viral DNA, is nearly identical to those of ASLV genomes. By sequence analysis, the coding region of the entire viral genome contains the three major retroviral structural genes, *gag*, *pol* and *env*, with the overall topography of 5′-LTR-*gag*-*pro*-*pol*-*env*-LTR-3′, similar to the genomic organization of a typical replication-competent retrovirus (**Fig. 2**).

Each of these three open reading frames (ORFs) are phased differently. According to amino acid sequence analysis, the *gag* ORF is 2243 bp long and encodes the Gag polyprotein precursor of 724 amino acids, which is acylated rather than myristoylated. The Gag polyprotein is cleaved by the viral protease into the various mature virion proteins. The N-terminal protein is the membrane-associated MA protein of 155 amino acids which, comparable with other retroviruses, should function by interacting with the inner face of the viral lipid envelope. Adjacent to the MA protein is the core virion protein, p31, which is a protein of 234 amino acids by sequence analysis. Of note, p31 contains proline-rich stretches that are similar to conserved prolin-rich elements found in the analogous products of other retroviruses, suggesting functional and evolutionary relationships of MA–CA junction proteins. The subsequent protein, p28, comprised of 232 amino acids, is the major CA protein. Then follows the NC protein of approximately 103 amino acids, a highly basic nucleic acid-binding protein which is presumably tightly complexed with the genomic viral RNA within the mature virion. Similar to the NC protein of ASLV, this protein contains two copies of the finger motifs, the Cys-His boxes. This is in contrast to the murine retroviruses whose NC proteins contain only one copy of the Cys-His box.

The viral protease is encoded by a distinct ORF (designated *pro*) and is expressed as a Gag-Pro polyprotein of 843 amino acids long, which is produced by ribosomal frameshift. The frameshift site is a heptanucleotide GGGAAAC, identical to that of the Mason–Phizer monkey virus (MPMV) and its related simian viruses. Amino acid sequence analysis of the N-terminus of the viral protease established it as a 116 amino acid long protein, autocatalytically cleaved 95 nt downstream of the frameshift site. It belongs to the aspartic proteinase class and as such

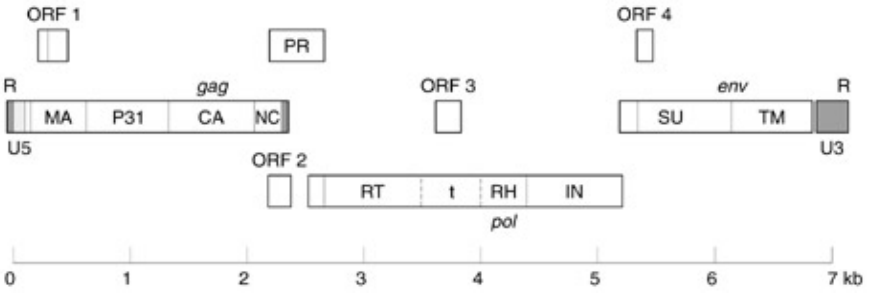

Figure 2 Coding regions of the LPDV genome deduced from ORF analysis of its nucleotide sequence.

contains two conserved hydrophobic elements pertaining to the enzyme active site, Asp-Thr-Gly and Ile-Leu-Gly-Arg.

The *pol* ORF of LPDV is transcribed as a Gag-Pro-Pol polyprotein of 1676 amino acids, produced by ribosomal frameshifting at the heptanucleotide sequence motif AAAUUUA, which is identical to that of ASLV genomes. This polyprotein is cleaved by the viral protease into the RT and the integrase (IN) proteins. There is a high genetic relatedness between the RT and IN of LPDV and those of ASLVs.

The *env* gene of LPDV is expressed via the *env* transcript whose splice donor site is located within the U5 domain; its splice acceptor site is located within the *env* ORF, 48 codons upstream to the Env initiation codon. The Env polyprotein is processed through proteolytic cleavage at the basic stretch, Arg-Glu-Lys-Arg, into the surface (SU) and transmembrane (TM) glycoproteins. These Env proteins are glycosylated through *N*-linked glycosylation of aspargine residues, 10 sites in the SU and four sites in the TM domains.

In addition to these four main ORFs, there are four short ORFs, overlapping the *gag*, the *pol* and the *env*. Whether or not any of these short ORFs are functional remains to be determined.

No viral oncogene resides within the LPDV genome.

Host Range and Propagation

In nature, LPD is observed only in turkeys. The age of onset is between 8 and 10 weeks of age, with a peak around 16 weeks of age. The cumulative mortality losses in a flock might reach 15–25%. Various strains of turkeys exhibit different susceptibility levels, ranging from low (4–8%) to high (25–36%).

Under experimental conditions, the chicken is the only other domestic bird which is susceptible to LPDV infection, developing both viremia and LPD.

Attempts to propagate LPDV in a variety of cell cultures have so far been unsuccessful.

Pathogenicity and Clinical Features

LPD is usually observed in small outbreaks. LPDV can spread horizontally between poults in contact. The incubation period for the natural disease is unknown, but is suggested to be as short as 7 weeks. The clinical course of the disease is acute, with practically no premonitory signs of the disease prior to death. In experimentally induced LPD, lesions are preceded by a viremia of C-type particles which develops 2 weeks after infection and persists in some birds for at least 8–10 months. Typical LPD lesions develop 3–6 weeks after infection. An unusual feature of the disease is that poults infected at 4 weeks of age develop a high incidence of the disease, whereas those infected at 1 day of age develop viremia in the absence of any clinical signs of the disease.

Clinically, the most affected organ is the spleen, followed by the thymus, pancreas and liver. Other organs such as the kidneys, gonads, lung and peripheral nerves can also be affected, but usually to a lesser extent.

The characteristic gross lesion is splenomegaly (**Fig. 3**). The affected spleen can reach 40–60 g. Its color is whitish or pale pink. The thymus and liver are also enlarged. The affected organs contain miliary gray-white foci which, in advanced cases, become confluent, forming large infiltrated grayish-white

Figure 3 Morphology of an LPDV-affected spleen as compared with a normal one.

lesions with irregular borders. Histologically, the characteristic microscopic lesions of LPD are infiltrative foci which consist of a pleomorphic population of mature and premature different-sized lymphoid cells such as lymphocytes, lymphoblasts, plasma cells, reticular cells and fusiform giant cells. The numerous mitoses of the infiltrated lymphoid cells suggest a proliferative character of the tumoral process.

In experimental cases, the surviving birds exhibit regressing lesions, suggesting that the tumoral process can be abrogated or reversed in resistant birds.

Anemia is frequently present; some affected birds are leukocytotic, others are leukopenic. Elevated IgG concentration has also been recorded. Up to 11 weeks postinfection, suppression of cell-mediated but not humoral immunity is detected.

Organotropism studies of LPDV showed that the replication of LPDV is confined to lymphoid organs. Cells residing in the bone marrow are the first to sustain virus expression. Thereafter, significant levels of LPDV expression can be detected in the thymus, and then in the spleen and the bursa of Fabricius. Among the lymphoid organs, the thymus acts as the main target for virus expression throughout the malady. Although virus expression takes place in all lymphoid organs, transformed foci are not detected in the bursa of Fabricius.

The mechanism by which LPDV exerts its leukemogenic potential has not yet been determined. Sequence analysis of the viral genome established LPDV as being devoid of a viral oncogene. Using inverse polymerase chain reaction (PCR), the viral genome was shown to be randomly integrated within the DNA of transformed foci in the afflicted lymphoid organs, thus excluding insertional mutagenesis as the mechanism responsible for LPD induction. It is hypothesized that the lymphoproliferative process of LPD is a premalignant stage that after several months, might develop into frank tumors through seldom-occurring insertional mutagenesis. It remains to be determined whether LPDV might encode a transactivator that could induce the expression of a cellular gene capable of stimulating lymphoproliferation.

Diagnosis

Owing to lack of overt clinical manifestations, early detection of LPDV is essential for preventing the rapid horizontal spread of the disease that can decimate flocks.

The main disease with which LPD can be confused is RE. The laboratory tests that are used to differentiate between the two infections are:

- *Virus isolation* LPDV cannot be isolated *in vitro*, either in embryonated eggs or in cell cultures. In contrast, REV can be grown in various types of cell cultures.
- *Antigen detection* LPDV can be specifically demonstrated in high-speed pellets of plasmas from affected birds, in buffy-coat cells and in frozen sections of affected spleen, employing an indirect ELISA or an indirect immunofluorescence test using LPDV-specific antiserum.
- *RT assay* A differential diagnostic test of LPDV based on the divalent cation preference of the viral RT was developed. Viral particles, obtained from high speed pellets of plasma are subjected to a standard templated RT reaction in the presence of either Mg^{2+} or Mn^{2+}. In contrast to the RT of REV that is catalyzed by Mn^{2+}, the RT of LPDV is active in the presence of Mg^{2+}.
- *Polymerase chain reaction* The availability of the nucleotide sequence of the LPDV genome enables specific diagnosis of LPDV employing the PCR. A simple, rapid, sensitive and highly specific PCR capable of providing differential diagnosis of LPD soon after infection was described.
- *Serology* Recently, a sensitive Western test for the detection of LPDV antibodies in sera of affected birds was developed by using bacterially synthesized highly immunogenic major viral proteins (p31 and CA) as antigens.

Future Perspectives

The molecular events underlying LPDV replication and oncogenesis are still obscure. Search for a permissive cell line will enable the investigation of LPDV infection at its molecular level. Furthermore, identification of putative LPDV-induced tumors in survivors of afflicted turkey flocks will likely enable studies addressing the molecular mechanism of LPDV oncogenicity. The development of an effective vaccine will help to eradicate LPDV infection and spread.

LYMPHOCYTIC CHORIOMENINGITIS VIRUS (*ARENAVIRIDAE*)

Contents

General Features

Raymond M. Welsh, Department of Pathology, University of Massachusetts Medical Center, Worcester, Massachusetts, USA

History

Lymphocytic choriomeningitis virus (LCMV) is an etiological agent for human 'acute aseptic meningitis' and 'grippe-like' infections and is maintained in nature by life-long persistent infections of mice (*Mus musculus*). Three strains still being studied today were initially isolated in North America in the 1930s. During an attempt to recover and passage virus from a suspected human case of St Louis encephalitis, C. Armstrong and R. Lillie isolated LCMV (Armstrong strain) from a monkey that developed a lymphocytic choriomeningitis. E. Traub next reported the isolation of a serologically indistinguishable virus contaminating his mouse colony (Traub strain), and T. Rivers and T. Scott isolated similar viruses from human meningitis patients (one being the WE strain). Subsequently, many other isolations from humans and animals were made, and a clear cause-and-effect relationship between LCMV and about 8% of the North American cases of human nonbacterial meningitis was established.

The LCMV infection of the mouse soon became an important model system for studying viral immunology. A distinguishing feature of the LCMV infection was that it established a long-term persistent infection in mice infected *in utero* or shortly after birth, whereas adult mice inoculated with LCMV either cleared the virus with lasting immunity or, in the case of an intracranial infection, died of a lethal meningoencephalitis. Antiviral antibody was difficult to detect in the persistently infected mice, and this led Burnet and Fenner to postulate that exposure to viral antigen before the maturation of the immune system resulted in mice becoming immunologically tolerant to LCMV and thus unable to clear the infection. It was this system that provided the basis for Burnet's theories of immunological tolerance that have stood the test of time. Subsequent work by Oldstone and Dixon, however, demonstrated that persistently infected mice did make antiviral antibody which was difficult to detect because of excess viral antigen. The antiviral antibody traveled in the circulation complexed to virus and complement, and these circulating as well as tissue-bound 'immune complexes' contributed to a progressive degenerative disease involving glomerulonephritis, arteritis, and chronic inflammatory lesions. In the acute infection both the clearance of the virus and the lethal meningoencephalitis were shown to be due mostly to the cytotoxic T lymphocyte (CTL) response. Antiviral CTL were first demonstrated in the LCMV model, and Zinkernagel and Doherty used this model to demonstrate the important concept of major histocompatibility complex (MHC)-restriction in CTL recognition. Persistently infected mice were eventually shown to have 'split-tolerance' to LCMV, in that although they could mount an antibody response to LCMV they could not generate the LCMV-specific CTLs which were needed to clear the infection.

Classification

LCMV is the prototype virus of the genus *Arenavirus* in the *Arenaviridae* family of RNA viruses, and although it has some homology with all arenaviruses,

expression studies in several different vector systems (plasmids, vaccinia virus and baculovirus). The vaccinia vectors have been used extensively by Whitton and Oldstone to map CTL epitopes within NP and GPC. Each viral structural protein contains a few linear amino acid sequences that represent major CTL determinants, but recognition is profoundly influenced by MHC haplotype.

Several independent lines of transgenic mice expressing LCMV cDNA genes have been produced in the laboratories of Oldstone and Zinkernagel. These mice display a T-cell nonresponsive (tolerant) phenotype towards the viral transgene products. However, infection of these transgenic mice with LCMV appears to overwhelm the non-responsive state leading to 'autoimmune-like' tissue damage in locations where the transgenes are expressed. Many details relating to the induction of the pathogenic immune response still remain to be clarified. The homologous nature of the system (expression of genes from a mouse virus in mice with the possibility to challenge with the original virus) should produce substantial new information on the nature of virus-induced immune responses and pathogenic events in the LCMV-infected LCMV transgenic mice.

Most of the survivors become lysogens, and carry the λ as a stable, mostly inert, prophage integrated in the bacterial chromosome. The lysogenic state – the presence of a prophage – can be detected in several ways. Lysogens are immune; they are not killed by superinfecting λ virions. The inert prophage is carried like a set of bacterial genes, and is passed on from generation to generation. However, certain treatments induce, or activate, the prophage. The induced prophage excises from the bacterial chromosome, replicates, packages itself, and lyses its host, releasing several hundred phage particles.

Because of its ability to lysogenize, λ makes a turbid plaque on a lawn of sensitive bacteria growing

on an agar surface. A plaque grows from a single phage killing a bacterium. The phage progeny diffuse through the agar, creating a circular, cleared area where additional bacteria have been killed. The turbid center of the λ plaque represents the lysogenic survivors growing amid a sea of λ virions. Lambda mutants unable to lysogenize are recognized by a clear plaque phenotype. Clear mutants kill all infected cells. Similarly, λ makes clear plaques on host mutants which cannot by lysogenized by λ. Finally, under conditions where λ lysogenizes 100% of infected cells, it makes no plaques at all.

The λ virion genetic map consists of blocks of functionally related genes, ordered with respect to time of expression after infection. Genes that are expressed very early are located near the center of the virion map and encode regulatory functions. The next blocks of genes to be transcribed include regulatory functions, as well as functions for DNA replication, recombination and integration. At the right end of the virion map are late genes involved in cell lysis, whereas the left virion end carries late genes encoding packaging, head and tail proteins. Joining of the two virion DNA ends after infection creates a single late gene operon, expressed from a single promoter.

The genetic map also links λ functions and the site upon which they act. For example, the λ O gene activates the λ origin of replication (*ori*) which lies within O. Cleavage of circular λ DNA to form the virion chromosome is accomplished by genes lying adjacent to *ter*, the cleavage site. This linkage reflects function–site specificity. Lambda recombines extensively with related (*lambdoid*) phage. Linkage reduces the chances of forming recombinants with functions incompatible with their sites of action.

The λ prophage is usually present as a single copy. Phage integration results from recombination between two unique sites, *attP* and *attB*, located on the phage and bacterial chromosomes, respectively. The *attB* site is located near the bacterial *gal* operon. The *attP* site is approximately in the center of the virion map. As a result of integration, therefore, the λ prophage gene order is a unique circular permutation of the virion genetic map. Indeed, the change in gene order upon λ integration provided the first evidence for circular DNA in bacteria.

Lysogeny is advantageous to λ because it offers a means of survival under adverse conditions. Free phage is sensitive to environmental stresses, to which a prophage, carried in a lysogen, is resistant. The frequency of lysogenization generally increases with conditions disfavoring lytic phage growth. If the bacteria are growing vigorously, and can support phage propagation, λ tends to enter the lytic rather that the lysogenic pathway. Conversely, infection of starved bacteria leads to lysogenization rather than cell killing. After several rounds of lytic growth, the supply of bacteria becomes limited and further lytic growth is disadvantageous. The surviving bacteria, which are attacked simultaneously by many phage, will tend to be lysogenized by infecting λ.

The prophage responds to changes in the environment that portend the death of the lysogen. In particular, agents that cause DNA damage will induce the prophage, allowing the newly assembled virus particles to escape the dying cell. Supporting the lysogenic lifestyle is expensive, and λ has evolved a complex genetic system to allow efficient lysogeny and induction. The phage genes directly involved in lysogenization, and which are dispensable for the lytic response, can be grouped in two classes: (1) genes required for establishing the lysogenic state; and (2) genes required for maintaining the prophage in a quiescent (repressed) state. These include genes needed for the regulation of other lysogeny-specific genes, for the integration of the prophage into the chromosome or for the excision of the prophage after induction. Mutation of either gene class prevents lysogeny, but for different reasons. Mutations blocking prophage repression lead to a clear plaque phenotype. Phage unable to integrate form turbid plaques (they can establish repression) but the surviving cells are not lysogenic. They are, instead, abortive lysogens. The infected cells carry repressed but unintegrated prophage. The repressed prophage cannot replicate autonomously, and are diluted away with cell division. Phage mutants unable to excise form turbid plaques containing stable lysogens. Although induction of these lysogens leads to cell death, viable phage particles are not released. The induced prophage remains bound to the bacterial chromosome, present in a gene order that cannot be appropriately expressed or packaged.

Mutations

Phage mutations that affect repression

Phage mutants that cannot repress lytic functions form clear plaques (λ*c* mutants). The mutants fall into two categories: (1) those which never lysogenize; and (2) others which rarely lysogenize. The latter class can be complemented by wild-type phage, or by phage mutant in a different complementation group.

The phenotypic difference between the two mutant classes reveals the components of the lysogenic response. A single prophage gene product is required to maintain λ in the quiescent state. This protein, the cI repressor, binds to two operator sites, oL and oR, that control two promoters, pL and pR. The pL and

pR promoters initiate transcription early in the lytic pathway, and the expression of the λ lytic functions depends upon their activity. By blocking pL and pR, the repressor prevents the transcription of most of the λ chromosome, maintaining λ as a prophage. The repressor also attaches to the operators of superinfecting phage, blocking the expression of their lytic genes as well; it therefore maintains λ prophage and makes the lysogen immune to superinfection.

The *c*I gene is the structural gene for λ repressor, hence the inability of λ*c*I mutants to form lysogens. Conditional *c*I mutations, such as the temperature-sensitive *cIts857* allele, have been isolated. λ*cI857* makes turbid plaques and forms lysogens at permissive (32°C) temperature. At the nonpermissive (42°C) temperature, λ*cI857* forms clear plaques and kills all infected cells. Lysogens obtained at 32°C can be maintained at that temperature. Shifted to 42°C, the repressor protein denatures, and the prophage is induced.

Two other clear-plaque mutants, λ*c*II and λ*c*III, define functions required for the initial synthesis of repressor in infected cells. The *c*II and *c*III genes are not needed to maintain λ as a prophage and, indeed, are not expressed in lysogens.

The observation that two λ functions, *c*II and *c*III, were needed only to initiate *c*I expression suggested that repressor positively regulates its own synthesis. An experiment showing that repressor was necessary and sufficient for *c*I expression was performed by Eisen, Periera de Silva and Jacob. These workers constructed a lysogen bearing a defective λ*c*I857 prophage that could not express lytic genes or genes *c*II and *c*III. The lysogen could be grown at 32°C or 42°C. As expected, it was immune to superinfection at the former but not at the latter temperature. However, lysogens grown at 42°C and then returned to 32°C did not regain immunity. Repressor synthesis had stopped in the absence of active repressor, and could not restart at the permissive temperature. Because prophage express repressor and few other functions, Eisen and his colleagues concluded that repressor was an obligatory activator of *c*I expression in lysogens.

Other λ mutants that form clear plaques define the sites of action of the *c*I and *c*II products. These mutations are not conditional, i.e. ambers or *ts*, indicating that they do not lie in the structural genes for proteins. The *cY* mutation defines a promoter, pRE, which is activated by *c*II, and which transcribes *c*I. Like *c*II mutants, λ*cY* mutants cannot initiate repressor synthesis on infection, but can form stable lysogens if provided with *c*I repressor by a complementing phage at the time of infection. The pRM mutation inactivates the repressor autoregulatory site. The pRM promoter is responsible for *c*I transcription in lysogens. The λpRM mutants form lysogens, but these are unstable. Unable to stimulate its own synthesis, repressor formed upon infection dilutes away, and the lysogen eventually induces.

The complementation pattern of the λ*c* mutants is distinctive. Complementation is tested by mixing mutant phage together, and spotting on a susceptible host. In the following complementation matrix, '−' indicates a clear spot and '+' indicates complementation, i.e. a turbid spot and the formation of lysogens.

	λ*c*I	λ*c*II	λ*c*III	λpRE	λpRM
λ*c*I	−	+	+	−	−
λ*c*II	+	−	+	+	+
λ*c*III	+	+	−	+	+
λpRE	−	+	+	−	+
λpRM	−	+	+	+	−

A consideration of the regulatory principles of λ can explain the above pattern. For example, λ*c*I cannot complement a λpRE mutant. A λ*c*I mutant can never lysogenize, and a λpRE mutant can only lysogenize if it can initiate repressor synthesis. Although the λ*c*I mutant can supply *c*II and *c*III products, these cannot act on the mutant pRE. What is required to initiate repressor synthesis in a pRE mutant is *c*I product, and this cannot be expressed by the λ*c*I mutant. In contrast, a λ*c*II, λ*c*III or λpRM mutant can all supply *c*I product to a λpRE mutant. The λ*c*II × λpRE and the λ*c*III × λpRE complementation assays are reciprocal. Lysogens carrying either member of the complementing pair can be recovered. In the case of complementing pairs that include λ*c*I or λpRM, it is the other partner that lysogenizes; stable λ*c*I or λpRM lysogens cannot form.

The final class of clear-plaque mutants inactivate the oL and oR operators. These mutants are virulent; unlike the λ*c* mutants they are not subject to immunity, and form plaques on λ lysogens. Naturally, they cannot lysogenize, and cannot be complemented by co-infection with a wild-type λ.

The λ*cro* product influences that balance between lysis and lysogeny. Cro protein, like cI repressor, binds to oL and oR. However, Cro inhibits *c*I transcription. Cro is essential for λ lytic growth. A λ*cI857cro* mutant fails to form plaques at 32°C. Infected cells overexpress cI; every infected cell is lysogenized. Cro also inhibits pL and pR, starting a

few minutes after infection. This inhibition is essential for λ development. Thus, *λcI857cro* does not grow at 42°C. In the absence of both cI and Cro, overexpressed pL and pR operon genes prevent phage development.

The analysis of heteroimmune phage, like the characterization of *λc* mutants, helped to define the regulatory loops in repressor synthesis. The various lambdoid phage have repressor and operators that function in a fashion similar to λ. The repression system can be phage-specific, however. For example, phage 434 forms lysogens that are resistant to 434 but sensitive to λ. Conversely, phage 434 forms plaques on λ lysogens. The biochemistry of this specificity is known. Lambda repressor does not bind to 434 operators and 434 repressor does not bind λ operators. The two phages are, nevertheless, remarkably similar, and readily recombine. By repeatedly recombining λ and 434, a phage that is almost entirely λ, but still has the repression profile of 434, was created. This phage, *λimm434*, defines a small continuous region (the immunity region) encoding the genes required for immunity specificity. These are the *cI* and *cro* genes of 434 and their sites of action at the oL and oR operators.

Host mutations that affect repression

Escherichia coli mutations that influence the lytic–lysogenic decision have been isolated and characterized, although their mechanism of action often proves elusive. Mutations inactivating the CRP–cAMP system cause λ to enter the lytic pathway. Based on the behavior of *crp* or *cya* mutants, it is likely that λ tends to lyse rapidly-growing cells because they have low intracellular cAMP levels. No CRP–cAMP-dependent λ promoter has been detected, suggesting that CRP–cAMP may regulate a host function required for lysogenization.

Mutations in *rnc* (RNaseIII) or *him/hip* also favor the λ lytic response. The genes *him* and *hip* encode the two subunits of integrative host factor (IHF) a low molecular weight histone-like protein. IHF binds in the DNA minor groove at specific sites in λ, and introduces a bend that exceeds 140°. The translation of the λ *c*III gene is reduced in *rnc* hosts, whereas *c*II translation is inhibited by *him* or *hip* mutations.

Mutations in the host *hfl* genes have the opposite effect on λ lysogeny; infection of *hfl* mutants leads exclusively to lysogenization. HflB (also designated FtsH) was shown to be a membrane bound, ATP-dependent protease that is responsible for the instability of *c*II protein. Transcription of *hflB* increases following heat shock. HflB degrades sigma^{32} as well as *c*II protein; both reactions are inhibited by *c*III protein.

Phage mutants defective in integration or excision

In addition to establishing and maintaining repression, the λ lysogenic pathway demands that the prophage be inserted in the bacterial chromosome. The integrated prophage must be stably inherited, i.e. not readily lost upon bacterial replication. Furthermore, upon induction, the activated prophage must detach rapidly, and replicate autonomously.

Lambda integration and excision is mostly promoted by phage-encoded functions. The host recombination pathways do not meet the needs of λ. The host pathways are relatively inefficient and are not polar. If phage integration occurred by recombination between extensive homologous segments in λ and *E. coli*, the resulting prophage would segregate frequently.

Lambda *int* mutants were isolated as turbid plaque formers that failed to lysogenize. The *int* mutation defines a function; *int* mutants can be complemented to form stable lysogens. The *λint* lysogens appear normal, and lyse after induction, but the lysate carries few viable phage particles. Thus Int is required for both integration and excision. In contrast, *xis* mutants integrate with wild-type efficiency, but fail to yield phage particles on induction. Neither the *int* nor the *xis* mutations affect the ability of λ to undergo generalized recombination. The Int and Xis proteins recognize sequences in *attP* and *attB* and promote site-specific recombination between them. Interestingly, λ also encodes functions that promote generalized recombination but the mutations in these genes, *redα*, *redβ* or *orf*, do not affect λ lysogeny.

Mutations in the λ *c*II gene also inhibit phage integration. In addition to promoting *c*I transcription, cII is needed for the transcription of *int* in infecting phage.

Phage mutations in the *λatt* site form turbid plaques and fail to lysogenize. Some of the mutants carry part of *λatt*, and arise by Int-promoted recombination between *λatt* and sites resembling *λatt* that lie in the phage *b* region. These *λb* mutants cannot be complemented by wild-type phage. Instead, co-infection leads to the formation of multiple lysogens, carrying tandem helper and *λb* mutant prophage.

Host mutants that block λ integration and excision

Only one type of host mutation is known that, by itself, directly affects λ integration and excision. *E.*

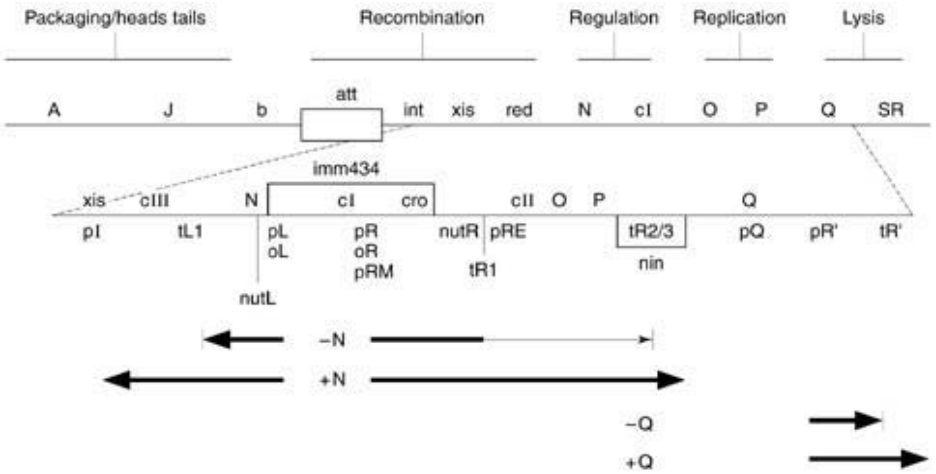

Figure 1 Map of lambda (not drawn to scale). Top line: the complete genome showing the organization by functional units and the location of a few key genes. Middle line: an expansion showing the organization of the λ immunity region and the extent of the nonhomology with phage 434. Bottom two lines: transcription patterns in the presence and absence of N. (Reproduced with permission, Cold Spring Harbor Laboratories.)

coli him or *hip* mutants do not support λ site-specific recombination. Recall that IHF plays a second role in the lysogenic response; it is required for *c*II translation, and thus for repressor expression.

The reconstitution of a purified cell-free λ integration-excision system confirms the genetic analysis. Int, Xis and IHF are sufficient to promote λ site-specific recombination. The *attP* site must be present in a supercoiled DNA molecule; *attB* is reactive in linear form. Under special circumstances, a second host factor, Fis, stimulates the excision reaction, but the physiological relevance of this is not clear.

How λ Establishes Lysogeny

After infection or induction, the transcription of the λ chromosome initiates at two promoters, pL and pR (**Fig. 1**). In the absence of phage protein synthesis, the pL transcript ends just promoter-distal to gene N, at the tL1 transcription termination site. The pR transcript is attenuated at site tR1, located just promoter-distal to *cro*, and terminates completely at tR2 and tR3, located in the *nin* region.

This pattern of abortive transcription is altered by the λ N gene product. The λ N protein suppresses transcription termination, allowing transcription to proceed outward into the phage chromosome. This mechanism of positive gene regulation is referred to as antitermination, and has now been described in higher eucaryotic systems. The expression of HIV appears to be regulated in a similar way by the product of the viral TAT gene. The mechanism of antitermination in λ is fairly well understood. N protein binds to sites in the pL and pR operon transcripts called *nut*. N, *nut* RNA, RNA polymerase and a set of host 'Nus' proteins, form a termination-resistant transcription complex. The λ *nut* sequence is not found in the *E. coli* chromosome, so the antitermination activity of N is restricted to the phage.

The extension of the pL and pR transcriptions under the influence of N activates other genes, including a second antitermination function, gene Q. The mechanism of action of Q is quite different from N. Unlike N, Q is a DNA-binding protein with a binding site in the pR′ promoter region. Transcription initiated at pR′ pauses after transcribing 16–17 nucleotides of the λ late transcript. This pause permits the modification of the transcribing RNA polymerase by Q protein. Terminators in the pR′ operon are suppressed, allowing expression of the λ late genes. The *c*III gene is transcribed from pL and *c*II from pR. The *c*II protein activates three promoters that are related not only by sequence but by function as well; all are required for successful lysogeny. The pRE promoter transcribes *c*I and the paQ promoter transcribes leftward (toward pR) from within Q. Like mutations in pRE (*c*Y), mutations in paQ present as a clear plaque phenotype. It is likely that convergent transcription from pRE and from paQ reduce the activity of pR, and thus the expression of lytic functions.

The third promoter activated by *c*II producer is pI, located within *xis* and transcribing leftward into *int*. The expression of *int* after infection derives exclusively from pI. This is surprising, as *int* is included in

the pL transcript. The failure of *int* to be expressed from pL is due to the instability of the pL transcript which, under the influence of N, extends into the *b* region. Within the *b* region, and present in the pL transcript, is the *sib* site. The pL transcript is cleaved at *sib* by RNaseIII and then rapidly degraded from the cleaved 3′ end into *int* by two exoribonucleases, polynucleotide phosphorylase and RNaseII. The pI transcript lacks *nut* and is not acted upon by N. It terminates before *sib*, and is relatively resistant to degradation.

The coordinate expression of *c*I and *int* by *c*II is important for successful lysogeny. On induction, however, rapid prophage excision is essential for the lytic response. Unlike infecting phage, *int* gene expression does not derive from the *c*II-dependent pI promoter. Instead, Int is expressed from pL. The relevant difference between the pL transcripts of infecting phage and induced prophage lies at the 3′ end. Integration at *attP* results in a genetic permutation that places the *b* region at the extreme prophage right. Thus, the prophage pL transcript does not include *sib*, and is stable.

The regulation of gene expression by sequences 3′ to the gene is called retroregulation. By making Int expression dependent on *c*II, λ reduces the chances of integration during the lytic cycle, when *c*II levels are likely to be low.

The *xis* gene is expressed exclusively from pL. In addition to promoting prophage excision, Xis inhibits integration. This inhibition, in theory, might be of benefit to excised and replicating prophage. Unlike Int, Xis is extremely unstable. In the lysogenic pathway, an infecting phage synthesizes phage functions for only a few minutes and is then repressed. Initially, an equilibrium between inserted and free phage may be present. As Xis decays, this equilibrium is shifted towards the integrated state, as Xis is required for excision.

The *c*II protein binds to pRE and pI at two TTGC sequences located in the −35 regions of the two promoters. *c*II is thought to bind as a multimer. The concentration of *c*II may be the most critical factor in determining the frequency of lysogenization. It is likely that high multiplicities of infection favor lysogenization because elevated *c*II concentrations are achieved early.

Maintenance of the λ Prophage

The λ oR region

The right operator region of λ is the site of interplay of two regulatory factors, the *c*I and Cro proteins. In addition, it includes two divergent promoters with antagonistic functions, pR and pRM. The pR promoter is repressed in a lysogen, is fully active early in the lytic response, and then is dampened later during lytic development. The pRM promoter is active in a lysogen and is repressed in the lytic pathway. *In vitro* studies show that the two promoters interfere with each other. The *c*I and Cro proteins determine which promoter is recognized productively by RNA polymerase.

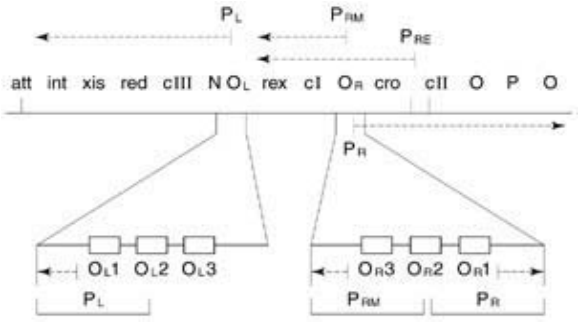

Figure 2 Regulation of λ *c*I and early lytic transcription. Transcription of early λ genes is initiated at pL and pR, and is subject to repression by *c*I repressor acting at oL and oR, respectively. Transcription of *c*I can be initiated either at pRM or pRE. Transcripts are indicated by dashed lines. The expanded diagrams illustrate spatial relationships between pL and three repressor binding sites in oL, and among pRM, pR and three repressor-binding sites in oR. Cro protein also binds at oR and oL to reduce transcription from pR, pRM and pL. (Reproduced with permission, Cold Spring Harbor Laboratories.)

Despite the complexity of the regulatory network at oR, the mechanism of oR control is understood in some detail (**Fig. 2**). There are three 17 bp repeated sequences in oR to which *c*I repressor binds. The repeats have dyad symmetry and recognize a repressor dimer. Each subunit of dimer binds one half-site.

The repeats are not identical, and have different affinities for *c*I protein *in vitro*. The oR1 sequence has the highest affinity, and is filled at the lowest *c*I concentrations. Although the oR2 and oR3 elements have equal 'intrinsic' affinities for *c*I, *c*I bound at oR1 interacts cooperatively with *c*I bound at oR2. Thus oR2 binds *c*I before oR3.

Cooperativity between *c*I dimers has another important consequence. It causes small decreases in *c*I concentration to have a major effect on repression. Unlike the *lac* operon, therefore, the induction of which is linear with respect to inducer concentration, induction of λ prophage is rapid and complete.

When *c*I is bound at oR1 and oR2, RNA polymerase is occluded from binding to pR. At the same time, the activity of pRM is enhanced. In part,

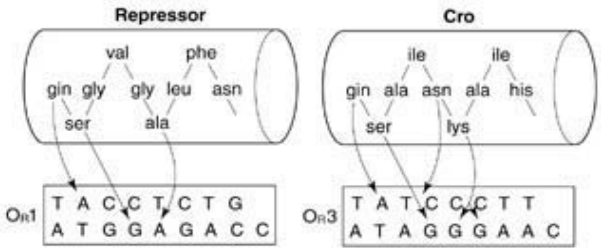

Figure 3 Pattern of amino acid–base pair interactions at oR. Shown are contacts between the amino acids of the *cI* repressor and Cro recognition helices and oR1 and oR3 half-sites, respectively. (Reproduced with permission, Blackwell Scientific Cell Press.)

this positive autoregulation results from the exclusion of RNA polymerase from pR. Additionally, the *cI* protein is a direct activator of transcription at pRM. Contacts between *cI* bound at oR2 and RNA polymerase bound at pRM enhance the rate of open complex formation about sevenfold. In theory, *cI* at high concentrations would bind oR3 and inhibit pRM. In the lysogen, *cI* is bound to oR1 and oR2; binding at oR3 has not been demonstrated.

The three mutations that confer virulence to λ lie in oR1, oR2 and oL. The oR1 and oR2 mutations reduce the binding of *cI* at oR, leading to constitutive pR expression. Constitutive pL expression provides N, which is required for λ late gene expression.

The order of addition of Cro to the oR sites is the opposite of *cI*. Cro binds as a dimer first to oR3, where it represses pRM. At higher concentrations of Cro, oR2 and oR1 are filled, reducing pR activity as well. Cro is a smaller protein than *cI*; cooperative interactions between Cro dimers bound at oR do not occur. At physiological levels of Cro, pR retains considerable activity.

The cI repressor

The *cI* protein has been studied in great detail. Its structure has been determined both by crystallographic analysis of *cI* and *cI*–operator DNA complexes, and by nuclear magnetic resonance (NMR) spectroscopy. These studies, as well as experiments using chemical probes, have demonstrated the contact points between *cI* and the operator.

The *cI* gene product is a 26 kDa, 236 amino acid protein that is organized in two distinct domains. The amino domain (residues 1 through 92) contacts operator DNA. Residues 93 through 132 form an unstructured bridge that connects the amino domain to the carboxyl domain (residues 133 through 236). The carboxyl domain is responsible for cooperative interactions between adjacent *cI* dimers. The carboxyl domains of *cI* monomers also interact, stabilizing the *cI* dimer. Interactions between the amino domains also contribute to dimer stability.

Prophage induction occurs when the two domains are separated by proteolytic cleavage between bridge region residues Ala111 and Gly112. Without the cooperative interactions provided by the carboxyl domain portion, the affinity of amino domain for oR is insufficient to sustain repression. Wild-type λ is induced by DNA-damaging agents, which activate RecA and induce the SOS response. The activated RecA binds to *cI* monomer and stimulates an intramolecular autocleavage reaction that involves an attack by the Lys192 residue on the Ala111–Gly112 peptide bond. Mutations in *cI* that prevent induction, called *ind,* lie at the cleavage site or at the RecA binding site.

The amino domain is folded into five α helices. When *cI* repressor is bound to the operator, the second α helix lies above the DNA major groove and serves to position α helix 3, the recognition helix, within the major groove. The recognition α helices of the *cI* monomers each sit in the major groove on the same DNA face and one DNA helical turn apart. Three amino acids in the recognition α helix, Gln, Ser and Ala, make contacts with oR base pairs (**Fig. 3**). A Gln residue, located just before α helix 2, contacts DNA phosphate residues. Finally, the first six residues of repressor, which are flexible, reach behind the DNA helix to make contacts with bases and the phosphate backbone within the operator on the opposite helix face.

The *cI* p^c mutations lie in or adjacent to residues in *cI* that are closest to RNA polymerase bound at pRM. The mutations are thought to prevent the contacts between *cI* and RNA polymerase that promote the formation of open complex at pRM. Although incapable of stimulating RNA polymerase at pRM, *cI* p^c binds to oR DNA and represses pR.

Cro

The structure of Cro is very similar to that of *cI*, as expected for proteins that bind variants of the same DNA sequence. As in *cI*, the Cro α helix 2 positions the recognition α helix 3, which inserts within the DNA major groove. The Gln and Ser residues of the *cI* α helix 2 are conserved in Cro, where they make the same base contacts. Instead of Ala, the Cro recognition helix includes an Asn and a Lys residue that make additional base contacts. The differences in α helix 2 account for the preference of *cI* for oR1 and of Cro for oR3.

Integration and Excision

The integration and excision of λ is a highly efficient recombination process. As shown by the analysis of mutations, it involves two phage-encoded functions, Int and Xis, which act upon the two recombining sites, the phage *attP* and the bacterial *attB* sites. The host IHF function is required; a second host function, Fis is stimulatory.

The amount of homology between *attP* and *attB* is small (15 bp) and the reaction is dependent upon the recognition of specific *att* sequences by Int and Xis. *attP* is considerably more complex than *attB*. Int recognition elements in *attP* are found from about −150 bp to +90 bp relative to the crossover region. There is only one *attB* site in *E. coli,* although *attB*-deleted strains can be lysogenized at low frequency by Int-promoted recombination at secondary *attB*-like sites.

The 40 kDa Int protein has several biochemical activities. It binds DNA with two distinct sequences. It is a topoisomerase type I, and can also act as a resolvase on *attP–attB* Holliday junctions.

The *att* sites are displayed in **Fig. 4.** The *attP* site consists of several regions with different roles in the site-specific recombination reaction. The arms of *attP* bind Int with high affinity at a consensus sequence, C/AAGTCACTAT, that is repeated several times. In the center of *attP* is the core region, consisting of a 15 bp *O* sequence that is also found in *attB*. Flanking *O* are second consensus Int binding sequences, CAACTTNNT. A single Int molecule binds to both arm and core sequences. Because the binding of Int to the latter is weak, Int bound to the arm sites must be brought close to the core. This is accomplished by binding *attP* DNA; IHF binds to specific *attP* sites and introduces a strong bend. The binding of Int to the core is IHF and DNA helix face dependent.

Int cleaves within the *O* regions of *attP* and *attB* to create a 7 bp overhang. The initial cleavage is in the top strand of *O*. Strand exchange creates a Holliday structure that is resolved by single-strand exchange between bottom strands. The Int cleavage reaction passes through an (*O*)-phosphotyrosine ester intermediate between Tyr342 of Int and the 3′-PO_4 terminus of the cleaved *O* sequence. In this respect, Int resembles other topoisomerase I enzymes, which also form an (*O*)-phosphotyrosyl linkage. Although intermediates in Int-promoted recombination can be isolated through genetic or biochemical manipulations, the reaction is normally concerted.

Note that as a result of recombination between *attP* and *attB,* two *att* sites are created that are different from either parent. The *attL* site, which lies to the left of the prophage, carries the right arm of *attP;* the *attR* site, lying to the right of the prophage, carries the *attP* left arm. Recombination between *attL* and *attR,* which leads to prophage excision and reformation of *attP,* requires Xis function. The binding sites of Xis and Fis are also shown in **Fig. 4.** How Xis blocks integrative recombination and promotes excisive

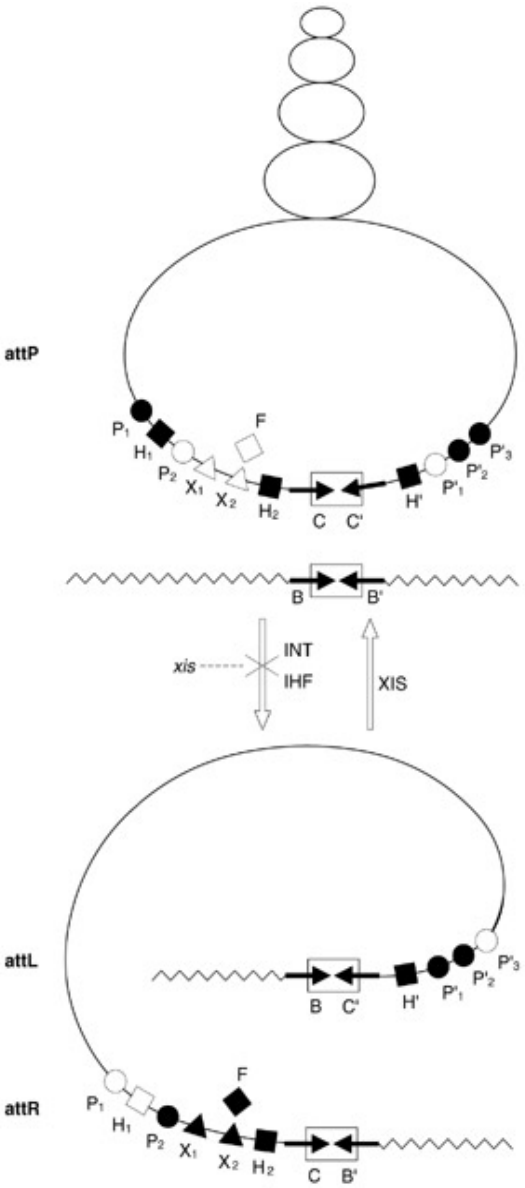

Figure 4 Integrative and excisive recombination pathways. The protein-binding sites for arm-type Int (○), core-type Int (→), IHF (□), Xis (△) and FIS (◇) are indicated by filled symbols when that site is occupied by its cognate protein to make a competent recombination partner for integrative (⇓) or excisive (⇑) recombination. Proteins required for each reaction (Int, IHF and Xis) are in bold. Inhibition by Xis indicated. (—), supercoiled λ chromosome; (〰), bacterial chromosome. (Reproduced with permission.)

recombination is not entirely clear, although the rationale for the effect is evident.

The outcome of phage λ infection is determined by specific proteolysis of the N antiterminator and the *c*II activator. Controlled protein degradation in regulatory cascades has been shown to be conserved in all organisms, controlling diverse processes such as growth and apoptosis.

MACHLOMOVIRUSES (*TOMBUSVIRIDAE*)

Steven A Lommel, Department of Plant Pathology, North Carolina State University, Raleigh, North Carolina, USA

History

Maize chlorotic mottle virus (MCMV) was first isolated from maize in Peru and named in 1973 and has since been reported in Argentina and Mexico. In 1976 MCMV was recovered from field corn along the Nebraska–Kansas border in the USA, where it is now endemic. In 1990, a severe outbreak of the virus was reported in winter corn breeding plots on the Island of Kauai Hawaii, USA. In 1978, it was shown that MCMV in co-infections with any corn infecting member of the *Potyviridae* produced a synergistic interaction resulting in a lethal disease termed corn lethal necrosis (CLN).

Taxonomy and Classification

MCMV is the type species and the only member of the *Machlomovirus* genus. Based on significant amino acid sequence homology in the viral replicase, the *Machlomovirus* genus has been placed within the family *Tombusviridae*. Recently, panicum mosaic virus, also known as Saint Augustine decline, has been sequenced and shown to be similar in genome organization and sequence homology to MCMV. It is likely, however, that a new genus will be created for panicum mosaic virus. The monotypic *Machlomovirus* genus is defined by a virus with 30 nm icosahedral virions composed of 180 copies of a 25 kDa capsid protein packaging a single genomic RNA of 4437 nucleotides. The key taxonomic features distinguishing this genus from other genera in the *Tombusviridae* are capsid protein sequence and structure more closely related to members of the *Sobemovirus* genus, and an additional 5′ proximal open reading frame which largely overlaps the pre-readthrough domain of the replicase.

Properties of the Virion

The virus is a 30 nm sphere when observed under a transmission electron microscope after negative staining. The virions appear smooth and icosahedral in shape. Based on electron micrographic observations and sequence similarity of the capsid protein with that of southern bean mosaic sobemovirus, the virion is hypothesized to be a $T = 3$ icosahedral virion formed by 180 copies of the 25 kDa capsid protein subunit. The virion packages the 4437 nucleotide single-stranded RNA genome.

Properties of the Genome

The structure of the *Machlomovirus* genome is deduced from the complete nucleotide sequence of MCMV. The genome is composed of one positive-polarity, single-stranded RNA of 4437 nucleotides. The genomic RNA is infectious as naked nucleic acid. The genomic RNA is capped at the 5′ terminus with m^7GpppA and is not 3′-terminally polyadenylated. The RNA contains four open reading frames (ORFs). The first ORF initiates at the first methionine codon, 118 nucleotides from the 5′ terminus. The ORF is capable of encoding a 32 kDa polypeptide which is synthesized *in vitro*. This first ORF largely overlaps, in a different reading frame, the second ORF, which initiates at nucleotide 137 and is capable of encoding a 111 kDa polypeptide. This ORF is punctuated by an in-frame amber termination codon creating a pre-readthrough ORF encoding a 50 kDa polypeptide. Both the 50 kDa and 111 kDa polypeptides are expressed *in vitro*. Similarly, the internal ORF capable of encoding a 33 kDa polypeptide is interrupted by an in-frame opal termination codon yielding a pre-readthrough 9 kDa polypeptide (**Fig.**

1). Neither of these predicted polypeptides have been observed *in vitro*. The fourth and 3′ proximal ORF encodes the 25 kDa capsid protein. The capsid protein encoding ORF overlaps the 3′ half of the preceding ORF in a different translational reading frame.

Physical Properties

MCMV virions sediment as a single species with a sedimentation coefficient ($s_{20,w}$) of 109 S and have an equilibrium density of 1.365 g ml^{-1} in CsCl. The weight of a virion is calculated to be 5.9 mDa. MCMV in plant sap has a thermal inactivation point of 80–85°C.

Replication

Little is known regarding the specifics of *Machlomovirus* replication. It is assumed that MCMV replicates by producing a negative-sense complementary copy of the viral RNA. The viral replicase most likely recognizes a structural feature on the viral sense RNA enabling it to initiate synthesis of the full-length complementary strand. After completion of complementary strand synthesis, the viral replicase then recognizes the 3′ terminus of the complementary strand to initiate synthesis of progeny genomic RNA. This replication strategy dictates that prior to replication, viral replicase must be expressed from the original infecting genomic RNA. Consistent with this assumption, the putative replicase ORFs are located at the 5′ terminus of RNA, making them easily accessible to translation. The 3′-terminal capsid protein ORF is expressed *in vivo* from a 1.1 kb subgenomic RNA. Presumably, viral replicase recognizes an internal sequence including an 11 nucleotide element upstream of the capsid protein ORF initiation codon. This sequence element is identical to the 3′ terminus of the full-length complementary strand. Once bound, the replicase synthesizes the sense capsid protein subgenomic RNA. Based on significant similarities in the genome organization and homology of various proteins with members of the *Carmovirus* genus, it was expected that MCMV would produce a second subgenomic RNA to facilitate the expression of the internal ORF yielding the 9 kDa and 33 kDa polypeptides. However, no second subgenomic RNA has been detected.

Geographic and Seasonal Distribution

MCMV has been reported in several countries dispersed throughout the Western Hemisphere. To date, these countries include Argentina, Mexico, Peru and the USA. MCMV is most likely present but not yet reported in other Western Hemisphere countries as well. Based on the fact that vector *Diabrotica* species are strictly New World, MCMV has the potential to be present and become established in any maize-growing region within the Western Hemisphere. The recent report from Hawaii that MCMV can be transmitted by thrips significantly increases the potential range of the virus.

In Nebraska and Kansas, MCMV has been traditionally restricted to the Republican River valley which borders these two states. In Kauai, Hawaii the virus is present in the winter nursery maize breeding plots. MCMV is endemic in the Lima, Huaral, Chancay, Lurin and Canete valleys in the Department of Lima, Peru.

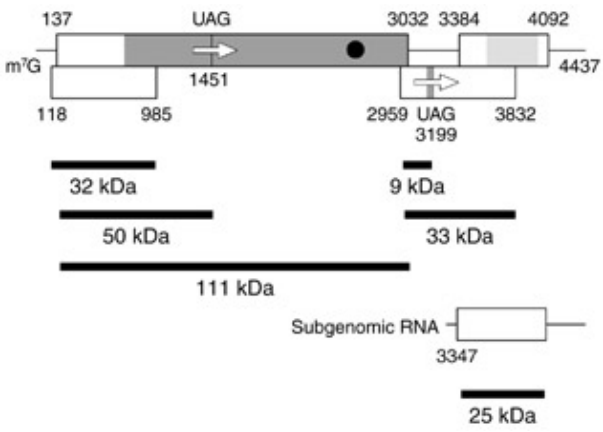

Figure 1 MCMV genome organization, polypeptides expressed and identification of conserved protein domains. The genomic and single subgenomic RNA are depicted as solid lines with open reading frames (ORFs) identified as open rectangles. Numbers above or below the borders of the ORFs identify initiation and termination codons defining the ORF. White horizontal arrows identify in-frame termination codons that must be periodically suppressed to allow expression of the readthrough polypeptides. Black bars below the RNAs represent viral encoded polypeptides predicted from the ORFs and, with the exception of the 9 kDa and 33 kDa readthrough polypeptides, proteins identified *in vitro*. Gray shaded region within the major ORF encoding the 111 kDa polypeptide identify domains with significant amino acid sequence similarity to polymerase proteins in the *Tombusviridae*. The black circle identifies the location of the canonical 'GDD' motif. The gray shaded region at the 3′ end of the ORF encoding the 9 kDa protein identifies an area of amino acid conservation with similar proteins involved in cell-to-cell movement from the carmoviruses. The light gray shaded region in the ORF encoding the 25 kDa capsid protein indicates where amino acid conservation occurs with *Sobemovirus* capsid proteins.

Host Range and Virus Propagation

Maize is the only known natural host for MCMV and it is readily mechanically transmitted to maize as well

as other indicator hosts. Depending on the maize genotype infected, the reaction to the virus can range from highly resistant to extremely susceptible. The inbred corn line N28ht is quite susceptible and produces excellent symptoms to MCMV and is the preferred propagation host. The experimental host range of the virus is restricted to the *Gramineae (Poaceae)*. The virus does not cause symptoms and probably does not infect dicots.

Genetics

The 4.4 kb MCMV genomic RNA is sufficient for replication in maize protoplasts. The genome contains four ORFs capable of encoding polypeptides of 111, 33, 32 and 25 kDa. The first ORF encountered on the 5′ end of the genome encodes a 32 kDa polypeptide (**Fig. 1**). No mutation studies have been performed on this ORF, nor does the 32 kDa polypeptide possess amino acid sequence similarity with any other known viral protein. The function, if any, of this protein is not known. The major ORF encoding the 111 kDa polypeptide is punctuated by an in-frame amber termination codon directing the synthesis of a 50 kDa pre-readthrough product. The readthrough portion of the 111 kDa polypeptide contains the canonical Gly-Asp-Asp (GDD) motif present in all RNA-dependent RNA polymerases. In addition, extensive amino acid sequence similarity exists between the carboxyl-half of the 50 kDa and the 111 kDa polypeptides and the replicases encoded by all of the species within the *Tombusviridae* (**Fig. 1**). As noted with other viruses within the *Tombusviridae*, neither the 50 kDa nor 111 kDa polypeptides possess an identifiable helicase motif. The internal ORF encoding a 33 kDa polypeptide is also interrupted by an in-frame opal termination codon yielding a pre-readthrough polypeptide of 9 kDa. The 9 kDa polypeptide, and particularly the carboxyl-terminus, possesses a high degree of amino acid sequence similarity to other small polypeptides encoded by *Carmoviruses* (**Fig. 1**). These small proteins are implicated in facilitating cell-to-cell movement of the virus infection. The putative 33 kDa readthrough protein has no identifiable sequence similarity to any other protein. The 3′ proximally located ORF encodes the 25 kDa capsid protein.

Serologic Relationships and Variability

To date, three different MCMV serotypes have been identified: Kansas serotypes 1 and 2 and the Peru serotype. The serotypes are differentiated by agar double-diffusion analysis. The Kansas serotypes 1 and 2 are prevalent in Kansas and have been identified as the virus that appeared in Hawaii.

Epidemiology

In Kansas and Nebraska, MCMV infections reoccur in the same locations within corn fields year after year. The areas of infection are discrete and little plant-to-plant spread seems to occur within a single growing season. These observations have led to the hypothesis that the virus is maintained in the soil from season to season. There are conflicting reports as to whether MCMV can survive in maize residue during maize-free periods. The virus has been shown to overwinter in plowed corn stubble. Alternatively, it is hypothesized that the larval stages of the corn rootworms, which have been shown to successfully transmit the virus, are capable of harboring infectious virus during the host-free periods.

The current thought is that MCMV can be introduced into geographically distinct maize growing regions by the introduction of an infected plant or by seed transmission. Once present, the virus can then persist in the region by infection in maize or by overwintering in the larval stages of the vector when the maize host is not present.

Transmission and Tissue Tropism

The virus is easily mechanically transmitted in the laboratory. Extensive research has been conducted on how MCMV is transmitted and maintained in nature, particularly during maize-free periods. MCMV can be transmitted by six species of beetle, belonging to the family *Chrysomelidae;* the cereal leaf beetle (*Oulema melanopa*), the corn flea beetle (*Systena frontalis* and *Chaetocnema pullicaria*), the southern corn rootworm (*Diabrotica undecimpunctata*), the northern corn rootworm (*D. longicornis*) and the western corn rootworm (*D. virgifera*). In Hawaii, MCMV has been shown to be transmitted by the thrip *Frankliniella williamsi*. MCMV can be, and is, seed transmitted at a very low level.

Pathogenicity

In Peru, losses in floury and sweet maize varieties to MCMV have been reported to be on the average of 10–15%. In experimental plots, inoculated plant yields were reduced by up to 59%.

When MCMV co-infects maize with any potyvirus, the synergistic interaction causing CLN occurs. In maize the most common potyviruses found in co-infections with MCMV are maize dwarf mosaic potyvirus (MDMV) A and/or B, and to a lesser extent wheat streak mosaic potyvirus. The symptoms

of CLN are much more severe than the additive symptoms of either MCMV or the potyvirus alone. CLN causes a severe systemic necrosis which culminates in death of the plant. In Kansas, crop losses due to CLN have been estimated to be between 50 and 90%, depending on the variety of corn and the year. If maize plants exhibit a rapid onset of necrosis followed by rapid plant death, it is likely that they are infected with both MCMV and a maize infecting potyvirus. The titer of MCMV in plants infected with both MCMV and a potyvirus is greater than five times higher than in plants infected with MCMV only.

Pathology and Histopathology

For field grown maize infected with MCMV, growth is stunted with the formation of short internodes. Leaf symptoms begin as chlorotic stripes running parallel to the veins, which later coalesce to produce elongated chlorotic blotches, finally resulting in leaf necrosis and epinasty. In severe infections of particularly susceptible lines, the extent of leaf necrosis can result in plant death. Male inflorescences are affected with hard panicles, short rachis and few spiklets. Fewer ears and ear malformation can also occur in severe infections. A general observation is that the younger the maize plant is when MCMV infects, the more severe the stunting and symptoms become. MCMV has been detected in all parts of an infected maize plant, including leaf, stem, roots, cob, husk, silk, kernel, seed, anther and sheath tissues.

Prevention and Control

The most effective control for MCMV will be the deployment of resistant varieties. A number of sources of resistance to MCMV have been identified and are being incorporated into commercial maize varieties throughout the Western Hemisphere. Alternatively, crop rotation with sorghum or another nonmaize crop has been shown to reduce the incidence of MCMV the following year. Soil fumigation apparently does not control MCMV.

CLN can be controlled by effectively controlling and eliminating the infection of either component virus. CLN has been controlled experimentally using a transgenic pathogen-derived resistance approach. Transgenic corn plants expressing the MDMV strain B capsid protein did not lead to CLN when inoculated with MDMV and MCMV.

Evolution

Based exclusively on the analysis of the amino acid sequence similarity of the various viral gene products, MCMV appears to be a composite virus composed of functional domains obtained from both *Tombusviruses* and *Sobemoviruses*. Additional domains of unknown phylogenetic origin are also present in the genome. The replicases of all known and sequenced positive-strand RNA viruses have been placed into three distinct phylogenetic supergroups. The MCMV replicase belongs in supergroup II along with the tombusviruses, carmoviruses, necroviruses, dianthoviruses, a subset of the luteoviruses, pestiviruses, hepatitis C virus, flaviviruses and the positive-strand RNA coliphages (notably Qβ) and the related yeast double-stranded RNA elements. It is generally assumed that the replicase from all of these viruses evolved from a common progenitor and was subsequently dispersed by modular evolution. The MCMV capsid protein fits into a rather large group of icosahedral-shaped viruses whose capsid protein(s) possess a conserved structural element termed the 'jelly-roll' conformation. It is suspected that this type of capsid protein has evolved only once. The capsid protein is most closely related to that of southern bean mosaic sobemovirus. The MCMV movement protein(s) have not been identified, however, significant similarity exists with a known movement protein from the *Carmoviruses*.

Future Perspectives

To date, the *Machlomovirus* genus is monotypic. It would not be surprising if additional machlomoviruses are identified in the near future. If new species are identified, it is likely that they would be found in monocot hosts from the temperate to subtropical climates in the Western Hemisphere. It is also anticipated that MCMV will be identified in maize in additional countries in the Western Hemisphere.

A full-length MCMV cDNA clone from which infectious RNA transcripts can be derived has been constructed. It is anticipated that a genetic study of the MCMV genome will be undertaken using this clone in the near future. It is expected that movement function and possibly vector transmission activities will be mapped to one or more of the unique ORFs.

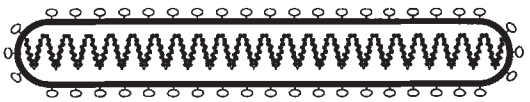
MARBURG AND EBOLA VIRUSES (*FILOVIRIDAE*)



Hans-Dieter Klenk, Werner Slenczka and **Heinz Feldmann**, Institut für Virologie, Philipps-Universität, Marburg, Germany

History

Marburg and Ebola viruses both cause severe hemorrhagic fevers. Marburg virus was first recognized in laboratory workers in Marburg, Germany, and Belgrade, Yugoslavia, in 1967. These workers had been exposed to tissues and blood from African green monkeys (*Cercopithecus aethiops*) imported from Uganda. There were 25 primary cases and six secondary cases in the outbreak. Seven of the primary cases died. Since then, sporadic, virologically confirmed Marburg disease cases have occurred in Zimbabwe, South Africa and Kenya. Ebola virus first emerged in two major disease outbreaks which occurred almost simultaneously in Zaire and Sudan in 1976. Over 500 cases were reported, with mortality rates of 88% in Zaire and 53% in Sudan. A single case was confirmed by virus isolation in Zaire in 1977, and in 1979 Ebola hemorrhagic fever occurred again in Sudan at the site that was involved in 1976. In 1994 the first case of Ebola virus disease occurred in western Africa, Cote d'Ivoire, when an ecologist was infected by examining a dead chimpanzee. Ebola virus re-emerged in Kikwit, Zaire, in 1995, with 316 cases and 245 deaths. From 1994 to 1997 three outbreaks of Ebola virus disease have been observed in Gabon. Ebola-Reston virus was first isolated from naturally infected nonhuman primates in 1989–1990, when *Cynomolgus* monkeys were imported from the Philippines into the USA, and later from monkeys at an export facility located in the Philippines. Further isolates have been made from exported Asian monkeys in 1992 in Italy and in 1996 in Texas, USA. While pathogenic for naturally and experimentally infected monkeys, Ebola-Reston virus may be less pathogenic for humans, having infected four animal caretakers without producing serious disease. At least three laboratory infections with Marburg and Ebola viruses (two fatal outcomes) occurred in Russia; a single nonfatal laboratory infection (Ebloa) occurred in the UK.

Taxonomy and Classification

Filoviruses are classified in the order *Mononegavirales*, a large group of viruses that have nonsegmented negative-stranded RNA as their genomes. The family *Filoviridae*, genus *Filovirus*, was created on the basis of unique morphologic, physicochemical, genetic and biological features of its members. Filoviruses are separated into two distinct species, Marburg and Ebola. The Marburg species consists of a single subtype Marburg including five strains. The Ebola

Taxonomy and Classification

Filoviruses are classified in the order *Mononegavirales*, a large group of viruses that have nonsegmented negative-stranded RNA as their genomes. The family *Filoviridae*, genus *Filovirus*, was created on the basis of unique morphologic, physicochemical, genetic and biological features of its members. Filoviruses are separated into two distinct species, Marburg and Ebola. The Marburg species consists of a single subtype Marburg including five strains. The Ebola

species is subdivided into four subtypes: Zaire, Sudan, Cote d'Ivoire and Reston. In terms of biohazard classification, filoviruses are classified as Biosafety Level 4 (BSL4) agents based on their high mortality rate, person-to-person transmission, potential aerosol infectivity, and absence of vaccines and chemotherapy. Maximum containment is required for all laboratory work with infectious material.

Properties of the Virion

By electron microscopy, filovirus particles are pleomorphic, appearing as long filamentous, sometimes branched forms, or as 'U'-shaped, '6'-shaped or circular forms. The particles vary greatly in length (up to 14 000 nm), but have a uniform diameter of about 80 nm. Virions purified by ratezonal gradient centrifugation are bacilliform in outline and show an average length associated with peak infectivity of approximately 665 nm for Marburg and 805 nm for Ebola virus. Except for the difference in length, filoviruses seem to be very similar in morphology. Virions contain a nucleocapsid consisting of a dark, central space (20 nm in diameter) surrounded by a helical capsid (50 nm in diameter) bearing cross-striations with a periodicity of approximately 5 nm. Within the nucleocapsid is an axial channel of 10–15 nm (**Fig. 1**). The nucleocapsid is composed of the genomic RNA and the large (L) protein, nucleoprotein and virion proteins 35 and 30. It is surrounded by a lipoprotein unit membrane envelope derived from the host cell plasma membrane. Spikes of approximately 7 nm length, spaced at approximately 10 nm intervals, are visible on the virion surface and are formed by the viral glycoprotein.

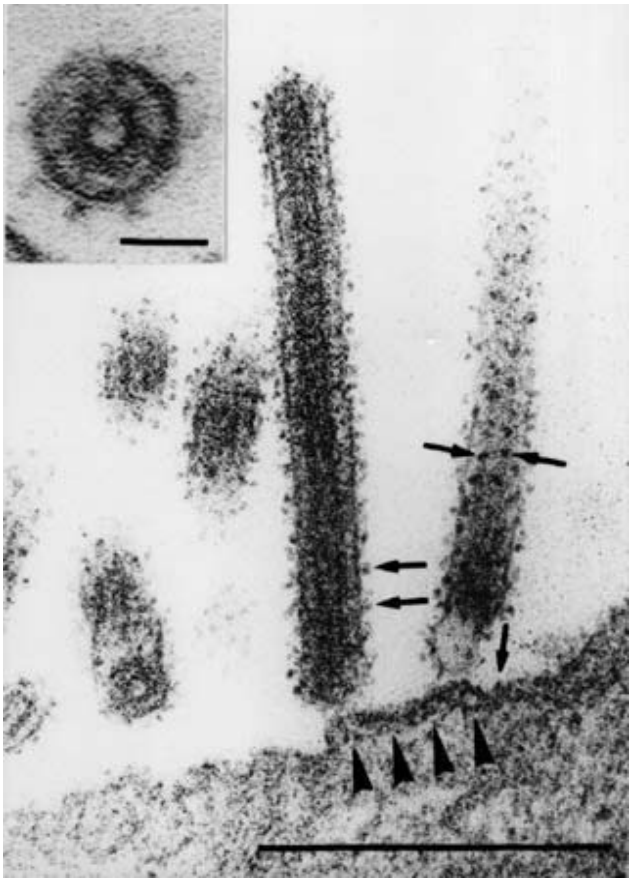

Figure 1 Marburg virus particles. An electron micrograph (ultrathin section) showing budding of Marburg virus particles from the plasma membrane of infected primary cultures of human endothelial cells. Particles consist of a nucleocapsid surrounded by a membrane in which spikes are inserted (arrows). The nucleocapsid contains a central channel (inset). The plasma membrane of infected cells is often thickened at locations where budding occurs (arrowheads). Bar = 0.5 μm; inset bar = 50 nm.

Physical Properties

Virus particles have a molecular weight of approximately $3–6 \times 10^8$ and a density in potassium tartrate of 1.14 g ml^{-1}. Uniform, bacilliform particles have a sedimentation coefficient of 1300–1400 S, whereas larger particles have a higher sedimentation coefficient. Virus infectivity is quite stable at room temperature. Inactivation can be performed by UV and gamma irradiation, 1% formalin, β-propiolactone, and brief exposure to phenolic disinfectants and lipid solvents, like deoxycholate and ether.

Properties of the Genome

The genome of filoviruses consists of a molecule of linear, nonsegmented, negative-stranded RNA which is noninfectious, not polyadenylated, and complementary to viral-specific messenger RNA. The genome amounts to 1.1% of the total virion weight and the sedimentation coefficient is 46 S (0.15 mol l^{-1} NaCl, pH 7.4). Filovirus genomes are approximately 19 kb in length and very rich in adenosine and uridine residues. Genomes show a linear gene arrangement in the order 3′ leader – nucleoprotein (NP) – viral structural protein (VP) 35 – VP40 – glycoprotein (GP) – VP30 – VP24 – polymerase (L) – 5′ trailer. All genes are flanked at their 3′ and 5′ ends by highly conserved transcriptional start (3′-CUnCnUnUAAUU-5′) and termination (3′-UaAUUCUUUUU-5′) signal sequences, respectively, which almost all contain the pentamer 3′-UAAUU-5′. Most genes are separated by intergenic sequences variable in length and nucleotide composition, but some genes overlap by the conserved pentanucleotide sequence. Subtype Zaire Ebola viruses show three overlaps that alternate with intergenic sequences (VP35/VP40, GP/VP30, VP24/

L), while the Marburg virus genome contains a single overlap at a different position (VP30/VP24). Extragenic sequences are present at the 3′ and 5′ end of filovirus genomes which are complementary at their very extremities. These sequences are comparable to those found in genomes of other nonsegmented negative-stranded RNA viruses and are known as leader sequences. However, neither (+) nor (−) leader RNAs have been detected in filovirus-infected cells.

Properties of Viral Proteins

Virions contain at least seven proteins with presumed identical functions for the different viruses. The electrophoretic mobility patterns of the structural proteins are characteristic for Marburg strains on the one hand and Ebola strains on the other. Four proteins are associated with the viral ribonucleoprotein complex (NP, L, VP30 and VP35), the single glycoprotein (GP) is inserted in the envelope, and the location of two proteins (VP40 and VP24) has not been determined exactly, but they seem to be membrane associated. The L protein is the largest protein and, like other L proteins of nonsegmented negative-stranded RNA viruses, represents the virion-associated RNA-dependent RNA polymerase. Its size, as calculated from the deduced amino acid sequence of the Marburg virus (Musoke strain) L gene, is 267 kDa. GP (Marburg virus 170 kDa; Ebola virus 160 kDa) is a type I transmembrane protein and inserted in the lipid membrane as a homotrimer, as shown directly for Marburg virus. It is reasonable to assume that GP is the mediator of virus entry into the cell. Functional sites for receptor recognition and binding, and perhaps for fusion, should be located on this protein. GP undergoes several post-translational modifications: glycosylation, acylation and proteolytic cleavage. The carbohydrate structures of this highly glycosylated protein account for >50% of its M_r. They include oligomannosidic and hybrid type *N*-glycans as well as bi-, tri- and tetra-antennary complex species, and high amounts of neutral mucin-type *O*-glycans. In contrast to Ebola viruses, sialylation of Marburg virus carbohydrate structures is cell line dependent. In case of Marburg virus GP, acylation occurs at cysteine residues located at the boundary between the membrane anchor and cytoplasmic domains. The Golgi-specific precursor (preGP) is proteolytically cleaved into the subunits GP1 and GP2 by a proprotein convertase, most likely furin. Mature GP (GP1/2) is a disulfide-linked complex of the cleavage subunits and is anchored in the membrane via the carboxy-terminal part of GP2. The major nucleoprotein (NP) (Marburg virus 96 kDa; Ebola virus 104 kDa) and VP30 (Marburg virus 28 kDa; Ebola virus 30 kDa), which may represent a minor nucleoprotein, seem to be intimately associated with the virion ribonucleoprotein complex. VP35 (Marburg virus 32 kDa; Ebola virus 35 kDa) is loosely associated with the ribonucleoprotein complex and seems to be a component of the transcriptase complex analogous to the P protein of paramyxoviruses and the NS (P) protein of rhabdoviruses. The functions of VP40 (Marburg virus 38 kDa; Ebola virus 40 kDa) and VP24 (Marburg virus 24 kDA; Ebola virus 24 kDa) are not known, but they are probably membrane components. VP40 is the most prominent viral structural protein and most likely represents the matrix protein of filoviruses. A nonstructural glycoprotein has recently been discovered with Ebola viruses. This protein, designated sGP, is the primary gene product of gene 4 and efficiently secreted from infected cells. Recently it was detected in high concentrations in the blood of acutely infected Ebola hemorrhagic fever patients. The function of sGP is unknown, but an interaction with the cellular and humoral host immune responses has been postulated. A similar protein is not found with Marburg viruses.

Replication

Cell entry seems to be mediated by GP as the only surface protein of virion particles. Studies on Marburg virus infections of hepatocytes have identified the asialoglycoprotein receptor as a receptor candidate. However, one has to postulate additional receptors as this protein is not expressed on many virus-susceptible cells. Whether the next step in virus entry involves a fusion process at the plasma membrane or fusion following endocytosis of virus particles is not known. The genetics of filoviruses are probably similar to those of *Paramyxoviridae* and *Rhabdoviridae*. Transcription and replication take place in the cytoplasm of infected cells. The 3′ leader of the genome probably provides the encapsidation site for the nucleoprotein as well as the entry site for the polymerase. Filovirus genomes are transcribed to yield mainly monocistronic subgenomic messenger RNA species which are complementary to viral genomic RNA. Transcription of the Ebola virus GP gene gives rise to at least two different messenger RNA species. The primary transcript encodes small (s) GP which is encoded by the amino-terminal open reading frame of gene 4. Full-length GP is expressed by transcriptional editing of a single nucleotide at a run of uridine residues that combines the sGP open reading frame with an overlapping additional reading frame in −1. The 5′ ends of the subgenomic RNAs

start precisely at the transcription start signal sequence, and the 3′ ends carry a poly(A) tail generated by the polymerase at a run of uridine residues located at the 5′ ends of all transcription termination signal sequences. Transcription efficiency might be influenced by gene order, formation of secondary structures at the 3′ ends of the genes, secondary structure formation within the intergenic sequences, overlapping genes, and presence of duplicated termination sites. Filovirus transcripts contain unusually long untranslated regions, especially at the 3′ ends. The 5′ end untranslated regions show a potential for a formation of stable hairpin structures, which might play a role in transcript stability and ribosome binding. Replication of the genome is mediated by the synthesis of a full-length complementary antigenome ((+) sense) which then serves as the template for the synthesis of progeny negative-stranded RNA molecules anticomplementary to the parental template RNA. The complementarity of the genome extremities suggests a single identical encapsidation site on the genome and antigenome and an identical entry site for the polymerase for both the transcription and the replication mode. The cytoplasm of virus-infected cells contains prominent inclusion bodies consisting of viral nucleocapsid. As infection proceeds, they grow and become highly structured. Budding of completed virus particles takes place at cell membrane sites which are altered by insertion of the viral glycoprotein and alignment of viral membrane-associated proteins as well as of preformed nucleocapsids.

Geographic Distribution

Filoviruses, with the exception of subtype Reston of Ebola viruses, appear to be indigenous to the tropical rain forest regions of Central Africa, as indicated by the geographic locations of known outbreaks and seroepidemiological studies. This is also suggested by the fact that almost all filovirus isolates from human patients are of African origin. This includes the European isolates of Marburg viruses that could be traced back to foci in Uganda, from where vervet monkeys were imported to Germany and the former Yugoslavia. The Ebola-Reston outbreak suggested for the first time the presence of a filovirus in Asia. Studies among captive macaques in the Philippines indicated that the source of Ebola-Reston virus might be wild nonhuman primates; thus, it appears that filoviruses are not confined to Africa.

Host Range and Virus Distribution

The natural reservoirs for human and nonhuman primate infections with filoviruses are unknown. Experimental hosts include monkeys, for which infection with Marburg and Ebola-Zaire virus are usually lethal, whereas some animals survive infections with Ebola-Sudan and Ebola-Reston viruses. Guinea pigs show febrile responses 4–10 days after inoculation with Marburg and Ebola viruses. However, none of these viruses kills guinea pigs consistently on primary inoculation. Ebola-Zaire virus is usually pathogenic for newborn mice after intracerebral and intraperitoneal inoculation. For growth in cell culture, primary monkey kidney cells and monkey kidney cell lines, usually Vero cells, are used. Filoviruses also grow in human endothelia maintained as primary cell cultures or as organ cultures.

Evolution

Molecular analyses of the genomes clearly demonstrated that filoviruses are the closest relatives to *Rhabdoviridae* and *Paramyxoviridae*. All nonsegmented negative-stranded RNA viruses share a similar genome organization, with conserved regions at both ends encoding the core and L proteins surrounding a variable part in the middle encoding the envelope proteins. Filovirus genomes are more complex than those of lyssaviruses and vesiculoviruses and align organizationally more closely to members of the genera *Paramyxovirus* and *Morbillivirus*. This relationship is confirmed on the amino acid level as demonstrated for the nucleoproteins and polymerases (L proteins). The Marburg species is genetically more homogenous. Comparative sequence analysis showed that two lineages coexist with the recent isolate from Kenya (Ravn strain, 1987) differing from the others by 21–23% at nucleotide level. Since this divergence is less than that separating Ebola subtypes (see below), the Ravn strain does not represent a distinct subtype. Significant differences within the Ebola species were first based on peptide and oligonucleotide mapping, which have since been confirmed by sequence comparison analysis of the glycoprotein genes. All four subtypes differ from one another by 37–41% and 34–43% at the nucleotide and amino acid level, respectively. Phylogenetic analysis of the glycoprotein open reading frame revealed a closer relationship of the three African subtypes compared with Reston, supporting the concept of an Asian origin of Reston viruses. Within individual subtypes of filoviruses the variation in nucleotide sequences has been shown to be $<7\%$ and even $<2\%$ among distinct subtype Zaire viruses. Recently it was reported that there is no genetic variability between strains isolated from different patients of single outbreaks in Gabon and Kikwit. All the data indicate a remarkable degree of stability over time for RNA viruses that are usually

thought to be extremely variable. Furthermore, it appears that filoviruses might have evolved into specific niches and may reflect a similar divergence in the natural hosts, assuming they have coevolved.

Serologic Relationships

Comparison of the two species of filoviruses, Marburg and Ebola, showed similarities between amino acid sequences of the structural proteins. This finding indicates that the structural proteins have maintained similar structures and functions. Despite this amino acid similarity, there is no indication that there is any significant serological (antigenic) crossreactivity between Ebola and Marburg viruses, but the different subtypes of the Ebola species share common epitopes. Neutralization tests for Marburg and Ebola viruses have not yet been shown sufficiently reliable to enable determination of taxonomic relationships.

Epidemiology

The reservoir of filoviruses remains a mystery. Many species have been discussed as possible natural hosts. However, no nonhuman vertebrate hosts or arthropod vectors have yet been identified. Epidemiological data, obtained in association with the 1967 Marburg outbreak and the 1994 Côte d'Ivoire case as well as the Ebola-Reston episodes, suggested monkeys as a potential reservoir of filoviruses. However, the high pathogenicity of filoviruses, especially of Marburg virus and subtypes Sudan and Zaire of Ebola virus, for nonhuman primates does not support such a concept. Similarities in biological properties to other viral hemorrhagic fever agents, such as 'Old World' arenaviruses, favor a chronic infection of an animal that regulates survival of filoviruses in nature. This is in line with recent data on experimentally infected fruit and insectivorous bats that demonstrated asymptomatic Ebola virus replication in these animals. Nosocomial transmission, mainly due to a lack of hygiene, is of major public health concern. Based on experiences of former episodes, isolation of patients and use of strict barrier nursing procedures (e.g. protective clothing, respirator) are sufficient to interrupt transmission.

Transmission and Tissue Tropism

The mode of primary infection with Marburg and Ebola viruses in any natural setting is not known. The physical contact route of infection is undoubtedly the most common means of transmission from humans to humans. Especially activities such as nursing and preparing bodies for burials are associated with an increased risk of becoming infected. One Marburg case was acquired by sexual contact more than 60 days after the original infection. Neonatal transmission has been reported for the 1976 outbreak in Zaire. Transmission by droplets and small-particle aerosols has been observed among experimentally infected and quarantined imported monkeys (Ebola-Reston virus, 1989–1990). This is confirmed by identification of filovirus particles in alveoli of naturally and experimentally infected monkeys. However, the contribution of aerosol transmission to the course of human outbreaks is still unknown.

Virus is usually recovered from acute-phase sera and has also been found in throat washes, urine, soft tissue effusates, semen and anterior eye fluid, even when the specimens were obtained late in convalescence. It has also been regularly isolated from autoptic material, such as spleen, lymph nodes, liver and kidney, but rarely from brain or other nervous tissues.

Pathogenicity

Marburg and Ebola viruses cause severe hemorrhagic fever in humans and laboratory primates. According to the evidence available to date, subtype Reston of Ebola virus causes hemorrhagic fever in monkeys, but appears to be apathogenic for humans. The subtype Zaire strains of Ebola virus apparently have the highest mortality in humans when compared with other subtypes or Marburg virus.

Clinical Features of Infection

Clinical symptoms are similar with Marburg and Ebola virus infections. Following incubation periods of 4–16 days, onset is sudden, marked by fever, chills, headache, anorexia and myalgia. These signs are soon followed by nausea, vomiting, sore throat, abdominal pain and diarrhea. When first examined, patients are usually overtly ill, dehydrated, apathetic and disoriented. Pharyngeal and conjunctival injections are usual. Most of the patients develop severe hemorrhagic manifestations, usually between days 5 and 7. Bleeding is often from multiple sites, with the gastrointestinal tract, lungs and gingiva the most commonly involved. Bleeding and oropharyngeal lesions usually herald a fatal outcome. Death occurs between days 7 and 16, usually from shock with or without severe blood loss.

Pathology, Histopathology and Pathogenesis

Marburg and Ebola viruses cause similar pathological changes in humans. The most striking lesions are

found in liver, spleen and kidney. These lesions are characterized by focal hepatic necrosis with little inflammatory response and by follicular necrosis of lymph nodes and spleen. In late stages of the disease, hemorrhage occurs in the gastrointestinal tract, pleural, pericardial and peritoneal spaces, and into the renal tubules with deposition of fibrin. Abnormalities in coagulation parameters include fibrin split products and prolonged prothrombin and partial thromboplastin times, suggesting that disseminated intravascular coagulation is a terminal event. There is usually also profound leukopenia in association with secondary bacteremia. Ebola-Reston virus causes similar pathological changes in monkeys, as described for human infections with Marburg and other subtype Ebola viruses. In Reston-infected animals it was clearly demonstrated that virus replication was extensive in fixed tissue macrophages, interstitial fibroblasts of many organs, circulating macrophages and monocytes, and less frequently in vascular endothelial cells, hepatocytes, adrenal cortical cells and renal tubular epithelium. Macrophages seem to be the first and preferred site of replication by filoviruses.

Clinical and biochemical findings support anatomical observations of extensive liver involvement, renal damage, changes in vascular permeability, and activation of the clotting cascade. Visceral organ necrosis is the consequence of virus replication in parenchymal cells. However, no single organ is sufficiently damaged to explain fatal outcome. Fluid distribution problems and platelet abnormalities indicate dysfunction of endothelial cells and platelets. Virus-induced release of humoral factors, such as cytokines, may increase endothelial permeability and may be a major factor in the shock syndrome regularly observed in severe and fatal cases.

Immune Response

Fatal filovirus infections usually end with high viremia and no evidence of an effective immune response. In monkeys infected with Ebola-Reston virus nonprotective antibodies have been observed shortly before death. Altogether, however, the data available today do not support an important role of neutralizing antibodies in virus clearance. Since circulating monocytes/macrophages are primary target cells in filovirus infections, and since the extensive disruption of the parafollicular regions in spleen and lymph nodes results in the destruction of the antigen-presenting dendritic cells, cellular immunity appears also to be affected during filoviral hemorrhagic fever. In addition to these cytolytic effects, there are several other mechanisms by which filoviruses may interfere with the immune system. Firstly, the high carbohydrate content of GP may suppress its immune reactivity. Secondly, the nonstructural sGP that is secreted from cells infected with Ebola virus may interfere with the virus-directed immune response. Thirdly, GP1 which is also secreted in large amounts from infected cells, may have similar effects. Fourthly, full-length GP displays a sequence motif homologous to an immunosuppressive domain observed in retroviral glycoproteins. Altogether, there is now a large body of evidence indicating that filoviruses induce immunosuppression in the infected host, which appears to be a major factor for the rapid spread and the severity of the disease.

Prevention and Control

Although neutralizing antibody titers in human convalescent sera can, if at all, only barely be detected in laboratory tests, there are anecdotal case reports suggesting the potential benefit of passive immunization against Ebola virus infection. Furthermore, recent reports from the 1995 outbreak in Zaire about effective treatment of acutely ill patients with whole blood transfusions from convalescent donors suggest that quantities of antibodies, predicted to be marginally effective in laboratory tests, may still be protective. There is experimental evidence that active immunization employing killed virus, recombinant expressed glycoprotein, and recombinant gene 4 (GP)-DNA (DNA vaccination) is partially successful in animals, suggesting that these may be feasible strategies to elicit protective immunity. At present, however, vaccines for human application are not available. A specific chemotherapeutic treatment is not available to date, but knowledge of the expected clinical course can anticipate medical complications, including disseminated intravascular coagulation, shock, encephalomyelitis, cerebral edema, kidney failure, superinfection, hypoxia and hypotension. Patients have to be isolated and clinical personal to be protected. Human interferon, human convalescent plasma and anticoagulation therapy has been used, but their success is still controversial.

Diagnosis

Because Marburg and Ebola viruses are highly virulent, special precautions need to be taken when samples are handled, and for some procedures biocontainment (BSL4) is necessary. For acute diagnosis polymerase chain reaction (PCR) and antigen-ELISA are suitable. For confirmation virus isolation

should be initiated in appropriate cell cultures (Vero E6 cells, MA 104 cells) from acute-phase serum or biopsy/autopsy materials (liver, spleen, lymph nodes, kidney, heart). During viremia particles can usually be visualized by electron microscopy. Serum antibody titers are determined by ELISA (IgM μ-capture, IgG) or indirect fluorescent-antibody immunofluorescence assay (IFA) (caution: prone to nonspecific positives). Serum from patients with suspected cases should be inactivated by gamma irradiation prior to serotesting. Neutralization tests are totally unreliable for filoviruses.

MAREK'S DISEASE VIRUS (*HERPESVIRIDAE*)

LN Payne, Institute for Animal Health, Compton, Newbury, Berkshire, UK

History

Marek's disease (MD) is a common lymphomatous and neuropathic disease of domestic fowl, and less commonly of turkeys and quail. It is named after the Hungarian pathologist, Jozsef Marek, who in 1907 first described the neuropathic form. In 1926, Pappenheimer and colleagues in the USA described many features of the disease and recognized visceral lymphomas as part of the pathology. Both the neural form (formerly termed 'neurolymphomatosis' or 'fowl paralysis') and the visceral lymphomatosis form (termed 'acute leukosis' or 'acute MD') were serious causes of economic loss to the poultry industry worldwide for many years (**Figs 1–3**).

Although MD was early considered to be an infectious disease, confusion with retrovirus-induced leukoses pathologically and in transmission experiments hindered understanding. However, experimental transmission of MD was established convincingly in the early 1960s, and in 1967 Churchill and Biggs in the UK and Nazerian, Solomon, Witter and Burmester in the USA established the cause as a herpesvirus. Two years later, MD virus (MDV) attenuated in tissue culture was shown to provide vaccinal protection against MD.

The nonpathogenic herpesvirus of turkeys (HVT) (turkey herpesvirus) was discovered in 1969 by Kawamura, King and Anderson in the USA, and in 1970 was shown to protect chickens against MD by Okazaki, Purchase and Burmester. Since then, HVT has become the most widely used vaccine against MD, and vaccination has greatly reduced mortality and economic loss from the disease. MD vaccinations were performed effectively until the late 1970s when evidence emerged from the USA of increased rates of

MAREK'S DISEASE VIRUS (*HERPESVIRIDAE*)

LN Payne, Institute for Animal Health, Compton, Newbury, Berkshire, UK

History

Marek's disease (MD) is a common lymphomatous and neuropathic disease of domestic fowl, and less commonly of turkeys and quail. It is named after the Hungarian pathologist, Jozsef Marek, who in 1907 first described the neuropathic form. In 1926, Pappenheimer and colleagues in the USA described many features of the disease and recognized visceral lymphomas as part of the pathology. Both the neural form (formerly termed 'neurolymphomatosis' or 'fowl paralysis') and the visceral lymphomatosis form (termed 'acute leukosis' or 'acute MD') were serious causes of economic loss to the poultry industry worldwide for many years (**Figs 1–3**).

Although MD was early considered to be an infectious disease, confusion with retrovirus-induced leukoses pathologically and in transmission experiments hindered understanding. However, experimental transmission of MD was established convincingly in the early 1960s, and in 1967 Churchill and Biggs in the UK and Nazerian, Solomon, Witter and Burmester in the USA established the cause as a herpesvirus. Two years later, MD virus (MDV) attenuated in tissue culture was shown to provide vaccinal protection against MD.

The nonpathogenic herpesvirus of turkeys (HVT) (turkey herpesvirus) was discovered in 1969 by Kawamura, King and Anderson in the USA, and in 1970 was shown to protect chickens against MD by Okazaki, Purchase and Burmester. Since then, HVT has become the most widely used vaccine against MD, and vaccination has greatly reduced mortality and economic loss from the disease. MD vaccinations were performed effectively until the late 1970s when evidence emerged from the USA of increased rates of

Figure 1 Paralysis of the legs in Marek's disease. (From Purchase (1985), in *Marek's Disease*, Payne, L.N. (ed), pp 17–42, Martinus Nijhoff Publishing, Boston, with permission.)

condemnation from MD of vaccinated broiler chickens and vaccination failure in older birds. The so-called very virulent strains of MDV were isolated from affected flocks, against which HVT provided poor protection. Subsequently effective new vaccination strategies were developed but these have required further modification following the appearance of even more virulent strains of MDV.

Apart from its importance in veterinary medicine and to the poultry industry, MD has attracted considerable interest in biomedicine as a model of a lymphoma caused by a herpesvirus and preventable by vaccination.

Classification and Properties of the Virus

MDV and HVT are typical herpesviruses, in the family *Herpesviridae*, subfamily Alphaherpesvirinae, genus Marek's disease-like viruses. The nucleocapsid measures 85–100 nm and has 162 hollow capsomeres. Enveloped particles measure up to 400 nm. The nucleoid has a spherical to toroidal structure. Although originally placed with the gammaherpesviruses because of their lymphotropism, molecular studies show that MDV and HVT are more closely related to the alphaherpesviruses, such as herpes simplex virus.

Three serotypes of the virus are recognized: serotype 1, which comprises a variety of strains of MDV which vary from being highly to weakly oncogenic; serotype 2, which contains nononcogenic strains of MDV, although a virulent strain has been reported, and serotype 3, represented by HVT, which is also nononcogenic. These serotypes are distinguished in polyclonal or monoclonal antibody tests, polypeptide pattern and DNA analysis.

Serotype 1 isolates can also be classified pathotypically as mild (mMDV), virulent (vMDV), very virulent (vvMDV) and very virulent plus (vv + MDV).

Properties of the Genome

The DNAs of serotype 1 MDV and HVT are linear double-stranded molecules of approximately 180 and 167 kbp, respectively. Structurally the genomes consist, like herpes simplex virus, of a long unique region (U_L) and a short unique region (U_S) bounded by

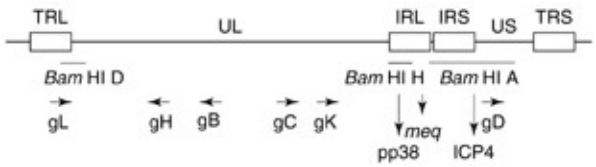

Figure 4 Schematic representation of the MDV genome. The 200 kbp sequence consists of a long unique sequence (UL) flanked by a terminal repeat (TRL) and an internal inverted repeat (IRL) and a short unique sequence (US) flanked by an internal (IRS) and an inverted terminal repeat region (TRS). Part of the BamHI linkage map and the positions of the MDV-specific proteins are shown. (From Venugopal and Payne (1995), *Avian Pathol.* 24, 597–609, with permission.)

inverted repeats (**Fig. 4**). Physical maps of restriction endonuclease fragments are available for MDV and HVT. There is little homology between the three serotypes under stringent hybridization conditions, although, under certain low-stringency conditions, the DNAs of serotype 1 MDV and HVT show about 70% homology. Some genes have been mapped, but those responsible for oncogenicity have not yet been identified. Candidate genes associated with oncogenicity include a 1.8 kb family, *meq* (which resembles the *jun/fos* family), *ICP4* and *pp38*.

Properties of Virus Proteins

More than 40 virus-specific polypeptides, many glycosylated, have been isolated from MDV- or HVT-infected cells. The A antigen detected by gel immunoprecipitation is a secreted cell-surface antigen of unknown function. Its gene is homologous to the *gC* gene of herpes simplex virus. The B antigen detected by immunoprecipitation stimulates virus-neutralizing antibodies and consists of three polypeptides. Its gene is homologous to the *gB* gene of herpes simplex virus. A C antigen has also been identified by immunoprecipation; its gene has not yet been identified.

Replication

Two main types of virus–cell interaction occur with MDV and HVT, similar to those described for other herpesviruses: (1) productive infections, which are cytolytic and in which virions are completely or partially formed; (2) nonproductive infections, which are noncytolytic and in which there is either no or only limited expression of the viral genome. Fully productive infection by MDV and HVT occurs *in vivo* in feather follicle epithelium from which enveloped infectious virus is released. RNA is transcribed from almost the whole viral genome. Semiproductive or restrictively productive infection occurs *in vivo* in lymphoid organs, epithelial cells and occasionally in tumors, and *in vitro* in cultured cells such as chick kidney cells or chick or duck embryo fibroblasts. Most of the virions produced are non-enveloped and noninfectious. Nonproductive infection by MDV is typified by lymphoma cells and by lymphoblastoid cell lines and transplantable lymphomas derived from them. Multiple (5–15) copies of the viral genome are present and are expressed by immortalization of the cells. Most of the viral genome is in the form of full-length closed circular DNA, but there is also evidence for some viral DNA integrated into the host chromosomes. A limited degree of latent MDV genome transcription has been demonstrated. HVT does not produce neoplastic transformation. A second type of nonproductive infection occurs in latently infected lymphocytes in birds infected with MDV or HVT, in which fewer than five viral genome copies are present.

Physical Properties

Cell-free preparations of MDV are stable at pH 7 but lose infectivity above and below this pH. Virus titer is stable at −65°C but titer is lost at −20°C. All infectivity is lost after 2 weeks at 4°C and after shorter periods at higher temperatures. Virus-infected feather materials retain infectivity at room temperature for many months. Cell-free MDV and HVT can be lyophilized in the presence of appropriate stabilizers. Cell-free MDV is sensitive to ether and formalin and is inactivated by common chemical disinfectants.

Viral Isolation and Propagation

Commonly favored for isolation of MDV or HVT in cell culture are viable whole blood cells, buffy coat cells, kidney cells or lymphoma cells. Almost all infectivity is lost from such tissues by treatments that disrupt cells. Cell-free MDV or HVT is present in feather follicle epithelium of infected chickens or turkeys, and viral preparations may be obtained by homogenization and sonication of skin with feather follicles or feather quill tips.

MDV or HVT can be detected in such materials by the following techniques.

1. Chick inoculation – in genetically susceptible chicks, pathogenic MDV induces microscopic lesions in nerves and other tissues from 2 weeks postinoculation and gross neural lesions and visceral lymphomas from 3 weeks. vvMDV can also cause an early mortality syndrome due to cytolytic infection. Nonpathogenic MDV and

HVT do not produce gross lesions, but may be detected by the presence of cell-associated viremia, precipitating or neutralizing antibodies, and antigen in feather tips.

2. Cell culture – cell-associated and cell-free MDV and HVT produce cytopathic plaques characteristic of herpesviruses within a few days when inoculated on to tissue culture monolayers of chick kidney cells, duck embryo fibroblasts, chick embryo fibroblasts and some other avian cells. Plaques vary in size and rate of development depending on the strain of virus, and degenerating cells contain type A intranuclear inclusion bodies. The virus in plaque cells is closely cell-associated, although some amounts of cell-free virus can be harvested from disrupted cells especially in medium containing stabilizers. Serial passage of pathogenic MDV in cell culture results in attenuation of the virus, a phenomenon used to produce vaccine strains.
3. Polymerase chain reaction assays have been developed which can discriminate between pathogenic and attenuated virus strains.
4. Embryonated eggs – MDV and HVT produce pocks on the chorioallantoic membrane of the chick embryo after yolk sac inoculation, but the technique is not of great practical value.

Distribution and Epizootiology

Under natural conditions, infection by MDV occurs mainly in domestic chickens and is ubiquitous among poultry populations throughout the world. Infection of turkeys and quail by MDV sometimes occurs and can cause clinical disease. In commercial chicken flocks, virtually all birds become infected, commonly within the first few weeks of life, and the virus persists throughout life. Whether or not infection leads to clinical disease is often unpredictable and depends on several factors, including the pathogenicity of the strain of MDV, the age at infection and the genetic constitution of the birds. Losses can be especially high in areas of intensive broiler rearing. Mixed infections can occur, and natural first infection by a nonpathogenic strain of MDV (of serotype 1 or 2) can provide immunity to subsequent infection by a virulent strain. HVT is widely distributed in turkey flocks. There is no evidence that MDV or HVT present any health hazard to humans.

The main source of MDV and HVT in the environment and the vehicle for virus spread is feather debris and dander from infected birds. Infectivity is also present in oral and nasal fluids. Contaminated poultry house dust and litter remain infective for many months. The darkling beetle (*Alphitobius diaperinus*) can carry MDV passively, but does not appear to be an important vehicle for spread of virus. The infections are readily transmitted by the airborne route. Egg transmission of MDV and HVT does not occur.

A number of stresses, including handling, change of housing, vaccination and debeaking, have been anecdotally associated with exacerbation of clinical MD in infected flocks, and experimental studies have shown that the stress induced by changes in social hierarchies of birds ('pecking orders') and genetically controlled responses to stress, as measured by corticosterone levels, can influence the incidence of disease.

Clinical Features

Four clinical forms of MD are recognized.

1. The 'classical form' refers to the neural form of the disease (formerly termed 'fowl paralysis' or 'range paralysis') in which up to a third of a flock may be affected with signs of paresis or paralysis, commonly of the legs and wings, occurring usually in birds of 2–12 months of age. Iritis sometimes occurs (**Fig. 1**).
2. The 'acute form' applies to the more virulent form of the disease in which lymphomatosis of various visceral organs is common, and where the mortality may reach 80% of a flock (**Fig. 3**). Birds may be affected as early as 6 weeks of age, and losses commonly occur between 3 and 6 months, and sometimes in adults. Neural involvement is usually also present. Lymphomatous involvement of the skin ('skin leukosis') and ocular involvement may also be evident. Visceral and skin lymphomas due to MD are important causes of carcase condemnation in poultry dressing plants.
3. 'Transient paralysis' is an uncommon acute encephalitic expression of infection by MDV, occurring in birds of 5–18 weeks of age. The sudden symptoms of locomotory disorders usually disappear within 24–48 h and mortality is low.
4. Birds may die from an 'acute mortality syndrome', before the onset of lymphomas. They show severe atrophy of the thymus and bursa of Fabricius, and degenerative changes in other tissues, as a result of a severe cytolytic infection.

Pathology and Pathogenesis

Enlarged peripheral nerves are present in almost all chickens with clinical signs of classical MD and in many with the acute form of the disease (**Fig. 2**).

Figure 5 Lymphoid cell infiltration in peripheral nerve of a chicken with Marek's disease. (From Payne (1972), in *Oncogenesis and Herpesviruses*, Biggs, P.M., de The, G., and Payne L.N. (eds), pp. 21–37, IARC Scientific Publications No. 2, International Agency for Research on Cancer, Lyon, with permission.)

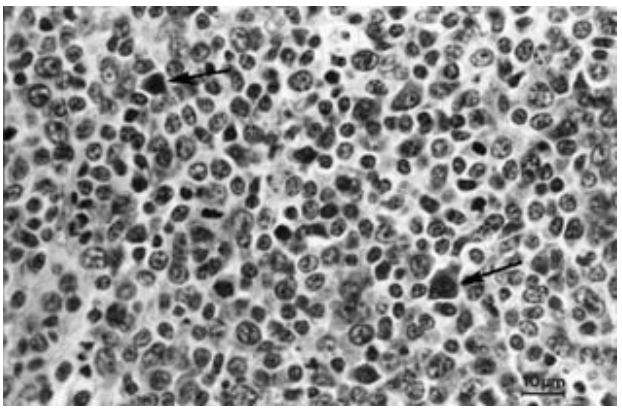

Figure 7 Ovarian lymphoma showing varying morphology of lymphoid cells, including so-called MD cells (degenerative lymphoblasts) (arrows). (From Payne (1985) in *Marek's Disease*, Payne, L.N. (ed), pp 43–75, Martinus Nijhoff Publishing, Boston, with permission.)

Affected nerves are usually two or three times their normal thickness, those commonly affected being the lumbosacral and brachial plexuses, the sciatic and brachial trunks and the celiac plexus. Two main pathological processes occur in the peripheral nerves: (1) a neoplastic lymphoproliferation (**Fig. 5**), similar to that which gives rise to lymphomas in other tissues (see later), and (2) a primary segmental cell-mediated demyelination (**Fig. 6**). Nerves with lymphoproliferation and demyelination have been termed A-type lesions, and those with demyelination, light inflammatory infiltration and interneuritic edema, B-type lesions. A mild form of the B-type lesion is termed C-type. Demyelination is associated with humoral and cell-mediated immune reactions to normal myelin.

Lymphomas in visceral organs occur in a minority of cases of classical MD, notably in the ovary (**Fig. 3**), and in various organs and tissues in acute MD, particularly the gonads, liver, spleen, proventriculus, kidneys, heart and skin. The lymphomas consist of a mixture of small and medium lymphocytes, lymphoblasts, reticulum cells and macrophages (**Fig. 7**). The majority of lymphoma cells are T cells and most of the other cells are B cells. Lymphoblastoid T cell lines (**Fig. 8**) and transplantable tumors can be developed from lymphomas. A minority of lymphoma cells and lymphoblastoid cells carry a membrane antigen,

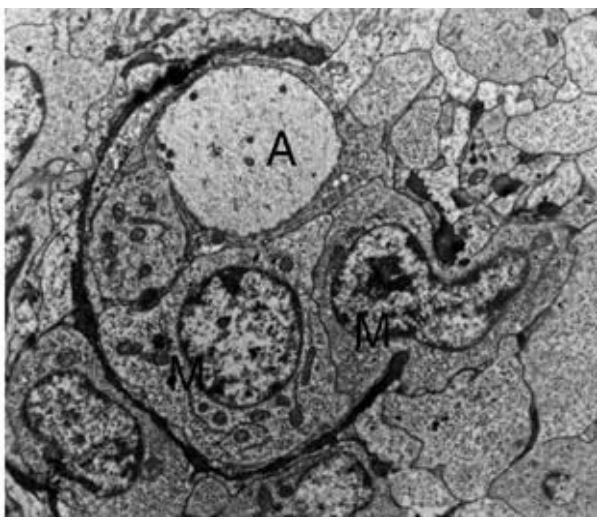

Figure 6 Invasion of a nerve fiber by macrophages (M) and demyelination of axon (A) in Marek's disease. (From Payne (1982), in *The Herpesviruses*, Vol. 1, Roizman, B (ed), pp. 347–431, Plenum Press, New York, with permission.)

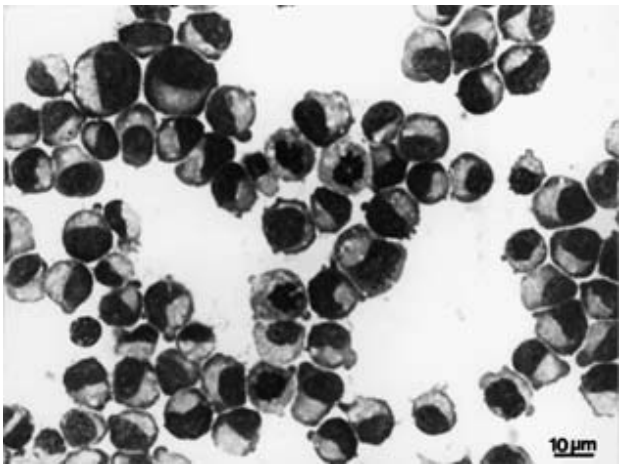

Figure 8 Lymphoblastoid cell line derived from a Marek's disease lymphoma. (From Frazier and Powell (1975), *Br. J. Cancer*, 31, 7–13, with permission.)

Marek's disease tumor-associated surface antigen (MATSA), once thought possibly to be a tumor antigen, but now considered to be a marker for an activated T cell.

Other pathological changes occurring in MD include lymphoid atrophy of the bursa of Fabricius and thymus, atherosclerosis and ocular changes. Lymphocytosis and, uncommonly, leukemia may occur. Lesions in the central nervous system are usually minimal in MD, although they are significant in the transient paralysis form.

The pathogenesis of MD is complex. Experimental studies indicate that, following infection, the virus produces an early restrictively productive and cytolytic infection mainly of B cells but also of some activated T cells. These events are seen as a phase of acute cytolytic infection particularly in the bursa, thymus and spleen occurring during the first week after infection, and there is an associated transient immunosuppression. At the end of this period, the infection switches to one of latent infection, particularly of activated T cells, associated with the development of immune responses. The regressive changes in the lymphoid organs tend to resolve and the normal architecture of the bursa, thymus and spleen is largely restored. At this time, activated T cells are believed to become targets for neoplastic transformation by MDV. CD4 + CD8−, CD4 − CD8+ and CD4 − CD8− T lymphocytes can be transformed, although lymphoblastoid tumor cell lines derived from MD lymphomas in chickens are almost exclusively CD4 + CD8− (helper) T cells. Lymphoblastoid cell lines of both T cell and B cell origin have been developed from MD lymphomas in turkeys. Development of lymphomas in chickens is associated with a second permanent period of immunosuppression and with atrophic changes in the bursa and thymus. During the first 2 weeks of infection, productive infection of feather follicle epithelium cells also becomes established with the appearance of intranuclear inclusion bodies, providing a source of cell-free infectious MDV.

Immune Responses

Birds infected with MDV develop both humoral and cell-mediated immune responses against a variety of MD-associated antigens, although the immunosuppression of MD may impair these responses. Antibodies against viral antigens can be detected in sera from infected birds by agar gel precipitation tests, immunofluorescence, virus neutralization, indirect hemagglutination, complement fixation and enzyme-linked immunosorbent assay. These antibodies are variously directed against internal antigens, membrane antigens and virus envelope. Precipitating antibodies appear 7–14 days after infection by MDV and are directed against the A (gC), B (gB) and C antigens in infected cells. Neutralizing antibodies, directed against gB antigen, peak between 6 and 12 days after infection, decline and then rise in titer, and correlate with survival. There is little evidence for significant humoral response against MD tumor cells. MDV-associated antibodies are passively transferred via the yolk to progeny chicks, and abrogate the severity of MDV infection during early life. Humoral responses are not essential for resistance to MD, since bursectomized birds may survive infection.

Cell-mediated immune responses occur against virus-associated antigens and possibly also against tumor-cell antigens believed to be present on lymphoblastoid line tumor cells. Original suggestions that MATSA was the antigen involved have not been confirmed.

Other immune responses detected include antibody-dependent cell-mediated cytotoxicity directed against virus-infected cells, and macrophages able to restrict MDV replication and MD lymphoblastoid cell line growth. Natural killer cells have also been shown to be cytotoxic to lymphoblastoid tumor cells.

Genetic Resistance

The existence of genetic resistance to MD among chickens has long been recognized, and susceptible and resistant lines can be developed by progeny testing, breeding from survivors or blood typing. Two distinct genetic loci that play a major role in controlling resistance have been identified. First, B-F region genes at the major histocompatibility (MHC)

locus, closely linked to B-G genes encoding B erythrocyte antigens, can influence resistance, the most notable being associated with the B^{21} allele. The resistant Cornell N line carries the B^{21} allele, in contrast to the susceptible P line which carries the B^{19} allele. B^{21}-associated resistance is absent at hatching but develops in early life, is accompanied by reduced numbers of infected T cells in comparison to susceptible birds, and may be due to a superior ability to reject infected or transformed T cells. A second type of resistance present at hatching, is shown by the Regional Poultry Laboratory line 6 birds and is associated with the lymphocyte antigen allele present at the non-MHC *Ly-4* locus. The resistance is associated with reduced numbers or susceptibility of target T cells for MDV infection or transformation.

Prevention and Control

MD is prevented mainly by vaccination, combined with good hygienic practices to minimize early exposure to MDV, and to some extent selection of genetically resistant stock.

Live virus vaccines have been used to control MD in commercial chickens since 1970. These are injected into chicks at hatching to provide early protection from pathogenic MDV. In recent years, an increasing number of chickens have been vaccinated *in ovo*, at 18 days of incubation. The minimum recommended dose of vaccine virus is 1000 plaque-forming units per chick. The vaccine viruses are nonpathogenic and establish a permanent infection that prevents lymphoma formation and clinical disease, although superinfection by pathogenic virus is not prevented.

Commercially available vaccines have been derived from all three serotypes, for use either alone or in combination.

Serotype 1 vaccines

Two types of commercial vaccine have been developed from this serotype.

1. Attenuated virulent serotype 1. The first commercial vaccine was of this type, developed by attenuation in cell culture of the virulent HPRS-16 strain of MDV. It is available only in a cell-associated form. Commercially its widespread use was soon superseded by the HVT (serotype 3) vaccine but it has retained some use for alternate-generation vaccination and also in combination with other serotype vaccines in localities with increased MD losses.
2. Attenuated mildly virulent serotype 1. This is exemplified by the CVI-988 (Rispens) strain of a cell-culture attenuated mildly virulent strain of MDV. It is also cell-associated, and has been widely used in The Netherlands and elsewhere. More recently it has been used in combination with HVT, and has shown protection against vv + MDV.

Serotype 2 vaccines

Serotype 2 viruses are naturally nonpathogenic strains of MDV which are widespread among poultry flocks. A representative of this serotype is the SB-1 strain which is protective, in a cell-associated form, against most strains of vMDV, but less so against vvMDV. In combination with HVT, SB-1 provides good protection against vvMDV.

Serotype 3 vaccines

The HVT represents serotype 3 and is typified by the FC-126 strain. It is widely used commercially in either a cell-associated form or a cell-free form and is highly effective against vMDV but less so when used alone against vvMDV.

Vaccine failure

A number of possible causes of vaccine failure have been recognized, the most important being challenge by MDV before vaccinal immunity has developed, delayed onset of vaccinal immunity due to interference by passively acquired antibodies, and the use of nonprotective strains of vaccine virus. Early exposure to MDV may be prevented by improved hygiene, and embryonal vaccination has been developed to provide earlier protection. Effects of passive antibodies have been counteracted by vaccinating alternate generations by different types of vaccine. Lack of protection by certain vaccines is seen when vvMDV is present: the use of bivalent vaccines, such as SB-1 plus HVT, is effective. However, even these are not fully protective against vv + MDV strains that have emerged.

Future Perspectives

Research on MD over the past 30 years has been remarkably successful in controlling one of the most serious worldwide diseases of poultry. Nevertheless, the emergence of the vv and vv+ strains of MDV during this period shows that new threats are likely to continue to appear and demand effective responses. Research continues on a wide front but most effort is currently devoted to molecular biological studies of MDV and HVT and with a view particularly to characterizing viral genes which encode antigens important in immunity and those responsible for viral virulence. This knowledge is being applied to the

development of recombinant vaccines needed to improve protection against disease. Interest is also focused on understanding the complex pathogenesis of MD, particularly the role of T cell subsets, and other cells, involved in transformation and immunity. Lastly, work on genetic resistance to MD continues, for the light it throws on the disease process, for understanding interactions between host genotype and vaccination, and because the availability of transgenic techniques in chickens means that development of genetically resistant chickens by this method offers an alternative to vaccination in disease control.

History

Acute measles is an early childhood disease resulting from infection by the highly contagious measles virus (MV). With the isolation of the virus by Enders and Peebles in 1954 experimentation became possible and allowed significant progress with the development of tissue culture systems, the availability of monoclonal antibodies and molecular biological approaches. The virus is distributed worldwide, monotypic in nature and no significant differences between isolates from different locations have been found. MV persists in nature in populations large enough to support it, although it causes an acute infection in any individual only once in a lifetime. Thus measles is a highly successful virus, which has efficiently exploited its potential for spread, particularly as it has no animal reservoir. On rare occasions, MV may persist for years in an individual, but it is not shed as infectious virus. A single attack of measles confers lifelong immunity, even in the absence of re-exposure to the virus. Consequently, to remain endemic in a given community the virus has to infect the young who are still susceptible. This process is so efficient that the first known report of measles (in Egyptian hieroglyphs) failed to recognize the infectious nature of the illness, and described it as a normal part of child growth and development. In the prevaccine era in developed countries measles was predominantly seen in children aged 5–9 years. Infections and epidemics centered around elementary schools, and by the age of 20, approximately 99% of subjects had seroconverted. With the introduction of measles vaccine the age incidence and percentage of measles cases in different age cohorts has changed. In countries with an optimal vaccination regimen, measles has shifted to the teenage group whereas in areas with inefficient vaccine programs children up to 4 years of age reveal a high primary measles attack rate. In Third World countries measles has its greatest incidence in children

History

Acute measles is an early childhood disease resulting from infection by the highly contagious measles virus (MV). With the isolation of the virus by Enders and Peebles in 1954 experimentation became possible and allowed significant progress with the development of tissue culture systems, the availability of monoclonal antibodies and molecular biological approaches. The virus is distributed worldwide, monotypic in nature and no significant differences between isolates from different locations have been found. MV persists in nature in populations large enough to support it, although it causes an acute infection in any individual only once in a lifetime. Thus measles is a highly successful virus, which has efficiently exploited its potential for spread, particularly as it has no animal reservoir. On rare occasions, MV may persist for years in an individual, but it is not shed as infectious virus. A single attack of measles confers lifelong immunity, even in the absence of re-exposure to the virus. Consequently, to remain endemic in a given community the virus has to infect the young who are still susceptible. This process is so efficient that the first known report of measles (in Egyptian hieroglyphs) failed to recognize the infectious nature of the illness, and described it as a normal part of child growth and development. In the prevaccine era in developed countries measles was predominantly seen in children aged 5–9 years. Infections and epidemics centered around elementary schools, and by the age of 20, approximately 99% of subjects had seroconverted. With the introduction of measles vaccine the age incidence and percentage of measles cases in different age cohorts has changed. In countries with an optimal vaccination regimen, measles has shifted to the teenage group whereas in areas with inefficient vaccine programs children up to 4 years of age reveal a high primary measles attack rate. In Third World countries measles has its greatest incidence in children

Table 1 Morbilliviruses

Virus	*Natural host*	*Experimental infection*
Measles (MV)	Human	Primates, cotton rats, mouse, rat, ferret, hamster
Rinderpest (RPV)	Cattle, pig, goat, sheep	Rabbit
Peste des petits ruminants (PPRV)	Goat, sheep	Pig
Canine distemper (CDV)	Dog, fox, ferret, lion	Mouse, hamster, pig, cat
Phocine distemper (PDV)	Seal, sea-lion	Dog, mink
Dolphin (DMV)	Dolphin	Cattle, sheep, goat, dog
Porpoise (PMV)	Porpoise	Cattle, sheep, goat, dog
Horse[a]	Fruitbat, horse	?

[a] The virus was isolated recently in Australia from horses, fruitbats and two humans with fatal respiratory infections. Its natural host is not yet known, the human infection was accidental.

under 2 years of age. Here the disease is a serious problem with a high mortality (up to 10%) and its morbidity and mortality correlate with malnutrition.

Taxonomy and Classification

Measles virus (MV) is a member of the *Morbillivirus* genus in the subfamily *Paramyxovirinae* of the *Paramyxoviridae* family. It has a nonsegmented RNA genome of negative polarity and lacks a detectable virion-associated neuraminidase activity. MV is, therefore, grouped into a separate genus, the morbilliviruses, of which it is the type species. Other members of this group include: peste de petit ruminants which infects sheep and goats (PPRV), rinderpest virus which infects cattle, canine distemper virus (CDV) which infects dogs, phocine distemper virus (PDV) which infects seals and sea-lions, dolphin morbillivirus (DMV) and porpoise morbillivirus (PMV). More recently, a morbillivirus has been isolated in Australia which infects horses and accidentally humans (**Table 1**).

Molecular Biology

MV particles are highly pleomorphic with an average size of 120–250 nm and consist of a lipid envelope surrounding the viral ribonucleoprotein (RNP) complex which is composed of genomic RNA associated with proteins (**Fig. 1**). Two glycosylated viral transmembrane proteins project from the envelope surface: (1) the hemagglutinin protein (80 kDa) mediating the attachment of virions to cellular surface proteins including the MV receptor CD46, and (2) the fusion protein (only active after host-cell-mediated cleavage of a 60 kDa precursor protein (F_0) into an F_1 (40 kDa)/F_2 (22 kDa) heterodimer) mediating fusion between viral and host cell membrane at neutral pH. They interact with the matrix (M) protein which, in turn, links the envelope to the RNP core structure. The latter contains the viral genomic RNA, an about 16 kb nonsegmented RNA molecule of negative polarity, fully encapsidated by N (nucleocapsid), and the viral polymerase complex consisting of the P (phospho-) and the L (large) proteins. The L protein is a multifunctional RNP-specific RNA polymerase synthesizing replicative intermediates, progeny viral genomic RNAs and mRNAs which are also capped, methylated, edited and polyadenylated by this enzyme. The P protein is a phosphoprotein and, as cofactor, controls L protein activity during transcription and replication.

MV replication is confined to the cytoplasmic compartment. The viral polymerase complex initiates transcription at a promoter sequence located within a noncoding region at the 3′ end of the viral genome. MV-specific mRNAs are then synthesized along the viral genome with the N-specific mRNA being most abundant (followed by P, M, F, H and L). At the gene junctions, the polymerase first polyadenylates and cleaves the nascent transcript before continuing transcription of the distal gene. Alternatively, the polymerase leaves the template at the gene junctions to reinitiate at the 3′ promoter sequence. This is the reason why there is a gradient of frequency of the individual MV mRNAs in the infected cell, and this represents an efficient strategy of how the virus controls the accumulation of the corresponding translation products. The polymerase also synthesizes complete copies of the viral genome to yield the positive-stranded antigenome, that, in turn, serves as template for the synthesis of genomic RNAs of negative polarity. The replicating genome is immediately encapsidated by the viral N protein, with which the polymerase complex subsequently assembles to yield the RNP core structures. These are then

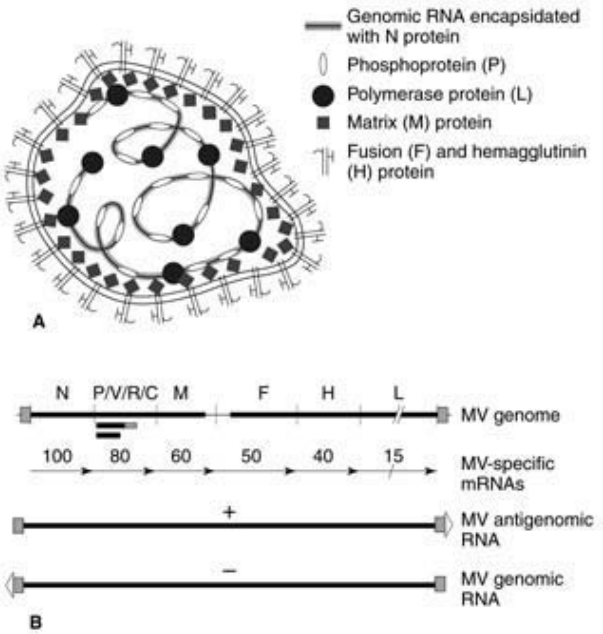

Figure 1 Measles virus, its genomic organization and transcription and replication. (**A**) The pleomorphic measles virus particle has two structural components: a host cell-derived lipid envelope bilayer in which the glycoprotein complex (containing fusion and hemagglutinin proteins) is inserted, and a ribonucleoprotein core complex consisting of the viral genomic RNA, tightly encapsidated with the nucleoprotein, and the viral polymerase complex (phospho- and large or polymerase proteins). These subunits are linked by the matrix (M) protein. (**B**) The polymerase complex initiates transcription at a promoter within the 3′ noncoding region (solid box) located upstream of the N-specific reading frame to sequentially transcribe the mRNAs for individual MV genes (arrows). The viral genes are interspersed by conserved intergenic regions where transcription either pauses (to be reinitiated at the 3′ promoter) or continues with the distal gene. Due to this phenomenon, MV specific mRNAs accumulate at different frequencies with the N-specific being most abundant (100%), the relative frequencies for the distal genes are also indicated above the arrows. For replication, the polymerase initiates within the 3′ noncoding sequence to synthesize positive-stranded replicative intermediates of the viral genome (antigenome). These, in turn, serve as templates for the synthesis of the negative-stranded genomic RNAs which, after encapsidation and association with the newly formed polymerase complexes are transported to the cell membrane to regions where the viral glycoproteins are inserted. Progenitor viral particles then bud from these locations.

transported to the cellular membrane at locations where the glycoproteins F and H are inserted, with a layer of M proteins beneath. Mature viral particles are then budding from the cell surface in order to find and attach to a new host cell. Receptor attachment mediated by the viral H protein triggers conformational changes within the F protein, thus enabling the F protein fusion domain to insert into the host cell membrane and initiating the fusion process. It is the activity of the glycoprotein complex that also mediates fusion between two adjacent cells thus enabling cell-associated spread of the virus. The fusion events occur at neutral pH and are responsible for the typical cytopathic effect of MV, the formation of giant cells, in tissue culture and *in vivo* (Warthin–Finkeldey cells in the respiratory epithelium).

The virus is dependent on the integrity of the envelope for infectivity and is inactivated by any procedure which disrupts this structure such as detergents or other lipid solvents. Particles are acid labile and inactivated below pH 4.5, although they remain infective in the range pH 5–9. The virus is also thermolabile. It may remain infective for two weeks at 4°C, but it is completely inactivated in 30 min at 56°C. At 37°C it has a half-life of 2 h. Virus can be stored for prolonged periods at −70°C and also freeze-dried.

Geographic and Seasonal Distribution

Measles occur worldwide and are endemic in regions with inadequate vaccine coverage. The efficiency of transmission is high and outbreaks have been reported in populations where as few as 3–7% of individuals are susceptible. There is generally no seasonal distribution of measles epidemics. The disease incidence in the northern hemisphere tends to rise in winter and spring when lowered relative humidity would favor respiratory transmission. In equatorial regions epidemics of measles can occur in the hot dry seasons. In large unimmunized populations, measles epidemics occur at regular intervals, and the number of susceptible individuals or the frequency of contact between infectious and susceptible individuals will lead to an increase in measles cases.

Host Range and Virus Propagation

Measles infections are confined to humans, although monkeys are also susceptible. Experimentally, only monkeys and cotton rats (*Sigmodon hispidus*) can be successfully infected intranasally. Rodents are generally nonsusceptible to inoculation by this route, and susceptibility to MV infection was not improved in both mice and rats genetically engineered to express the MV receptor CD46. Intracerebral infection with certain MV strains leads to the development of CNS diseases in rodents which have been extensively used to study the pathogenesis of MV-induced CNS-diseases in humans.

Both *in vivo* and in tissue culture, almost any cell type of human and primate origin supports MV

replication. During primary infection, MV reveals a pronounced tropism for peripheral blood mononuclear cells and is found in both lymphocytes and monocyte/macrophages. Apparently, in lymphocytes MV is replicated only efficiently after activation, whereas monocytes may not support productive replication at all. As a key determinant for viral tropism, the MV receptor consisting of a complex between CD46 and moesin is expressed on the surface of susceptible cells. Several isoforms of CD46, whose natural function is to protect cells from lysis by activated complement, exist, and all of them have been shown to support MV uptake. Expression of CD46 is not the only determinant of MV tropism. Stable expression of human CD46 does not confer susceptibility to MV-infection in many mouse cells and in CD46 transgenic animals. Rodent brain cells support MV replication both *in vivo* after experimental infection and in tissue culture, although they do not express CD46. Thus, additional or alternative receptors as well as intracellular factors that so far have not been characterized also essentially determine MV tropism.

Measles can be isolated directly from blood or from urine sediment cells using susceptible tissue cultures. These include primary human embryo kidney (HEK) or continuous cell lines derived from green monkey kidney cells (Vero or CV-1). Epstein–Barr virus-transformed B-lymphoblastoid cell lines (B95a, BJAB) are preferentially used for MV isolation as they reveal a high susceptibility to MV present in clinical specimens. Moreover, MV isolated in B95a cells differed in some biological properties from those adapted to Vero cells, suggesting that MV is subject to host cell-mediated selection. Cytopathic effects (CPE) usually develop between 48 h and 15 days, and consist either of a broad syncytium or of a stellate form.

Genetics and Evolution

The monotypic nature of MV in serological terms has masked the existence of a set of genotypes which accumulate mutations continuously. During the recent past, the molecular epidemiology of MV has been intensely studied to reveal whether MV strains differ in pathogenicity or to monitor the antigenic drift in wild-type MV strains. Sequence analyses on vaccine and wild-type MV strains as well as isolates from persistent MV central nervous system (CNS) infections (SSPE) have enabled the construction of evolutionary trees that clearly indicate their relationship. The sequence of the COOH-terminal 151 amino acids of the N protein of 46 strains of MV revealed an up to 7.2% divergence in the coding sequence and 10.6% divergence in the amino acid sequence between the most unrelated strains. MV strains group into several different genotypes some of which are extinct (i.e. have not been isolated recently) or are still cocirculating in the human population. The vaccine strains differ markedly from the wild-type isolates, but efficiently control MV infection with viruses of different genotypes. The CNS-derived isolates are similar to wild-type viruses. Based on these sequence similarities, it was possible to identify wild-type MVs that had circulated in a given population as infectious agents and found later in brain material from patients with subacute sclerosing panencephalitis (SSPE).

Serologic Relationships and Variability

Measles virus is monotypic in nature, i.e. only a single serotype of the virus has been described. Antigenic differences as observed with monoclonal antibodies between vaccine and wild-type viruses need further study as it is not clear how much this affects the ability of wild-type strains to replicate and be transmitted from persons with waning immunity generated by vaccination with a different genotype. MV isolates have been obtained from many different locations and from patients with different clinical conditions. Much effort has been invested in attempts to distinguish between these viruses and, in particular, to identify any strains which might be predisposed toward the production of encephalitis or SSPE. Conventional serological techniques have, so far, failed to demonstrate any significant differences. Thus infection by any one MV confers immunity to them all.

Epidemiology

The efficient spread of the virus is mediated by aerosol droplets and respiratory secretions which can remain infectious for several hours. Acquisition of the infection is via the upper respiratory tract, the nose and, possibly, the conjunctivae. Virus is also shed in the urine but this is unlikely to be an important means of transmission. The spread of measles has been used as a convenient example to illustrate the principles of epidemiology, and it has been calculated that any community of less than 500 000 is unlikely to have a high enough birth rate to supply the number of susceptible children required for the continuous maintenance of the virus in the population. In fact, there has been documentation of the complete elimination of measles from isolated groups which remained free of the disease until its reintroduction from outside, when susceptible individuals were once more at risk. There appears to be an interrelationship between continuous urban transmission and rural

outbreaks. Given the minimum population of 400 000–500 000 susceptible individuals to sustain measles transmission, rural transmission is likely to be initiated by cases from nearby cities. This observation underlines the importance of coverage not only at a country, but even at the village or community level.

Measles often leads to more serious disease in such communities experiencing the illness for the first time, because all age groups are susceptible to the infection. The WHO estimates that globally 45 million cases and 1.2 million deaths occur annually due to measles. In general, measles mortality is highest in children under 2 years of age and in adults. Death from uncomplicated measles is rare in the developed world, but the introduction of the virus to the Fiji Islands in 1875 resulted in an epidemic with a fatality rate of 20–25% and introduction into Greenland in 1951 produced an epidemic which infected 100% of the susceptible population and resulted in a death rate of 18 per 1000.

Natural immunity is known to last for at least 65 years even in the absence of re-exposure. In 1781 measles disappeared from the Faroe Islands following an epidemic and was not reintroduced until 1846. Individuals old enough to have experienced the disease 65 years previously were still protected. This unusual persistence of immunity has suggested that MV may normally persist inside the body and restimulates immunity from within.

Transmission and Tissue Tropism

MV is spread by droplets and first gains entry into the body through the upper respiratory tract or conjunctivae where it initially replicates. The first sign of infection is virus replication in the draining lymph nodes and destruction of lymphoid tissue which leads to a pronounced leukopenia. The virus then spreads to the rest of the reticuloendothelial system and respiratory tract through the blood (primary viremia). About five days after infection the virus overflows from the compartments in which it has hitherto been replicating, to infect the skin and viscera, kidney and bladder (secondary viremia). Although spread into the CNS does not usually occur, CNS involvement is quite frequent since about 50% of patients present with electroencephalogram (EEG) and cerebrospinal fluid (CSF) changes. Giant cells, lymphoid hyperplasia and inflammatory mononuclear cell infiltrates are observed in all infected tissues.

Pathogenicity

There is no evidence that circulating MV strains would be of different pathogenicity. This has been extensively analyzed when MV outbreaks occurred in populations with a high vaccine coverage in the late 1980s. Apparently, host rather than viral determinants are associated with MV pathogenicity such as immunocompetence. In addition, no particular MV strains could be associated with the developement of late CNS complications of acute measles. In West Africa, increased mortality after MV vaccination was due to the use of a high-titer instead of medium-titer vaccine strain.

Clinical Features and Infection

About 10 days after exposure the patient enters the prodromal phase which lasts from 2 to 4 days. The initial symptoms consist of fever, malaise, sneezing, rhinitis, congestion, conjunctivitis and cough. At the beginning of the prodromal stage, a transitory rash can sometimes develop which has an urticarial or macular appearance, but disappears prior to the onset of the typical exanthem. Once the exanthem has reached its height, the fever usually falls and the conjunctivitis as well as the respiratory symptomatology begin to subside. Antibody titers rise, virus shedding then decreases and the patient rapidly improves. Continuation of clinical symptoms of the respiratory tract or fever suggests complications (**Table 2**). Modified measles occur in partially immunized hosts such as infants with residual maternal antibodies or in the course of live vaccine failure. The illness is mild and follows the regular sequence of events seen in acute measles but is less symptomatic. Atypical measles may develop after incomplete measles vaccination prior to exposure to MV and present with high fever, headache, abdominal pain, myalgia, dry cough and a pleuritic chest pain. Unlike typical measles, the exanthem develops on the distal extremities and spreads centripetally with involvement of the palms and soles. Patients often develop pneumonia with a lobular or segmental appearance accompanied by pleural effusion. Recovery from the pulmonary symptomatology is rather slow, and pulmonary lesions can sometimes be still seen by radiography months after onset of the disease.

Complications of acute measles are relatively rare, and result mainly from opportunistic secondary infection of necrotic surfaces such as those in the respiratory tract. Bacteria and other viruses can invade to cause pneumonia or other complications such as otitis media and bronchitis. The most severe complications caused directly by measles virus are giant cell pneumonia and subacute measles encephalitis, both of which occur in the immunocompromised patient as well as acute measles encephalitis and SSPE in which no underlying susceptibility factor has been

Table 2 Established MV-associated diseases and their pathogenesis

Disease	*MV-infection*	*Pathogenesis*
Acute measles	Generalized	Acute, self-limiting infection
Modified measles	Generalized	Acute, less symptomatic infection in partially immunized hosts
Atypical measles	Generalized	Acute infection following exposure after incomplete vaccination
Measles pneumonia (giant cell pneumonia)	Generalized, lung	Interstitial pneumonia
Pneumonia, bronchitis, otitis media	Generalized	Opportunistic bacterial infections
Measles encephalitis (AME)	Generalized; virus undetectable in CNS	Virus-induced autoimmune disease
Subacute sclerosing panencephalitis (SSPE)	CNS	Persistent infection of brain cells
Measles inclusion body encephalitis (MIBE)	CNS	Persistent infection of brain cells in the immunocompromised host

identified. Unusual manifestations which may complicate acute measles are myocarditis, pericarditis, hepatitis, appendicitis, mesenteric lymphadenitis and ileocolitis. If measles infection occurs during pregnancy spontaneous abortions or stillbirth may occur. Congenital malformations have also been reported. Acute encephalitis during measles (AME) is observed at a frequency of about 1 per 1000–3000 cases, and is fatal in about 15% of cases. Encephalitis usually develops when exanthem is still present within a period of 8 days after the onset of measles. Long-term sequelae include selective brain damage with retardation, recurrent convulsive seizures, hemi- and paraplegia. SSPE is a rare, fatal, slowly progressing inflammatory disease of the brain occurring years after acute measles. For unknown reasons, boys are more likely to develop SSPE than girls and no unusual features of the acute measles have ever been demonstrated. The course of SSPE is variable and usually starts with intellectual deterioration or psychological disturbance. Neurological or motor dysfunctions may take the form of dyspraxia, generalized convulsions, aphasia, visual disturbances or mild, repetitive simultaneous myoclonic jerks. Viral invasion of the retina often leads to a chorioretinitis affecting the macular area followed by blindness. Finally the disease proceeds to progressive cerebral degeneration leading to coma and death. The illness usually lasts months to several years and is inevitably fatal.

Pathology and Histopathology

At the beginning of the rash giant cells are present in the sputum, nasopharyngeal secretions and urinary sediment cells. MV is present in blood and secretions, and the patient is highly infectious. During this period, giant cells containing inclusion bodies (Warthin–Finkeldey cells) are formed in lymphoid tissue and in the epithelial surfaces of the trachea and bronchi. Koplik's spots, the pathognomonic enanthem of measles, appear on the buccal and lower labial mucosa opposite the lower molars which begin to fade some two to four days after the onset of the prodromal phase as the rash develops. The distinctive maculopapular rash appears, about 10–12 days after exposure, behind the ears and on the forehead from where it spreads centrifugally to the feet within three days involving the face, neck, trunk, and upper and lower extremities. Once the entire body is covered the rash starts fading, sometimes accompanied by a fine desquamation. Histologically, the rash is characterized by vascular congestion, edema, epithelial necrosis and round cell infiltrates. MV-induced pneumonia is characterized by the formation of giant cells, squamous metaplasia of the bronchiolar epithelia and alveolar lung cell proliferation. Virus can easily be detected in lung biospsy material. To the contrary, MV is usually not found in the CNS of patients with measles encephalitis. Histopathological findings rather include demyelination, perivascular cuffing, gliosis, and the appearance of fat-laden macrophages near the blood vessel walls. CSF findings in measles encephalitis consist usually of mild pleocytosis and absence of measles antibodies. As SSPE develops on the basis of a persistent MV infection of the CNS, viral nucleic acids, proteins and intracellular nucleocapsid structures are detected in large amounts in neurons and glial cells. Characteristically, the expression of the viral envelope proteins is found severely impaired in SSPE brain material, and this is based on both transcriptional attenuation of and accumulation of mutations within the corresponding viral genes (**Fig. 2**). Due to these particular restrictions, budding of infectious viral particles does not occur, and the

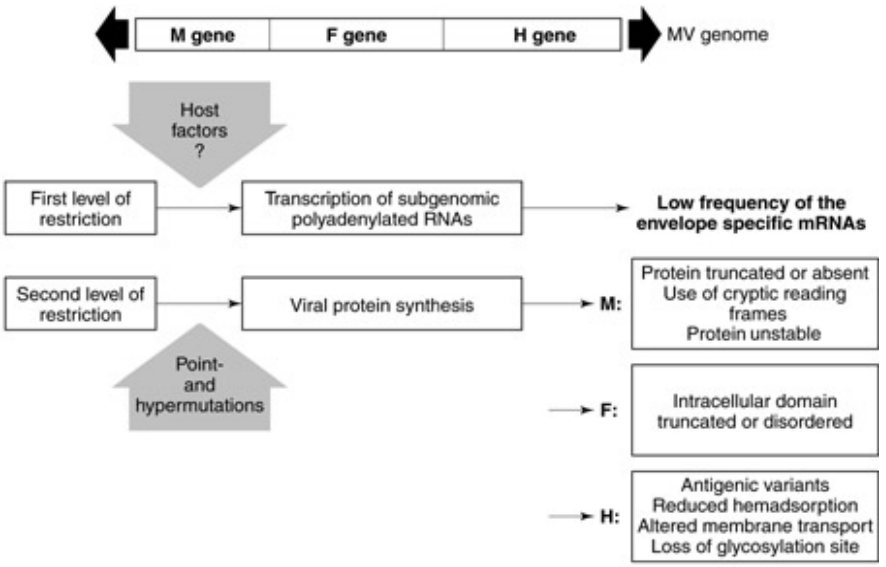

Figure 2 Measles virus gene expression is restricted in persistent brain infections. Whereas MV N and P proteins are easily detected within infected cells in brain material from patients with SSPE, the expression of the viral envelope proteins M, F and H is extremely low or undetectable. Viral gene expression is restricted both on the level of transcription and translation of the envelope-specific mRNAs. Host cell factors are presumably involved in downregulation of MV transcription, particularly that of the envelope protein genes which are distally located (see also **Fig. 1**). In addition, mutations are found within these reading frames which are due to the infidelity of the viral polymerase (point mutations) or are actively introduced by a host cell enzyme (as clustered transitions, called hypermutations). These mutations interfere with the production of functional envelope proteins.

virus is able to survive intracellularly in the presence of an efficient immune response. Neuropathologically, a diffuse encephalitis affecting both the white and the gray matter is seen, characterized by perivascular cuffing and diffuse lymphocytic infiltration. Glial cells may proliferate, and fibrous astrocytes, neurons and oligodendroglial cells contain intranuclear viral inclusion bodies. Giant cell formation or membrane changes consistent with virus maturation are absent. Characteristic EEG changes consist of periodic high-amplitude slow wave complexes (Radermecker) which are remarkably stereotyped in that their form remains identical in any given lead. They are bilateral, usually synchronous, symmetrical and consist of two or more delta waves which appear biphasic or polyphasic. Another pathognomonic finding is the state of hyperimmunization against measles virus as well as the prominent virus-specific gammaglobulin increase in CSF which is of restricted heterogeneity reflecting intrathecal Ig synthesis.

Immune Response

The rash clearly marks the onset of the immune response to infection as determined by the appearance of antiviral antibody and the infiltration of mononuclear cells into local areas of virus replication and the appearance of virus-specific T cells in the blood. Virus is then rapidly cleared from blood and tissue. Antibodies are induced to most viral proteins and can be measured by their biological effects. N-specific antibodies are most abundant and rapidly produced. They are the major antibodies detected in complement fixation tests; however, they are not protective. Virus-neutralizing antibodies are directed against the H protein, as they prevent the viral attachment to host cells. These antibodies are protective and can be measured by the inhibition of MV-induced agglutination of monkey erythrocytes (HI) and in neutralization tests. F-specific antibodies are not neutralizing but are important to prevent viral spread by cell fusion.

Activation of MV-specific cellular immunity is of greater importance for overcoming the acute infection than that of the humoral immune response. This is supported by the fact that children with agammaglobulinemia recover from acute measles normally whereas those with T cell deficiencies frequently have severe complications. Both MV-specific CD4+ and CD8+ T cells are present in the blood during acute measles, and lysis of MV-infected cells *in vitro* has been documented with CD8+ cytotoxic T lymphocytes and major histocompatibility (MHC) class II

restricted CD4+ T cells. Cytokine patterns observed in patients' plasma reveal that initially predominantly interleukin (IL)-2 and interferon γ (IFN-γ) are produced followed by high levels of IL-4. A delayed hypersensitivity reaction is implicated in the production of the rash, and thus the rash is not observed in patients with T cell deficiencies. After resolution of the rash, both CD4+ and CD8+ memory cells can be found in peripheral blood.

Concomitant with the induction of an efficient MV-specific immune response, immunity to other antigens is severely suppressed. This is characterized *in vivo* by a marked lymphopenia, an increased susceptibility to opportunistic infections and a transient loss of delayed-type hypersensitivity (DTH) reactions. Proliferation of lymphocytes isolated from measles patients is strongly impaired in response to recall antigen, allogen and mitogens. This transient general immune suppression is the major reason for the high morbidity/mortality rate associated with this disease particularly in Third World countries.

Prevention and Control

Currently, a live attenuated vaccine is used worldwide. The first attenuated vaccine strain was the Edmonston B strain produced by serial passage of the virus in human kidney cells, human amnion cells, chick chorioallantoic membrane and, finally, duck embryo cells. This vaccine was administered intramuscularly or subcutaneously 12–18 months after the disappearance of maternal antibodies. It was effective and achieved seroconversion in 95% of recipients, but side effects of mild measles were common (5–10%). The side effects and necessity to provide additional gammaglobulin led to the development of the further attenuated and less reactogenic Schwartz and Moraten (Enders) strains derived by further passage in the chick embryo at lowered temperature. Both vaccines produced a 95% seroconversion rate. In recent years, the Edmonston strain was further attenuated by passing it in human diploid cells. This vaccine, referred to as Edmonston Zagreb strain, has been shown to produce higher seroconversion rates than the Schwartz vaccine when administered at the same age. Similar observations have been made with the AIK-C vaccine, produced in Japan. Levels of antibodies induced are protective but generally lower than after measles and are still measurable up to 15 years after immunization in the absence of boosting infections.

In the prevaccine era, an estimated 4–5 million cases occurred annually in the USA and by the age of 15 years 95% of the population seroconverted. Following the rigorous implementation of the MV vaccination program, the case reports have fallen dramatically from 500 000 annually to 26 000 in 1978 and 1500 in 1983. From 1984 through 1988 only 3700 cases were registered. As a result of measles vaccination, the mortality and AME have also declined and the available experience indicates that SSPE can also be prevented by measles vaccination. However, in 1989 and 1990 a dramatic increase in acute measles cases was observed in industrialized countries with high vaccine coverage such as the USA indicating that lifelong immunity may not be induced by the application of live measles vaccine. As a result of these measles epidemics, the American Academy of Pediatrics (AAP) and the Immunization Practices Advisory Committee of the USA (ACIP) recommended a change from a one-dose to a two-dose schedule for measles vaccination which is expected to be optimal for measles control and eventual elimination. The first dose of measles vaccination should be administered at 15 months of age, as delayed primary measles vaccination (at 15 months of age or later) significantly reduces measles risk at later ages. A second dose is recommended at 4–6 years of age by ACIP, whereas the AAP recommends revaccination at the age of 11–12 years.

Future Perspectives

Since MV has no animal reservoir, it is an obvious target for a controlled campaign aimed at the eradication of the virus. In the USA and Canada, where vaccination of all children is required at or before commencing school, quite startling results have been achieved. Case reports have fallen by over 99% but eradication has not yet been achieved. In Germany and the UK, where vaccination is not mandatory, distrust of vaccination has led to a lower acceptance rate and less dramatic results have been achieved. In the Third World, where the consequences of MV infection are most severe, considerable effort has been expended with comparatively little return. Vaccination in these areas has so far failed to yield dramatic results. This is largely due to the epidemiology of measles in these areas. Interrupting transmission through vaccination would require high vaccination coverage rates early in life (>80%), and even with extremely high vaccination coverage rates outbreaks can be expected to occur. In order to achieve high population immunity in endemic areas, both the regimen of vaccine application and the generation of vaccines which are safe and efficient even in the presence of maternal antibodies require

further improvement. Progress made in the molecular biology of MV could lead to the development of genetically engineered measles vaccines which should be free of side effects and possibly suitable for the immunization of individuals currently at greatest risk, such as young infants or those suffering from chronic debilitating diseases.

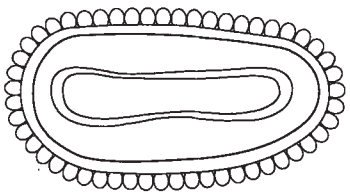
MOLLUSCUM CONTAGIOSUM VIRUS (*POXVIRIDAE*)



LC Archard and **BA Soteriou**, Division of Biomedical Sciences, Imperial College School of Medicine, London, UK

CD Porter, Institute for Cancer Research, London, UK

History

Molluscum contagiosum is a benign skin tumor of humans resulting from enhanced basal cell proliferation. The disease was first described by Bateman in 1814 and the characteristic intracytoplasmic inclusion bodies (molluscum bodies) were described independently in 1841 by Henderson and Paterson. The viral etiology of the disease was eventually established in 1905, when Juliusberg successfully transmitted the disease to one of three individuals inoculated with a filtered extract of molluscum contagiosum lesions. Molecular studies of the virus have been greatly hindered by the nonavailability of a means of propagation *in vitro*.

Taxonomy and Classification

Molluscum contagiosum virus (MCV) belongs to the *Poxviridae* family of DNA viruses and is a member of the subfamily *Chordopoxvirinae* (poxviruses of vertebrates). MCV is the sole member of the genus *Molluscipoxvirus* and is antigenically unrelated to any other genera of this subfamily, within which species are serologically related. Molecular studies have identified three subtypes of the virus (MCV I, II and III: **Fig. 1**) which show a degree of genome diversity greater than that shown amongst species of other poxvirus genera (e.g. the orthopoxviruses). The MCV subtypes are independent but closely related and cause clinically indistinguishable lesions.

Properties of the Virion

The MCV particle is approximately 100 × 200 × 300 nm in size and has the morphology typical of a poxvirus. The mature virion consists of inner and outer membranes enclosing a dumbbell-shaped core, with two lateral bodies underlying the membranes. The virion core contains the viral genome and virus-encoded enzymes necessary to establish the cytoplasmic site of replication in the newly infected cell, including those for viral gene transcription and mRNA modification. Virions purified from clinical lesions have similar physical and chemical properties to those of vaccinia virus with respect to sedimentation characteristics, DNA content and absence of RNA.

further improvement. Progress made in the molecular biology of MV could lead to the development of genetically engineered measles vaccines which should be free of side effects and possibly suitable for the immunization of individuals currently at greatest risk, such as young infants or those suffering from chronic debilitating diseases.

History

Molluscum contagiosum is a benign skin tumor of humans resulting from enhanced basal cell proliferation. The disease was first described by Bateman in 1814 and the characteristic intracytoplasmic inclusion bodies (molluscum bodies) were described independently in 1841 by Henderson and Paterson. The viral etiology of the disease was eventually established in 1905, when Juliusberg successfully transmitted the disease to one of three individuals inoculated with a filtered extract of molluscum contagiosum lesions. Molecular studies of the virus have been greatly hindered by the nonavailability of a means of propagation *in vitro*.

Taxonomy and Classification

Molluscum contagiosum virus (MCV) belongs to the *Poxviridae* family of DNA viruses and is a member of the subfamily *Chordopoxvirinae* (poxviruses of vertebrates). MCV is the sole member of the genus *Molluscipoxvirus* and is antigenically unrelated to any other genera of this subfamily, within which species are serologically related. Molecular studies have identified three subtypes of the virus (MCV I, II and III: **Fig. 1**) which show a degree of genome diversity greater than that shown amongst species of other poxvirus genera (e.g. the orthopoxviruses). The MCV subtypes are independent but closely related and cause clinically indistinguishable lesions.

Properties of the Virion

The MCV particle is approximately 100 × 200 × 300 nm in size and has the morphology typical of a poxvirus. The mature virion consists of inner and outer membranes enclosing a dumbbell-shaped core, with two lateral bodies underlying the membranes. The virion core contains the viral genome and virus-encoded enzymes necessary to establish the cytoplasmic site of replication in the newly infected cell, including those for viral gene transcription and mRNA modification. Virions purified from clinical lesions have similar physical and chemical properties to those of vaccinia virus with respect to sedimentation characteristics, DNA content and absence of RNA.

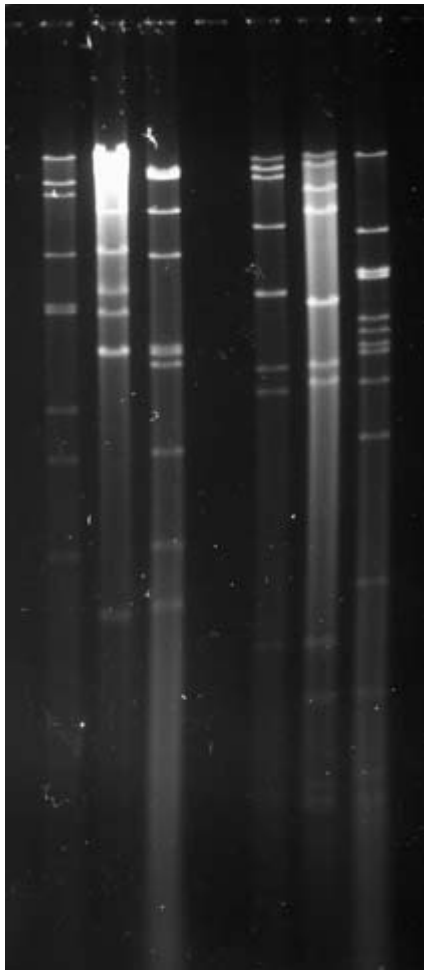

Figure 1 Restriction digests of DNA from MCV subtypes I–III. Digests with the restriction enzymes *Cla*I (left-hand panel) and *Bam*HI (right-hand panel) of DNA from MCV isolates of subtypes I, II and III (right to left).

Properties of the Viral Genome

The genome of MCV is a single, linear double-stranded DNA molecule. It is about 190 kb long, typical of poxvirus genomes which range from 130 kb (parapoxviruses) to 280 kb (avipoxviruses). In common with all poxvirus genomes and related to their mode of replication, the termini are covalently closed, the whole genome being a continuous strand of self-complementary DNA. The regions most easily denatured and so lowest in G + C content are those at the ends of the genome. The overall G + C content of MCV DNA is high (63%) and dissimilar to that of orthopoxviruses (34%). This base composition results from biased codon usage in MCV genes, with G or C occurring preferentially at the third codon position.

As with other poxvirus genomes, MCV DNA has terminal inverted repeats which vary in size from about 4 kb to 10 kb in particular isolates but are identical at each end of the genome. These inverted repeats contain numerous tandem repetitions, generally present as two major blocks: the length polymorphism arises from variation in the copy number of each particular tandem repeat sequence. These features are related to the mechanism of DNA replication.

Comparison of restriction endonuclease maps has defined three independent subtypes of MCV, designated MCV I, II and III, among over 250 isolates. Cross-hybridization shows that despite their distinguishable restriction maps, the subtypes are closely related at the nucleotide level and their genomes are essentially colinear. An exception to this colinearity is a 12 kb region unique to MCV I DNA and mapping around 150 kb from the left terminus; the significance of this is unknown as there are no biological differences apparent between the viral subtypes.

Partial nucleotide sequences from several MCV subtypes and the complete genomic sequence of one type have been analyzed extensively. This has demonstrated open reading frames whose predicted translation products are conserved both at the amino acid level and geographically between MCV and orthopoxviruses, confirming the principle of general colinearity of their genetic organization. There are, additionally, MCV genes whose putative products have no homologue in orthopoxviruses and, conversely, some orthopoxvirus genes are not represented in MCV. Specifically, analysis of the complete genomic sequence suggests that MCV encodes 182 proteins, of which 105 have homologues in orthopoxviruses: these include functions involved in genome replication and expression, suggesting that basic mechanisms are similar. The remaining 77 have no known homologues in other poxviruses and some may be involved in the evasion of host immune responses: examples include inhibitors of chemokine activities and of apoptosis (see below).

Properties of the Viral Proteins

More than 40 polypeptides are detectable in purified virions. Two major structural proteins, present in surface or subsurface virion layers but absent from virion cores, show size variation between independent isolates. An MCV homologue of the vaccinia virus major envelope antigen has a predicted 62% amino acid sequence similarity to the vaccinia protein, despite the marked difference in nucleotide composition of MCV and vaccinia DNA. However, amino acid identity in the N-terminal region preceding the apparent transmembrane domain is lower (26%) and

may explain the lack of antigenic crossreactivity of MCV and vaccinia.

Comprehensive analysis of the complete MCV genomic sequence reveals 182 open reading frames. Putative translation products of 105 of these show varying levels of homology with early or late vaccinia virus gene products, and some demonstrate conservation of geographical location between the genomes. As many vaccinia genes associated with virus genome replication and expression and some encoding structural proteins of the virion have counterparts in MCV, the implication is that functions required for the replication of a large DNA virus in the cytoplasm of infected cells are conserved between these antigenically unrelated poxviruses.

Of the 77 MCV genes with no obvious counterparts in other poxviruses, some have a degree of homology with cellular proteins, a number of which may be related to evasion of host immune responses (see below). Examples include a chemokine homologue with broad-spectrum chemokine antagonist activity and inhibitors of several pathways of apoptosis.

Despite the fact that the hypertrophic skin lesion is generated by increased proliferation of basal cells which do not support MCV replication (see below), no genes with homology to growth factors such as the epidermal growth factor (EGF)-like vaccinia virus growth factor have been found.

Replication and Transcriptional Control

MCV is typical of poxviruses in its genome structure and cytoplasmic site of replication and is expected to be functionally similar to the group as a whole in these respects. The open reading frames detected by MCV DNA sequence analysis show tight clustering of genes, transcribed from opposing strands in either direction, as seen in vaccinia virus. Transcriptional promoter and termination sequences are highly conserved by comparison with orthopoxviruses and, being AT-rich, are particularly obvious in relation to the GC-rich coding sequences of MCV DNA. For example, the 15 bp core promoter in the 5′ non-translated region of 29 known vaccinia early genes is similar in sequence and location in the corresponding MCV genes. Analogously, the TAAAT transcriptional initiator sequence of vaccinia late gene promoters is conserved in MCV homologues. Some orthopoxvirus genes contain both early and late promoter consensus sequences, and this remarkable combination of transcription signals is preserved in most of their MCV counterparts. Intermediate vaccinia promoters containing an AAANAA core sequence located 11–13 nucleotides upstream of a TAAA transcription initiator site are also conserved in the MCV gene homologues.

Transcription stops 20–50 bp downstream of the TTTTTNT termination sequence of vaccinia early genes and this sequence is present at the end of many predicted MCV early genes. Termination of transcription of late genes is poorly characterized but consensus early promotor sequences are often present, implying adjacent early genes.

Poxvirus DNA is replicated as a concatemer and resolution to genomic DNA in vaccinia is controlled by near terminal, late promoter-like sequences consisting of a TAAAT element separated by 7–9 nucleotides from a run of 5–7 consecutive T residues; this signal is conserved in MCV DNA.

These features suggest that genetic organization, control of gene expression and DNA replication in MCV is similar in many respects to vaccinia. A recombinant vaccinia virus containing an MCV type I DNA fragment, which includes the p43K gene encoding the major envelope antigen, has been used to demonstrate that MCV promoter elements are recognized by the transcriptional mechanisms of a serologically unrelated poxvirus.

Geographic and Seasonal Distribution

Molluscum contagiosum occurs worldwide and year round. Its incidence has been variously reported as 10% of children in Papua New Guinea in 1971, 4.5% of the entire population of a Fijian village in 1966 and 1.2% of outpatients in Scotland between 1956 and 1963. Preliminary data suggest that there is a different geographical distribution of the three MCV subtypes. The relative occurrence of MCV I to MCV II ranges from 1:1 in a small (eight patients) American study group, 2:1 for Australia, 3:1 for the UK, to 50:1 for Scotland. MCV III is relatively rare (approximately 1% of cases).

Host Range and Viral Propagation

MCV is one of two poxviruses regarded as being specific for the human host; the other is variola, the agent of smallpox. There have been occasional reports of molluscum contagiosum-like disease in other species, although these have not been substantiated by molecular analysis. MCV has been transmitted by inoculation to human subjects, but similar experiments with monkeys, apes, sheep, fowl, guinea pigs and mice were unsuccessful.

Attempts to grow the virus on the chick embryo chorioallantoic membrane, in human embryonic skin organ cultures and in primary and continuous cell cultures have been unsuccessful, although in the last

system limited transmission of a cytopathic effect (CPE) and induction of interferon were observed. Propagation of MCV in human amnion cells was reported, but attempts to repeat this were unsuccessful. The MCV-induced CPE lasted for 10 days, after which the cells returned to normal and could respond to fresh challenge. Virus attachment and release of virion cores into the cytoplasm occurred, but uncoating of the cores did not follow and the infection cycle aborted. Simultaneous infection with other poxviruses did not release MCV from this block. Limited replication in human foreskin grafted to mice has been reported.

As for the human papilloma viruses, the inability to culture MCV is thought to be due to the need for keratinocytes at a defined stage of differentiation, which is difficult to obtain or sustain *in vitro* but which is necessary for completion of the uncoating process. In this respect, MCV behaves as a host-dependent conditional lethal mutant.

Genetics, Evolution, Serological Relationships and Variability

Little is known of these aspects of MCV but they are expected to be similar to the poxvirus group as a whole. Specific antibody is generated during infection but MCV is serologically distinct from other poxviruses. Independent MCV isolates show variability in the size of the genomic inverted terminal repeats, as seen in orthopoxviruses. Nucleotide sequence analysis demonstrates a high degree of homology between the MCV subtypes, although their restriction endonuclease maps show greater variation than is seen between species of the orthopox, parapox or capripoxvirus genera. Phylogenetic analysis based on the sequence of the viral DNA polymerase, an enzyme essential to replication of a DNA virus in the cytoplasm of infected cells, suggests that MCV branched from a trunk common to the evolution of orthopoxviruses and parapoxviruses, after divergence of the avipoxviruses.

Epidemiology, Transmission and Tissue Tropism

The incidence of molluscum contagiosum varies in different populations. Infectivity is relatively low in a European environment, with a peak incidence of between 10 and 12 years of age. In contrast, the Fiji study showed that 25% of households harbored more than one case and the peak incidence was in children aged between 2 and 3 years.

Transmission of MCV is mechanical. Mature virus reaches the surface of the skin at the disease site by extrusion from the lesion core. Transmission follows close physical contact (hence *contagiosum*), presumably gaining access via a break in the skin. MCV replicates in the keratinocytes of the epidermis but not in the cells of the stratum basalis.

Molluscum contagiosum infection in adults is commonly transmitted by sexual contact. Molluscum contagiosum is prevalent in the sexually active and its incidence is rising commensurately with other sexually transmitted diseases, and in association with immunosuppression.

Pathogenicity

The incubation period varies from 1 week to several months. Infection is self-limiting and most individual lesions resolve spontaneously within a few months without treatment. However, the disease may persist as a result of autoinoculation, questioning the protective value of specific antibody. Complications may result from intradermal lesion rupture, giving rise to an inflammatory response. Inflammation is generally associated with clinical resolution of the lesion, suggesting that the virus-coded chemokine inhibitor may be functional in maintenance of persistent infection. For the majority of patients the disease is no more than a cosmetic problem, although persistence over long periods may imply impaired immunity. Widespread lesions are common in patients with atopic dermatitis.

Clinical Features of Infection

Molluscum contagiosum lesions consist of papules, 2–4 mm in diameter, with an umbilicated center, from which a white curdy core can be expressed. They may be solitary or clustered and can occur anywhere on the skin, although rarely on the palms and soles. Giant solitary lesions, with diameters of 15 mm or more, and intrafollicular lesions are rare variants. The lesions are often barely apparent and may go unnoticed by patients. However, eczema can develop around the lesions and they can become inflamed and secondarily infected prior to resolution. Molluscum contagiosum on the eyelids may be associated with conjunctivitis.

Pathology and Histopathology

In the molluscum contagiosum lesion, the epidermis grows down into the dermis and projects above the surface as a papule. The basement membrane remains intact. The basal cells are larger and more columnar than usual and intracytoplasmic inclusion bodies (Henderson–Paterson or molluscum bodies), the site of virus assembly, appear first in the cells of the

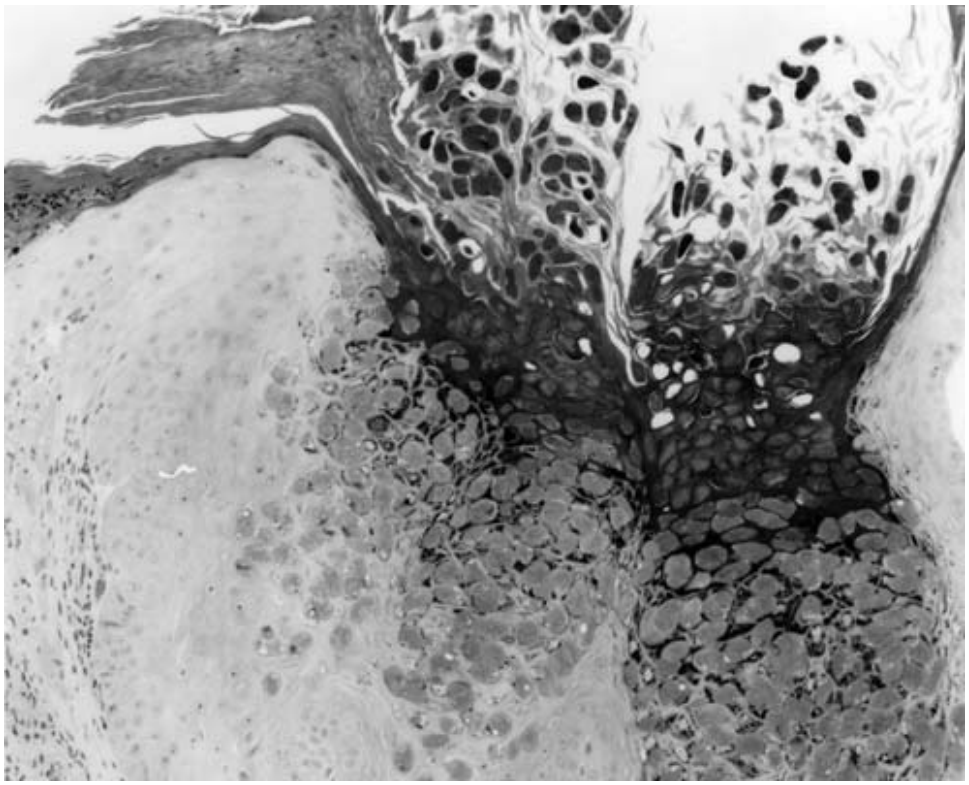

Figure 2 Molluscum contagiosum lesion. Skin section showing lobules of keratinocytes containing large intracytoplasmic inclusions (molluscum bodies). The stratum corneum has disintegrated in the center of the lesion, releasing the molluscum bodies and generating a central crater. Hematoxylin and eosin; ×100. (Reproduced with permission from Dr D Woodrow and R Barnett, Charing Cross Hospital, London.)

stratum spinosum. The molluscum bodies expand and fill the cytoplasm as the affected cells migrate through the stratum granulosum towards the surface (**Fig. 2**). Viral particles are present exclusively in the cytoplasm of infected cells and do not occur in basal cells or in uninfected cells adjacent to the lesion: the latter continue to develop normally. The virion colony is enclosed by a sac within each infected keratinocyte. In the stratum corneum, the degenerating keratinocytes with their inclusion bodies become enmeshed in the keratin network. The central core of the lesion is an expressible soft material consisting of husks of epidermal cells packed with the elementary bodies of the virus.

The molluscum contagiosum tumor results both from hypertrophy of epidermal cells, due to the presence of the virus-packed inclusion bodies, and from hyperplasia of basal cells, which show a twofold reduction in their division time. Infected cells migrate through the epidermis at a more uniform rate of 9–15 days to reach the stratum granulosum, compared with 9–30 days for uninfected cells. Viral DNA replication occurs within the first 4–5 days, and host transcription is inhibited. Some hyperplasia of the dermal fibroblasts subjacent to the lesion has been reported, although these cells, like the basal cells, do not contain virus. It has been proposed that MCV-infected keratinocytes may secrete a virus-encoded growth factor, analogous to vaccinia virus growth factor, which stimulates the proliferation of adjacent cells. Analysis of the MCV genomic sequence reveals no such coding capability (see above) and so this stimulation may be a secondary effect, mediated by a cellular product induced by infection of keratinocytes.

Immune Response

Lesions can persist in normal individuals for months or years without any sign of inflammation. Even when some lesions are removed, others may appear and the virus can be difficult to eradicate. There is a lack of T lymphocytes and natural killer cells in the base of the lesions and no inflammatory infiltrate in the early eruptive phase. While some orthopox genes encoding proteins expected to inhibit cellular immune responses (e.g. complement activation, interferon, tumor necrosis factor and interleukin 1 activities) are not represented, MCV encodes a truncated CC-type chemokine which lacks agonist activity but is a broad-spectrum chemokine antagonist. Both encode a

3β-hydroxysteroid dehydrogenase activity. Resolution may be accompanied by erythema, initially at the base of the lesion, and a predominantly mononuclear infiltrate has been taken to imply a cell-mediated immune response. In one study, two-thirds of patients had an antibody response, predominantly of the IgG class. The lack of response in the remainder may be due to the superficial site of infection and the outward migration of infected cells within the epidermis. Most patients retain virus-specific antibody after resolution. The involvement of immune responses in the resolution of molluscum contagiosum lesions is implicated by the observation that lesions may be numerous, widespread and long-lasting in the iatrogenically immunosuppressed, those with atopic dermatitis and those with acquired immunodeficiency syndrome (AIDS).

Prevention and Control

Treatment, when given, involves lesion disruption by expression of the core, or removal by curettage.

MOUSE MAMMARY TUMOR VIRUS (*RETROVIRIDAE*)

Jaquelin P Dudley, The Department of Microbiology and Institute for Cellular and Molecular Biology, The University of Texas at Austin, Austin, USA

History

The mouse mammary tumor virus (MMTV) first was reported in 1933 by the Jackson Memorial Laboratory and by Korteweg in 1934 as an extrachromosomal influence on the incidence of breast cancer in inbred mouse strains. Initial crosses between high-mammary-cancer-incidence mice and low-mammary-cancer-incidence mice revealed that progeny invariably had the mammary cancer incidence of the female

3β-hydroxysteroid dehydrogenase activity. Resolution may be accompanied by erythema, initially at the base of the lesion, and a predominantly mononuclear infiltrate has been taken to imply a cell-mediated immune response. In one study, two-thirds of patients had an antibody response, predominantly of the IgG class. The lack of response in the remainder may be due to the superficial site of infection and the outward migration of infected cells within the epidermis. Most patients retain virus-specific antibody after resolution. The involvement of immune responses in the resolution of molluscum contagiosum lesions is implicated by the observation that lesions may be numerous, widespread and long-lasting in the iatrogenically immunosuppressed, those with atopic dermatitis and those with acquired immunodeficiency syndrome (AIDS).

Prevention and Control

Treatment, when given, involves lesion disruption by expression of the core, or removal by curettage.

MOUSE MAMMARY TUMOR VIRUS (*RETROVIRIDAE*)

Jaquelin P Dudley, The Department of Microbiology and Institute for Cellular and Molecular Biology, The University of Texas at Austin, Austin, USA

History

The mouse mammary tumor virus (MMTV) first was reported in 1933 by the Jackson Memorial Laboratory and by Korteweg in 1934 as an extrachromosomal influence on the incidence of breast cancer in inbred mouse strains. Initial crosses between high-mammary-cancer-incidence mice and low-mammary-cancer-incidence mice revealed that progeny invariably had the mammary cancer incidence of the female

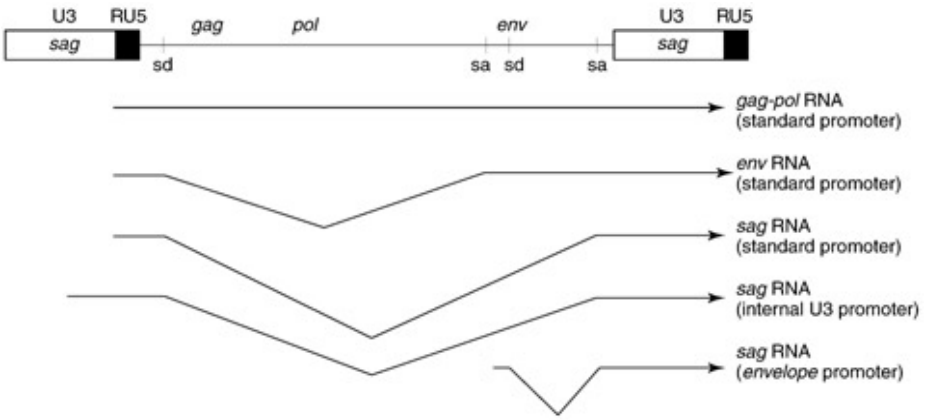

Figure 1 Proposed structure for spliced MMTV RNAs from promoters in the U3 and envelope regions. Arrows show the direction of transcription, and the V-shaped regions indicate sequences that are removed by splicing. All RNAs are shown with respect to a provirus containing the viral structural genes, *gag*, *pol* and *env*. LTRs are shown as boxes. RNAs initiating from the internal U3 promoter may contain additional splicing events upstream of the splice shown.

parent. Subsequently, Bittner showed that an extrachromosomal factor was transmitted through maternal milk, and this factor was later associated with viral particles, termed B-particles, that could cause breast cancer in susceptible animals.

Taxonomy and Classification

MMTV is the prototype species of the genus Gammaretrovirus-B within the family *Retroviridae*. Type B viruses (approximately 100 nm in diameter) are distinguished from other retroviruses by their characteristic morphology under the electron microscope, including an acentric electron-dense core. Milk-borne strains of MMTV often incorporate the name of the inbred mouse strain from which they were derived, e.g. C3H MMTV or MMTV (C3H). Endogenous MMTV proviruses found in the germline of most common inbred mouse strains are referred to as *Mtv* followed by an Arabic number, e.g. *Mtv-8*.

Properties of the Virion

The B-type particle contains a genomic RNA dimer that contains two copies of a single-stranded linear RNA encapsidated by NC protein as a helical ribonucleoprotein (RNP); reverse transcriptase (RT) is closely associated with this RNP. Surrounding the RNP is an icosahedral capsid (although this structure is not entirely clear) composed of CA protein, and this capsid is bound to the envelope by the matrix protein, MA. The detergent-sensitive viral envelope contains numerous spikes that are composed of a transmembrane (TM) protein and a surface (SU) protein.

Properties of the Genome

The viral RNA is bounded at either end by a short direct repeat (R) (15 bases) (**Fig. 1**). Unique regions are present at the 5′ (U5) and 3′ (U3) ends of the genome, and these regions comprise approximately 120 and 1200 bases, respectively. The primer-binding site (PBS), located just downstream of U5, is an exact complement of 18 nucleotides from the 3′ end of tRNA3Lys. Although the 'psi' site for RNA packaging has not been defined, this site is likely to include the region between U5 and the splice donor site for the envelope (*env*) mRNA. The PBS precedes the *gag* region that encodes the nonglycosylated proteins of the virion in the order NH_2-MA-p21-CA-NC-COOH, and this region is followed by the genes for protease (PR) and RT. At the 3′ end of the genome, the envelope proteins are encoded in the order NH_2-SU-TM-COOH just prior to the U3 and R regions. Unlike most other retroviruses, which contain multiple stop codons within the long terminal repeat (LTR), MMTV has an open reading frame (simply known as *orf* or *sag*) within the U3 region. The *sag* gene encodes a protein that has been conserved in all known strains of endogenous and milk-borne MMTVs. The Sag protein plays a critical role in transmission of milk-borne virus from the gut of newborn mice to the mammary gland (see below).

Virus Replication

As with other retroviruses, little is known about the processes that govern the entry and exit of MMTV from infected host cells. However, it is clear that the surface glycoprotein gp52 (SU) mediates the attachment of the virus to the host-encoded viral receptor

(also known as MTVR). Monoclonal antibodies against gp52 will block viral entry. Following entry and partial uncoating due to adsorptive endocytosis, the virally encoded reverse transcriptase produces a double-stranded (ds) DNA copy (also known as the provirus) of the viral RNA. The viral RT synthesizes a minus-strand DNA primed by lysyl-tRNA to form an RNA–DNA hybrid. Using the virally encoded ribonuclease H, the majority of the virion RNA is degraded, and the plus-stranded DNA is completed to form the provirus that, in contrast to the template RNA, contains a long terminal repeat composed of U3, R and U5 regions (**Fig. 1**).

The provirus then enters the nucleus subsequent to nuclear membrane breakdown during mitosis, and viral DNA integrates using the MMTV-encoded integrase (IN) protein, one of the products of the *pol* gene. The IN protein introduces an asymmetric cut 2 bp from the linear ends of the provirus as well as an asymmetric break exactly 6 bp apart on opposite DNA strands of the host cell chromosome. Although there appear to be no discrete sites for proviral integration, like other retroviruses, it is possible that integration occurs preferentially in regions that have an open chromatin structure, e.g. transcriptionally active sites. Following joining events, the repair of the virus–cell junction generates a direct repeat of cellular DNA that, in turn, flanks the viral LTRs. This structure resembles the transposable elements of bacteria, yeast and *Drosophila*.

The integrated provirus contains all the signals necessary for recognition by RNA polymerase II, and many of these signals are present in the U3 region of the LTR. Generally, transcription from the standard promoter is initiated in the 5′ LTR starting at the U3/R junction and terminating at the R/U5 junction in the 3′ LTR (**Fig. 1**). Because of the terminal redundancy, the polyadenylation signals are present in both LTRs, but the sequence in the 5′ LTR is ignored because of the multipartite nature of the poly(A) signal. Termination appears to be reasonably inefficient, and a number of MMTV transcripts probably terminate in the adjacent cellular DNA. Transcripts are capped by cellular enzymes in the nucleus. A portion of this RNA leaves the nucleus in the unspliced form, whereas the remainder is spliced in at least two alternative ways to generate the *envelope* mRNA and, in some cases, the *superantigen* or *sag* mRNA.

Full-length transcripts (8.7 kb) are translated into Gag, Gag-Pro and Gag-Pro-Pol precursor proteins. Since *pro* (the viral *protease* gene) and *pol* (the *polymerase* gene) are out-of-frame with respect to *gag* and each other, two independent ribosomal frameshifts are required to obtain Gag-Pro and then Gag-Pro-Pol. Because of the ribosomal frameshifting events, the viral PR and RT are made at a fraction of the amounts of Gag synthesized. The viral envelope mRNA is translated into a precursor protein on membrane-bound polyribosomes. The protein precursor is modified by glycosylation in both the endoplasmic reticulum and the Golgi, and protein cleavage to SU and TM also occurs in the latter compartment. The *sag* mRNA (approximately 1.4 kb) appears to be translated into a type II transmembrane protein of 36 kDa; this protein is glycosylated and reportedly cleaved to generate a C-terminal 18 kDa fragments. Sag is associated with major histocompatibility complex (MHC) type II protein. Unlike the other virally encoded proteins, Sag is not believed to be a structural component of virions (see below).

Recent evidence suggests that *sag* mRNA can be initiated from at least two other MMTV promoters (**Fig. 1**). One of these promoters is located within the U3 region of the LTR, resulting in RNA initiation approximately 500 bp upstream of the U3/R junction. This RNA can be processed to form both singly and doubly spliced RNAs containing only the *sag* open reading frame. In addition, a promoter within the envelope region gives a spliced RNA with a different splice donor, but the same splice acceptor as that originally described for spliced *sag* RNAs from the standard promoter. The use of the standard promoter, the internal U3 promoter or the *envelope* promoter for synthesis of Sag protein appears to be specific for different strains of MMTV. The amount of spliced *sag* mRNA produced from any of these promoters appears to be very low compared to the amount of *gag-pol* or *env* mRNAs produced.

The precursors for Gag, Gag-Pro, and Gag-Pro-Pol aggregate within the cell cytoplasm into procapsids (approximately 70 nm in diameter) that are referred to as intracytoplasmic A particles. This process is distinct from the maturation of C-type particles which assemble the Gag precursors at the cell surface membrane concomitant with the budding process. Presumably the precursor proteins are folded so that nucleocapsid and RT proteins are sequestered inside the particle to interact with a dimer of viral RNA. The viral PR, which is present in a fraction of the Gag precursors, is apparently responsible for the cleavage events that produce the mature virion proteins MA, p21 (function unknown), CA and NC. The procapsid very likely initiates budding through viral glycoprotein-modified cellular membranes following interaction between the MA protein and the cytoplasmic tail of the TM protein. RT appears to be inactive in newly forming virions since enzyme activation requires several cleavage events by PR to form the infectious mature B-particles.

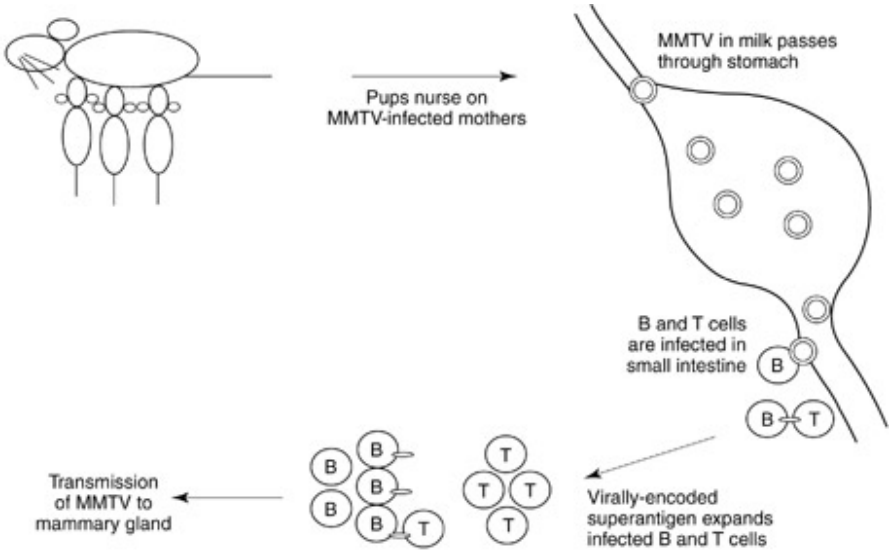

Figure 2 Life cycle of milk-borne MMTV. Newborn pups ingest virus-infected milk from their mothers, and virus particles pass through the stomach to encounter lymphoid cells associated with the gut epithelial cells. B cells become infected and express Sag at the cell surface in conjunction with MHC class II protein. The Sag–MHC complex is recognized by specific T cell subsets that respond by the release of cytokines. These cytokines stimulate the proliferation of bystander B and T cells that may be the target for additional MMTV integrations. Cytokines also amplify the number of previously infected cells. The mechanism for transfer of MMTV infection by lymphoid cells to the mammary gland is unclear.

Transmission and Tissue Tropism

MMTV is transmitted horizontally through maternal milk (called exogenous or milk-borne virus) or vertically through the germline (endogenous viruses). The exogenous viruses are responsible primarily for the high mammary cancer incidence of mouse strains such as RIII and C3H. However, some strains, such as GR, carry an endogenous virus (in this case, *Mtv-2*) that is also transmitted through milk.

Our current understanding of MMTV transmission through milk is shown in **Fig. 2**. MMTV particles ingested from mother's milk survive passage through the stomach during the first few weeks of life prior to maturation of the intestinal tract. These particles enter the small intestine where they probably cross the intestinal epithelial layer via the specialized M cells; under this layer, MMTV virions encounter and infect B cells. Following integration and transcription of the infectious provirus, the Sag protein is presented at the B-cell surface in association with MHC class II protein. Sag is recognized by a certain subset of T cells that are stimulated to release cytokines. Such cytokines trigger the proliferation of additional B and T cells, leading to the amplification of infected cells. Thus, MMTV develops a reservoir of infected lymphoid cells through typical viral replication events that require dividing cells to establish an integrated provirus as well as through division of previously infected cells. Both T and B cells are required for MMTV transmission since knockout or transgenic animals lacking either lymphoid subset cannot be infected by the milk-borne route. This lymphoid cell reservoir is apparently required to preserve MMTV infectivity prior to the onset of puberty in mice when a source of dividing mammary gland cells is available. Recent data also suggest that Sag-mediated stimulation of lymphoid cells is required to improve the efficiency of viral transfer within the mammary gland. MMTV production is increased during lactation when glucocorticoid hormones elevate transcription from the hormone-responsive element (HRE) in the LTR U3 region (**Fig. 3**). Increased expression of virions during lactation ensures that large amounts of particles will be produced at a time when newborn offspring can be infected.

Horizontal transmission of MMTV by seminal or salivary fluid has been reported. It is possible that the low infectivity of most body fluids (other than milk) is attributable to the presence of virally infected lymphoid cells and the absence of large amounts of infectious MMTV particles.

Genetics

MMTV causes mammary adenocarcinomas by infection of the mammary epithelium with either exogenous or endogenous virus. The genetic factors that influence mammary tumor incidence in mice include

(1) the presence or absence of milk-borne virus, (2) the presence of an infectious endogenous MMTV, (3) cellular factors that determine genetic resistance and susceptibility to the virus and (4) host factors that may influence the immune response (including the Sag response) or hormonal levels in the animals. The presence of milk-borne virus has been shown in all high-mammary-cancer-incidence strains by foster-nursing experiments, as originally described by Bittner. However, shortly thereafter, it was discovered that high-mammary-cancer incidence strains (such as C3H) could be converted permanently to a lower mammary tumor frequency by foster-nursing them on low-mammary-cancer-incidence strains (e.g. BALB/c). Such strains, known as C3Hf, have a mammary tumor incidence between 38 and 47% (average latency 600 days) in multiparous animals whereas C3H strains containing milk-borne MMTV have a mammary tumor incidence of 88–95% (average latency 300 days) in breeding females. Mammary tumors appearing in C3Hf mice are the result of expression of a replication-competent endogenous provirus known as *Mtv-1*. Strains, such as BALB/c and C57BL, which have a mammary tumor incidence of 1% or less and long tumor latencies, lack a replication-competent MMTV.

A number of cellular and host factors also influence the incidence of mammary tumors in different mouse strains. Most of these factors have not been defined, but it is likely that many of them affect the ability of MMTV to replicate. For example, the resistance of C57BL mice to MMTV infection appears to be the result of failure to express the MHC class II I-E molecule, one of two available class II molecules in the mouse. Although many MMTV Sag proteins apparently interact with class II I-A, this interaction is less efficient than the Sag/class II I-E complex in the stimulation of lymphoid cells. Loss of class II molecules is not the only defense against MMTV infection. The presence of endogenous MMTV proviruses that express Sag proteins results in the deletion of Sag-reactive T cells in the thymus during the period when the immune system selects against self-reactive T cells. Because the Sag proteins from different MMTV strains react with different T-cell subsets, endogenous MMTVs provide protection against milk-borne infection by MMTVs that encode Sags with the same T cell receptor (TCR) reactivity. For example, endogenous *Mtv-7* expresses a Sag protein that reacts with and causes deletion of Vβ6+ T cells; therefore, the milk-borne MMTV (SW) strain that encodes a TCR Vβ6-reactive Sag cannot infect mouse strains that carry *Mtv-7* because these mice lack the T cell subset required for efficient MMTV transmission.

Resistance to exogenous MMTV infection is usually a recessive characteristic, and this has been used to determine if various mouse strains have the same or different resistance genes. For example, C57BL and I strain mice are resistant to infection by C3H MMTV, yet F_1 hybrids of these strains have a high incidence of mammary cancers when infected by C3H virus. This result suggests that I strain mice ($H\text{-}2^j$) encode a functional MHC class I-E molecule that can complement the defect in C57BL mice and overcome resistance to MMTV infection. Resistance of I strain mice to MMTV infection has been linked to a strong immunological response to the virus. This idea is supported by experiments that indicate that the H-2 histocompatibility locus, particularly the D end that excludes the involvement of class II molecules, influences the susceptibility of different mouse strains to MMTV infection. Similar experiments have shown that NH mice (also resistant to C3H MMTV infection) have an independent resistance factor, perhaps related to hormonal changes that lead to early reproductive difficulties in this strain.

Traditional types of genetic experiments with MMTV have been difficult for two reasons. First, since MMTV does not form plaques or foci *in vitro*, cloning of viral stocks has not been possible. Second, molecular cloning of an intact MMTV provirus (easily obtained for most retroviruses) has been difficult for some MMTV strains because of selection against a specific region of *gag* called the 'poison' sequence. However, this difficulty has been overcome by combining the 5′ end of an endogenous virus (e.g. *Mtv-1*) with the 3′ end of an exogenous virus (e.g. C3H MMTV). Such hybrid proviruses have been transfected into tissue culture cells and shown to produce infectious virions that retain oncogenicity for the mammary gland *in vivo*.

Pathogenicity

MMTV induces primarily type A and B mammary adenocarcinomas or adenoacanthomas which often are preceded by preneoplastic lesions known as hyperplastic alveolar nodules (HANs). The appearance of HANs has been used as a means of quantifying MMTV virion preparations. The mammary tumors that arise may be hormone-independent (C3H tumors) or hormone-dependent (GR or RIII tumors). Many hormone-dependent or plaque (P)-type tumors progress to hormone-independent tumors.

Insertional mutagenesis has been presumed to be involved in MMTV-induced tumors because of the relatively long period of tumor latency and the apparent absence of a virally encoded oncogene.

Table 1 Common integration sites found in MMTV-induced mammary tumors

Locus	*Gene family*	*Mouse chromosome*	*Integration frequency*
Wnt1 (Int-1)	Wingless	15	80% in C3H; 70% in BR6; 30% in GR
Fgf3 (Int-2)	Fibroblast growth factor	7	65% in BR6; 5% in C3H; 20% in GR
Notch4 (Int-3)	Notch	17	20% in Czech II; 8% in BR6
Wnt3 (Int-4)	Wingless	11	10% in GR
Cyp19 (Int-5/Int-H/aromatase)	Cytochrome P450; aromatase	9	3 chemically induced BALB/c hyperplasias
Fgf4 (Hstf-1/Fgfk)	Fibroblast growth factor	7	10% in BR6
Fgf8	Fibroblast growth factor	19	80% in *Wnt-1* transgenic
Int-6		15	6% in *Fgf3* transgenic
Wnt10b	Wingless	15	23% of *Fgf3* transgenic

Nusse and Varmus first identified a common region of MMTV integration in 80% of C3H mammary tumors originally known as *int-1*, but renamed *Wnt-1* to signify its homology with the *Drosophila* gene *wingless*. However, current data have implicated at least nine different loci (termed *int* or integration site genes) in MMTV-induced mammary tumors (summarized in **Table 1**). Most of these integration sites share the following characteristics.

1. The majority of MMTV integrations are outside the *int* coding regions, and the MMTV promoter is rarely used to initiate *int* gene transcription. Thus, an unmodified Int protein is produced.
2. The MMTV provirus apparently activates *int* gene transcription over considerable distances (some in excess of 15 kb).
3. A definite orientation specificity of the provirus with respect to the *int* gene has been observed.
4. *int* gene transcription is not detectable in normal adult mammary gland.
5. Transcription of *int* genes appears to be regulated developmentally.
6. All *int* genes appear to be conserved evolutionarily, and a number of these genes encode growth factors or truncated growth factor receptors.

Such observations are all consistent with the transcriptional activation of conserved genes that are normally silent in the mammary gland; these genes are activated by their proximity to enhancer sequences present in the MMTV LTR. Recent evidence suggests that more than one of the *int* genes may be activated by MMTV proviral insertion in the same tumor cell; different Int proteins in mammary cells apparently cooperate during the generation and progression of tumors.

MMTV also induces T-cell lymphomas, presumably as a byproduct of replication in T cells. Like MMTV-induced mammary tumors, these lymphomas contain clonally acquired MMTV proviruses. However, unlike virally induced mammary tumors, MMTV proviruses from T-cell lymphomas invariably contain a large and specific deletion of 350–500 bp that removes several negative regulatory elements (NREs) as well as the 3′ one-third of the *sag* gene (**Fig. 3**). Many of these LTR deletions are accompanied by a duplication of U3 sequences that presumably act as a T cell-specific enhancer. Substitution of such modified LTRs into a mammotropic molecular clone causes the resulting virus to induce exclusively T cell lymphomas. However, current data do not indicate whether the alteration of *cis*-acting or *trans*-acting LTR sequences or both contribute to T cell tumor induction.

Several other tumor types, including kidney and pituitary tumors, have been shown to contain acquired MMTV proviruses. Most, if not all, of the proviruses found in these tumors also have LTR deletions, suggesting that there is a strong selection against an intact U3 region during MMTV replication in nonmammary cells.

Transcriptional Regulation

The tissue distribution of MMTV expression is linked tightly to viral transcriptional control. Many of the control elements located within the LTR have been mapped by mutation studies or by DNA-binding studies with nuclear factors (NF) (**Fig. 3**). As for many other promoters recognized by RNA polymerase II, the standard MMTV promoter contains a TATA element that is located approximately 30 bp upstream of the transcription initiation site (+1). Just

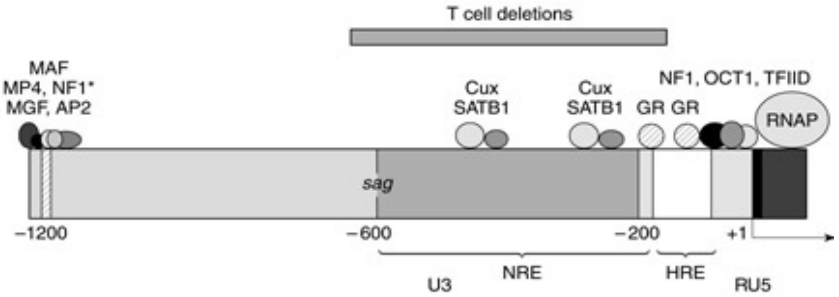

Figure 3 Location of transcription regulatory sequences within the MMTV LTR. DNA binding factors are shown as circles or ovals. In some cases, the exact number and position of the DNA-binding sites is unknown. The mammary gland enhancer is shown near the 5′ end of the LTR. The maximal deletion observed in acquired MMTV proviruses from T cell tumors is shown above the LTR; the deletion always includes the Cux and SATB1 sites shown within the NRE and, in some cases, a portion of the HRE. There appear to be multiple binding sites for OCT-1 upstream of the TATA box. Numbers below the LTR refer to the distance (in nucleotides) from the transcriptional start site of the standard promoter (+1). Circles are not intended to indicate the relative size of the DNA-binding proteins or their interactions with each other. Abbreviations: NRE, negative regulatory element; HRE, hormone response element; SATB1, special AT-rich binding protein 1; NF1, nuclear factor 1; NF1*, a member of the NF1 family; TFIID, transcription factor IID; GR, glucocorticoid receptor; OCT1, octamer-binding protein 1; RNAP, RNA polymerase II. This list of binding factors is not intended to be comprehensive; other tissue-specific and constitutive factors that bind to the MMTV LTR have been reported.

5′ to this element (−60 to −38) is a region containing 10 bp direct repeats that are mutation-sensitive and bind the nuclear factor OCT-1 (OTF-1). A third mutation-sensitive region (located at approximately −70) serves as a binding site for NF-1.

The MMTV HRE is one of the best characterized transcriptional control elements, and it has served as a model system for the study of hormonally regulated genes. Early experiments showed that MMTV proteins and virion production were increased 10- to 50-fold in the presence of glucocorticoid hormones, and this hormonal effect was demonstrable within 15 min of hormone addition, suggesting that glucocorticoids act to stimulate transcription initiation. Progesterone and androgens have also been shown to elevate MMTV-specific RNA levels. Hybrid constructs containing a minimal MMTV HRE linked to a reporter gene have shown that the hormonal inducibility of MMTV is conferred in *cis,* consistent with the presence of at least four binding sites for steroid receptors located approximately between −80 and −190. Each of these binding sites contains the consensus sequence TGTTCT, yet DNase I footprinting experiments indicate that different steroid receptors have unique DNA contacts. There appears to be cooperativity among receptor-binding sites so that the effects of binding are not strictly additive.

Although most of the receptor-binding studies have used naked DNA, some experiments have suggested that hormone receptors allow NF-1 accessibility to MMTV DNA–nucleosome complexes since NF-1 does not bind to nucleosome complexes in the absence of hormone-bound receptor. Mutations within the OCT-1 and NF-1 sites appear to affect both basal and glucocorticoid-stimulated transcriptional levels, but NF-1 may not be crucial for the response to progesterone.

The MMTV specifies several enhancer elements, and the HRE behaves as a conditional enhancer since it can function upstream or downstream of a promoter in either orientation. More recently, enhancer elements that affect mammary gland-specific transcription have been identified at the extreme 5′ end of the U3 spanning the region from −1094 to −858. These elements contain binding sites for multiple nuclear factors, including MP4, MAF, MGF (Stat5), AP-2, and a member of the NF-1/CTF transcription factor family. Synthesis of some factors is inducible by prolactin, epidermal growth factor, or tumor necrosis factor α (TNFα). Current data suggest that these factors cooperate with the HRE to provide maximal stimulation of the MMTV promoter during lactation when milk-borne transmission occurs.

Several negative elements have been reported upstream of the HRE or between the proximal and distal NRE. At least two of these NREs are deleted in MMTV proviruses integrated in T cell lymphomas, suggesting that these NREs suppress transcription in T cells. These NREs are bound by at least two homeodomain proteins called special AT-rich binding protein 1 (SATB1) and Cux/CDP. Intriguingly, the highest levels of SATB1 are expressed in T cells, but not in mature B cells or lactating mammary gland, and mutations in one SATB1 binding site elevate transcription from the MMTV promoter in transient

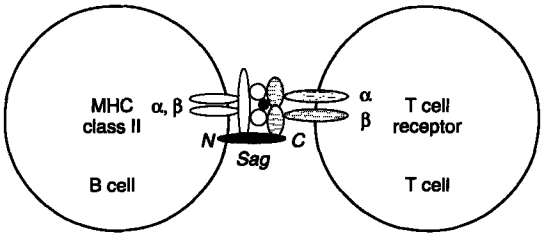

Figure 4 Interaction of MMTV Sag with the T cell receptor (TCR). The α and β chains of the TCR on CD4+ T cells combine to recognize a peptide (foreign or self) (small black circle) residing in the binding pocket of the α and β chains of the MHC class II molecule on MMTV-infected B cells. The C-terminal end of Sag interacts with the variable portion of the TCR β chain, although the TCR α chain has been reported to affect Sag binding. Accessory molecules such as CD4 probably affect the stability of Sag–TCR interaction.

transfection assays and in lymphoid tissues of transgenic mice. These data suggest that MMTV transcription is highest in lactating mammary gland because the mammary gland enhancer is active and because transcriptional suppression is abolished due to the absence of Cux and SATB1.

Immune Response

Recently, endogenous MMTVs have been found to cosegregate in mouse-breeding experiments with several genes that encode minor-lymphocyte-stimulating (Mls) antigens or Sag proteins. Unlike conventional antigens where a peptide associates with the groove formed by the MHc class II α and β chains, the central portion of Sag binds to the class II molecule (**Fig. 4**). Both endogenous and exogenous MMTVs encode Sag. Since Sag is a type II transmembrane protein, the C-terminal portion is available to interact with the TCR on a subset of CD4+ or CD4 + CD8+ cells. Sag reacts with the variable portion of the β chain of the TCR instead of the junction of the α and β chains, and therefore, Sag recognizes entire classes of T cells (up to 30% of the entire T cell repertoire). This is in sharp contrast to conventional antigens that recognize the TCR on less than 1 in 10^4 T cells. Sag stimulation leads to the rapid deletion of reactive cells if Sag is expressed in the thymus, whereas if expression occurs in nonthymic cells, but is low or absent in thymus, deletion of reactive cells appears to be slower.

Sag is a relatively conserved protein, except at the C-terminus where interaction occurs with the TCR. The polymorphism of the C-terminus has been shown to correlate with the reactivity to specific TCR β chains; for example, C3H MMTV Sag reacts with Vβ14 and 15 chains, whereas *Mtv-3* Sag reacts with Vβ3 and 5 chains. Molecular switching experiments have shown that the C-terminal half of Sag is sufficient to specify TCR reactivity, and recent experiments indicate that virtually any mutation (including two or three amino acid substitutions) within the 30–40 polymorphic C-terminal amino acids is sufficient to abolish Sag reactivity and function. Because T cells mediate MMTV infection of the mammary gland, deletion of certain T cell subsets by endogenous MMTV Sags provides immunity against specific milk-borne MMTVs or potentially other pathogens that require the same T cell subsets for infection.

Future Perspectives

MMTV has proven to be an invaluable model for studies of: the molecular mechanism of hormone action, the tissue-specificity of transcriptional control, the immune response, and mechanisms of oncogenesis. There is every reason to believe that MMTV will continue to provide insights into many biological mysteries.

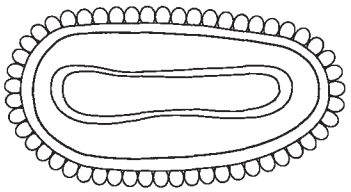
MOUSEPOX AND RABBITPOX VIRUSES (*POXVIRIDAE*)



Frank Fenner, John Curtin School of Medical Research, Australian National University, Canberra, Australia

Ectromelia (mousepox) virus and rabbitpox virus share two features; they are both orthopoxviruses and both are known only as infections of laboratory animals, the mouse and rabbit respectively.

Ectromelia Virus

History

Ectromelia virus was discovered in 1930 by Marchal, as a spontaneous infection of laboratory mice at the National Institute of Medical Research in London. It was called infectious ectromelia because of the frequent occurrence of amputation of a foot in animals that had recovered from infection. Soon after, Barnard showed by UV microscopy that it had oval virions about the same size as those of vaccinia virus. The only other experiments done with the virus at that time involved studies of experimental epidemics by Topley and his colleagues.

In 1946 Burnet, in Melbourne, showed that ectromelia virus was serologically related to vaccinia virus. During experimental epidemics carried out in Burnet's laboratory, Fenner found that in animals that did not die of acute hepatitis there was a rash, and he named the disease mousepox. Subsequent studies led to the development of a model to explain the spread of virus around the body in generalized virus infections with rash.

In laboratories in Europe and the USA the virus was regarded as a major menace to colonies of laboratory mice, and stringent steps were taken to prevent its entry to the USA. Only after extensive outbreaks in several cities of that country in 1979 were studies of the virus undertaken in the USA, in high-security laboratories.

Classification

Ectromelia is a species within the genus *Orthopoxvirus*, as evidenced by the morphology of the virion, crossprotection tests and restriction endonuclease mapping. Most strains of ectromelia virus recovered from naturally infected mouse colonies appear to be of high virulence. However, a substrain of Marchal's original strain was attenuated by serial passage on the chorioallantoic membrane.

Geographic Range and Seasonal Distribution

Ectromelia virus has been spread around the world inadvertently by scientists working with laboratory mice, and has been repeatedly reported from laboratories in several countries of Europe and from Japan and China. Mousepox has never been enzootic for prolonged periods in mouse colonies in the USA, but accidental importations sometimes occurred with mice or mouse tumor material from European laboratories, with devastating consequences.

There is only one report of the occurrence of ectromelia virus in wild animals, an unconfirmed report of its presence in several species of wild rodents in Germany.

Host Range and Virus Propagation

Ectromelia virus produces disease in *Mus musculus* and several other species of mice. The rabbit, guinea pig and rat can be infected by intradermal or intranasal inoculation, with the production of small skin lesions or an inapparent infection. Ectromelia virus will grow on the chorioallantoic membrane of the developing chick embryo.

Epidemiology

In laboratory mice, ectromelia virus is infectious by all routes of inoculation; it always produces a generalized infection but there are local lesions in the lungs after intranasal inoculation and in the peritoneal cavity after intraperitoneal injection. The response of mice is strongly conditioned by mouse genotype (see below).

The usual source of natural infection is via minor abrasions of the skin, which may occur from contaminated bedding or during manipulations by animal handlers. Infection may also occur by the respiratory route, but probably only between mice in close proximity to each other. A primary lesion usually develops at the site of infection. Since mice are readily infected by inoculation, virus-contaminated mouse serum, ascites fluid or mouse cells, tumors or tissues constitute a risk to laboratory colonies previously free of infection.

Enzootic mousepox

Mousepox was enzootic in many mouse breeding establishments in Europe and Japan until the 1960s. A variety of mechanisms probably operated to maintain the virus, without so disrupting the mouse breeding program as to make control mandatory. One important factor was probably the high level of genetic resistance and trivial symptomatology exhibited by many mouse genotypes. Another may have been maternal antibody. Another possible mechanism for maintaining enzootic infection is chronic, clinically inapparent infection, which sometimes occurs after oral administration, when some mice show infection of Peyer's patches, excretion of virus in the feces and lesions in tail skin.

Susceptibility of different strains of mice

Analysis of spontaneous epizootics and deliberate experiments in the 1980s showed that C56BL/6 and AKR mice were highly resistant to mousepox and BALB/c, DBA and CH3 mice were highly susceptible. Although there was no clinical evidence of infection in C57BL/6 mice except for the swelling of the inoculated foot, serial transmission between such mice was observed for at least six generations. Strain differences are best demonstrated after footpad inoculation or in natural epizootics, as C57BL mice are relatively susceptible by intranasal, intracerebral or intraperitoneal infection.

Experimental epidemiology

In the early 1920s the British bacteriologist, Topley, embarked upon a long-term study of experimental epizootics in mice housed in specially designed cages. Studies of long-continued epizootics of ectromelia (1.75 and 3.25 years) in herds of mice maintained by the regular addition of normal mice suffered from the fact that the only indication of infection was death. In similar experiments carried out after the demonstration of the nature of the virus and the pathogenesis of the disease, Fenner, working at the Hall Institute in Melbourne, constructed life tables for mice exposed to a virulent and an attenuated strain of virus. In addition, closed epizootics were used to study several parameters of naturally spreading orthopoxvirus infection, such as immunization with vaccinia virus and the effects of old age. More recently, Anderson and May have used the results of the long-term experiments by Greenwood and Fenner in an analysis of the population biology of infectious diseases.

Pathogenesis

Fenner used mousepox as a model system for the study of generalized viral infections. Mice were infected in the footpad, and after an incubation period of some 7 days (as found in natural infections) a local ('primary') lesion developed at the inoculation site. A few days later some mice died, with no other visible skin lesions but with acute necrosis of the liver and spleen, and in those which survived a rash developed which went through macular and pustular stages before it scabbed.

By titrating organs of infected mice at daily intervals after inoculation, he showed that during the incubation period the virus passed through the mouse body in a stepwise fashion: infection, multiplication and liberation, usually accompanied by cell necrosis, first in the skin, and then the regional and possibly the deeper lymph nodes until it reached the bloodstream (primary viremia). Working in Canberra during the 1960s, Mims showed that during the primary viremia, virus was ingested by the phagocytic littoral cells of the liver and spleen. After a day or so, much larger amounts of virus were liberated into the circulation and during this secondary viremia focal infection of the skin and other organs occurred. There was again an interval during which the virus multiplied to high titer before visible changes were produced, so that an interval of 2 or 3 days usually elapsed between the appearance of the primary lesion and the secondary rash. Some animals died before skin lesions appeared, but titration experiments and histological examination showed that early skin lesions were present.

Clinical Features of Infection

Early workers described two forms of the disease, a rapidly fatal form in which apparently healthy mice died within a few hours of the first signs of illness, and showed extensive necrosis of the liver and spleen at autopsy, and a chronic form characterized by ulcerating lesions of the feet, tail and snout. Fenner found that in natural infections most mice developed a primary lesion (**Fig. 1A,B**), usually on the snout, feet or belly. Subsequently, virus multiplied to high titer in the liver and spleen. Some mice died at this stage, but if they survived they almost invariably developed a generalized rash (**Fig. 1C**).

Age affects the response of genetically susceptible mice. Both virulent and attenuated strains produced higher mortalities in suckling mice and in mice about a year old than in the 8-week-old mice.

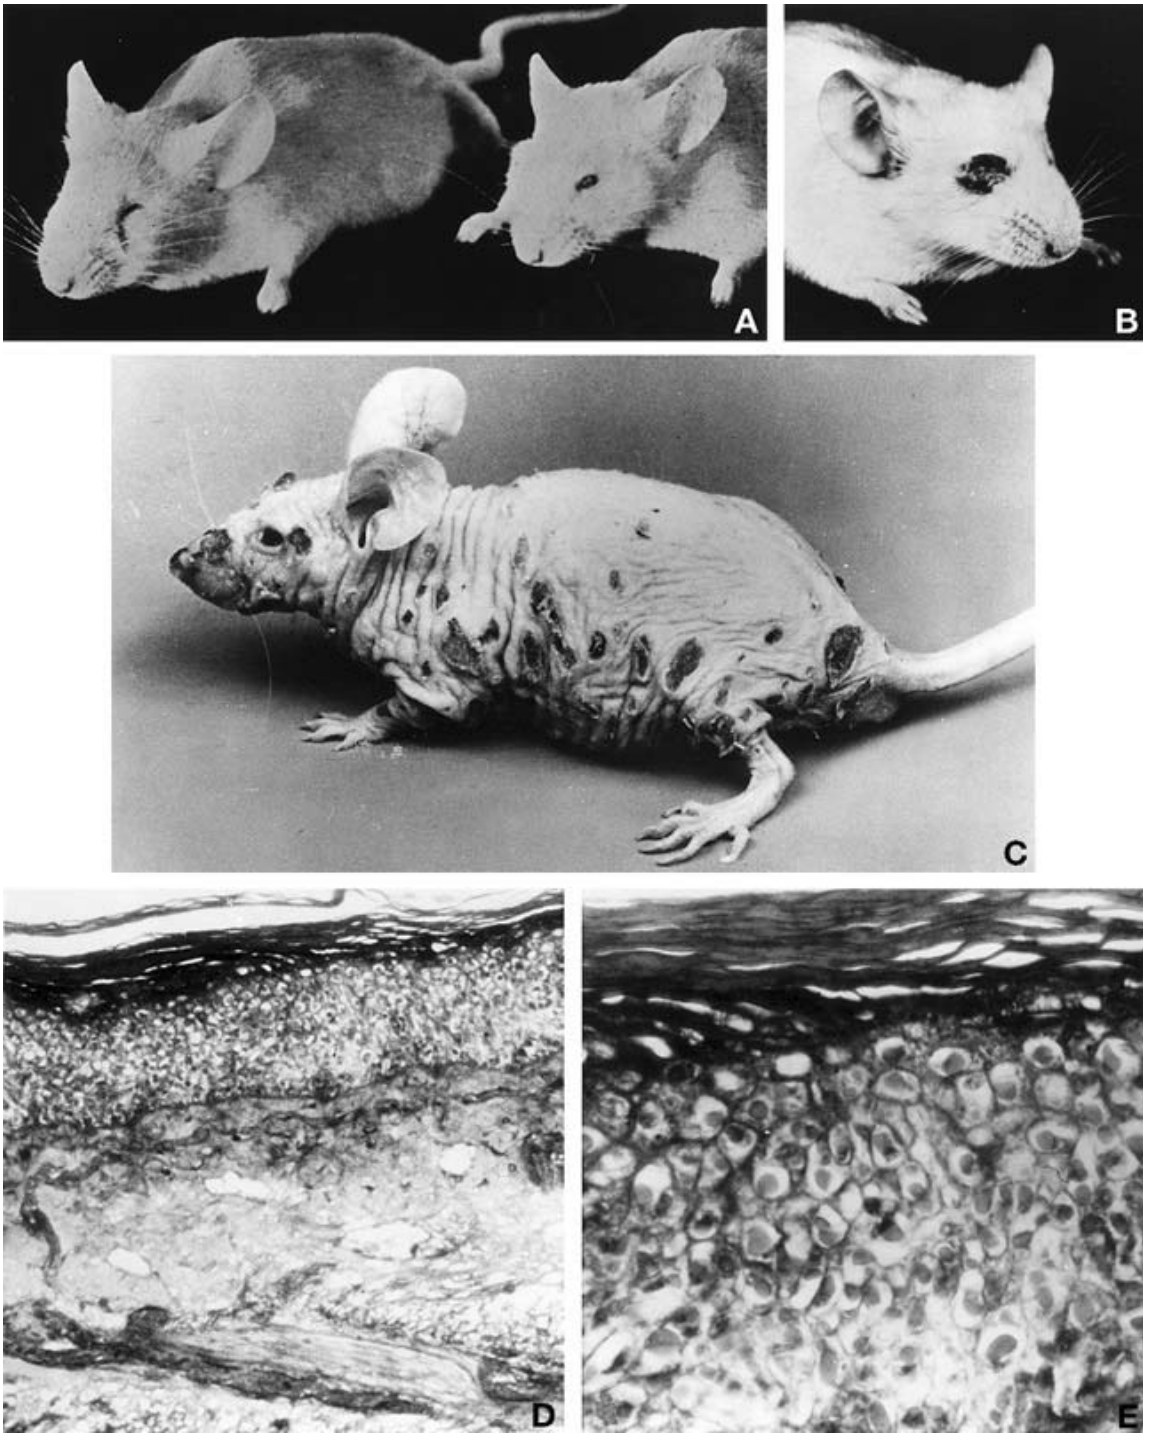


Figure 1 (**A**) An early primary lesion of mousepox beneath the left eyebrow of an outbred susceptible mouse exposed to infection with ectromelia virus 7 days earlier. Comparison with the normal mouse on the right shows the swelling of the face due to edema around the primary lesion. (From Fenner F (1948) *J. Pathol. Bacteriol.* 40: 529. (From Fenner F (1948) *Br. J. Exp. Pathol.* 29: 29. Reproduced with permission of the publisher, Blackwell Science Ltd.) (**C**) The rash of mousepox as it appears 14 days after infection, in a naturally infected genetically hairless mouse (not athymic). Similar lesions occur beneath the hair of other strains of susceptible mice and can be clearly demonstrated by epilation. (Courtesy of the Zentralinstitut für Versuchtiere, Hannover, Germany.) (**D**) Low power and (**E**) high power view of a section of the skin of the foot of a mouse injected with ectromelia virus in the footpad 6 days earlier. Mann's strain. Almost every epithelial cell contains an eosinophilic A-type inclusion body. With most strains of ectromelia virus, these A-type inclusion bodies contain large numbers of mature virions.

Pathology and Histopathology

The pathological changes in naturally occurring mousepox in susceptible mice are quite characteristic. Additional lesions in the peritoneal cavity or lung occur after intraperitoneal or intranasal inoculation respectively; these are important because mousepox sometimes occurs after unwitting passage of ectromelia virus by these routes.

Intracytoplasmic inclusion bodies

Ectromelia virus produces two types of intracytoplasmic inclusion body in infected cells, A-type and B-type. The latter occur in all poxvirus infections and are the sites of viral multiplication; more characteristic of mousepox are the prominent acidophilic inclusion bodies (A-type), which are always found in infected epithelial cells but rarely in liver cells (**Fig. 1D,E**).

Skin lesions

The earliest primary lesions that could be recognized macroscopically were the seat of advanced histological changes, for viral multiplication had then been in progress for several days. There was no macroscopic breach of the skin surface, but the dermis and subcutaneous tissue were edematous and there was widespread lymphocytic infiltration of the dermis. Inclusion bodies could be seen in the epidermal cells at the summit of the lesion. Necrosis of these epidermal cells was followed by ulceration of the surface. The exudate formed a scab, beneath which healing occurred. Histologically the changes of the rash were similar to those in the primary lesion.

Lesions of the liver

The liver and spleen were invariably invaded during the incubation period and virus multiplied to high titer there. The liver remained macroscopically normal, until within 24 h of death, when it appeared enlarged and studded with minute white foci. The necrotic process extended rapidly and at the time of death the liver was enlarged, with many large semiconfluent necrotic foci. In animals which survived, the liver usually returned to its normal macroscopic appearance, but occasionally numerous white foci occurred.

Histologically, little change was apparent until macroscopic changes had appeared, although with fluorescent antibody staining it could be shown that infection always occurred first in the littoral cells of the hepatic ducts, from which it spread to contiguous parenchymal cells (**Fig. 2**). Numerous scattered foci of necrosis then appeared throughout the liver parenchyma, and in fatal cases these rapidly extended until they became semiconfluent. The portal tracts showed slight infiltration with lymphoid cells, but A-type inclusion bodies were rarely found in infected hepatic parenchymal cells. Liver regeneration commenced early and was active, especially in nonfatal cases, and fibrosis did not occur.

Lesions of the spleen

The spleen showed macroscopic changes at least a day earlier than the liver, and higher titers of virus were found in the spleen. Virus reached the spleen in infected lymphocytes, which initiated infection in the substance of the follicles. While infected follicles were destroyed by the spreading infection, neighbouring follicles showed the proliferative response characteristic of antibody production.

In surviving mice, lesions of the spleen varied from small, raised plaques about a millimeter in diameter to strands of fibrous tissue which after severe attacks almost completely replaced the normal splenic tissue. These changes constitute reliable autopsy evidence that a mouse has recovered from an attack of mousepox.

Lesions of other organs

The regional lymph nodes draining the site of the primary lesion were enlarged from the time that the primary lesions could be detected, and they usually showed localized areas of necrosis, with pyknotic nuclear debris in a featureless background. In fatal cases the gut was often engorged and the lymphoid follicles enlarged. Small necrotic foci with typical inclusion bodies occurred in the intestines in most acutely fatal cases of mousepox. Occasionally, especially in very young mice, there were hemorrhagic foci in the kidneys.

Lesions after intraperitoneal inoculation

There is no primary skin lesion, but in acutely fatal cases the necrosis of the liver and spleen resembles that found after natural infection. In addition there is usually some increase in intraperitoneal fluid and a considerable amount of pleural fluid, and the pancreas is often grossly edematous. In animals that survive the acute infection there is a great excess of peritoneal and pleural fluid, the peritoneal surfaces of the liver and spleen are covered with a white exudate, the walls of the gut are thickened and rigid, and there is often fat necrosis in the intraperitoneal fat. Extensive adhesions between the abdominal viscera develop later.

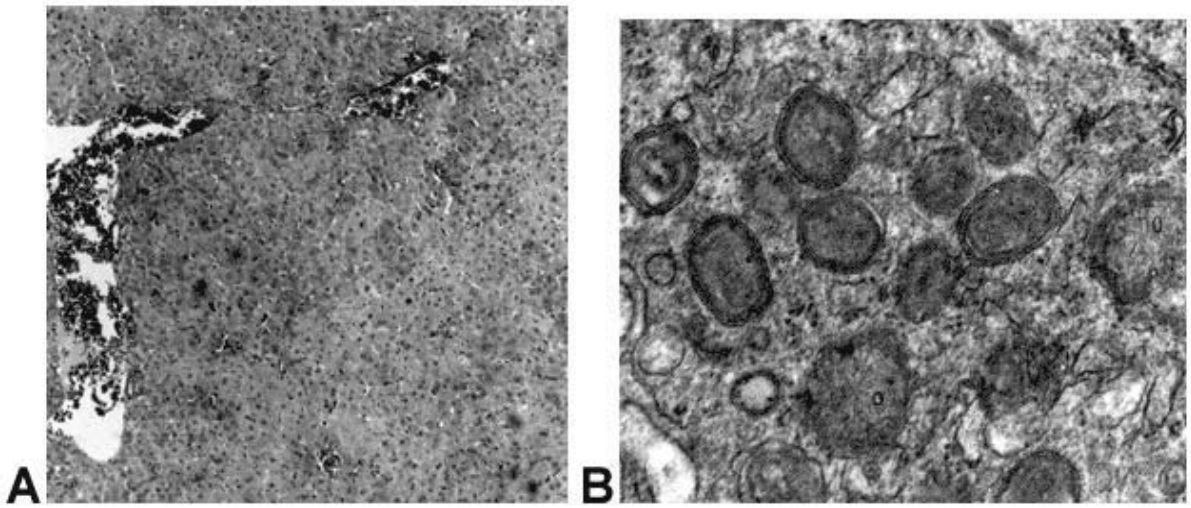

Figure 2 (**A**) Section of the liver of a mouse sacrificed when moribund, 7 days after the injection of a large dose of ectromelia virus in the footpad. There is extensive irregular necrosis of the hepatic cells, with little inflammatory reaction; no A-type inclusion bodies are found. (**B**) Electron micrograph of the same liver; there are numerous virions in the cytoplasm of most hepatic cells. (Courtesy of D. O. Irving, John Curtin School of Medical Research.)

Lesions after intranasal inoculation

When small doses of virus are inoculated intranasally there is usually little change in the lungs except patchy congestion; the changes in the liver and spleen are those characteristic of naturally acquired mousepox. With larger doses of virus, congestion of the lungs is more pronounced and consolidation may occur, and, when very large doses are given, death occurs with patchy or complete consolidation of the lungs and little change in the liver and spleen. The apparent pneumotropism is due to the fact that the local reaction which occurs after the intranasal inoculation of very large doses of virus kills the animal before there is time for the characteristic changes in the liver and spleen to occur.

Immune Response

Active immunity

Two weeks after infection, mice are solidly immune to reinfection by footpad inoculation of the virus. This immunity declines slowly but even a year after recovery multiplication of the virus after footpad inoculation is confined to the local skin lesion.

Passive immunity

Newborn mice received some antibody via the placenta but much more in the milk during the first 7 days after birth. Maternal antibody declines to undetectable levels by the seventh week after birth, but before this it confers protection against death but not against infection with moderate doses of ectromelia virus.

Serologic changes

Sera from mice which have recovered from mousepox contain antibodies that can be recognized by a variety of serologic tests. Hemagglutination-inhibition tests were long used for serologic surveys of mouse sera in the USA, but during outbreaks in 1979–1980 it was found that they occasionally gave both false-positive and false-negative results. ELISA is now preferred for large-scale screening tests.

Cell-mediated immunity

Understanding of the role of cell-mediated immunity in mousepox has been greatly expanded by the investigations of Blanden and his colleagues in Canberra. The full story is complicated and involves different classes of T cells and the H-2 antigens. Briefly, mechanisms controlling viral growth in the liver and spleen are operating 4–6 days after infection. Virus-specific cytotoxic T cells are detectable 4 days after infection and reach peak levels in the spleen 1–2 days later, while delayed hypersensitivity is detectable by the footpad test 5–6 days after infection. In contrast, significant neutralizing antibody is not detectable in the circulation until the eighth day.

Mice pretreated with antithymocyte serum die from otherwise sublethal doses of virus due to uncontrolled viral growth in target organs. These mice have impaired cell-mediated responses but normal neutralizing antibody responses, elevated interferon

levels in the spleen, and unchanged innate resistance in target organs.

Very large doses of interferon or immune serum transferred to preinfected recipients are relatively ineffective against the established infection in target organs, but immune spleen cells harvested 6 days after donor immunization transfer specific and highly efficient antiviral mechanisms which rapidly eliminate infection from the target organs, although neither antibody nor interferon is detectable in the recipients. The active cells in the immune population are cytotoxic T cells, which retard viral spread by lysing infected cells before the assembly of progeny virions. This T-cell activity attracts blood monocytes, which contribute to the elimination of infection.

Laboratory Diagnosis

Diagnosis of a suspicious case

Mousepox can be diagnosed by the microscopic or electron microscopic examination of the tissues of suspected cases, the diagnostic features being the distinctive eosinophilic cytoplasmic inclusion bodies and the poxvirus particles, respectively. Virus can be recovered in mouse embryo cell cultures. Inoculation of genetically susceptible nonimmune mice will produce the symptoms and signs described earlier, whereas vaccinated mice of the same strains should prove resistant.

Screening tests for mouse stocks

The consequences of the reported discovery of mousepox in a mouse colony are so serious that it is unwise to rely on any one serologic test for diagnosis. ELISA should be used as the basic screening test, and any positive results should be confirmed by another serologic test.

Prevention and Control

Most well-managed laboratory colonies of mice are now free of mousepox, and the aim is to keep them free of the disease while still importing mice (for genetic purposes) or mouse organs or tissues (as sources of arboviruses, for example, or tumors). Quarantine and regulation of the importation and distribution of ectromelia virus or materials infected with it is mandatory in the USA; however, such regulations offer no protection against unsuspected sources of infection, and various procedures involving serologic testing and vaccination have been proposed.

Future Perspectives

Mousepox is now very rare as a natural infection in laboratory colonies of mice and it is likely that strict controls on its use will continue to restrict its study in all except a few laboratories. However, workers in Australia, the USA and the UK are now using it as a model for studies of such problems as immunocontraception and the role of the many homologues of mammalian immunomodulatory genes that are found in all poxviruses. Laboratory workers importing mice or mouse products will need to be aware of the risk of introducing the disease and of methods for minimizing its spread if it is accidentally introduced.

Rabbitpox Virus

History and Classification

Rabbitpox is a laboratory artifact, due to the infection of laboratory rabbits with vaccinia virus, usually with 'neurovaccinia' variants; hence this account of rabbitpox virus will omit reference to those aspects that are covered in the entry on vaccinia virus.

The name 'rabbitpox' was originally given to devastating outbreaks of a generalized disease, likened to smallpox in humans, in a colony of laboratory rabbits at the Rockefeller Institute of Medical Research in New York in 1932–1934. Other scientists had been working with neurovaccinia virus in rabbits in an adjacent room before the outbreak. The virus recovered from the outbreak, which was called rabbitpox virus, was shown to be very similar to neurovaccinia virus in its biological properties, and subsequently the restriction map of the Utrecht strain (see below) was found to be almost identical with that of vaccinia virus.

Another outbreak occurred in The Netherlands in 1941. It began among rabbits, bought from a dealer, a few days after they were introduced into the laboratory colony, and spread amongst the stock rabbits. The disease was usually lethal, death occurring before there was time for the development of a rash. The virus that caused this outbreak, designated rabbitpox-Utrecht, caused similar highly lethal epizootics when it 'escaped' in the Institut Pasteur in Paris in 1947; other outbreaks have been described in laboratory rabbits in the USA in the 1960s.

Epidemiology

In all outbreaks, spread appeared to occur by the respiratory route, and experiments confirmed that infection occurred readily by this route. Rabbits infected by contact were not infectious for other

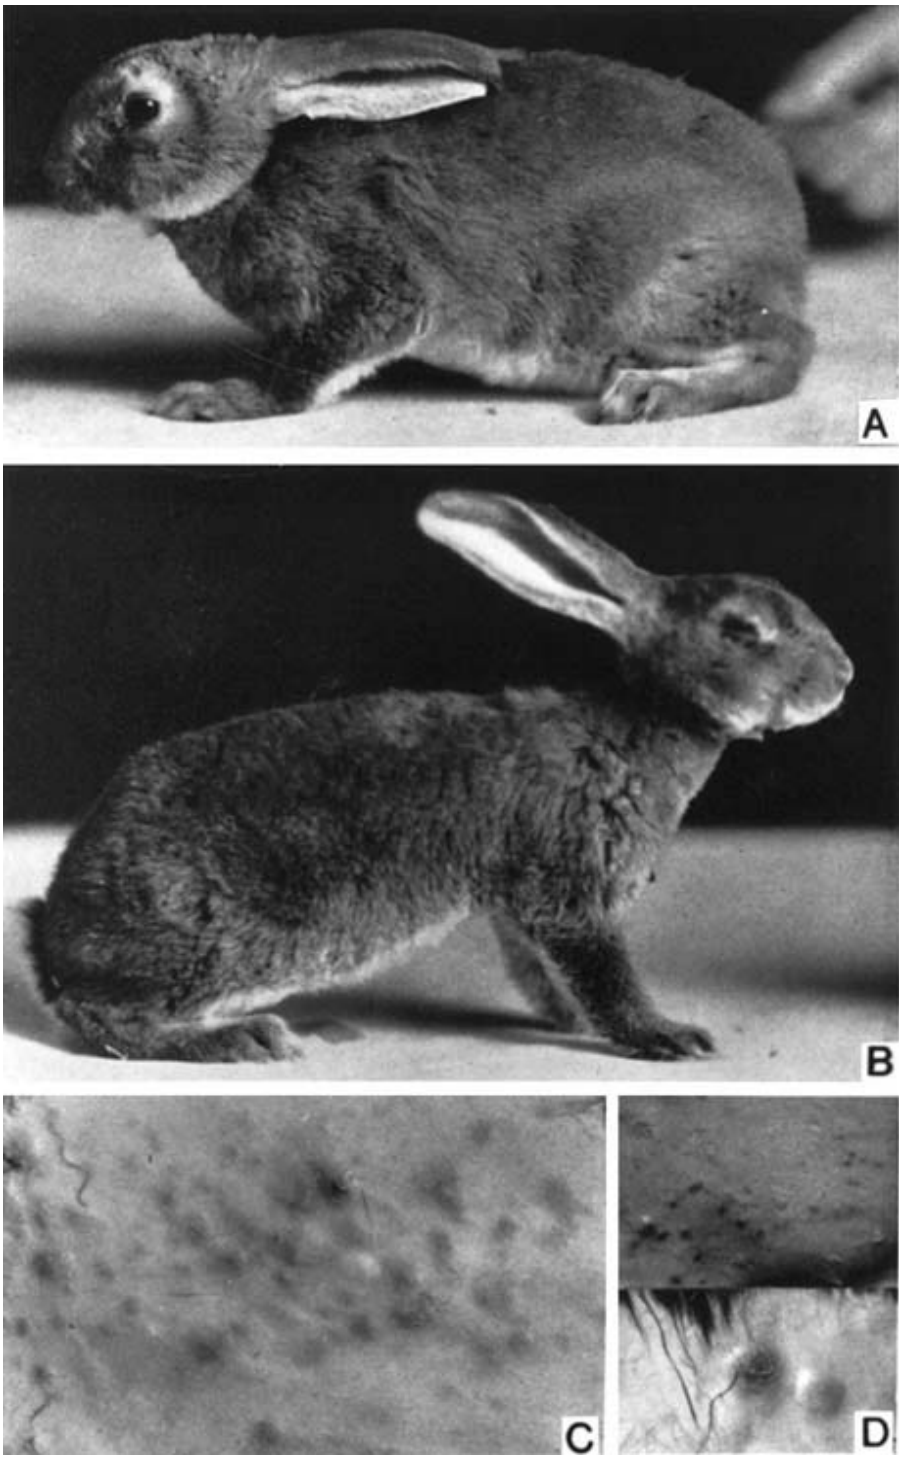

Figure 3 Rabbitpox. (**A**) and (**B**) Littermates with different types of disease. The course of infection was mild in the rabbit shown in the upper panel and external lesions were limited in the skin; the animal in the lower panel was seriously ill and its posture is a manifestation of acute respiratory distress resulting from extensive mouth lesions. (**C**) Cutaneous lesions on the trunk. The coat in this area was loose and easily plucked by hand. Papules varied in size, up to one centimeter in diameter, even among papules of the same age. (**D**) Skin of a pregnant doe self-plucked for nest fur, showing both dry crusted pustules and others in earlier stages of development. (From Greene, HSN (1934) *J. Exp. Med.* 60: 427, with permission.)

rabbits until the second day of illness, which was usually 5 days after infection. Actual contact was not necessary: transmission could occur across the width of a room, and air sampling revealed the presence of rabbitpox virus in the air of rooms housing infected rabbits.

Genetics

Since 1960 the Utrecht strain of rabbitpox virus has been used for genetic studies on poxviruses, as it was found to give rise to white pock mutants on the chorioallantoic membrane and host range mutants in a pig kidney cell line, both of which entail deletions and transpositions of DNA. Recombination experiments with the white pock mutants were used to construct the first crude 'genetic map' produced for an animal virus.

Pathogenesis

A good deal of experimental work has been carried out on the pathogenesis of rabbitpox as an animal model of smallpox, with results that were largely confirmatory of those obtained with mousepox. In rabbits infected by the intranasal instillation of a small dose of virus, by aerosol, or after intradermal inoculation or contact infection, there was a stepwise spread of virus through the organs, although the incubation period was shorter than in mousepox and there seemed to be little delay at the regional lymph nodes. Viremia was leukocyte-associated.

Clinical Features of Infection

Rabbitpox caused an acute generalized disease in which a rash appeared in animals that survived long enough, presenting as pocks on the skin and mucous membranes (**Fig. 3**). Rabbits dying of hyperacute infection showed no obvious skin lesions, the so-called 'pockless' rabbitpox. Such infections are analogous to acutely lethal cases of mousepox, and perhaps to early hemorrhagic-type smallpox, in which death occurs before there is time for pustular skin lesions to develop.

Pathology and Histopathology

The most distinctive lesions are the pocks on the skin and mucous membranes, and occasionally small areas of focal necrosis are found in the internal organs (liver, spleen, lung, testes, ovaries, uterus, adrenals and lymph nodes). In the so-called pockless form, a few pocks may occur around the mouth and they may be visible on the shaved skin. The most prominent gross lesions are pleuritis, focal necrosis of the liver, enlarged spleen, and edema and hemorrhage of the testes.

Rabbitpox virus, being a strain of vaccinia virus, produces B-type inclusions (Guarnieri bodies) in infected cells, but not the prominent A-type inclusions found in cells infected with ectromelia virus.

Immune Response

Rabbits that have recovered from rabbitpox are immune to infection with vaccinia virus, but in very severe infections rabbits die before there is time for an effective immune response. The importance of enveloped virions in the pathogenesis and immunology of orthopoxvirus infections was first demonstrated in experiments with rabbitpox virus. Passive immunization with sera that did not contain antibody to the viral envelope failed to protect rabbits against challenge infection, even though the neutralization titer of the ineffective antiserum (produced by immunization with inactivated vaccinia virus) was much higher, as judged by conventional neutralization tests. This work helped to explain the failure of inactivated vaccinia to provide protection against infection with orthopoxviruses.

Prevention and Control

Since rabbitpox appears to be a laboratory artifact, owing to the introduction of strains of vaccinia virus that can spread from one rabbit to another in rabbit colonies, prophylaxis appears to be a matter of preventing such events. They were rare even when vaccinia and especially neurovaccinia viruses were extensively used in animal experiments, several decades ago, and it is unlikely that further episodes will occur now that most research with vaccinia virus utilizes cultured cells rather than intact animals. Nevertheless, laboratory managers who use rabbits should be aware of the possibility that some strains of vaccinia virus can spread naturally from one rabbit to another. If such an outbreak did occur again, the appropriate method of control would be slaughter of all animals in the colony and disinfection of animal quarters.

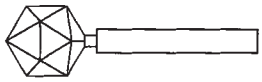
MU-LIKE PHAGES (*MYOVIRIDAE*)



Michael S DuBow, McGill University, Montreal, Quebec, Canada

Introduction

Since the pioneering work of Barbara McClintock with the mobile genetic elements of maize, DNA transposition has been shown to be a ubiquitous process in all well-studied life forms. Transposable elements were originally thought to be capable only of intragenomic DNA transposition. However, since DNA transposition can lead to the duplication of genetic information (whether it is directly from DNA→DNA, or RNA→DNA→RNA), it was not surprising that this mechanism could be used for the propagation and amplification of a virus genome. It was Larry Taylor, in 1963, who first reported the discovery of a virus which uses DNA transposition as a lifestyle. He named this temperate coliphage Mu (for *Mu*tator) because he found that its prophage was capable of randomly inserting in the bacterial chromosome, including within a gene, and thus providing Mu lysogens with a much higher frequency of auxotrophic mutants. This phage was initially called Mu-1 because it was assumed that other transposable mutator phages would be subsequently found. However, only one other bacteriophage that uses DNA transposition as a lifestyle, called D108, has been characterized from *Escherichia coli*. This phage was initially studied as a generalized transducing phage different from P1, and only later shown to be related to phage Mu. In contrast, transposable phages have been found to be quite common within the genus *Pseudomonas*, and can be readily isolated from lysogens of bacteria of this genus. Several other reports have also identified transposable phages in Gram-negative bacteria, though no transposable phages have yet been found in either Gram-positive bacteria or archaebacteria. It is significant to note that DNA transposition as part of the life cycle is used by the retroviruses present in eucaryotes from yeast (Ty elements) to man [human immuno-deficiency virus (HIV)] for the integration of their reverse-transcribed genomes. This entry will summarize what is known of transposable phages and will highlight both their similarities and differences at the molecular level.

Transposable Phage Life Cycle

The three best-studied transposable phages include the coliphages Mu and D108, as well as the *Pseudomonas* transposable phage D3112. These phages all share several important properties, in addition to the fact that their genomes act as mobile genetic elements:

1. The phage genomes are all composed of double-stranded DNA, approximately 37 kb in length.
2. Chromosomal DNA is covalently linked to both ends of the mature phage DNA in the capsid. The right end of the phage genome contains approximately 1000–3000 bp of DNA, while the left end contains approximately 50–150 bp in Mu and D108, and 30–33 bp of DNA in D3112.
3. All of these phages are capable of a low level of generalized transduction.
4. These phages cause 5 bp duplications at the target site of integration during DNA transposition.
5. The lytic cycle takes approximately 60 min at 37°C. However, the burst size of Mu and D108 (50–100 phages per cell) is higher than that of D3112 (10–50 phages per cell).
6. These transposable phages are all temperate, and between 5 and 10% of the infected cells will ultimately go on to form lysogens.
7. The genetic maps and gene organization of the phages are strikingly similar (**Fig. 1**). The arrangement of the repressor genes, and early and late operons, may indicate evolutionary relatedness. However, the phages are heteroimmune and their virion proteins do not cross react in Western blots. Mu and D108, however, are highly related (approximately 90% at the DNA level) and their virion proteins are immunologically related.

The life cycle of a typical transposable bacteriophage is outlined in **Figure 2**, but the discussion below will focus on coliphages Mu and D108. These two phages recognize and attach to different lipopolysaccharide components on the cell surface of their respective hosts. In the case of Mu, after phage attachment the DNA is injected into the cell along with the product of the *N* gene, which binds to the extremities of the injected DNA (phage plus host) where it acts to noncovalently circularize and partially supercoil the infecting DNA. The DNA is then inserted into a random location within the host genome (either on the chromosome or on a plasmid) in a conservative reaction with both infecting strands being integrated. Nonetheless, this is a true DNA

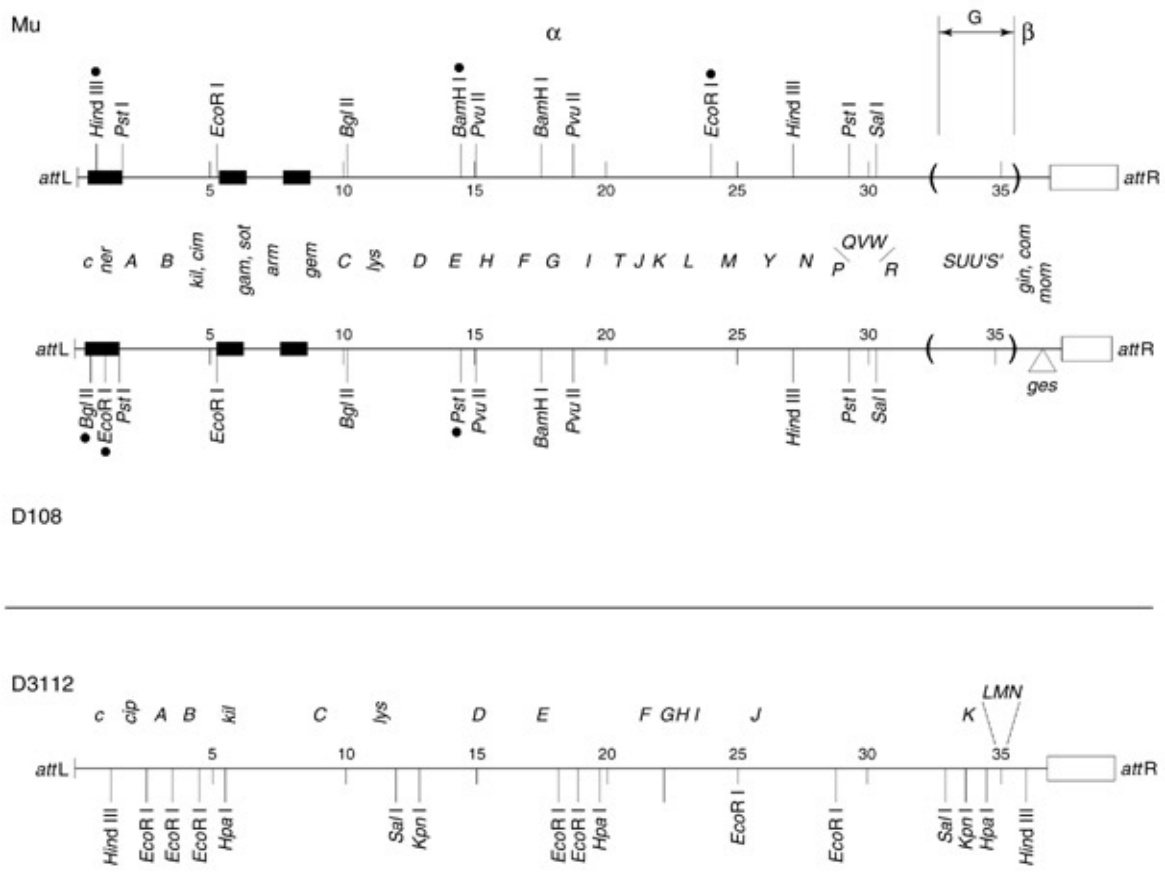


Figure 1 Physical and genetic maps of coliphages Mu and D108, and *Pseudomonas* phage D3112. The location of genes and restriction endonuclease cleavage sites are indicated. The Mu and D108 genomes are divided into three segments, α, the G-loop and β. The regions of nonhomology between Mu and D108 are indicated by thickened lines, plus the 520 bp insertion, containing the ges gene, located near the D108 right end. Restriction site polymorphisms between Mu and D108 are indicated by a • next to the enzyme site.

transposition event in that 5 bp at the target sequence are duplicated and directly flank the inserted DNA. It is important to note that the flanking host DNA of the infecting genome is not integrated along with the phage DNA. If the lysogenic response is chosen, the product of the *c* gene (the repressor) is expressed, and this DNA-binding regulatory protein regulates its own synthesis and represses the expression of the early (lytic cycle) phage operon. Alternatively, if the lytic cycle is chosen, or if a lysogen is induced, the early operon is expressed. This gives rise to the synthesis of the transposase protein (*A* gene product) which is unstable and used *in vivo* stoichiometrically. Transposase, along with other phage- and bacterial-encoded proteins, catalyzes the duplicative transposition of the phage genome to other random bacterial genomic locations. Towards the end of the lytic cycle, the *ner* gene product represses the expression of the early operon, and the late operon is expressed through the positive action of the *C* gene product. The late operons encode functions required for capsid construction and genome maturation. The integrated and dispersed viral genomes are then matured from the host chromosome starting near the left end (*att*L). Double-stranded cleavages are made in the adjacent host DNA, and the viral genomes then begin to be encapsidated. Because these genomes are too small to fill up a phage prohead, adjacent chromosomal DNA from the right end of the phage genomes is also encapsidated prior to the second DNA cleavage and maturation of the phage DNA and subsequent addition of the virion tails. The bacteria then lyse and liberate the progeny phages, to begin the cycle anew.

The transposable phage genomes are always inserted within host DNA (as are all DNA copies of mobile genetic elements). Thus, even in the virus capsid, the viral genome is 'inserted' in chromosomal DNA. In the newly infected cell, phage DNA can therefore transpose from its 'old' genomic location to

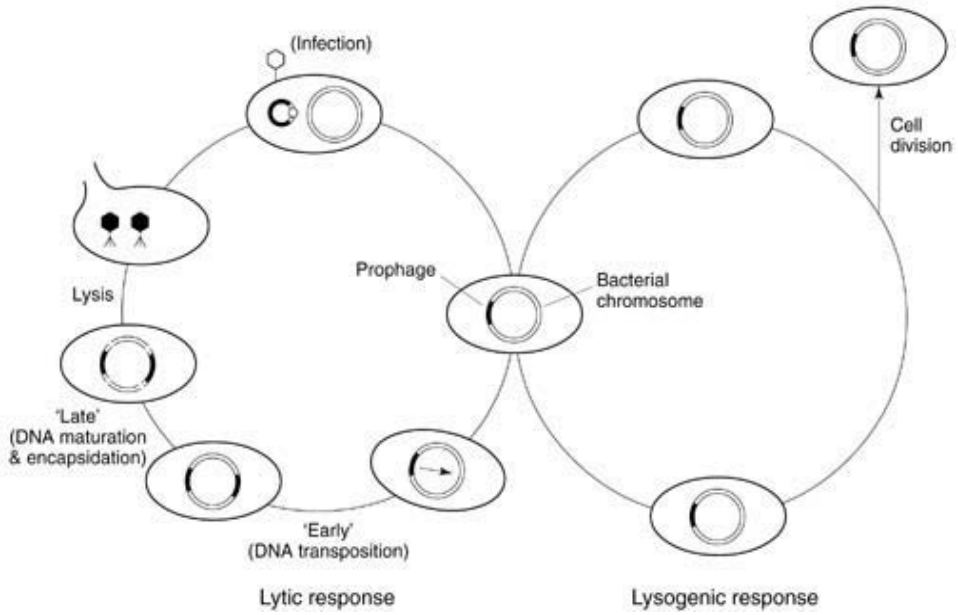

Figure 2 Outline of the life cycle of a transposable phage. The phage genome is represented by a solid line, while the bacterial DNA is represented by a double line. The Mu phage N protein is represented by an open circle joining the infecting DNA. Only two phage genomes are shown during the lytic cycle.

a new chromosomal site. It should be stressed that the transposable bacteriophages form a prophage irrespective of whether or not they choose the lytic or the lysogenic pathway for propagation. Moreover, during the lytic cycle these phages are amplifying their genomes through transposition to form an increasing number of prophages within their host's DNA. This mode of genome propagation presents interesting problems for phage DNA maturation and encapsidation, as these phages use headfull packaging and the chromosomal DNA behaves as a large discontinuous concatemer substrate for DNA maturation.

Lytic/Lysogenic Decision and Regulation of Early Gene Expression

The left end regulatory regions of Mu, D108 and D3112 contain the elements necessary for control of gene expression and the decision between lytic growth or lysogeny. A glance at the regulatory region (**Fig. 3**) of these three transposable phages reveals a distinct organizational resemblance and, perhaps, evolutionary relatedness. The following discussion will again concentrate on the transposable coliphages Mu and D108. At an indeterminate time after infection, the early operon is expressed and the phage transposes, in a conservative reaction, into host DNA. It is unclear at this time whether the choice between lytic or lysogenic growth is made prior to, during, or after the first integration of the infecting phage DNA. Phages Mu and D108 have a promoter, called P_c, which is the major promoter for expression of the repressor gene (*c*). The repressor genes of the phages are transcribed from right to left on the genetic maps and the repressor proteins are nonhomologous and incapable of binding to each other's operator sites or conferring immunity to superinfection by the other phage. In the lysogenic state, repressor binds to two operator sites in phage D108, and three operator sites in phage Mu. These operators repress the expression of the early operon (from promoter P_e), yet somehow allow continued expression of repressor for the maintenance of lysogeny.

During lytic growth (including the induction of a lysogen), the early genes are expressed from promoter P_e. This results in the production of proteins from the *ner* gene and the *A* (transposase) and *B* genes. The Ner protein binds to its operator and acts as a repressor to turn off expression of the repressor operon and commit the phage to the lytic cycle. The Ner protein is also capable of turning down expression of the early operon to allow a level of early gene expression sufficient to amplify, via DNA transposition, the viral genome. This is necessary because the transposase protein of Mu is used stoichiometrically and is unstable *in vivo*, thus requiring its continued expression. *In vitro*, Mu DNA transposition reactions containing elevated levels of Mu transposase protein predominantly result in 'suicide' intramolecular transposition products. Consequently, transposase

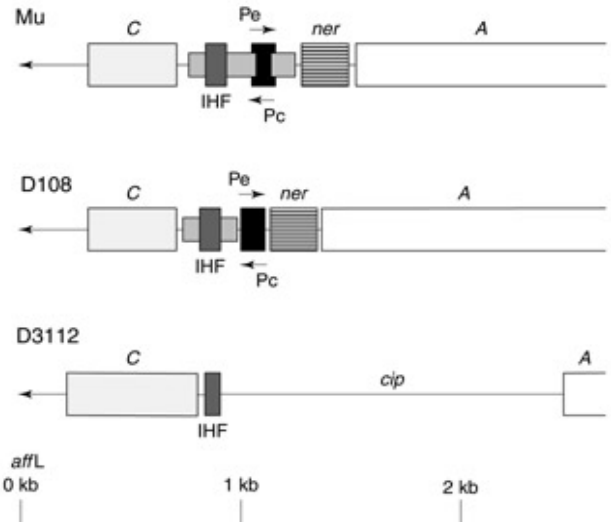

Figure 3 Maps of the Mu, D108 and D3112 left end regulatory regions. The genes and sites are drawn approximately to scale. The repressor (c) genes (▩), *ner* genes (■), and the 5′ ends of the A genes (□) are shown. The binding sites for IHF (▩), Ner (■) and repressor (▨) are also delineated. The arrows for Pe and Pc represent the 5′ ends of the mRNA for the early and repressor promoters, respectively. The scale at the bottom shows the distance (in kb) from the left end (*att*L) of the phage genomes.

gene expression must be adequately regulated to ensure a productive lytic cycle. It is the binding of the bacterial protein IHF that allows RNA polymerase to initiate transcription from the early promoter even in the presence of the Ner repressor. The mechanisms governing gene regulation and the lytic/lysogenic decision in phages Mu and D108 are not as well studied as in phage λ. Nonetheless, the outline of these mechanisms is now being elucidated, as is the fact that DNA supercoiling and local DNA conformation play a role in the relative expression of the overlapping, yet divergent, P_e and P_c promoters.

Transposable *Pseudomonas* phage D3112 bears striking similarities, though not homologies, to transposable coliphages Mu and D108. Phage D3112 also encodes a repressor protein in its left end which can act to confer immunity to D3112 superinfection *in vivo*. This repressor gene is transcribed from right to left on the genetic map of phage D3112. Moreover, D3112 contains an IHF site, which is capable of being bound by *E. coli* IHF *in vitro*, in a location on the phage DNA which is similar to that of Mu and D108 (**Fig. 3**). However, the transposase gene of phage D3112 does not begin until well after 2 kb from the left end. A *ner*-like function, called *cip*, has been postulated to exist in phage D3112 and to be located between the repressor and transposase genes. However, the region containing the *cip* gene is well over 1.5 kb in length and several open reading frames, on both strands, have been found, though none of these protein products bind to D3112 DNA *in vitro* when overexpressed in crude protein extracts. Thus, D3112 may regulate its early and repressor genes in a manner different from that of the coliphages Mu and D108.

Mechanism of DNA Transposition

The high frequency of DNA transposition undergone by Mu during the lytic cycle (up to 100 events per cell per one hour lytic cycle) has made it highly amenable to biochemical and genetic analysis. It was Mu DNA transposition that was the first system to be available for study *in vitro*. Analysis of this system has demonstrated that the requirements for DNA transposition are the Mu *A* (and *B*) gene products, *E. coli* histone-like protein HU, Mg^{2+}, ATP, a supercoiled 'donor' plasmid containing the left and right ends of Mu in the proper orientation, and a target DNA molecule. The DNA sequences at the Mu left and right ends contain three transposase-binding sites (termed L1–L3 and R1–R3, respectively), as well as an enhancer-like element located between base pairs 890 and 1000 from the Mu left end. This element, termed the IAS (internal activating sequence), helps to bring the two ends of Mu DNA together in a synaptic complex catalyzed by the Mu transposase and *E. coli* Hu proteins. Mu transposase protein, the N terminus of which contains homology to the DNA-binding domain of the Mu repressor, is capable of binding not only to the ends of Mu DNA (using a second DNA-binding domain), but also to the 01 and 02 repressor operators (in effect, the IAS). When the ends are

brought together, a nick is placed at the extreme 3′ ends of Mu DNA in a nucleoprotein complex containing transposase tightly bound to the L1, R1 and R2 sites. Mg^{2+} ions are required for the transposase-induced single-strand cleavage. The strand-transfer reaction utilizes the nucleoprotein complex, plus the 3′-hydroxyl groups at the Mu ends acting as the attacking nucleophiles, to nick and ligate to the target DNA in a 5 bp 5′-staggered fashion. Following DNA replication, primed by the free 3′ ends of the target sequence, Mu DNA is replicatively copied using the bacterial DNA replication machinery. Filling in the gaps leaves the characteristic 5 bp directly repeated duplication of the target sequence. This mechanism of DNA transposition can also account for all of the DNA rearrangements (e.g. co-integrate formation, deletions, translocations, inversions, etc.) that Mu DNA is capable of catalyzing *in vivo*. In addition, the mechanism allows a conservative transposition of Mu DNA to occur. In this case, after the initial ligation to the target DNA site, a second set of nick-ligation reactions at the Mu termini, plus filling in of the target sequence gaps, will lead to both DNA strands being inserted at the new location.

Phages D108 and D3112 also cause 5 bp duplications at the site of insertion. D108 and Mu are over 90% homologous at the DNA level, yet are non-homologous in their left and regulatory region (*c*, *ner* and the 5′ end of the *A* gene). However, their three transposase-binding sites are very well conserved, though the IAS is not. *In vivo*, Mu and D108 can catalyze the transposition of each other's DNA, although, owing to the nonhomology of their repressor binding sites and IAS, to a lower extent than the homologous DNA. The N-terminal portion of the putative transposase protein of D3112 shares 40% amino acid homology with that of phage Mu. However, the D3112 left end DNA sequences have no similarity to that of phages Mu and D108.

The initial infecting Mu DNA transposition reaction may proceed by a variation of the duplicative transposition reaction outlined above. However, the infecting Mu DNA is only partially supercoiled due to the noncovalent attachment of the terminal DNA sequences. Moreover, the initial reaction is a conservative reaction in which both strands of the infecting molecule are integrated without significant DNA replication occurring.

Late Gene Expression and DNA Maturation/Encapsidation

Late in the lytic cycle, the Ner protein is responsible for the reduction of early gene expression. Conversely, the product of the *C* gene is a positive activator of late gene transcription in phage Mu which allows the σ^{70} form of RNA polymerase to transcribe the late genes from several promoters scattered throughout the rightmost two-thirds of the Mu genome. These genes encode the morphogenetic functions of the virus as well as genes for host range determination (the G-loop) and a DNA modification function (see below).

Mu DNA maturation begins by the recognition of a sequence, called *pac*, which is located between nucleotides 32 and 54 from the Mu left end and nestled between the first two transposase-binding sites (L1 and L2). This sequence is identical in Mu and D108, and these phages can package each other's genomes *in vivo* and *in vitro*. A double-stranded cleavage is then made in the adjacent host DNA between 50 and 150 nucleotides from the left end of Mu and D108. There is preference for this double-stranded cleavage to occur in 10 bp intervals, indicative of a process that occurs once every helical turn of DNA. The enzyme(s) responsible for this process (called 'pacase'), as well as the nature of the reaction that causes these cleavages, is not currently known. The prohead is then filled with DNA with the left end entering first and, as the Mu genome is too small to totally fill the prohead, the terminal cleavage for Mu DNA maturation is made in the adjacent host DNA between 1 and 3 kb from the right end. Recently, an *in vitro* reaction to study this packaging mechanism has been developed and the template requirement was determined to be circular DNA, in this case an entire Mu prophage inserted within the plasmid pSC101, while the poorest substrate was mature Mu DNA. The packaging reaction requires Mg^{2+} ions, a crude extract prepared from Mu-infected cells late in the lytic cycle, spermidine and ATP. It was also shown that the presence of transposase can inhibit the reaction, suggesting that the depletion of active transposase protein is necessary to allow the Mu prophages to be competent for DNA packaging. The cells are finally lysed, and the progeny phage released, by the action of the *lys* gene product.

DNA Modification Function Encoded by Mu and D108

Phages Mu and D108 encode an unusual DNA modification function from the *mom* or *mod* genes, respectively. The consensus recognition sequence, 5′ C/G A C/G Py 3′ is the recognition site for this modification function. The modified base is the adenine residue, and it is modified to the unusual nucleotide α-*N*-(9-β-D-2′-deoxyribofuranosylpurin-6-yl)glycinamide. This unusual modification of DNA is not required for Mu lytic or lysogenic

growth, though it does act to protect the phage DNA from several bacterial restriction endonucleases.

The *mom* gene has an unusual mode of regulation of its gene expression. Its promoter is positively regulated both by the C gene product of Mu, as well as the host Dam methylase. In addition, the *mom* gene consists of two open reading frames which overlap, one of which comprises the *com* gene. The *com* gene encodes a 62-amino acid zinc finger protein which binds to *mom* mRNA and acts to destabilize a translational inhibitor stem loop structure to expose the Shine-Dalgarno sequence for *mom* translation initiation. The net effect is for *mom* function to be expressed late in the lytic cycle. However, owing to the Dam regulation of the *mom* promoter, *mom* is more highly expressed after prophage induction than after infection. This is most likely due to the *mut*H gene product of *E. coli* acting as a repressor of *mom* transcription by binding to unmethylated (or hemimethylated) dam (5′ GATC 3′) sites in the *mom* promoter.

The Invertible G-Loop

Phages Mu and D108, but not the transposable phages of *Pseudomonas*, contain an invertible region located near their right end. This 3015 bp region was initially identified as a heteroduplex bubble in electron micrographs of denatured and renatured Mu DNA. It has since been found that the invertible G segment of Mu and D108 plays a role in the adsorption specificity and host range of these two phages. The tail fiber proteins of Mu and D108 are partially encoded by these regions such that, in one orientation, the expression of the S and U genes leads to phages that can adsorb to *E. coli* K12 (for example). In the other orientation, the G-loop will encode the two genes S′ and U′, which yields phages which are incapable of adsorption to *E. coli* K12, but can adsorb to other Gram-negative bacteria such as *Citrobacter freundii*. The N-terminal portion of the S and S′ genes are identical and encoded by the adjacent sequences to the left of the invertible G-loop. Transcription proceeds into the G-loop (from left to right) and, in one orientation, gives rise to an mRNA that contains the constant N-terminal region of the S gene, plus the C-terminal region of the S gene and the entire U gene. In the other orientation, the constant region of the S gene is now transcribed with the carboxyl portion of the S′ gene and then the U′ gene. Thus, the S and S′ genes share their N termini, but differ in their C-terminal sequences, yielding phages which recognize different lipopolysaccharide components on the exterior of the cell.

The inversion of the G segment is catalyzed by a gene just to the right of the G-loop and before the *mom*/*com* genes and *att*R. The product of this gene, called *gin* (for *G inversion*), catalyzes the reaction through 34 bp inverted repeat segments that flank the G-loop. This reaction is stimulated by a thermostable host protein, called Fis, which binds to a site within the *gin* gene and which acts as an enhancer for efficient catalysis of G-loop inversion. Since G-loop inversion is a relatively slow and inefficient process *in vivo*, the majority of phages that arise after infection generally contain their G-loop in the initial orientation that occurred upon infection. However, phages prepared from induction of lysogens will have had adequate time during growth of the culture to arrange their G-loops in one or the other orientation, and will thus give rise to an approximately equal mixture of phages with their G-loops in one, or the other, orientation.

Gin is a member of, and related to, other DNA invertases. For example, the C-loop of bacteriophage P1 fulfills a similar function to the G-loop in determining the phage's host range, and its inversion is catalyzed by a protein homologous to Gin. Moreover, Gin can catalyze the inversion of the C-loop of P1, in spite of the fact that the C-loop of P1 contains 600 bp inverted repeats flanking the invertible segment. Gin is also highly homologous to the *Salmonella* flagellum invertase (*hin*) and contains a striking degree of homology with the resolvase protein of Tn*3* (TnpR).

Transposable Phages from the Genus *Pseudomonas*

Transposable phages have been found to be quite common in the genus *Pseudomonas*. Much of this work has been the result of extensive research by Dr Victor Krylov and his co-workers at the Institute for Genetics and Selection of Industrial Micro-organisms in Moscow, Russia. They have isolated a wide variety of transposable phages, including phage D3112, and have studied a great deal of their biology. All of the transposable phages of *Pseudomonas* have been found to be inducible by DNA-damaging agents, which is not the case for bacteriophage Mu. The DNAs of many of these phages have been isolated and characterized by restriction enzyme and electron microscopic heteroduplex analyses. This has allowed the transposable phages to be sorted into four main evolutionarily related groups. These groups are named according to their best characterized member. The phages of the B3 group appear to be less related to the other three groups. For example, there is more extensive host DNA present in their left ends (50–

100 bp) than in the phages of the other groups such as D3112 (30–33 bp). Western blot analysis using Mu virion antiserum has revealed that the virion proteins of phage D3112 are non-homologous to those of Mu or D108. Phage D3112, however, does contain repressor and transposase genes that are organized in a similar manner to phages Mu and D108, as well as an IHF site suggestive of the presence of an IHF-like protein in *Pseudomonas aeruginosa*.

The extensive physical characterization of these phage genomes, as well as the construction of viable hybrid phages by homologous recombination, has revealed the presence of regions that are conserved among the various transposable *Pseudomonas* phages. These regions are interspersed with areas of nonhomology, and suggest that the phages have evolved by a process of modular evolution. It is unclear at this time why these phages should be so common within the genus *Pseudomonas*, yet only two such transposable phages have been found in *E. coli*. It is possible that the transposable phages may be a consequence, or source, of the unusual metabolic and genomic plasticity observed within the genus *Pseudomonas*.

Transposable Phages of Other Bacteria

Reports of transposable phages from other bacterial species have been rare. Nonetheless, phage VcA1, from *Vibrio cholera*, has been shown to be a Mu-like transposable phage. It is interesting to note that its genome is approximately 37 000 bp in length. However, very little is known of its genetics or mechanism of transposition. This phage can create co-integrates of plasmids into the *V. cholera* genome and suggests that transposition of the genome progresses through a co-integrate intermediate, as seen for the other transposable phages. Phage VcA1 appears to also randomly insert within the *V. cholera* chromosome, and lysogens contain an increased frequency (0.6–2%) of auxotrophic mutations, a result similar to that observed in coliphage Mu and D108 lysogens.

A second phage, called Psi (ψ), was shown to be a mutagenic temperate phage of *Agrobacterium tumefaciens*. This phage also contains a double-stranded DNA genome of approximately 38 kb in length, and lysogens of this temperate phage contain various chromosomal mutations. However, these mutants were found to be leaky and to revert at a detectable frequency. Further work has shown that phage ψ DNA forms a covalently closed and supercoiled molecule after infection, and integrates into the chromosome at a unique site to form a prophage. This suggests that ψ is much more like phage λ in the behavior of its DNA. The increased frequency of mutations observed in lysogens may be due to some product expressed in the lysogen which acts as a mutator-like enzyme.

Lastly, a coliphage, called B278, has also been observed to act as a mutator-like phage. However, very little information is available concerning this 87 kb double-stranded DNA phage and the behavior of its genome.

The Use of Transposable Phages as Genetic Tools

The properties of transposable phages that enable integration into random locations in host DNA, and that catalyze a wide variety of DNA rearrangements, have allowed molecular biologists to prepare a number of derivatives of these transposable phages for *in vivo* genetic engineering. One important characteristic of these phages is to act as insertional mutagens and thus allow the creation of stable recessive mutations. The use of cloned antibiotic resistance markers within the phage genomes allows the facile cloning and characterization of the gene in which the prophage is inserted. In addition, a number of mini-Mu derivatives have been prepared which contain the *cis*-acting sequences required for transposition (and, in many cases, the transposase gene). These mini-Mu derivatives can contain reporter genes cloned near their right end and allow the determination of the expression of the gene in which they are inserted through the use of gene fusions. Upon infection, or induction of a thermosensitive helper prophage, one can create virtually any genetic combination that one wishes *in vivo*. Moreover, various plasmid replicons have been cloned within the ends of mini-Mus to allow these mini derivatives to be used as cloning vehicles such that the adjacent DNA is packaged by a helper phage and, when introduced to a new cell by infection, will circularize to form a plasmid derivative containing the gene to be studied. A wide variety of host range mutants of Mu have allowed it to be grown in many Gram-negative bacterial species, and recent research is directed at the preparation of D3112 derivatives to allow all of the benefits of Mu to be used in the medically and industrially important genus *Pseudomonas*.

Thus, it can be seen that transposable phages can provide model paradigms for the study of gene expression, DNA inversion and DNA transposition. It is important to note in this regard that the mechanism of HIV-1 DNA integration appears to be identical to that used by Mu, and that this transposition reaction mechanism may thus be conserved from bacteria to humans. The use of Mu and other transposable phages as *in vivo* gene manipula-

tion vehicles has greatly aided the studies of their host bacteria at the molecular level. It is perhaps not a great leap to predict that these kinds of benefits will some day be extrapolated to the genomes of all well-studied organisms.

MUMPS VIRUS (*PARAMYXOVIRIDAE*)

Bertus K Rima, The Queen's University of Belfast, Belfast, Northern Ireland

History

The primary clinical manifestation in mumps is swelling of the salivary glands because of parotitis. This symptom is so characteristic that the disease was recognized very early as different from other childhood illnesses which give rise to skin rashes. Hippocrates described mumps as a separate entity in the fifth century BC. He also noted swelling of the testes (orchitis) as a common complication of mumps. Infection in the central nervous system (CNS) and meninges in some cases of mumps was first noted by Hamilton in 1790. In 1934, Johnson and Goodpasture demonstrated the filterable nature of the causative agent and Koch's postulates were fulfilled by infection of human volunteers with virus propagated in the salivary glands of monkeys.

Taxonomy and Classification

Mumps virus (MuV) is sensitive to ether and other membrane-destroying reagents and has hemagglutinating and neuraminidase activity (HN). It contains a nonsegmented negative-stranded RNA genome. MuV is now classified in the family *Paramyxoviridae*, subfamily *Paramyxovirinae* and placed in the genus *Rubulavirus* with Newcastle disease virus and several other mammalian viruses on the basis of genetic characteristics. Paramyxoviruses consist of an inner ribonucleoprotein (RNP) core surrounded by a lipid bilayer membrane from which spikes protrude. The latter are involved in the hemagglutination and neuraminidase activities as well as the hemolysis of erythrocytes of different origins. The latter reflects the ability of the virus to fuse with infected cells. Fusion is required for the entry of the RNP cores into cells.

Properties of the Virion

The MuV virion appears to be roughly spherical with diameters ranging from 100 to 300 nm when grown in cultured cells or eggs, but bizarre rod-shaped and other pleomorphic particles have been observed. Electron microscopy shows that MuV has the typical paramyxovirus structure with a lipid bilayer membrane surrounding an internal RNP complex, the nucleocapsid. This contains the RNA genome covered with nucleocapsid protein (N) as well as a phosphoprotein (P) and the large (L) protein. The RNP is surrounded by a lipid bilayer membrane derived from the host cell in which the matrix protein of the virus is embedded. This protein interacts with the internal core N protein and the viral glycoproteins. Spikes (10–15 nm in length) protrude from the membrane and these contain the viral glycoproteins (HN and F) in homo- or hetero-oligomeric complexes the composition of which has not yet been elucidated. The internal nucleocapsid displays the herring-bone structure characteristic of *Paramyxoviridae* and is approxi-

tion vehicles has greatly aided the studies of their host bacteria at the molecular level. It is perhaps not a great leap to predict that these kinds of benefits will some day be extrapolated to the genomes of all well-studied organisms.

MUMPS VIRUS (*PARAMYXOVIRIDAE*)

Bertus K Rima, The Queen's University of Belfast, Belfast, Northern Ireland

History

The primary clinical manifestation in mumps is swelling of the salivary glands because of parotitis. This symptom is so characteristic that the disease was recognized very early as different from other childhood illnesses which give rise to skin rashes. Hippocrates described mumps as a separate entity in the fifth century BC. He also noted swelling of the testes (orchitis) as a common complication of mumps. Infection in the central nervous system (CNS) and meninges in some cases of mumps was first noted by Hamilton in 1790. In 1934, Johnson and Goodpasture demonstrated the filterable nature of the causative agent and Koch's postulates were fulfilled by infection of human volunteers with virus propagated in the salivary glands of monkeys.

Taxonomy and Classification

Mumps virus (MuV) is sensitive to ether and other membrane-destroying reagents and has hemagglutinating and neuraminidase activity (HN). It contains a nonsegmented negative-stranded RNA genome. MuV is now classified in the family *Paramyxoviridae*, subfamily *Paramyxovirinae* and placed in the genus *Rubulavirus* with Newcastle disease virus and several other mammalian viruses on the basis of genetic characteristics. Paramyxoviruses consist of an inner ribonucleoprotein (RNP) core surrounded by a lipid bilayer membrane from which spikes protrude. The latter are involved in the hemagglutination and neuraminidase activities as well as the hemolysis of erythrocytes of different origins. The latter reflects the ability of the virus to fuse with infected cells. Fusion is required for the entry of the RNP cores into cells.

Properties of the Virion

The MuV virion appears to be roughly spherical with diameters ranging from 100 to 300 nm when grown in cultured cells or eggs, but bizarre rod-shaped and other pleomorphic particles have been observed. Electron microscopy shows that MuV has the typical paramyxovirus structure with a lipid bilayer membrane surrounding an internal RNP complex, the nucleocapsid. This contains the RNA genome covered with nucleocapsid protein (N) as well as a phosphoprotein (P) and the large (L) protein. The RNP is surrounded by a lipid bilayer membrane derived from the host cell in which the matrix protein of the virus is embedded. This protein interacts with the internal core N protein and the viral glycoproteins. Spikes (10–15 nm in length) protrude from the membrane and these contain the viral glycoproteins (HN and F) in homo- or hetero-oligomeric complexes the composition of which has not yet been elucidated. The internal nucleocapsid displays the herring-bone structure characteristic of *Paramyxoviridae* and is approxi-

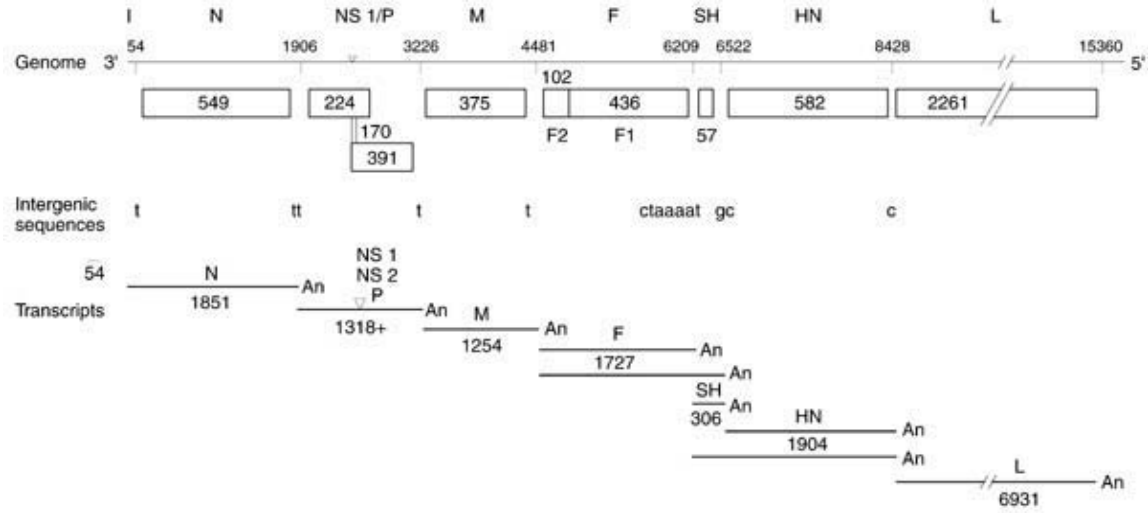

Figure 1 Gene order and transcription of mumps virus genome. ▽, editing site; An, poly(A) tail.

mately 1 μm in length with a diameter of 17 nm and an internal central core of 5 nm. Some of the pleomorphic particles have been reported to contain more than one RNP structure. The biological significance of such polyploid particles has not been investigated.

Properties of the Genome

MuV (as all other paramyxoviruses) has a single nonsegmented negative-stranded RNA genome. The nucleotide sequence of the entire genome of 15 384 nucleotides is now known. The order of the genes of MuV and transcription of the genome is depicted in **Fig. 1**, and is similar to that of other paramyxoviruses. **Figure 1** also shows the number of amino acid residues in each protein and the lengths of each messenger RNA.

Properties of the Proteins

The presence of six structural proteins, i.e. the nucleocapsid (N) protein, the phosphoprotein (P), the matrix protein (M) and the large protein (L) as well as two glycosylated membrane-spanning proteins, the hemagglutinin-neuraminidase (HN) and fusion (F) protein, has been demonstrated in mumps virions. Furthermore, the virus induces the synthesis of at least two and possibly more nonstructural proteins from transcripts of the NS1/P gene. The properties of the proteins of MuV are summarized in **Table 1**. It should be emphasized that this assignment is largely based on analogy of the MuV proteins with those of other paramyxoviruses, as gene identifications have not been carried out directly for all genes. However, the similarities to other paramyxoviruses are so striking that this assignment is beyond dispute. Recently, the presence of SH protein has been demonstrated in MuV-infected cells using antisera to peptides derived from the deduced amino acid sequence. It is not clear as yet whether the protein is incorporated into virions. At least one strain (Enders) expresses the SH gene as a tandem readthrough transcript with the F gene in tissue culture. It is unlikely that the SH protein is translated from such an F-SH bicistronic mRNA and growth of this strain in tissue culture may not require the expression of this protein.

Physical Properties

The MuV virion is very susceptible to heat and treatment with UV light. The UV target size is one genome equivalent of RNA. The virus is also inactivated by 0.2% formalin and the presence of the lipid bilayer leads to sensitivity to ether and chloroform. Treatment with 1.5 M guanidine hydrochloride leads to selective inactivation of neuraminidase and not hemagglutinating activity of the virus. This indicates that separate domains of the HN molecule are responsible for these two functions.

Replication

MuV is capable of infecting a variety of cells in culture even though *in vivo* it may be more restricted. The attachment of MuV is mediated primarily through the interaction of the HN protein with a sialoglycoconjugate receptor, but the exact nature of the MuV receptor is not known. The cooperative

binding of a number of HN molecules to cellular receptors probably leads to invagination of the host's membrane and this may allow fusion protein in its proteolytically cleaved activated state to fuse the membrane of the virus and the host cell. Whether viropexis is another mechanism of entry of MuV is not known.

After introduction of the RNP into the cell, primary transcription of the negative-stranded genome occurs mediated probably by the L and P proteins of the virion. This leads to the synthesis of positive-strand monocistronic mRNAs encoding the proteins of MuV (see **Fig. 1**). The presence of RNA-dependent RNA polymerase has been demonstrated in MuV virions but the role of the various viral proteins in this has not been assessed directly. Most of what follows is analogous to other paramyxoviruses. The first gene encoding the N protein is preceded by a leader region. No reports have appeared on the presence or absence of encapsidated or unencapsidated leader transcripts in infected cells or on the question of whether the leader region is transcribed in tandem with the first gene. The transcription complex recognizes the 3′ end of the genome and transcribes the genes in the order given in **Fig. 1**, stopping at each of the intergenic regions and synthesizing the polyadenylate tails of the various mRNAs by presumed repeated transcription (stuttering) of a poly(U) stretch in the genome.

The sequence signals surrounding the stop and start sites of transcription have the following (positive-strand) consensus:

$$\binom{A_3}{T_4}T\binom{A_3A_5}{T_4T_2}A\binom{G_6}{T_1}AAAAAA(A)\text{-intergenic-}$$

$$A\binom{A_5}{G_2}G\binom{C_5C_5}{R_2A_2}NN\binom{A_4A_6}{G_3G_1}$$

The intergenic sequences in the genome are short (1–7 nucleotides; **Fig. 1**). Occasionally, the transcription stop and start signal sequences are ignored and tandem readthrough transcripts of two or more genes are generated. At any intergenic sequence there is a finite chance that the RNA polymerase complex will leave the template. This gives rise to a transcription gradient in which the 3′ proximal gene (N) is most frequently transcribed and the 5′ proximal L gene very infrequently. The gradient has not been quantified in MuV-infected cells.

Cotranscriptional editing has been shown to be responsible for the generation of mRNAs encoding the P and NS2 proteins of MuV. Insertion of one or up to five extra G residues occurs at a site in the NS1 gene with a sequence similar to the polyadenylation signal. This leads to the formation of mRNAs that encode the NS2 or P protein or NS1, NS2 or P proteins with an extra glycine residue respectively. Recognition of transcription signals appears to be dependent on host as well as viral factors. Viral strains adapted to eggs give rise only to large tandem readthrough RNA transcripts when they are used to infect mammalian cells in culture, but monocistronic mRNAs are generated in chicken embryo fibroblasts.

The mRNAs of MuV are polyadenylated but the 5′ structure (presence and methylation state of cap) has not been determined. The mRNAs are translated by the cell's protein-synthesizing machinery and there is no indication of preferential translation of viral mRNAs or shut-off of translation of host mRNAs in MuV-infected cells. Indications in the literature of temporal translational control and control of transcription and translation of host mRNAs by the presence of viral glycoproteins in the cell membrane have not been confirmed.

The roles of various viral proteins and their post-translational modifications are indicated in **Table 1**. The processing pathway for the HN protein differs from that for the F protein. The HN protein forms oligomers during transport through the Golgi apparatus, and carbohydrate side chains are modified slowly in the *trans*-Golgi cisternae, whereas the fusion protein is maturing rapidly with respect to its glycosylation. The proteolytic cleavage of the F_0 precursor into the F_1 and F_2 activated complex has already occurred in the *trans*-Golgi cisternae.

Replication of the genome probably starts with the same promoter as is used for transcription, but all the intergenic sequence signals are ignored during this process. One long positive-stranded RNA molecule is formed which is encapsidated by the N protein immediately after the start of synthesis. The concentration of the N protein may regulate the balance between transcription and replication. The positive-strand in the RNP then forms the template for further negative-strand synthesis again with concomitant encapsidation by N protein. The presence of small leader transcripts from the positive-strand has not been reported.

There are a number of outstanding issues with respect to the replication of MuV which are not yet clear, some of which are specific to the virus. The roles of the 'V'-like NS1 and the NS2 nonstructural proteins in the processes of replication, transcription, translation and assembly have not been elucidated. Neither is it clear what role the SH protein plays. Studies on the assembly of the RNP and the localization of the P and L proteins as well as the

transport of the whole complex to the plasma membrane also remain to be carried out for MuV. Particularly, since the host cell cytoskeleton appears to play a role in the replication of other paramyxoviruses, it is important to investigate this aspect of MuV replication.

Budding probably takes place as a consequence of the interaction of the matrix protein with the RNP (most probably the C-terminal part of the N protein) and the cytoplasmic domains of the viral glycoproteins which accumulate in patches on the cell membrane. RNPs containing the genome or the antigenome strands have been found in mumps virions, but whether the budding process is selective in favoring inclusion of genomic, negative strand RNPs into virions is not yet clear. The budding process itself and its regulation have not been studied in great detail for MuV.

Both the F and the HN protein appear to play a role in fusion of virus-infected cells and syncytium formation. This is indicated by the observations that firstly, fusing (syncytium forming strains) as well as nonfusing strains contain cleaved activated F protein, secondly, levels of neuraminidase are higher in nonfusing strains and thirdly, proteolytic cleavage of the HN protein can activate fusion.

Geographic and Seasonal Distribution

The virus has a worldwide distribution and requires a minimum population for it to be able to circulate by continuous infection. The minimum population size is assumed to be similar to that for measles virus (approximately 250 000) but no systematic study has been undertaken to ascertain this for mumps virus. Before successful control of mumps by vaccination had been achieved, outbreaks of mumps were more often observed in the winter and spring than in the summer, at least in the temperate northern hemisphere, but this seasonal pattern was not observed in the tropics.

Evolution

From the fact that human populations have only become dense enough to sustain MuV about 4000 years ago, it has been suggested that the virus must have evolved from another animal pathogen. However, a closely related primate or other animal pathogen has not yet been identified.

Host Range and Viral Propagation

Humans are the only known host for the virus but dogs can be infected and show parotid swelling, though they do not pass on the virus. The virus can infect a variety of animals experimentally, including monkeys, cats, dogs, ferrets and a number of rodent species such as rabbits, suckling rats and mice, hamsters and guinea pigs. Its adaptation to growth in 8-day-old embryonated eggs allowed the biological activities of the virus to be studied before the advent of tissue culture. The virus infects a wide range of cells in culture and causes a distinct cytopathic effect in most cell cultures with either rounding of and

Table 1 Properties of the proteins of MuV

Protein	*Size in SDS-PAGE[a] (kDa)*	*Function*
Nucleocapsid (N)	68–73	Phosphorylated structural protein of nucleocapsid, protects genome from RNases, possible role in regulation of transcription and replication, S antigen
Phospho- (P)	45–47	Phosphorylated protein associated with the nucleocapsid; possible role in transport of N protein, role in RNA synthesis
Large (L)	>200	Protein with RNA polymerase activity associated with the nucleocapsid; possibly protein kinase, role in capping, methylation and polyadenylation?
Matrix (M)	39–42	Hydrophobic protein associated with inner side of membrane, role in budding by interactions with the N, HN and F proteins
Fusion (F)	65–74	Acylated, glycosylated protein F_2–F_1 heterodimer activated by proteolytic cleavage, hemolysis antigen. Fusion of membrane of virus with host cells may also involve HN
Hemagglutinin–neuraminidase (HN)	74–80	Acylated and glycosylated protein with hemagglutinin and neuraminidase activity; role in fusion and attachment, major V antigen
Small hydrophobic (SH)	6	Membrane protein, detected in infected cells but not in virions so far
Nonstructural NS1 (V)	23–28	Phosphorylated protein role unknown, Cys-rich (metal-binding?) domain
Nonstructural NS2	17–19	Phosphorylated protein role, unknown, artifact of misediting?

[a]Abbreviations: SDS-PAGE, sodium dodecyl sulfate–polyacrylamide gel electrophoresis; kDa, mass of the protein in kilodaltons.

detachment of the cells from the substratum or widespread syncytium formation. This cytopathic effect varies from strain to strain as fusing and nonfusing variants have been described. The virus also readily establishes persistent infection in tissue culture systems, a property shared with many of the other viruses in the family *Paramyxoviridae*. Only low titers of virus are produced in such infections.

Serologic Relationships and Variability

MuV is a monotypic virus. Tests with human sera indicate the presence of only a single serotype. The virus crossreacts serologically to a low extent with human parainfluenza virus type 2 and simian virus 5. At the more detailed level of single epitopes of MuV, variability between strains has been demonstrated using monoclonal antibodies, with the HN and N proteins displaying the greatest variability. Recent sequence comparisons have demonstrated the existence of more than six genotypes of MuV.

Genetics

Temperature-sensitive or any other conditional lethal mutants of MuV have not been reported. Recombination has not been described in any nonsegmented negative-strand RNA virus. Although host range mutants have not been isolated, the adaptation of the virus to growth in eggs or in chicken embryo cells requires a number of blind passages, and strains so adapted do not readily grow or form plaques in mammalian cells in culture. Neutralizing monoclonal antibody escape mutants of the HN protein are the only type of MuV mutants described.

Epidemiology

Outbreaks of mumps show annual periodicities but the length of the cycle may vary as a result of poorly understood factors from 2 to 7 years. Traditionally, the virus caused severe problems when troops were assembled for war and it was observed that male recruits from rural populations were affected more often. It is, therefore, assumed that children in isolated, rural and island populations are exposed to the virus later in life than those in densely populated urban conglomerates. The infection gives rise to lifelong immunity from disease, but it is not clear whether a single dose of vaccine achieves the same. The existence of a number of different genotypes has allowed the development of molecular epidemiology for mumps. Specific genotypes appear to dominate in Japan and China, respectively. In some European epidemics two genotypes have been found to cocirculate. Changes in nucleotide sequences of viral isolates during an epidemic have not been studied but differences between viral isolates from a given geographical area over a timespan of several years indicate that the virus gradually accumulates nonexpressed and to a lesser extent expressed mutations. However, strains isolated more than 40 years apart are still recognized easily as belonging to a specific genotype.

Transmission and Tissue Tropism

The virus grows in the upper respiratory tract and the salivary glands and is transmitted in salivary droplets. Patients are infectious from 3 days before until approximately 4 days after the onset of clinical symptoms. Mumps can also cause viruria but this is not considered important in transmission. Transmission occurs only in the acute phase, and longer term mumps infections are known not to produce infection in susceptible contacts. From the attack rate in virgin populations, it can be concluded that the virus is highly contagious ($R = 5$) but not as contagious as, for example, measles ($R = 16$–450) and chickenpox viruses. The infection is systemic and the virus can multiply in a wide variety of tissues in the human host. The tropism for the pancreas, particularly the β cells, has been implicated as a potential link between MuV and juvenile onset diabetes mellitus, but direct evidence for a link is missing (**Table 2**).

Clinical Features of the Infection

The incubation period of infection with MuV is 14–21 days, but occasionally has been estimated to extend much longer (>50 days). The most common clinical feature is parotitis. However, as much as one-third of infections are subclinical. Other complications such as orchitis in males are frequent (**Table 2**). Contrary to popular belief, orchitis has not been linked to an increase in male sterility. Mastitis occurs in females with the same frequency and the incidence of both these clinical features increases with the age at which MuV infection is first contracted. MuV was the most common cause of viral meningitis and encephalitis in the US before vaccination controlled the virus. The encephalitis is usually benign although minor neurological changes, learning and concentration impairments and sudden deafness are well documented sequelae in a number of patients. More rare complications are oophoritis, thyroiditis, pancreatitis, otitis, retinitis, conjunctivitis and keratitis (**Table 2**).

Pathology and Histopathology

Upon infection, the virus replicates primarily in the nasal mucosa and the epithelial layer of the upper

respiratory tract and penetrates the draining lymph nodes after which a transient viremia occurs. From this, various target organs such as the salivary glands, the kidney, pancreas and the CNS are infected. Infection in the salivary glands produces the most predominant clinical feature of the virus. Viral replication leads to tissue damage and the subsequent immune response leads to inflammation and swelling of the gland. Dissemination to the kidneys can lead to prolonged infection of this organ and viruria. Virus can be isolated from throat swabs, salivary fluid and urine. Involvement of the CNS may be as high as 50% of cases and parotitis is not required for this to take place. MuV can be readily isolated from the cerebrospinal fluid (CSF) in cases of meningoencephalitis.

Pathogenicity

Strains of different pathogenicity for animals have been described. Similar differences have not been described for human infection, but varying levels of meningitis have been shown to be associated with some MuV strains (see below). The ability of different strains to infect the CNS of suckling hamsters after intraperitoneal injection has been correlated with their ability to fuse cells in culture. Some strains do not spread to the CNS and the ability to infect neurons after CNS penetration also varies. MuV strains appear to establish persistent infections readily in the CNS of suckling hamsters and mice. Some neutralizing monoclonal antibody escape mutants show alterations in neuropathogenicity in a rodent model.

Immune Response

Whether the humoral or cellular immune response (CMI) is the most important in clearance of MuV from the infected host is unknown. Both play a role but neither seems required for successful control of

Table 2 Clinical features, complications and prognosis of mumps virus infection in various organs

Organ	*Clinical feature*	*Frequency*	*Pathology*	*Prognosis*
Salivary gland	Parotitis (bilateral or unilateral)	95% of symptomatic cases	Blockage of duct of Stensen	Swelling disappears usually in 3–4 days
Submaxillary and sublingual salivary glands	Parotitis (bilateral or unilateral)	Rare	—	Swelling subsides in 3–4 days
Testes	Orchitis (mostly unilateral)	25% of males	—	Good; no lasting effect on sperm production
Breast	Mastitis	15% of females	—	Good; cause of virus in breast milk
Ovaries	Oophoritis	Rare	—	Good
Meninges	Meningitis fever/ vomiting	Mononuclear pleocytosis in CSF in 40–60% of cases	Ependymal epithelium destroyed by virus	Benign and self-limiting: ataxia some permanent damage possible
Brain	Encephalitis	2% of cases <1% = fatal	Virus spreads by neuronal pathways	Poor
Kidney	—	—	—	Good/cause of viruria
Pancreas	Pancreatis with nausea and vomiting	50% of cases	Could be due to interferon responses rather than specific tissue infection	Good/no established link to IDDM
Middle ear	Deafness	Very rare <3%	Cochlear infection	Permanent deafness is very rare
Heart	Myocarditis	Very rare	Fibroelastosis	Altered ECG; can cause myocardial infarct
Blood	Immunosuppression	All cases	Infection in macrophages and lymphocytes	Viremia resolves
Fetus	Abortion in first trimester	Frequent	Virus is widespread in tissues of aborted fetus	In live births CMI response in the absence of humoral response

IDDM, insulin-dependent diabetes mellitus; ECG, electrocardiogram; CMI, cellular immune response.

the infection by the host. Eleven days after infection, the humoral immune response is well established and the presence of neutralizing viral antibodies probably terminates viremia. Similarly, the appearance of IgA in the salivary fluid terminates excretion of infectious MuV via saliva. The time of first appearance of cytotoxic T lymphocytes reactive with MuV is unclear, but these have been demonstrated in blood of patients with the natural disease as well as in vaccinees. The magnitude and effectiveness of this response may be related to the genetic (HLA) background of the host. A complication in the development of the CMI response is the tropism of the virus for T and B cells. Reduction in CMI responses to antigens previously recognized has been observed, but the mechanism is unclear. It is less severe and of shorter duration than the immunosuppression associated with measles. The virus grows well in activated but not in resting T lymphocytes and infection of the CNS during MuV infection is thought to occur via transfer of infected monocytes into the choroid plexus. Perinatal exposure of the fetus to MuV by the placenta of the infected mother does not appear to lead to infection of the fetal tissues, but can give rise to anomalous immune responses to MuV in the newborn child. In these, CMI but no humoral responses are detectable. One neutralizing B-cell epitope has been defined in the HN gene of MuV but no other B- or T-cell epitopes have been delineated, as yet.

Prevention and Control

Adaptation of the virus to growth in eggs and chicken embryo cells allowed an early development of life attenuated vaccines for mumps. In 1946, Enders observed that adaptation of MuV to chicken cells was associated with the loss of virulence for monkeys. Killed virus preparations have been used for human vaccination but these do not lead to life-long protective immunity. In general, the disappointing appearance of atypical cases of measles after vaccination with killed virus has led to a preference for live attenuated viruses for the control of paramyxoviruses. Mumps vaccination has substantially reduced the incidence of mumps worldwide. In the USA, the incidence of mumps after licensing of the vaccine in 1967 dropped from 76 per 100 000 to 2 per 100 000 population. There are now a number of live attenuated vaccine strains such as the Jeryl Lynn, Rubini and others available for MuV. These are usually administered in a trivalent vaccine, which contains live attenuated strains of measles and rubella virus as well as MuV (MMR). Recently, the Urabe strain has been removed from MMR vaccines since reports in several countries indicated a higher incidence of meningitis associated with the use of this strain of MuV. Most developed countries have now gone over to a two-dose schedule for MMR vaccination.

MuV and Inclusion Body Myositis

MuV has been implicated in the past in inclusion body myositis. However, recent research using *in situ* hybridization, polymerase chain reaction (PCR) and immunocytochemistry has been unable to link MuV to the paramyxovirus-like nucleocapsids observed in muscle cells of patients with this disease. In contrast, myocarditis in patients with fibroelastosis has been associated with the presence of mumps viral RNA demonstrated with reverse transcriptase-PCR. The link to arthritis is also unclear (**Table 2**).

Future Perspectives

The generation of a cDNA clone which represents the full length of the MuV genome and rescue of virus from such a clone will allow a further definition of structure and function relationships and the role that various proteins play in attenuation of the virus. The generation of vectors that express individual viral proteins will allow dissection of the humoral and cellular immune responses and, hopefully, a better description of the role that both have in virus clearance. It is paramount that the immune status of vaccinees and their susceptibility to reinfection and the occurrence of sequelae is monitored after the introduction of large-scale vaccination. Factors involved in the neurovirulence of the virus remain to be determined.

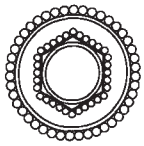
MURINE LEUKEMIA VIRUSES (*RETROVIRIDAE*)



Hung Fan, Department of Molecular Biology and Biochemistry, University of California, Irvine, California, USA

History

Murine leukemia viruses (MuLVs) were originally identified by breeding of high-leukemia-incidence mouse strains in the 1920s and 1930s by Furth. Attempts to passage a cell-free filterable leukemogenic agent were ultimately successful, leading to independent MuLV isolates by Gross, Friend, Moloney, Rauscher and others. Different MuLVs induce distinct leukemias: Gross and Moloney MuLVs induce T lymphoma, while Friend and Rauscher MuLVs induce erythroleukemia. C57 Black 6 mice were found to develop T lymphoma with high incidence after X-irradiation, and Kaplan isolated another MuLV associated with the leukemogenesis, RadLV. Beginning in the 1970s, MuLVs have been among the most intensively studied retroviruses. Much of basic retroviral replication was worked out for MuLVs, and they have also been important subjects for the study of retroviral leukemogenesis and carcinogenesis in general.

During the early tumorigenesis experiments, passage of MuLV or MuLV-induced tumor cells occasionally gave rise to variants with increased pathogenicity *in vivo*. In some cases, solid tumors instead of leukemias were induced. Further studies indicated that these variants were classical acute transforming retroviruses that carry transduced cellular oncogenes. These viruses and their corresponding oncogenes include Moloney murine sarcoma virus (M-MSV, the *mos* oncogene), Harvey MSV (H-*ras*), Kirsten MSV (K-*ras*), FBJ MSV (*fos*) and Abelson MuLV (*abl*). More recently isolated acute transforming murine retroviruses include AKT8 (*akt*) and myeloproliferative sarcoma virus (*mpl*). In addition, the original Friend MuLV stocks contained an acute transforming retrovirus, spleen focus-forming virus (SFFV). The oncogene of SFFV is a deleted form of recombinant envelope glycoprotein (see below). Since these acute transforming viruses are replication defective, they are generally propagated by co-infection with a 'helper virus', a replication-competent MuLV that supplies the viral proteins necessary for replication.

Classification, Structure and Replication

MuLVs are members of the family *Retroviridae*, genus *Gammaretrovirus*. The structure and genetic organization of MuLVs are typical of all simple retroviruses. The virions are enveloped particles of 120–150 nm, with a classical C-type morphology. The viral envelope surrounds a spherical capsid (core) that contains the RNA genome. Virions also contain three virus-encoded enzymes (reverse transcriptase (RT), integrase (IN) and protease (PR)), as well as cellular transfer RNA, one of which (usually $tRNA^{Pro}$) is a primer for viral DNA synthesis. The RNA genome is a dimer of two identical positive-stranded RNAs of *c.* 8.2 kb. As with all simple retroviruses, MuLV genomes contain three genes: 5′-*gag-pol-env*-3′. The *gag* gene encodes the capsid proteins: a matrix protein (MA or p15, *c.* 15 kDa), a capsid protein (CA or p30, *c.* 30 kDa), a nucleocapsid protein (NC or p10, *c.* 10 kDa) and a type-specific protein of 12 kDa (pp12) whose function is unknown. The order within the *gag* gene is 5′-MA-pp12-CA-NC-3′. The *pol* gene encodes the viral enzymes in the order 5′-PR-RT-IN-3′. The *env* gene encodes two envelope proteins (from 5′ to 3′): a glycosylated surface protein (SU or gp70, *c.* 70 kD) and a transmembrane protein (TM or p15E, *c.* 15 kD).

MuLVs also encode a nonstructural form of glycosylated *gag* polyprotein ($gPr80^{gag}$) that is exported to the cell surface and shed into the medium. The fact that glycosylated Gag is conserved among all MuLVs as well as the closely related feline leukemia virus suggests that it plays a role in virus replication. While glycosylated Gag mutant viruses replicate well *in vitro*, glycosylated Gag is required for efficient *in vivo* replication. For instance, if glycosylated Gag-negative MuLVs are infected into animals, there is a strong *in vivo* selection for back-reversion to the glycosylated Gag-positive genotype. The glycosylated Gag is also a major pathogenic determinant for a neurotropic MuLV (see below). A portion of glycosylated Gag protein (the C-terminal half) is shed from infected cells, and the remainder (the N-terminal half) is embedded in the plasma membrane of the infected cell.

MuLV replication is typical of all retroviruses, with the following steps:

- Binding of viral particles to cell surface receptors. This involves physical interaction of the envelope

SU (gp70) protein with a cellular protein (the receptor – see below).
- Fusion of the viral and cellular plasma membrane, resulting in internalization of the viral core into the cytoplasm.
- Activation of reverse transcriptase to synthesize double-stranded viral DNA using the viral RNA genome as template.
- Transport of the viral DNA (in the form of a complex with some of the viral core proteins – the preintegration complex) to the nucleus. In order for the preintegration complex to enter the nucleus, the infected cell must past through mitosis, during which the nuclear envelope breaks down.
- Integration of viral DNA at random chromosomal sites to yield the provirus form. This process is mediated by the viral integrase (IN) protein.
- Transcription of integrated proviral DNA by cellular RNA polymerase II to give genomic RNA.
- Transport of viral mRNA (unspliced and spliced) to the cytoplasm and translation to give viral proteins. The initial viral translation products are polyproteins that contain all of the protein domains for each of the genes.
- Packaging at the plasma membrane of genomic viral RNA with viral proteins to form virus particles that bud from the cell surface. Infection by MuLVs is not lytic, and results in stably infected producer cells.
- Maturation of the released virus particles by cleavage of the polyproteins by the viral protease (PR). This maturation is essential for infectivity; immature virions are not infectious.

As a result of reverse transcription, the resulting viral DNA is longer than its template RNA, containing long terminal repeats (LTRs) at either end. LTRs can be divided into three regions, U3-R-U5, according to their origins in the viral RNA. The U3 region contains promoter and enhancer sequences necessary for viral transcription, as well as the signals for RNA cleavage/polyadenylation. The organization of a viral LTR and its relationship to virion RNA is shown in **Fig. 1**.

The virus specifies all of the enzymes necessary for viral DNA synthesis (RT), integration (IN) and proteolytic maturation (PR). These processes can be carried out *in vitro* using purified MuLV particles or enzymes.

As with all retroviruses, translation of MuLV Gag and Pol proteins is from unspliced RNA. Initiation is at the N-terminus of the *gag* gene, giving rise to either a Gag polyprotein (processed to the Gag proteins) or a Gag-Pol polyprotein (processed to Pol proteins). The balance between *gag* and *pol* translation (20:1) is

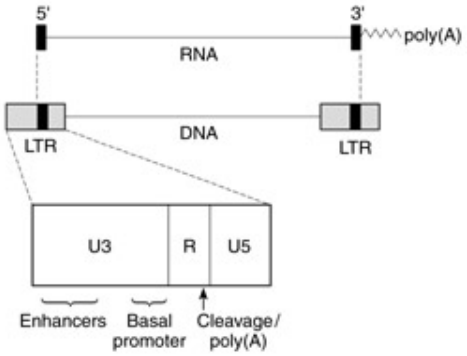


Figure 1 MuLV DNA organization. The relationship of reverse transcribed MuLV DNA to its template viral RNA is shown. The dark boxes on the RNA indicate direct repeats (R regions) at either end of the viral RNA. The LTRs on either end of the viral DNA are shown. The subdivision of the LTR into the U3, R and U5 regions is shown, as is the location of enhancer, basal promoter and cleavage/polyadenylation signals. When integrated proviral DNA is transcribed, initiation begins at the U3–R junction in the upstream (5′) LTR, and terminates at the R–U5 boundary in the downstream (3′) LTR.

controlled by suppression of an amber termination codon (by a cellular glutaminyl tRNA) between the *gag* and *pol* genes. This mechanism is different from most other retroviruses that generate Gag-Pol fusion proteins by translational frameshifting. Ribosomes also initiate on unspliced mRNA at a CUG codon slightly upstream from the AUG initiation site for the Gag and Gag-Pol polyprotein preprecursors; this yields the primary translation product that is processed independently to glycosylated Gag polyprotein. Env polyprotein is translated from a singly spliced mRNA.

Early classification of MuLVs was based on serology. Group-specific antigens were shared by all MuLVs, and were later found to be predominantly on Gag proteins (hence the name Gag, for group-specific antigens). Type-specific antigens subdivided the MuLVs into the Friend–Moloney–Rauscher (FMR) group and the Gross virus group. The main proteins carrying type specificity are the Env proteins, as well as ppl2^{gag} protein. Current classification of MuLVs is based on host range (see below).

Distribution of MuLVs and Endogenous Viruses

MuLVs are widely distributed in domestic and feral mice. While the original isolations were from laboratory mouse strains, related MuLVs have been isolated from wild mice. The wild mouse MuLVs have been important because they have shown new receptor specificities and pathologies (see below).

All mouse strains carry genetic information for MuLV-related viruses (endogenous viruses) in their chromosomes. Endogenous viruses represent rare germline infections, which result in mendelian transmission of the integrated proviruses to all progeny. Most endogenous MuLV proviruses are replication-defective, although some inbred mouse strains (e.g. AKR) carry and spontaneously activate replication-competent endogenous viruses. Treatment of cells from other strains by DNA-demethylating agents such as halogenated pyrimidines (e.g. bromodeoxyuridine (BrdU) or 5-AzaC) can activate endogenous viruses as well. There are approximately 50–80 endogenous MuLV proviruses in most mouse strains. In evolutionary terms, they were recently acquired – other subspecies of mice have significantly different patterns of endogenous viruses, although distantly related endogenous elements (usually defective) can be found in all mammals, including humans. Moreover, different inbred strains of laboratory mice have endogenous MuLV proviruses at different chromosomal loci. This extensive polymorphism can be exploited for mouse genetic mapping. In some cases, the integration of an endogenous MuLV virus into a cellular gene has caused a genetic mutation (e.g. the *dilute* and *hairless* mutations). The endogenous MuLVs represent germline infection by three different MuLVs, based on differences in their *env* regions (see below): xenotropic, polytropic and modified polytropic.

Host Range

The host range of an MuLV is controlled by two systems. The first system is the interaction of envelope glycoprotein (SU) with the cell surface receptor. On the basis of cell surface receptor specificities, five different classes of MuLVs have been identified so far: ecotropic, xenotropic, amphotropic, polytropic (or MCF recombinant) and 10AA1. These groups can be distinguished on the basis of interference assays: cells infected with one MuLV are resistant to superinfection by another MuLV of the same class, owing to blockage of the receptor by SU protein of the first virus. The species specificity of the MuLVs is also useful in separating the different classes. Ecotropic MuLVs (most exogenously infecting MuLVs) infect mouse-derived cells, but not cells from other species. The ecotropic MuLV receptor is a membrane transporter of basic (cationic) amino acids (mCAT-1). Xenotropic viruses (generally endogenous viruses) infect nonmouse cells but not mouse cells, while amphotropic viruses infect both mouse and nonmouse cells. The amphotropic MuLV receptor is a membrane transporter of inorganic phosphate (PIT-1). MCF recombinant viruses are *env* recombinants that arise during *in vivo* passage in mice of ecotropic viruses; they result from recombination with endogenous polytropic (or modified polytropic) MuLV proviruses. MCF MuLVs also infect both mouse and nonmouse cells (but by a different receptor from that of amphotropic MuLVs). 10A1 MuLV has dual specificity: it can infect cells via the amphotropic receptor (PIT-1), or by a related phosphate transporter (PIT-2).

The second MuLV host range system is Fv-1 restriction or N/B tropism. This is controlled by the mouse Fv-1 locus. Mice of the Fv-$1^{n/n}$ genotype (prototypic strain NIH) are susceptible to infection by N-tropic viruses (e.g. AKR MuLV) and relatively resistant to B-tropic MuLVs (e.g. RadLV). Similarly Fv-$1^{b/b}$ mice are resistant to infection by N-tropic viruses, and susceptible to B-tropic viruses. Fv-1 resistance is dominant, i.e. Fv-$1^{n/b}$ mice are resistant to infection by both N-tropic and B-tropic viruses. However, forced passage of viruses in restrictive cells can result in development of NB-tropic viruses that can infect cells of any Fv-1 genotype. Many exogenous MuLVs (e.g. Moloney, Rauscher, Friend) are NB-tropic. At the cellular level, Fv-1 restriction is after viral penetration, but before viral DNA integration, although the exact mechanism by which this occurs remains to be determined. N/B tropism and cell receptor specificity are independent host range systems. For instance, M-MuLV is an NB-tropic ecotropic virus, and 1504A MuLV is an N-tropic amphotropic virus. The Fv-1 gene has been molecularly cloned; it encodes a Gag protein of a distantly related retrovirus.

Leukemogenesis by MuLV

MuLVs induce leukemias in mice with latencies ranging from 2 to 18 months, depending on the strain of virus and strain of mouse. Neonatal infection is by far the most efficient means of leukemogenesis, whereas infection of adults is not leukemogenic for most viruses. Prior to development of leukemia, the predominant sites of infection are hematopoietic tissues (bone marrow, spleen, thymus), although the tissue specificity of the enhancers in the LTR can modulate this. In addition, infection in the intestines has also been reported for M-MuLV, although it is possible that this represents mucosal lymphoid cells. MuLVs can presumably infect a number of other cell types (at least as far as integration of proviral DNA), as they can act as helper viruses for acute transforming murine retroviruses that induce fibrosarcomas, osteosarcomas and carcinomas. Several characteristic events occur during MuLV leukemogenesis. The most

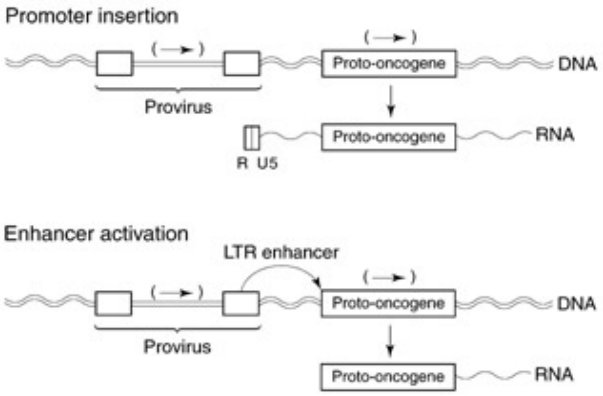

Figure 2 Proto-oncogene activation during retroviral leukemogenesis. The promoter insertion mechanism is illustrated at the top of the diagram. In this case, transcription initiates in the downstream LTR of an inserted provirus and proceeds into proto-oncogene-coding sequences. The result is overexpression of the proto-oncogene (as a hybrid transcript) under the control of the retroviral LTR. The enhancer activation mechanism is illustrated at the bottom of the diagram. In this case, the LTR enhancer activates transcription from the proto-oncogene via its own promoter.

well-understood event is LTR activation of proto-oncogenes (first elucidated by Hayward for avian leukosis virus; **Fig. 2**). Although retroviral DNA integration is generally random with respect to chromosomal location, when independent MuLV-induced tumors are examined, common sites of proviral insertion are detected. These sites reflect activation of a cellular proto-oncogene in the tumor by the viral LTR (either through its enhancer sequences or by 'promoter insertion'). This activation supplies an oncogenic stimulus to the cell, resulting in outgrowth of a monoclonal tumor. Many proto-oncogenes have been found to be activated by different MuLVs, as summarized in **Table 1**.

Oncogenesis is a multistep process, and LTR activation of proto-oncogenes probably supplies only one step in the process. Several experiments support this conclusion. First, sequential LTR activation of additional proto-oncogenes has been associated with *in vitro* tumor progression of M-MuLV-induced tumor lines. Second, even for acute murine retroviruses such as Abelson MuLV and Friend SFFV (which carry their own oncogenes), other events, such as LTR activation of cellular proto-oncogenes by the helper virus or by the transforming virus, or inactivation of a tumor suppressor gene (p53), also appear to be involved. Third, mice transgenic for the *pim*-1 proto-oncogene (activated in many M-MuLV-induced tumors) do not rapidly develop leukemia. However, infection of these mice with M-MuLV results in extremely rapid induction of T lymphomas, resulting from LTR activation of a second proto-oncogene (c-*myc* or n-*myc*). Also, crossbreeding of mice transgenic for *pim*-1 and for c-*myc* results in high tumor incidence in doubly transgenic progeny.

A feature of MuLV leukemogenesis is that the specificity of the disease is largely controlled by the specificity of the LTR enhancers. Chimeras between

[c]Insertion at *p53* inactivates its function.

Moloney MuLV (T lymphoma) and Friend MuLV (erythroleukemia) have been generated by molecular cloning; substitution of Friend enhancers into the M-MuLV LTR converts M-MuLV from T lymphomagenic to erythroleukemogenic, and vice versa. This can be explained by LTR activation of proto-oncogenes (**Fig. 2**): for LTR activation to occur, the enhancers must be active in that particular differentiated cell type.

The long latency of MuLV-induced disease is only partially due to the time needed for the low probability insertion of a provirus near a proto-oncogene in an incipient tumor cell. Other experiments have indicated virus-driven preleukemic events. Tumor transplantation in AKR spontaneous leukemia and Moloney MuLV-induced leukemia has identified 'potentially leukemic cells' (PLCs) that precede the development of leukemia. Moreover, the PLCs are first evident in the bone marrow and spleen, but not in the thymus, where the tumors eventually develop. Other virus-induced changes observed in AKR and M-MuLV-induced leukemia include thymic atrophy and mild splenomegaly. The preleukemic splenomegaly represents hematopoietic hyperplasia of multiple lineages that may result from a defect in bone marrow hematopoiesis.

Another characteristic event in MuLV leukemogenesis is the appearance *in vivo* of MCF recombinant viruses. As described above, these are *env* gene recombinants between the infecting (or endogenously activated) MuLV and endogenous MuLV proviruses, and they are characteristically found in leukemic animals. All MCF recombinants contain chimeric *env* genes. In addition, some also show changes in the LTR, which increase the strength of the promoters/enhancers. Several lines of evidence indicate that MCFs are important for leukemogenesis. First, injection of MCF recombinants can acelerate leukemogenesis in AKR mice. Second, mice carrying the $Rmcf^R$ genetic allele are resistant to MCF recombinant formation, and they are also relatively resistant to leukemogenesis by Friend MuLV. Third, an enhancer variant of M-MuLV (Mo+PyF101, containing heterologous polyoma virus enhancers inserted into the LTR) does not generate MCF recombinants *in vivo* under conditions where it is poorly leukemogenic. Finally, in spontaneous leukemia of AKR mice (caused by endogenous ecotropic Akv MuLV), the proviruses in tumor cells are generally MCF recombinants, and many tumors are not infected with the original Akv MuLV.

The predominant evidence is that MCF recombinants act late in leukemogenesis, i.e. that they are the 'proximal leukemogens'. For instance, as mentioned above, in T lymphomas of AKR mice, the proviruses responsible for activating proto-oncogenes are MCF recombinants. It has also been shown that MCF envelope glycoprotein can bind to hematopoietic growth factor receptors such as the erythropoietin receptor. Infection with MCF viruses can render cells independent from growth factors such as erythropoietin (epo) and perhaps interleukin 2 (T cell growth factor). Thus MCF glycoprotein may provide infected hematopoietic cells with an autocrine signal for growth, leading to abnormal proliferation. Epo receptor binding and induction of epo-independent growth of erythroid precursors is even more dramatic for the gp55 oncogene form encoded by Friend SSFV.

Despite the clear role for MCF recombinants in efficient leukemogenesis by MuLVs in mice, they are not absolutely required for disease. This is evident since: (1) mice genetically resistant to MCF formation ($Rmcf^R$) still develop F-MuLV-induced leukemia (although with a longer latency); (2) mice infected with Mo+PyF101 M-MuLV can develop leukemia; and (3) M-MuLV can induce T lymphoma in rats, which cannot form MCFs because they do not harbor endogenous polytropic MuLV proviruses.

Neuropathic MuLVs

Certain MuLV strains (e.g. the CasBrE MuLV of wild mice, the *ts*1 mutant of M-MuLV and certain strains of Friend MuLV) cause neurological symptoms. This is generally evident as hind limb paralysis, or occasionally hemiplegia. Spongiform lesions in the brain or spinal cord accompany the neuropathology, and they are reminiscent of the spongiform lesions associated with the dementia of the acquired immune deficiency syndrome (AIDS) in humans. Studies with genetic recombinants indicate that the nature of the envelope glycoprotein (SU) determines whether the virus is neuropathic. In addition, the severity of disease is influenced by the LTRs, presumably reflecting the relative infection efficiency of neural tissue. Also for one particularly neuropathic MuLV (a recombinant between Friend and CasBrE MuLVs), the glycosylated Gag protein is an important determinant in neuropathogenicity.

The mechanism by which neuropathic MuLVs cause disease is not understood. While efficient infection of the CNS is necessary for eventual development of neurological symptoms, it is not sufficient, as some areas of the brain or central nervous system show substantial infection but no degeneration. Most of the neuropathic MuLVs infect microglial cells in the brain, but it is less clear if they infect neuronal cells. Brain capillary endothelial cells may also be infected.

Immunodeficiency (MAIDS)

An MuLV stock originally isolated by Duplan induces immunodeficiency in infected mice. Mice infected with this stock show hyperproliferation of B lymphocytes and ultimately develop T cell anergy and immunodeficiency (both B and T lymphoid). This has been referred to as murine acquired immune deficiency syndrome (MAIDS), and it has been studied as a model for human AIDS. Further experiments led to isolation of a defective MuLV genome (MAIDS or LPBM5 virus) that makes a truncated Gag polyprotein that is responsible for induction of the immunodeficiency. It appears that MAIDS virus causes a B-lymphoproliferative disease that secondarily leads to immunodeficiency. It has also been proposed that MAIDS virus encodes a 'superantigen' that leads to polyclonal proliferation of B lymphocytes and ultimately to exhaustion of lymphoid precursors, although this model is currently less favored.

MuLV-based Retroviral Vectors

Retroviral vectors are currently of great interest for introduction of genes into eucaryotic cells, and many retroviral vectors are based on MuLV. The principles of generating a retroviral vector are shown in **Fig. 3**. The gene of interest is inserted into a deleted form of an MuLV genome by molecular cloning. The viral sequences in the vector include those *cis*-acting sequences necessary for reverse transcription, integration and transcription of vector RNA (the LTRs and adjacent sequences), as well as signals that are responsible for packaging of vector RNAs into retroviral particles. The target gene may be inserted in a vector such that it is transcribed from the LTR, or it may be inserted under control of an internal promoter. Frequently, a second gene that allows for selection of cells expressing the retroviral vector (e.g. bacterial neomycin phosphotransferase, selectable in mammalian cells by resistance to the antibiotic G418) is also included. The cloned retroviral vector is then transfected into 'packaging cells'. Packaging cells express all of the retroviral proteins (Gag, Pol and Env) but do not release virus particles carrying viral RNA themselves, owing to the lack of packaging signals on the mRNAs for the retroviral proteins. The transfected packaging cells will release viral particles containing RNA transcribed from the transfected vector DNA. These particles can infect cells, reverse transcribe and integrate the vector DNA, yielding cells stably harboring integrated vector DNA. Packaging lines based on amphotropic MuLV allow for

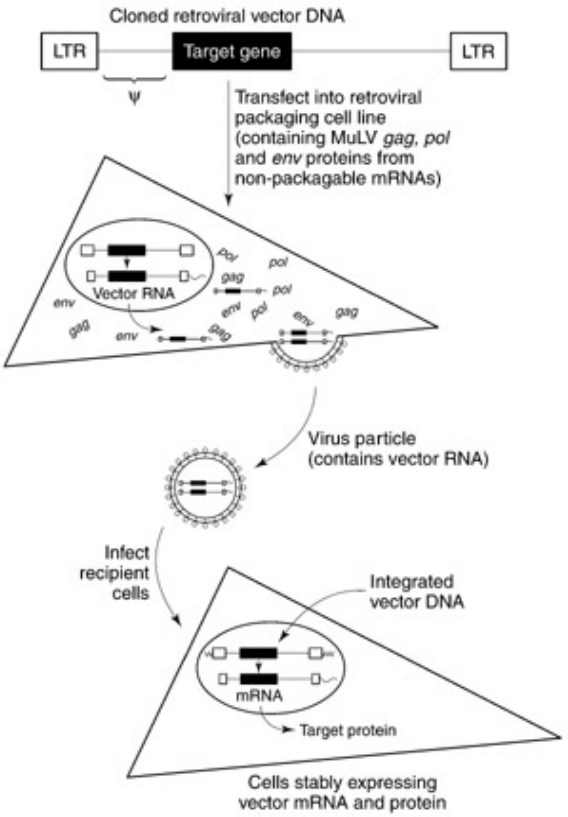

Figure 3 MuLV-based retroviral vectors. Organization of cloned retroviral vector DNA is shown at the top of the diagram. The target gene is inserted into a deleted version of an MuLV provirus; the critical viral sequences are the LTRs and the sequences required for packaging of RNA into retroviral particles (Psi). Upon transfection of the vector DNA into a retroviral packaging cell line, transcribed vector RNA will be packaged into virus particles and released. These virus particles are then infected into recipient cells, in which reverse transcription and integration of the vector DNA takes place. Transcription from the vector DNA into RNA followed by translation leads to stable expression of the target protein. Expression from retroviral vector DNA is highly efficient, much more so than from DNA introduced into cells by transfection.

generation of retroviral vectors that can infect a wide variety of cells, including human cells.

Retroviral vectors offer several advantages: infection is not lytic to cells, the transduced DNA is stably integrated into host cell chromosomal DNA, and expression from DNA integrated by retroviral infection is much more efficient than from transfected DNA. Retroviral vectors have been of particular interest for gene therapy experiments (e.g. correction of genetic defects such as severe combined immunodeficiency). Current technical problems include maintaining vector expression over prolonged periods of time in whole animals or people, infection of stem

cells and achieving expression in specific differentiated cell types.

Recent modifications to MuLV-based vectors include the use of vesicular stomatitis virus (VSV) envelope glycoprotein (G protein) to pseudotype the vector particles in place of MuLV Env protein. The advantage is that VSV-G pseudotyped particles can be concentrated to higher titers by ultracentrifugation under conditions where MuLV Env protein would be lost from the virions. Packaging systems have also been developed that allow efficient MuLV-based vector production after transient transfections. These have the advantage that vectors expressing genes that are toxic to stably transfected cells can be produced. Another area of vector development involves modification of the MuLV Env protein by addition of binding domains from other proteins. The goal of this appoach is to generate vectors that specifically bind to and infect certain cell types. Some success has been achieved by this approach (e.g. targeting vectors to cells that express the erythropoietin receptor), although the vector titers are still very low.

NECROVIRUSES (*TOMBUSVIRIDAE*)

Frank Meulewaeter, Plant Genetic Systems NV, Gent, Belgium

History and Classification

The *Necrovirus* genus belongs to the family *Tombusviridae* and contains all viruses that are closely related to tobacco necrosis virus (TNV). Tobacco necrosis was first described in 1935 by Smith and Bald as a viral disease of tobacco seedlings in greenhouses. On mechanical inoculation of a wide range of plants, the virus produced necrotic lesions in the inoculated leaves but did not cause systemic infection. In the 1960s and early 1970s, several new isolates of TNV were characterized. Based on the level of immunological crossreactivity between their coat proteins, the TNV isolates were divided into two major groups: the TNV-A and -D serotypes. Some of the TNV isolates are associated with small viruses. These satellite viruses are dependent for their propagation on the presence of TNV as a helper virus. In 1980, the sequence of the RNA genome of STNV-1 (a satellite virus of TNV-A) was the first full-length sequence of a plant viral RNA reported. It took another 10 years before the first sequence of a TNV isolate was published. At this moment several TNV isolates have been sequenced and it has become apparent that at least two groups of TNV isolates can be distinguished that are sufficiently different to be considered as separate species: TNV-A and TNV-D. In the mean time, two new viruses, olive latent virus 1 (OLV-1) and leek white stripe virus (LWSV), appeared sufficiently related to TNV to be included in the *Necrovirus* genus.

Symptoms, Distribution and Transmission

TNV is naturally present in the roots of a great variety of plants. Worldwide, around 20 different isolates have been described. Isolates are differentiated on the basis of host range and the symptoms that are induced on mechanically inoculated leaves. Typically, the size and color of the lesions on primary leaves of French bean are characteristic for specific isolates. These may vary from pinpoint lesions to lesions that spread along the veins and eventually kill the inoculated leaf. TNV does not induce systemic infection in most test plants, except for *Nicotiana benthamiana* in which several TNV isolates cause systemic mottling and stunting.

In general, TNV virulence is not associated with systemic disease symptoms and plant growth is not affected. Exceptions are the Augusta diseases of tulip, stipple streak of bean, and necrosis disease of cucumber and soybean. LWSV causes winter whitening of leek, which is characterized by a white striping of leaf blades and has spread epidemically in France since 1987. Latent systemic infections by TNV have been detected in woody crop plants, like apple and pear. Similarly, OLV-1 was isolated from symptomless olive trees.

Several strains of TNV have also been found in soils and in rivers and irrigation water. The virus particles present in the drainage water of infected plant roots are believed to be the virus source that establishes new plant infections. This is achieved through association with the zoospores of its natural vector, the chytrid soil fungus *Olpidium brassicae*. The virus particles attach on the outside of the zoospores in a strain specific reaction. Upon penetration of the fungus in a plant root, the TNV particles are concomitantly transmitted and the plant gets infected. The virus determinant for vector specificity probably lies within the coat protein. This specificity was exploited to achieve transient gene expression in plant roots. Purified TNV coat protein was used to encapsidate plasmid DNA containing a *cat* gene under control of a CaMV 35S promoter. Transfer of the nucleoprotein complex by *Olpidium brassicae* into wheat roots resulted in transient expression of the *cat* gene in the root cells. The epidemiology of LWSV suggests that its vector is also soil-borne.

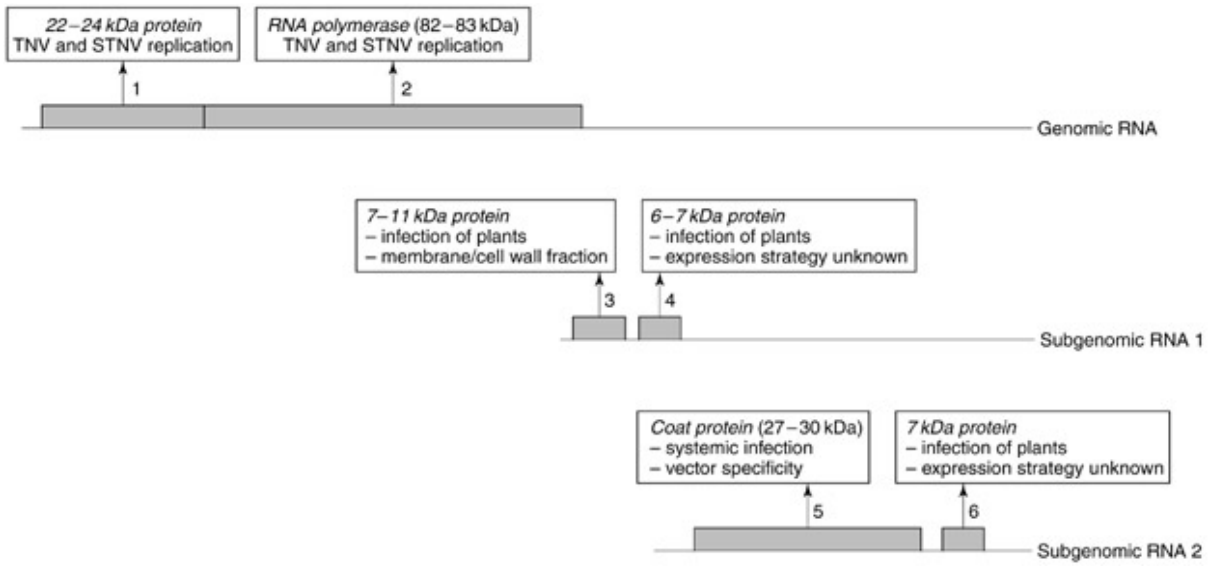

Figure 1 Genome organization and expression of the necroviruses. The locations of the major ORFs of TNV-A are shown on the RNAs from which they are presumably translated. The function of the encoded proteins as determined for TNV-A/D is given in the boxes. In TNV-D, the equivalent of ORF 6 overlaps with the 3′ end of ORF 2, whereas it is absent in the other necroviruses.

Properties of Virions

TNV and STNV form icosahedral viral particles with diameters of 28 and 17 nm, respectively, and triangulation numbers of 3 and 1, respectively. The three-dimensional structure of the STNV particle has been determined at 0.3 nm resolution. It consists of one genomic RNA molecule packaged by 60 STNV coat protein molecules. The TNV particles consist of one genomic RNA encapsidated in 180 copies of TNV coat protein and have also been crystallized. Both TNV and STNV are very stable viruses. The thermal inactivation point of most strains is about 90°C. Exceptions are a German TNV isolate that loses infectivity at 50–60°C, and TNV-B, which is very unstable on freezing and purification.

Genome Organization and Homologies

The necroviruses contain one single-stranded genomic RNA of a length between 3660 and 3760 nucleotides (nt). The genomic RNA is of positive polarity and has an organization that is similar to that of the carmoviruses. The TNV RNA has a 5′ terminal di- or triphosphate and lacks a 3′ terminal poly(A) tail or tRNA-like structure. The full-length RNA sequence has been determined for TNV-A, -D and -D^H and for LWSV and OLV-1. Infective cDNA clones are available for the three TNV isolates.

The necrovirus genome contains five or six major open reading frames (ORFs) (**Fig. 1**). No large ORFs are present on the complementary minus strand. The 5′ ORF encodes a protein of 22–24 kDa. It ends with a UAG stop codon. Suppression of this stop codon would result in the synthesis of an 82 kDa protein. This 82 kDa protein has amino acid sequence motifs characteristic for viral RNA polymerases and is thus the putative polymerase. Typically, this protein does not contain RNA helicase or capping motifs. The putative polymerase of OLV-1 shows high homology with that of TNV-A, whereas that of LWSV is more closely related to the TNV-D polymerase.

The second largest ORF is located near the 3′ end of the genome and encodes the viral coat protein. The size of the coat protein varies between 28 and 30 kDa. The necrovirus coat protein is very similar to the coat protein of southern bean mosaic virus. By analogy, it probably consists of an amino-terminal arm that interacts with the RNA and a C-terminal shell domain that forms the outer surface of the virus particle. The coat proteins of the TNV isolates are more closely related to each other than to that of the other necroviruses.

All necroviruses contain two small ORFs between the polymerase and the coat protein genes. These ORFs encode proteins of 6–11 kDa. The level of homology between these proteins shows a similar hierarchy as for the polymerase proteins. Both TNV-A and -D contain a sixth ORF that is not found in LWSV and OLV-1. This ORF encodes a 7 kDa protein. In TNV-D it overlaps with the 3′ end of the polymerase ORF, whereas in TNV-A it is located

downstream of the coat protein coding region. These two proteins show a low level of homology.

Gene Function

The coat protein gene was identified on the basis of the size and amino acid composition of the encoded protein, and by immunoprecipitation of its *in vitro* translation product with coat protein antiserum. TNV mutants that have internal deletions in the coat protein gene replicate efficiently in protoplasts. For TNV-D, the coat protein deletion mutant induced the same symptoms as wild-type virus in inoculated leaves. However, it did not cause a systemic infection in *N. benthamiana*. This indicates that the coat protein or intact virus particles are required for efficient long-distance movement. Cell-to-cell movement, however, does not require the coat protein.

Deletion of the central portion of the readthrough region of the 82 kDa protein ORF abolished TNV-D replication. This is compatible with the idea that the 82 kDa protein is the viral RNA polymerase. However, expression of the 82 kDa protein is probably not sufficient for RNA replication as a mutant that has the internal amber stop codon replaced by a tyrosine codon failed to replicate in protoplasts. This suggests that both the 22 kDa protein and the 82 kDa readthrough protein are required for RNA replication. Expression of the corresponding TNV-A proteins from a chimeric transgene was sufficient to support the replication of the satellite virus in tobacco. Moreover, mutation of the three small ORFs from TNV-D did not affect replication in protoplasts. This shows that the 22/23 kDa and 82 kDa proteins are the only TNV proteins that are required for TNV and STNV RNA replication.

The mutants in the three small TNV-D ORFs failed to show symptoms in plants. This suggests that these small proteins are involved in cell-to-cell movement in the plant. This is in agreement with the observation that in TNV-D infected plants one of these proteins could be detected in the combined cell wall and cell membrane fraction.

Genome Expression of TNV

In vivo protein labeling of TNV-infected leaves showed the induction of specific proteins, several of which correspond in size to TNV-encoded proteins. However, the coat protein and the TNV-D P7a are the only viral-encoded proteins that have directly been shown to accumulate in TNV-infected plants. By analogy with related viruses, it is most likely that the genomic RNA serves as mRNA for the 23 kDa protein and its readthrough protein. In a wheat germ translation system, however, the major translation products of the TNV-A genomic RNA are the 23 kDa protein and the coat protein. No 82 kDa protein synthesis by suppression of the amber stop codon could be observed. Expression of this protein in infected plant cells would thus require factors that are not present in the wheat germ system.

Coat protein synthesis from the genomic RNA in the wheat germ system is most likely the result of internal initiation of translation. However, studies in tobacco protoplasts did not reveal internal initiation by TNV sequences. *In vivo,* the coat protein is most likely synthesized from a subgenomic RNA. Necroviruses produce two subgenomic RNAs that are 3′-coterminal with the genomic RNA. For TNV-A, the shortest subgenomic RNA has a length of 1224 nt and is the mRNA for the coat protein. The longer subgenomic RNA of TNV-A is 1501 nt long and the first AUG codon is the start codon of the first small ORF. This subgenomic RNA is thus probably the mRNA for the 8 kDa protein. Moreover, *in vitro* translation experiments suggested that the subgenomic RNA might also direct the synthesis of the 6 kDa protein from the downstream ORF. The mechanism by which this could occur is, however, unclear. If and how the third small ORF of TNV is expressed is unclear as no subgenomic RNA is found that has this ORF at its 5′ end.

An important feature of the TNV genomic RNA is the absence of a 5′ cap and a 3′ poly(A) tail. Similarly, there are no indications that the subgenomic RNAs are capped. Both the cap and the poly(A) tail are crucial for the translation of most cellular mRNAs. However, synthesis of TNV coat protein from subgenomic RNA 2 is very efficient in infected tobacco protoplasts, with one coat protein molecule made per mRNA every 10–12 s. This efficient cap-independent translation requires sequences from both the subgenomic RNA leader and trailer. The trailer element contains an 18 nt sequence, which is absolutely conserved in related viruses and is required for cap-independent translation of barley yellow dwarf virus. This suggests that both viruses might share a similar mechanism for cap-independent translation.

Replication Strategy

Relatively little is known about the replication strategy of necroviruses. The only proteins that are absolutely required for TNV RNA replication are the 22/23 kDa and 82 kDa proteins. TNV can accumulate to very high levels in infected cells. In tobacco protoplasts the genomic RNA of TNV-A accumulates up to 10% of total RNA within 36 h after inoculation. TNV accumulation is reduced by the presence of

STNV. This reduction is proportional to the efficiency of STNV replication. This indicates that the STNV RNA competes with the TNV RNA for a limiting amount of replicase. The accumulation of the genomic RNA is linear in time up to 24 h after inoculation. In contrast, accumulation of the subgenomic RNAs slows down about 10 h after inoculation. Infected cells also accumulate three RNAs that are complementary to the genomic RNA. These RNAs correspond in size to the genomic and the two subgenomic RNAs and are also isolated from infected plants as part of three double-stranded RNAs. The full-length minus-strand RNA is probably the substrate for the synthesis of both the genomic and the subgenomic RNAs. This however requires experimental verification. The *cis*-acting sequences that are required for TNV replication have not been systematically mapped. Deletion mutants revealed that the 3′ sequences that are required for TNV replication are contained within the last 367 or 342 nt of TNV-D or TNV-A, respectively.

Satellite Viruses

TNV is commonly associated with viral icosahedral particles of about 17 nm diameter. These satellite virus particles consist of a single genomic RNA packaged by 60 coat protein subunits of 22 kDa. Three STNV serotypes have been described: STNV-1, STNV-2, and STNV-C. The earlier described STNV-4 is identical to STNV-2. The coat protein is the only protein encoded by the STNV RNA. This RNA has a length of 1220–1240 nt and lacks both a 5′ cap structure or Vpg and a 3′ poly(A) tail. The STNV RNAs are dependent for their replication on the presence of specific TNV isolates. For instance, STNV-1 and -2 RNA replication is supported by TNV-A, whereas the STNV-C RNA is replicated in the presence of TNV-D and not of TNV-A. Expression of both the 23 and 82 kDa protein of TNV-A is sufficient to support the replication of STNV-2 in tobacco protoplasts. In plants, however, STNV might depend on other TNV proteins for specific functions, like cell-to-cell transport.

The RNAs of STNV-1 and -2 show very similar organizations. The 5′ untranslated region is short (29 or 32 nucleotides). The extreme 5′ end can fold into a potential hairpin structure that is similar to the structure predicted for the 5′ end of the TNV-A RNA. The coat protein coding region is about 600 nt long and is followed by a 620 nt long trailer sequence. The trailer sequence shows a sequence similarity of 64% between STNV-1 and -2, which is higher than for the coat protein coding region (55%). The trailer can fold into phylogenetically conserved secondary structures. A first stem–loop structure is located just downstream of the coding region and is followed by three pseudoknots, one small hairpin, and a long stem–loop structure that includes the 3′ end of the RNA.

The coat protein coding region can be deleted without affecting replication in protoplasts. In contrast, both the leader and trailer sequences are important for replication of the STNV RNA. The 3′-terminal hairpin of STNV-2 is required for replication in protoplasts whereas the three pseudoknots and hairpin II have a quantitative effect on RNA accumulation. The only STNV 5′sequence that is required for an efficient replication is the 5′ terminal stem–loop structure. As a similar stem–loop structure is found at the 5′ end of the TNV-A RNA this might be one of the elements that specify the replication of both RNAs by the same viral RNA polymerase. At the 3′ end, there is no obvious primary or secondary structure similarity between the STNV-2 and the TNV-A RNAs that might explain their recognition by the TNV-A replicase.

STNV has been a model system for studying cap-independent translation in plants for more than 25 years. Translation of the STNV RNA is not increased by adding a cap to the 5′ end of the RNA and requires low levels of initiation factors for optimal translation. Deletion analysis of both the STNV-1 and -2 RNAs revealed a translational enhancer domain (TED) in the first 120 nt of the trailer, including hairpin I and part of the first pseudoknot. TED enhances translation of the STNV RNA in a wheat germ translation system more than an order of magnitude. Deletion of TED renders STNV translation cap-dependent. When fused to a heterologous mRNA, TED stimulates cap-independent translation both in a wheat germ translation system and in tobacco protoplasts. This stimulation is largely independent of the position of TED within the mRNA but is strictly dependent on the primary sequence of TED. Furthermore, the 5′ 38 nucleotides of the STNV-2 RNA cooperate with TED to further increase cap-independent translation both *in vivo* and *in vitro*. Two features of the STNV leader and TED could explain the dependence of TED for full activity on STNV 5′ sequences. First, the STNV leader contains two conserved regions of complementarity with TED that would allow base pairing between the leader and TED. Secondly, both the leader and TED show complementarity with the 3′ end of the 18S ribosomal RNA. Mutational analysis of STNV sequences complementary between leader, TED, and the 18S ribosomal RNA showed the importance of the primary sequence for the cooperative interaction but did not reveal a role for the complementarity.

The structures of the STNV-C leader and trailer are substantially different from those of STNV-1 and -2. The leader is 101 nt long and contains two AUG codons, the second of which is in frame with the coat protein initiation codon. This raises the question of how translation of the coat protein ORF is initiated. The STNV-C trailer is predicted to form a complex secondary structure, consisting of four pseudoknots and eight hairpins, that is clearly different from that of the STNV-1 and -2 trailers. As for STNV-2, the 3′-terminal structures of STNV-C are required for replication of the RNA.

Future Perspectives

Although the necroviruses are of limited economic importance, they have been studied for a long time as model systems for satellite virus replication and cap-independent translation. These will also be some of the most interesting aspects of the necrovirus research in the future. The availability of full-length infective cDNA clones of TNV-A and -D, as well as of all known STNV strains now provides the opportunity to investigate at the molecular level what elements of both the helper and satellite viruses determine the specificity of satellite activation. Furthermore, translation studies of both the STNV and TNV RNAs might help to unravel the mechanism of cap-independent translation in plants. Finally, the replication strategy of the necroviruses and the function of the various TNV-encoded proteins in the viral life cycle will require more detailed research.

NEPOVIRUSES (*COMOVIRIDAE*)

MA Mayo and **AT Jones**, Scottish Crop Research Institute, Dundee, UK

History

The name 'NEPO virus' was proposed in 1963 by Cadman for a group of NEmatode transmitted viruses with POlyhedral particles. The convenience of the grouping and the euphony of the name led to its rapid acceptance, and nepoviruses were one of the first 16 groups of plant viruses to be recognized as taxa and assigned names by the International Committee on Taxonomy of Viruses (ICTV). Originally the group comprised ArMV, CLRV, RpRSV, SLRSV (now considered a tentative nepovirus), TRSV and TBRV (see **Table 1** for acronyms) but now it has grown to contain 29 definitive viruses (see later). However, not all current members are transmitted by nematodes and some are transmitted in association with pollen.

Taxonomy and Classification

The Sixth Report of ICTV lists 29 definitive members and eight tentative members of the genus *Nepovirus* (**Table 1**) in the family *Comoviridae*. The principal characters used at present to assign a virus to this genus are: isometric particles about 28 nm in diameter; a single coat protein of approximate molecular weight 53 000–60 000; and a bipartite genome with RNA-1 of about 8 kb and RNA-2 between 4 and 7 kb.

The genus can be subdivided in various ways. The simplest is by the size of RNA-2 so that, for example, subgroup I would comprise viruses with RNA-2 of <5 kb (i.e. a difference of >3 kb between RNA-1 and RNA-2) and subgroup II would comprise the remainder. More elaborate schemes have been proposed and both serological properties and geographical distribution have been used as discriminatory characters (**Table 1**). The genus is classified in the family *Comoviridae*, along with the genera *Comovirus* and *Fabavirus*. The largest genome RNA molecules of viruses in this family are similar in size and, at least for nepoviruses and comoviruses, the genomes are organized similarly, in that each RNA encodes a polyprotein which is cleaved by proteases to yield the

The structures of the STNV-C leader and trailer are substantially different from those of STNV-1 and -2. The leader is 101 nt long and contains two AUG codons, the second of which is in frame with the coat protein initiation codon. This raises the question of how translation of the coat protein ORF is initiated. The STNV-C trailer is predicted to form a complex secondary structure, consisting of four pseudoknots and eight hairpins, that is clearly different from that of the STNV-1 and -2 trailers. As for STNV-2, the 3′-terminal structures of STNV-C are required for replication of the RNA.

Future Perspectives

Although the necroviruses are of limited economic importance, they have been studied for a long time as model systems for satellite virus replication and cap-independent translation. These will also be some of the most interesting aspects of the necrovirus research in the future. The availability of full-length infective cDNA clones of TNV-A and -D, as well as of all known STNV strains now provides the opportunity to investigate at the molecular level what elements of both the helper and satellite viruses determine the specificity of satellite activation. Furthermore, translation studies of both the STNV and TNV RNAs might help to unravel the mechanism of cap-independent translation in plants. Finally, the replication strategy of the necroviruses and the function of the various TNV-encoded proteins in the viral life cycle will require more detailed research.

NEPOVIRUSES (*COMOVIRIDAE*)

MA Mayo and **AT Jones**, Scottish Crop Research Institute, Dundee, UK

History

The name 'NEPO virus' was proposed in 1963 by Cadman for a group of NEmatode transmitted viruses with POlyhedral particles. The convenience of the grouping and the euphony of the name led to its rapid acceptance, and nepoviruses were one of the first 16 groups of plant viruses to be recognized as taxa and assigned names by the International Committee on Taxonomy of Viruses (ICTV). Originally the group comprised ArMV, CLRV, RpRSV, SLRSV (now considered a tentative nepovirus), TRSV and TBRV (see **Table 1** for acronyms) but now it has grown to contain 29 definitive viruses (see later). However, not all current members are transmitted by nematodes and some are transmitted in association with pollen.

Taxonomy and Classification

The Sixth Report of ICTV lists 29 definitive members and eight tentative members of the genus *Nepovirus* (**Table 1**) in the family *Comoviridae*. The principal characters used at present to assign a virus to this genus are: isometric particles about 28 nm in diameter; a single coat protein of approximate molecular weight 53 000–60 000; and a bipartite genome with RNA-1 of about 8 kb and RNA-2 between 4 and 7 kb.

The genus can be subdivided in various ways. The simplest is by the size of RNA-2 so that, for example, subgroup I would comprise viruses with RNA-2 of <5 kb (i.e. a difference of >3 kb between RNA-1 and RNA-2) and subgroup II would comprise the remainder. More elaborate schemes have been proposed and both serological properties and geographical distribution have been used as discriminatory characters (**Table 1**). The genus is classified in the family *Comoviridae*, along with the genera *Comovirus* and *Fabavirus*. The largest genome RNA molecules of viruses in this family are similar in size and, at least for nepoviruses and comoviruses, the genomes are organized similarly, in that each RNA encodes a polyprotein which is cleaved by proteases to yield the

mature virus proteins. Comoviruses and fabaviruses differ from definitive nepoviruses in having two particle proteins of approximate molecular weights 43 000 and 25 000, but so do some tentative nepoviruses (**Table 1**). Recently comparisons among nucleotide sequences have prompted the suggestion that the tentative nepovirus SDV should be classified in a genus distinct from any of the three current genera. The distinction between the current genera is mainly in the type of vector; comoviruses are transmitted by beetles, fabaviruses by aphids, and several nepoviruses by nematodes. However, nematode transmissibility is not a requirement for membership of the genus because it has been demonstrated for only one-third of the viruses listed in **Table 1** that they are transmitted by nematodes.

Virion Properties

Particles of definitive nepoviruses are 26–30 nm in diameter and appear to have hexagonal outlines in the electron microscope. Some particles are penetrated by negative stain. Typically, particles of nepoviruses are of three types, named according to their relative rates of sedimentation. Top component (T) particles sediment at about 50S and contain no RNA, middle component (M) particles sediment at 86–128S and contain 27–40% RNA and bottom component (B) particles sediment at about 115–134S and contain 42–46% RNA. With some nepoviruses, T particles are less stable than the nucleoprotein M and B particles and do not survive some purification procedures. Freezing can cause a loss of nucleic acid from nucleoprotein particles of some nepoviruses and this can result in the appearance of T particles.

Nepovirus particles contain two sizes of RNA molecule (**Table 1**). M particles contain the smaller species (RNA-2) of 3.8–7 kb, B particles contain either a single 8 kb molecule (RNA-1) or, with nepoviruses that have RNA-2 molecules of <4 kb, two molecules of RNA-2. Because of their different RNA contents, T, M and B particles can be resolved by sedimentation to equilibrium in CsCl.

The coat proteins of definitive nepoviruses consist of molecules with molecular weights of 53 000–60 000 (**Table 1**). Calculation suggests that nepovirus particles have 60 of these protein molecules, presumably arranged in a $T = 1$ structure. Some tentative members of the genus have two or three types of protein molecule in their coat protein which have a combined monomer molecular weight of 60 000–70 000 (**Table 1**).

Genome Properties

Organization

Nepovirus RNA molecules are 3′-polyadenylated and are linked at their 5′ ends to a small protein (VPg). The sequences for the VPg of GFLV, ToRSV, GCMV and TBRV comprise 24–28 amino acids with a putative consensus sequence of:

$$E/D\text{-}x_{(1-2)}\text{-}Y\text{-}x_{(2)}\text{-}R\text{-}N\text{-}x_{(4-5)}\text{-}R.$$

Protease treatment, which degrades the VPg, either abolishes (e.g. TRSV, TBRV) or diminishes (e.g. RpRSV) the infectivity of nepovirus RNA. Translation of nepovirus RNA *in vitro* yields large polypeptides which correspond in size to the approximate coding capacity of each RNA species. Smaller polypeptides arise by proteolysis of each polyprotein but this process is very inefficient *in vitro*. Nucleotide sequences are known for the RNA of several nepoviruses and each contains one large open reading frame. The 3′ noncoding regions of the RNA-1 and RNA-2 of each nepovirus are virtually identical but only about ten of the 5′-most nucleotides of the 5′ noncoding regions are the same in the two RNA species. The polyprotein encoded by RNA-2 contains the coat protein at the C-terminal end and one or two other proteins, one of which may have a transport function. The polyprotein encoded by RNA-1 contains putative polymerase, protease and helicase domains. **Figure 1** shows the proposed genetic map of the polyproteins of TBRV, GFLV, GCMV, ToRSV (RNA-1 and RNA-2) and RpRSV and SLRSV (RNA-2 only). Cleavage at particular dipeptide sites is characteristic of polyprotein genomes cleaved by

Table 2 Dipeptides cleaved during proteolytic processing of nepovirus polyproteins

N-S	BLMV

virus-coded proteases. The cleavage sites so far identified in nepovirus polyproteins are shown in **Table 2.**

Genetics

The two genome RNA species of nepoviruses are analogues of linkage groups. By inoculating plants with heterologous pairs of RNA from related strains and characterizing the resulting pseudo-recombinant isolates, functions have been assigned to each RNA. For RpRSV, RNA-1 determines systemic symptoms in *Chenopodium quinoa,* infection of Lloyd George raspberry, systemic invasion of *Phaseolus vulgaris* and the type of symptom induced in *C. quinoa*; RNA-2 determines the serotype of the particles, transmission by nematodes and chloroplast symptoms in *Petunia hybrida.* TBRV RNA-1 can replicate in inoculated protoplasts in the absence of RNA-2 and therefore presumably encodes the enzymes necessary for RNA replication and for the protease activity needed to release these enzymes from the polyprotein precursor. Progeny RNA molecules from such an experiment are infective and, because VPg is essential for TBRV RNA to be infective, it was inferred that RNA-1 also encodes the VPg. Sequencing located the VPg in the RNA-1 polyprotein (**Fig. 1**). With RpRSV and CLRV, there is evidence that at least one phenotypic character is controlled by more than one determinant (epistasis) and that some determinants have more than one phenotypic effect (pleiotropy).

Sequence Comparisons

Comparisons among the amino acid sequences of corresponding proteins of those nepoviruses for which sequence is known show few marked similarities. Most information is available for coat proteins. Among six coat proteins compared, the percentage identity was greater than about 24% only between viruses known to be serologically related (GFLV and ArMV; TBRV and GCMV). For other proteins in comparisons among TBRV, GCMV, GFLV and ToRSV, only the putative polymerase (81% for TBRV/GCMV; 45–53% among other pairs) and NTP-binding proteins (67% for TBRV/GCMV; 30–40% among other pairs) showed any significant similarities. A consensus cysteine protease motif is discernible in multiple sequence alignments of the putative protease sequences, and a consensus sequence has been proposed for nepovirus VPg (see above). But the percentage identity among either proteases or VPgs is not much different from that between unrelated proteins.

Satellites

Several nepoviruses have strains that support the multiplication of satellite RNA molecules. Some satellites (e.g. those of TBRV, SLRSV, GFLV, ChYMV and ArMV) are mRNA larger than 0.7 kb and encode proteins with molecular weights of 40 000–50 000. Others (e.g. those of TRSV, CYMV and ArMV) are about 0.3 kb and do not encode protein. These smaller satellites undergo self-cleavage during replication.

Geographic Range

Most nepoviruses are distributed throughout Europe or North America but a few appear much more restricted geographically. By contrast, GFLV occurs worldwide due to its widespread dissemination in planting stock.

Host Range and Virus Propagation

Most nepoviruses have wide natural and experimental host ranges that include woody and herbaceous plants. A notable exception is GFLV which is confined to grapevine in nature. Diseases of several important crop plants are induced by nepovirus infection and the viruses are prevalent in perennial species. Hosts include both monocotyledonous and dicotyledonous angiosperm plants and also some gymnosperms. The commonest experimental hosts used for the propagation of nepoviruses are *C. quinoa, Cucumis sativus, Nicotiana clevelandii, Pe. hybrida* and *Ph. vulgaris.*

Particles of many nepoviruses are stable and relatively easy to purify by clarification with butan-1-ol, alone or mixed with chloroform, followed by differential centrifugation and/or precipitation from solutions of polyethylene glycol. Particles of other nepoviruses are much less stable and may reach only

low concentrations in herbaceous hosts. Yields are usually 0.5–5 mg from 100 g of infected leaf.

Transmission

Some nepoviruses are transmitted by nematodes (**Table 1**) which are soil-inhabiting dorylaimid species in the genera *Longidorus* and *Xiphinema*. The nematodes acquire virus by feeding for a few hours on roots of infected plants. They can remain viruliferous thereafter for up to 9 weeks (*Longidorus* spp.) or 11 months (*Xiphinema* spp.) but the virus is lost when the nematodes molt. There is no evidence that nepoviruses multiply in their vectors. Nepovirus particles have been detected in the stylet lumen and attached to the guiding sheath of *Longidorus* spp. (RpRSV, TBRV) or the cuticular lining of the esophagus of *Xiphinema* spp. (ArMV, GFLV, TRSV, SLRSV). Experimentally, nepoviruses are readily transmissible by mechanical inoculation, although woody species can be difficult to infect and can yield poor inocula unless additives such as nicotine solution are used. A characteristic of most nepoviruses is that a high proportion (often >50%) of the seeds from an infected plant will germinate to give an infected plant (**Table 1**). Infection in seeds can come from either gamete although pollen from infected plants may not compete effectively with healthy pollen for fertilization of the ovule. Pollen transmission leading to infection of the mother plant appears to be a feature of the natural spread of CLRV and probably of BLMV.

Pathogenicity: Effects on Host Plants

Grapevine fanleaf is the most widespread and economically significant nepovirus worldwide due to the widespread dissemination of infected plants and of its nematode vector in planting stocks. Yield losses can be 50%. Many nepoviruses induce ringspots in certain hosts; chlorotic or necrotic rings on inoculated leaves and concentric rings or line patterns on the first leaves to be infected systemically. Leaves that are infected later may show no symptoms although they contain the virus ('recovery' phase). However, in many species, both naturally and experimentally inoculated, infection is symptomless; the rarity with which infected wild plants show symptoms indicates a close adaptation to these hosts, and suggests that nepoviruses are primarily pathogens of wild plants. All known nepoviruses infect *Chenopodium* species and many nepoviruses induce necrotic or chlorotic local lesions, making them useful assay plants.

Epidemiology

For nematode-transmitted nepoviruses, diseased plants occur in patches and spread from such infection foci is slow, reflecting the restricted mobility of the vector. Plants germinated from infected seeds are important sources from which nonviruliferous nematodes can acquire virus. Nepoviruses can be disseminated in seeds from infected plants over long distances to provide sources of inoculum into previously nepovirus-free areas for acquisition and transmission to crop plants by the relatively immobile vectors. Seed transmission is also important for the long-term survival of nepoviruses in the soil. An exception is GFLV which, in nature, does not infect common weed species but survives in long-lived pieces of grapevine root.

Many crop hosts of nepoviruses (such as grapevines and fruit trees) are vegetatively propagated, and so the propagation and movement of virus-infected plant stocks has been an important method of long-distance dispersal of these viruses (e.g. GFLV).

Cytopathology

Cells infected with some nepoviruses often contain cytoplasmic inclusion bodies which are readily detectable, some even by light microscopy. They contain membranous vesicles, endoplasmic reticulum and ribosomes, and are formed at a relatively early stage of infection; the bodies resemble those found in cells infected with cowpea mosaic comovirus. Another major cytological effect is the formation of tubules which contain virus particles in linear arrays. Such tubules are sometimes found in plasmodesmata between cells. Electron microscope observations suggest that nepovirus replication occurs in the cytoplasm, probably in or near the inclusion bodies.

Prevention and Control

Nepovirus infection is controlled by (1) establishing healthy stocks of plant material and distributing material certified to be virus-free, (2) planting resistant cultivars when available, (3) fumigating infested soil with nematicidal chemicals and (4) good weed control to remove possible sources of virus for re-infection.

NERVOUS SYSTEM VIRUSES

Richard T Johnson, The Johns Hopkins University School of Medicine, Baltimore, Maryland, USA

Introduction

Most viral infections of the nervous system represent serious and potentially life-threatening complications of systemic viral infections. With the possible exception of rabies, viruses are not neurotropic in the literal sense of having a specific affinity for the nervous system. Some viruses frequently invade the nervous system yet seldom cause serious disease; for example, mumps virus may cause meningitis but even during uncomplicated mumps parotitis cerebrospinal fluid changes in over 50% of patients indicate probable nervous system infection. Other viruses, such as herpes simplex virus, rarely infect the central nervous system; but when they do, they often cause fatal disease. Thus both mumps and herpes simplex viruses are regarded as neurotropic; mumps is highly neuroinvasive but has limited neurovirulence; herpes simplex has low neuroinvasiveness but is highly neurovirulent. Such variations are dependent on the structural and functional determinates of nervous system invasion, on the particular neural cells which specific viruses infect, on the effect of this infection on the host cells, and on the immune response or immunopathologic responses to the infection. Several terms need definition:

- *Neurotropic:* able to infect neural cells;
- *Neuronotropic:* able to infect neurons in contrast to other nervous system cells;
- *Neuroinvasive:* able to enter the nervous system;
- *Neurovirulent:* able to cause neurologic disease.

Anatomic Considerations

Both structural and functional features of the central nervous system present a unique milieu for viral replication. The blood–brain barrier and the compact structure of the brain and cord pose formidable barriers to the entry or dissemination of viruses within the nervous system. Furthermore, neurons are unique cells with high metabolic rates, intense membrane specialization, and no regenerative capacity. The same barriers that exclude viruses also limit access of immunocompetent cells and antibodies, and the nervous system lacks an intrinsic lymphatic system and has a paucity of phagocytic cells. Thus, the barriers that inhibit virus invasion also deter viral clearance. Therefore, many persistent infections involve the central nervous system.

The blood–brain barrier was originally conceptualized from the observation that dyes, such as trypan blue, stain all tissues except the brain and spinal cord after injection into the systemic circulation. The barrier at the cerebral capillary level consists of tight junctions between the capillary endothelial cells (beyond which most dyes do not pass), a dense basement membrane around the cells and tightly opposed astrocytic footplates. In the choroid plexus, the blood–cerebrospinal fluid barrier is structurally different. The capillaries of the plexus are fenestrated,

NERVOUS SYSTEM VIRUSES

Richard T Johnson, The Johns Hopkins University School of Medicine, Baltimore, Maryland, USA

Introduction

Most viral infections of the nervous system represent serious and potentially life-threatening complications of systemic viral infections. With the possible exception of rabies, viruses are not neurotropic in the literal sense of having a specific affinity for the nervous system. Some viruses frequently invade the nervous system yet seldom cause serious disease; for example, mumps virus may cause meningitis but even during uncomplicated mumps parotitis cerebrospinal fluid changes in over 50% of patients indicate probable nervous system infection. Other viruses, such as herpes simplex virus, rarely infect the central nervous system; but when they do, they often cause fatal disease. Thus both mumps and herpes simplex viruses are regarded as neurotropic; mumps is highly neuroinvasive but has limited neurovirulence; herpes simplex has low neuroinvasiveness but is highly neurovirulent. Such variations are dependent on the structural and functional determinates of nervous system invasion, on the particular neural cells which specific viruses infect, on the effect of this infection on the host cells, and on the immune response or immunopathologic responses to the infection. Several terms need definition:

- *Neurotropic:* able to infect neural cells;
- *Neuronotropic:* able to infect neurons in contrast to other nervous system cells;
- *Neuroinvasive:* able to enter the nervous system;
- *Neurovirulent:* able to cause neurologic disease.

Anatomic Considerations

Both structural and functional features of the central nervous system present a unique milieu for viral replication. The blood–brain barrier and the compact structure of the brain and cord pose formidable barriers to the entry or dissemination of viruses within the nervous system. Furthermore, neurons are unique cells with high metabolic rates, intense membrane specialization, and no regenerative capacity. The same barriers that exclude viruses also limit access of immunocompetent cells and antibodies, and the nervous system lacks an intrinsic lymphatic system and has a paucity of phagocytic cells. Thus, the barriers that inhibit virus invasion also deter viral clearance. Therefore, many persistent infections involve the central nervous system.

The blood–brain barrier was originally conceptualized from the observation that dyes, such as trypan blue, stain all tissues except the brain and spinal cord after injection into the systemic circulation. The barrier at the cerebral capillary level consists of tight junctions between the capillary endothelial cells (beyond which most dyes do not pass), a dense basement membrane around the cells and tightly opposed astrocytic footplates. In the choroid plexus, the blood–cerebrospinal fluid barrier is structurally different. The capillaries of the plexus are fenestrated,

lack a basement membrane and are surrounded by a loose stroma. Dyes and particles readily pass into the choroid plexus but are prevented from entering the cerebrospinal fluid by tight junctions located at the apices of the secretory epithelial cells of the choroid plexus. Tight junctions between the arachnoid cell over the surface of the brain complete the barrier.

There is no comparable barrier between the brain and the spinal fluid. The ependymal cells are not joined by tight junctions and, therefore, there is a free exchange between the extracellular space of the brain and the cerebrospinal fluid. The bulk flow is centrifugal, however, and solutions in the cerebrospinal fluid have limited entry into central nervous system tissue in normal circumstances. Furthermore, the intracellular gap between neural cells measures only 10–15 nm, less than the diameter of even the smallest virus, so that free movement of virus particles or inflammatory cells within the extracellular space is relatively restricted.

Neurons have specialized membranes for the transmission and receipt of specific messages; they also have axonal extensions to carry signals to and from distant neuronal populations, motor endplates, and sensory endings. In humans these cytoplasmic extensions may exceed a meter in length. These features are important in viral infections, since different subpopulations of neurons have different receptors usurped by viruses to permit entry into cells. Furthermore, viruses in some cases can be carried by axoplasmic transport systems either into the nervous system or within the nervous system where axonal processes link functionally related neurons. The high metabolic rates and lack of regenerative capacity may be important in chronic noncytopathic infections. A generalized infection that deranged cellular metabolism or caused shortened cell survival might present as a neurological disease and might have pathological findings restricted to the nervous system. Lack of neuronal replacement also assures that latent infection of neurons confers lifelong persistence in the host.

Antibodies found in the normal central nervous system are derived entirely from the serum. Antibody levels of immunoglobulin G (IgG) are approximately 0.4% of the serum levels. Since diffusion of macromolecules across the barrier is largely size dependent, immunoglobulin M (IgM) is present in even lower levels. Complement is largely excluded. When inflammation disrupts the blood–brain barrier, antibody molecules leak into the nervous system along with other serum proteins. When a mononuclear inflammatory response is mounted against infection, T lymphocytes usually enter the nervous system first followed by macrophages and B lymphocytes. These B cells from the peripheral circulation move into the perivascular space and can generate immunoglobulins intrathecally.

Pathways of the Central Nervous System Invasion

Viruses have been shown to enter the nervous system both along nerves and from the blood. The first experimental studies of viral invasion employed rabies, herpes simplex or polioviruses, all of which under experimental circumstances can penetrate the nervous system along peripheral nerves. The precise mechanism of neural spread remained a mystery for many years, since it was thought that the axoplasm slowly oozed in an anterograde direction. It was proposed that virus might move in perivascular lymphatics, by ascending infection of the supportive cells within the peripheral nerve, or even by replication in axons; a speculation that is now untenable because of the observed lack of ribosomes or protein synthesis within axons. In the 1960s active anterograde and retrograde axon transport systems were found. Viruses or other particles can be taken up in vesicles at the nerve terminals and transported to the cell body of the sensory or motor neuron (**Fig. 1**). This neural route of entry is important in primary viral infections such as rabies and possibly poliomyelitis. Retrograde transport also moves herpes simplex and varicella-zoster viruses from mucous membranes or skin into sensory ganglia at the time of primary infection. Subsequently, anterograde transport carries the reactivated virus from the ganglia to the periphery during exacerbations. Anterograde transport of herpes simplex virus by nerves innervating the dura from the trigeminal ganglia may explain the unique temporal lobe localization of herpes simplex virus encephalitis.

The olfactory spread of virus is a variation of neural spread. In the olfactory mucosa neural fibers provide a unique pathway; the apical processes of receptor cells extend beyond the free surface of the epithelium as olfactory rods and the central processes synapse in the olfactory blub. These are the only nerve cells with processes that link the central nervous system and the ambient environment. Indeed, some colloidal particles placed on the olfactory mucosa can be found in the olfactory bulbs within 1 h. Experimental studies show that viruses can enter through this route, and this may occur in some aerosol infections in humans such as laboratory accidents or rabies virus infections in bat-infested caves. Also the olfactory pathway has been postulated as a possible route of herpes simplex virus entry into the nervous system as an alternate explanation for the orbital-

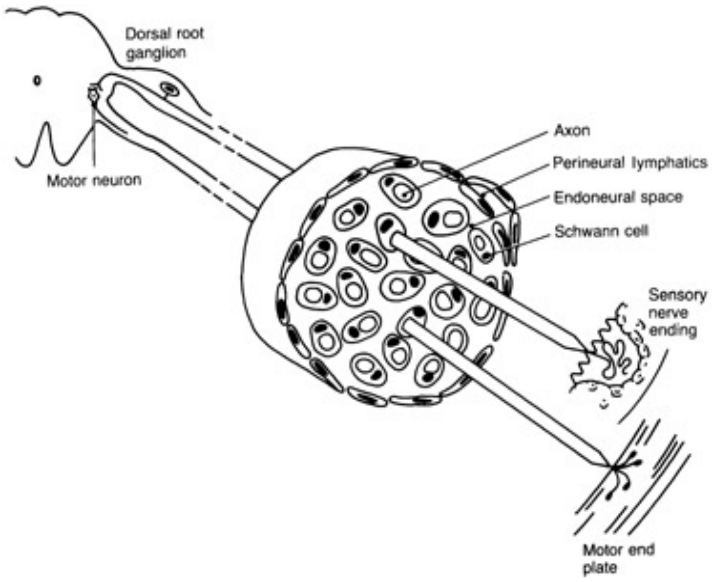

Figure 1 Schematic diagram of possible routes of neural spread of viruses to the nervous system. (Reproduced with permission from Johnson RT (1982) *Viral Infections of the Nervous System,* New York, Raven Press.)

frontal and medial temporal lobe localization of herpetic encephalitis. Nevertheless, despite the apparent ease of spread along this route, it appears to be a rare route of natural infection.

In most experimental and natural infections, viruses invade the brain from the blood. Historically, the blood–brain barrier was believed to be impervious to viruses. This belief was based in part on the fact that viruses experimentally inoculated directly into brain cause disease after a brief inoculation period, whereas the incubation period after intravenous inoculation is longer and comparable to that following cutaneous or peritoneal inoculation. The reason for this delay in infection is that virus in the blood is rapidly removed by the reticuloendothelial system; therefore, intravenous inoculation is, in fact, an inoculation primarily of the Kupffer cells of the liver and other reticuloendothelial cells. Therefore, virus must establish a nidus of peripheral replication that can effectively seed a viremia of sufficient magnitude and duration to allow invasion across the blood–brain barrier (**Fig. 2**). Thus, some viruses grow in lymphatics and seed into the blood directly via the thoracic duct, others grow in vascular epithelial cells, and others replicate in highly vascular tissue such as muscle.

A persistent viremia can be achieved by several mechanisms. Rate of clearance is dependent upon particle size; small particles such as togaviruses and flaviviruses can maintain high titer plasma viremias with sufficient rapid replication in peripheral tissue. Other viruses adsorb to red blood cells and thus evade clearance. Many large viruses such as measles and herpesviruses infect white blood cells thus evading clearance and replicating at the same time.

Some viruses enter the nervous system across the capillary endothelium and others across the choroid plexus. Some viruses infect the capillary endothelial cells and simply grow into the brain while others are able to transit across endothelial cells despite their paucity of endopinocytotic vesicles. Entry in infected leukocytes is a theoretical possibility but leukocyte traffic into the nervous system is limited, although trauma or inflammation due to other causes may predispose the nervous system to infection with viruses that infect white blood cells. Although there are areas of increased blood–brain barrier permeability, no viral infection has been shown to selectively infect these areas. Other viruses, such as mumps virus, grow in choroid plexus epithelium and seed into cerebrospinal fluid. Thus, the clearance of particles by the reticuloendothelial system, barriers of non-susceptible extraneural cells, production of interferon and other nonspecific inhibitors, and the physical barriers of the nervous system itself probably explain why viral infections of the brain are rare, even though systemic infections with the potential pathogens are very common.

Infection of Neural Cells

Once a virus has penetrated into the nervous system it must contact a susceptible cell and spread through the compact neuropil which is a theoretical problem. The fact that some viruses can be neutralized by extra-

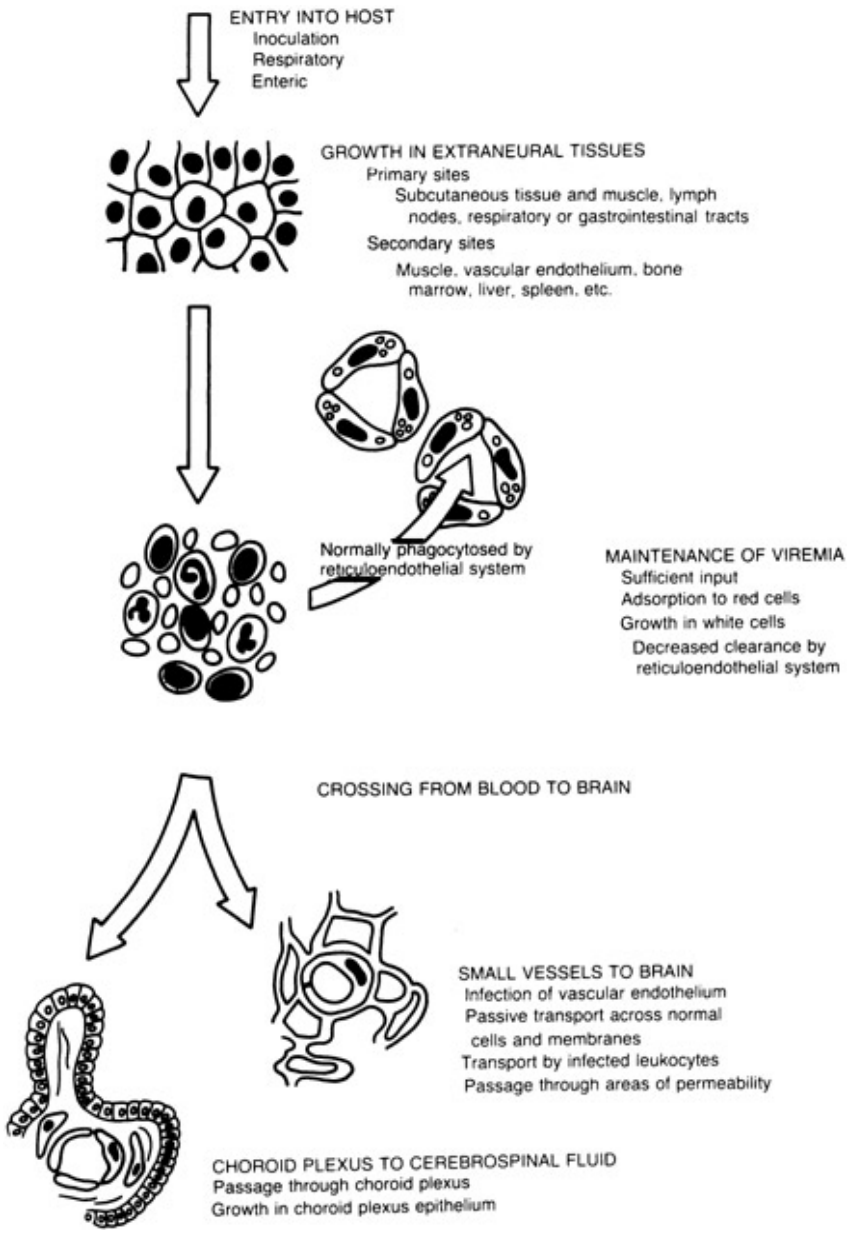

Figure 2 Schematic diagram of steps in the hematogenous spread of viruses to the nervous system. (Reproduced with permission from Johnson RT (1982) *Viral Infections of the Nervous System,* New York; Raven Press.)

cellular antibody even after central nervous system invasion shows that viruses such as togavirus and flaviviruses do spread in extracellular space, but this is not true of larger viruses. Conversely, the compact neuropil may facilitate the contiguous cell-to-cell spread of viruses. For example, in subacute sclerosing panencephalitis, a chronic brain infection of humans with measles virus, extracellular, enveloped virus is never seen, and there are enormous titers of extracellular antibody. Apparently the fusion protein allows measles virus to move from cell to cell through the brain.

Cell-to-cell spread may also involve axoplasmic transport causing infection of functionally linked cells; for example, in poliovirus infections the virus is rapidly spread through the motor system. Some viruses infect only neuronal populations such as rabies, polioviruses, and the arthropod-borne viruses, and some only infect selective neuron populations. Other viruses, such as herpes simplex virus, appear to infect neurons and glial populations with little selectivity.

Infection limited to vascular endothelial cells is found with rickettsial infections but is not recognized

in any viral infection of the nervous system. Infection limited to choroid plexus and meningeal cells appears to occur with those viruses that cause benign meningitis. In experimental studies with a number of viruses, widespread lytic infection of ependymal cells can lead to closure or stenosis of the aqueduct of Sylvius and resultant hydrocephalus. Similar aqueductal stenosis and hydrocephalus has been described in children after mumps virus meningitis.

The selective infection of oligodendrocytes has been recognized in nature in the disease progressive multifocal leukoencephalopathy caused in humans by the JC virus and in monkeys by SV-40 virus. In the course of immunosuppression, now seen most frequently with acquired immunodeficiency syndrome (AIDS), a selective lytic infection of oligodendrocytes causes multifocal areas of demyelination in the brain.

With changes in age, the specificity of infection and vulnerability of neural cells may change. For example, bluetongue virus infection of fetal sheep destroys the precursors of neurons and glia of the subependymal plate which leads to hydranencephaly or porencephaly depending on the age of fetal development, whereas the virus fails to infect the mature postmigratory cells in the late gestational or postnatal animal. Similarly, the external granular cells of the cerebellum in fetal or newborn animals are selectively infected by parvoviruses, and destruction of these mitotic cells leads to the granuloprival cerebellar degeneration seen in both natural and experimental animal infections.

Mechanisms of Cell Damage

Viral infection can have diverse effects on the host cell.

- Virus products may disrupt the integrity of the plasma membrane of the cell causing cell lysis.
- Infection with many viruses activates programmed cell death or apoptosis. This process of cell elimination is important in embryonic development, normal cell turnover, immunocyte clone deletion and other homeostatic processes but is particularly important in the nervous system, where massive cell elimination takes place during sculpting of the brain and cord and tight inhibition of apoptosis of mature neurons is required since they have no replicative capacity. This activation of death suppressor genes has explained the age-dependent effects of some neurotropic viruses.
- Virus genes or gene products may accelerate or inhibit host cell growth rate or can transform the cell so that it lacks contact inhibition.
- Infection can alter the antigenic composition of the cytoplasmic membrane making the cell the target of cytotoxic T cells and autoimmune cell lysis. This is the process that causes acute meningoencephalitis and death in mature mice infected with lymphocytic choriomeningitis virus.

Noncytopathic infections of neural cells also occur and lead to persistent infection with no disease or disorders without obvious histological changes. For example, neuroblastoma cells in culture infected with noncytopathic viruses such as rabies can show normal morphology, growth rates and protein synthesis, but reduced synthesis of specific neurotransmitters or receptors. These have been termed 'luxury functions', although *in vivo* the ability of neurons to synthesize transmitters or receptors would hardly be considered a luxury. Analogous noncytopathic infection has been demonstrated in mice congenitally infected with lymphocytic choriomeningitis virus. Congenitally infected mice are usually 'runts', but studies have shown selective infection of cells of the anterior pituitary that normally generate growth hormone. The animals are actually pituitary dwarfs responsive to growth hormone therapy.

Indirect cell damage can occur in viral infections that lead to sensitization of the host to neural antigens. This has been demonstrated in rats infected with coronaviruses, where the infection of neural cells leads to a cell-mediated autoimmune response to myelin proteins and to subsequent demyelination that can continue in the absence of ongoing infection. In postmeasles encephalomyelitis of humans, autoimmune demyelination appears to occur in the absence of infection of neural cells. Infection of lymphoid tissue leads to disruption of normal immune regulation, and about 1 per 1000 persons develop a symptomatic autoimmune reaction to myelin basic protein.

Other indirect mechanisms of neural cell damage have been postulated to explain the diverse neurological diseases seen in the course of human immunodeficiency virus (HIV) infection. The virus does not appear to cause infection of neurons, although neuronal processes and function are altered. The primary cells that are infected are macrophages and the microglia of the brain derived from macrophage populations. Possibly viral proteins produced by these cells or cytokines released by these cells interfere with neuronal function or are toxic to neurons or glial cells. For example, tumor necrosis factor, a lymphokine often elevated in brains of neurological-affected AIDS patients, has been shown *in vitro* to induce demyelination.

Clinical Features

Acute infections

The varied clinical features of viral infections of the nervous system can be explained in large part by the factors discussed above. Thus, a virus may infect only meningeal or ependymal cells, and cause a clinical syndrome known as viral meningitis or acute aseptic meningitis. This clinical syndrome is characterized by fever, headache and nuchal rigidity secondary to meningeal irritation but without clinical signs suggesting parenchymal disease. The commonest causes of acute viral meningitis are enteroviruses and mumps virus.

Encephalitis is a clinical syndrome in which, in addition to fever, headache and stiff neck, there is paralysis, seizures or other evidence of parenchymal disease of the brain. The commonest causes of severe encephalitis in man are herpes simplex virus and the arthropod-borne viruses. The former infects neurons and glia and causes diffuse necrotizing encephalitis in the newborn, but focal encephalitis in the immune child or adult presumably because diffuse virus spread is contained by immune responses. Focal signs, hallucinations, behavioral abnormalities and aphasia are more common with herpes encephalitis because of the localization to temporal lobes. Arboviruses have a propensity to infect neurons, and some flaviviruses tend to infect basal ganglia and brainstem neurons causing movement disorders and sudden respiratory failure. If signs of spinal cord involvement accompany encephalitis the term encephalomyelitis often is used. However, the term encephalomyelitis is also used to distinguish an acute postinfectious demyelinating disease of assumed autoimmune origin from acute viral encephalitis. Postinfectious encephalomyelitis (or acute disseminated encephalomyelitis) usually occurs 3–14 days after exanthems (measles, varicella or rubella) or respiratory infections (mumps, influenza and others) and clinically is characterized by the abrupt onset of fever, obtundation, seizures and multifocal neurological signs.

The clinical syndromes of rabies and poliomyelitis are the most distinctive of viral infections because of the selective infection of specific populations of neurons. Polioviruses selectively infect motor neurons which leads to flaccid paralysis. Rabies virus infects limbic system neurons with a relative sparing of cortical neurons early in disease leading to behavioral abnormalities. Rabies virus infections represent a diabolical adaptation of virus to animal host, causing the animal to remain alert but to lose timidity and develop aggressive behavior to transmit the virus. The advantage of this selectivity is evident considering that strains of rabies that cause the so-called 'dumb' or passive rabies are seldom transmitted in nature.

Slow infections

Slow infections are characterized by long incubation periods of months to years followed by an afebrile progressive disease. The term was originally coined in veterinary medicine to describe several transmissible diseases in sheep. The prototype slow infections are scrapie, a chronic noninflammatory spongiform encephalopathy due to a transmissible agent in which no nucleic acid has been identified (a prion), and visna, a chronic inflammatory encephalomyelitis caused by a lentivirus.

The first slow infections identified in humans was kuru, a progressive ataxia of a tribal group in New Guinea where the agent, resembling the agent of scrapie, was transmitted by ritual cannibalism. Creutzfeldt–Jakob disease, a subacute dementia with myoclonus, is a worldwide disease due to prion agents. In both of these human spongiform encephalopathies the clinical disease progresses irrevocably to death in about six months, but without fever or other clinical or histological findings to suggest infection.

In 10–15% of cases of Creutzfeldt–Jakob disease transmission is genetic resulting from insertions or point mutations in the gene coding for the prion protein. Some of these mutations result in phenotypes resembling sporadic Creutzfeldt–Jakob disease except that onset may be at an earlier age and progression to death may be more prolonged; in other mutations the phenotype is distinctive as in Gertmann–Straussler disease with prominent cerebellar ataxia or familial fatal insomnia where sleep disturbances dominate the early phase of disease. In rare cases, transmission has been iatrogenic with corneal and dural grafts, with neurosurgical procedures and with the injection of pituitary hormones extracted from human cadavers. Recent evidence suggests some cases are transmitted from beef contaminated with bovine spongiform encephalopathy. In the vast majority of cases no abnormality of the prion gene is found, and no common exposure is detected; in 85% of cases the mode of transmission is unknown.

Dementia, a chronic deterioration of cognitive function, is also caused by several conventional viruses. Subacute sclerosing panencephalitis is a chronic dementing illness caused by measles virus. One per million otherwise healthy children develop this chronic illness at an average of seven or eight years after uncomplicated measles. Dementia evolves slowly, associated with myoclonic movements and high levels of measles antibody in serum and cerebrospinal fluid. Children usually die a year or

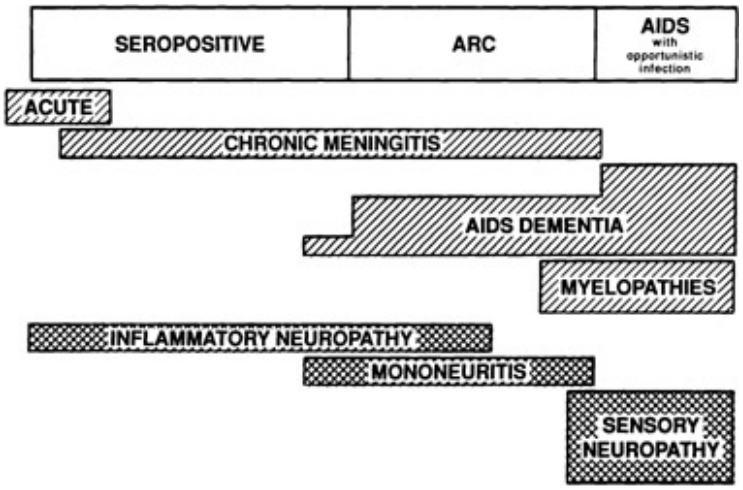

Figure 3 Schematic diagram of human immunodeficiency virus-related neurological diseases. Disease affects central (diagonal lines) and peripheral (cross-hatched lines) nervous systems, evolve at different stages of infection (asymptomatic seropositive, AIDS-related complex [ARC] and full-blown AIDS) and occur at different frequencies (indicated by vertical width). (Reproduced with permission from Johnson RT, McArthur JC and Narayan O (1988) *FASEB J* 2: 2970.)

less after the onset of clinical signs, but survival may vary from six weeks to six years. The disease is due to a subacute, slowly progressive diffuse infection of neurons and glial cells.

Progressive multifocal leukoencephalopathy due to JC virus also evolves as a slow viral infection with a selective infection of oligodendrocytes and a progressive demyelinating disease. Multifocal neurological signs evolve including cognitive dysfunction, paralysis, blindness and disorders of speech. Fever is absent and the cerebrospinal fluid shows no evidence of inflammation. Disease progresses relentlessly to death over a period of months.

Clinical symptoms associated with HIV are very diverse (**Fig. 3**). This virus now represents the commonest viral infection of the nervous system. From prospective studies of cerebrospinal fluid changes, it appears that the majority of people infected with the virus have early invasion of the nervous system; that is, the virus is highly neuroinvasive. However, early during this infection, neurological disease is rare. A presumed autoimmune disorder occasionally causes a demyelinating peripheral neuropathy (Guillain–Barré syndrome); acute meningitis is occasionally seen at the time of seroconversion or during early asymptomatic infection. An asymptomatic pleocytosis is often found. At this stage therefore, the virus is not highly neurovirulent. However, after the onset of immunodeficiency the infection is neurovirulent; 50% of AIDS patients develop progressive dementia with cerebral involvement, myelopathies or painful sensory neuropathies. The pathogenesis of these complications is unknown, but they are thought to be due to some viral protein or lymphokine incited by the virus because of the relative paucity of the virus in the nervous system and its localization to the microglial and macrophage populations.

Tropical spastic paraparesis complicating human T cell leukemia virus, type 1, infections is a recently recognized slow nervous system infection. Less than 2% of the patients infected with this virus develop either acute T cell leukemia or neurological disease. Since many of those infected are infected by breast milk and the onset of tropical spastic paraparesis is usually in the fourth or fifth decade of life, the incubation period is extraordinarily long. A subacute disease develops with progressive paralysis of the lower extremities associated with impotence, incontinence and sensory symptoms, but usually minimal sensory findings. Disease progresses slowly until the patients are wheelchair bound, but the disorder remains primarily at the level of the thoracic spinal cord. The involvement of the upper extremities is minimal with hyperreflexia but usually good function, and there is usually little, if any, indication of cerebral involvement. Early pathology in the spinal cord has shown vasculitis. In late stages hyalinization of vessels with necrosis and demyelination of spinal cord are found, and findings are most prominent in the thoracic cord. Whether virus replicates in any cells other than T lymphocytes is still uncertain. These observations lead to the questions of why less than 1 in 100 who are infected develop disease; why the incubation period is as long as 40 years; why the disease localizes to the thoracic spinal cord; and why over years the disease becomes relatively quiescent despite the fact that there are ongoing high levels of

intrathecal antibody synthesis suggesting that there is still antigenic stimulation by virus within the nervous system.

Identification of viruses or virus-like agents (prions) in a variety of chronic neurological diseases has led to speculation of a viral etiology for multiple sclerosis, Parkinson's disease, amyotrophic lateral sclerosis, Alzheimer's disease, schizophrenia and other illnesses. Experimental evidence for viruses in these chronic diseases is still tenuous.

NEWCASTLE DISEASE VIRUS (*PARAMYXOVIRIDAE*)

Peter T Emmerson, Department of Biochemistry and Genetics, Medical School, University of Newcastle upon Tyne, Newcastle upon Tyne, UK

History

Newcastle disease was the name given by Doyle to a highly contagious viral infection of poultry, also known as fowl pest, which was first reported on a farm near Newcastle upon Tyne, UK, in 1926. Shortly after the reported disease at Newcastle, two further outbreaks occurred in the UK, one in Somerset and the other in Staffordshire. At about the same time, a disease with similar symptoms was observed in Java (in the city now known as Jakarta), Indonesia, and shortly thereafter in other regions of southeast Asia, notably around seaports of the Indian Ocean. Subsequent crossimmunity tests showed that the viruses isolated in southeast Asia and Newcastle upon Tyne were indistinguishable. The causative agent of the disease in Newcastle upon Tyne was identified as a virus which was distinct from fowl plague (avian influenza virus), although the symptoms bore some resemblance. It is thought likely that the virus was transported to the port of Newcastle upon Tyne by ship from southeast Asia. Whatever its origin, the new disease emerged or was first recognized in 1926 and rapidly spread throughout the world.

Newcastle disease was first recognized in various countries as a highly pathogenic disease with up to 100% mortality. In California, a relatively mild respiratory disease was first observed in the mid-

intrathecal antibody synthesis suggesting that there is still antigenic stimulation by virus within the nervous system.

Identification of viruses or virus-like agents (prions) in a variety of chronic neurological diseases has led to speculation of a viral etiology for multiple sclerosis, Parkinson's disease, amyotrophic lateral sclerosis, Alzheimer's disease, schizophrenia and other illnesses. Experimental evidence for viruses in these chronic diseases is still tenuous.

NEWCASTLE DISEASE VIRUS (*PARAMYXOVIRIDAE*)

Peter T Emmerson, Department of Biochemistry and Genetics, Medical School, University of Newcastle upon Tyne, Newcastle upon Tyne, UK

History

Newcastle disease was the name given by Doyle to a highly contagious viral infection of poultry, also known as fowl pest, which was first reported on a farm near Newcastle upon Tyne, UK, in 1926. Shortly after the reported disease at Newcastle, two further outbreaks occurred in the UK, one in Somerset and the other in Staffordshire. At about the same time, a disease with similar symptoms was observed in Java (in the city now known as Jakarta), Indonesia, and shortly thereafter in other regions of southeast Asia, notably around seaports of the Indian Ocean. Subsequent crossimmunity tests showed that the viruses isolated in southeast Asia and Newcastle upon Tyne were indistinguishable. The causative agent of the disease in Newcastle upon Tyne was identified as a virus which was distinct from fowl plague (avian influenza virus), although the symptoms bore some resemblance. It is thought likely that the virus was transported to the port of Newcastle upon Tyne by ship from southeast Asia. Whatever its origin, the new disease emerged or was first recognized in 1926 and rapidly spread throughout the world.

Newcastle disease was first recognized in various countries as a highly pathogenic disease with up to 100% mortality. In California, a relatively mild respiratory disease was first observed in the mid-

1930s. This disease, with a mortality usually less than 15%, was first called pneumoencephalitis but was later shown to be caused by a virus which was indistinguishable immunologically from Newcastle disease virus (NDV). The observation that NDV was not always highly pathological was important and was followed by numerous reports of other strains with low virulence. Such isolates were used later as live vaccines.

Taxonomy and Classification

Newcastle disease virus is a member of the genus *Rubulavirus* of the family *Paramyxoviridae* in the order *Mononegavirales*. This order consists of viruses possessing a genome of nonsegmented, single-stranded RNA of negative sense (i.e. complementary to the mRNA sense). The order *Mononegavirales* contains four separate families of viruses: the *Paramyxoviridae*, the *Rhabdoviridae*, the *Filoviridae* and the recently assigned *Bornaviridae*. The family *Paramyxoviridae* is divided into two subfamilies, the *Paramyxovirinae* and the *Pneumovirinae*. The *Paramyxovirinae* subfamily is divided further into three genera: *Paramyxovirus* (type species human parainfluenza virus 1), *Morbillivirus* (type species measles virus) and *Rubulavirus* (type species mumps virus). Prior to 1995, NDV was classified as a member of the *Paramyxovirus* genus.

Other members of the *Rubulavirus* genus include human parainfluenza viruses 2, 4a and 4b, mumps virus, simian parainfluenza viruses 5 and 41 (SV5 and SV41), porcine rubulavirus and the avian paramyxoviruses 2 to 9 (where NDV is also known as avian paramyxovirus 1). The genus *Morbillivirus* includes measles virus, canine distemper virus and rinderpest virus. The genus *Paramyxovirus* includes Sendai virus and human parainfluenza viruses type 1 and 3. The genus *Pneumovirus* includes human respiratory syncytial virus, bovine respiratory syncytial virus, pneumonia virus of mice and turkey rhinotracheitis virus.

Properties of the Virion

NDV is a pleomorphic, membrane-enveloped virus of roughly spherical shape ranging in diameter from 150 to 400 nm. It contains a helical nucleocapsid structure 1000 nm long and 17–18 nm in diameter, with a central hole of 5 nm. The main protein subunit of the nucleocapsid is the nucleocapsid protein (NP). Two other proteins, the phosphoprotein (P) and the large (L) protein are also associated with the nucleocapsid. The envelope is a lipid bilayer derived from the host cell plasma membrane and has embedded in it, and protruding from it, the spike glycoproteins hemagglutinin-neuraminidase (HN) and fusion (F). The matrix protein (M) is interposed between the nucleocapsid and the viral envelope (**Fig. 1**).

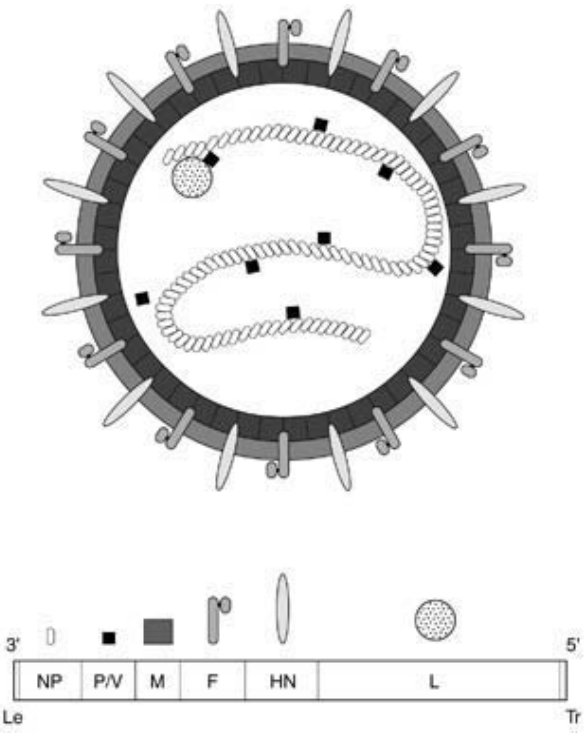

Figure 1 Newcastle disease virus.

Properties of the Genome

The genome of NDV is a linear, single strand of RNA of 15 186 nucleotides and of negative polarity. This strand must be transcribed into mRNA by the virion-associated RNA-dependent RNA polymerase before translation can take place. The genomic RNA itself is not infectious. On the genomic RNA, the genes are arranged in the order: 3′-NP-P-M-F-HN-L. There is a leader sequence at the 3′ end, upstream of the NP gene, and a trailer sequence at the 5′ end, downstream of the L gene.

The leader sequence (Le in **Fig. 1**) is 55 nucleotides long, and the first eight nucleotides of the leader sequence are identical in NDV, Sendai, measles and human parainfluenza 3 viruses.

The trailer sequence (Tr in **Fig. 1**) is 56 nucleotides long in strains Ulster and D26, and 114 nucleotides long in strain Beaudette C, based on the apparent poly(A) signal at the end of the L gene. Use of these differently located poly(A) signals would change the length of the corresponding mRNA but not affect the length of the L gene coding sequence or the total length of the genome. The nine nucleotides at the 5′

terminus of the trailer sequences of NDV and human parainfluenza virus type 3 are identical.

The genome displays inverse complementarity at its termini, with 11 out of 12 nucleotides at the 3′ terminus of the genome identical to those at the 3′ terminus of the positive-sense antigenome. This is to be expected as the 3′ end of the genome and the 3′ end of the antigenome both act as promoters to which the RNA-dependent RNA polymerase must bind to initiate transcription and replication.

Properties of Virus Proteins

The nucleocapsid protein NP, M_r 53 162 in strain Ulster, binds tightly to the genomic and antigenomic RNAs, producing helical structures. RNA that is not bound to NP cannot be transcribed or replicated. By analogy to studies with related viruses, the concentration of free (unassembled) NP within the infected cell is thought to control the relative rates of transcription and replication.

The phosphoprotein (P), M_r 42 241 (strain Ulster), is subject to phosphorylation. Together with the L protein it forms the viral polymerase (P-L). The P gene is transcribed to give two different mRNAs. One is a faithful copy of the P gene and leads to normal P protein production. The other has an extra guanosine residue inserted during transcription, which leads to the production of another protein, designated V, which has a cysteine-rich zinc binding domain. The letter 'vee' stems from the use of the roman numeral V to designate a fifth protein in SV5-infected cells.

The matrix protein (M), M_r 39 605 (strain Beaudette C), interacts with both the viral membrane and the nucleocapsid and is involved in viral assembly.

The fusion protein (F), one of two integral membrane glycoproteins, is first produced as an inactive precursor F_0 (M_r 59 042 before glycosylation in strain Beaudette C) which is cleaved post-translationally to give two disulfide-linked F_1 and F_2 polypeptides in the active protein. The active protein permits penetration of NDV into host cells by fusion of the viral envelope with the host cell plasma membrane.

The hemagglutinin-neuraminidase protein (HN), M_r 63 149 before glycosylation in strain Beaudette C, the other integral membrane glycoprotein, is responsible for the attachment of the virus to sialic acid-containing receptors on the cell surface. It also mediates cleavage of sialic acid residues from the surface of virions and infected cells and may be responsible for prevention of self-aggregation of viral particles during budding. In some avirulent NDV strains a larger inactive precursor HN_0 protein is cleaved to give the biologically active HN.

The large (L) protein, M_r 248 822 (strain Beaudette C), is required, together with the P protein, for viral RNA synthesis. The L protein is present in only about 30 copies per nucleocapsid. It is also probably involved in methylation, capping, phosphorylation and polyadenylation.

Replication

The replication of NDV, as with all viruses with negative-strand RNA genomes, is complicated by the absence in the mammalian host cells of the machinery to replicate RNA. The negative-sense RNA genome cannot be translated directly into protein but must first be transcribed into a positive-strand (mRNA) copy. Since the virus cannot therefore synthesize the required RNA-dependent RNA polymerase on entry, these proteins (L and P) must enter the cell with the genome on infection. Replication is considered together with transcription in the next section.

Transcription

Transcription and replication take place in the cytoplasm. Immediately after penetration, the virus initiates transcription by the P-L protein complex (an RNA-dependent RNA polymerase) using the RNA in the nucleocapsid as template. The transcriptive complex isolated from NDV-infected cells contains the viral nucleocapsid composed of a single strand of genomic RNA completely covered with NP protein, together with L and P proteins.

Viral RNA synthesis must be regulated such that it produces monocistronic mRNAs during transcription but full-length positive-strand complementary copies of the genomic RNA to act as templates for full-length negative-strand RNA synthesis during replication. Replication differs from transcription in that it requires *de novo* protein synthesis.

The 3′ leader contains the viral promoter for synthesis of the positive-sense RNAs (mRNA and antigenome). The P-L polymerase presumably binds to the promoter and transcribes the genome sequentially, beginning with the leader, and stopping and restarting at the gene-end and gene-start transcription signals in the RNA template. This process, primary transcription, produces mRNAs in amounts which decrease as the polymerase moves along the genome, due to attenuation at each intergenic control sequence. The first of the mRNAs to be translated produces NP.

For transcription to occur in this way, the polymerase must restart at the beginning of the NP gene after terminating at the end of the leader sequence. This is thought to be the critical step in the switch

between transcription to give individual mRNAs or replication to give full-length (+) antigenome. In order to give full-length antigenomic RNA the P-L polymerase must ignore the stop and start signals at the gene junctions. This is thought to be accomplished by binding to the nascent (+) RNA of newly synthesized NP which permits read-through of the stop signals by the polymerase, giving full-length (+) antigenomic RNA entirely coated with NP.

Replication of the virus then requires that the full-length (+) antigenome be used as template to produce full-length (−) strands for packaging. This requires binding of the polymerase to the promoter at the 3′ end of the (+) strand followed by complete synthesis of a complementary (−) strand. In this direction, there are no stop and start signals at the gene junctions.

Efficient replication of some paramyxovirus genomes requires that the genome length be an exact multiple of six. This 'rule of six' holds for the NDV genome length of 15 186 nucleotides and is thought to be the result of the binding of each NP monomer to exactly six nucleotides of RNA in the production of the helical nucleocapsid structures. This suggests that initiation of (−) strand synthesis only occurs if the last six nucleotides at the 3′ end of the antigenomic (+) strand, which constitute an essential part of the promoter, are precisely covered by one NP monomer.

Translation

The amounts of NDV proteins produced in infected cells suggests that transcription is polar, sequential and discontinuous. Thus, NP mRNA is the most abundant, while L mRNA is the least abundant, and this is reflected in the levels of protein synthesized.

Post-translational Processing

The newly synthesized NP, P and L proteins rapidly associate with the cytoskeletal framework and assemble into the nucleocapsid together with the genomic RNA.

The newly synthesized HN and F_0 proteins are inserted into the membrane of the rough endoplasmic reticulum, transported to and through the Golgi apparatus and inserted into the plasma membrane. Glycosylation of the HN and F proteins is initiated in the rough endoplasmic reticulum and further processed in the Golgi apparatus.

Assembly

The components of the virus are assembled at the host cell plasma membrane and mature virus is released by budding. Assembly probably involves binding of the M protein to the NP of the nucleocapsids and also to the HN and F proteins embedded in the cell membrane.

Geographic and Seasonal Distribution

NDV is very widely distributed, almost worldwide. Because of the wide variation in the severity of the disease caused by different strains it is likely that many outbreaks go unreported, particularly those involving strains of low pathogenicity. Vaccination by mesogenic and lentogenic strains is very widespread and this is likely to mask the presence of virulent strains of the virus. The geographic distribution of the disease can change rapidly. For example, a pigeon-adapted variant of NDV, apparently originating in Iraq in 1974, spread from there to Europe, reaching the UK in 1983, where limited spread to domestic poultry occurred in 1984.

Newcastle disease is a serious problem throughout Asia and the commercial poultry industry is totally dependent on control by vaccines. The disease is thought to be endemic throughout southeast Asia. It is a major problem in much of Africa, where traditional poultry raising at the village level is common and where effective vaccination is difficult to achieve. Velogenic virus has been recorded in the USA and many countries in South America. Canada and Chile were free of the disease in 1985 (the last survey) but vaccination was practised. Only two countries in Europe, Luxembourg and Norway, have never recorded outbreaks of NDV. NDV is present in certain parts of the former USSR and vaccination is practised. In 1985 no velogenic strains were reported in the former USSR. In Australia and New Zealand, avirulent strains are present in the poultry population, as indicated by the production of antibodies, but no disease is evident and vaccination is not routinely carried out.

An outbreak of Newcastle disease in poultry in Northern Ireland in 1997, which resulted in the death or compulsory slaughter of more than 900 000 birds, led to the order by the UK government of 15 million emergency vaccinations.

Newcastle disease has been reported in both temperate and tropical regions and it occurs in all seasons.

Host Range and Virus Propagation

Approximately 240 of the 8000 known species of birds have been shown to be susceptible to NDV and it is likely that virtually all species are susceptible. Chickens seem to be the most susceptible, while ducks and geese appear to be resistant even to those viruses that

are most pathogenic for chickens. Ducks and geese are often infected with the virus but rarely show clinical signs. Canaries, parrots and cranes have also been reported to be fairly resistant. Such birds, when infected, may shed velogenic virus for several weeks without showing any signs of disease. NDV causes mild conjunctivitis in humans.

NDV replicates at the site of entry, usually the conjunctiva, or the respiratory or alimentary tracts. It spreads rapidly to neighboring cells and by the second day there is considerable inflammatory cell infiltration. By the fifth day, the inflammatory reaction decreases and by the eighth day viremia is apparent. Within 48 hours of infection, high titers of virus are present in the kidney, lungs, spleen and bursa and quite high titers are present in the duodenum, trachea, pancreas and brain. Mesogenic and lentogenic strains may not reach the brain.

NDV can be readily grown in embryonated hens' eggs and in several tissue culture systems, notably chick embryo fibroblasts.

Genetics

The pathogenic and nonpathogenic strains of NDV presumably arise from each other by mutation. Sequence analysis of the HN and F genes of various strains has shown that susceptibility to cleavage of the precursor F_0 and HN_0 glycoproteins to their active form is determined by the specific sequences at or near the cleavage site. Mutations at these sites have major effects on the virulence of the strains.

Evolution

Sequence analysis of the genomes of various NDV strains and other paramyxoviruses is beginning to permit the construction of phylogenetic trees. For example, analysis of the L gene of various paramyxoviruses indicates a close relationship between NDV and parainfluenza virus type 2. Further sequencing of other viruses will eventually give a detailed account of the evolutionary relationships. Similarly, a start has been made at comparing gene sequences within NDV. Analysis of the HN sequences of 13 NDV strains permits the construction of a preliminary evolutionary tree, which, for example, places the mesogenic Beaudette C strain on the same 'branch' as the avirulent B1 strain.

Serologic Relationships and Variability

Some 30 years after the initial isolation of NDV in Newcastle upon Tyne, a paramyxovirus serologically distinct from NDV was isolated in Yucaipa, California, which caused serious outbreaks of disease in turkeys. A third paramyxovirus, serologically different from both types, was isolated from turkeys in Canada in 1967 and the USA in 1968. In the following decade there was a large increase in the number of isolations of serologically distinct paramyxoviruses throughout the world. It was suggested that the nomenclature should be based on the serological tests and that groups of viruses should be termed PMV-1 for NDV, PMV-2 for the Yucaipa type, PMV-3 for the North American turkey isolate, and so on. Furthermore, it was proposed that the names should also include the species of the bird from which the virus was first isolated, the geographical location, a reference number (if any) and the year of isolation. For example, a paramyxovirus isolated from domestic ducks in New York in 1978 is given the serotype PMV-9/duck/New York/22/78.

Antigenic variation has been studied by the use of monoclonal antibodies. On this basis, NDV (PMV-1) isolates can be differentiated and grouped into at least eight groups (A–H) which appear to correlate with shared biological and epizootiological properties.

Epidemiology

There have been at least three panzootics. The first began in 1926 and spread to most countries before it eventually subsided in the late 1950s as the result of widespread vaccination. The second panzootic emerged in the late 1960s in the Middle East and spread rapidly to all continents and most countries by 1973. The third panzootic appears to have emerged in the late 1970s in the Middle East and is thought to have been spread across Europe and then to many other countries by racing pigeons, both by contact during races and by international trade in the birds.

Transmission and Tissue Tropism

The virus is transmitted by inhalation and ingestion. Indeed, live vaccines can be administered by both methods, either as an aerosol spray or in the drinking water.

Pathogenicity

NDV strains differ widely in pathogenicity, depending largely on the host cell-specific cleavability and activation of the HN and F glycoproteins (discussed above). Whereas velogenic strains such as Herts 33 kill virtually 100% of an infected poultry flock, avirulent strains such as Hitchner B1 kill an extremely low percentage, if any.

Clinical Features of Infection

The first clinical sign in the bird is loss of appetite, usually about the fourth or fifth day after infection. Respiration is increased and is characterized by long, gasping inhalation through a half-opened beak. In many cases there is diarrhea and a thick mucus discharge from the nostrils and the mouth. The bird's temperature rises gradually until about the sixth or seventh day and falls quickly to below normal just before death.

Pathology and Histopathology

There is considerable strain dependence in the pathology of NDV infection. Birds infected with velogenic and mesogenic virus show gross lesions to the respiratory system. Changes to the trachea can vary from excess catarrhal exudate to severe hemorrhage. Less frequently, the lungs may be enlarged and congested. Also, swelling of the face tissue and eyelids is associated with edema, which may extend throughout the connective tissue of the neck and around the trachea.

Immune Response

The HN and F surface glycoproteins are important in the humoral response to NDV infection. On infection of a susceptible cell, the HN protein binds to a receptor containing neuraminic acid. Penetration into the cell is mediated by fusion of the viral envelope with the lipid bilayer of the cell, which requires the F protein. Monoclonal antibodies raised against the HN and F proteins have been used to map the antigenic sites within these proteins. Furthermore, the HN and F coding sequences when cloned into fowlpox or Marek's disease virus vectors protect chickens against a potentially lethal infection with NDV.

Prevention and Control

Full protection against Newcastle disease requires a combination of hygienic precautions and vaccination. Until recently, the only vaccines available against NDV were either live strains of low virulence or inactivated strains. Among live avirulent strains, Hitchner B1 and La Sota are used extensively worldwide as primary vaccines. Vaccines can be administered by a variety of convenient methods including addition to the drinking water and the spraying of aerosols. Where such mass treatment is not necessary, vaccines may be administered in a more controlled fashion by individual application to the eye or nostril, or by beak dipping. In Europe and North America, secondary vaccines are usually inactivated in oil emulsions and administered by injection. In many countries where virulent NDV is enzootic, live mesogenic secondary vaccines may be used.

Recently, recombinant DNA techniques have been used to construct genetically engineered bivalent viral vaccines. Inoculation of chickens with fowlpox virus containing the NDV HN or F genes protects them against both fowlpox and Newcastle disease. Similarly, vaccination with Marek's disease virus (herpes disease of turkeys) containing the NDV HN or F genes protects them against both Marek's disease and Newcastle disease. The first recombinant viral vaccine to be approved by the US Department of Agriculture was a recombinant fowlpox virus carrying the NDV HN and F genes.

The worldwide poultry industry is of great economic importance and the large-scale, intensive rearing of poultry greatly increases the vulnerability to infection. Some idea of the magnitude of the problem is given by the report that in the former USSR, where some large premises house up to two million adult birds, more than three billion birds are vaccinated against NDV each year.

Newcastle disease vaccine is probably the most widely used viral vaccine in the world.

Future Perspectives

The use of recombinant DNA technology can be expected to lead to the production of safer, more effective vaccines, as they can be more readily tailor-made to requirements and subsequently modified as required. Genetic engineering also offers the opportunity to construct multivalent vaccines in which the genes for several different antigens can be inserted into the same vector. In addition to the present recombinant vaccines available, which consist of the NDV HN or F gene sequences inserted into attenuated fowlpox or Marek's disease virus vectors, it should be possible to include the coding sequences for the surface glycoproteins of other poultry pathogens such as infectious bronchitis virus, infectious bursal disease virus, infectious laryngotracheitis virus, and so on.

NODAVIRUSES (*NODAVIRIDAE*)

L Andrew Ball, Department of Microbiology University of Alabama at Birmingham, Birmingham, Alabama, USA

Introduction

Nodaviruses are small, nonenveloped, isometric, riboviruses with bipartite, positive-sense RNA genomes. Within the *Nodaviridae* there are two genera: the alpha nodaviruses which predominantly infect insects, and the beta nodaviruses which infect fish. Under experimental conditions, some family members can also replicate in mammalian, plant or yeast cells. The two genomic RNAs (called RNA 1 which contains about 3100 nucleotides, and RNA 2 which contains about 1400 nucleotides) are both required for productive infection. These RNAs are copackaged in 29–32 nm diameter virions that contain a single major coat protein of approximately 40 kDa. The small genome size of these viruses, their unique genome strategy, abundant replication, ease of purification, and accessibility to high resolution structural analysis make the nodaviruses attractive systems for studies of RNA replication, gene expression, virion assembly and three-dimensional structure.

Members of the Family

The alpha nodaviruses include seven recognized members: nodamura virus (NOV, the type species of the genus), black beetle virus (BBV), flock house virus (FHV), boolarra virus (BoV), Manawatu virus (MwV), *Lymantria ninayi* virus (Greenwood) (LNV_G), and New Zealand virus (NZV) which is also known as *Drosophila* line 1 virus (DLV). These viruses were isolated from mosquitoes (NOV), New Zealand black beetles (BBV), two species of grass grubs (FHV, BoV and MwV) and gypsy moths (LNV_G).

The beta nodaviruses were discovered only within the last few years, but distinct viral species have now been isolated from several marine fish: striped jack nervous necrosis virus (SJNNV, the type species of the genus), barfin flounder nervous necrosis virus (BFNNV), *Dicentrarchus labrax* (sea bass) encephalitis virus (DlEV), Japanese flounder nervous necrosis virus (JFNNV), Lates calcarifer (barramundi) encephalitis virus (LcEV), redspotted grouper nervous necrosis virus (RGNNV), and tiger puffer nervous necrosis virus (TPNNV). Typically, these viruses were isolated from immature fish larvae and hatchlings in commercial fish hatcheries where they can cause significant economic losses. Capsid protein sequences show that the two genera are distantly related, but the viruses within each genus share antigenic determinants although they all show distinct reactivities. NOV is more distantly related to the other alpha nodaviruses than are the other six. No serological relationship has been found to any virus outside the *Nodaviridae*.

Host Range

All the alpha nodaviruses were originally isolated from insects, and some of them can be transmitted experimentally to several different insect species, including mosquitoes, bees, ticks, beetles and moths. In the laboratory, larvae of the wax moth (*Galleria mellonella*) provide convenient hosts. SJNNV and the other beta nodaviruses were isolated from fish larvae,

NODAVIRUSES (*NODAVIRIDAE*)

L Andrew Ball, Department of Microbiology University of Alabama at Birmingham, Birmingham, Alabama, USA

Introduction

Nodaviruses are small, nonenveloped, isometric, riboviruses with bipartite, positive-sense RNA genomes. Within the *Nodaviridae* there are two genera: the alpha nodaviruses which predominantly infect insects, and the beta nodaviruses which infect fish. Under experimental conditions, some family members can also replicate in mammalian, plant or yeast cells. The two genomic RNAs (called RNA 1 which contains about 3100 nucleotides, and RNA 2 which contains about 1400 nucleotides) are both required for productive infection. These RNAs are copackaged in 29–32 nm diameter virions that contain a single major coat protein of approximately 40 kDa. The small genome size of these viruses, their unique genome strategy, abundant replication, ease of purification, and accessibility to high resolution structural analysis make the nodaviruses attractive systems for studies of RNA replication, gene expression, virion assembly and three-dimensional structure.

Members of the Family

The alpha nodaviruses include seven recognized members: nodamura virus (NOV, the type species of the genus), black beetle virus (BBV), flock house virus (FHV), boolarra virus (BoV), Manawatu virus (MwV), *Lymantria ninayi* virus (Greenwood) (LNV_G), and New Zealand virus (NZV) which is also known as *Drosophila* line 1 virus (DLV). These viruses were isolated from mosquitoes (NOV), New Zealand black beetles (BBV), two species of grass grubs (FHV, BoV and MwV) and gypsy moths (LNV_G).

The beta nodaviruses were discovered only within the last few years, but distinct viral species have now been isolated from several marine fish: striped jack nervous necrosis virus (SJNNV, the type species of the genus), barfin flounder nervous necrosis virus (BFNNV), *Dicentrarchus labrax* (sea bass) encephalitis virus (DlEV), Japanese flounder nervous necrosis virus (JFNNV), Lates calcarifer (barramundi) encephalitis virus (LcEV), redspotted grouper nervous necrosis virus (RGNNV), and tiger puffer nervous necrosis virus (TPNNV). Typically, these viruses were isolated from immature fish larvae and hatchlings in commercial fish hatcheries where they can cause significant economic losses. Capsid protein sequences show that the two genera are distantly related, but the viruses within each genus share antigenic determinants although they all show distinct reactivities. NOV is more distantly related to the other alpha nodaviruses than are the other six. No serological relationship has been found to any virus outside the *Nodaviridae*.

Host Range

All the alpha nodaviruses were originally isolated from insects, and some of them can be transmitted experimentally to several different insect species, including mosquitoes, bees, ticks, beetles and moths. In the laboratory, larvae of the wax moth (*Galleria mellonella*) provide convenient hosts. SJNNV and the other beta nodaviruses were isolated from fish larvae,

but the breadth of their natural or experimental host ranges have not been determined. Although some fish cell lines that support virus replication have been identified, replication of the beta nodaviruses has yet to be carefully studied in cell culture.

In the region of Japan where NOV was isolated from a mosquito, high levels of neutralizing antibodies were found in pigs, suggesting that the natural host range of the virus may include these animals. In the laboratory, NOV replicates abundantly in suckling mice and hamsters, causing hind limb paralysis and 100% mortality five to seven days after inoculation. Adult animals are unaffected. NOV also kills adult bees, as well as some species of mosquitoes, giving it the very unusual property of causing lethal infections in both insects and mammals. On the other hand, FHV has no effect on suckling mice, but can productively infect plant protoplasts and even replicate in plant cells if they are inoculated with viral RNA. Indeed, FHV RNA can replicate well not only in insect, plant, and vertebrate cells, but also in the yeast *Saccharomyces cerevisiae*. *Drosophila* cells in culture support abundant replication of BBV, FHV or BoV, and FHV readily forms plaques on monolayers of these cells. Transfection of NOV RNA into baby hamster kidney cells in culture results in vigorous replication and the production of large amounts of infectious virus. No cellular receptors for nodaviruses have been identified.

Virion Composition

Nodavirus particles are composed of a protein shell surrounding one molecule of each of the two genomic RNAs. Evidence for copackaging of the RNAs comes from the uniform sedimentation coefficient (135–140S) and buoyant density (1.33–1.35 g ml^{-1}) of the particles, measurements of their particle weight (about 9×10^3 kDa) and total RNA content (about 16%), and the demonstration that the two viral RNAs can be crosslinked by UV irradiation of virus particles. Most compelling, however, is the linear relationship that exists between virus particle number and infectivity as determined by plaque assay of FHV. Since both viral RNAs are required for a productive infection, this result establishes that they are copackaged.

The protein shell is composed of 180 protomers arranged with icosahedral symmetry on a $T = 3$ surface lattice (i.e. the asymmetric structural unit contains three chemically identical protomers). In the alpha nodaviruses, each protomer is composed of one copy of the capsid proteins β (about 40 kDa) and γ (about 5 kDa), which are produced by a single proteolytic cleavage of the coat protein precursor, protein α (about 45 kDa). Cleavage occurs relatively slowly after virus assembly, so fresh virus preparations usually contain a small amount of uncleaved protein α. Since protein γ is small and stains poorly, it has been overlooked in the characterization of some of the nodaviruses, but in BBV, FHV and NOV it is present in virions in equimolar amounts with protein β.

The amino acid sequences of the coat protein precursors (α) of several of the alpha and beta nodaviruses have been inferred from the nucleotide sequences of the corresponding RNA 2 segments. They contain about 400 amino acid residues and clearly represent members of the same evolutionary lineage. The protein α sequences of BBV and FHV are 87% identical to one another, and about 50% identical to those of NOV and BoV. In contrast, they share only about 10% sequence identity with the capsid proteins of the beta nodaviruses. All α protein sequences have very basic regions near their N-termini, where about one-third of the first 50 amino acid residues are lysines or arginines. For the alpha nodaviruses, cleavage of protein α to form proteins β and γ occurs near the carboxy terminus, between asparagine 363 and alanine 364 in the BBV and FHV proteins, and the same two residues are present at the homologous positions in the proteins of NOV and BoV, suggesting evolutionary conservation of the cleavage site. Beta nodavirus particles contain roughly equal amounts of two related capsid proteins of 40 and 42 kDa. It has not yet been determined whether these correspond to the precursor protein α and its larger cleavage product β.

Three-Dimensional Structure of Virions

The three-dimensional structures of some of the alpha nodaviruses have been determined at atomic resolution by X-ray diffraction and also examined by cryoelectron microscopy and image reconstruction. The protomers of BBV consist of five distinct regions:

- a crystallographically disordered (and therefore mostly invisible) amino terminal domain of 60 amino acid residues which lies inside the virion;
- an eight-stranded anti-parallel β-barrel (as seen in the structures of many other animal and plant virus protomers);
- a surface protrusion composed mostly of β sheet and formed by three large insertions between strands of the β barrel;
- an internal domain that includes the carboxy terminus of protein β and the amino terminus of protein γ, and consists of two α helices that extend towards the interior of the virion;

- an invisible disordered region inside the virion that is composed of the carboxy terminal 28 amino acid residues of protein γ.

It seems probable that the highly basic amino termini of the nodaviral coat proteins interact with some of the phosphate residues of the viral RNAs. In the BBV virion, 180 protomers are arranged with icosahedral symmetry to form a shell that extends from an internal radius of 95 Å to an external radius of 170 Å . However, most of the β-barrel structure and the amino acid residues that are responsible for the interprotomer contacts lie between 120 Å and 145 Å from the center of the particle. The site of cleavage of protein α to form proteins β and γ lies within the central cavity of the virion.

Despite having identical amino acid sequences, the protomers adopt slightly different conformations depending on which of three quasi-equivalent positions they occupy in the icosahedral lattice. The most crucial difference is that in one-third of the protomers, the peptide region composed of residues 20–31 is icosahedrally ordered and can therefore be seen in the crystal structure, where it occupies an intersubunit groove on the internal face of the protein shell. Underlying this peptide, about 20 nucleotides of the viral RNA genome can be seen, in the form of helical duplexes that further fill one-third of the intersubunit grooves, 30 in each virion. Protomers that interact across such filled grooves lie in the same plane forming a dihedral angle of 180°, whereas those that interact across unfilled grooves form a dihedral angle of 136°. This topological difference in a subset of the interprotomer interactions is largely responsible for the overall size and shape of the protein shell.

Genome Structure and Coding Potential

The molecular genetics of the alpha nodaviruses are summarized in **Fig. 1.** Nodaviruses contain two single-stranded RNA molecules, both of which are necessary for productive infection. The larger RNA encodes RNA replicase functions and replicates autonomously when introduced into appropriate cells in the absence of the smaller genomic RNA. From this it has been inferred that RNA1 encodes the entire viral contribution to the RNA-dependent RNA polymerase. The smaller RNA encodes the coat protein precursor α. The RNA 5′ ends are capped but the structure of their 3′ ends, which are not polyadenylated, remains an enigma. Alpha nodavirus RNAs are unreactive with RNA ligase or poly(A) polymerase, enzymes that react with 3′ —OH groups on RNA molecules. The basis for this lack of reactivity is unclear, but covalent modification of

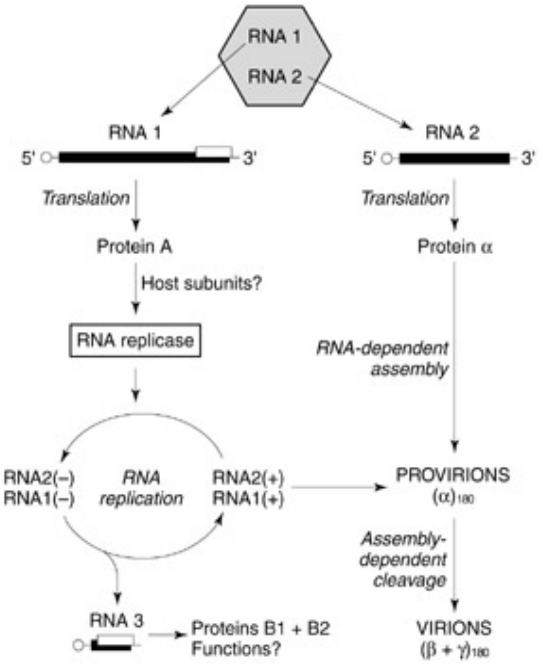

Figure 1 Genome strategy and replication cycle of the alpha nodaviruses. (Reproduced with permission from Ball and Johnson 1998.)

the 3′ end by a 'blocking group', perhaps a protein, has been proposed. However, RNA extracted from purified FHV does not incorporate a significant amount of radioactivity from labeled amino acids, nor does it yield an N-terminal sequence when subjected to Edman degradation. These results make it unlikely that the viral RNAs have a protein attached to their 3′ ends. Alternative possibilities are an unusually stable RNA secondary structure that masks the 3′ end, or perhaps covalent attachment to a small non-protein entity. The reactivity of the 3′ ends of beta nodaviral RNAs has not been reported.

A single long open reading frame starts at nucleotide 40 in FHV RNA 1 and ends at nucleotide 3033, encoding protein A (998 amino acid residues; 112 290 Da). The amino acid sequence of protein A contains a clear polymerase motif including glycine-aspartate-aspartate at positions 691–693, showing that it is the catalytic subunit of the viral RNA-dependent RNA polymerase. The carboxy terminus of protein A is overlapped by a short open reading frame that starts at nucleotide 2738 in FHV RNA 1, ends at nucleotide 3055, and encodes protein B2 of 106 amino acid residues (11 633 Da). The function of protein B2 is unknown, but its amino acid sequence predicts a high content of α-helix. It appears to be essential for the production of infectious virus, but not for RNA replication *per se*. Proteins A and B2 are

made in infected cells, but neither is found in virus particles.

The messenger RNA for protein B2 is a small RNA (RNA 3) that represents the 3′ terminal 387 nucleotides of RNA 1. It is produced during the replication of RNA 1, but is not packaged in virions. Like RNAs 1 and 2, its 5′ end is capped and its 3′ end is blocked. Ten nucleotides upstream of the AUG codon that initiates the protein B2 open reading frame, RNA 3 contains another AUG codon. This AUG lies in the same reading frame as protein A and initiates the synthesis of low levels of protein B1, which represents a carboxy terminal fragment of protein A. However, protein B1 is not essential for the replication of FHV, and BoV RNA 3 does not encode this protein.

Regulation of Viral Gene Expression

Despite their genetic simplicity, nodaviruses show temporal control of the synthesis of both their RNAs and proteins. As with other positive-stranded RNA viruses, the initial event after genome uncoating is the translation of the viral RNA, and the proteins produced from the input RNA can most easily be examined in cell-free translation systems. There, RNA 1 directs the synthesis of protein A and RNA 2 directs the synthesis of protein α. Neither B protein is synthesized by RNA extracted from purified viruses. In infected cells, the first synthetic events that can be readily detected are the replication of RNA 1 and the synthesis of RNA 3, shortly followed by the replication of RNA 2. These RNA syntheses occur in the cytoplasm and are catalyzed by the RNA-dependent RNA polymerase encoded in RNA 1. Synthesis of RNAs 1 and 2 in approximately equimolar amounts continues throughout the 24–36 h infectious cycle, whereas RNA 3 synthesis is transient and diminishes about 10 h after infection.

After amplification of the input RNA by replication, translation of protein A from RNA 1, and protein B2 from RNA 3 can be readily detected against a gradually diminishing background of host cell protein synthesis, which is progressively inhibited. Synthesis of protein α from RNA 2 starts 2–3 h later than that of proteins A and B2, but then increases rapidly and dominates the protein synthetic capacity of the infected cell for the remainder of the infectious cycle. By contrast, the synthesis of proteins A and B2 is transient and both are strongly repressed later in infection, despite the continued presence of their messenger RNAs. However, when RNA 1 replicates in the absence of RNA 2, proteins A and B2 and RNA 3 are synthesized continuously, and accumulate to unusually high levels. This result indicates that RNA 2 or its translation product is responsible for both the transcriptional and translational repression of proteins A and B2. In cell-free systems, RNA 2 is a much stronger message than RNA 1 and synthesis of protein α outcompetes the synthesis of protein A. A similar effect probably operates in infected cells, although it has been suggested that RNA 3 or protein B2 also contributes to the repression of protein A synthesis. Transcriptional repression of RNA 3 synthesis is mediated by RNA 2 itself, perhaps via a direct base-pairing interaction between RNA 2 positive strand and the promoter for RNA 3 synthesis on the negative strand of RNA 1. The net effect of these control mechanisms is that early in infection the major products are RNAs 1 and 3 and their encoded proteins A (RNA replicase) and B2 (unknown function), whereas later synthesis is dominated by the genomic RNAs 1 and 2 and the coat protein precursor α.

RNA Replication

Deproteinized RNA extracted from cells late in infection contains single-stranded, positive-sense RNAs 1, 2 and 3 in an abundance that approximates that of the ribosomal RNAs. Also detected are small amounts of double-stranded versions of these three RNA species, which amount to less than 5% of the total viral RNA. This demonstrates the presence of full-length negative strands that correspond to each of the three viral RNAs, but the intracellular state of these negative-strand RNAs before deproteinization is unknown.

Infected cells also contain a membrane-bound RNA-dependent RNA polymerase activity that can be partially purified and rendered template-dependent by treatment with micrococcal nuclease. This enzyme preparation can use positive-strand RNA 1, 2 or 3 as template and synthesize the corresponding negative-strand to produce double-stranded RNAs. However, complete RNA replication *in vitro*, with the net synthesis of RNAs 1 and 2 of the same sense as the input templates, requires the presence of intact membranes or a synthetic cationic lipid. Protein A copurifies with the RNA replicase activity, whereas most of protein B2 does not. However, the enzyme has not been purified sufficiently to enable its polypeptide composition to be determined, so the possible involvement of host cell subunits is an unresolved question. But since FHV replicase can function in cells of yeast, insect, plant or vertebrate origin, any required host cell components must be highly conserved.

Full-length cDNA clones of FHV RNAs 1 and 2 can be transcribed *in vitro* to produce infectious RNAs. Transcribed *in vivo* from an expression vector, these

cDNAs direct the synthesis of a self-replicating RNA 1 and a replication-competent RNA 2, respectively. Site-directed mutations that eliminate the protein B2 open reading frame or the initiation site for RNA 3 synthesis (but leave the protein A open reading frame intact), do not interfere with the autonomous replication of RNA 1, suggesting that protein B2 is not an essential component of the RNA replicase. Indeed, it is hard to see how protein B2 could be necessary for RNA replication since the production of its messenger RNA depends on replicase activity. However, protein B2 appears to fulfill an important function of some kind since mutations that eliminate its expression have invariably been found reverted in infectious viruses recovered from mutant cDNA clones.

The nature of the template for synthesis of positive-strand RNA 3 is unclear. During the initial stages of RNA replication, it is thought to be a partial or complete negative strand of RNA 1, which directs RNA 3 positive strand synthesis by internal initiation. This mechanism of subgenomic RNA synthesis resembles that seen in other RNA virus families, such as the togaviruses and bromoviruses. The presence in infected cells of double-stranded RNA 3 implies that the positive strand is a competent template for negative strand synthesis and this has been confirmed using partially purified RNA polymerase. However, it is unclear whether the RNA 3 negative strand can direct RNA 3 positive strand synthesis, i.e. whether RNA 3 truly replicates. Deletion analysis of the RNA 2 cDNA shows three regions of the template that are necessary for efficient replication: the 5′ and 3′ termini, and an internal region between nucleotides 520 and 720. The role of this internal region is unknown.

The unequal abundance of the positive and negative strands implies a difference in their efficiency of synthesis, presumably at initiation at the 3′ ends of the negative and positive strand templates, respectively. The 3′ terminal 65 nucleotides of BBV, FHV and BoV RNA 2 can be folded into similar secondary structures consisting of two adjacent hairpin loops that are preceded and connected by partially conserved sequences, and it is likely that these sequences and structures are involved in template recognition and the initation of negative strand synthesis. However, no corresponding structures exist at the 3′ terminus of the negative strand, so the elements involved in the more efficient recognition of this template are unclear. The only common feature is the resemblance between the 5′ sequences of RNAs 1, 2 and 3, which for FHV are 5′ GUUU..., 5′ GUAA..., and 5′ GUUA..., respectively. The RNA replicases from BBV, FHV and BoV can replicate each others' RNAs and genetic reassortants between these three viruses are viable. NOV RNA and replicase share a different specificity.

Virion Assembly

Assembly of FHV occurs in the cytoplasm in close association with intracytoplasmic membranes, and involves the coat protein precursor α and RNAs 1 and 2. Intermediates in the assembly pathway have not been identified, except for a 140S particle, the provirion, which differs from the mature virion in that it contains uncleaved protein α rather than proteins β and γ. Newly synthesized protein α is incorporated into provirions within a few minutes, whereas the incorporation of RNAs 1 and 2 occurs slowly, with a half-time of about 10 h. Following provirion formation, protein α slowly cleaves to form β and γ with a half-time of about 4 h at 22°C. This cleavage increases the stability of the virus particle substantially and renders it infectious. Since the site of cleavage lies within the interior of the virion, proteolysis is thought to be mediated by the coat protein itself, acting autocatalytically.

Nucleotides 186–217 of FHV RNA 2 are necessary for packaging the RNA into virus particles. This region forms a bulged stem–loop structure which may be the element recognized for nucleation of assembly on RNA 2. The mechanism responsible for copackaging one molecule of each of the two viral RNAs is not clear. A region of potential base-pairing between BBV RNAs 1 and 2 was proposed as a possible site of RNA–RNA interaction, but it is not conserved in the FHV sequences. Nevertheless, RNAs 1 and 2 are released as a 27S complex following gentle disruption of NOV, and purification of RNA 1 completely free of RNA 2 requires repeated separations, suggesting the existence of direct RNA 1–RNA 2 interactions that may be involved in copackaging.

Virus–Host Cell Interactions

In general, nodavirus infections of permissive cells in culture induce only mild cytopathic effects, which may in part account for the very high yields of virus that can be obtained from infected cultures (in excess of 10^6 virus particles per cell). Three days after infection of *Drosophila* line 1 cells with BBV, the progeny virus constitutes about 20% of the total cellular protein, and several of the *Nodaviridae* form paracrystalline arrays of virus particles in the cytoplasm of infected cells. Despite the high virus yields, most infected cells remain intact and metabolically active even late in infection, and little virus is released. However, a progressive inhibition of host cell protein

synthesis occurs during infection, due in part to the accumulation of large amounts of RNA 2 which is a very active messenger.

A small fraction of cultured *Drosophila* line 1 cells routinely survives infection with FHV and on examination the cells are found to be persistently infected. Viruses isolated from persistently infected cultures replicate poorly even in fresh cells, because their coat protein genes have accumulated multiple mutations. However, the establishment of persistence has been attributed to cellular changes rather than the mutations in the viral capsid gene which arise later. Defective viral RNAs that have suffered substantial deletions and rearrangements can be isolated from viruses harvested from persistently infected cultures, and the structures of these RNAs may provide insight into the *cis*-acting sequences necessary for RNA replication and encapsidation.

Epidemiology and Pathogenesis

The readiness with which alpha nodaviruses establish persistent infections in cell culture probably reflects their propensity to establish inapparent and persistent infections in their insect hosts. These infections can reduce egg viability and slow the development of the host without causing significant mortality. Under other conditions, such as overcrowding of the host, however, nodaviruses cause epizootic infections with high mortality. Such infections can be economically damaging in the case of SJNNV disease among hatchery-reared fish larvae. Large numbers of SJNNV particles are found in the brain and other cells of the central nervous system, and the infected larvae show abnormal swimming behavior and nervous necrosis.

Intraperitoneal inoculation of NOV into mice less than about 14 days old causes severe hind limb paralysis due to replication of the virus in the hind limb musculature and degeneration of spinal cord neurons. Mice inoculated when they are older than about 21 days show no signs of disease. It is not clear whether this change is due solely to the development of a responsive immune system, but 7-day-old mice born to or suckled by immunized mothers are completely resistant to intraperitoneal challenge with NOV. In wax moth larvae, NOV replicates predominantly in muscle cells, but cells of many other tissues are also susceptible to infection which kills the larvae.

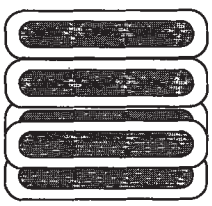
NONOCCLUDED BACULOVIRUSES



John P Burand, University of Massachusetts – Amherst, Amherst, Massachusetts, USA

History

The nonoccluded baculoviruses (NOB) are a loosely associated group of enveloped, rod-shaped viruses which, in many respects resemble the occluded baculoviruses except that they are not found associated with a protein crystal occlusion body. Only three NOBs have been studied to any significant extent. The first NOB to be identified was the *Oryctes* virus (Or-1V). The isolation of this virus resulted from a field study conducted throughout Southeast Asia in 1963, to find an agent that could be used to control the rhinoceros beetle, *Oryctes rhinoceros*, a pest on tropical palm plantations in the South Pacific. The virus was not naturally occurring in areas of the South Pacific where *O. rhinoceros* had been accidentally introduced and had become a pest. Since its initial discovery the virus has been found in insect populations in the Philippines, Sumatra, West Kalimantan, Thailand and India. Today, the virus is used to control beetle populations and serves as the best model for the use of a virus for insect pest control.

NORWALK AND RELATED VIRUSES (*CALICIVIRIDAE*)

Mary K. Estes and **Isabelle Leparc-Goffart**, Division of Molecular Virology, Baylor College of Medicine, Texas Medical Center, Houston, Texas, USA

History

Diarrheal illnesses of humans have been documented since the dawn of history. In spite of the discovery during the past century of numerous enteric bacteria and parasites, the etiology of a major portion of diarrheal illnesses remained unknown until the 1970s. It was assumed by exclusion that viruses were responsible for a significant portion of these illnesses. Thus, volunteer studies were initiated in the 1940s and 1950s because most viruses could not be propagated *in vitro* or in an animal model. These studies attempted to determine if illness could be induced with a presumptive nonbacterial viral agent by feeding bacteria-free fecal filtrates, derived from adults with acute nonbacterial gastroenteritis, to adult volunteers. Illness was induced demonstrating that the nonbacterial suspensions were indeed etiologic agents of acute gastroenteritis. The filtrates were named after the source of the original specimen, e.g. Marcy (Marcy State Hospital, Utica, New York), Niigata (Niigata Prefecture, Japan) and FS (Family Study, Cleveland, Ohio). These agents were passaged serially to other volunteers and also characterized antigenically in crosschallenge studies. However, because none of the infectious agents could be identified further *in vitro* or in an animal model, the etiology of acute nonbacterial gastroenteritis remained elusive. In the 1950s and 1960s, the introduction of tissue culture technology led to the discovery of over 100 new viruses, many of which were isolated in feces, but none of these new viruses could be implicated as an important etiologic agent of acute gastroenteritis. In the late 1960s, human embryonic organ cultures of the respiratory tract were used to successfully isolate several fastidious respiratory coronaviruses. Prompted by this success, renewed efforts were made to isolate viruses from fecal specimens of patients with viral gastroenteritis by utilizing human embryonic intestinal organ culture; these studies failed to identify an etiologic agent. It was considered that perhaps the lack of success was due to the absence of an infectious agent in the fecal specimen used as inoculum. Fecal suspensions prepared in the 1940s and 1950s, as described above, that were known to be infectious in challenge studies were either exhausted or not available at that time for evaluation with these newer techniques. Thus, in the early 1970s, a 'second generation' of volunteer studies was initiated. In one of these, a filtrate made from a rectal swab specimen from a secondary case of gastroenteritis from an outbreak of 'winter vomiting disease' that affected about 50% of the students and teachers in an elementary school in Norwalk, Ohio, was found to induce gastroenteritis in adult volunteers. This illness-inducing filtrate was serially passaged to other volunteers and was designated as the Norwalk agent. Attempts to cultivate or identify an infectious agent *in vitro* with the newer cell or intestinal organ culture techniques or in animals were unsuccessful.

In 1972, application of immune electron microscopy (IEM) led to the discovery of 27 nm virus-like particles in an infectious stool derived from the Norwalk outbreak and to the etiologic association of these virus-like particles with the Norwalk, Ohio outbreak. The 27 nm Norwalk particles thus became the first virus to be implicated as the cause of epidemic nonbacterial gastroenteritis; it was discovered without the use of any *in vitro* or animal model system. IEM also led to the discovery of other gastroenteritis agents such as the Montgomery County, Hawaii and Snow Mountain agents. Approximately 1 year after the discovery of the Norwalk virus, rotaviruses, the major etiologic agents of acute gastroenteritis of infants and young children, were discovered by electron microscopic techniques, again without the benefit of any *in vitro* system or animal model.

Taxonomy and Classification

The classification of viruses responsible for acute gastroenteritis was first based on morphology. For example, Norwalk virus was the prototype of a group of agents initially called small round-structured viruses (SRSVs). Recently, rapid advances in molecular biology have allowed these viruses to be classified based on their genome characteristics and most of the previously named SRSVs belong to the *Caliciviridae*.

The family *Caliciviridae* contains four genera: *Lagovirus*, 'Norwalk-like viruses', 'Sapporo-like viruses' and *Vesivirus*. The human caliciviruses responsible for epidemic gastroenteritis belong to

Table 1 Human calicivirus classification and antigenic relationships among the caliciviruses

		Antigenic relationships	
Genus	*Virus strain*[a]	*Determined by serologic IEM and/or crosschallenge studies in volunteers as described in the text*	*Determined by ELISA with hyperimmune antisera raised against recombinant Grimsby, Norwalk and Mexico virus-like particles*
'Norwalk-like viruses'	Norwalk	Distinct serotype	Distinct type
	Hawaii	Distinct serotype	Unknown
	Snow Mountain	Distinct serotype	Unknown
	Lorsdale	Unknown	Unknown (probably same as Grimsby)
	Southampton	Unknown	Unknown
	Mexico	Unknown	Distinct type
	Grimsby	Unknown	Distinct type
'Sapporo-like viruses'	Sapporo	Distinct serotype	Unknown
	Manchester	Unknown	Unknown

[a] Only a representative subset of virus strains in each genus ('Norwalk-like viruses' and 'Sapporo-like viruses'). See Green *et al.* (1999) for complete listing of strains.

the genus 'Norwalk-like viruses' (type species: Norwalk virus) and 'Sapporo-like viruses' (type species: Sapporo virus) (**Table 1**).

Properties of the Virion

These nonenveloped viruses contain a genome of single-stranded RNA of positive polarity. They have a diameter of 27–40 nm by negative stain electron microscopy and a buoyant density of 1.33–1.41 g ml^{-1}. These viruses, which are shed in the feces of individuals with gastroenteritis, cannot be propagated in cell cultures.

The virions are composed of a single capsid protein. Structural analysis of virus particles from stool is limited by the low number of particles present in these samples. However, by negative stain electron microscopy, the Norwalk virus has an indistinct 'feathery' outer edge and an indistinct surface substructure, although there is a suggestion of indentations on its surface (**Fig. 1A**). Expression of the capsid protein using the baculovirus system results in the self-assembly of the Norwalk virus protein into virus-like particles (VLPs) (**Fig. 1B**). By negative stain electron microscopy, these VLPs have a similar morphology to the native virus. The structure of these VLPs has been resolved by electron cryomicroscopy and computer image processing. The capsid exhibits a $T = 3$ icosahedral symmetry. The major structural protein folds into 90 dimers that form a shell domain from which arch-like capsomers protrude. A key characteristic of this architecture is 32 cup-shaped depressions at each of the icosahedral fivefold and threefold axes.

Genome Organization

In 1990, the genome of Norwalk virus was cloned and characterized. More recent studies have characterized and sequenced completely other viruses belonging to

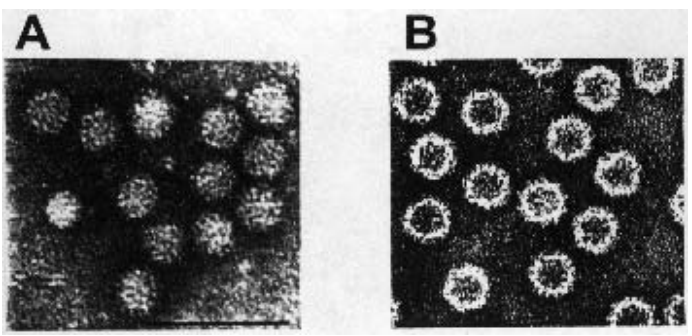


Figure 1 Negative stain electron micrographs of (**A**) Norwalk virus purified from stool of a volunteer (#547) given Hu/NVL/NV/1968/US, and (**B**) recombinant Norwalk virus-like particles produced and purified from insect cells infected with a recombinant baculovirus expressing ORF 2 and ORF 3 of Norwalk. Bar = 100 nm.

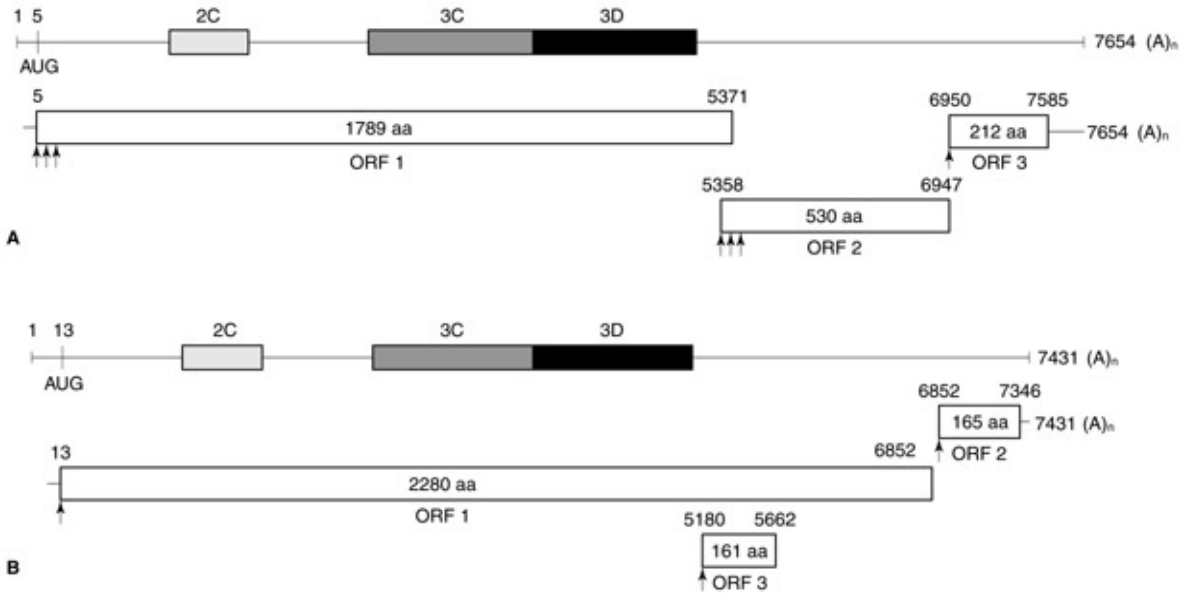

Figure 2 Genome organization of human caliciviruses. (**A**) Genome organization of Norwalk virus. The first ORF encodes the nonstructural proteins; ORF 2 encodes the capsid protein; and ORF 3 encodes a small basic protein. (**B**) Genome organization of Manchester virus (Liu *et al*, 1997). ORF 1 encodes the nonstructural proteins and the capsid protein, followed by ORF 2 (the homologue of the Norwalk virus ORF 3) encoding a small basic protein. ORF 3 is encoded by an out-of-frame sequence within ORF 1.

one of the two human calicivirus genera, either in the 'Norwalk-like viruses' (Norwalk virus, Lordsdale virus and Southampton virus) or in the 'Sapporo-like viruses' (Manchester virus). These viruses contain a positive-sense polyadenylated single-stranded RNA of approximately 7.6 kb (**Fig. 2**).

The genome of 'Norwalk-like viruses' is organized in three major open reading frames (ORFs). For Norwalk virus, the first ORF at the 5′ end encodes a large polyprotein of 1738 amino acids (aa) with a predicted molecular weight of 193.5 (193.5 K). This polyprotein contains short motifs of similarity with the 2C (helicase), 3C (cysteine protease), and 3D (RNA-dependent RNA polymerase) proteins of picornaviruses (**Fig. 3**). Thus, the 5′ end of the genome of the 'Norwalk-like viruses' codes for a precursor of

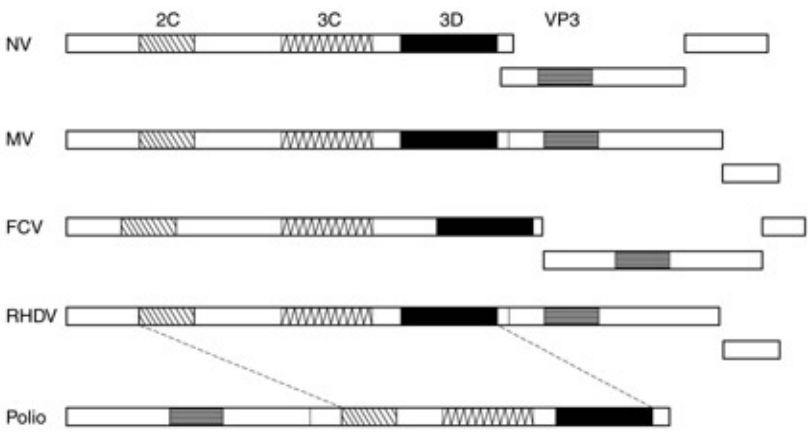

Figure 3 Comparison of the genomic organization between caliciviruses and picornaviruses. The genomic organizations of Norwalk virus (NV), Manchester virus (MV), feline calicivirus (FCV), rabbit hemorrhagic disease virus (RHDV), and poliovirus (Polio) are compared by showing the locations of the motifs within the genomes that are similar to the 2C helicase (▨), 3C cysteine protease (▩), 3D RNA-dependent RNA polymerase (■) and VP3 (▤) capsid protein of poliovirus.

the nonstructural proteins. ORF 2 encodes a 530aa (56.6 K) protein, the capsid protein. The ORF 2 protein expressed in insect cells self-assembles into virus-like particles as explained above (**Fig. 1B**). ORF 3 at the 3′ end of the genome is predicted to code for a small protein of 212aa (22.5 K) with a very basic charge (isoelectric point of 10.99). The ORF 3 protein does not have sequence similarity with any other proteins in the GenBank and its function remains unknown, although recently the ORF 3 protein has been found in VLPs expressed from cDNA constructs that contain both ORF 2 and ORF 3.

The genome of 'Sapporo-like viruses' is organized slightly differently. For Manchester virus, the first ORF codes for the nonstructural proteins as well as the capsid protein, which is found in-frame at the end of the nonstructural proteins. This genome organization is similar to that found in the animal calicivirus rabbit hemorraghic disease virus (RHDV) belonging to the genus *Lagovirus* (**Fig. 3**). ORF 2 encodes a predicted small highly basic protein of unknown function, similar to ORF 3 for Norwalk virus. Manchester virus contains a third ORF within the capsid protein which could encode another small basic protein. The significance of this ORF is unclear as it is not seen in any of the other calicivirus genomes sequenced thus far, and the small protein it potentially encodes shows no sequence homology to other viral proteins in the database.

Serologic and Phylogenetic Relationships

Four distinct serotypes of the 'Norwalk-like viruses' (Norwalk, Hawaii, Snow Mountain and Taunton) and one serotype of the 'Sapporo-like viruses' (Sapporo) were originally described by serologic IEM studies employing virus particles shed in stools as antigen and paired sera of infected individuals as the source of antibody. These serotype designations assumed that antibody reactivity by IEM reflects the reactivity of neutralizing antibodies. This may not be the case. Therefore, serotypes remain to be more clearly defined, a goal that is unable to be achieved due to the lack of a cultivation system. Early volunteer studies also examined the ability of different viruses to induce crossprotection. Based on these studies in addition to IEM, Norwalk, Hawaii and Snow Mountain viruses were defined as separate serotypes (**Table 1**). More recently, the antigenic relationships between these viruses have been examined by ELISA using hyperimmune antisera raised against virus-like particles. By this method, Norwalk, Mexico and Grimsby viruses are antigenically distinct.

The genetic relationships between the viruses within the calicivirus and the picornavirus families are being unraveled by sequence analysis of nucleic acids amplified directly from stools using reverse transcription–polymerase chain reaction (RT-PCR). Sequence comparisons of the full-length capsid protein of a number of viruses belonging to the four genera of the calicivirus family and of picornaviruses can be used to generate phylogenetic relationships but detailed understanding of the biological significance of these relationships awaits successful cultivation of these fastidious viruses.

Host Range and Virus Propagation

Attempts to cultivate the Norwalk and related viruses in tissue or organ culture have been unsuccessful. Efforts to find an animal model that develops illness after virus administration also have failed. However, chimpanzees become infected subclinically following administration of the Norwalk virus by the alimentary route; they shed soluble Norwalk antigen in the feces and develop serologic evidence of infection by IEM and radioimmunoassay (RIA).

Epidemiology

Human caliciviruses are the major known etiologic agents of acute nonbacterial gastroenteritis that cause clearly defined outbreaks that affect adults, school-aged children and family contacts; infrequently, these outbreaks involve infants and young children. Outbreaks occur in all seasons of the year in various communal settings, including schools, recreational and swimming facilities, cruise ships, restaurants, families and nursing homes. In an analysis of 74 gastroenteritis outbreaks from 1976 to 1980 (most of which were selected because they were nonbacterial), 42% were associated with Norwalk virus. These were minimal estimates because assays to detect evidence of infection were not available for most members of this group of agents until recently. Recent epidemiologic data using new assays to detect human caliciviruses indicate almost all (>90%) of reported gastroenteritis outbreaks in the United States and the Netherlands are caused by these viruses.

The prevalence of serum antibody to Norwalk virus in individuals in developed and developing countries is markedly different: in developing countries, antibody is acquired early in life and ≥90% of individuals have antibody by 2 years of age. In the United States, such antibody is acquired slowly during childhood and more rapidly in adulthood so that, by age 50, at least 80% of individuals have antibody. Although Norwalk virus may be associated with mild

Table 2 Response of 50 adult volunteers (19–39 years old) given Norwalk virus

Response	*% of infected volunteers[a] (n = 41)*	*% of uninfected volunteers (n = 9)*
Seroconversion	98	0
Antigen excretion	88	0
Infection	100	0
Asymptomatic	32	0
Symptomatic	68	0
Symptoms with clinical illness ($n = 28$)		
Diarrhea	86	0
Vomiting	57	0
Nausea	96	10
Abdominal cramps	96	0
Headache/bodyache	96	40
Chills	36	0
Fever (>37.8°C)	32	0

[a] Infection determined by antigen shedding and/or antibody response.
Data from Graham *et al* (1994).

gastroenteritis in infants and young children in developing countries, there is no evidence that it causes severe, life-threatening diarrhea in this age group.

Transmission

Human caliciviruses are highly contagious. Transmission of infection occurs by the fecal–oral route. The virus is found in the feces and has been detected in vomitus. A common source of infection, such as contaminated water or food, is frequently described. Person-to-person spread has also been demonstrated. Airborne transmission has been proposed because of the rapid spread of illness when a common source is not identified. Recent studies have shown that the virus may also be spread by individuals with subclinical infections, and virus can be shed for a longer time than previously recognized ($\geq$ 14 days postinfection).

Pathogenicity

Volunteers inoculated with Norwalk or Hawaii viruses develop characteristic transient histopathological mucosal lesions of the upper small intestine that includes broadening and blunting of the villi along with microvillus shortening on an intact mucosa. Mononuclear cell infiltration of the lamina propria and cytoplasmic vacuolization are also observed. Brush-border enzyme levels (alkaline phosphatase, sucrase and trehalase) are decreased during acute illness. Adenylate cyclase levels in the jejunal mucosa are not increased. The gastric and rectal mucosa are not affected histologically. Nausea and vomiting, common characteristics of this infection, may be caused by a delay in gastric emptying.

Clinical Features of Infection

Norwalk virus illness may begin abruptly with vomiting or diarrhea, or both. The spectrum of illness may vary widely in individual patients. For example, in experimentally infected adults, one volunteer vomited 20 times and required parenteral fluid therapy, whereas a second volunteer had no vomiting but eight diarrheal stools. The relative frequency of these and other symptoms was recently described for 50 volunteers challenged with Norwalk virus and is similar to those seen in natural outbreaks and in infection with other human caliciviruses. Of 50 volunteers orally administered Norwalk virus, 41 (82%) became infected; of these infections, 68% were symptomatic and 32% asymptomatic (**Table 2**). The most common symptoms with clinical illness are nausea, malaise and abdominal cramps. Diarrhea is usually watery without mucus, blood or leukocytes. Norwalk illness is usually mild, lasting 12–48 hours. It should be noted, however, that infrequently severe Norwalk virus gastroenteritis has been observed in middle-aged patients; in addition, Norwalk virus gastroenteritis has also been a contributing factor to the death of elderly, debilitated individuals.

Immune Response

The mechanism of immunity to human calicivirus remains an enigma as it deviates from the charac-

teristic pattern observed with most acute infectious illnesses in several ways: (1) adults are highly susceptible to both naturally occurring and experimentally induced Norwalk virus illness, as approximately 50% of unselected volunteers become ill after challenge; (2) the presence of preexisting serum antibody (measured by ELISA) does not appear to correlate with protection; and (3) short-term immunity has been demonstrated but long-term immunity may be absent. For example, 12 volunteers who were challenged with Norwalk virus on two separate occasions showed markedly different clinical responses: six became ill after initial and subsequent rechallenge 27–42 months later, whereas the others failed to develop illness following either challenge. Serum antibody did not correlate with protection. Paradoxically, individuals who became ill possessed higher levels of serum antibody to Norwalk virus than those who were resistant to challenge. The lack of correlation of serum antibody with protection may reflect the fact that the serum antibody detected was ELISA binding antibody and not neutralizing antibody. Correlation between antibody and protection may be seen when local intestinal neutralizing titers can be measured.

Diagnosis

A specific diagnosis of Norwalk virus gastroenteritis in an individual patient cannot be made on the basis of clinical signs and symptoms. Until recently, diagnosis remained essentially a research problem because reagents were not readily available. Diagnosis is made by detection of Norwalk virus in a stool specimen or the demonstration of a fourfold or more antibody increase in a patient's paired sera. Detection of a serologic response is more efficient than virus detection for demonstrating evidence of Norwalk virus infection. Early assays for these viruses included IEM (for the entire group), and RIA and/or ELISA for the Norwalk, Hawaii and Snow Mountain viruses, as well as immune adherence hemagglutination assay (IAHA) for the Norwalk virus. The cloning of Norwalk virus provided a major impetus to the study of the natural history of Norwalk virus infection because of the potentially unlimited source of antigen in the form of recombinant baculovirus-expressed virus-like particles (**Fig. 1b**). This capsid antigen shares antigenic specificity with native Norwalk virus by IEM and ELISA. The availability of animal antisera to recombinant Norwalk VLPs has also enabled the development of an ELISA for virus antigen detection. The antigen ELISA is highly sensitive but also highly specific. Similar antigen ELISAs using VLPs from Grimsby, Hawaii, Snow Mountain, Mexico and Sapporo viruses are being developed, as well as other assays that can detect more broadly cross-reactive antigenic epitopes. Until these assays become widely available, detection of the viral genome by RT-PCR is a favored method for diagnosis. Because diagnostic reagents previously were not available, it was suggested from analysis of numerous Norwalk virus outbreaks that a provisional diagnosis of Norwalk virus infection can be made if the following criteria are met: (1) bacterial or parasitic agents are not detected; (2) the incubation period is 24–48 hours; (3) vomiting occurs in at least 50% of ill individuals; and (4) the mean or median duration of illness is 12–60 hours.

Treatment

There is no specific antiviral therapy for Norwalk virus gastroenteritis: treatment therefore consists of fluid and electrolyte replacement therapy. Oral administration of isotonic fluids is usually sufficient for replacement of fluid and electrolyte loss. However, parenteral administration of fluids may be required if the vomiting or diarrhea is too severe to be managed by oral fluid replacement. Oral administration of bismuth subsalicylate can significantly reduce the severity and duration of abdominal cramps in volunteers challenged with Norwalk virus; the median duration of gastrointestinal symptoms was reduced from 20 hours to 14 hours, but this treatment did not affect significantly the number, weight and water content of stools and the level of virus excretion.

Prevention and Control

Because of the highly infectious nature of Norwalk virus infection, careful handwashing and effective disposal of contaminated material should help to reduce transmission. Careful attention to hygienic precautions in the preparation of food and monitoring the purity of drinking water or swimming facilities should also be practiced. Although the mechanisms of immunity to Norwalk virus remain unclear, the increasing recognition of the importance of these infections suggests that a vaccine might be useful if it is shown to be effective. Recombinant Norwalk virus-like particles represent one vaccine candidate. These VLPs are highly immunogenic when administered orally or intranasally to mice without adjuvant and they have also been shown to be safe and immunogenic when administered orally to volunteers. It is likely that evaluation of the immune response to these particles will help us understand immunity to these enteric infections.

Future Perspectives

Following the discovery of Norwalk virus and other human caliciviruses, a major impediment to their characterization was the inability to propagate them in tissue culture. Thus, all studies relied on the availability of particle-positive stools as the source of antigen. In spite of this limitation, important advances were made in the elucidation of the epidemiology, natural history, immunology and characterization of this group, with special emphasis on the prototype Norwalk strain. The cloning, characterization and expression of human calicivirus genomes represent another major breakthrough in the study of these viruses. Recent epidemiologic studies (allowed by new diagnostic assays) indicate that the epidemiology of infections with these viruses is not well understood, and infections are more common than realized previously. We predict that as human caliciviruses are studied, they will be found to play a significant role(s) in both acute and chronic human illness whose etiologies are currently unknown.

General Features

PPC Mertens, Pirbright Laboratory, AFRC Institute for Animal Health, Pirbright, Woking, Surrey, UK

History

Orbiviruses are responsible for a number of economically important diseases of domesticated and wild animals, including African horse sickness virus (AHSV), epizootic hemorrhagic disease virus (EHDV) and bluetongue virus (BTV). Some orbivirus species (**Table 1**) (including Great Island virus, Changuinola virus and under special circumstances AHSV) include virus strains that can infect humans. However, the incidence of such infections is unusual or rare and their study is limited. Colorado tick fever virus (CTFV), which causes a rarely fatal disease of humans, was originally classified as an orbivirus (see Classification) and will also be considered here for historical reasons.

African horse sickness (AHS) was recognized as early as 1780, during the early days of European colonization and the importation of horses into southern Africa, which resulted in epizootics and high levels of mortality in the infected animals. The causative agent was shown to be filterable in the early twentieth century and has been studied in South Africa since 1887, with antigenic variation between strains recognized as early as 1908. The virus is considered enzootic only in sub-Saharan Africa but has also caused major epizootics in the Middle East, the Indian subcontinent, North Africa and the Iberian Peninsula.

Epizootic hemorrhagic disease (EHD) has occurred as periodic outbreaks in deer in the southeastern USA since 1890. The New Jersey and South Dakota strains were isolated in 1955 and 1956, respectively, and a second serotype was isolated in the Canadian province of Alberta in 1962. Types 3 and 4 were isolated in Nigeria in 1974. The virus has also been isolated from a range of other animals including cattle, which may represent a 'reservoir' host. Ibaraki virus causes an acute febrile disease of cattle, first recorded in Japan in 1959 and, although it is also classified within serotype 2, it is regarded as an atypical EHDV (see under Genetics). There are also at least six serotypes of EHDV in Australia (1, 2, 5, 6, 7 and 18), which are known to infect cattle, buffalo and deer without causing clinical disease.

Bluetongue is believed to have been originally described as a disease of sheep and cattle in South Africa in the late eighteenth century. However, it was not until the first decade of the twentieth century that the disease was reported in the scientific literature as 'malarial catarrhal fever'. The name 'bluetongue' was suggested in 1905 by Spreull, who showed that the agent was filterable and could be transmitted to goats and cattle, causing an unapparent infection.

Until 1943 bluetongue was regarded as a disease of ruminants that was exclusive to Africa. However, at this time an outbreak occurred in Cyprus, killing approximately 2500 sheep and causing 70% mortality in infected animals. It was subsequently suggested that less virulent strains had also caused earlier but unrecognized outbreaks in the island and subsequent outbreaks occurred in 1946, 1951, 1965 and 1977. Bluetongue was recorded in the 1940s in Palestine and Turkey and by 1950 it was present in Israel. In 1948 an apparently new disease known as 'sore muzzle' was recognized in Texas and in 1952 BTV serotype 10 was isolated from sheep with this disease in California. BTV serotypes 11, 17, 13 and 2 were subsequently isolated in New Mexico in 1955, Wyoming in 1962, Idaho and Florida in 1967 and Florida in 1983, respectively. Bluetongue serotype 10, which caused a single epizootic in Spain and Portugal in 1956, was reported in West Pakistan in 1958 and 1960 and in India in 1961. The disease has continued to occur at irregular intervals in the Indian subcontinent and therefore can be regarded as enzootic in this area. Before 1977 Australia was considered to be free of bluetongue virus. However, in 1978 a virus, which had been collected 2 years earlier in the Northern Territory, was reported to be indistinguishable from BTV. Eight virus serotypes have now been isolated in Australia.

Orbiviruses have the potential to cause very high levels of mortality on introduction into areas that are usually free of the disease and which therefore contain immunologically naive populations of susceptible host species. In endemic areas, they also cause a significant reduction in the productivity of domesticated animals. Infectious BTV has been detected in bull semen. Some early experiments (although apparently not reproducible and therefore of doubtful significance) indicated the possibility of long-term persistence of virus, coupled with immunotolerance, in cattle naturally infected *in utero*. There are therefore restrictions on import of both animals and germline materials (semen and ova) from infected areas, although the exact regulations, involving quarantine periods or even a complete import ban, differ from country to country.

The dangers posed by AHSV include high mortality in horses as well as economic losses associated with uncontested equestrian events and unfilled sporting contracts. Until it was controlled, the outbreak in Spain and Portugal (1987–1991) represented a very real threat to the staging of the equestrian events at the 1992 Barcelona Olympics.

Other orbivirus serogroups include viruses which affect a range of different animal species (**Table 1**).

Colorado tick fever (CTF) was first recognized in humans as a separate clinical entity in 1930, although cases of disease with a similar description had been recorded as early as 1850. The virus was isolated in 1948 from Rocky Mountain wood ticks (*Dermacentor andersoni*), confirming its status as a vector and indicating both long-term persistent infection of ticks and trans-stadial transmission. The infection of a number of rodent species was confirmed in 1960, and detection of prolonged viremia in hibernating *Citellus lateralis* (golden-mantled ground squirrel) suggested an alternative overwintering mechanism for the virus. Humans are considered as a 'dead-end' host, while rodents and other wild species, as the 'natural hosts', represent a reservoir for the virus in the field. Although CTF was originally considered as a relatively benign infection in humans, this view was modified in 1955 when a small number of more severe cases were recorded in children, which included central nervous system involvement and at least one death. An effective vaccine against CTF was prepared in the early 1960s but because of the usually benign nature of the infection it was not used.

Eyach virus (EYAV) was isolated in Europe in 1976 and, although serologically related, is distinct from the original American isolates of CTFV. Other less closely related coltiviruses have been isolated from humans and mosquitoes in China and Indonesia (including several isolates of Banna virus in 1987) (see Classification).

Classification

Orbivirus and *Coltivirus* are two of the nine genera (*Aquareovirus, Coltivirus, Cypovirus, Fijivirus, Orbivirus, Orthoreovirus, Oryzavirus, Phytoreovirus* and *Rotavirus*) within the family *Reoviridae* (**Tables 1** and **2**). The physical, serological and chemical properties of the virus particle, as well as its host range and genome characteristics, are all important factors in virus recognition and classification within these different genera. Mature virions of BTV (the type species of the genus *Orbivirus*) do not contain a lipid envelope. However, they can leave the infected host cell by budding through the cell membrane, transiently acquiring an unstable membrane envelope in the process. The intact virus particle has a double

Table 1 Viruses of the genus *Orbivirus* (total 158) by serogroup (species), serotypes, host species and principal vector

Virus serogroup (species)	*Serotypes*	*Host species*	*Principal vector*
African horse sickness virus species (AHSV)	AHSV 1–9	Equids, dogs, elephants, camels, cattle, sheep, goats, predatory carnivores and, in special circumstances, humans	*Culicoides*
Bluetongue virus species (BTV)	BTV 1–24	Cattle, sheep, goats, camels. elephants, (domestic and wild ruminants), predatory carnivores	*Culicoides*
Changuinola virus species (CGLV)	12 named serotypes	Humans, rodents, sloths	Phlebotomine flies, mosquitoes
Chenuda virus species (CNUV)	7 named serotypes	Seabirds	Ticks: *Ornithodoros*; *Argas*
Chobar Gorge virus species[a] (CGV)	2 named serotypes	Bats	Ticks: *Ornithodoros*
Corriparta virus species (CORV)	3 named serotypes	Humans, rodents	Culicine mosquitoes
Epizootic hemorrhagic disease[f] virus species (EHDV)	EHDV 1–8	Cattle, sheep, deer, camels, llamas, wild ruminants, marsupials	*Culicoides*
Equine encephalosis virus species (EEV)	EEV 1–7	Equids	*Culicoides*
Eubenangee virus species (EUBV)	4 named serotypes	Unknown[b] (isolated from insect vectors)	*Culicoides* and anopheline, culicine mosquitoes
Great Island virus species[c,d] (GIV)	36 named serotypes	Seabirds, rodents, humans	Ticks: *Argas*; *Ornithodoros*; *Ixodes*
Ieri virus species[e] (IERIV)	3 named serotypes	Birds	*Culex* mosquitoes
Lebombo virus species (LEBV)	Single serotype (LEBV-1)	Humans, rodents	Culicine mosquitoes
Orungo virus species (ORUV)	ORUV 1–4	Humans, camels, cattle, goats, sheep, monkeys	Culicine mosquitoes
Palyam virus species (PALV)	11 named serotypes	Cattle, sheep	*Culicoides* and culicine mosquitoes
Umatilla virus species (UMAV)	4 named serotypes	Birds	Culicine mosquitoes
Wad Medani virus species (WMV)	2 named serotypes	Domestic animals	Ticks: *Boophilus*; *Rhipicephalus*; *Hyalomma*; *Argas*
Wallal virus species (WALV)	2 named serotypes	Marsupials	*Culicoides*
Warrego virus species (WARV)	2 named serotypes	Marsupials	*Culicoides* and anopheline, culicine mosquitoes
Wongorr virus species[c] (WGRV)	8 named or numbered serotypes	Cattle, macropods	*Culicoides* and mosquitoes
Tentative species and unassigned viruses within the genus:			
Andasibe virus (ANDV)			Mosquitoes
Ife virus (IFEV)		Rodents, birds, ruminants	Mosquitoes
Itupiranga virus (ITUV)			Mosquitoes
Japanaut virus (JAPV)			Mosquitoes
Kammavanpettai virus (KMPV)		Birds	Unknown
Lake Clarendon virus (LCV)		Birds	Ticks
Matucare virus (MATV)			Ticks
Ndelle virus (NDEV)		Rodents	Unknown
Tembe virus (TMEV)			Mosquitoes

[a] Chobar Gorge and Fomede are related but distinct as analyzed by complement fixation tests. These viruses form the Chobar Gorge virus species (serogroup).
[b] There is serological evidence that members of the Eubenangee virus species may infect marsupials.
[c] The 36 virus isolates, currently grouped within the Great Island virus species, as well as the eight virus isolates in the Wogorr virus species have not been extensively compared in serum neutralization assays. However, preliminary serological studies of the Great Island Virus species indicate that they may represent different serotypes.
[d] The newly recognized Great Island virus species contains virus isolates previously classified in the Kemerovo virus and Great Island virus complexes of the Kemerovo serogroup.
[e] Ieri, Arkonam and Gomoka are closely related viruses and form the Ieri virus species (serogroup).
[f] Isolate '318' may represent another, ninth, serotype of EHDV.

Table 2 Viruses of the genus *Coltivirus*, by serogroup (species), serotypes host species and principal vector

Virus serogroup (species)	*Serotypes or nucleotypes*[a]	*Host species*	*Principal vector*
Coltivirus group A			
Colorado tick fever virus species (CTFV)	2 named serotypes (CTFV and S6-14-03)	Rodents, humans	Ixodidae ticks
Eyach virus species (EYAV)	3 named nucleotypes (Eyach virus, AR 577, AR 578)	Possibly humans	Ixodidae ticks
Coltivirus group B			
JKT-7075 virus species (JKT-7075)	1 named nucleotype (JKT-7075)		(Culex mosquitoes)
JKT-6423 virus species (JKT-6423)	4 named nucleotypes (JKT-6423, JKT-6969, JKT-7043, Banna virus)	Humans, other vertebrates	Culex and anopheles mosquitoes
Tentative species and unassigned viruses within the genus			
Chinese isolates that belong most probably to JKT-6423 species based on serological and electrophoretic profiles analyses: HN59, HN131, HN191, HN295			

[a] Nucleotypes distinguishable by RNA sequence analysis and differences in genome segment migration patterns (electropherotype).

protein capsid, with a M_r of approximately 10.8×10^7 and a diameter of 80 nm. The virion is spherical in appearance but has icosahedral symmetry, with an indistinct surface structure as viewed by negative staining and electron microscopy (**Fig. 1**). Removal of the outermost capsid layer releases 'core particles' which have an M_r of approximately 6.7×10^7 and icosahedral symmetry but also appear spherical. The core itself is composed of an outer core surface layer with a maximum diameter of 73 nm and an internal 'subcore' protein layer which has a maximum diameter of 59 nm (sizes determined for BTV cores by x-ray crystallography). The core surface is composed entirely of the VP7 protein, arranged as a lattice with $T = 13\ l$ symmetry, producing characteristic ring-shaped capsomeres that gave rise to the name for the genus, *Orbivirus* (Latin *orbis* = ring or circle). These rings, which can be seen by electron microscopy, are composed of either five or six separate wedge-shaped units, which represent trimers of VP7(T13) (illustrated for AHSV in **Fig. 1**).

The orbivirus genome is composed of ten linear segments of double-stranded RNA (dsRNA) that are identified as segment 1 to segment 10, in order of increasing electrophoretic mobility. A single copy of each segment is packaged per virus particle (ranging in size (BTV) from 3954 to 822 bp: total size of 19.2 kbp, total M_r of 13.1×10^6). The migration pattern of the genome segments during agarose gel electrophoresis (and therefore their relative sizes) appears to be characteristic of the virus serogroup (species). Replication of orbiviruses is associated with the formation of viral 'tubules' (composed of non-structural protein NS1) and viral inclusion bodies (VIBs), which are the site of virus morphogenesis, in the cytoplasm of infected cells.

Within each genus of the family *Reoviridae* the prime determinant for inclusion of virus isolates within a single virus species is their ability to exchange (reassort) genome segments during co-infection of individual cells, thereby exchanging genetic information and generating viable progeny virus strains. However, data providing direct evidence of segment reassortment between isolates is limited and other parameters can be used to examine the level of similarity that exists between isolates. These data can then be used to predict the compatibility of strains for reassortment and to identify the serogroups (orbiviruses) or nucleotypes (coltiviruses) that are recognized as distinct virus species. The different species parameters used to give this polythetic definition of virus species within the family *Reoviridae* include: serological comparisons (identification of serogroups); comparisons of RNA/protein sequences; crosshybridization analyses; analysis of conserved terminal regions on the RNA; identification as a recognized virus serotype (neutralization types) that is already classified within a known virus species; host range; and analysis of genome segment electrophoretic migration patterns (electropherotype) by agarose gel electrophoresis.

The orbiviruses were initially divided into serogroups (species) on the basis of crossreaction of isolates in complement fixation (CF), agar gel immunodiffusion (AGID) and fluorescent antibody tests. More recently enzyme linked immunosorbent assay (ELISA) and competition ELISA, using either serogroup specific monoclonal antibodies (to protein VP7

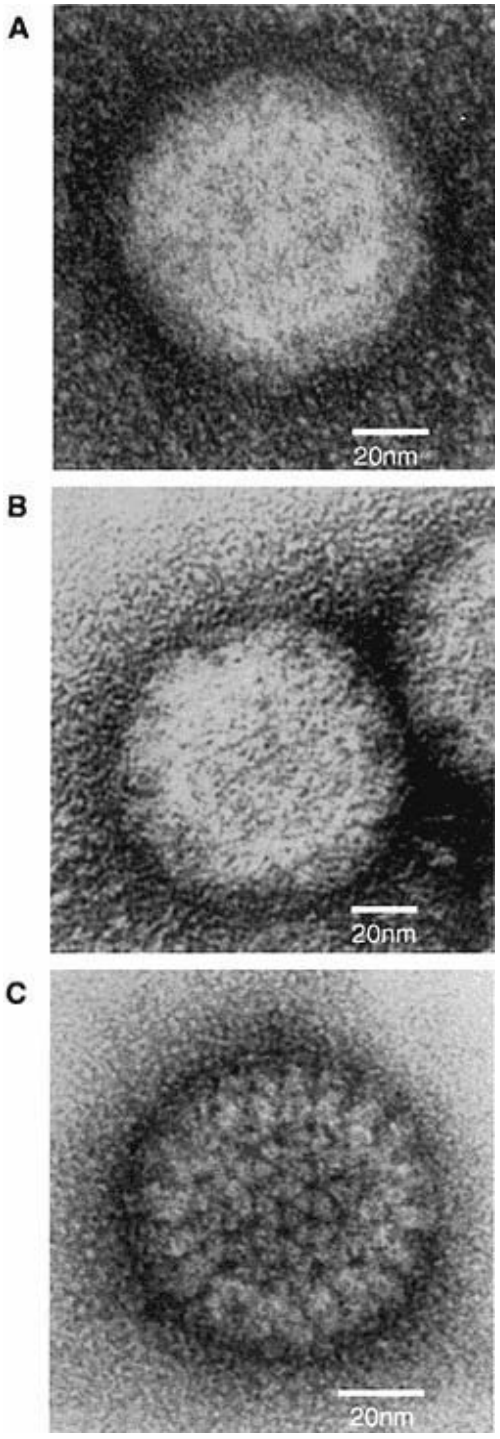

Figure 1 AHSV virus and core particles. Electron micrographs of AHSV serotype 9 particles, purified using CsCl gradient centrifugation and stained with 2% aqueous uranyl acetate. (**A**) Virus particles, showing the relatively featureless surface structure. (**B**) Infectious subviral particles (ISVP), containing cleaved outer capsid protein VP2 and showing some discontinuities in the outer capsid layer. (**C**) Core particles, from which the entire outer capsid has been removed, to reveal the structure of the VP7(T13) core surface layer and showing the ring-shaped capsomeres made up of VP7(T13) trimers, which give rise to the name 'orbivirus'.

(T13)) or polyclonal antisera, have been used to detect BTV, AHSV or EHDV specific antigens, or virus specific antibodies in sera from infected animals. Since these tests are accepted internationally for diagnostic purposes, they are therefore also being used for the classification of unknown viruses within specific orbivirus serogroups (species).

Low level but significant crossreactions can exist between some members of different serogroups, suggesting relatively closer relationships and a possible requirement for supergroups (for example a group to include AHSV, bluetongue virus, Eubenangee virus, equine encephalosis virus (EEV) and EHDV). The viruses previously classified within the Kemerovo serogroup of orbiviruses were originally separated into four antigenic complexes, which showed some serological crossreactions with each other and with the newly recognized Ieri virus species (**Table 1**). However, the viruses within these complexes have recently been reclassified, on the basis of compatibility for reassortment, as three distinct species. These are Great Island virus (containing the Great Island and Kemerovo virus complexes), Chenuda virus and Wad Medani virus (**Table 1**). There is also some evidence that larger differences can exist between serotypes within a single serogroup or species (for example EHDV), suggesting that more than one test system may be required to conclusively classify individual viruses within specific serogroups.

Colorado tick fever virus (CTFV) is the prototype species of the genus *Coltivirus* (sigla from Colorado tick fever virus). CTFV particles also have a double-layered capsid, with an estimated maximum diameter of 60–80 nm and a central core that is about 50 nm in diameter. Electron microscopic studies using negative staining have shown that particles have icosahedral symmetry and a relatively smooth surface structure. The majority of the viral particles are nonenveloped, but a few acquire an envelope during passage through the endoplasmic reticulum. Coltiviruses are found associated with intracytoplasmic granular matrices (which may be similar to VIBs of the orbiviruses), arrays of intracytoplasmic filaments or tubules and fine kinky threads. The coltivirus genome consists of 12 dsRNA segments that are named segment 1 to segment 12 in order of electrophoretic migration. The genome comprises approximately 28 kbp, with segment lengths ranging between 4.14 kbp and 675 bp (total M_r approximately 18×10^6). The difference in genome segment number was the primary reason for the reclassification of the coltiviruses as a separate genus within the family *Reoviridae*. Isolate S6-14-03, from a hare collected in California in 1976, is classified as a second serotype of CTFV (**Table 2**). Eyach virus (EYAV), isolated from *Ixodes* ticks in

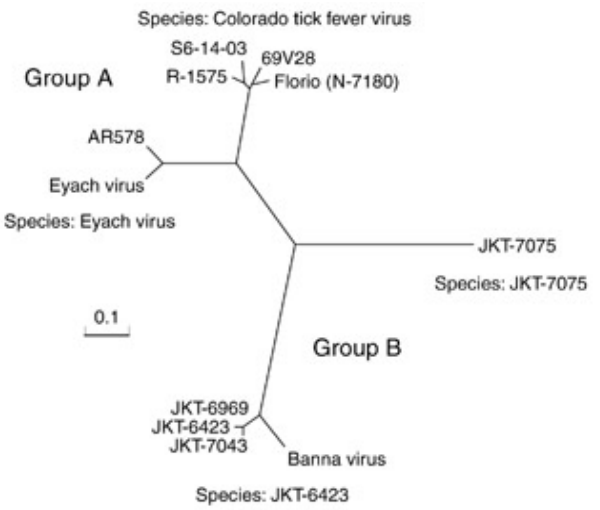

Figure 2 Unrooted neighbor-joining tree created using the program 'Clustal X', depicting groupings for the deduced amino acid sequence of translation products from genome segment 12 of different coltiviruses. The two groups (A and B) that are currently recognized are labelled. Bar marker represents the number of substitutions per site. The relationships illustrated were not corrected for multiple amino acid substitutions. (The RNA sequence data was kindly provided by Houssam Attoui.)

West Germany and France, represents a second distinct species within the group A coltiviruses, distinguished on the basis of serology and RNA sequence analysis (only 50–60% RNA sequence homology was detected in genome segment 12, between these European and American isolates; **Fig. 2**). However, EYAV does show some serological crossreaction with S6-14-03 in crossneutralization assays.

The Indonesian (JKT6423, JKT6969, JKT7041, JKT7075) and Chinese isolates of coltivirus (HN59, HN131, HN191, HN295, Banna virus) show no significant RNA sequence homology in the smaller genome segments with group A viruses but do show some significant amino acid sequence similarity and have been classified as group B coltiviruses (**Fig. 2**). Group B also contains two species (nucleotypes: JKT-7075 and JKT-6423; **Table 2**), which can be separated on the basis of RNA genome segment migration patterns (electropherotype) and RNA sequence analyses (sharing 40–60% RNA sequence homology in the smaller genome segments) (**Fig. 2**).

Geographic and Seasonal Distribution

Bluetongue virus is transmitted by *Culicoides* species (biting midges) and is only enzootic in areas where adults of the vector species are present and active for the majority or all of the year, thus maintaining a continuous series of virus infection cycles in vector and vertebrate host species. The species of *Culicoides* known to act as vectors for BTV are most active in the temperature range 18–29° and are almost inactive below 10° or above 30°. Relatively small rises in temperature within this active range can also increase their efficiency as vectors. Temperatures below 0°, which are maintained for approximately 2 hours or more, will kill adult *Culicoides*; therefore, in areas at relatively greater latitudes the vectors may not be present or active in significant numbers throughout the whole year, and the virus may be absent or only maintained at low levels for part of the year (usually in winter). Under these circumstances the incidence of infection and disease may be dependent on reintroduction in each year that it occurs, or can show major seasonal fluctuations in line with that of vector populations (see Epidemiology). Such a situation is illustrated by the outbreak of AHS in Spain, Portugal and Morocco (1987–1991), where cases were detected only in late summer and autumn. The effects of high temperatures together with relatively low humidity may be particularly significant in Africa, where it is evident that the Sahara represents an effective barrier to the spread of bluetongue and other orbiviruses, from sub-Saharan Africa to the Mediterranean region.

The distribution of bluetongue is effectively restricted to a band around the world between 50° North and 30° South in America and between 40° North and 35° South in the rest of the world (**Fig. 3**). Although the distribution of BTV and some other orbiviruses is relatively widespread, not all of the serotypes of each species are present at each location. In consequence the introduction of a new serotype into areas already enzootic for BTV can result in disease, even in host animals with neutralizing antibodies against those types already present.

Those orbiviruses and coltiviruses that are transmitted by tick vectors show geographic distribution which is also critically dependent on that of vector species. In the case of CTFV this is primarily the tick *Dermacentor andersoni*. Both vector and disease are principally limited to areas of the states and provinces in the western half of America and Canada (**Fig. 3**). The occasional isolation of virus outside this area may reflect a wider distribution or the significance of other vector species. The incidence of CTF shows seasonal variations in response to the peak activity of rodents and the adult tick population in spring and early summer. Overall, the geographic distribution of the coltiviruses is less well studied than that of the orbiviruses. However, the isolation of viruses of group A from America and Europe, and group B

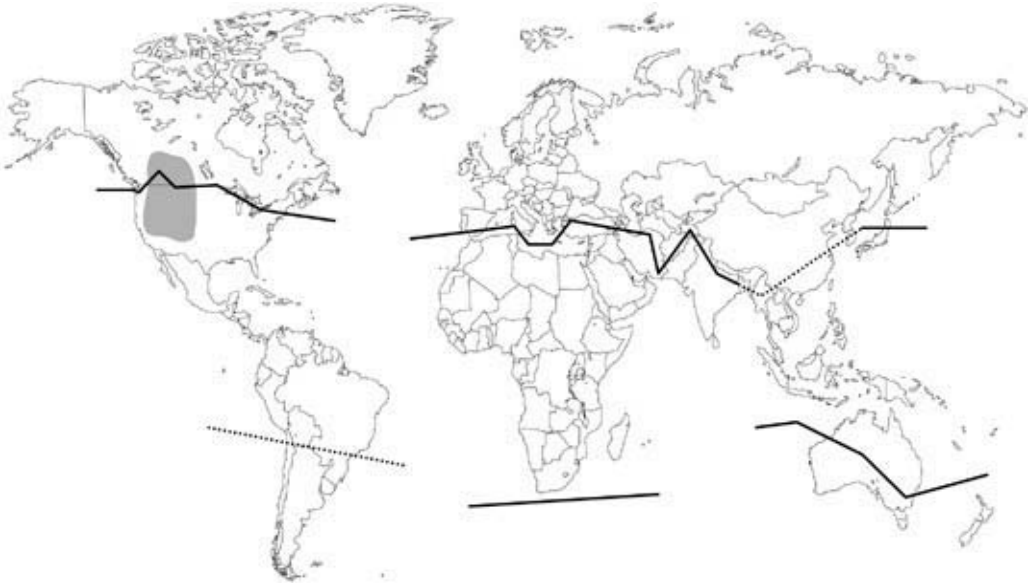

Figure 3 World distribution of the members of the bluetongue virus group and of Colorado tick fever virus (shaded area). The northern and southern limits of BTV distribution are indicated by a line. The dotted line indicates where the limit is uncertain. (From data supplied by R. F. Sellers (personal communication) and from Knudson DL and Monath TP).

viruses from Indonesia and China, suggests that they may be widely distributed.

Host Range and Virus Propagation

The importance of the diseases caused by some orbiviruses and coltiviruses has led to a tendency to consider them primarily in the context of their vertebrate hosts or in mammalian systems. However, the essential role of the vectors in transmission demonstrates the importance of virus infection and growth in insect or arthropod systems. This also suggests that some aspects of virus replication or its properties may be the result of adaptation to the vector rather than the vertebrate host species (see Transmission and Tissue Tropism). The host and vector range of the members of the different *Orbivirus* and *Coltivirus* species is outlined in **Tables 1** and **2**. In some cases the virus has been isolated from an invertebrate species only and no vertebrate host is known.

Information concerning the infection and replication of these viruses in the arthropod vectors is limited. The best studied of the orbiviruses in this respect is BTV and, although there are in excess of 1000 species of *Culicoides* worldwide, only 17 have been connected with BTV and six are known to be capable of transmitting the virus. These include *C. variipennis, C. imicola, C. fulvus, C. actoni, C. wadai* and *C. nubeculosus,* with possible involvement by *C. insignis* and *C. brevitarsis*. On purely epidemiological grounds it seems unlikely that many of the remaining *Culicoides* species will prove to be competent vectors and a large proportion of them may be refractory to infection. Confirmation of this and an understanding of the molecular basis for vector susceptibility and competence will depend on further study.

Members of the BTV and EHDV serogroups are normally restricted to domesticated and wild ruminants, including sheep, goats, cattle, camels, llamas, deer and antelope. African horse sickness is considered to be a disease primarily of horses and other equids. However, eating infected meat has been reported to cause a fatal viral pneumonia in dogs. BTV and AHSV have also been reported to infect large carnivores in Africa. There is serological evidence that AHSV can infect elephants and AHSV isolates have been made from camels, cattle, sheep and goats. Under unusual circumstances, involving inhalation of dust from freeze dried preparations of neurotropic vaccine strains, there is evidence to indicate that AHSV can infect humans, causing encephalitis and retinitis. Any possible risk to human health posed by consumption of AHSV-infected meat has not yet been fully evaluated.

Some orbiviruses can also infect marsupials, humans, rodents, bats, monkeys, sloths and (in the case of the Great Island, Ieri and Umatilla virus species) particularly birds. The coltiviruses include virus species which have been detected in ticks, rodents, humans and other vertebrates. Under experimental conditions many orbiviruses can infect mice or embryonated chicken eggs and these animal hosts

are routinely used for virus isolation from infected blood samples, or from insect vectors. The high levels of mortality in adult mice, if infected via a nasal route with some strains of AHSV, may have relevance to the reported cases of AHSV in humans believed to have become infected with neurotropic vaccine strains by the same route. Such experimental animal systems can provide useful models for studies of virulence factors in these viruses, as has been shown with members of the Great Island and AHSV serogroups (see Pathogenicity).

For most experimental purposes, including analyses of virus serotype in serum neutralization tests, the viruses are grown in tissue culture systems. Details of purification methods have been published for whole orbivirus particles, infectious subviral particles (ISVPs), core particles, attenuated vaccines, and antigens for diagnostic purposes, using BHK21, Vero, mouse myeloma (NSI) or other cell lines. Bluetongue virus has also been shown to grow in an *Aedes albopictus* and a *Culicoides* cell line (C6/36 cells and KC cells respectively).

Genetics

When two compatible orbiviruses or coltiviruses co-infect the same cell, their genome segments can reassort, so that the resultant progeny virus particles contain a mixture of segments derived from the two parental viruses (see Classification). Analysis by high percentage (e.g. 10%) polyacrylamide gel electrophoresis (PAGE) provides a simple method for separation of different dsRNA genome segments and can often be used to distinguish segments of identical size from even closely related viruses. This separation appears to reflect variation in the primary sequence of the RNA. It is therefore ideally suited for analysis of the parental origins of the genome segments present in reassortant progeny viruses. Using this technique the process of reassortment has been shown to occur in tissue culture systems, in some cases with sufficiently high frequency for the parental virus genotypes to be present as a minority in the progeny virus population. The process of reassortment has also been shown to occur in both vertebrate and invertebrate hosts and is therefore considered to be a potentially important factor in the generation of genetic diversity in virus populations in the field.

The coding relationships between the genome segments and viral proteins have been determined by direct *in vitro* translation of individually purified and denatured genome segments of BTV, EHDV and AHSV. Variation in dsRNA migration rates during PAGE, leading to changes in migration order of genome segments from different viruses, has led to some confusion over the coding assignments for BTV. However, the migration patterns of bluetongue virus genome segments, when analysed by agarose gel electrophoresis (AGE), appear to be solely dependent on molecular weight and are remarkably consistent, even for isolates of different virus serotypes or from different geographical origins. Using migration order during AGE to identify different BTV genome segments, it is therefore possible to produce a consistent coding assignment that is applicable to the BTV serogroup as a whole.

Other orbivirus species also produce variable genome profiles when analyzed by PAGE and more consistent profiles when compared by AGE. These include AHSV, Palyam, Corripata and EHDV serogroup members. The consistent nature of the AGE electropherotype has proved to be of real value in determinating the species of unknown or incorrectly classified virus isolates (results which have been confirmed by subsequent serological analyses). Virus isolates from the EHDV serogroup that have been compared by AGE analysis of their genome profile can be divided into two groups. The Ibaraki isolate (Japan) and isolates from Australia are distinct from the American, African and Indian isolates, giving an RNA migration pattern that shows greater similarity to that of the BTV serogroup members (particularly in the faster migration of genome segment 9). These data suggest that in relative terms the EHDV isolates from Australia and the Far East have a deletion in this genome segment.

By making reassortant viruses from two parental strains with distinct characteristics it is possible to relate differences in the properties of the individual progeny virus strains with specific genome segments and, by using genome segment to protein coding assignments, with specific viral proteins. This 'genetic' approach has been applied to studies of virulence factors in Great Island virus (GIV) and AHSV species (see Pathogenicity) and to analyses of outer capsid protein involvement in determination of virus serotype in both BTV and GIV species (see Evolution and Immune Response).

Although reassortment can take place with high frequency, the genome composition of orbivirus strains can apparently remain relatively constant over long periods in the field, even though cocirculating with similar viruses. This stability may result from incompatibility, in terms of their potential for reassortment, between certain viruses. There may also be functional constraints which affect the relative viability of reassortant progeny virus in the field. In this context it has been found that at least some reassortant viruses have increased replication times, or form smaller plaques in tissue culture systems.

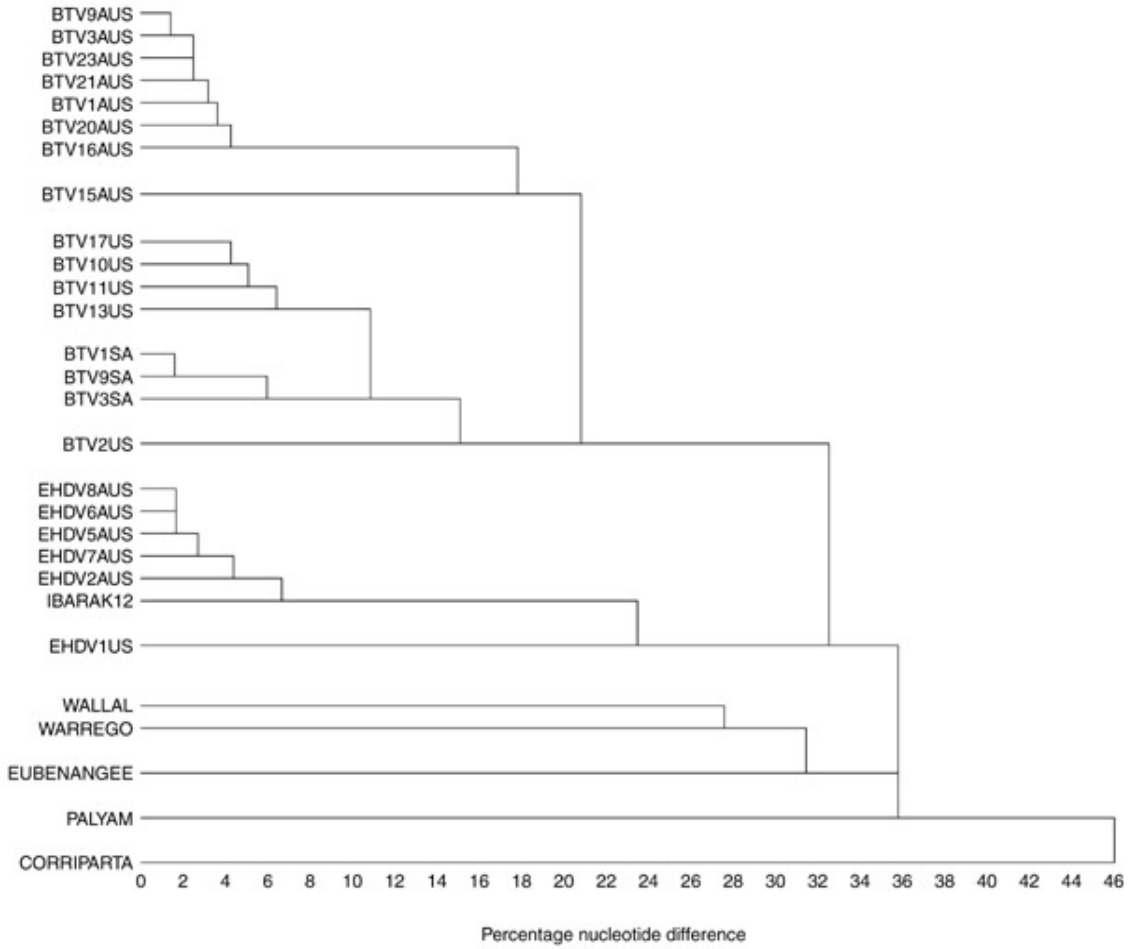

Figure 4 Phylogenetic associations of orbivirus isolates from Australia (AUS), South Africa (SA) and North America (US). Equivalent regions of the VP3 gene for the orbivirus isolates were compared using the DNADIST and KITSCH programmes to generate a single most parsimonious tree. (From RNA sequence data kindly provided by Allan Gould, from Gould A and Pritchard L I (1990).

Evolution

It has been suggested by several authors that the concept of the 'species' as 'the largest aggregate of individual organisms that evolves as a unit having a common gene pool' has direct relevance to these segmented genome viruses. The exchange of genetic information by reassortment of genome segments is in some ways directly analogous to sexual reproduction. Available information indicates that, although reassortment can occur within orbivirus serogroups, for example between members within the Great Island virus, Wallal virus, AHSV or BTV serogroups, there is no evidence for reassortment between members of different serogroups. These data provide the basis for the current classification of orbiviruses into species, primarily on their compatibility for reassortment.

Within the different orbivirus species (for example BTV) there is evidence of RNA and protein sequence variation depending on the geographical origin of the virus isolate, irrespective of virus serotype. This may reflect the accumulation of mutations, coupled with reassortment, resulting in coevolution of the common gene pool within separated locations (for example, Australia, Africa and North America). Gould and Pritchard have suggested that the term 'topotype' should be applied to each distinct group. The initial crosscomparisons, using representative RNA sequence data from genome segment 3 of BTV (**Fig. 4**), indicate that viruses can be grouped within a single 'topotype' if they show <8% sequence difference in this genome segment, while BTV or EHDV strains which contain >11% but <23% variation can be grouped within different topotypes. These data also demonstrate higher levels of sequence variation in genome segment 3 between members of different serogroups, in most cases >30%, although Wallal and Warrego virus species appear to have a relatively

closer relationship, with only approximately 26% variation. Further study is still required to determine both the number of different topotype groups (seven have been recognized) and to confirm that such sequence variation remains consistent across the majority of genome segments within a single virus isolate, despite the possibility of genome segment reassortment with other virus strains occurring in the field. These observations clearly demonstrate that not all isolates of a single *Orbivirus* serotype can be regarded as identical, or even necessarily very similar, and care must be taken to identify precisely each virus strain isolated or used for any research work.

The virus serotype within each *Orbivirus* serogroup is controlled by the specificity of interactions between neutralizing antibodies with the proteins that compose the outer capsid shell and therefore by the genome segments from which these proteins are translated. The two major outer capsid proteins of BTV (proteins VP2 and VP5) are encoded by genome segments 2 and 6, respectively (as separated by AGE). Segment 2 and to a lesser extent segment 6 exhibit a higher degree of RNA sequence variation than the other genome segments, which correlates with virus serotype. This reflects the interaction of VP2 with neutralizing antibodies and its involvement in determination of virus serotype. Reassortment studies have indicated that if the protein VP5 sequence is significantly different between parental strains, it may also have a role in controlling the progeny virus serotype. Although VP5 does not appear to contain neutralizing epitopes, it has been suggested that it may influence virus serotype indirectly by affecting the conformation of protein VP2. In cases where segment 2 and 6 reassortment has been shown to have such an effect, there is at least some evidence of one-way serological crossreactions with the parental virus types, indicating the exposure of 'new' neutralizing epitopes in the progeny particles. Considerable difficulties have been encountered in producing and isolating such VP2/VP5 reassortants, and a longer replication time has been observed in at least one such case, suggesting that a functional linkage may exist between the outer capsid proteins. Production and survival of this type of reassortant between parental viruses containing significantly different forms of genome segments 2 and 6 may therefore be particularly rare in the field. However, it is conceivable that any consequent exposure of new neutralizing epitopes could play a very significant role in the generation and evolution of new virus serotypes.

Serologic Relationships and Variability

Orbivirus genome segments coding for the non-structural proteins (segments 5, 8 and 10 of BTV, encoding proteins NS1(TuP), NS2(ViP), and NS3/NS3a respectively) and the core structural proteins (segments 1, 3, 4, 9 and 7 of BTV, encoding proteins VP1(Pol), VP3(T2), VP4(Cap), VP6/VP6a(Hel) and VP7(T13), respectively), are usually more conserved within serogroups than those coding for the outer capsid proteins (segments 2 and 6 of BTV, encoding proteins VP2 and VP5, respectively); however, in the AHSV species, genome segment 10 (coding for protein NS3) shows a relatively high level of sequence variation (up to 35%) that does not correlate with virus serotype. (Note: TuP, tubule protein; ViP, viral inclusion body matrix protein; Pol, polymerase; T2, major virion structural protein with $T = 2$ icosahedral symmetry; Cap, capping enzyme (guanylyltransferase and transmethylase); hel, Helicase; T13, major virion structural protein with $T = 13$ icosahedral symmetry.) On the basis of RNA sequence analyses and serology, genome segment 10 and protein NS3 of AHSV can be divided into three groups (α, β and γ) (**Fig. 5**). Reassortment studies using a mouse model system have demonstrated an effect of NS3, from different groups, in the control of virulence. However, these studies have also indicated that variations in NS3 can influence the timing of progeny virus particle release from infected insect cells. The vector status of individual insects is at least partially determined by 'barriers' that influence the release and dissemination of virus from the initial site of infection in the gut (see Transmission and Tissue Tropism). The nature of genome segment 10 could therefore also have some effect on the ability of *Culicoides* to transmit AHSV.

The different *Orbivirus* species (serogroups) can

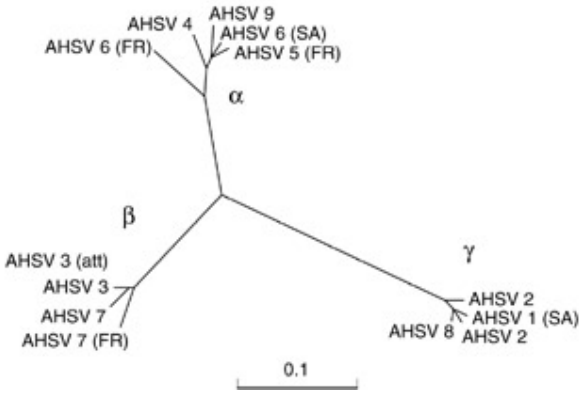

Figure 5 Unrooted neighbor-joining trees depicting groupings for genome segment 10 from isolates of various African horse sickness virus serotypes based on nucleotide differences. Three groups are evident, labeled as α, β and γ. Bar represents 1% nucleotide variation. (The RNA sequence data was kindly provided by Lesley-Ann Martin. Nick Knowles constructed the phylogenetic trees.)

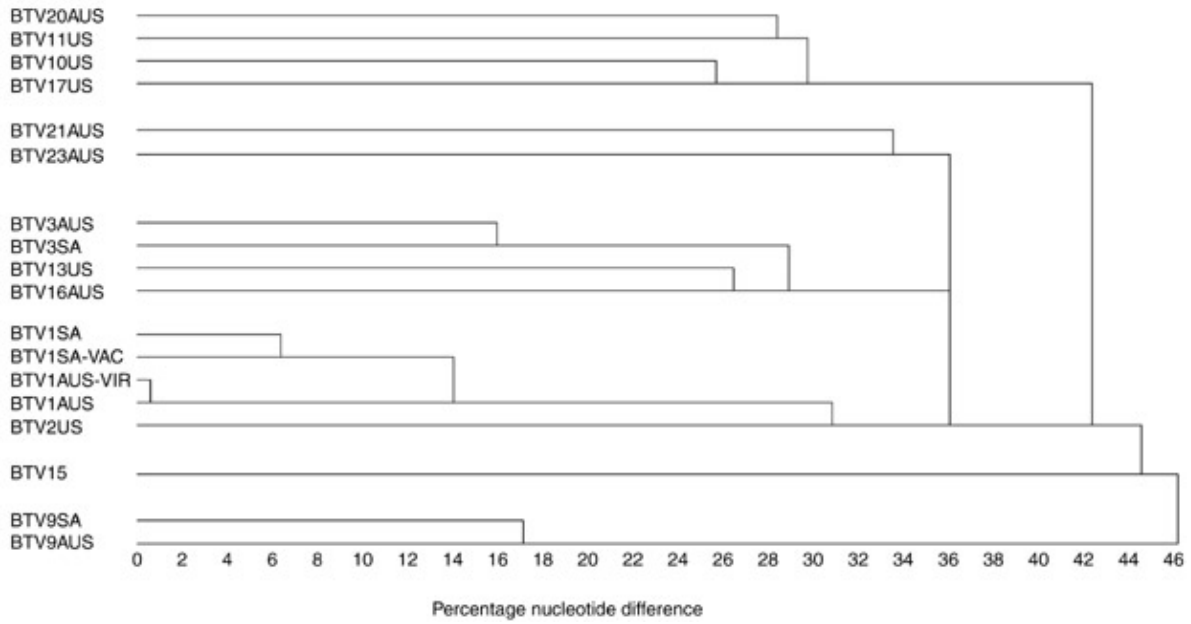

Figure 6 Phylogenetic associations of BTV serotypes from different geographic locations of the world. Equivalent regions of each VP2 gene (from nucleotide 975 to 1190; relative to BTV1AUS VP2) was used to calculate the interrelationships between each BTV serotype. (Data kindly provided by Allan Gould.)

be distinguished by complement fixation, agar gel immunodiffusion, fluorescent antibody staining, ELISA and competition ELISA, using reactions with 'reference' preparations of group specific antibodies. In several of these test systems, VP7(T13), which is the protein on the surface of the virus core of BTV, has been shown to be immunodominant and of major significance. However, RNA sequence data indicate that the gene coding for VP7(T13) is more variable within a serogroup (species) than those encoding some of the other core and nonstructural proteins. This may indicate some partial exposure of VP7(T13) to antibody selective pressure. It has been reported that some VP7 specific monoclonal antibodies can react with whole virus particles, leading to suggestions that this core surface protein is partially exposed in the intact virion. However, more recent studies indicate that this reaction may result from damage to the outer capsid during sample preparation and that the VP7(T13) core surface layer is not normally exposed in the intact virion.

From the practical point of view, sequences from genome segment 5 (coding for nonstructural protein NS1(TuP)) may be most suitable for use as serogroup specific nucleic acid probes or in group specific PCR-based test systems. This is partly because this genome segment is transcribed into the most abundant viral mRNA in infected cells but also because it is reported to be highly conserved within an orbivirus species (serogroup), while displaying >40% sequence variation between species.

The most variable but serotype-specific of the BTV genome segments and proteins are segment 2 and VP2 (the major neutralization antigen), respectively. From the limited data that are currently available for BTV (for example, between bases 975 and 1190 of segment 2; **Fig. 6**), viruses within the same serotype, regardless of geographic origin or 'topotype', appear to contain <19% RNA sequence variation in genome segment 2. In contrast, viruses that are classified as different serotypes appear to contain >26% RNA sequence variation in the same region. However, additional studies using crosshybridization of nucleic acid probes generated from genome segment 2 have demonstrated that at high washing stringencies, although such probes can be used to detect some isolates of the same serotype, they do not detect them all, while at lower stringencies they will also bind to RNA from other distinct but closely related serotypes. It may not therefore be possible to produce 'serotype specific' nucleic acid probes from segment 2 that are capable of simultaneously detecting all and only members of each individual serotype.

The variation in segment 2 that is observed within a serotype may reflect mutations, like those between 'topotypes', that have accumulated in geographically separated viruses. There is also a wide range of variation in the percentage difference in segment 2

nucleotide sequence that is observed between viruses from different serotypes. This provides evidence for relatively closer grouping of some serotypes (for example BTV 3, 13 and 16, with <32% RNA sequence difference; **Fig. 6**), as well as and relatively more distant relationships between 'nucleotype' groups, with higher levels of variation (>34%, <46%). The limited data presented in **Fig. 6** suggest that each genome segment 2 from viruses within a single serotype may have a common ancestry. These data also suggest relatively closer ancestral relationships for genome segment 2 from virus serotypes within a single 'nucleotype' and may have important implications for the origins and spread of different virus serotypes found in different parts of the world.

Data from the analysis of reassortant viruses demonstrate that variation in genome segment 6 (coding for VP5, the other major outer coat protein of BTV) can also have a significant influence on virus serotype. In viruses containing relatively similar VP2 proteins, the influence exerted by VP5 on serotype may further complicate attempts to develop serotype specific nucleic acid probes based on the RNA sequence of genome segment 2 alone.

Epidemiology

Competent individuals of vector species are thought to become infected with orbiviruses for life. However, adults of many vectors are relatively short lived and there is no evidence for transovarial transmission in the vector, or for high levels of persistent viremia in the vertebrate host. BTV and the other orbiviruses, which are transmitted by short-lived *Culicoides* species, are therefore thought to be maintained in the field primarily by continuous cycles of infection through the host and vector. In consequence, their distribution is dependent on the abundance of both susceptible hosts and the competent adult vectors. The vertebrate hosts have a wide distribution and relatively stable population numbers throughout the year. The distribution of the vectors as well as their level of activity and longevity is therefore a critical factor for both the spread and maintenance of these viruses in the field (see Seasonal and Geographic Distribution).

The most significant factors affecting vector activity and distribution are climate and the availability of suitable breeding sites. In areas where cold weather conditions (particularly frosts) occur during part of the year, adult individuals of many vector species may be absent or inactive, in terms of virus transmission (see Seasonal and Geographic Distribution), for periods longer than the 'normal' viremia in the infected vertebrate host (up to 100 days in cattle and 30 days in sheep; see Transmission and Tissue Tropism). Under these conditions the virus cannot reinfect emerging flies and is unable to persist in the field; outbreaks of disease will therefore be dependent on reintroduction during each year that it occurs. In consequence there are geographically isolated areas of the world, for example the UK, where susceptible and serologically naive host populations coexist with seasonally variable but competent populations of vector species. Introduction of the virus into such an area could result in a devastating, even if short-lived, epizootic.

Viruses, including orbiviruses, can be introduced into new areas by importation of infected animals (for example import of an AHSV infected zebra into Spain in 1987). However, there is evidence to indicate that introduction of infected individuals of vector species can also result in outbreaks of disease. *Culicoides* species and other flying insects can be moved large distances, even across oceans, by wind currents and, if infected, can result in wind-borne spread of these viruses. Transmission by this route is believed to have occurred during movement of BTV serotype 4 from Turkey/Eastern Mediterranean region/Syria to Cyprus in August 1977, from Cyprus to Turkey in October 1977 and movement of AHSV from Turkey to Cyprus in 1960.

Ticks have a longer lifespan (>1 year) than mosquitoes or *Culicoides* species (<2 months); therefore, although individuals of all vector species are believed to become infected for life, only the tick vectors can provide a reliable overwintering mechanism for virus. Seasonal distribution of CTFV and the tick-borne orbiviruses is therefore less dependent on continuous reinfection of the emerging vector population, but is dependent on seasonal activity of individuals of the vector species.

The importance of bluetongue as a disease is most clearly illustrated on those occasions when the virus has been introduced into areas from which it is normally absent, containing both competent vector species and serologically naive but susceptible populations of mammalian hosts. Arguably the most extreme example of this is the major epizootic of bluetongue caused by a serotype 10 virus in the Iberian peninsula in 1956. Within the first 4 months the disease had killed approximately 180 000 sheep, with a mortality of close to 75%. Policies of quarantine, slaughter and compulsory annual vaccination (subsequently discontinued) led to the eradication of the disease from this area within 4 years and no subsequent cases have been reported. There is evidence that bluetongue virus may also cause significant economic losses in enzootic situations around the world, although these are usually less dramatic,

resulting in part from decreased productivity and reduced milk yield rather than extensive fatalities. AHSV is believed to persist in Africa as the result of a normal infectious cycle through an unknown mammalian host species (probably zebra) and *Culicoides*. In this context the horse can be regarded as simply an indicator host for the presence of the virus. The dangers posed by AHSV are also illustrated by the results of its recent introduction into Spain (1987), causing an outbreak of AHS that continued for 4 years and required extensive human intervention to prevent its long-term persistence in the southern part of the Iberian Peninsula. The virus spread to Portugal and Morocco, persisting in Mediterranean Africa up to 1991, causing the loss of more than 3000 horses with a mortality of greater than 95% in infected animals. Earlier epidemics in 1959–1961, in the Middle East and Indian subcontinent, were reported to have killed as many as 300 000 horses, donkeys and mules. The epizootic of bluetongue in Spain in 1956–1960 and the persistence of AHS in that area both illustrate the importance of import/export regulations that are designed to prevent the spread of new viruses (e.g. AHSV) to countries currently free of the disease, for example Australia and the Americas.

EHDV causes disease and significant levels of mortality in wild white-tailed deer populations in North America but does not appear to severely affect sheep or cattle. Ibaraki virus, which is classified as an EHDV, albeit atypical, is serologically similar to EHDV serotype 2 (Alberta strain) but does not cause disease in sheep. However, Ibaraki virus has produced symptoms similar to clinical bluetongue in Japanese cattle. There are also at least six serotypes of EHDV in Australia known to infect cattle, buffalo and deer without causing clinical disease. Isolations of EHDV have been made in Africa and India and serological surveys have indicated that it is present in the Far East (Japan and Korea) in the eastern Mediterranean region, South America and Indonesia.

Transmission and Tissue Tropism

Multiplication of bluetongue virus takes place in spleen, bone marrow, macrophages and vascular endothelial cells. BTV has been isolated from blood for up to 30 days postinfection in sheep and up to 100 days in cattle. A short-lived viremia has also been observed in newborn lambs naturally infected *in utero*, which may effectively extend the normal period of viremia in sheep. This may also have significance in overwintering of the virus (see Epidemiology).

Individuals of vector species become infected by ingestion of viremic blood from infected vertebrate hosts. *Culicoides* can ingest approximately 0.1 μl of blood, which may contain approximately 100 $TCID_{50}$ (50% tissue culture infectious dose) of virus. BTV is believed to initiate infection via the cells of the midgut wall. Once infection of these cells is established, progeny virus particles are released into the insect hemocele. Secondary targets may then become infected, including the fat body and, most significantly from a transmission point of view, the salivary gland. The release of virus into saliva is thought to be essential for reinfection of the vertebrate host during subsequent blood meals. At ambient temperatures of 25°, productive infection of the salivary glands and the ability to transmit the virus takes approximately 7 days after ingestion of the original viremic blood meal. Females of the *Culicoides* vectors take blood meals from vertebrate hosts prior to egg laying. They can be expected to take a blood meal approximately 3 days after they emerge, laying eggs for the first time 2 days later. Although they can feed again 1 day after egg laying, the earliest they will be able to transmit the virus is approximately 7 days after infection (10 days after emergence), assuming that conditions remain favourable for relatively active behaviour (see Geographic and Seasonal Distribution).

There is considerable variation between different species of *Culicoides*, and even between populations or individuals within the same species, in terms of their susceptibility to infection and ability to transmit BTV or presumably other orbiviruses. Much of this difference appears to reside at the initial stages of infection of the midgut epithelium (the gut barrier), as even some normally 'nonvector' species can support replication and transmit the virus if infected by direct injection into the hemocele. The barriers to transmission can be divided into a mesenteron infection barrier that can prevent even initial infection of the gut cells, a mesenteron escape barrier that prevents release of progeny virus particles into the hemocele and a dissemination barrier that prevents released virus from infecting secondary target tissues such as the salivary glands. There is no evidence for either a salivary gland infection or escape barrier.

The BTV particle can be modified by treatment with proteolytic enzymes (such as trypsin, chymotrypsin or plasmin) resulting in cleavage of one of the proteins (VP2) in the outer capsid and production of infectious subviral particles (ISVPs) (**Fig. 1**). This modification increases particle infectivity by approximately 100 times for *C. variipennis* or *Aedes albopictus* cell lines (KC cells and C6/36 cells) and results in a similar increase in oral infectivity for adults of *C. nubeculosus* and *C. variipennis* (compared to either intact virus particles or cores). It is considered likely that serum proteases from the mammalian host, or insect gut proteases, can modify the virus particles,

leading to infection of the insect vector primarily by ISVPs. Core particles of BTV have a much lower specific infectivity for mammalian cell lines, approximately 10^5 times lower as compared with either intact virus particles or ISVPs. However, core particle infectivity is also much higher (increased by approximately 10^4) for a *C. variipennis* cell line and is comparable to that of intact virus particles. These observations suggest that host cell binding and penetration functions of the virus are not entirely limited to the BTV outer capsid proteins but are also properties of the outer core protein layer (VP7(T13)). This conclusion is supported by core particle/cell binding studies with both insect and mammalian cell lines, and the neutralization of core particle infectivity by antibodies to VP7(T13).

Although detailed information concerning the replication of orbiviruses and coltiviruses in their arthropod vectors is limited, there is little evidence for significant changes in fecundity, lifespan or behavior as the result of orbivirus infection in any of the known vector species. In mammalian cells (BHK21) 100% cytopathic effect (CPE) and cell death have been observed within 24 h of BTV infection. In contrast, although BTV replicates in both *Aedes albopictus* and *Culicoides* cell lines, with continuous release of virus into the media, little or no CPE or cell lysis is observed. It appears likely that orbiviruses infect susceptible cells within the insect vector throughout their normal lifespan, resulting in persistence of virus replication. In the absence of cell lysis as a result of infection, an alternative mechanism of virus release from *Culicoides* cells appears to be essential for dissemination of virus from the gut to the salivary glands, and therefore for transmission between individual mammalian hosts. The orbiviruses express a small nonstructural protein (NS3), encoded by genome segment 10, that can mediate the release of virus particles from the infected cell. Although this property of NS3/NS3a may have relevance to infection in mammalian systems (see Pathogenicity), resulting in rapid spread and superinfection of cells, it may have originally evolved as an essential component of the infection strategy of the orbiviruses for the insect vector species (see Serologic Relations and Variability).

Pathogenicity

Members of the BTV and EHDV serogroups are normally considered to infect domesticated and wild ruminants, while AHSV primarily infects horses and other equids. The severity of the disease varies from fatal to unapparent in both domesticated and wild animals, depending not only on the virus strain but also on the breed or species of host animal. Most cases of BTV infection in sheep are subclinical or relatively mild and complete recovery occurs within a few weeks. Mortality rates of 2–30% have been reported in South Africa, while estimated mortality rates of 5%, with morbidity rates averaging 10%, have been reported for outbreaks in North America. However, much higher mortality rates (as high as 75%) have been reported on introduction of the virus into serologically naive populations of sheep in nonendemic areas (for example, in Portugal and Spain in 1956). Although bluetongue virus is believed to infect many, if not all, African antelope species, these infections tend to be mild or remain inapparent. In contrast, epizootics were described in 1976 and 1984 in American pronghorn antelope in Wyoming, which killed approximately 3200 and 300 animals, respectively. Although African breeds of sheep show greater resistance to BTV, breeds from areas normally free of the disease can be highly susceptible and suffer a high rate of mortality on infection with virulent strains. The breeds of sheep that are most susceptible to BTV are believed to be Dorset horn and Soay, both of which are of British origin. In contrast, cattle and goats infected with BTV will normally show a relatively mild or inapparent infection.

The variation of pathogenicity for different species is particularly evident with AHSV. Although zebra have been suggested as an important host involved in virus maintenance in the field and in importation of the disease to new areas (Spain, 1987), the virus usually only causes a mild or unapparent infection. However, in the indicator host (the horse) the virus can cause mortality of over 95%. African breeds of horses have lower susceptibility to the disease than those from Europe. This may be partly due to protection by maternal antibodies for sufficient periods for younger animals to be challenged naturally and acquire their own immunity. It may also result from selection of more resistant individuals. Mules and donkeys can also be infected by AHSV and there is evidence that the African breeds are relatively resistant, while those in Europe show mortality thought to be in excess of 75%. The presence of maternal antibodies and selection of resistant individuals may also explain the relatively low incidence of clinical BTV in sheep in some enzootic areas. Overt disease is more frequently the result of introduction of a new strain, particularly of a different serotype, from another area.

External factors and stress not normally encountered under laboratory conditions can also significantly affect the final outcome of infection. In arid areas any reduction of an animal's ability to reach water and food supplies, caused for example by BTV

infection in sheep, may result in a significant rise in mortality.

Under experimental conditions a virulent strain of BTV 3 was shown to become nonlethal after a single passage in tissue culture cells. This may result from specific selection and replication of nonlethal components of the virus population in this system. Unfortunately these observations have limited studies of virulence factors associated with specific genome segments by reassortment, as such studies require the use of tissue culture systems. A similar loss of pathogenicity was not observed with AHSV isolates, and studies of virulence using genome segment reassortment and a mouse model system have now been completed. Genome segment 2, encoding the larger outer coat protein VP2, appeared to have a primary role in the control of virulence. However genome segment 5, encoding the smaller outer capsid protein VP5, also appeared to play a role, and segment 10, encoding the other variable protein of AHSV (NS3), was involved in generation of an intermediate, partially virulent phenotype. Other reassortment studies using horses have confirmed the involvement of NS3 in control of virulence. It appears likely that cell infection and tropism (controlled by outer capsid proteins), as well as the rate and timing of cell release (controlled by NS3), may be important factors in the spread of infection within the host.

Neurovirulence of the Great Island virus species has also been analyzed in mice, using reassortant viruses. These studies showed involvement of genome segments 4 and 5, which encode the two major outer capsid proteins. It was also demonstrated that reassortant viruses could have modified or even increased virulence characteristics.

Alteration of virus strains by many repeated passages in mouse brain and/or tissue culture systems are the most important methods for production of the live but attenuated *Orbivirus* vaccines. Some of these vaccine strains have significantly increased infectivity for mice via an oral route and are regarded as neurotropic (see Host Range and Virus Propagation). Live vaccines also have the potential to exchange genome segments with other vaccine or wild-type viruses and thereby generate progeny virus strains which may have novel and even more dangerous characteristics. Killed vaccines have also been developed for CTFV and AHSV.

Clinical Features of Infection

There is great variation in the response of the vertebrate host to orbivirus infection, ranging from a subclinical or mild febrile response to more severe and even fatal infection.

Bluetongue in sheep is characterized by a rise in body temperature, which may last for up to 14 days, accompanied by an increase in respiration rate. Edema and inflammation around the face, mouth and nose are often observed, accompanied by hemorrhages in the mucous membranes of the mouth, which range from petecheal to ecchymotic. In a few cases the tongue becomes swollen, markedly congested and may protrude from the mouth. Although this feature of infection is transitory, the cyanotic appearance of the tongue in such cases gave rise to the name for the disease. The epithelial lesions of the mouth may become chronic and ulcerated, resulting in bacterial infection and necrosis. Coronitis or inflammation and degeneration of skeletal muscles can result in lameness and an unwillingness or inability to stand. Vomiting may result from smooth muscle lesions of the esophagus and pharynx, leading to pneumonia, which is frequently fatal. Other features include hemorrhages at the skin–horn junction (periople) and in some cases torticollis, which is usually terminal. Transmission of BTV from infected ewes to the ovine fetus, resulting in infection, may cause abortion and malformation, particularly with attenuated vaccine strains (see Pathology and Histopathology). Although direct (experimental) infection of the fetus *in utero* in cattle will have similar results, the virus is not thought to cross the bovine placenta under normal circumstances. EHDV and BTV are reported to produce essentially similar symptoms in deer, and Ibaraki virus is reported to produce symptoms, similar to clinical bluetongue, in cattle.

Four forms of AHS are recognized. These include the febrile type, which is relatively mild, resulting in a complete recovery within a few days. The pulmonary type is more severe and is nearly always fatal. It is characterized by rapid temperature rise, rapid respiration rate, breathing difficulties, a dry painful cough and nasal discharge of serum that has leaked from damaged pulmonary blood vessels. This also results in frothing in the lungs, causing suffocation from blockage of the pulmonary alveoli and subsequent death. The third form is the cardiac or edematous type and is characterized by temperature rise and very marked edema of the head and neck, including notably the supraorbital fossae, which may also extend throughout the whole body but not the limbs. The heart is affected, causing an increase in pulse rate. The fourth, mixed type of disease is rarely seen in the living animal because of superimposition of the symptoms of the other types and is usually recognized by postmortem examination.

Colorado tick fever is characterized in humans by

abrupt onset of fever, chills, headache, retro-orbital pain, photophobia, myalgia and generalized malaise. Abdominal pain occurs in about 20% of patients and a rash is relatively uncommon (<10%). Other symptoms include diarrhea or constipation and loss of appetite for tobacco. A diphasic or even triphasic febrile pattern has been observed, usually lasting 5–10 days. Severe forms of the disease involving infection of the central nervous system or hemorrhagic fever, or even both, have been infrequently observed, nearly always in children under 12. At least three such cases have proved to be fatal. Although congenital infection with CTFV does appear to occur, the risks of abortion and congenital defects remain uncertain.

Pathology and Histopathology

In sheep the replication of BTV takes place in hemopoietic and lymphoid tissues, including the spleen, bone marrow, monocytes, macrophages, neutrophils, vascular endothelial cells and draining lymphoid tissues. Lesions in acute infections are caused primarily by vascular thrombosis occurring in the capillaries and small blood vessels, resulting in hemorrhage and edema within the surrounding tissues. In the squamous layers of the skin and mucosa, vacuolation and necrosis of the epithelial cells can result, developing into erosions and ulcerated areas in more chronic cases. Skeletal muscle degeneration is frequently seen as focal areas within the muscle mass, associated with hemorrhages and edema. Lesions have been described in many other organs and appear to relate primarily to breakdown in the microvasculature, resulting in thrombosis, hemorrhage, edema, ischemia and necrosis of surrounding tissues. Affected organs include the heart, lungs, spleen, thymus, kidneys, skeletal muscles and a range of other tissues. In fetuses infected at the 5 and 6 week stage, encephalopathies and malformation occur, particularly with an egg adapted vaccine strain of serotype 10. The primary importance of virus replication in the vascular endothelium and the resultant damage to the microvascular system is also very clear in both EHDV and AHSV infections.

At the intracellular level, BTV replication is characterized by the production of viral inclusion bodies (VIBs) that are the site of core particle replication and assembly. There is evidence from electron microscopy studies of both mammalian and insect cells that the outer capsid proteins are added only at the periphery of the VIBs. In persistently infected insect cells in cell culture, VIBs continue to grow and by 21 days may occupy up to 25% of the cell volume. Although release of virus particles and reinfection of cells appears to be a feature of orbivirus replication, the presence of only a single VIB in these persistently infected cells suggests that VIBs may fuse, or may absorb the 'superinfecting' particles. Reassortment of genome segments between virus strains may therefore occur within such fused VIBs. Progeny virus particles attach to filaments of the cytoskeleton, producing an effect like strings of beads when viewed by electron microscopy. During replication of BTV and other orbiviruses, long tubular arrays of viral protein NS1(TuP) are formed. These 'tubules' have a helical structure and vary in diameter between different *Orbivirus* species but have an (as yet) unknown role in virus replication. However, virus particles are sometimes seen to be attached at regular distances along the length of the tubules within the cytoplasm of the infected cell, suggesting a specific and functional association.

Within the cytoplasm and sometimes also in the nucleus of CTFV infected cells, bundles of filaments characterized by cross-striations are observed. These structures may be analogous orbivirus 'tubules'. CTFV infected cells also contain intracytoplasmic granular matrices that may be analogous to orbivirus VIBs.

Immune Response

The humoral response to orbiviruses includes the development of relatively long lived serotype specific neutralizing antibodies, usually within 2 weeks of infection and always detectable in animals that develop viremia. There is evidence to indicate that these antibodies, which are directed against epitopes on one of the outer capsid proteins, are involved in protection against challenge with the same virus serotype. In the case of BTV the neutralization epitopes are located on the larger outer protein (VP2), although reassortment studies indicate that the smaller outer capsid protein (VP5) also exerts some influence on virus serotype (see Serologic Relationships and Variability). In members of the Great Island virus species there is evidence (also from analyses of reassortant viruses) that genome segment 5 or 6, which encodes the smaller outer coat protein, has a primary role in neutralization and determination of serotype. From monoclonal antibody studies with BTV, there is evidence of neutralizing epitopes that partially crossreact between at least some virus serotypes. It has been observed that sequential infection of sheep with different BTV serotypes results in production of a progressively broad spectrum of neutralizing antibodies against a number of additional BTV serotypes. This production of neutralizing antibodies to virus serotypes not previously encoun-

tered may also reflect the involvement of serotype crossreactive sites in BTV neutralization.

Antibodies against outer capsid components form the basis of neutralization assays to determine virus serotype. However, antibodies are also produced against the other core structural proteins and nonstructural proteins, which are more conserved between serotypes. These antibodies, particularly those against the protein surface of the core VP7(T13), can be used to determine the virus serogroup, which correlates with virus species. The BTV core particle is itself infectious, particularly in vector insect cell systems, and can be neutralized by polyclonal or monoclonal antibodies to VP7(T13) that crossreact between serotypes.

Killed virus vaccines have been developed for AHSV, some other orbiviruses and CTFV. Significant levels of antibodies to nonstructural virus proteins are not produced in response to these vaccines, as their presence is dependent on *de novo* protein synthesis and virus replication. In these circumstances detection of antibodies to NS1(TuP) of BTV has been used to distinguish vaccinated (killed virus) from infected animals. However, in view of the antigenic variability of NS3 of AHSV (see Serologic Relationships and Variability), care must be taken in the development and validation of any assay system designed to detect virus replication.

Protection against challenge with BTV and AHSV can occur in the absence of neutralizing antibodies. BTV induces virus specific cytotoxic T cells in both sheep and mice, which can partially protect animals from BTV challenge (using adoptive transfer techniques in monozygotic sheep). Most BTV specific T cells appear to be serotype crossreactive as assessed by both antigen specific proliferation assay and cytotoxicity assays. However, T cell lines and clones have been isolated that are BTV serotype specific. One such clone with a helper T cell phenotype (CD5+, CD4+, CD8−, T-19−) was shown to react with a site on outer capsid protein VP2 and produced large amounts of interleukin 2 and interferon γ when stimulated with either intact virus particles or with purified VP2 alone. BTV serotype specific antigenic sites for B cells and at least one site for ovine helper T cells are therefore both located within VP2 (the major neutralization antigen of BTV). Ovine cytotoxic T cell lines (CD8+) which are BTV serotype crossreactive have been isolated, although the protein specificity involved has not been determined. Separately, an ovine CD8+ T cell line has been isolated in which the majority of cells appear to be specific for BTV core proteins, but the function of the cells has yet to be determined.

The outer core protein VP7(T13) of AHSV forms crystalline arrays within the cytoplasm of infected cells. These crystals, which are relatively simple to purify, can be used to raise a serotype crossreactive and protective immune response that is not dependent on antibodies to outer capsid proteins or antibodies that can neutralize intact virus particles.

B cells require antigen specific helper T cells in order to produce virus specific antibodies. The isotype of antibodies is influenced by lymphokines produced by these cells. Production of cytotoxic T cells also appears to form a significant part of the host response to orbivirus infection. It is therefore clear from the available data that the T cell response as a whole also plays an important role in protection against BTV and other orbiviruses.

Prevention and Control

Prevention and control measures are applied to those orbiviruses that cause economically important disease in domesticated animals. The most significant of these measures are intended to prevent introduction of viruses not already present into areas that may contain both susceptible hosts and competent vector populations. The results of such introductions were illustrated in the Iberian peninsula in 1956–1960 with BTV and 1987–1991 with AHSV. The measures used to control the import of virus vary from country to country, involving restrictions on movement of animals and germline material (semen and ova) from infected areas. These restrictions, which may include quarantine periods, or even a complete ban on importation, are inevitably dependent on sensitive tests for both virus and antibodies. With the inability to confirm a carrier state for BTV in cattle, there is pressure for some relaxation of the current import/export restrictions, particularly if coupled with adequate testing of individual animals. Within endemic and epizootic areas other control measures are used; these may include restriction of animal movement, vaccination, control of insect vector populations and slaughter. Rapid and sensitive species (serogroup) specific diagnostic tests (ELISA) for both virus antigens and antibodies form an essential part of control and eradication programmes. However, serum neutralization assays are still used identify virus serotype. More rapid serotyping tests are not yet reliable or generally available but would also be a valuable tool in the overall control of these viruses.

Live attenuated vaccines have been developed for many BTV serotypes. A BTV serotype 4 strain was used as a monovalent vaccine in South Africa, as early as 1907, for more than 40 years. More recently, polyvalent attenuated vaccines containing a total of 15 serotypes have been administered in South Africa as three, weekly pentavalent vaccinations. The seg-

mented nature of the BTV genome and the ability of the genome segments to reassort suggest that the use of such polyvalent vaccines could potentially give rise to problems of increased antigenic diversity. Reassortment studies also indicate that reassortant virus strains may have different, or even enhanced, virulence characteristics in comparison to either parental strain. The original use of a serotype 4 BTV strain for vaccination could have some connection with the central antigenic relationship believed to exist between BTV 4 and other serotypes isolated in Africa.

Polyvalent live AHSV vaccines are used in South Africa as two separate preparations containing serotypes 1 to 6, or 7 and 8. Serotype 9 is not included because protection for this type is believed to be conferred by type 6. All of the viruses used were attenuated by serial passage in BHK-21 cells, apart from serotype 3 which was attenuated by passage in mouse brains. A polyvalent AHSV vaccine containing all nine serotypes is also being used in Egypt. A monovalent AHSV serotype 4 vaccine was used in Portugal, Morocco and Spain to help control the recent outbreak of disease caused by this serotype. The vaccine has been used in horses, both in the affected area and in a surrounding 'buffer zone', together with restrictions on animal movement and controls of insect vector populations in the immediate vicinity of animal accommodation.

A vaccine strain of BTV serotype 10 has been licensed in America for use in sheep only. Although vaccination gives protection of the animal, its use has been shown to be linked to cases of abortion and malformation of the ovine fetus. No vaccines are generally available for EHDV, although a vaccine was developed and used for the control of Ibaraki virus in Japan and experimental vaccines have been developed for some EHDV strains (for example strain 318).

In the case of CTF, personal protection against tick bite is the most effective control measure against virus infection and disease. In recreational areas such as camp grounds and parks, frequent inspection for ticks and their removal before attachment, together with the use of repellents, such as permethrin, and protective clothing are all recommended. Control measures against the tick vector have been considered and an inactivated vaccine was tested in volunteers in the early 1960s. However, because of the usually benign nature of CTFV infection and the limited numbers of cases reported each year (less than 200 cases per year in North America between 1976 and 1990), the use of the vaccine as a public health measure was not considered appropriate. Since CTFV can be transmitted by infected blood transfusion, it is recommended that CTF patients do not give blood for at least 6 months.

Future Perspectives

Potentially one of the most important, although uncertain, future developments associated with the orbiviruses, coltiviruses and other viruses with arthropod vectors is the effect that global warming may have on the distribution and overwintering of the vector populations. It is conceivable that the predicted changes in world climate will increase the spread of competent vectors and reduce periods of the year during which the adults are absent or inactive. This may increase the size of the enzootic areas to include areas or even countries that are now normally free from disease but which contain large populations of highly susceptible and serologically naive host animals.

New virus species (serogroups) and serotypes within existing serogroups continue to be isolated and recognized. It seems likely that new host and vector species may be demonstrated for both existing and newly isolated virus strains. Studies are currently underway to analyze the molecular basis of both insect and viral factors that may be involved in vector status of species, populations and individuals of *Culicoides*. New diagnostic tests, for example competition ELISA using polyclonal or monoclonal antibodies, are being developed for additional orbivirus serogroups (other than those already available for BTV, AHSV and EHDV). The sensitivity of polymerase chain reaction-based tests may also have important practical applications in both sensitive detection systems and characterization tests for these viruses, particularly if coupled with a crosshybridization assay, such as dot or northern blots.

The development of tests that can distinguish between vaccinated and infected animals may prove to be significant. These tests, which detect antibodies to serotype crossreactive nonstructural proteins in animals that have been infected but not in those that have received an inactivated or recombinant vaccine, may remove the understandable resistance to some vaccination programs. The currently used attenuated vaccines cause seroconversion that is indistinguishable from that in naturally infected animals. As a result of import/export restrictions, the use of such vaccines can lead to a drop in the animal's value, either for export or as a source for germline material. The use of killed vaccines and suitable tests could avoid these problems.

Molecular biology techniques have been used to express individual orbivirus proteins, both singly and in various combinations. These proteins represent a valuable resource for research, and together with the particles into which they self-assemble, may also form the basis of both safe and effective recombinant

vaccines, or noninfectious diagnostic antigens. However, the cost of the reagent or vaccine, if high relative to the value of the animal, may remain a significant consideration limiting their use.

The analysis of the entire genome RNA sequence for representative strains of BTV and subsequently of AHSV, together with the deduced amino acid sequences, have been major steps forward in orbivirus research (see Molecular Biology, below).

Recently, baculovirus-expressed VP7 proteins of BTV and AHSV have been crystallized for use in x-ray diffraction studies, resulting in the resolution of their organization and atomic structure. The resulting model for VP7, inserted into a structural model derived by cryoelectron microscopy, was used to produce a structural model for the entire VP7(T13) surface layer of the BTV core particle (see Molecular Biology). Recently BTV cores have also been crystallized and used for x-ray diffraction studies, allowing resolution of the atomic structure of both the entire 780 copies of VP7(T13) in the outer layer of the native particle, as well as the 120 copies of VP3(T2) in the underlying subcore layer. Collectively these structural studies have provided information on the organization of the dsRNA genome and the location of the core associated enzymes within the central space of the subcore, at the vertices of the icosahedron. Further crystallographic and electron cryomicroscopy studies have indicated that the mRNA synthesized by the core is extruded via a pore in the subcore shell (VP2(T2)) and released from the particle.

Structural data, together with results from ongoing studies – to identify and characterize enzymatic functions of the minor viral proteins, as well as their interactions, properties and active sites; to analyse protein–protein and protein–RNA recognition sites involved in replication and assembly; to characterize individual T cell and B cell epitopes; to identify virus–cell binding sites in both vertebrate and invertebrate systems; and to identify alternative overwintering mechanisms for the virus – will inevitably lead to a better understanding of virus replication, transmission and interaction with the vector and with the mammalian host's immune system. These data will also help in the design of methods and reagents for virus control and diagnosis.

Further studies of RNA and protein sequence variation between virus isolates will improve our understanding of the evolutionary relationships within the different virus groups and their movement on a global basis, and will help to confirm the status of 'topotypes' or 'nucleotypes' as potential components of a more comprehensive and accurate orbivirus nomenclature system.

The most important future research development affecting viruses from each of the different genera and species within the family *Reoviridae* as a whole will be the development of effective 'reverse genetics' or 'rescue' systems to facilitate the direct manipulation of virus gene sequences. This will allow the roles of different RNAs, proteins and even individual motifs to be analyzed with unprecedented precision and would lead to our better understanding of these complex and economically important viruses.

Properties of the Virion

Members of the genus *Orbivirus* within the family *Reoviridae* are currently classified within 19 distinct serogroups (species). Details of the structure, genetics and molecular properties of orbiviruses have largely been gleaned from studies of one serogroup, the bluetongue virus (BTV), the type species of the genus.

Orbiviruses are nonenveloped with two protein shells and a genome consisting of ten double-stranded RNA (dsRNA) segments. In the electron microscope when viewed by negative staining, orbivirus particles (70–85 nm diameter; sedimentation coefficient 570S) have a poorly defined surface structure exhibiting a 'fuzzy' appearance. Beneath this ill-defined outer virion structure, is a 70 nm diameter icosahedral inner shell, termed the 'core' (470S) which has a well-defined capsomeric structure. In contrast to conventional microscopy, cryo-electron microscopy of BTV particles reveals that the outer capsid also has an icosahedral morphology with a diameter of 86 nm diameter. The outer capsid consists of two proteins of distinctive shape, one globular and almost spherical, the other sail-shaped. The sail-shaped spikes project 4 nm beyond the globular protein. The capsomeric surface of the core, underneath the outershell, exhibits icosahedral symmetry with a triangulation number (T) of 13 in a left-hand configuration. The distinctive feature of the surface structure of the core is the presence of 132 aqueous channels at all 5- and 6-coordinated positions and 260 prominent knob-like structures at all the local and strict threefold axes (**Fig. 1**). These knobs which are about 40 Å (4 nm) in length and 40 Å (4 nm) in diameter at the surface of the core, are arranged as six-membered rings, with five-membered rings at the vertices or the icosahedron. These rings give rise to the genus name (*orbis*: Latin: ring or circle). The aqueous channels are about 80 Å (8 nm) deep and 80 Å (8 nm) wide at the core surface. The knobbly morphological units are connected at a lower radius at all the local and strict twofold axes forming saddles between the knobs. The protruding knobs give a bristly appearance to cores by cryomicroscopy. The knobbly capsomers are assembled on an inner layer (210–290 Å, 21–29 nm). The exterior surface of the innermost layer is almost spherical but it has an angular appearance due to the variations in thickness of the protein shell. The viral nucleocapsid and the segmented dsRNA genome are located at a radius of <210 Å (21 nm). More defined description has been discussed under the section of x-ray crystallography (see later).

The Virus Genome

The BTV virus genome is composed of 10 dsRNA segments in equimolar amounts, representing a single copy of each segment per particle. The RNA, when extracted under acidic conditions (pH 4.0) with sodium dodecyl sulfate (SDS) and phenol, occasionally appears as an unfragmented continuous structure. Under the electron microscope this structure has a rosette configuration with 10 varying length loops that emanate from a central area resembling a doughnut. The relative size of each of the 10 loops is approximately equivalent to the sizes of the individual gene segments. The RNA segments are numbered 1 to 10 in order of migration in SDS-polyacrylamide gel electrophoresis (PAGE) and are also referred to as large, medium and small segments (i.e. L1–L3, M4–M6 and S7–S10). Their relative order of mobility may vary according to the electrophoretic conditions used (agarose or acrylamide gel electrophoresis, etc). The dsRNA profiles of members representing each orbivirus serogroup are generally distinctive by PAGE and also differ from those of other members of the *Reoviridae* family.

The complete sequences of all 10 dsRNA segments of BTV serotype 10 (BTV-10) have been determined. In addition, a number of RNA segments of other BTV serotypes and those of other BTV serotypes and those of other orbiviruses (e.g. epizootic hemorrhagic disease virus (EHDV) and African horse sickness virus (AHSV)) have been sequenced.

Table 1 Coding assignments (proteins) of the BTV-10 viral RNA segments

Genome segment[a]	*No. of bp*	*Protein*	*No. of aa*	*Protein size*	*Location*
L1	3954	VP1	1302	149588	Core
L2	2926	VP2	956	111112	Outer shell
L3	2772	VP3	901	103344	Core
M4	2011	VP4	654	76433	Core
M5	1639	VP5	526	59163	Outer shell
M6	1770	NS1	552	64445	Tubules
S7	1156	VP7	349	38548	Core
S8	1123	NS2	357	40999	Nonstructural
S9	1046	VP6	328	35750	Core
S10	822	NS3	229	25572	Nonstructural

[a] Genome segment nomenclature based on order of migration during age and on descending order of size. During PAGE the migration of segments 5 and 6 is frequently but not always reversed.

The 10 dsRNA segments of BTV have conserved end sequences. For the mRNA sense strand of each duplex, these involve six nucleotides at the 3′ ends and eight nucleotides at the 5′ ends of BTV-10. For BTV-10, the genome is 19 218 bp in length with molecular weight 13×10^6. The sizes of the BTV-10 RNAs range from 3954 bp (L1, mol. wt. 2.7×10^6) and 822 bp (S10, mol. wt. 5×10^5). The overall base ratio of the genome is 28.1% A, 28.1% U and 21.9% C, 21.9% G. The base ratios of the individual segments are quite similar (i.e. A and U range from 29.3 to 25.4%; G and C from 24.6 to 20.7%). The 5′ noncoding regions range from 8 nucleotides (nt) (M4) to 34 nt in length (M6). The 3′ noncoding sequences are generally longer, i.e. from 31 nt in length (M5) to 116 nt (S10).

Other conserved features can be recognized in most of the segments. For example, nine of the ten segments of BTV-10 have another A following the 5′ conserved sequence (i.e. at position 7), six of the segments have two A residues at positions 7 and 8. At the 3′ ends of the positive-sense strands the conserved sequence is preceded by AC in 7 of the 10 segments, and in the remaining three segments (M4, M5 and M6) it is preceded by CA or CC. Also UU dimers are found proximal to the 3′ ends in seven of the segments (L1, L2, M5, M6, S7, S8 and S9). The 3′ noncoding regions of seven of the segments (L3, M4, M5, S7, S8, S9 and S10) are purine-rich. The 5′ and 3′ terminal sequences of the 10 mRNA strands of BTV and other orbiviruses (EHDV, AHSV, etc.) have inverted complementary sequences capable of forming intramolecular hydrogen bonds (i.e. end-to-end hydrogen bonding) and share some common features (e.g. a looped out sequence proximal to the 3′ termini). A high percentage of the nucleotides (e.g. 379 out of a possible 578 bp of S7 of BTV-10) of each RNA strand can form intramolecular duplex structures (stem–loop configurations) that are not only similar between the corresponding segments of various BTV serotypes but also similar to those of EHDV and AHSV.

Apart from the BTV-10 L1 segment the first AUG codon on the positive-sense mRNA strand of each of the segments initiates a long open reading frame. The L1 segment has an additional AUG codon upstream of the codon which initiates the open reading frame (residues 7–9). There are two methionine codons in the same reading frame in the S10 RNA sequences, one at position 20–22, the other at nucleotides 59–61. Four of the BTV-10 gene products end at the termination codon UGA (L1, M5, S8 and S10), four at UAG (L2, L3, M6 and S7) and the remaining two at UAA codons (M4 and S9). **Table 1** summarizes the coding assignments of the 10 genome segments of BTV-10.

The evolutionary relationships of the 24 BTV serotypes and related orbiviruses have been studied extensively at the genetic level, using a number of experimental approaches, including sequence comparisons. Data demonstrate that apart from RNA segments L2 and M5, all other eight RNA segments are highly conserved. Despite this sequence conservation, variations do exist for each RNA segment representing the various BTV serotypes as well as for various isolates within a serotype. In addition, high frequency of segment reassortment can occur between different BTV serotypes (in cell cultures, vertebrate hosts, or *Culicoides* vectors), generating new genotype combinations.

The Virus Proteins

Each dsRNA genome segment of BTV codes for the synthesis of one major protein. The outer capsid of

the virion contains two major proteins, VP2 and VP5 protein, which constitute approximately 40% of the total protein content of the virus. The core particle contains two major (VP3, VP7) and three minor proteins (VP1, VP4, VP6). The structural proteins are numbered VP1 to VP7 in order of their decreasing sizes on PAGE. Three nonstructural proteins (NS1, NS2, NS3) are also synthesized in infected cells, in addition to the seven structural proteins. The amino acid sequences of each of the 10 proteins of BTV-10 and various proteins of other serotypes have been deduced from cDNA analyses of the viral RNAs. The genes have been expressed in insect cells by recombinant baculoviruses and the proteins analyzed in terms of structure and function. The characteristics of proteins are summarized below.

The two outer capsid proteins

A total of 180 molecules of VP2 are present per BTV virion and form spike-like structures on the outer shell. The VP2 protein is the product of the L2 segment and has a molecular size of 111 kDa. The VP2 protein appears to be hydrophilic and contains many charged residues. It is rich in aromatic residues and conserved cysteines which may indicate a highly ordered, disulfide-bonded structure. The VP2 proteins of at least six different serotypes (BTV-1, -2, -10, -11, -13, -71) have been sequenced. It exhibits the greatest sequence variation of all the structural proteins. The VP2 protein of these six BTV viruses share 32–72% identical amino acids. Sequence alignments reveal distinct variable and conserved regions. For example, the C-terminus and a middle region of the molecule are well conserved with the absolute conservation of an octapeptide (NPYPCLRG) at position 360–367. The overall predicted secondary structures and functional plots of the VP2 proteins exhibit remarkable similarities among the serotypes reflecting limited evolution. Low levels of VP2 sequence homology can also be identified among BTV, EHDV and AHSV, particularly at the N- (50%) and C- (60%) terminal regions (20 amino acids at each end).

The VP2 protein is the principal antigen that determines serotypes. It is also the hemagglutinin protein. It elicits serotype-specific neutralizing antibodies which confer protection against homologous virus infection in vertebrate hosts. However, the neutralizing epitopes of VP2 are conformation dependent. VP2 purified from SDS-PAGE failed to induce neutralizing antibodies. Recombinant baculoviruses that express VP2 proteins induce antibodies that neutralize the infectivity not only of the homologous virus, but also to a lesser extent of some other heterologous BTVs, reflecting their closer relationship (e.g. BTV-4, -10, -11, -17). The immunity elicited in sheep provides protection against virulent virus challenge. VP2-specific monoclonal antibodies neutralize virus infectivity and provide passive protection against homologous virus challenge. The regions of VP2 that are involved in determining serotype specificity, neutralization and protective activities, have not yet been identified.

The VP2 protein is involved in the attachment of virus to cells. When VP2 is removed, the infectivity and the binding of the derived particles are significantly less than for complete virion particles. Intermediate subviral particles (ISVP) of BTV that still contain the chymotrypsin, tryspin or plasmid cleavage products of VP2 are, however, fully infectious. ISVP also have increased infectivity for insect vectors or insect cells. Although cleavage of VP2 does not affect cell attachment, ISVPs lack hemagglutination activity.

The second outer capsid protein, VP5 which appears to have a globular structure, is composed of 526 amino acids with molecular weight 59 kDa. In contrast to VP2, the primary sequences of the VP5 protein are much more conserved (in some cases up to 94%) among the various BTV serotypes and distinct variable regions are not easily discernible. The protein also shares relatively strong sequence homology (59–62%) with the VP5 protein of other orbiviruses, particularly EHDV. The BTV VP5 protein is rich in certain nonpolar amino acids such as alanine and isoleucine and has low content of tryptophan. It is noteworthy that following the methionine at the N-terminus, a single glycine residue is shared by the VP5 proteins of all BTV and EHDV analyzed so far. However, the protein is not myristoylated. .

The BTV VP5 may also contribute in the induction of neutralization-specific immune responses. A mixture of lysates of insect cells infected with two recombinant baculoviruses, one expressing VP2 and the other VP5 induces higher neutralizing antibodies in sheep than the single recombinant virus expressing VP2.

The two major core proteins VP3 and VP7

The BTV VP3 protein (103 kDa) is coded by the L3 segment and is a major structural protein of the inner capsid. It contains group-specific antigenic determinants. The L3 RNA (and VP3 protein) sequences are highly conserved among the various BTV serotypes analyzed so far. For example, there are 126 differences between the nucleotide sequences of BTV-10 and BTV-17 (out of a total of 1772 nucleotides), and only nine amino acid changes (out of 901), i.e. 0.15% of the possible sites where a single nucleotide change would

cause an altered amino acid. High levels of amino acid sequence homology have been demonstrated among the VP3 proteins of BTV, EHDV and AHSV reflecting the structural constraints in VP3. The baculovirus-expressed VP3 recognizes not only antibodies of all BTV serotypes, but also those of EHDV and AHSV. The VP3 protein is generally hydrophobic in character with relatively few hydrophilic regions. It contains few cysteine residues, but is abundant in nonpolar amino acids.

The protein VP7 is encoded by the BTV M7 RNA segment and is the major structural component of BTV cores comprising at least 36% of the total core protein. The sequence data obtained for the VP7 proteins of BTV, AHSV and EHDV indicate that the three viruses are closely related at the genetic level. Some 64% of the BTV-10 and EHDV-1 VP7 amino acids are identical in type and position, 44% of the EHDV and AHSV VP7 sequences and 44% of the BTV-10 and AHSV-4 sequences. The amino acid composition of the BTV VP7 protein differs considerably from that of the other BTV gene products. It is deficient in charged amino acids (19–20%) and rich in hydrophobic amino acids. VP7 has only one lysine which is remarkable since the other gene products are lysine-rich.

The VP7 protein has been synthesized by recombinant baculoviruses. The protein is highly immunogenic and reacts with antibodies raised to BTV, AHSV and EHDV. x-ray diffraction studies of crystallized VP7 obtained from recombinant baculoviruses exhibit two different symmetries, hexagonal and monoclinic. These crystals can diffract up to 2 Å (0.2 nm) resolution. The expressed proteins in crystals are clustered in trimers. The atomic structure of VP7 trimer is discussed later.

When VP3 and VP7 are synthesized simultaneously by a recombinant virus or *in vitro* (by transcription–translation of mRNA), they form icosahedral core-like particles (CLPs) as shown in **Fig. 2**. These resemble authentic BTV cores in size, shape and in the VP7:VP3 stoichiometry. It appears that 780 copies of VP7 forms 260 trimers or knobby capsomers of the core surface and for 260 trimers there are 120 copies of VP3 in the core. However, unlike the rotavirus VP6 (which is equivalent to the BTV VP7), the BTV VP7 does not self-assemble to form a morphological (core-like) structure. VP3 serves as a scaffold for the assembly of the VP7 trimers. VP7 of certain orbiviruses (e.g. AHSV) can self-assemble to form crystals composed of flat sheets of hexagonal rings. These rings are similar to the six-membered rings of VP7 trimers seen in the core surface layer. VP3 on the other hand, can form icosahedral subcore-like structures alone, and can interact with each of the three minor proteins (VP1, VP4 and VP6) indicating that it serves a primary role in formation of the virus capsid. The VP7 layer not only gives increased rigidity and stability to the core particle, it can also play a role in cell entry and infection by the core, in particular, in insect vector/cells. Both outer capsid proteins, VP2 and VP5, interact with each other and as well as with VP7 to form the double-capsid structure. Without the core, the outer capsid cannot be formed. The topography of the four major proteins in the virion that have been obtained from recent data is shown in **Fig. 3**.

The three minor core proteins VP1, VP4 and VP6

The RNA segments L1, M4 and S9 encoding the three minor proteins, are highly conserved among BTV serotypes. The largest RNA segment (L1) codes for the minor core protein, VP1 (150 kDa). This basic protein has a positively charged C-terminus, and the highest predicted net positive charge (+27.5). It exhibits a number of hydrophobic domains, based on its predicted amino acid sequence, size, location and molar ratio in the core, VP1 protein is the virion-associated RNA-directed RNA polymerase. The protein shares some sequence homology with the DNA- and RNA-directed RNA polymerases of eucaryotic, prokaryotic polymerase and those of other viruses. It contains a GDD motif characteristic of RNA polymerases. In addition, cell lysates infected with a recombinant baculovirus expressing VP1 protein catalyze the synthesis of polynucleotide chains in an *in vitro* system. The protein is also capable of binding BTV mRNA.

The second minor (estimated 20–24 copies per virion) core protein VP4 (76 kDa), is rich in charged amino acids and hydrophilic. It has a particularly strong hydrophilic domain at the C-terminus. VP4 exists as a dimer in solution and in baculovirus core-like particles (also likely within the core). A leucine zipper in the center of the molecule is responsible for the dimerization of VP4. The VP4 protein possesses various enzymatic activities. It has a nucleoside triphosphatase activity, the significance of which is not clear. The VP4 protein has a guanylyl transferase activity (i.e. an RNA capping enzyme). It binds GTP and transfers the GMP moiety to *de novo* synthesized uncapped BTV ssRNA to produce capped products. The protein also has methyltransferase activities which catalyze the methylation of capped BTV RNA to form methylated cap1 structures (m^7GpppGpm..) at the 5′ termini. Both methyltransferase type 1 and type 2 activities are associated with VP4, indicating that it is the only protein required for the complete BTV capping reaction.

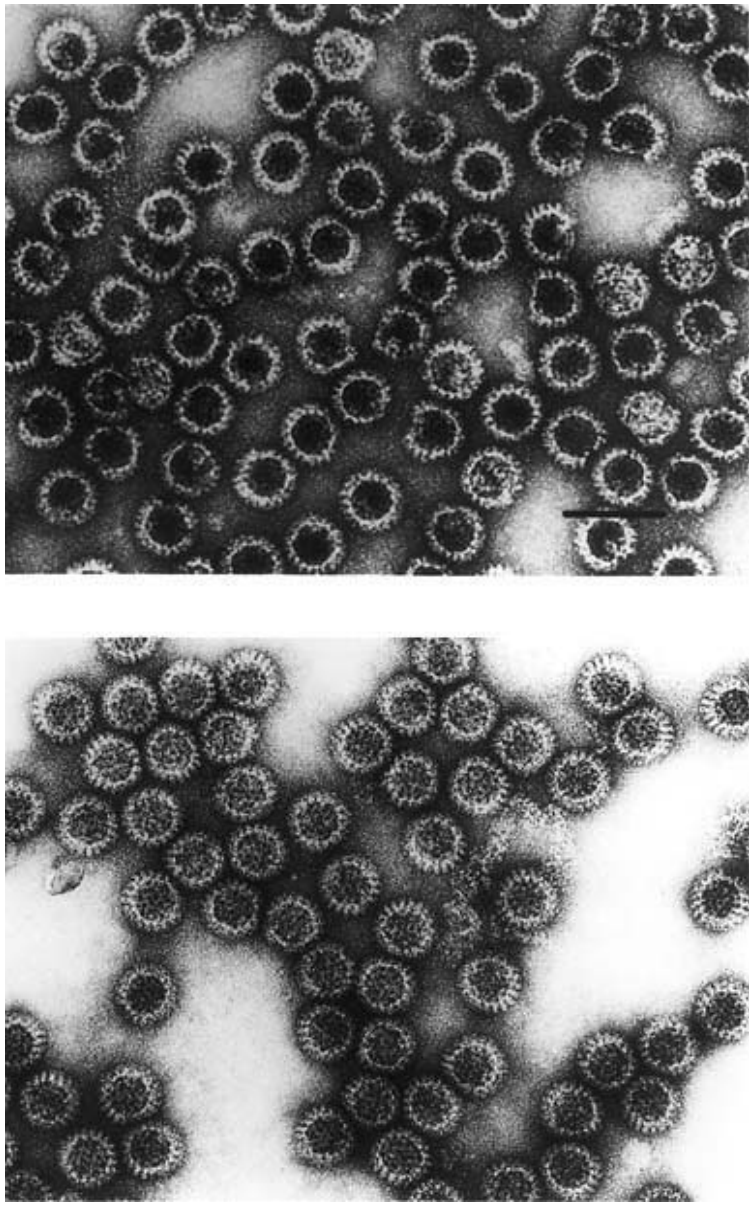

Figure 2 Lower micrograph consists of BTV cores derived from BTV virions. Top micrograph shows cores made by coexpression of VP3 and VP7.

The third minor core protein VP6 (35.8 kDa), is rich in basic amino acids (Arg, Lys and His). It has only one cysteine and a low proportion of aromatic amino acids, or asparagine or glutamine residues. VP6 is rich in glycine residues (40 out of 328 amino acids, 12%) with 12 glycines located between residues 88 and 116. The VP6 protein has been demonstrated to have high binding affinity for both ss- and dsRNA and DNA suggesting its close association with the viral genome in virions. In addition, RNA-dependent ATPase and helicase activities have been identified associated with the purified VP6 protein. The protein also has an ATP binding activity. RNA unwinding of duplexes which occurred with both 3′ and 5′ overhand templates, as well as with blunt-ended dsRNA is thought to be essential during the synthesis of RNA within viral particles, as part of the virus replication cycle.

The three nonstructural proteins, NS1, NS2 and NS3

The nonstructural protein NS1 forms tubules in the cytoplasm of cells infected with orbiviruses. It is

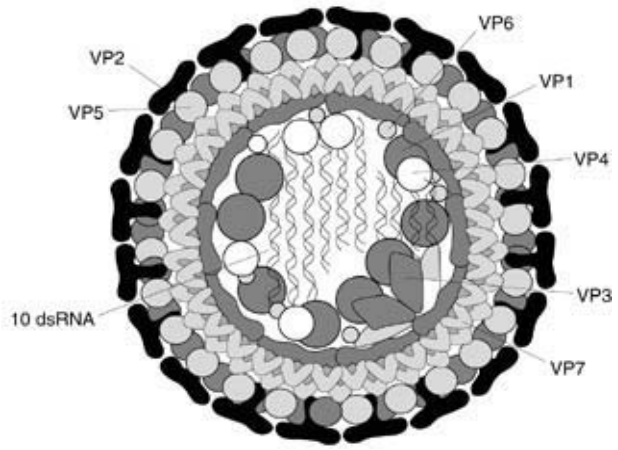

Figure 3 Schematic of BTV showing the topography of the seven structural proteins.

encoded by the M6 RNA segment. The protein is synthesized in large amounts, comprising some 25% of the virus-specified proteins in the infected cells. The protein converts rapidly into high-molecular-weight tubular structures with a sedimentation coefficient 300–500S. These tubules are predicted to be involved in virus assembly, although the exact nature of their role remains unknown. They are characteristic features of orbivirus-infected cells (see 'Replication'). The NS1 protein (64 kDa) is rich in cysteines (16 residues) which suggests a highly ordered, disulfide bond-linked structure. The protein is highly conserved (up to 96%) among the various stereotypes of BTV, but distinct from those of EHDV and AHSV. However, all 16 of the cysteine residues in the NS1 sequence are conserved between the three orbiviruses, suggesting that they are important for maintenance of structure. The NS1 protein has several regions of hydrophobic amino acids distributed throughout the molecule, particularly in the C-terminal half. Mutational studies demonstrated that both N- and C-termini and the cysteines at amino acids (aa) 337 and 340 are essential for tubule formation. Analysis of a panel of monoclonal antibodies has established that an NS1 antigenic site is located near to the carboxy terminus of the protein which is accessible to the surface of the tubules. Expression of the NS1 gene in insect cells by a recombinant baculovirus yields large amounts of NS1 tubules which are morphologically and immunologically similar to the authentic BTV-derived tubules. The average diameter of these tubules appears to be 52.3 nm. They can be up to 1000 nm long. The structure of the helical surface lattice of tubules has been determined using cryoelectron microscopy and computer-image processing to a resolution of 40 Å (4 nm). The NS1 protein molecule is about 5.5 nm in diameter and forms a dimer-like structure, so that the tubules are composed of helically coiled ribbons of NS1 dimers, with 21 or 22 dimers per turn. The surface lattice displays P2 symmetry and forms a one-start helix with a pitch of 9.1 nm. The tubules exist in two slightly different pH-dependent conformational states.

NS2, the second largest nonstructural protein (41 kDa), is encoded by RNA segment S8. It is the only viral-specific phosphoprotein. The protein has the lowest proportion of threonines of all the BTV gene products, but an average content of serine. Both mammalian and recombinant baculovirus-derived NS2 proteins are phosphorylated at serine residues only. NS2 has a high content of cysteines, mostly located near the C end, which suggests a highly ordered structure in that region. Overall, the protein is hydrophilic and rich in charged amino acids. The protein possesses ssRNA-binding ability, a property which is independent of its phosphorylation state. Deletion of up to 130 amino acids (out of 357) from the C-terminus yield a protein that can still bind RNA. It appears that the first 40 amino acids of the N-terminus of the molecule are essential for RNA binding. In particular, the arginines at amino acids 6 and 7 and a lysine at amino acid 4 are required for ssRNA binding. By immunoelectron microscopy, it has been demonstrated that NS2 protein is located within the BTV-induced viral inclusion bodies (VIB). However, it is not associated with virus particles in infected cells. Recombinant baculoviruses that express NS2 form morphological structures similar to VIBs found in BTV-infected cells.

The third nonstructural protein is NS3 (25.6 kDa). It is encoded by the smallest RNA segment, S10, and is highly conserved among BTV serotypes, although it is more variable among different AHSV serotypes. A second protein (NS3A) of 24 kDa is also detected in low abundance in infected cells. These two proteins are related to each other. NS3A is synthesized from the second in-frame translation initiation codon. Both proteins are integral membrane glycoproteins and are involved in virus egress from infected cells. The NS3 sequence contains two putative transmembrane domains at amino acids 118–141 and 162–182 and two potential asparagine-linked glycosylation (aa 63 and 150), one of which is located between the two hydrophobic domains. Both hydrophobic domains span the cell membrane, however, only the site at aa 150 is responsible for N-linked glycosylation of the NS3 protein. It is noteworthy that NS3 proteins of certain AHSV serotypes do not possess such potential glycosylation sites.

Three-dimensional x-ray Crystallographic Structure of Orbivirus Proteins and Particles

VP7

The BTV-10 VP7 crystal structure at 2.5 Å (0.25 nm) resolution revealed a unique molecular architecture of trimeric nature. Each monomer consists of two distinct domains, the 'upper' and 'lower' and are twisted such that the top domain of one monomer rests on the lower domain of a threefold related subunit in a clockwise direction (see **Fig. 4**). The interactions between subunits are extensive and there are contacts between the top domains related by threefold symmetry and also with the symmetry-related bottom domain. There are both hydrophobic interactions and specific hydrogen bond interactions which bind the two domains strongly. Despite the extensive interactions there are cavities at the center of the trimer (along the threefold axis) surrounded by predominantly uncharged residues.

The smaller upper domain of VP7 forms the 'head region' or the VP7 trimer which forms the knobby projections seen by cryoelectron microscopy on the outer surface of the core and contains the central one-third of the polypeptide chain of the molecule (aa residues 121–249). In the trimer, the three upper domain subunits, each of which is folded into an antiparallel β-sandwich, are intimately associated via two extended loops from each subunit, both with each other and with all possible threefold related subunits. The topologies of the two groups of β-sheets are A'BIDG and CHEF, corresponding to a jelly roll structure. One loop (the D–E loop), consisting of aa 198–208, interacts with both trimeric partners at the top of the molecule. Below this loop, aa 133–141 form another loop (the A–B loop), clipping onto the inner-face of the β-sandwich of an adjacent subunit. The x-ray structure of upper domain of AHSV-4 VP7 has also been solved and has shown similar structural arrangement. The characteristic feature of the upper domains of both molecules is the presence of an Arg-Gly-Asp (RGD) motif which may be responsible for binding of the orbivirus core to a cellular integrin receptor. The lower domain of the VP7 trimer is composed entirely of α helixes and long extended loops. This domain contains the N-terminus (1–120) and the C-terminus (250–349) of the molecule (**Fig. 4**). There are nine helices, five are in the N-terminal half and four in the C-terminal half. In the center of the domain is an antiparallel, four-helix bundle composed of amino acid residues 2–17 and 54–73 from the N-terminus and amino acids 276–288 and 304–322 from the C-terminus. The connection between the two domains is exposed, and is easily accessible to proteolysis. The single lysine residue of BTV-10 VP7 is situated in the junction of the two domains. The helices in the bottom domain pack together tightly.

Figure 4 The structure of VP7 trimer rendered from x-ray crystallographic analysis. The threefold symmetry axis of the trimer is disposed vertically so that the flat base at the bottom of the image forms the inner surface of the outer VP7 layer of the core, which adheres to the VP3 subcore. Note the clear division into two domains, the upper domain contains mainly β-strands (shown as arrows), whereas the lower domain is constructed of a number of closely packed helices. (Reproduced from Grimes *et al* (1995) *Nature* 373: 167.) One subunit is outlined with a dashed line to clarify the twist of the subunit trimer with respect to the molecular 3-fold axis. **(For color references see Color Plate 13.)**

Core particle

High resolution (23 Å) cryoelectron microscopy and x-ray crystallographic structures at 3.5 Å resolution have been determined for two different BTV serotypes (BTV 1 SA and BTV-10). From these data an atomic model has been constructed for the structure and organization of the major protein components within the core particle.

The organization of 260 VP7 trimers follows precisely $T = 13$ icosahedral lattice, in accordance with the theory of quasi-equivalence. By fitting the x-ray structure of an individual VP7 trimer onto the cryoelectron microscopy BTV core structure it is clear that the threefold axis of the trimer (85 Å (8.5 nm) long) is perpendicular to the core surface and the broader base of the trimer (65 Å (6.5 nm)) contacts

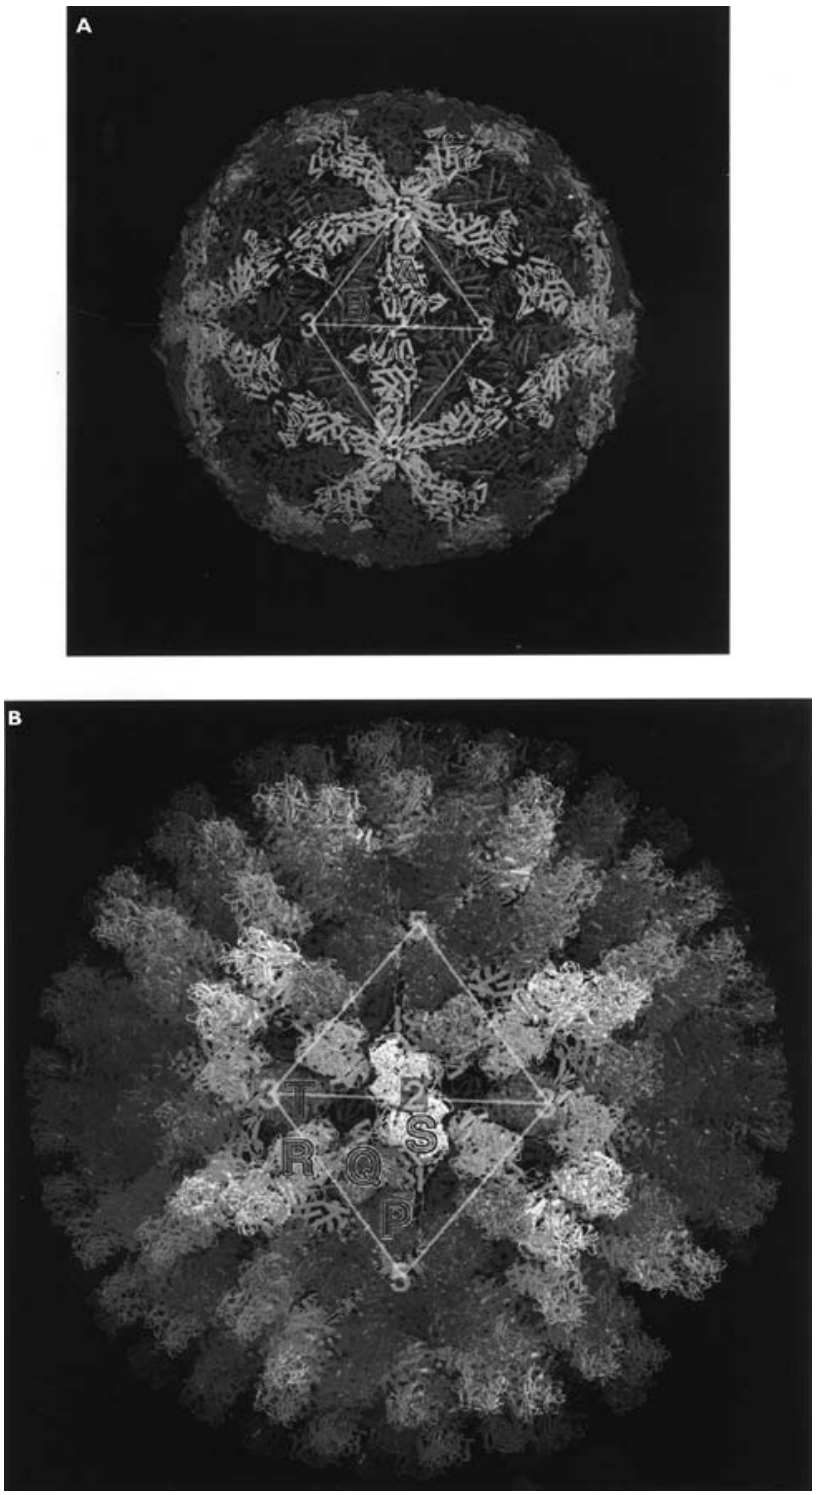

Figure 5 The essential features of the architecture of the native BTV core as determined by x-ray crystallography and cryoelectron microscopy. The icosahedral asymmetric unit is the triangular area defined (as marked) by the symmetric axes of the icosahedron. (**B**) The core surface layer composed of 780 copies of VP7, arranged as 260 trimers with $T = 13$ symmetry. The asymmetric unit contains 13 copies of VP7, arranged as five trimers P, Q, R, S and T: colored red, orange, green, yellow and blue, respectively. Trimer 'T' sits on the icosahedral threefold axis, and thus contributes only a monomer to the unique portion of the capsid. (**A**) The inner capsid layer of the BTV core (the subcore) composed of 120 molecules of VP3, arranged with $T = 2$ symmetry according to the principles of 'geometrical quasi-equivalence'. The icosahedrally unique molecules, of VP3 A and B, are colored in red and green, respectively. Note the completely different structural environment of the A and B molecules. (Reproduced from Grimes *et al* (1998) *Nature* 395: 470–478. Copyright 1998, Macmillan Magazines Ltd. **(For color references see Color Plate 17.)**

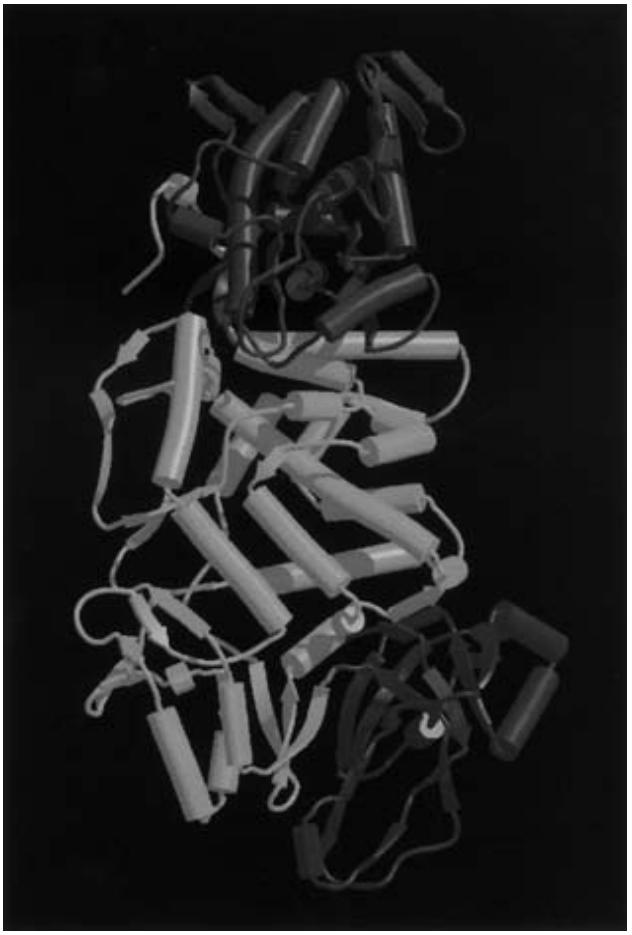

Figure 6 A representation of the VP3 B molecule, color-coded by domain. The 'apical' domain is shown in blue (residue 297–588), the 'carapace' domain in green (residues 7–297, 588–698 and 855–901) and the 'dimerization' domain in red (residue 698–855). (With acknowledgement to J. Grimes and D. Stuart for provision of the image.) **(For color references see Color Plate 18.)**

the internal network of the VP3 of the subcore. The VP7 layer occupies between 295 Å and 365 Å (29.5–36.5 nm) from the center of the core. As shown in **Fig. 5** (see also Plate 17 for color) five VP7 trimers at different distances from the fivefold axis form a protomeric unit (labeled as P to T: red, orange, green, yellow and blue). These trimers show relatively little variation in their structure throughout the core surface layer.

The 260 trimers of VP7 adhere to a scaffold that is made up of only 120 VP3 molecules indicating a symmetry mismatch in the interactions between the bases of the 260 trimers of VP7 and the 120 molecules of VP3. Indeed, the interactions between VP7 and VP3 occur in 13 different relative positions. The flat base of VP7 trimers, with a large number of hydrophobic residues, are mainly responsible for the interactions with VP3. The interacting base of the trimers is formed largely by the three copies of helix 2 and the segments of the chain (aa 22–27 and aa 44–52) leading into and out of this helix.

The helical lower domains are involved in extensive interactions with the lower domains of the other VP7 trimers. These interactions are mediated through helix–helix packing and helix–loop binding. The interaction between the three VP7 lower domains in the trimer are complex.

The inner protein shell known as the 'sub core', is composed entirely of 120 copies of the VP3 protein, that are organized as an icosahedral lattice with $T = 2$ symmetry. The VP3 subcore shell has a maximum diameter of 59 nm, forming a central space with an internal diameter of 38 nm, that contains both the genome and the minor viral proteins.

The individual VP3 molecule forms a flat, elongated wedge shape (13–35Å thick × 75 Å wide × 130 Å long (1.3–3.5 × 7.5 × 13 nm)), which contains many α helices as well as β strands and is made up of three distinct domains (**Fig. 6**) (see also Plate 18 for color). The apical domain (residues 298–587) is situated closest to the fivefold axes in the intact particle. The carapace domain (residues 7–297, 588–698 and 855–901) forms a rigid plate that represents the majority of the surface of the subcore shell. The dimerization domain (residues 699–854), which forms quasi-twofold interactions between individual A group molecules, is situated furthest away from the fivefold axes.

The 120 copies of VP3 are arranged as two groups (A and B) to form the subcore layer (**Fig. 7**) (see also Plate 20 for color). Five of the A group molecules (shown in green) are arranged as a five-pointed star around each fivefold axis. Five additional B group molecules (shown in red) are positioned, one between each of the points of the star, but at a greater distance from the fivefold axis. In this way the VP3 molecules form a convex dish-shaped decamer. Twelve decamers, positioned one at each of the fivefold axes are arranged edge to edge, so as to form the complete subcore VP3 shell. The A and B forms of VP3 interact between different decamers via the dimerization domain. These interactions and interactions between the three different 'B form' molecules of VP3 around the icosahedral threefold axis (again between decamers) appear likely to play a role in holding the decamers together to form the subcore shell. It is possible that the formation of dimers, trimers, pentamers or decamers of VP3 could represent assembly intermediates but their relative significance is as yet unknown.

The inner surface of the VP3 shell interacts directly with the minor protein components (VP1, VP4 and

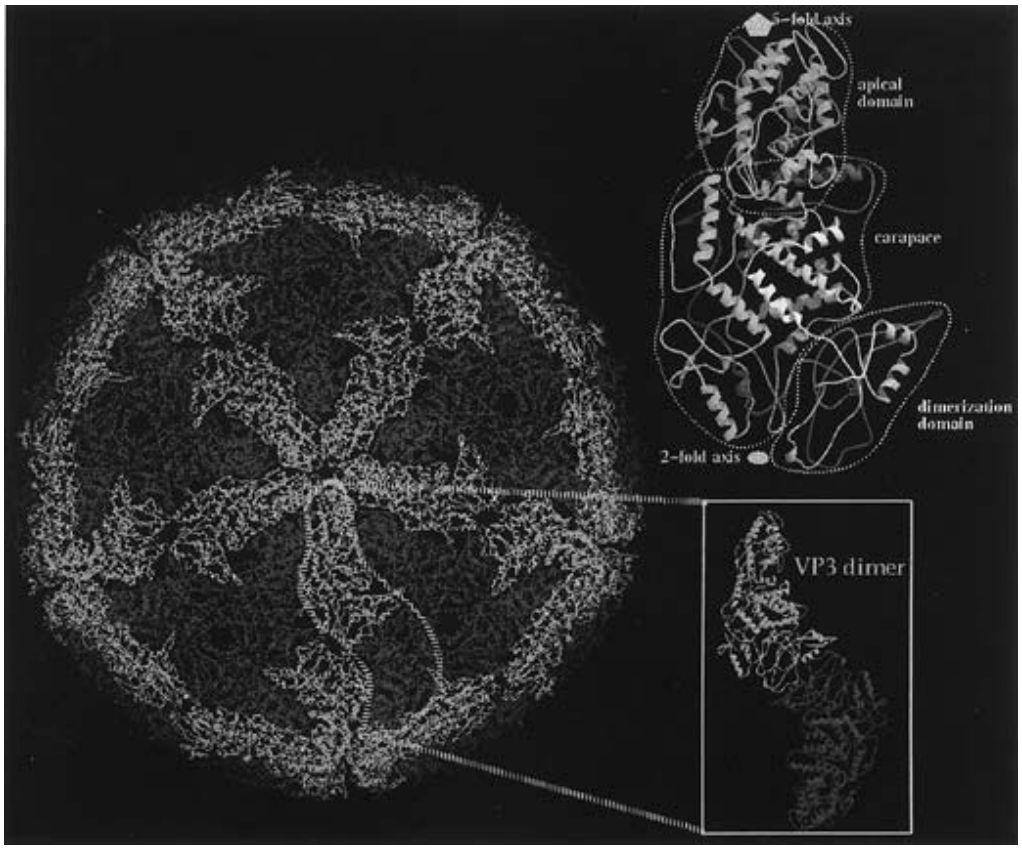

Figure 7 Overall structure and architecture of the VP3 layer of the BTV subcore. Each of 120 molecules has a structure similar to that illustrated on the right of the image. (Reproduced from Stuart *et al* (1998) African Horse Sickness Virus. *Arch. Virol. Suppl.* 14: 235–250.) **(For color references see Color Plate 20.)**

VP6) of the transcriptase complexes (TCs), which are situated at the fivefold axes, within the central space. The TCs (10–12 in total) appear to be present as a single complex at the vertices of the icosahedral particle and therefore do not have strict icosahedral symmetry. As a consequence, their density as viewed by crystallography is averaged around the fivefold axis and appears smeared. It has not yet been possible to resolve their structure, or their interactions with the dsRNA in atomic detail.

The inner surface of the VP3 subcore shell has relatively few charged residues and has a series of shallow grooves. These features may be essential to organize the dsRNA molecules of the genome and to allow them to be transported rapidly and simultaneously through the active sites of the TCs and then repackaged during each round of transcription. Much of the genomic RNA can also be detected by x-ray crystallography, as electron density within the central core space (**Fig. 8**) (see also Plate 19 for color). The dsRNA appears to be highly ordered and approximately 80% of the entire genome can be modeled as four distinct concentric layers that have center to center spacing between RNA strands of 26–30 Å (2.6–3.0 nm). This spacing is consistent with the formation of the RNA into a liquid crystal array, with interactions between the individual layers lubricated by counterions. This would retain the RNA molecules in a highly ordered and closely packed structure but would also allow them a high level of fluidity, that is necessary for their rapid transport and processing by the TCs. As a consequence of the spacing of the A and B forms of VP3, the grooves in the inner surface of the subcore shell form a spiral around the fivefold axis. The outer dsRNA layer appears to interact with these grooves and can also be modeled as a spiral extending outwards from the TC. It is uncertain how the RNA molecules pass inwards to the next and subsequent concentric shells but it seems likely that simple steric clashes with near neighbors and possibly interactions with a lysine residue (807) on a flexible loop of VP3 B, may be important factors in their organization. The density detected in the inner layers of RNA gets progressively weaker, suggesting that its organization

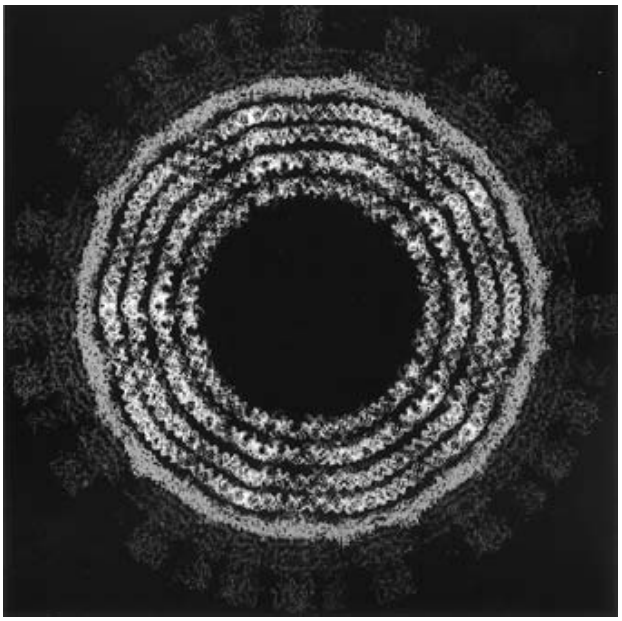

Figure 8 Thin section through the structure of the core of BTV (as determined by x-ray crystallography of native cores of BTV1 and BTV10). The VP7 outer layer of the core is shown in dark blue, the thin VP3 subcore layer in pale blue and the four layers of the genomic dsRNA are predominantly yellow. (Reproduced from Stuart *et al.* (1998) African Horse Sickness Virus. *Arch. Virol. Suppl.* 14: 235–250.) **(For color references see Color Plate 19.)**

and icosahedral symmetry is progressively less rigid. Nevertheless there does appear to be some elements of spiral organization to each of the RNA layers.

Activation of the core-associated enzymes in the presence of magnesium ions and NTP substrates causes conformational changes around the fivefold axis of the core, resulting in movement outwards of the major proteins (VP3 and VP7) and opening of a pore in the VP3 layer at the fivefold axis. The mRNAs synthesized by the core-associated transcriptase complexes are extruded through this pore, then pass out through the central space in the pentameric rings of VP7 trimers. There are also pores in the VP3 layer at the threefold axes but in the intact core particle these are completely blocked by the T trimer of VP7.

Replication

Although field isolates of BTV from infected ruminants or insects often replicate poorly in cultured cells, they can readily be adapted to growth *in vitro*. Such viruses replicate in the cytoplasm of a wide variety of vertebrate and invertebrate cells in culture. No direct proof is available on the nature of the receptor to which BTV binds although analysis of BTV–erythrocyte interaction has implicated specific sialic acid-containing oligosaccharides in the glycophorin of human and animal erythrocytes. Binding to both erythrocytes and vertebrate cells is mediated by the BTV outer coat protein VP2.

Following adsorption, BTV enters vertebrate cells through the normal cellular process of receptor-mediated endocytosis. Thus, shortly after infection the virus is found in vesicles that lead to degradation and removal of at least one, and perhaps both, of the outer coat proteins of the virus. The outer capsid layer can also be removed *in vitro* by treatment with metal ions (Mg^{2+}), or by reduced pH. An increase in endosomal (and lysosomal) pH by addition of lysomotrophic weak bases or acidic ionophores to cells before infection, results in the failure of endocytosed virus particles to initiate replication. Current data imply that core particles enter the cytoplasm by penetration of the endosomal membrane. In the cytoplasm, the partially or completely uncoated particles bind to the cell's intermediate filaments and activate the transcription of viral RNA. *In vitro*, mRNA synthesis can be activated by proteolytic digestion and removal of the outer capsid of the virus. This modification allows free access of the nucleoside triphosphates to the genome and the extrusion of the newly synthesized mRNA to the cytoplasm.

The BTV RNA polymerase itself has not been fully characterized. More than one protein may be involved in transcription. The structural integrity of the core particle may be essential for maintaining the full transcriptional activity of the virus.

The molar ratios in which the different mRNAs are transcribed remain the same throughout the infection cycle. The ratios of mRNAs synthesized *in vivo* and *in vitro* are also identical. Unlike reovirus, these molar ratios are not inversely proportional to their molecular weights. For example, segment M6 encoding the NSI protein is transcribed much more rapidly and efficiently than the segment S10 encoding the NS3 protein.

Replication of orbivirus dsRNA has not been extensively studied. It is presumed that the overall strategy of replication and transcription are similar to those of reoviruses and rotaviruses. The mRNA of BTV is capped and methylated during the transcription process. The minor protein VP4 is responsible for the modification of the mRNAs. During transcription the negative-sense strand of each duplex is the template for the synthesis of mRNA species. These are synthesized and extruded from cores and program the synthesis of virus proteins. After *de novo* synthesis, structural and nonstructural viral proteins (e.g. NS2) associate with the viral mRNA species which leads to formation of nascent progeny subcore,

core particles and concomitant synthesis of dsRNA. The two outer capsid proteins (VP2 and VP5) are subsequently added onto the nascent core particles prior to the release of the newly formed virions.

It has been shown using the appropriate recombinant baculovirus expression vectors that the BTV minor proteins (VP1, VP4 and VP6) are incorporated within synthetic BTV CLPs and virus-like particles (VLPs) in the absence of mRNAs (or genomic RNA) or nonstructural proteins. A specific mechanism must exist for the recognition and incorporation of mRNA species. Such a mechanism could involve not only the virus-induced nonstructural proteins, such as NS2, but also particular sequences and structures of the mRNA species themselves. The conservation of the terminal regions of these RNAs may be of relevance to the question of their recruitment to the sites of particle morphogenesis and encapsidation into cores and eventually virions. The secondary structures of the mRNAs, if formed within viral cores that are transcriptionally active within cells, may facilitate mRNA egress from particles and may also contribute to the overall stability of the viral mRNA species within the cytoplasm of infected cells and its interaction with ribosomal components for the purpose of translation.

Infection of cells with BTV leads to a rapid inhibition of cellular macromolecular synthesis. The first sign of virus replication is the accumulation of a fibrillar network around the infecting core particles in the cytoplasm resulting in formation of a viral inclusion body (VIB). With increasing time postinfection, the size and number of the VIBs increase. Immunogold electron microscopy has confirmed that VIB are rich in ssRNA and the phosphorylated NS2 protein. In addition, the VIB matrix contains the two major core proteins VP3 and VP7. Subcore and core particles are made within the VIB matrix and interact with outer capsid proteins only at the periphery of VIBs. The major outer coat protein VP2 is not a VIB constituent. Indeed, it is only found at the surface of the VIB structure, at the locations where core particles mature to form progeny virus particles.

NS1 protein is the predominant constituent of viral-specific tubules found throughout the cytoplasm. Although tubules are the hallmark of orbivirus-infected cells, their function in virus replication is unknown. NS1 is also found associated with core-like structures within VIBs, as well as intracellular and released virus particles. However, tubules can be removed from virus particles during purification. VIBs, tubules and intracellular virus particles bind to the vimentin-rich, intermediate filament networks of the cell's cytoskeleton.

Immunoelectron microscopy indicates that VP2 is added to developing virus particles either at the periphery of VIBs or following binding to the cytoskeleton. Analyses of intracellular virus particles have revealed significant differences in the organization and/or the amount of VP2 associated with cytoskeleton-associated or free virus particles in the cell cytoplasm. Although the majority of newly synthesized virus particles remain cell-associated, a proportion leave infected cells (depending on the cell type). Released viruses also differ from their intracellular counterparts with respect to the organization of the VP2 protein in the outer coat.

Large accumulations of virus particles are found on the surface of BTV-infected cells and retain an association with the underlying cortical layer of the cytoskeleton. Virus particles are observed to leave infected cells in either of two ways. First, and particularly early in infection, particles can be seen to bud through the cell membrane and acquire, at least temporarily, an envelope. However, no virus antigen can be detected at the surface of such enveloped particles. Second, egression of virus particles from infected cells is accomplished by a process of extrusion where individual and groups of virus particles move through the plasma membrane. This appears to happen without a significant effect on host cell viability. The minor nonstructural protein NS3 has been located in areas of the plasma membrane where virus particles are leaving, suggesting a role for this protein in this process.

Future Perspectives

Although significant progress has been made on elucidating structure–function of BTV genes and gene products, little is known about the intracellular assembly process and the stoichiometries of the viral components in the morphogenetic pathway of virion assembly. The baculovirus expression system has provided a method to understand how and which viral proteins interact and assemble to form virus particles. It can be anticipated that the availability of large quantities of viral components and the core- and virus-like structures will not only lead to further understanding of their three-dimensional structure at the atomic level, but also facilitate future investigations of the mechanisms of viral replication.

Viruses Affecting the Heart

Introduction

Viruses may affect the heart in a number of different ways. Developmental defects may occur as a result of intrauterine infection by such viruses as rubella, and infection of the myocardium may be induced by a large number of viruses in different groups, although infection by enteroviruses probably represents the commonest cause of acute and chronic heart muscle disease. As yet, there is little evidence to support the role of viruses as a cause of endocardial disease.

Although the myocardium is exposed during the viremic phase of infection to a large number of viruses, only a minority give rise to clinically apparent cardiac disease. Nevertheless, asymptomatic myocarditis is probably relatively common since histological studies of myocardial tissue obtained from young adults killed accidentally reveal a focal myocarditis in 0.8–3% of tissues. Since a focal myocarditis may induce a fatal arrhythmia, it is perhaps not surprising that autopsies carried out on young persons who died unexpectedly have shown that about 15% have evidence of myocarditis. In a small proportion of those experiencing a subclinical myocarditis, it is possible that virus may not be cleared by immune mechanisms and persist to result in the development of chronic heart muscle disease over a period ranging from a few months to several years. Some studies suggest that approximately 25% of patients with acute myocarditis fail to recover fully and develop chronic cardiac disease.

Etiology

Table 1, although not comprehensive, lists viruses that may induce cardiac disease. Some are involved commonly [e.g. enteroviruses, human immunodeficiency virus (HIV) and, if acquired congenitally, rubella] whereas others are uncommon [e.g. varicella-zoster, cytomegalovirus (CMV) and hepatitis B]. Many of these viruses involve the heart as part of a clinically obvious generalized infection (e.g. varicella, mumps and rabies) whereas in others, cardiac disease is the primary presenting clinical feature. The more common causes of viral heart disease are discussed below, but some of those occurring less commonly are listed in **Table 1**.

Cases categorized as 'cardiovascular' in the WHO *Global Surveillance of Virus Diseases Programme* from 1978 to 1985 shows that enteroviruses, particularly coxsackie B viruses, followed by influenza B and A viruses are the commonest viruses associated with cardiac disease; in most cases the association is likely to relate to acute myocarditis or pericarditis.

Intrauterine and perinatal infections

Intrauterine or perinatal infections may induce developmental defects of the heart. Thus, if acquired during the first trimester, maternal rubella may result in a number of cardiac abnormalities, particularly a patent ductus, septal defects or pulmonary stenosis. A focal myocarditis may also be present. If acquired in pregnancy, human parvovirus infection (B14) infects the fetus and induces cardiac failure as a result of a severe anemia caused by viral destruction of fetal erythrocyte precursors. This may result in a hydrops fetalis and cause miscarriage or stillbirth.

Enteroviruses, particularly coxsackie B viruses, may cause severe neonatal disease with mortality rates approaching 40–50%. Infection may be acquired transplacentally, perinatally via contamination with maternal fecally excreted virus or via other infants in

If acquired in pregnancy, human parvovirus infection (B14) infects the fetus and induces cardiac failure as a result of a severe anemia caused by viral destruction of fetal erythrocyte precursors. This may result in a hydrops fetalis and cause miscarriage or stillbirth.

Enteroviruses, particularly coxsackie B viruses, may cause severe neonatal disease with mortality rates approaching 40–50%. Infection may be acquired transplacentally, perinatally via contamination with maternal fecally excreted virus or via other infants in

Table 1 Viruses affecting the heart

Viruses	*Clinical features*
Enteroviruses	Acute myopericarditis (postnatally acquired) Acute myocarditis during generalized intrauterine or perinatal infection DCM
Influenza A and B	Myocarditis as one feature
HIV	Myocarditis, cardiomyopathy
Mumps	Myocarditis (seldom symptomatic but electrocardiograph changes may occur in about 5–15%)
Measles	Myocarditis (very rare)
Rubella	Developmental defects if congenitally acquired, sometimes with focal myocarditis
Arboviruses: Dengue Yellow fever Chikungunya	Myocarditis as one feature
Rabies	Myocarditis as one feature
Hepatitis B	Myocarditis as one feature (very rare)
Varicella-zoster	Myocarditis as one feature
CMV	Myocarditis may occur in transplanted allografts (rare)
Herpes simplex	Myocarditis during generalized neonatal infection
Epstein–Barr	Myopericarditis as one feature (rare)
Adenoviruses	Myocarditis (very rare)
Vaccinia	Myocarditis (rare)

the nursery who are excreting enteroviruses. A severe generalized infection with multisystem involvement may be evident at birth or a few days afterwards; death often results from heart failure due to severe myocarditis.

More recently, it has been recognized that, if acquired *in utero* or perinatally, HIV 1 may induce a cardiomyopathy in infancy which may result in arrhythmias and sudden death.

Acute myopericarditis

Acute myocarditis is defined as an 'inflammatory cell infiltration of the myocardium with necrosis and/or degeneration of adjacent myocytes, not typical of ischemic damage associated with coronary arterial disease'. There is invariably some pericardial involvement in patients with myocarditis and vice versa; because of this, they will be considered together, although the clinical features of one may predominate over the other.

Role of enteroviruses

Although many of the viruses listed in **Table 1** may cause acute myopericarditis, the accumulated data from a number of virological studies suggest that enteroviruses are the commonest cause of this disease. Serological studies employing techniques to detect virus-specific immunoglobulin M (IgM) indicate that about 33% to almost 50% of cases of acute myopericarditis are induced by enteroviruses, these findings being supported by the fact that enteroviral RNA has been detected in 20–40% of endomyocardial biopsies. As there are over 70 enterovirus serotypes, molecular biological studies generally employ sequences for hybridization or primers for polymerase chain reaction (PCR) which are highly conserved among this group of viruses. Because of this, and as virus-specific IgM responses may be broadly reactive against a number of enteroviruses, it is difficult to establish which particular enteroviruses are involved. However, the finding that many patients with myopericarditis often have high neutralizing antibodies to coxsackie B serotypes, and that this group of viruses is cardiotropic in certain strains of mice, suggests that coxsackie B viruses are more likely to be involved than other enteroviruses in the pathogenesis of acute myopericarditis.

HIVs may cause myocardial damage, although the prevalence of myocardial disease in patients with acquired immune deficiency syndrome (AIDS) has not been clearly established. However, one series suggested that it occurs in as many as 50% of cases. *In vitro* studies suggest that HIV is unable to gain entry into myocytes, and studies attempting to detect HIV in myocardial biopsies employing hybridization studies have produced conflicting results. Nevertheless, although myocarditis may be induced by HIV itself,

since the virus has been isolated from heart muscle, it is also possible that one or more opportunistic infections may also induce myocardial damage.

Chronic cardiac disease

Apart from enteroviruses and more recently HIV, there is as yet little information relating to the role of viruses in chronic cardiac disease. Two forms of chronic cardiac disease are associated with enterovirus infection, chronic relapsing myopericarditis and dilated cardiomyopathy (DCM).

Chronic relapsing myopericarditis About 20% of patients who develop acute myopericarditis in which the features of pericardial involvement predominate experience a relapsing course which may extend over a period of months or years. About 60% of such patients have a persistent enterovirus-specific IgM response during the relapsing course of the disease, which is indicative of a persistent antigenic stimulus. However, it is seldom possible to isolate virus from patients' stools or nasopharyngeal secretions during the acute phase and hardly ever during the relapsing course.

DCM DCM is defined as 'heart disease with intrinsic muscle dysfunction, excluding such causes as valvular heart disease and ischemic heart disease'. In developed countries, the disease has an estimated annual incidence of 100 000 and end-stage disease is, next to ischemic heart disease, the commonest cause of cardiac transplantation. The results of serological and nucleic acid hybridization studies suggest that enteroviruses may be involved in 20–40% of cases. *In situ* hybridization shows that replication of enteroviral RNA is focal and more restricted than in acute myocarditis and that the number of infected myocardial cells relates to the severity of disease.

Chronic heart muscle disease has been detected in children as well as adults with HIV 1 infection, including patients with different risk-behavior patterns. In general, cardiac disease is more likely to be present in patients with the later stages of HIV-associated disease. As specific antiviral chemotherapy and the prophylaxis and treatment of opportunistic infections improve survival time, it is possible that more cardiac disease will be seen to be the cause of death among HIV-infected patients.

Infection following cardiac transplantation

CMV infections occur commonly following cardiac transplantation. The severity of the infection is dependent on the severity of the immunosuppressive regime and the serological status of the donor and recipient. Thus CMV infections, often severe, occur in up to 60% of seronegative recipients transplanted with allografts from CMV-positive donors, infection usually being acquired via the allograft and occurring 6–8 weeks post-transplantation. If both donor and recipient are seropositive for CMV, infection is likely to be less severe and may result from infection via the allograft or re-activation of the patient's own CMV. Infection is associated with a significantly higher rate of graft rejection and graft-associated atherosclerosis. It is important to establish a diagnosis rapidly, since patients usually respond well to treatment with ganciclovir. Ganciclovir may also be used prophylactically in order to prevent seronegative recipients developing severe CMV following transplantation with an allograft from a seropositive donor.

Atherosclerosis

Atherosclerosis, particularly coronary heart disease, represents one of the leading causes of death in most industrialized countries. Furthermore there is now an increasing prevalence of disease in developing countries who are adopting a Westernized lifestyle. It has been recently postulated that viruses, particularly CMV, may play a role (see under Pathogenesis below).

Epidemiology

The epidemiology of influenza and other viruses listed in **Table 1** is described in entries on each of the specific viruses.

Since the accumulated data from a number of studies suggest that enteroviruses are the most frequent group of viruses involved in the pathogenesis of acute and chronic cardiac disease, it is appropriate to comment briefly about the epidemiology of this group of viruses. Enteroviruses are ubiquitous, and infection is spread by the fecal–oral route. In countries with poor standards of hygiene and sanitation, infection occurs in infancy and childhood, often subclinically. In industrialized countries, exposure to infection is often delayed and adults may experience some more severe manifestations of infection, including myopericarditis. In tropical climates where overcrowding and poor sanitation prevail, infection occurs throughout the year; up to 30% of infants under the age of 2 may be found to be excreting enteroviruses at any one time. In temperate climates enterovirus infections occur more commonly in summer and autumn, and epidemics with one or more serotypes tend to occur in 3–5 year cycles.

Pathogenesis

With the exception of enteroviral myocarditis, there

is comparatively little information relating to the pathogenesis of virally induced acute cardiac disease. However, since influenza A has been detected in cardiac tissues of a few patients with influenza who develop myocarditis, it is possible that damage may be induced directly by viral destruction of myocytes, although the possibility of immunopathological mechanisms cannot be excluded, particularly as membrane-bound viruses contain host antigens.

Whether or not patients experiencing enterovirus infection develop an acute myopericarditis depends on a complex interplay between viral and host factors. Experimentally induced acute enterovirus myocarditis in the mouse is histologically similar to human myocarditis in many respects, with extensive infiltration of lymphocytes, particularly T cells. However, murine myocarditis can only be induced if selected mouse strains and cardiotropic coxsackie B viruses, e.g. CVB-3m, are used. However, it is now known that enteroviruses have a particularly high mutation rate; some natural isolates of coxsackie B virus strains differ from the prototype by as many as 12 epitopes and the rate of mutation may be high as 10^{-4}. Minor but subtle changes in polypeptides expressed on the viral capsid may affect tissue tropism markedly. The accumulated data from a number of experimental studies in mice, together with the finding that virus is seldom isolated from patients' secretions or excretions recovered from cardiac tissue, suggest that enterovirus-induced myocardial damage is likely to represent a postinfectious autoimmune disease. Viral clearance probably results from synergistic responses between neutralizing antibodies, NK cells and macrophages, cardiac damage resulting from destruction of heart muscle fibers mediated by cytotoxic T lymphocytes recognizing virally induced neoantigens on monocyte membranes.

Two hypotheses have been suggested to explain the pathogenesis of enterovirus-induced dilated cardiomyopathy, the first being that disease results from persistent but defective viral replication, which may disrupt myocyte gene expression, impairing the function but not destroying the myocytes. The presence of relatively high amounts of viral RNA template strands in cardiac tissue of patients with dilated cardiomyopathy lends support to this hypothesis and may explain why infectious virus or viral antigens cannot be detected in the cardiac tissue of patients with dilated cardiomyopathy. The second hypothesis proposes that dilated cardiomyopathy has an autoimmune basis; virally induced alterations in MHC antigen expression resulting in exposure of neoantigens of the immune system represent a possible mechanism. Sharing of viral antigens with host cardiac tissue (molecular mimicry) may provide an alternative mechanism. Although a number of autoimmune phenomena have been detected in patients with dilated cardiomyopathy, it remains to be established whether they are involved in the pathogenesis of disease or merely represent epiphenomena.

The role of viruses in the pathogenesis of atherosclerosis among humans is speculative. However, Marek's disease virus (MDV), which is a herpesvirus affecting fowls, induces atherosclerosis in chickens; feeding on cholesterol-rich diets accelerates the disease progress. The administration of a live attenuated vaccine does not result in the development of atherosclerosis but prevents development of MDV-induced arterial lesions in chickens exposed to MDV. Among humans, evidence that CMV induces atherosclerotic change is much more circumstantial. CMV nucleic acid sequences and viral antigens have been detected in arterial smooth muscle including the coronary arteries of young adults experiencing traumatic deaths. Such lesions have been described in areas of the arterial wall showing early atherosclerotic changes. There is also some evidence that suggests that patients having transplants who become infected with CMV are particularly likely to develop accelerated atherosclerosis in the coronary arteries of the transplanted organ.

Clinical features

Acute myopericarditis Some patients present with a 3–4-day history of such nonspecific clinical features as malaise, myalgia, sore throat and fever, before developing the clinical features of the disease whereas others may present initially with cardiac manifestations including chest pain, tachycardia out of proportion to fever, gallop rhythm and breathlessness. A pericardial friction set may be available. Death may result from arrhythmias or from circulatory collapse. Raised cardiac enzymes and electrocardiograph (ECG) changes may resemble those seen in acute myocardial infarction if the myocarditis is restricted to a localized region of the myocardium. More commonly, the ECG is nonspecific but patients in whom the features of pericarditis predominate may have ST elevation. Some 80–90% of patients make a full recovery although a few die in the acute stage and others develop DCM, the features of which may appear rapidly or occur after many years following a prolonged latent phase.

Pericarditis in patients with AIDS Pericarditis is not uncommon in patients with terminal AIDS although this disease rarely contributes to the patient's death. However, pericarditis may occur

earlier and this may be neoplastic or infectious in etiology. A number of different infectious agents may be involved, including viruses, particularly those that cause opportunistic infections in patients with severe immunodeficiency disorders. It is important to distinguish between a neoplastic and an infectious cause since specific antimicrobial therapy may affect the patient's prognosis favorably.

DCM DCM often presents insidiously with increasing shortness of breath, lethargy and clinical features associated with cardiac failure since the heart has an impaired pump function. The absence of heart-valve, coronary-artery or lung disease is suggestive of DCM, which should be confirmed histologically by examination of an endomyocardial biopsy. In contrast with acute myopericarditis, the prognosis is poor, the 5-year survival rate being about 50% in the absence of cardiac transplantation.

Laboratory diagnosis

Specific virological investigations for many of the viruses listed in **Table 1** are described in the respective entries dealing with these infections.

Enteroviruses are the commonest cause of acute myopericarditis and, although attempts should be made to isolate virus from stools and nasopharyngeal washings, virus excretion is only rarely present when patients present with symptoms, as cardiac events occur relatively late in the course of infection, since they are probably induced by immunopathological mechanisms. By the time patients present with cardiac disease, neutralizing-antibody responses have usually reached maximum levels. Although high titers may provide circumstantial evidence of recent infection, such titers may persist for a varying but often prolonged time after infection, which may be subclinical and therefore unrelated to the patient's current illness. Detection of enterovirus-specific IgM may be useful, since its presence is indicative of a current or recent antigenic stimulus; such responses usually persist for 3–6 months but occasionally longer following an acute infection. Although up to 50% of patients with acute myopericarditis may have an enterovirus-specific IgM response, such responses may be detected in 5–10% of apparently healthy persons, presumably the result of a recent subclinical enterovirus infection. In patients from whom endomyocardial biopsies are obtained, attempts may be made to detect enterovirus RNA by hybridization studies employing cDNA-labeled probes or by PCR.

Enteroviruses may be readily isolated from excretions and secretions as well as organs obtained at autopsy from infants with severe generalized neonatal enterovirus infection.

Although evidence of possible enterovirus infection in patients with DCM may be obtained by detecting enterovirus-specific IgM responses, some workers have been unable to demonstrate consistent differences between patients and controls. Examination of endomyocardial biopsies or cardiac explants using molecular biological techniques to detect enteroviral RNA are, of course, more reliable but, because of sampling errors, it may be necessary to examine a large number of sections.

A diagnosis of infection by CMV in cardiac-transplant patients may be achieved either by isolating virus from the patient's urine or nasopharyngeal secretions or, more rapidly, by detecting the presence of CMV antigens by immunofluorescence in urine or nasopharyngeal secretions or in the buffy coat. In patients who develop pneumonitis, viral antigens may be detected in washings obtained by bronchoalveolar lavage.

Viruses Affecting the Pancreas

Introduction

During the viremic phase of many systemic infections, pancreatic infection is likely to be common. However, as most viral infections are not fatal and because pancreatic changes may be subtle and therefore not adequately investigated, less attention has been directed towards the viral effects of pancreatitis than is the case for many other organs.

Nevertheless, studies on children with disseminated fatal viral infections showed that pancreatic lesions, often with islet cell destruction, were present in patients with coxsackie B, CMV, varicella-zoster and congenitally acquired rubella. In addition, pancreatitis has been observed following mumps and, less commonly, following Epstein–Barr virus (EBV) infection and hepatitis B virus infections. The finding that hepatitis B surface and core antigens have been detected in the acinar cells of patients with hepatitis B antigenemia suggests that this virus may replicate in pancreatic tissue. Although such filoviruses as Marburg and Ebola induce generalized infections with severe hepatic involvement, some patients develop clinical features of acute pancreatitis, and post-mortem studies have demonstrated areas of focal pancreatic necrosis.

EBV infections are closely involved in the pathogenesis of Burkitt's lymphoma and this lymphoma may be found at autopsy to involve the pancreas relatively commonly. It may present clinically as a diffuse enlargement of the pancreas, this being due to

the tumor itself, or a pancreatitis resulting from tumor lysis induced by chemotherapy.

Mumps

The exact frequency of pancreatitis complicating mumps is not known although a figure of about 5% has been suggested. Experimental studies employing human cell cultures have shown that mumps virus may destroy islet cells.

Patients present with epigastric pain, often severe, and vomiting, during which time serum amylase levels are markedly raised. In general, patients make a good recovery although rarely a severe hemorrhagic pancreatitis may occur.

Enteroviruses

Some studies have suggested that enteroviruses, particularly coxsackie B viruses, may cause acute pancreatitis although the commonest etiological factors are biliary disease and alcohol abuse. In order to assess the incidence of enteroviruses as a cause of acute pancreatitis, large-scale multicenter clinical and virological studies are required, employing some newly developed virological techniques.

CMV

Postmortem studies have shown histological changes in the pancreas consistent with CMV infection in infants dying with severe congenitally acquired CMV. Immunocompromised patients, including those with AIDS, may develop severe disseminated opportunistic infections by herpes, particularly CMV infections in which pancreatic lesions may be detected. However, pancreatitis is not generally a prominent feature of post-transplant CMV infection but, when it occurs, is often associated with a fatal outcome.

Role of viruses in the pathogenesis of insulin-dependent (Type I) diabetes mellitus (IDDM)

In recent years, considerable attention has been focused on the role of viruses in the pathogenesis of IDDM. It occurs in about 1 in 1000 children in industrialized countries and there is some evidence that the incidence is increasing. This disease, which has a strong autoimmune component, represents a complex interplay between genetically determined and environmental factors, and viruses may play a role. That environmental factors are important is suggested by the finding that IDDM is discordant in approximately 50% of identical twins when disease is initially diagnosed among persons aged less than 40.

Experimental studies in mice, case reports and seroepidemiological studies have implicated such viruses as coxsackie B, mumps, rubella, CMV and reoviruses.

Experimental studies

Picornaviruses may induce diabetes in certain inbred strains of mice. It is probable that susceptibility is conferred by an inherited autosomal trait. The gene product controlling susceptibility may be a virus receptor on the plasma membrane of β cells complementary to epitopes on certain picornaviruses. Encephalomyocarditis virus (EMCV) and strains of coxsackie B viruses induce lytic infections in islet cells, and infected mice develop abnormal glucose tolerance and hyperglycemia. Two variants of EMCV, D and B, have been identified, the D variant inducing prolonged hyperglycemia as well as retinal and renal damage resembling diabetic complications in humans. The B variant is non-diabetogenic, but prior infection protects mice from infection by the D variant. The B variant is deficient in at least one oligonucleotide, 20–25 nucleotides in length. Coxsackie B viruses usually infect acinar cells but β-cell tropism can be induced by passage in pancreatic cultures rich in islet cells. Such virus strains induce a transient hyperglycemia in susceptible mice.

In vivo, lymphocytic choriomeningitis virus (LCMV) induces a persistent infection in the absence of cytocidal changes in newborn mouse β cells. Infected mice develop hyperglycemia and abnormal glucose tolerance, possibly as a result of viral gene products competing with insulin synthesis.

All three reovirus serotypes may induce pancreatic damage involving the acinar cells in newborn mice. However, reoviruses 1 and 3 can infect and damage islet cells. Mice infected with reovirus 1 are runted and develop polyendocrine disease with a transient diabetes, developing autoantibodies directed not only against islet cells but the other endocrine organs including anterior pituitary and thymus as well as the gastric mucosa of uninfected mice. Polyendocrine disease associated with autoantibodies may also be seen in patients with recently diagnosed IDDM.

Evidence linking virus infection with IDDM in humans

Congenitally acquired rubella Follow-up studies on children with congenitally acquired rubella have shown that 20% of infants whose mothers were infected during the 1941 Australian epidemic and 12.5% during the 1963–1964 USA epidemic developed IDDM, islet cell antibodies being present in 20%. This suggests that more patients will develop IDDM in due course. Clinical manifestations of disease are often delayed until adolescence or adult life.

The distribution of human leucocyte antigen (HLA) types is typical of those among patients with autoimmune disease, including patients with IDDM that is not associated with congenitally acquired rubella. Thus, there is a significant increase in HLA DR3, some increase in HLA DR4 and a virtual absence of HLA DR2. Islet cell surface antibodies, which precede the onset of IDDM by months or years, have a cytotoxic effect on islet cell cultures. Although autoimmune mechanisms undoubtedly play an important role in the pathogenesis of IDDM following congenitally acquired rubella, the method by which this virus triggers this has not been established.

Anecdotal reports of IDDM associated with acute viral infections A small number of cases of IDDM have occurred in which the onset of diabetes was associated with well-documented infection by mumps or coxsackie B viruses. Although this association may be merely temporary since such infections are common in childhood, detection of coxsackie B4 virus or its antigens in pancreatic tissue of a fatal case and the finding that when this virus as well as a coxsackie B5 virus isolated from a nonfatal case induced hyperglycemia in mice, suggests that these virus strains have diabetogenic potential. The virus from the fatal case induced infiltration of inflammatory cells and β-cell necrosis in the mouse pancreas, coxsackie B antigen being detected in the β cells. Five cases have so far been reported in which laboratory-confirmed coxsackie B virus infection occurred contemporaneously with the onset of the symptoms of IDDM.

Despite these observations, it must be appreciated that IDDM has many of the features of a classical autoimmune disease, the presence of islet cell antibodies and of abnormal glucose tolerance preceding the onset of IDDM by months or years. This suggests that perhaps only exceptionally can acute viral infections cause such extensive destruction of β cells to precipitate the rapid development of IDDM.

IDDM has also occasionally been reported among children who have recently developed mumps, particularly if there has been evidence of an acute pancreatitis. Studies carried out in Norway in the earlier part of this century drew attention to the finding that epidemics of mumps were followed by an increased number of deaths from juvenile diabetes within a 4-year period. More recently, islet cell antibodies have been detected in a high proportion (46%) of patients with mumps and infectious mononucleosis (over 50%), although not in patients infected with enteroviruses, measles and postnatally acquired rubella. However, if mumps virus is significantly related to the pathogenesis of IDDM, the extensive use of attenuated mumps vaccine in the USA, and now elsewhere, should result in a marked decline in the incidence of IDDM; this has not been observed in the USA.

Seroepidemiological studies

A number of studies have been conducted comparing serological responses to coxsackie B viruses among patients with IDDM and matched controls. Most of the earlier studies employed neutralization, but, more recently, tests to detect enterovirus-specific IgM have been used. Although there is a tendency for a greater proportion of patients with IDDM to have higher neutralizing-antibody responses, this pattern is inconsistent. Tests to detect enterovirus-specific IgM responses have been carried out in the UK and Scandinavia; in certain years, there appears to be a close correlation between virus-specific IgM responses and the onset of IDDM but not in others. The accumulated data from serological studies suggest that if enteroviruses are involved in the pathogenesis of IDDM, they may precipitate symptomatic disease in patients who already have compromised β-cell function rather than initiate the train of events that results in autoimmune mechanisms that progressively destroy β cells over a prolonged period. This hypothesis is supported by the finding that mice given a subdiabetogenic dose of streptozotocin, a β-cell poison, develop β-cell destruction, abnormal glucose tolerance and hyperglycemia when challenged with a nondiabetogenic strain of a coxsackie B virus.

Hypotheses to explain virally induced IDDM in humans

In addition to IDDM very occasionally resulting from an acute lytic viral infection or viral infection precipitating disease in patients with already compromised β-cell function, alternative and perhaps more plausible mechanisms are likely. Firstly, persistent viral infections may occur, resulting in the conservation of the vital but not specialized functions of β cells. The possibility that such phenomena may be induced by enteroviruses, for example coxsackie B viruses, should not be discounted since picornaviruses are now established as causes of persistent infections in animals (e.g. foot and mouth disease, Theiler's virus infections) and man (chronic cardiac disease, chronic fatigue syndrome). The finding that immunoreactive α-interferon has been found in pancreatic tissue removed at necropsy from patients with IDDM may support the presence of virally induced disease. Most of these specimens also showed hyper-expression of MHC Class I antigens, similar findings being present in cases of acute infantile pancreatitis, most of

which were caused by coxsackie B virus infections. Molecular biological techniques, particularly PCR, will be useful in determining whether viruses can be detected and shown to persist in residual β cells among patients with IDDM.

Secondly, viral infection may induce IDDM by triggering autoimmune responses; a persistent infection is also consistent with such a hypothesis. Autoimmune responses may result from epitope sharing between viral and cellular components (a molecular mimicry), the induction of anti-idiotype responses which may react not only with viral antibody but also viral receptors on the cell surface, or the aberrant expression of MHC Class II antigens on epithelial cell surfaces. Thus, viral infection, perhaps asymptomatic, may induce γ-interferon which in turn may result in the expression of aberrant HLA DR antigens on the surface of endocrine epithelial cells which will enable them to function as antigen-presenting cells, presenting cell antigens to autoreactive T cells. This hypothesis is consistent with the prolonged latent phase between infection with a virus and the clinical manifestations of IDDM.

Viruses Affecting the Kidney

Viruses may reach the kidney during the viremic phase of infection, and replicate within the organ. A number of outcomes are possible including asymptomatic replication, direct virally induced specific damage, the establishment of viral latency or indirect damage via such secondary mechanisms as hypovolemia and immune-complex deposition.

It is probable that few viruses exert a direct effect on the kidney, but this may merely reflect the lack of appropriate investigations. The extent of asymptomatic infection is also unknown as postmortem studies are only likely to be conducted if macroscopic changes are evident, or if antemortem biochemical or physiological indicators are suggestive of renal pathology. However, indirect evidence of asymptomatic renal involvement can be found by the detection of whole virus or viral antigen in the urine.

Following certain infections, most notably with CMV, certain adenoviruses and human polyomaviruses [JC virus (JCV) and BK virus (BKV)] latency is established and re-activation as evidenced by excretion in the urine may occur at intervals throughout the patient's life. In an immunocompetent person, such re-activations lead only rarely to symptomatic infection, but, in immunosuppressed patients, such latent viruses may play a significant part in their morbidity and even mortality.

Certain viruses may cause renal damage indirectly. Such secondary mechanisms include hypovolemia following hemorrhage, or alteration in endothelial permeability, leading to oliguria, anuria and increased blood urea nitrogen (BUN), or immune-complex deposition in the glomerular basement membrane with subsequent alteration of glomerular function.

Immune-complex deposition
Hepatitis B
CMV
HIV?
Arenaviruses

Table 2 summarizes the viruses that fall into the above categories. However, as a virus may fall into more than one category, such divisions, although helpful, should not be treated as discrete entities.

CMV

CMV belongs to the family *Herpesviridae* and has a morphology by electron microscopy indistinguishable from the other members of the family. A detailed account of the viral properties and epidemiology can be found elsewhere in this volume. Like other herpesviruses it has the capacity to incorporate its viral DNA into host cells and can therefore establish a latent infection in salivary gland epithelium, lymphocytes, kidneys and probably other organs. Occasionally the virus re-activates and infectious virions can be found in the urine and/or saliva. Such re-activations are usually asymptomatic, thus allowing horizontal spread within the community. Indeed, in the immunocompetent patient, even primary CMV infection causes only minimal morbidity thus maximizing contact of the infected host with other susceptible

individuals. In primary infections, viruria provides evidence of renal involvement, cytomegalic cells being most pronounced in the proximal tubules of the cortex; these cells may also be found in the loop of Henle and collecting tubules. Infiltrates containing early and late CMV antigens are commonly seen and in severe disease immune complexes may be deposited in the glomeruli. Although kidney infection may be prolonged, it rarely results in renal dysfunction. However, CMV plays an important role in the morbidity and mortality of transplant patients. As the virus remains latent in the distal tubular epithelium, it is possible to transmit infection following transplantation. In patients who are seronegative prior to the operation, there is an estimated 70–80% acquisition of primary CMV if the donor organ is CMV positive but only 5% if the donor organ is CMV negative. However, there is also a degree of morbidity amongst seropositive recipients of seropositive kidneys. Between 60 and 95% experience either reactivation or re-infection following transplantation; restriction enzyme analysis may help to distinguish between these. The extent of the disease (e.g. pneumonitis, gastroenteritis, leukopenia, enhanced graft rejection) is in part governed by the degree of immunosuppression, and patients with a poor transplant history who receive additional treatment are at greater risk from CMV. In patients experiencing graft rejection there is a distinct glomerulopathy in the presence of CMV viremia, characterized by enlargement of endothelial cells, mononuclear cell accumulation and fibrillar material in the glomerular capillaries. It is not certain whether CMV is directly responsible for this pathology. Other possible mechanisms include immune-complex disease and immunological cross-reactivity (molecular mimicry) between CMV and HLA DR β chain which share sequence homology. Prophylaxis with acyclovir and more recently gancyclovir, which is currently reserved in the UK for seronegative recipients of seropositive kidneys and seropositive recipients of seropositive kidneys who are receiving additional immunosuppresive therapy, has shown a decrease in morbidity and mortality from CMV in these patients.

Hepatitis B

Details of the properties and epidemiology of hepatitis B can be found elsewhere in this volume.

Extrahepatic manifestations of viral hepatitis are seen in approximately 10–20% of patients, the pathogenesis of which is thought to be immune-complex-mediated. Glomerulonephritis and nephrosis associated with hepatitis B has been described in both adults and children in numerous studies. Children, in particular, may not exhibit liver disease and in some adults it may also be minimal or absent. Complexes of hepatitis B antigen and immunoglobulin have been demonstrated in the serum and glomeruli of patients with membranous nephropathy, thus supporting the hypothesis that the disease is immune-complex-mediated. A membranous glomerulonephropathy is more likely to develop in adults who acquire the disease in childhood and who are hepatitis e antigen positive. The prognosis in children tends to be good but, approximately 10% of adults are given maintenance dialysis and about one-third show poor progress despite attempts to treat with interferon.

HIV

A detailed account of the viral properties and epidemiology is given elsewhere in the Encyclopedia.

Patients with HIV infection can manifest a spectrum of potentially reversible forms of acute renal failure and a unique form of glomerulonephropathy. The entity of HIV-associated nephropathy was first described in 1984 and is increasingly being recognized. It is characterized by distinct clinical and pathological features thought to be caused by direct viral damage. It causes irreversible renal failure and this provides the additional problem of managing HIV patients on dialysis units.

A variety of renal lesions, particularly tubulointerstitial, have been found at postmortem. These include, for example, nephrocalcinosis and interstitial nephritis which are associated with an antemortem history of electrolyte disorders. Evidence of glomerular involvement in the form of focal segmental glomerulosclerosis has also been found. This is associated with heavy proteinuria in excess of 3.5 g per day and rapidly progressive renal failure. It is more commonly found in young black men, about half of which are intravenous drug users, the remainder belonging to other well-recognized risk groups.

Another postmortem finding is that of diffuse mesangial hyperplasia associated with deposits of IgM and C3. An immune-complex mechanism has been proposed but the antigen involved remains elusive. Such lesions are rarely associated with overt disease.

Adenoviruses

The family *Adenoviridae* comprises over 47 human serotypes which have been divided into six subgenera based on the sequence homology of their DNA. A further division of the subgenus B (B1, B2), based on differences in DNA-restriction sites, has identified

Table 3 Hantaviruses that cause human disease

Genus	*Host*	*Human disease*	*Geographical distribution*
Hantaan	*Apodemus agrarius* (field mouse)	Hemorrhagic fever with renal syndrome	Korea, E. USSR, Manchuria, China
Seoul	*Rattus* species (wild/lab)	Hemorrhagic fever	East Asia, world-wide, seaports
Puumala	*Clethrionomys glareolus* (bank vole)	Nephropathia epidemica	Scandinavia, Europe, W. USSR
Prospect Hill	*Microtus pennsylvanicus* (meadow vole)	Infection only	USA

four serotypes (11, 14, 34, 35) known to establish low-grade persistent infections of the kidney. It is likely that viral replication proceeds at a reduced rate in this situation, since, during acute infection, the adenovirus switches off expression of host mRNA leading to an unregulated production and consequent accumulation of viral protein in the cell nucleus, with destruction of normal cell function. These latent viruses are most commonly re-activated in immunosuppressed patients, such as those with AIDS, and in bone- and renal-transplant recipients. There have also been occasional reports of adenovirus 11 being transmitted during kidney transplantation leading to hemorrhagic cystitis in the recipients.

Human polyomaviruses

BKV and JCV are the two polyoma viruses (family *Papovaviridae*) known to infect man. These non-enveloped icosahedral double-stranded DNA viruses are antigenically distinct and exhibit minimal cross-reactivity in serological tests. BKV is acquired in early childhood, about 90% by 5 years, most people having antibodies that persist through adult life. The acquisition of JCV is less clear cut, with rates varying greatly among different populations. In the UK, the virus is acquired more slowly with only 5% of 5 year olds and 50–60% of adults showing evidence of infection. In the USA, initial acquisition is higher and there is a further increase after 50 years with the level reaching about 75%. Infection is thought to be transmitted via the respiratory route, with virus reaching target organs via the blood.

In the immunocompetent host, following primary infection, virus remains latent in the kidney, nucleotide sequences having been found in a number of kidneys at postmortem. Immunosuppression, particularly if it leads to a deficiency of T cells, can result in virus re-activation with excretion of virus in the urine. In renal-transplant recipients and pregnant women, both viruses re-activate frequently, but in bone-marrow-transplant recipients, BKV re-activation greatly exceeds that of JCV.

Some 25–45% of renal-transplant patients excrete virus in the urine postoperatively which may last from weeks to months. As with CMV, infection may be primary, or result in re-activation or re-infection. BKV is more likely to produce a re-activation/re-infection and JCV, a primary infection. However, unlike CMV these viruses mainly cause asymptomatic infection. If infection leads to renal dysfunction, it may be misdiagnosed as graft rejection and consequently immuno-suppressive therapy increased. This may result in the development of ureteric stenosis in the transplant recipient.

About 40–50% of bone-marrow-transplant patients have been found to excrete polyomavirus, mainly BKV, in the urine about 2–8 weeks after transplant. Again most infections are not associated with illness. However, late-onset BK viruria has been associated with late-onset hemorrhagic cystitis, the frequency being greater in autologous transplant patients.

Hantaviruses

The genus *Hantavirus* (family *Bunyaviridae*) has four members known to cause human disease, namely Hantaan, Seoul, Puumala and Prospect Hill virus. These segmented single-stranded negative-sense RNA viruses are enzootic in wild rodents and cause persistent asymptomatic infection with excretion in body fluids despite high titers of neutralizing antibodies. There is no evidence of vertical transmission in animals. Transmission to humans is by inhalation of aerosolized excreta. Although this therefore requires close contact, there is no evidence of person to person spread.

Table 3 summarizes the enzootic host, nature of human disease and geographical distribution of each genus.

Korean hemorrhagic fever (KHF) or hemorrhagic

fever with renal syndrome (HFRS) was first described in 1951 and is by far the most severe of the diseases. About 33% of those infected experience hemorrhagic manifestations, the remainder having an influenza-like illness. Some 10–15% experience hypovolemic shock and 5–10% die. Clinical features of a typical severe case include a sudden onset of high fever, myalgia and malaise which lasts approximately 3–7 days, followed by a relatively short hypotensive phase characterized by petechial hemorrhages, proteinuria and thrombocytopenia. About one-third of deaths occur as a result of hypovolemic shock at this stage. During the oliguric phase, which can last up to 1 week, a further 50% of deaths occur. The final phase of diuresis may last for weeks, with full recovery taking about 6 months.

Undoubtedly some of the renal damage is the result of hypovolemia but evidence of direct viral damage has also been found at the microscopic level. Renal tubules show evidence of congestion, desquamation and necrosis.

The Seoul virus produces less severe disease with a lower fatality rate than Hantaan virus infection.

Although nephropathia epidemica, an acute fever with renal involvement, has been known for years in Scandinavia, it has only recently been attributed to the Puumala virus. Again the disease is relatively mild with a mortality rate of less than 1%.

Prospect Hill virus, which is enzootic in meadow voles in the USA, very rarely produces human disease.

Colonized experimental rats may act as a reservoir of Hantaan virus and have been responsible for a number of outbreaks of HFRS among laboratory personnel in Japan, Korea and Belgium. Worldwide surveys have shown evidence of urban and laboratory rats infected with hantaviruses in parts of Asia, Europe and the Americas where as yet no disease has been reported, suggesting that such agents exist all over the northern hemisphere where rodents can be found. It may, therefore, be worth considering the diagnosis of hantavirus infection in cases of idiopathic glomerulonephritis.

Arenaviruses

These are a group of enveloped single-stranded RNA viruses, three of which cause hemorrhagic fever in man: Lassa in West Africa, Junin in Argentina and the Machupo virus in Bolivia. These viruses, like the hantaviruses, are also enzootic in wild rodents causing asymptomatic infection with persistent virus excretion in the urine. Spread to humans is via contact with the infected excreta, which may occur both in the natural setting, when rodents are caught for food, and in the laboratory. Cases of laboratory acquired infection, although few in number have been associated with considerable mortality. Although disease induced by these viruses is probably due to their direct cytolytic action, LCMV, another arenavirus, is known to exert its effects by immunologically mediated mechanisms.

The hemorrhagic arenaviruses produce a similar disease pattern in man, with an insidious onset of chills, malaise, headache, retroorbital pain, myalgia and nausea. This is followed by fever, conjunctival injection rash and edema of the face, neck and lower thorax. Hypotension with oliguria and bleeding from the gums and nose, hematemesis, hematuria and malena then develop. The oliguria may lead to anuria and profound neurological problems may also develop.

Evidence for direct viral replication and subsequent renal involvement is the development of renal tubular acidosis, indicative of tubular lesions. Viral antigens have also been demonstrated in tubular epithelium. Postmortem examination of the kidneys in Argentinian hemorrhagic fever shows patchy tubular and papillar necrosis together with other less-specific changes of generalized vasocongestion and multiple hemorrhages.

Glomerular function appears to be directly related to cardiac output and is reduced in consequence of the hypovolemia associated with changes in capillary endothelial cells. Despite the fall in serum Na^+ and K^+ concentrations, there is an increased excretion of these electrolytes producing hyperosmotic urine. This is due to an increased production of antidiuretic hormone (ADH), either autonomously or as a result of the hypovolemia.

There is little evidence to support the development of immune complexes during infection with the hemorrhagic fever arenaviruses, there being no glomerular deposition of immunoglobulin, complement (C3) or viral antigens, this being in sharp contrast to infection with LCMV. It would seem, therefore, that renal damage is the result of a combination of direct viral damage to the renal tubules and hypovolemia with consequent reduction in glomerular function.

Diagnosis

A variety of methods can be employed such as direct visualization of virus by electron microscopy, viral antigen detection by immunofluorescence, virus isolation and serology. Close consultation with laboratory personnel ensures that the appropriate specimens are collected and the right tests are carried out.

CMV can be isolated from a variety of specimens including urine, nasopharyngeal secretions, periph-

eral blood lymphocytes and others such as bronchoalveolar lavage and lung biopsies. Demonstration of a cytopathic effect in a human fibroblast cell line may take up to 3 weeks, which is inappropriately long if prompt treatment is needed. In renal-transplant patients, it may be critical to distinguish rapidly between graft rejection and acute CMV where management of immunosuppressive drugs would be diametrically opposed. In this situation, the detection of early antigen fluorescent foci (DEAFF) test can be employed which gives a result in 24 h. In this technique, samples of urine, peripheral blood lymphocytes and nasopharyngeal or bronchial washings are absorbed on to a monolayer of human fibroblasts (e.g. HELS), incubated overnight and the presence of early antigen detected by a series of specific antibodies, the last of which is labelled with fluorescein. CMV-specific nuclear antigen may then be demonstrated with the aid of a fluorescence microscope. Results should be interpreted with caution before the recommendation of specific treatment, as a positive urine or throat swab alone may be due to asymptomatic re-activation and not represent active disease. The finding of a positive result in peripheral blood lymphocytes is, however, highly significant.

Serological tests may also aid diagnosis, for example, demonstrating a rising complement-fixating titer (CFT) of antibodies to adenoviruses. In primary CMV infection, seroconversion can be demonstrated using a latex test or CFT, but, for re-activation/re-infection, it is necessary to demonstrate rising titers using CFT. In an immunocompetent patient, with the use of a sensitive and specific solid-phase radioimmunoassay, CMV-specific IgM can be detected in about 90% of primary infections but not in re-activation infections. However, in the immunosuppressed patient, results are less clear cut, with some patients with a primary infection failing to produce CMV-specific IgM and approximately one-third producing IgM antibodies during re-activation or re-infection.

Viruses Affecting the Thyroid

The effect of viruses on the thyroid is an area that has been underresearched; there are few reports of specific viruses being associated with thyroid disease.

Both acute and subacute thyroiditis have long been thought to have a viral etiology, but no specific association has been found despite numerous studies measuring broad spectra of viral antibodies in paired serum samples. However, an association between antibodies reactive with microsomal and/or thyroglobulin fractions of thyroid tissue has been found in 20–40% of congenital rubella sera. Thyroid function was found to be abnormal (showing both hypo- and hyperthyroidism) in 5% of all congenitally infected children being restricted to those with thyroid autoantibodies. The finding of rubella virus antigen in a biopsy of thyroid tissue from a 5-year-old boy with congenital rubella and Hashimoto's thyroiditis suggests that virus may persist in the tissue even though no virus is isolated. It is interesting to note that there is a certain degree of sequence homology between the N terminus of the C protein of rubella virus and human thyroglobulin, and it is therefore possible that antibodies result from molecular mimicry.

Although a study of HIV-positive children showed them to be euthyroid, approximately one-third of the patients had elevated baseline and peak thyrotropin levels in response to thyroid-releasing hormone (TRH), suggesting a state of compensated hypothyroidism. It is possible that suitable alterations in thyroid regulation may contribute to failure to thrive in some HIV-positive children. A study comparing adults with AIDS, asymptomatic HIV-positive patients and healthy controls showed that there was a decreased tri-iodothyronine uptake and free thyroid hormone in AIDS and HIV-positive patients in comparison with controls, this being inversely related to an elevated serum thyroid-binding globulin (TBG) in the same patients. There was no correlation between thyroid function and the T helper/suppressor cell ratio. It would appear that any viral effects on the thyroid gland are minimal, and overt disease is as yet undescribed.

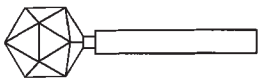
P

P2, 186 AND RELATED PHAGES (*MYOVIRIDAE*)



Ian B Dodd and **J Barry Egan**, Department of Biochemistry, University of Adelaide, Australia

Introduction

P2 was isolated by G. Bertani in 1951 from the Lisbonne and Carrère strain of *Escherichia coli*. 186 was isolated by F. Jacob and E. Wollman in 1961 from *E. coli* from human feces. HP1 was the first phage to be isolated from *Haemophilus influenzae* Rd.

P2, 186 and HP1 are the best characterized members of a large and widespread family of temperate double-stranded (ds) DNA bacteriophages. P2 can infect *E. coli, Shigella, Serratia, Klebsiella* and *Yersinia* species but the only known host for 186 is *E. coli* strain K12. Many phages serologically related to P2 have been isolated, with such phages common in natural environments. The genomes of P2, HP1 and 186 have now been completely sequenced and related DNA sequences have been obtained for phages PSP3 (*Salmonella*), K139 (*Vibrio cholerae*), ϕCTX (*Pseudomonas aeruginosa*) and S2, a close relative of HP1. The ϕR67 and ϕR86 defective prophages of *E. coli* are P2-related, as is a chromosomal DNA segment from *Haemophilus somnus*.

The available DNA sequences of the P2-like phages indicate that they are not closely related to other temperate and virulent phages. Thus, they continue to be useful alternative model systems for studying phage morphogenesis, DNA replication, the control of gene expression and site-specific recombination. A unique feature of these phages is their ability to serve as helpers for the P4 family of satellite bacteriophages. In addition, the ϕR67 and ϕR86 prophages contain different retrons (reverse transcriptase-producing elements) inserted at the same location in the prophage. The P2 family of phages may also be medically important; ϕCTX carries a gene for a mammalian cytotoxin that is expressed by the prophage.

Taxonomy and Classification

P2 and 186 virions are indistinguishable and have icosahedral heads of 62 nm diameter and 135 × 18 nm inflexible tails with a contractile sheath and multiple tail fibers of 40–50 nm. On the dubious criterion of virion structure they are classed with T4 and P1 in the *Myoviridae*. The HP1, K139 and ϕCTX virions are similar to P2 but their inclusion in the P2 family is based on DNA sequence similarity.

Genome Structure

The genomes of the P2 family are dsDNA of about 30–35 kb with cohesive ends. The P2 genome is 33 574 bp, 186 is 30 624 bp and HP1 is 32 355 bp.

To a first approximation, the genomes of P2, 186 and HP1 can be divided into early-expressed and late-expressed regions (**Fig. 1**). The late region encompasses two-thirds of the genome and contains the genes for construction of virus particles and cell lysis. The early region is concerned primarily with the choice between the lytic and lysogenic modes and with replication of the phage DNA. The majority of the genome is transcribed rightward. The juxtaposition of the early and late regions is the same in all three phages. However, the location of the cohesive end site (*cos*) is different in HP1 (**Fig. 1**).

The P2, 186 and HP1 genomes each contain 42 genes (**Table 1**). P2 and 186 share 32 homologous or known analogous genes whose order on the phage chromosome is completely conserved (**Fig. 1**). HP1 is less closely related, sharing only nine genes with P2 and 186 (**Table 1**).

Molecular Biology

Lytic versus lysogenic development

The temperate lifestyle involves two alternative modes of reproduction. The lytic cycle comprises infection, rapid DNA replication, virion construction, cell lysis and reinfection. In lysogeny, the P2 family

Table 1 P2 and 186 genes and their functions

Gene[a]			
P2	*186*	*HP1*	*Function (comment)*
Q	*orf2*	*orf15*	Capsid portal vertex
–	*W*		Unknown. (Homology to large terminase subunit)
P	*orf12*	*orf16*	Large terminase subunit
O	*V*	*orf17*	Capsid scaffold
N	*T*	*orf18*	Major capsid protein
M	*R*	*orf19*	Small terminase subunit
L	*Q*		Head completion
X	*orf23*		Tail
Y	*orf24*	*hol*[b]	Lysis – holin
K	*P*	*lys*[b]	Lysis – endolysin. (K and P homologous to λ R)
lysA	–		Lysis – timing
lysB	*orf27*		Lysis – timing
orf	*orf28*	*orf*	Unknown
R	*N*		Tail completion
S	*orf31*		Tail completion
orf30	–		Unknown
V	*orf32*		Tail spike
W	*M*		Baseplate? (Homology to T4 baseplate wedge)
J	*L*		Baseplate/tail fiber
I	*orf38*		Tail
H	*K*	*orf31*	Tail fiber. (Partial homologies with many phages)
G	*orf45*		Tail fiber assembly. (Partial homologies with many phages)
fun	–		Confers T5 resistance on lysogen
F_I	*J*	*orf23*[b]	Tail sheath
F_{II}	*I*	*orf24*[b]	Tail tube
E	*H*		Tail. (Programmed translational frameshift)
T	*G*		Tail
U	*F*		Tail
D	*D*		Tail
ogr	*B*		Late promoter activator. (Zinc finger DNA-binding protein)
–	*orf69*		Unknown – not essential
int	*int*	*int*	Integrase
C	*cI*	*cI*	Immunity repressor
cox[b]	*apl*[b]	*cox*[b]	Excision and transcriptional control
–	*cII*		Establishment of lysogeny. (Transcriptional activator)
orf78	–		Unknown. (Overexpression lethal)
–	*fil*		Inhibitor of cell division
–	*dhr*		Inhibitor of host replication – improves burst size
B	–		Replication. (DnaC analogue?)
–	*orf79*		Unknown – not essential
orf80	–		Unknown. (Overexpression lethal)
orf81	–		Unknown
orf82	*orf80*		Unknown. (Overexpression of Orf82 lethal)
–	*orf81*		Unknown – not essential
orf83	*orf83*		Unknown – not essential in 186
–	*orf84*		Unknown – not essential
A	*A*	*rep*	Replicase. (Rolling circle replication)
orf91	–		Unknown
tin	–		Makes lysogen resistant to T-even phages
old	–		Makes lysogen resistant to λ
–	*tum*		Prophage induction. (Antirepressor)
–	*orf97*		Unknown. (Overexpression inhibits 186 infection)

[a] All known P2 and 186 genes are listed, along with HP1 genes of known function.
[b] Analogous gene products show little or no homology.

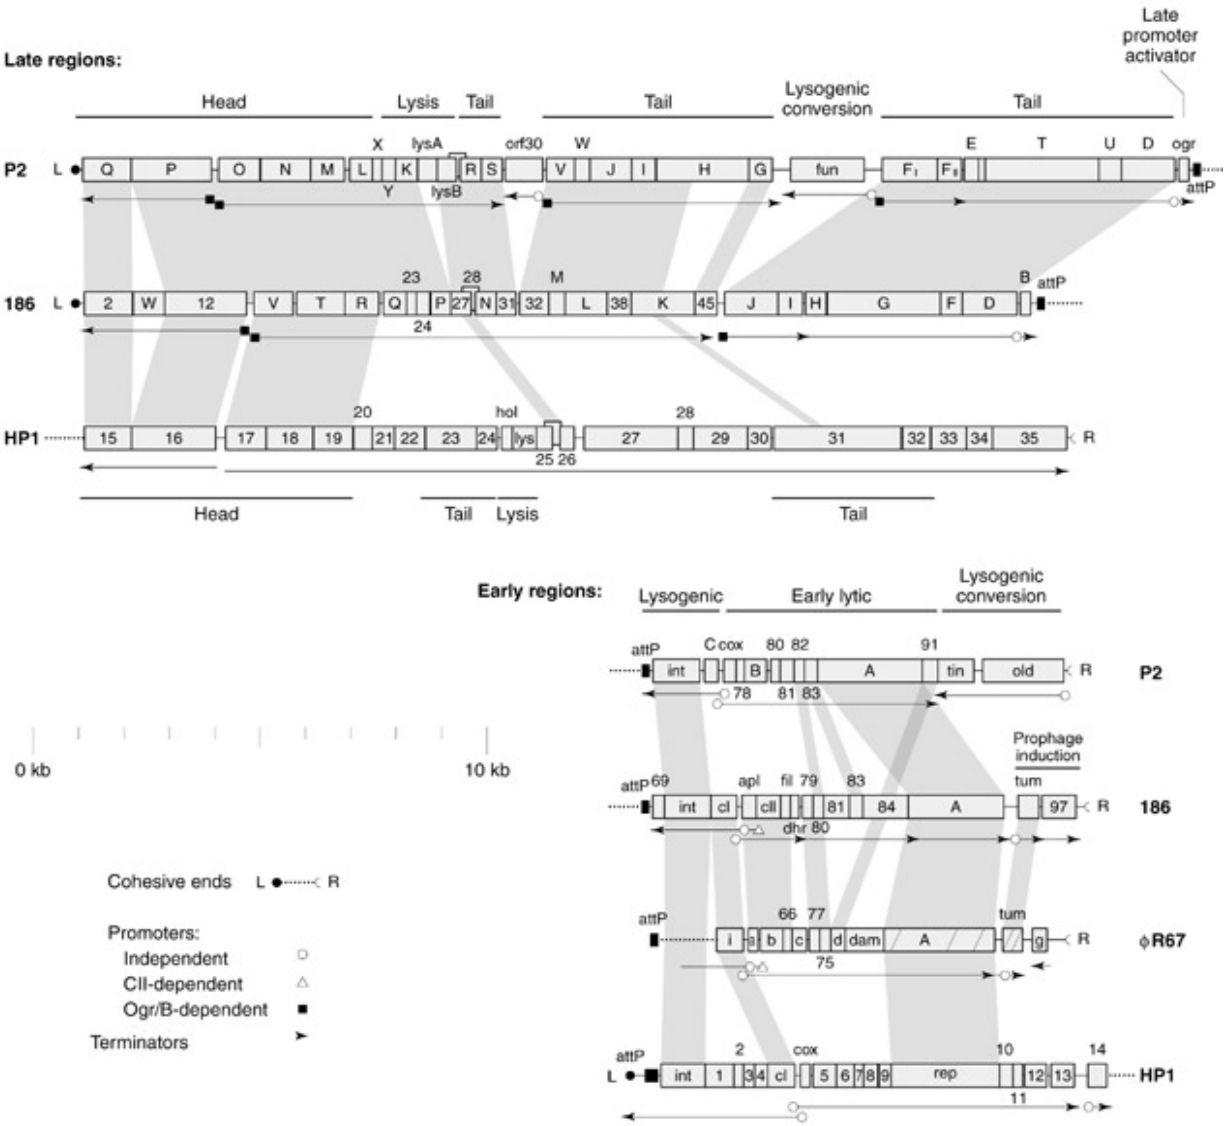


Figure 1 The genomes of P2, 186 and HP1. The late regions (left end of P2/186, right end of HP1) and early regions (right end of P2/186, left end of HP1) are aligned separately. The ϕR67 early region sequence is included. Genes are denoted by gray boxes. RNA transcripts are shown by lines with known or predicted transcriptional signals indicated (see key). Amino acid sequence homology is indicated by shading. A scale is included. Slashes within the ϕR67 *A* and *tum* genes indicate disruptive frameshift mutations. Coordinates are taken from the genome sequences of P2 (Genbank entry AF063097), 186 (Genbank entry B1U3222), HP1 (Genbank entry BHU24159) and the partial sequence of ϕR67 (Genbank entry ECO67RTDM).

prophages are integrated at specific sites on the bacterial chromosome by the Campbell mechanism, the lytic genes are repressed and the phage DNA is replicated passively.

The choice of reproductive mode is controlled by a transcriptional switch that controls whether the lytic or lysogenic genes are expressed and a recombinational switch that controls whether the phage DNA is in the integrated or excised state. These switches are encoded and coordinated in this phage family by a distinctive gene and promoter arrangement (**Fig. 2**). In common with many other temperate phages, there are divergent lysogenic and early lytic operons, with the first gene of the lysogenic operon (*cI* or *C*) encoding the immunity repressor, and the first gene of the lytic operon (*cox* or *apl*) encoding a repressor of lysogenic transcription. However, a unique set of three important features is shared by these phages.

1. The lytic and lysogenic promoters are arranged face-to-face, their transcripts overlapping by 40–70 bases.

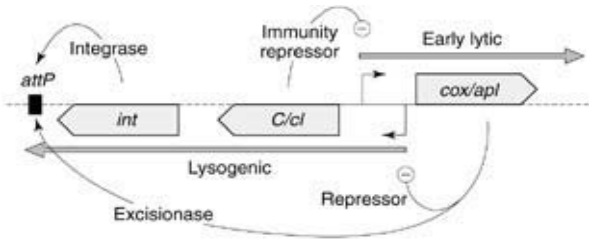

Figure 2 Lytic–lysogenic control features shared by P2, 186 and HP1. Promoters are shown as kinked arrows and their transcripts as thick gray arrows. Genes are indicated as gray boxes and the activities of their products by thin lines.

2. The integrase gene (*int*) is located in the lysogenic operon.
3. The Cox and Apl proteins combine their repressor role with an excisionase function.

Features 2 and 3 simplify the coordination of the transcriptional and recombinational switches in comparison to λ but the face-to-face promoter arrangement leads to some mechanistic complexities in the transcriptional switch.

Lysogeny

Maintenance of lysogeny The CI or C proteins enforce the lysogenic transcriptional state, binding to and repressing the early lytic promoter (**Fig. 3**) and allowing the transcription of the lysogenic operon. 186 CI also binds to sites 350 bp upstream and downstream of the lytic promoter, providing a marginal improvement in repression, and binds at the promoter of the late control gene (see below). The P2, HP1 and φR67 immunity repressors contain recognizable helix-turn-helix DNA-binding (HTH) motifs at their N-termini; a similar location of an HTH-like motif in 186 CI is supported by its general homology with the HP1 and φR67 repressors. 186 CI has been shown to self associate, to bind DNA cooperatively and to recognize two different DNA sequences.

The immunity repressors stimulate their own synthesis in lysogeny by at least one of two indirect mechanisms. First, by their repression of lytic transcription they block the expression of the Cox/Apl proteins, which would otherwise repress lysogenic transcription. Secondly, the P2 and 186 immunity repressors can stimulate transcription from the lysogenic promoter up to 10-fold even in the absence of Cox/Apl, by relieving the lysogenic promoter from inhibition by the convergent lytic promoter. The activity of the strong lytic promoter inhibits lysogenic transcription some 10–20-fold by an uncharacterized mechanism. Negative transcriptional autoregulation

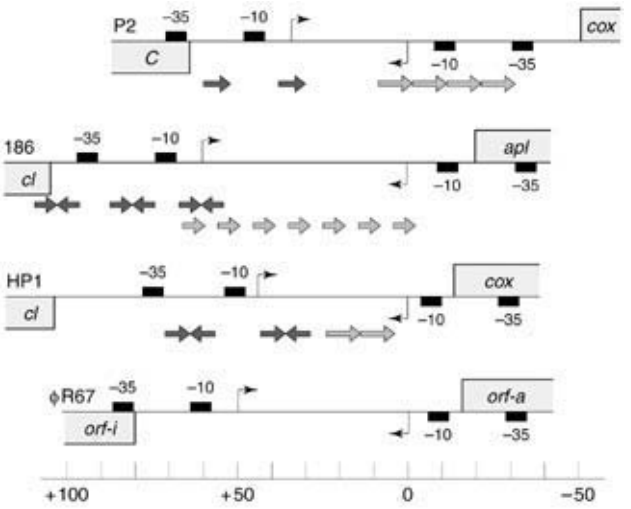

Figure 3 The lytic–lysogenic promoter regions of P2, 186, HP1 and φR67. The known or predicted transcription start points of the face-to-face early lytic and lysogenic promoters are indicated by bent arrows. HP1 has a second, weaker, early lytic promoter 28 bp upstream of the major promoter. The sequences are aligned at their lysogenic promoters to highlight the different spacings of the convergent promoters. The *C/cI* and *cox/apl* genes are shown as gray boxes. Known or predicted DNA recognition sequences for the immunity repressor are depicted as dark gray arrows; Cox/Apl binding sites by light gray arrows.

at high concentrations of the immunity repressor is also apparent in all three phages.

The repression of the lytic operon in lysogeny means that the excisionase (Cox or Apl) is not present and the prophage remains integrated. The *int* gene is transcribed in lysogeny and a 186 prophage produces detectable Int activity. However, a P2 prophage does not produce active Int, due at least in part to post-transcriptional effects. Of unknown significance is the location of *attP* downstream of *int* in the lysogenic operon, which means that the 3′ end of the *int* mRNA changes on integration and may also be affected by Int binding at *att*.

In 186 and HP1 there are additional genes in the lysogenic operon whose expression may confer properties on the lysogen. P2 contains three known lysogenic conversion genes but these are not located in the lysogenic operon and lie instead to the right of the early lytic operon or in the late region. The *old* gene provides resistance of λ infection, *tin* blocks T-even phage infection and *fun* inhibits T5. These genes comprise some 12% of the P2 genome and appear from their high AT content to be recently acquired by P2 from a foreign genome. The HP1 *orf14* gene may be expressed from its own promoter in a lysogen.

Establishment of lysogeny The transition from

lytic to lysogenic development requires establishment of the lysogenic transcriptional state and integration of the phage DNA. The locations of the immunity repressor, integrase and excisionase genes mean that both these requirements can be met simply by an increase in lysogenic transcription and a simultaneous or subsequent decrease in lytic transcription. In 186, like λ, the establishment of lysogeny requires a lytic gene, *cII*, whose product activates transcription of the lysogenic operon from a promoter upstream of the lysogenic promoter. CII binds upstream of this promoter to inverted repeat sequences two turns of the helix apart. φR67 has a *cII* homologue and almost identical CII binding sequences. In contrast, P2 has no *cII* gene and there is no *cII*-like gene apparent in HP1. Presumably, in these latter phages, the choice of lytic versus lysogenic development depends on the relative expression of the two early operons soon after infection. In the absence of phage proteins the strengths of the HP1 lysogenic and lytic promoters are very similar so each choice should occur with a reasonable frequency. However, in P2, like 186, the lysogenic promoter is much weaker than the lytic promoter so it is intriguing that P2 can establish lysogeny without a CII.

No λ-like effects of host physiology or multiplicity of infection on the establishment of lysogeny have been described for P2, 186 or HP1 (except for the SOS system, see below). The Hfl protease mutations that influence λ CII do not affect 186. It has been reported that IHF is needed for the establishment or maintenance of the lysogenic transcriptional state in P2 and binds upstream of the lytic promoter. However, a role for this site is yet to be demonstrated; a similarly located IHF binding site in 186 does not affect phage development.

Prophage induction The transition from lysogeny to lytic development is termed prophage induction. This process represents a major functional division in the P2 family, with P2 and other family members forming non-inducible prophages while 186, HP1 and PSP3 prophages are SOS-inducible. Prophage induction requires two steps: derepression of lytic transcription and excision of the prophage. In P2, the first step is unaffected by SOS induction and the second step is naturally inefficient.

Derepression of the 186 prophage is initiated in response to SOS induction by expression of a phage antirepressor gene, *tum*. The *tum* gene is located to the right of the early lytic operon and is normally repressed by LexA. Tum is a reversible inhibitor of CI DNA binding but does not bind to the DNA itself. φR67 contains a remnant of a *tum*-like gene. SOS induction of HP1 is puzzling, since no *tum* homologue or other LexA-controlled gene is apparent and the CI protein lacks sequences characteristic of RecA-stimulated autoproteolysis.

Derepression of lytic transcription makes Apl/Cox available to catalyze prophage excision. Sufficient Int to carry out the excisive reaction may already be present in the lysogen due to its expression from the lysogenic transcript. However, P2 and HP1 excisive reactions *in vitro* require high levels of Int, so an increase in *int* expression may be needed. No *int*-specific promoters have been detected. The low level of Int production from the P2 prophage is responsible for the inefficient excision of P2.

Repression of the lysogenic promoter is a second role of Apl during 186 prophage induction. Tum inhibition of CI is inefficient and Apl seems to assist the transition to the lytic transcriptional state in the presence of low levels of CI. Whether Cox plays a similar role in P2 and HP1 is not known. All three proteins bind to directly repeated DNA sequences spaced one turn of the DNA helix apart that overlap the RNA polymerase (RNAP) binding region at the lysogenic promoter (**Fig. 3**) and may thus assist derepression during prophage induction by blocking further transcription of the immunity repressor gene. Since the CI and Apl binding sites overlap, Apl may also interfere directly with CI repression of the lytic promoter. 186 Apl is monomeric in solution, binds cooperatively and bends the DNA severely. P2 Cox also appears to bind cooperatively. HP1 Cox is tetrameric in solution. The Cox/Apl proteins each contain an obvious HTH motif but show little similarity outside these motifs.

Site-specific recombination The HP1 and P2 integration and excision reactions are among the better characterized phage recombination systems. The recombination mechanism and its control conform broadly to the λ model but show specific differences in the arrangement of protein binding sites at *attP* (**Fig. 4**). The Int proteins are related to the λ family of integrases and, like λ Int, bind to two distinct DNA sequences. The *attB* sites are simple, comprising a pair of inverted core-type Int binding sequences disposed about the short overlap or strand exchange region. The HP1 and 186 *attB* sites, but not the P2 *attB* site, are located in tRNA genes and the overlap regions are the 7 bp tRNA anticodon loop sequences. The overlap regions in *attP* are flanked by additional arm-type Int binding sites. In HP1 *attP* there are also additional core-type Int binding sequences in the arm regions. The three Ints share strong amino acid similarity and the DNA recognition sequences of the HP1 and 186 Ints are related.

The host DNA-bending factor IHF is required for

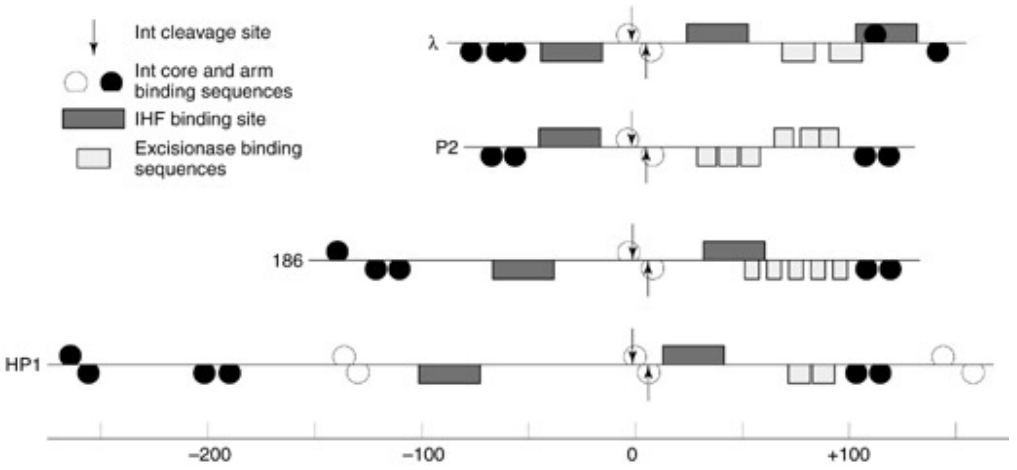

Figure 4 Comparison of the *attP* sites of λ, P2, 186 and HP1. The locations of Int, IHF and excisionase binding sequences are indicated above or below the DNA strands to indicate their orientation. The λ *att* site is shown P′OP and the Fis binding site is omitted. The Int binding sites for 186 and the Int cleavage sites for P2 have not been confirmed.

efficient integration and excision *in vitro* and binds between the exchange site and the Int arm sites in each *attP* arm except for the P2 right arm. Unlike λ, the host protein Fis does not seem to affect P2 or HP1 excision.

In P2, HP1 and 186, as in λ, the excisionase protein binds in one arm to a cluster of direct repeat sequences (**Fig. 4**). The 186 Apl and P2 Cox proteins bind cooperatively and appear to bend the DNA. HP1 Cox binds to *attP* with 4:1 and 8:1 stoichiometries. Like the lambdoid excisionases, Cox and Apl are thought to work by altering the spatial orientation and accessibility of the Int sites in the *att* arm and thus to affect the way that Int bridges between its core and arm sites. As well as stimulating the excisive reaction *in vitro*, the Cox proteins also inhibit the integrative reaction. The Int binding site adjacent to the HP1 Cox sites is needed for integration and inhibits excision *in vitro*; Cox binding interferes with Int binding to this site.

Lytic cycle

Early lytic transcription Upon cell entry and before phage proteins are made, transcription from the early lytic promoter in P2 and 186 is much stronger than lysogenic transcription. The lysogenic promoters are intrinsically weak and are inhibited even further by the active lytic promoter. Any reciprocal inhibition, of the lytic promoter by the lysogenic promoter, does not seem to be significant in these phages. In contrast, the HP1 lysogenic promoter is as strong as the tandem lytic promoters and each inhibits the other some 10-fold.

HP1 Cox repression of the lysogenic promoter may therefore be needed to prevent CI being produced and blocking lytic development but HP1 *cox*$^-$ mutants have not yet been studied in infection. 186 Apl and P2 Cox also repress the lysogenic promoter but mutants in these genes are neither impaired in lytic development after infection nor lysogenize at high frequencies. Presumably, the weakness of lysogenic transcription in the absence of the immunity repressor makes P2 Cox and Apl redundant for lytic development after infection. P2 Cox and 186 Apl, like λ Cro, also negatively regulate early lytic transcription. However, unlike λ Cro, this activity is not essential for lytic development. HP1 Cox does not appear to depress lytic transcription.

The early lytic operons of P2, 186, HP1 and φR67 contain 9–11 genes. The essential replicase gene, *A/rep* (see below), is the only clearly homologous gene in all four phages. The replicase gene in the φR67 prophage is disrupted. Most of the early genes have unknown functions and are not essential. P2 contains a second replication gene, *B*, that is dispensable in some conditions (see below). Both 186 and P2 carry a number of cell-lethal genes (**Table 1**); the 186 genes *dhr* and *fil* inhibit host DNA replication and cell division, respectively.

Early lytic transcription has not been studied in P2 or HP1. In 186, the initial transcript is antiterminated at a Rho-independent termination signal downstream of *dhr* by a mechanism unknown. It is not like the N system of λ, since 186 efficiently infects each class of *nus* mutants. It appears also that antitermination does not require any known 186 protein. The extended transcript is processed by RNAse III, cutting at a site

within the *fil-dhr* region. The *A* gene has no recognizable ribosome binding site and its translation requires translation of the preceding *orf84*, the stop codon of which overlaps the initiation codon of *A*. In most cases early lytic transcription terminates within the start of *A* but we expect that, on those occasions that translation of A is initiated, this termination will be suppressed and RNAP will continue to the end of *A* (**Fig. 1**).

Replication P2 and 186 replication is via a rolling circle (RCR) mechanism similar to ϕX174. Replication is initiated by an A protein-catalyzed single-strand endonucleolytic cut at an origin within the *A* gene and proceeds rightward. The P2 A cleavage site has been identified and similar sequences are conserved in 186 and HP1. The P2 A, 186 A and HP1 Rep proteins show large patches of strong amino acid identity, and share the three amino acid motifs characteristic of RCR proteins. The HP1 *rep* gene is sufficient for minichromosome replication but no further replication studies have been performed.

P2 replication requires also the product of the phage gene *B*, and host functions such as DnaB, DnaE, DnaG and Rep, but not the host initiation functions DnaA and DnaC. P2 B is involved in priming lagging strand synthesis, apparently interacting with DnaB and thus presumably acting as a DnaC analogue. However, B is not required in a *lon* host or in co-infection with P4 or when replicating as a minichromosome, and it would be interesting to know whether a B^- mutant requires DnaC under such circumstances.

Replication of 186 DNA is similar to that of P2, but there is no 186 analogue of P2 B. Accordingly, 186 replication has a requirement for host DnaC. Phage 186 replication also requires, indirectly, host DnaA, which reflects a need for concomitant host initiation – thus 186 replication can occur in an integratively suppressed *dnaA* mutant. Like P2, 186 replication requires host *rep* function and, interestingly, *rep* mutants that block 186 replication but not P2 replication are known. Further mutation in gene *A* can overcome this block, suggesting some interaction between Rep and the A replicase. Phage 186 replication is transiently blocked in a host cell UV irradiated before phage infection, which possibly reflects its dependence on concomitant initiation of host replication, which is itself transiently inhibited by UV.

Late gene transcription The expression of the late genes in P2 and 186 requires an activator of the late promoters, Ogr or B. These proteins are members of a family of small, DNA-binding, zinc-finger transcriptional activators found in P2-like phages and their P4-group satellites. The metal ion is coordinated by four cysteines with the arrangement $C\text{-}X_2\text{-}C\text{-}X_{22}\text{-}C\text{-}X_4\text{-}C$.

The *ogr* and *B* genes are expressed during early lytic development from their own, factor-independent promoters (**Fig. 1**). The 186 *B* gene is directly repressed by the immunity repressor and is transcribed coordinately with the early lytic operon. In contrast, the promoter of the *ogr* gene is weak and not under immunity control. Activation of the late promoters does not occur until the end of early lytic development and is dependent on phage replication. Thus, increased gene dosage of the activator gene or of the late genes seems to be required.

Ogr, B and other members of the Ogr family activate the σ^{70}-dependent phage late promoters by binding to a dyad-like DNA element centered near the -55 position. The Ogr protein interacts with the carboxyl domain (at least) of the α subunit of RNAP and the interacting regions have been mapped on both proteins. Four late promoters have been identified in P2, whereas 186 may be able to transcribe its late genes with only three promoters.

HP1 does not encode an Ogr homologue and no late control protein has yet been identified, although its existence is suggested by the presence of two oppositely oriented 28 bp conserved sequence elements in the region between the divergent late genes *orf16* and *orf17*.

Late gene function: morphogenesis and lysis The construction of active phage particles and cell lysis have been reasonably well characterized in P2. All but two of the 26 late genes of 186 have homologs in P2, whereas HP1 shares only six late genes with P2 and 186.

Capsid/packaging Construction of DNA-filled P2 capsids requires six gene products. The majority of the capsid is formed from the N protein with the aid of an internal capsid scaffold protein, O. N and O are proteolytically processed to shorter forms during capsid maturation. Q forms the portal vertex in the capsid to allow DNA entry. The DNA is packaged from monomeric circles and requires a 125 bp region around *cos*. Cutting and packaging is carried out by the terminase proteins M and P in the presence of proheads and ATP but does not require IHF. Phage 186 encodes an extra protein, W, that is homologous to the central region of P/Orf12 and which may modulate terminase activity. The L protein completes the head. HP1 encodes homologues of all the capsid proteins except L, suggesting that HP1 may require a different protein to complete a P2-like head to suit its nonhomologous tail. Despite the similarity of the terminase proteins, the HP1 *cos* site sequence is unlike

the *cos* sites of P2 and 186 and is cut to give a 7 base rather than a 19 base 5′ extension.

Tail P2 tails are constructed using 15 phage genes and contain six tail fibers attached to a baseplate with a single spike, a tube with contractile sheath and a collar involved in head attachment. Tail construction is not well understood; the functions of a few tail genes are given in **Table 1.** The P2 *E* gene (and probably 186 *H*) produces two proteins by a programmed translational frameshift. The P2 baseplate protein W and 186 M show similarity to a T4 baseplate wedge protein. The C-terminus of the tail fiber protein, presumed to be involved in specifying host attachment during infection, is different in P2 and 186 and shares short motifs with various other phages, including λ, P1, Mu, T2, T3, T7 and HP1. Apart from this short region in HP1 Orf31, the tail genes of HP1 show no significant homology with 186 or P2 and the gene order is different. Nevertheless, the HP1 tail has a similar structure to those of P2 and 186.

Lysis Lysis follows the λ strategy, with a phage holin protein forming holes in the inner membrane to allow a phage lysozymal enzyme to access and degrade the cell wall. The P2 and 186 lysis proteins are homologous, with the endolysin homologous to λ R, but are not similar to the HP1 lysis proteins. The P2 *lysA* and *lysB* genes affect the timing of lysis. Despite the general lack of homology with HP1 in this region, a short gene of unknown function located downstream of the lysis genes is conserved in P2, 186 and HP1.

Diversity in the P2 Family

As well as providing a useful contrast with other well-studied temperate phage systems, the P2 family phages display a considerable diversity within their own group. HP1 is a chimera of sequences that are strongly related to P2/186 and sequences that are completely different. Even P2 and 186, although closely related, have evolved remarkably different lifestyles within the temperate phage niche. The P2 prophage takes up almost permanent residence in the host chromosome and makes a large commitment to fortifying this state. In comparison, 186 is nomadic; it devotes little of its genome to protecting its lysogenic home and breaks camp as soon as danger threatens. The near future promises to reveal further diversity as more relatives are characterized.

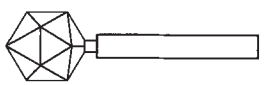
P4 PHAGE (SATELLITES)



Gianni Dehò and **Daniela Ghisotti**, Dipartimento di Genetica e di Biologia dei Microrganismi, Università degli Studi di Milano, Milano, Italy

The Satellite Phage and its Alternative Life Styles

P4 is a genetic element at the crossroad of plasmids and viruses. A P4 virion is made of a linear, double-stranded, cohesive-ended DNA molecule 11.6 kb long, encapsidated into a tailed icosahedral protein head (**Fig. 1**). What is peculiar is that all its tail and most capsid proteins are not encoded by the P4 genome but by a helper phage, P2. As a consequence, P4 may undergo lytic cycle only if a helper phage genome is present in the host *Escherichia coli*. Discovered by E. Six in 1963, bacteriophage P4 is the prototype of 'satellite viruses'.

P4 requires all the helper's genes necessary for the construction of the head and the tail and to lyse the host cell (P2 late genes). Notably, a specific P4-encoded function directs the assembly of the head proteins produced by P2 into a small-size head suited to encapsidate the P4 DNA molecule, which is one-third the length of the helper's genome.

In the absence of a helper phage, the P4 genome may be maintained as a freely replicating multicopy plasmid. Moreover, both in the presence and in the

the *cos* sites of P2 and 186 and is cut to give a 7 base rather than a 19 base 5′ extension.

Tail P2 tails are constructed using 15 phage genes and contain six tail fibers attached to a baseplate with a single spike, a tube with contractile sheath and a collar involved in head attachment. Tail construction is not well understood; the functions of a few tail genes are given in **Table 1**. P4 PHAGE (SATELLITES)

Gianni Dehò and **Daniela Ghisotti**, Dipartimento di Genetica e di Biologia dei Microrganismi, Università degli Studi di Milano, Milano, Italy

The Satellite Phage and its Alternative Life Styles

P4 is a genetic element at the crossroad of plasmids and viruses. A P4 virion is made of a linear, double-stranded, cohesive-ended DNA molecule 11.6 kb long, encapsidated into a tailed icosahedral protein head (**Fig. 1**). What is peculiar is that all its tail and most capsid proteins are not encoded by the P4 genome but by a helper phage, P2. As a consequence, P4 may undergo lytic cycle only if a helper phage genome is present in the host *Escherichia coli*. Discovered by E. Six in 1963, bacteriophage P4 is the prototype of 'satellite viruses'.

P4 requires all the helper's genes necessary for the construction of the head and the tail and to lyse the host cell (P2 late genes). Notably, a specific P4-encoded function directs the assembly of the head proteins produced by P2 into a small-size head suited to encapsidate the P4 DNA molecule, which is one-third the length of the helper's genome.

In the absence of a helper phage, the P4 genome may be maintained as a freely replicating multicopy plasmid. Moreover, both in the presence and in the

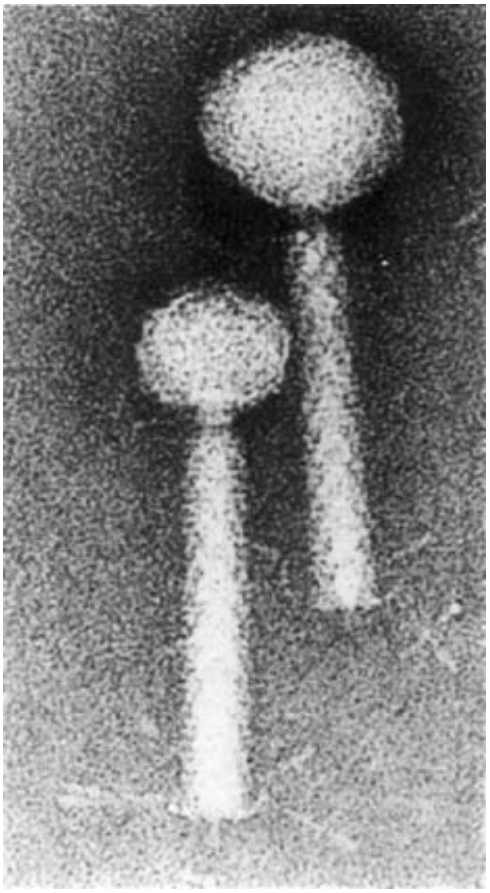

Figure 1 Satellite bacteriophage P4 (left) and its helper P2 (right) virions. Negative stain with phosphotungstate. The tail structures are about 135 nm long; the P4 and P2 heads are, respectively, 45 nm and 62 nm in diameter. Electron micrograph by Robley C. Williams, Unversity of California, Berkeley. absence of the helper, P4 may lysogenize the host cell by integrating its genome into the bacterial chromosome and establishing prophage immunity. The alternative life styles of P4 are illustrated in **Fig. 2.**

By no means may P4 be considered a 'defective P2', since the two replicons are unrelated to each other. Rather, P4 may be thought of as a plasmid that evolved the ability to be specifically transduced by a class of bacteriophages, thus acquiring the potential for horizontal propagation.

Like P4, other phages such as the filamentous phages and the temperate phages P1 and N15, may be stably maintained as autonomously replicating plasmids in the bacterial host. These natural phasmids (phage–plasmid) make less definite the boundary between plasmids and viruses. Understanding the life cycle of P4 and other viruses that can establish a permanent interaction with the host cell, such as temperate phages and retroviruses, has been instrumental in developing a different perception of the biologic meaning of viruses. No longer can these genetic elements be considered merely as 'infectious agents' but, rather, as part of a large pool of mobile genetic information that can be exchanged among living cells.

Genome Organization

The genome organization of P4 is shown in **Fig. 3A** and the known genes and functions are detailed in **Table 1.** All the functions required for lysogenic, lytic and plasmid development are located in the right 80% of the genome and include the origin of replication *ori*1, the two main α and *sid* operons, which are transcribed divergently from the *ori*1 site, the prophage integration *att* site, and the *int* (integrase) gene in a monocistronic operon at the left of *att*. The genes in the two constitutively expressed operons at the left of *int* (nonessential region) may be deleted without affecting the lysogenic, lytic or plasmid development.

The α operon, which is transcribed leftwards from the two promoters P_{LE} and P_{LL}, encodes both genes required for P4 lytic and plasmid propagation (α and *cnr*, replication; ϵ, helper prophage derepression), and the prophage immunity determinants required to prevent P4 replication in the lysogenic condition. Thus control of the α operon expression from its two promoters is crucial for the establishment and maintenance of the different developmental phases and involves complex and elegant mechanisms (see below).

The *sid* operon codes for regulatory and morphogenetic proteins involved in the plasmid and/or lytic development: the positive regulator Delta, which can both activate the satellite and *trans*-activate the helper late operons (*bona fide trans*-activation, i.e. the activation of unexpressed genes of one chromosome by the gene product(s) of a different chromosome, was first described in the P2-P4 system); and two proteins with a role in P4 head morphogenesis: Sid, which determines the small size of the P4 capsid, and Psu, a bifunctional protein that helps to stabilize the viral particle (capsid 'decoration' protein) and suppresses transcription termination at Rho-dependent terminators (polarity suppressor). The *sid* operon is transcribed late after infection from its unique P_{sid} promoter that is activated by P4 (Delta) and P2 (Ogr)-encoded positive regulators.

DNA Replication

P4 replicates as a circular DNA molecule in a bi-

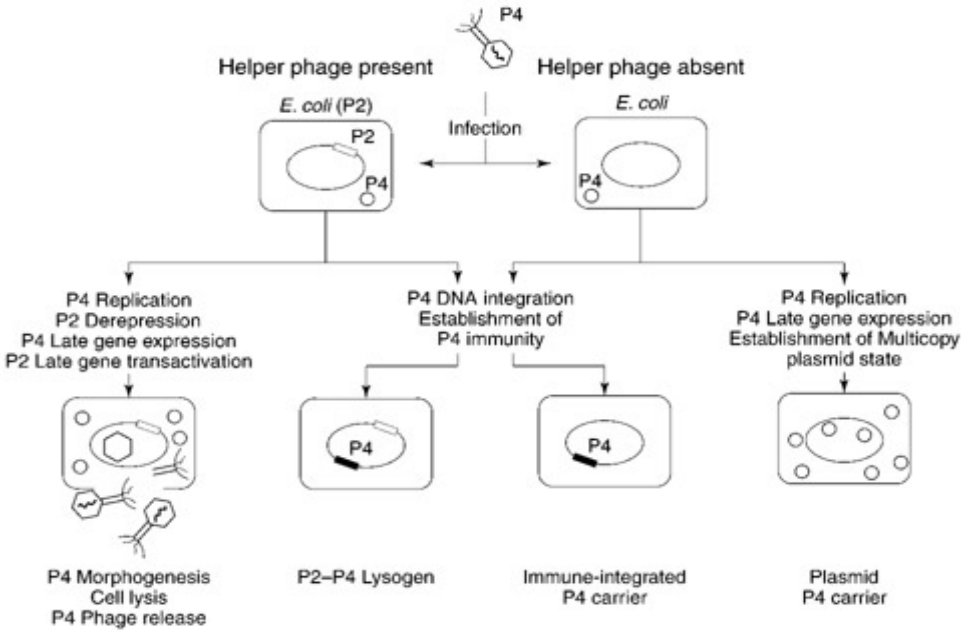

Figure 2 P4 life cycle. See the text for explanation. (Modified from Dehò G, Bertoni G and Polissi A (1992) In: Galli E, Silver S and Witholt B (eds) *Pseudomonas Molecular Biology and Biotechnology*, p. 358. Washington DC: American Society for Microbiology.)

Table 1 Bacteriophage P4 genes and functions

Gene or site	*Gene product and/or function encoded*
cos	19 nt long cohesive ends
gop	Causes host cell killing in the absence of β
β	Inhibits *gop* killing
*c*II	Function unknown. Mutants kill the host cell
int	Integrase
att	Site for integrative recombination
crr	Required in *cis* for DNA replication
α	Essential for replication. Primase, helicase, *ori*1 and *crr* recognition and binding
*ori*2	With *crr* supports α-dependent *ori*1-independent replication
cnr	Controls DNA replication and plasmid copy number
*orf*151	Function unknown
ϵ	Derepression of the P2 helper prophage
kil	Kills the bacterial host if overexpressed
t_{imm}	Rho-dependent transcription termination. Elicits strong transcription termination from P_{LE} when the CI RNA is present
*c*I	Prophage immunity. Encodes the CI RNA
P_{LE}	Constitutive promoter
*orf*199	Function unknown. Its translation prevents transcription termination from P_{LL}
vis	Negative regulator of P_{LL}; stimulates P_{sid}; binds P_{LL}, P_{sid}, and *att*; putative excisionase
P_{LL}	Late promoter. Positively regulated by P4 Delta and P2 Ogr and Cox proteins; negatively regulated by Vis
*ori*1	Origin of DNA replication
P_{sid}	Late promoter. Positively regulated by P4 Delta and P2 Ogr, stimulated by Vis
sid	Small head determination. External procapsid scaffold.
δ	P4 and P2 late promoter activator
psu	Capsid decoration protein and polarity suppression

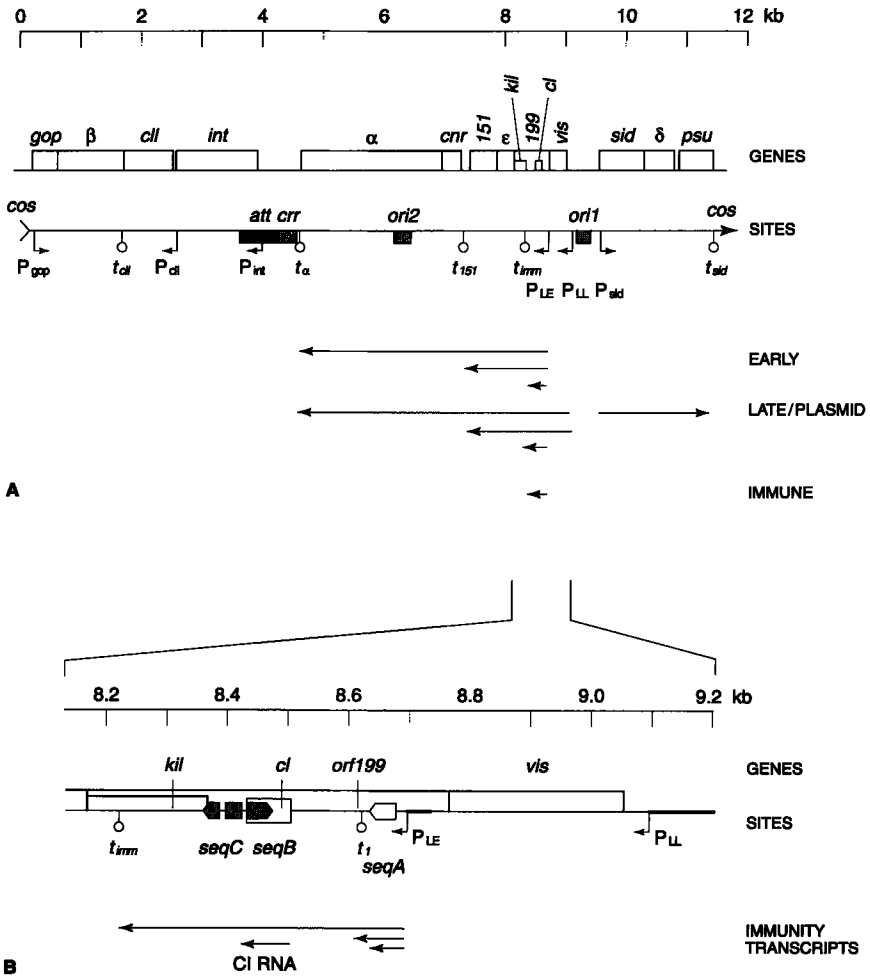

Figure 3 (**A**) Physical and genetic map of P4 and (**B**) P4 immunity region. Coordinates are from the annotated complete nucleotide sequence of P4, GenBank accession number X51522. Transcription start and termination sites are indicated by bent arrows and hanging open circles, respectively. The arrows beneath the map in panel A indicate the early, late and immune phase transcripts from the two main operons. t_1 (**B**) is a weak Rho-independent terminator. For other explanations see **Table 1** and the text. (Modified from Sabbattini P, Forti F, Ghisotti D and Dehò G (1995) *J. Bacteriol.* 177: 1425, and from Briani F, Zangrossi S, Ghisotti D and Dehò G (1996) *Virology* 223: 57.)

directional θ-type manner starting at the *ori*1 site. A second site, *crr*, is essential in *cis* for P4 replication.

P4 replication depends on both host and phage genes. Host-encoded functions are necessary for elongation (DNA polymerase III, SSB proteins) whereas initiation proteins such as DnaA (initiator), DnaB (helicase), DnaC (DnaB complex) and DnaG (primase), as well as the Rep helicase, which is involved in the chromosome replication forks progression, are not required. All such functions are provided by the essential product of the P4 α gene. Alpha is a multifunctional protein: it has primase and helicase activity, binds specifically to octameric repeats located in both *ori*1 and *crr*, and can oligomerize, thus inducing the formation of DNA loops between *ori*1 and *crr*. Finally, Alpha interacts with the P4 encoded Cnr protein, which modulates P4 DNA replication and controls the plasmid copy number. The modular structure of Alpha is shown in **Fig. 4** and a model for P4 replication is proposed in **Fig. 5**.

The presence of both *ori*1 and *crr* in the proper orientation on a miniplasmid is sufficient to allow Alpha-dependent, Cnr-regulated replication. Constructs lacking *ori*1 and carrying both *crr* and the *ori*2 site (a 270 nt region within α with no homology to either *crr* and *ori*1) still replicate in an Alpha-dependent fashion. Thus it appears that P4 is a composite of two replicons. Whether the *ori*2 replicon is a relic of a P4 ancestor or it is still functional under

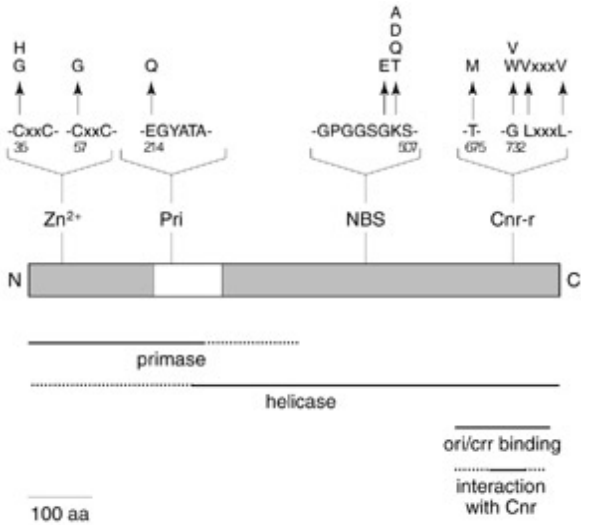

Figure 4 Functional domains of the P4 Alpha protein. The grey bar represents the Alpha protein; its functional domains are indicated by the solid and dotted lines below. Highlighted in white is a 120 amino acid region exhibiting sequence similarity to primases of IncI and IncP plasmids. The amino acid consensus sequences of conserved motifs are reported on top, and the amino acid changes affecting the different activities are listed over the arrows. Pri (primase motif) is conserved among several prokaryotic primases; Zn^{2+}, metal binding motif found in other prokaryotic primases and DNA-repair proteins; Mg^{2+}, potential metal binding site, has similarity with other DNA and RNA polymerases; NBS (type A nucleotide binding site) is found in other helicases of small DNA and RNA viruses; the Cnr-r site, defined by Cnr resistance mutations, interacts with the Cnr protein. (Modified from Ziegelin G, Calendar R, Lurz R and Lanka E (1997) *J. Bacteriol.* 179: 4087.)

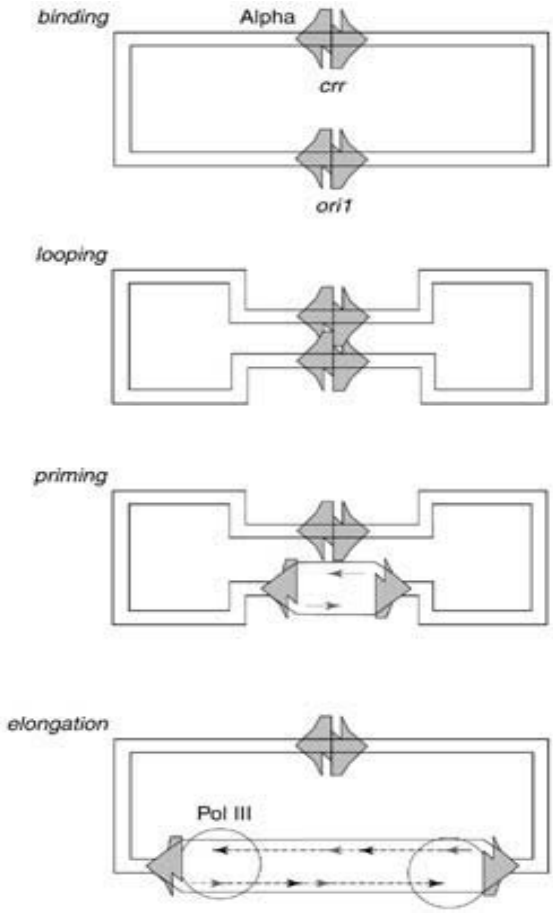

Figure 5 A model for P4 replication. Alpha protein (gray irregular polygon) binds to both *ori*1 and *crr* sites in oligomeric form and may cause looping of P4 DNA (continuous double line) by protein–protein interactions. Alpha is thought to make RNA primers (short, continuous arrow) both at the origin of replication (priming) and at the replicative forks for lagging strand priming (elongation). Dotted arrows: newly synthesized DNA; circles: DNA polymerase III.

some physiological conditions has not yet been ascertained.

Lysogeny

Lysogenization by P4, which may occur in either the presence or absence of the helper, requires integration of the P4 genome in the bacterial chromosome and the establishment of the immune condition which prevents expression of the replication genes.

Integration

Integration of the P4 genome into the host chromosome occurs according to the Campbell model by site-specific recombination between the P4 and the bacterial *att* sites; the latter corresponds to the 3′-end of a gene (*leuX*) encoding a $tRNA^{Leu}$ isoacceptor. Recombination occurs within a 20 nt-long core region identical in both phage and host *att* sites so as to preserve the integrity of the *leuX* gene sequence upon prophage integration, and requires the P4 Int protein. Little is known about excision, that may occur both spontaneously and, at much higher efficiency, upon infection of a P4 lysogen by the helper phage. Vis, the negative regulator of P_{LL}, is coded by the first P4 gene to be expressed upon P2 infection of a P4 lysogen (see below) and can bind to the *attP* region. It has been suggested that Vis may play a role also in P4 prophage excision.

Integration within known or putative tRNA genes appears to be a widespread phenomenon among both prokaryotic and eukaryotic mobile genetic elements such as viruses, plasmids and transposons; this may reflect structural and/or mechanistical features (such as the presence of palindromic sequences, the repetition of sequences and/or structures within a genome, the conservation among species) offered by tRNA

genes that may be exploited for evolution of integration systems.

Immunity

For most known temperate phages, immunity is elicited by a repressor protein which prevents transcription initiation at promoter(s) controlling expression of lytic functions.

The P4 immunity mechanism is unique among the known phages for several aspects: (1) P4 α operon expression is prevented by premature termination of transcription starting at the constitutive promoter P_{LE}; (2) the P4 immunity factor is a short, stable RNA (CI RNA); (3) transcription termination is controlled via RNA–RNA interactions between the CI RNA and two specific target sequences on the nascent transcript; (4) the CI immunity factor is produced by specific processing of the same transcript that it controls.

Uncommitted phase Immediately after infection of a sensitive cell, irrespective of the presence of a helper genome, P4 DNA circularizes through its cohesive ends and enters the early, 'uncommitted' regulatory phase, which will be followed either by the immune or the late-plasmid mode of transcription. In this transient phase the α operon is transcribed from the constitutive promoter P_{LE} and a burst of P4 DNA replication is observed.

Transcription from P_{LE} appears to be termination prone and yields RNA molecules of different length: (1) full-length mRNA 4.1 kb long, which covers the entire operon; (2) 1.3 kb mRNA, which stops at a terminator just upstream of the replication genes *cnr* and α; and (3) a family of transcripts less than 0.5 kb long, which do not extend beyond a strong Rho-dependent terminator, t_{imm} (**Fig. 3A**).

Prophage immunity About 15 min after infection transcripts reading through t_{imm} can no longer be detected. Transcription of P4 lytic and plasmid functions from P_{LE} is turned off by efficient transcription termination at t_{imm} and thus only the immunity region is expressed. This latter transcription pattern of the α operon is only detectable in the immune prophage condition.

Establishment and maintenance of the immunity transcription mode depends on genetic determinants located within a 500 nt region (immunity region, **Fig. 3B**) that includes P_{LE}, the downstream untranslated leader region, and t_{imm}, which is located within *kil*, the first translated gene downstream of P_{LE}.

The untranslated leader region of the P_{LE} transcript is rich in direct and inverted repeats that may allow the formation of multiple, mutually exclusive secondary structures in the leader RNA. A region, called *seqB*, exhibits complementarity with both the *seqA* and *seqC* sites, located upstream and downstream of *seqB*, respectively. *seqB* is internal to *cI*, which encodes the CI RNA (**Figs 3b** and **6**), a small RNA generated by processing of the leader transcript.

Transition from the early transcription pattern, with expression of full-length mRNA, to the immune pattern, where transcription is totally restricted to the immunity region, is concomitant with the appearance of the mature CI RNA. Moreover, the presence in the cell of the CI RNA is sufficient to efficiently cause premature transcription termination at t_{imm} in an infecting phage: thus the CI RNA is the P4 immunity factor.

Most recessive mutations that cause an immunity defect map in *seqB*, whereas *seqA* and *seqC* double mutants are insensitive to P4 immunity. Mutations in both *seqA* and *seqC* that restore complementarity with a *cI* mutation in *seqB* also re-establish efficient transcription termination. Thus the *seqA* and *seqC* sites in the nascent transcript appear to be the targets of the P4 immunity factor, both being required for the establishment and the maintenance of prophage immunity. CI RNA-target interaction appears to occur primarily between complementary regions predicted to be single-stranded by computer analysis (**Fig. 6**).

The mechanism of P4 immunity is not completely understood. The complementary sequences in the immunity region may allow both intra- and intermolecular pairing of RNA molecules. Before the appearance of CI RNA upon P4 infection, a substantial transcription of the entire α operon is allowed, whereas transcription terminates efficiently as soon as the mature CI RNA is produced in the cell. This suggests that intramolecular interactions in the leader sequence allow readthrough, whereas intermolecular interactions between the CI RNA and the nascent leader transcript cause strong termination.

seqC overlaps the ribosome binding site and the start codon of *kil*, the first translated gene in the P_{LE} transcript. This suggests that termination at t_{imm} might be indirectly elicited by the immunity mechanism by preventing *kil* translation; this may allow access of the Rho factor to t_{imm}, thus causing transcription termination. However, a more direct role of the CI RNA and/or the untranslated leader RNA on transcription termination and/or stability of the P_{LE} transcript has not been ruled out.

The CI RNA is processed from the P_{LE} transcripts by RNase P, an endonucleolytic ribozyme also involved in maturation of tRNAs, which specifically generates the 5′-end of the mature molecule; polynucleotide phosphorylase, which degrades RNA

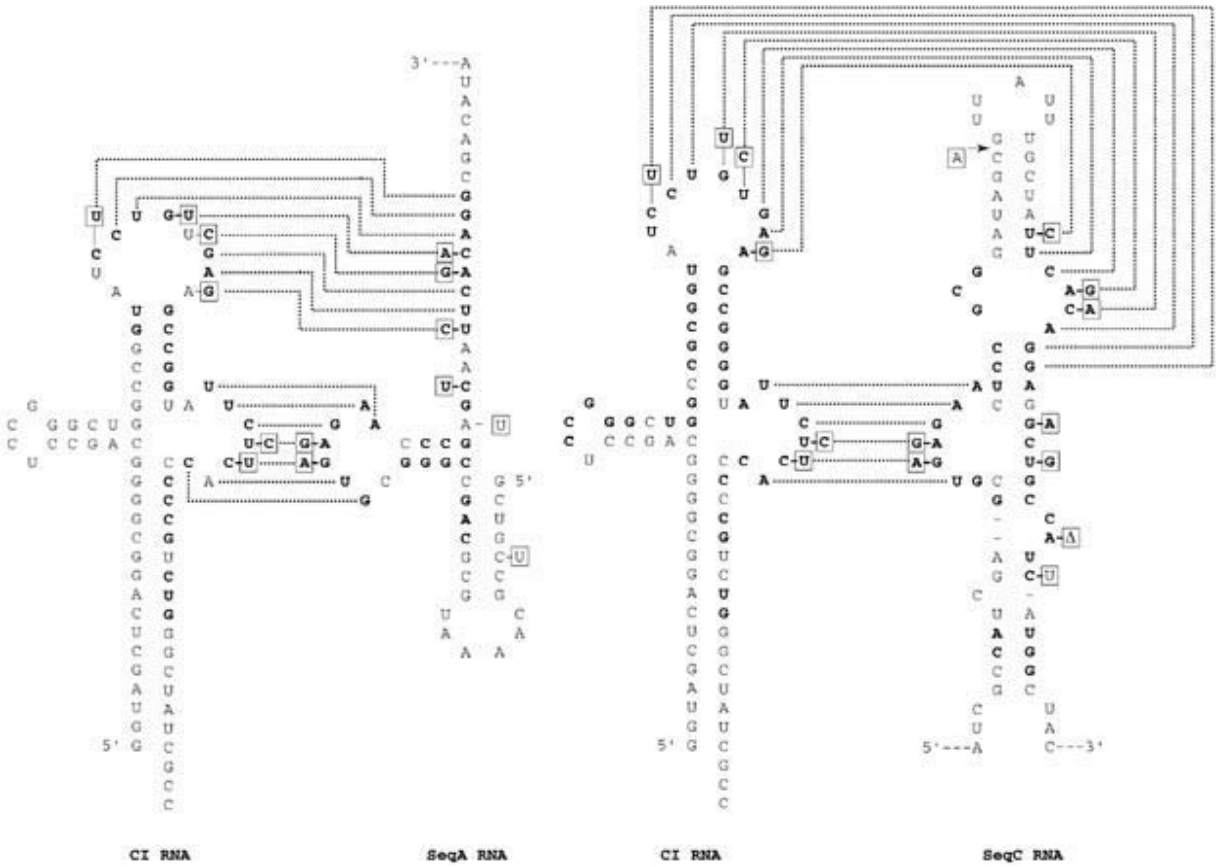

Figure 6 Predicted secondary structure of the CI RNA and possible interactions with *seqA* and *seqC* in the leader transcript of the immunity region. *seqB-seqA* and *seqB-seqC* complementary bases are in boldface type. The complementary bases in single-stranded regions are connected by dotted lines. The base changes in the P4-like retronphage ΦR73 are boxed. Arrow indicates insertion, Δ deletions. (Modified from Sabbattini P, Six E, Zangrossi S, Briani F, Ghisotti D and Dehò G (1996) *Virology* 216: 389.)

exonucleolytically from the 3′-end, is also required for efficient processing of the P4 immunity factor.

Multicopy Plasmid State and Lytic Cycle

The late-plasmid transcription pattern

Both the plasmid state and the late phase of the lytic cycle are characterized by continuous expression of the α and *sid* operons, due to the activation of the positively regulated late promoters P_{sid} and P_{LL}. The pathways leading to their activation, however, are different in the two developmental conditions, and are discussed below.

P_{LL} is located 400 nt upstream of P_{LE} and the transcripts starting at P_{LL} encode two additional genes: *vis* and *orf*199; the latter overlaps *kil* in frame (**Fig. 3B**) and thus Kil is a truncated form of Orf199.

In the late-plasmid transcription mode P_{LE} is still active: the short transcripts characteristic of the lysogenic condition are abundantly produced and premature termination at t_{imm} occurs efficiently. On the contrary, transcription from the upstream promoter P_{LL} is not subject to the strong termination mechanism of P4 immunity. This seems to be due to *vis–orf*199 translation that may impede interactions between the P_{LL} transcripts and the Rho factor and/or the CI RNA, thus preventing transcription termination.

In most temperate phages the choice between lysis and lysogeny depends on the activation of either of two mutually exclusive regulatory patterns. In P4, on the contrary, the late-plasmid and the immune modes of transcription are not mutually exclusive; rather, the late-plasmid mode is superimposed on the immunity control and the choice between lytic-plasmid versus lysogenic development appears to rely on the activation, or lack thereof, of the two late promoters P_{LL} and P_{sid}.

The P4 late promoters and their transcriptional activators

Both P_{LL} and P_{sid}, like the promoters of the late

Figure 7 Amino acid sequence of the late gene *trans*-activating factors of P2- and P4-like phages. NucC is encoded by a cryptic prophage of *Serratia marcescens*. δI and δII are the N and C terminal halves of Delta, respectively. The amino acids used to define the consensus sequence are in bold. Bottom line: letters underlined, amino acids present in all the seven sequences; upper case letters, amino acids present in six sequences; lower case letters; amino acids present in four or five sequences. (Modified from Pountney DL, Tiwari RP and Egan JB (1997) *Protein Sci.* 6: 892.)

(morphogenetic) operons of P2, are positively controlled by the P4 encoded Delta and the P2 encoded Ogr transcriptional activators.

Ogr is the prototype of a class of transcriptional activators that control the late operons of phages related either to P2 or P4. These activators are small proteins (72–81 amino acids) with a zinc-finger-like metal-binding domain. P4 Delta, however, is twice as much the size of the other members of the family, contains two zinc-binding motifs, and appears to be a tandem duplication of the basic module (**Fig. 7**). Both domains of Delta are required for transcriptional activity.

The Ogr-family activators interact with the C-terminal domain of the RNA polymerase α subunit and bind to a consensus sequence centered at about −55 nt from the transcription start point in all the responsive σ^{70}-dependent promoters. The P4 P_{sid} promoter, however, contains a second copy of the consensus sequence in the −18 region (**Fig. 8**) that appears to quench transcription activation by Delta, since mutations in the P_{sid} −18 region increase Delta-dependent promoter activity. This seems to explain why Delta-promoted transcription is less efficient from P_{sid} than from P2 late promoters.

Although P_{LL} and P_{sid} share the positive regulators Delta and Ogr, they differ in three aspects that are relevant for the plasmid and the lytic development: (1) a low basal level of transcription from P_{LL} may be detected early upon infection, due to an overlapping weak promoter P_{LL}*. No basal level of transcription has been detected from P_{sid}; (2) transcription from P_{LL} is repressed by Vis, the product of the first gene downstream of P_{LL}, whereas Vis appears to enhance Delta-dependent transcription from P_{sid}. Accordingly, the Vis binding site for P_{LL} is located immediately downstream of the transcription start, whereas a Vis-binding consensus sequence is located upstream in P_{sid}; (3) P_{LL} can be activated by the helper early gene product Cox, whereas P_{sid} cannot. The Cox-binding region is located −60 to −150 in P_{LL} (**Fig. 8**).

The multicopy plasmid state

Upon infection by wild-type P4, the multicopy plasmid state may be established at low frequency, the lysogenic cycle being preferred in the absence of a helper phage genome. Mutations affecting P4 immunity may increase the frequency of plasmid establishment.

The average number of P4 plasmid genomes per *E. coli* cell is about 30–50, and an integrated copy may also be found, but it is not essential for the plasmid maintenance. The steady level of P4 replication appears to depend on the regulatory loops controlling

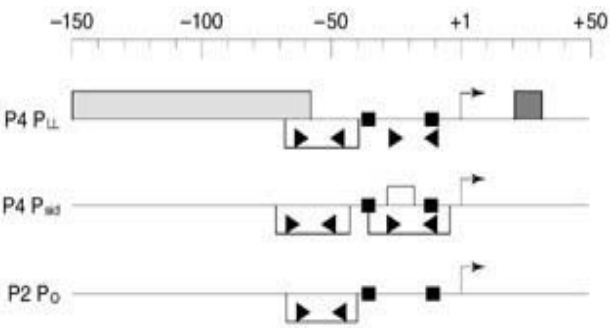

Figure 8 Structure comparison of the P4 and P2 late promoters. The figures on the top scale indicate the nucleotide position from the transcription start point (bent arrow). The short black bars are the −35 (TRGYgt) and −10 (cAaaMT) late promoter consensus sequences; the black and gray boxes are the Vis and Cox binding sites, respectively; the open boxes are the Delta binding sites, and the inverted arrowheads indicate the conserved TGT-ACA dyad elements within the Delta binding sites. The P2 P_O promoter is shown as a representative of the P2 late promoters.

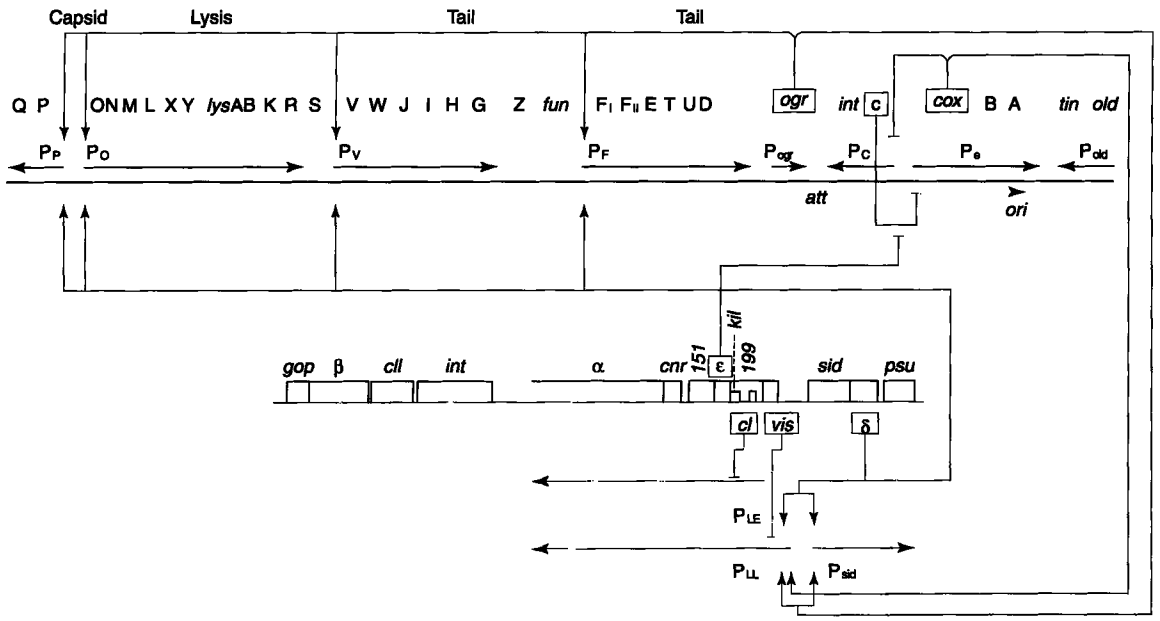

Figure 9 Regulatory loops controlling expression of P4 and P2 late genes. Straight arrows, transcription units. Transcriptional or functional activation and inhibition are indicated by bent lines ending with an arrowhead or with a minus sign, respectively. The P2 map is not drawn to scale. (Modified from Lindqvist B, Dehò G and Calendar R (1993) *Microbiol. Rev.* 57: 683.)

P_{LL}, which is activated by Delta and repressed by Vis (**Fig. 9**). This poses the unsolved problem of how P_{sid} transcription (and, as a consequence, the plasmid regulatory state) is primed upon infection, when Delta is not yet present in the cell. It is possible that the right operon may be transcribed at a very low basal level in a Delta-independent manner. Alternatively, either Vis or other unidentified P4 functions might be involved.

The lytic cycle

The P4 lytic cycle requires efficient exploitation of the helper phage genetic information to obtain the morphogenetic and lysis gene products. This may occur under different scenarios: (1) P4 infecting a repressed P2 lysogen; (2) P4 and P2 co-infecting a nonlysogenic host; (3) a P4 lysogen being infected by P2; (4) a P4-plasmid carrier being infected by P2. In each of these situations, the satellite phage senses the presence of the helper and responds by activating its own functions that will in turn modify the pattern of gene expression of the helper. Reciprocal regulatory interactions developed in this satellite–helper system involve lifting the immunity mechanisms (mutual derepression) and direct activation of the late operons (reciprocal *trans*-activation) of both phages. Moreover, morphopoietic interactions are elicited by P4 in order to assemble a capsid of the correct size. The type and timing of the satellite–helper interactions vary in the different infection conditions and give different outputs, in terms of satellite vs. helper virions produced, that appear to fit the reproductive strategies of the satellite phage.

Satellite–helper regulatory interactions When P4 infects a repressed P2 lysogen and the lytic option is set, the helper prophage immunity is lifted by the essential P4 ε gene product. P2 derepression leads to expression of the helper early genes (*cox* and the replication genes A and B), and to activation of unidirectional P2 replication *in situ*, without excision of the integrated prophage genome. The low P2 excision frequency, together with the interference on P2 growth due to the efficient production of small capsids, appear to be responsible for the fact that mostly a progeny of P4 virions is produced. Thus in an environment of P2 lysogenic bacteria, where P2 replication would be inhibited by the P2 prophage immunity, all the morphogenetic potential is efficiently directed toward the P4 propagation.

The mechanism of P2 derepression is not known, although Epsilon seems more likely to interfere with the repressor protein itself rather than directly activate the P2 early genes. P2 derepression is essential for P4 lytic growth in a P2 lysogen, but the underlying molecular mechanisms are not known. It seems, however, that this step is required for the timely activation of the helper's morphogenetic operons by the P2 Ogr and/or the P4 Delta proteins. Either

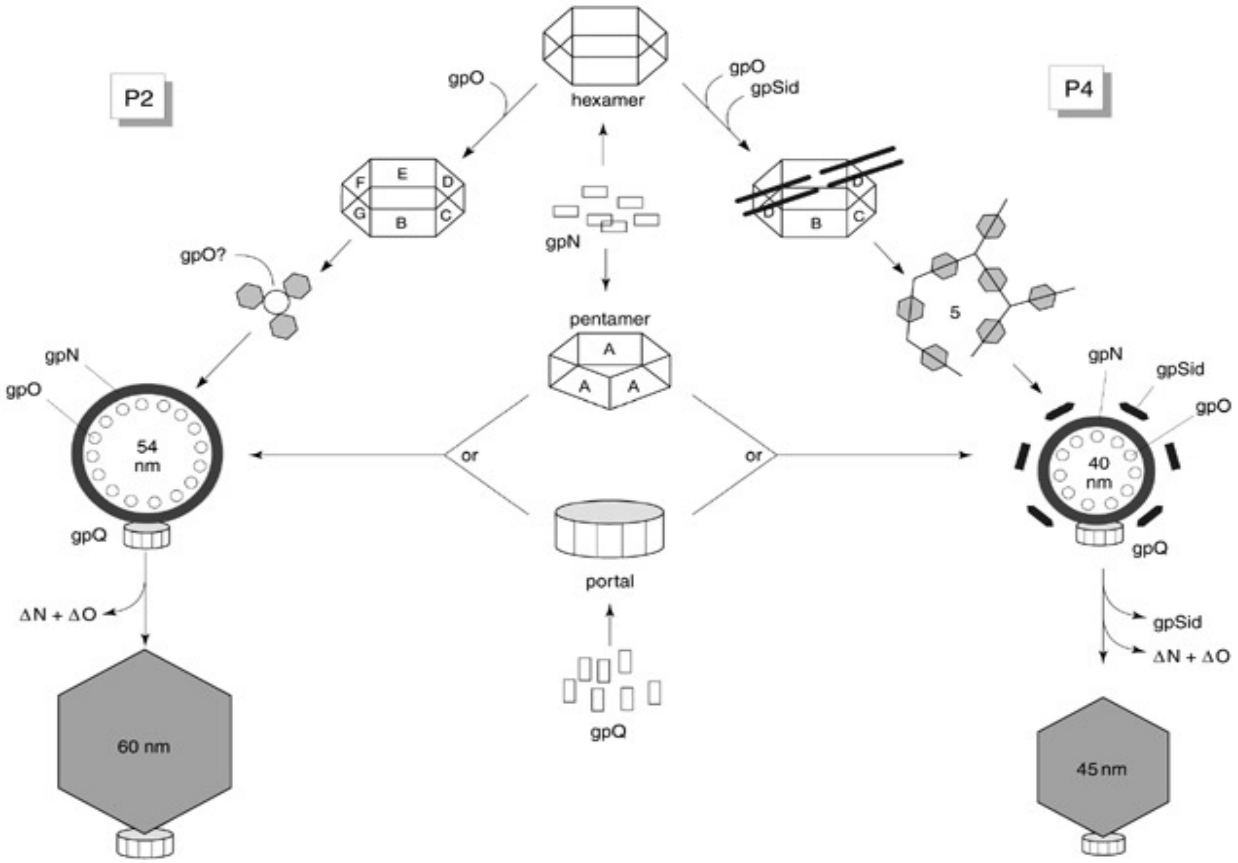

Figure 10 Schematic model for P4 and P2 capsid assembly. The gpN (gp = gene product) precursor (open rectangles) are assumed to form uncommitted hexamers, which will subsequently associate with the scaffolding proteins gpSid (filled bars) and/or gpO. The letters B to G indicate the different quasi-equivalent positions of gpN in the hexameric capsomers. In P4, the gpSid-gpN hetero-oligomers become connected by gpSid bridges into 5-fold rings (about to close in the Figure), with trivalent branching at every icosahedral 3-fold axis. In P2, the speculative function of gpO (in the absence of gpSid) would be to connect three gpN hexamers into a complete icosahedral face with triangulation number $T = 7$. The resulting shell structures will undergo maturation, involving shell expansion, processing of gpN, and removal of the scaffold molecules. (From Marvik OJ, Dokland T, Nøkling R, Jakobsen E, Larsen T and Lindqvist BH (1995) *J. Mol. Biol.* 251: 59.)

transcriptional activator is sufficient to *trans*-activate both P4 and P2 late genes, although in the presence of both Ogr and Delta functional proteins the P4 lytic cycle occurs more timely and efficiently than with a single activator.

When P4 and P2 co-infect a nonlysogenic host, the burst size of P2 is reduced and a progeny of both phages is produced in about the same proportions. Interference on P2 growth is stronger if P4 infects the host earlier than P2. This fits with a balanced spreading of both P4 and P2 in a dynamic competition in a nonlysogenic population. The ϵ derepression activity is dispensable for P4 lytic cycle, although it appears to be required for interference with the helper's growth.

Infection of a P4 lysogenic strain by P2 induces the P4 lytic cycle. The yield of P4 phage, however, is low (ca. one per cell) and interference on P2 growth is not observed. Thus also under such a condition the P4 genome can be rescued, albeit at low efficiency, and survives host cell death. The P4 prophage senses the infection of the helper via the early P2 Cox protein, which activates P_{LL} and thus the expression of the α operon. Cox does not activate P_{sid}, which lacks the Cox binding site and, later on after infection, may be efficiently activated by the P2 Ogr protein.

When P2 infects a cell carrying P4 in the plasmid condition, the Cox function is not required to induce P4 lytic cycle since the P4 late promoters are already activated. In such conditions P4 strongly interferes with P2 growth and mostly P4 virions are produced.

From the above description it is apparent that P4 has developed sophisticated regulatory strategies to exploit P2 and maximize the chances for its own horizontal transmission in bacterial populations that may differ with regard to the presence and the state of the helper phage.

Morphogenesis The helper phage P2 packages its 33 kb genome into 60 nm isometric capsids made up of 60 hexameric and 12 pentameric capsomers. A complex capsid maturation pathway involves proteolytic processing of the capsid proteins as well as structural reorganization of the shell lattice. The capsomers are made of the N-terminal processed products (N*) of the P2 *N* gene. P4 interferes with the P2 morphogenetic pathway by directing the assembly of a 45 nm isometric capsid (made of 30 hexamers and 12 pentamers) more suitable for its own three times smaller genome. A schematic model for P4 and P2 capsid assembly is shown in **Fig. 10.**

The P4 *sid* gene product is sufficient to direct the assembly of P4-sized heads by interacting with the P2 *N* gene product and forming a continuous dodecahedral scaffold on the outside of the procapsid particles. The only other known example of external scaffolding in phage morphogenesis is provided by ΦX174. Maturation of the procapsid involves proteolysis of the P2 *N* gene product to give not only the N* but also a substantial amount of two partially processed forms, h1 and h2. In addition, the Psu protein associates on the top of the hexameric capsomers and stabilizes the phage particle. Psu is the only P4 encoded protein that may be found in the mature P4 virion, but it is not essential for P4 morphogenesis.

The P4 dependence on the helper for the morphogenetic pathway includes DNA maturation and packaging. Circular DNA molecules are the preferred substrate for packaging by both P2 and P4 proheads. A staggered double-strand cut that generates the 19 nt long single-stranded cohesive ends of the mature genome occurs within a 55 nt-long sequence, essential for DNA packaging, that is identical in P2 and P4.

Natural History

Although, to our knowledge, a systematic search for satellite phages has not been performed, another P4-like P2-dependent phage, ΦR73, has been serendipitously identified in a natural isolate of *E. coli*. P4 and ΦR73 exhibit more than 95% sequence identity in the *crr-cos* essential region. Exceptions are gene *δ*, which is only 31% identical and does not show the tandem-duplication structure of P4 *δ* gene, and the immunity region, with 85% identity. ΦR73 immunity system is similar to that of P4, but each phage is insensitive to the immunity of the other prophage. This heteroimmunity is due to six base differences in the single stranded *seqB* region of the CI RNA and to compensatory base substitutions in the target sites *seqA* and *seqC* (**Fig. 6**).

The *int* genes of the two phages diverge considerably (40% identity) and no homology exists between their *att* sites. ΦR73 prophage has been found integrated at the 3′ end of *selC*, which encodes the selenocystyl-tRNA. The nonessential region to the left of the *att* site in ΦR73 appears to be rearranged, relative to P4; interestingly, to the right of *att*, ΦR73 carries a retron, a chromosomal element encoding reverse transcriptase and responsible for the synthesis of a peculiar single-stranded DNA–RNA chimeric molecule called msDNA.

At least three distinct P4-related sequences, named CP4 for 'cryptic P4' phage, have been identified in the completely sequenced *E. coli* K genome, and cross-hybridization of P4 DNA with a large proportion of *E. coli* clinical isolates has been reported. These seemingly P4 related prophage remnants witness the diffusion of P4-like satellite phages and the role they may have played in horizontal gene transfer in natural populations of *E. coli*.

PAPILLOMAVIRUSES – ANIMAL

William C Phelps, Department of Virology, Glaxo Wellcome Inc, North Carolina, USA

Alison A McBride, National Institute of Allergy and Infectious Diseases, Laboratory of Viral Diseases, National Institutes of Health, Bethesda, Maryland, USA

History

Warts or papillomas have been recognized in animals for centuries. One of the earliest reports was from the stablemaster for the Caliph of Baghdad who first described equine warts in the ninth century AD. Contemporary with the discovery of 'filterable agents' by Ivanowski, Beijerinck, Loeffler, and Frosch at the end of the nineteenth century, Penberthy (1898) demonstrated the infectious transmission of warts in dogs and Ciuffo confirmed a viral etiology for papillomas with the report of the transmission of warts in humans using sterile filtrates. Bovine warts were also recognized to be contagious; however, demonstration of viral transmission did not occur until 1929. Cottontail rabbit papillomavirus (CRPV) or Shope papillomavirus was isolated and described in 1933 by Richard Shope.

Following the observations by Peyton Rous in 1935, that benign rabbit warts could progress to malignant carcinoma, the Shope papillomavirus system became a favorite model for the study of carcinogenic progression in animals. As one of the earliest indications that viruses could be involved in the development of cancer, this model has been instrumental in the study of viral oncology and neoplastic progression, and has contributed to our recognition of cancer as a multistep process. The potential for malignant conversion of virus-induced benign lesions is a hallmark of papillomaviruses (PVs) and was important in the recognition of the role of the human papillomaviruses (HPVs) in cervical cancer.

Up to the 1980s, research on the papillomaviruses had been relatively slow due primarily to the absence of a conventional, permissive cell culture system for virus propagation. Although great difficulties persist even today for *in vitro* replication of PVs, the advent of molecular cloning early in the 1980s greatly expanded the capacity for experimental manipulation of the viral genomes and brought renewed vigor to papillomavirus research.

Taxonomy and Classification

Papillomaviruses belong to the *Papovaviridae* family of DNA viruses that includes mouse polyoma and the monkey virus, SV40. The family name, 'Papova' is derived from the first two letters of the three principal virus groups, PApilloma, POlyoma, and simian VAcuolating virus (SV40). Based on comparative structural and genetic characteristics, these viruses are considered as two discrete subfamilies: *Papillomavirus* and the *Polyomavirus* (polyoma, SV40, JC, BK). The members of the *Papovaviridae* family share a number of properties including a relatively small size, nonenveloped icosahedral capsids, and a double-stranded, covalently closed, supercoiled DNA genome that replicates in the nucleus of infected cells in association with cellular histones.

Classification of papillomaviruses into types is based first upon species specificity, and second, upon the degree of relatedness of the viral genomes. For example, six different PV types that infect cattle have been isolated and described. The bovine papilloma viruses (BPV) types (1–6) are numbered sequentially according to their chronological order of identification. To distinguish individual PV types, the initial classification scheme described in the 1970s was based on measuring the extent of nucleic acid sequence homology using liquid hybridization under stringent conditions of dissociation and reannealing. More recently, with the availability of DNA sequence data on the vast majority of PV genomes, classification of PV types is carried out through comparison of the nucleotide sequence of specific regions of the genome. To be considered a new PV type, the DNA sequence of the E6, E7, and L1 open reading frames should not exceed 90% identity when compared to other known PV sequences. If DNA sequence identity exceeds 90%, the genome is considered a subtype or variant. Papillomaviruses have been isolated and characterized from a number of animals including cattle, sheep, deer, horses, rabbits, dogs, mice, birds and nonhuman primates such as monkeys (**Table 1**). To date, DNA sequence information has become available on about 25 different PV types isolated from among these diverse animal families.

Geographic Distribution

PV infections of animals occur worldwide although virus types can display some geographic variability,

Table 1 Well characterized animal papillomaviruses

Host	*Lesion*	*Designation*
Domestic cattle	Fibropapilloma, papilloma	BPV 1–6
Cottontail rabbit	Papilloma	CRPV
Domestic dog	Oral papilloma	COPV
Domestic sheep	Papilloma, fibropapilloma	OvPV 1, 2
Deer	Fibroma	DPV
European elk	Fibroma	EPV
Reindeer	Fibropapilloma	RPV
Harvest mouse	Papilloma	MmPV
Multimammate rat	Papilloma, keratoacanthoma	MnPV
Chaffinch	Papilloma	FPV
Chimpanzee	Oral	ChPV
Pigmy chimpanzee	Oral	PCPV
Rhesus macaque	Genital	RhPV
Long-tailed macaque	Genital	MfPV
Colobus monkey	Papilloma	CgPV 1, 2

and may be observed to cause periodic, localized outbreaks. For example, endemic CRPV infection is typically confined to the populations of wild cottontail rabbits in the mid-western US. As the wild rabbit host is found throughout the US, it is not clear what exogenous factors may contribute to the geographic exclusivity of enzootic CRPV infection.

BPV-4 causes alimentary tract papillomas and was associated with a high rate of progression to carcinoma in Great Britain. Subsequent studies revealed that bracken fern grown in that region, contained a cocarcinogenic substance that promoted progression of alimentary papillomas to squamous carcinomas and urinary bladder tumors. BPV-1 causes naturally occurring fibropapillomas in cattle. In the US, lesions are typically found on the head, neck, and shoulders whereas in Germany, lesions on cattle are more often seen on the abdomen, legs and back. Although different virus types will preferentially infect different tissues, in this instance, the site variability of BPV-1 infected lesions is likely due to differences in animal husbandry.

Host Range and Virus Propagation

PVs infect a broad range of vertebrate species and are especially prevalent in mammals. Three PV infections have been described in avian species; the genomes of two have been cloned and partially characterized thus far (chaffinch and gray parrot). Papillomatous lesions have also been described in species of amphibians (e.g. newts and salamanders) and reptiles (e.g. snakes, turtles and crocodiles) although a PV etiology has not yet been confirmed.

Infection with specific PVs has been confirmed in approximately 50 different mammalian species. One of the hallmark features of PVs is pronounced host specificity with infection being typically restricted to closely related animals of a given family. For example, CRPV naturally infects the cutaneous epithelium of wild cottontail rabbits, and experimental infection of related jackrabbits or snowshoe rabbits will result in the growth of papillomas and production of infectious particles. In contrast, although experimental infection of domestic rabbits induces growth of papillomas, the lesions are typically nonproductive containing little or no infectious virus. CRPV-induced benign warts on domestic rabbits appear to support normal early viral gene expression and genome replication, but are unable to support late gene expression and virus particle production. In addition, benign lesions of domestic rabbits are roughly three times more likely to progress to carcinoma than comparable lesions in wild rabbits, the natural host. The genetic determinants of the host that are responsible for the variability in pathogenic outcome are thus far, not well defined. Recent studies have suggested a role for polymorphic genes of the major histocompatibility complex that are important for recognition of viral antigens.

There are two subgroups of bovine papillomaviruses; one which causes fibropapillomas and the other epithelial papillomas. BPV types 3, 4 and 6 were isolated from true papillomas whereas types 1, 2 and 5 were isolated from fibropapillomas. BPV types 1 and 2 exhibit a slightly broader host range causing endemic fibropapillomas in cattle and nonproductive (i.e. no infectious virus produced) sarcoids in horses. Experimental infection with BPV types 1 and 2 results in a somewhat broader host range and results in nonproductive fibromas in horses, hamsters, rabbits, pikas and mice. The ability of BPV-1 to infect and transform mouse cells in culture enabled the development of a focus-forming assay that was critical to early work to genetically define viral genes responsible for cellular transformation and genome replication.

Canine oral papillomavirus (COPV) infection is seen sporadically in domestic dogs of all ages. In contrast to BPV-1 and -2, COPV cannot successfully infect mice, hamsters, or guinea pigs in the laboratory; however, COPV has been detected in feral coyotes. During the last ten years, several PVs have been isolated from nonhuman primates including monkeys and chimpanzees. As both the primate PVs and their hosts are examined more closely, it is possible that we may find that certain HPVs will infect certain primates and that certain primate PVs will infect humans.

Another method for the extension of the inherent host range of PVs is through the use of transgenic animals. Recently, both transgenic rabbits and mice have been described harboring CRPV and BPV-1, respectively. These systems provide additional tools to examine a myriad of specific issues regarding tissue-specific expression, cellular transformation, cytogenetic abnormalities associated with carcinogenic progression, and immune recognition and tumor immunity. BPV-1 transgenic mice will develop nonproductive epidermal fibropapillomas after a delay of 8–9 months. The warts occasionally become malignant and are locally invasive. Extrachromosomal BPV-1 DNA is found exclusively in the wart tissue in contrast to the normal skin and tissues that harbor only integrated, transcriptionally silent BPV DNA. CRPV transgenic rabbits develop an extensive population of cutaneous papillomas within 1–3 months, and viral mRNAs are only expressed in skin tumors, not in normal tissues.

Several systems have been developed to propagate the papillomaviruses. Small pieces of epithelial tissue can be infected with virus and implanted in the renal capsule of an immunocompromised mouse; this results in the production of virion particles. Skin from various species can also be grafted onto immunocompromised mice and either infected with virus or transfected with viral DNA. The infected xenograft will form a papilloma-like lesion that, in some cases, can produce virion particles. Artificial skin equivalents (organotypic rafts) can also be grown in tissue culture and this system can also support the viral life-cycle. Although these systems are still far from ideal, they are being used to begin to understand the complete viral life cycle.

Genetics

The emergence of techniques for molecular cloning in the late 1970s permitted viral genomes to be isolated and propagated in the laboratory to provide an unlimited source of homogeneous viral DNA for study. In 1980, Doug Lowy and co-workers showed that BPV-1 virus and cloned viral DNA could morphologically transform established mouse cell lines. The viral DNA was shown to persist extrachromosomally and replicate as a stable episome. As a result of these features, BPV-1 has been the model system of choice for the genetic analysis of the viral transformation, DNA replication, and transcriptional regulatory functions.

The genetic information of all PVs is expressed from a single strand of the double-stranded genome which, by convention with the polyomaviruses, is divided into three regions (**Fig. 1**). The long control region (LCR) is a 1 kb sequence containing many of the viral transcriptional regulatory signals as well as the origin of replication. The early region contains those opening reading frames (ORFs) expressed primarily in nonproductively infected cells (labelled E1–8 in descending order of size). The late region contains the ORFs for the capsid proteins L1 and L2, which are expressed only in productively infected cells and are dispensable for BPV-1 DNA replication and *in vitro* transformation of mouse cells. A polyadenylation site (poly(A)) for the early messages is located between the early and late regions whereas the late transcripts use a second poly(A) site in the LCR. Transcriptional termination within the late region occurs in nonproductively infected cells and may prohibit expression of the late mRNAs in these cells.

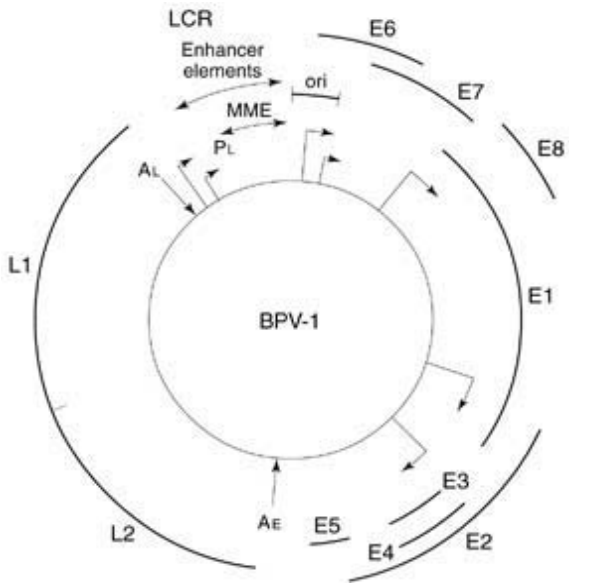

Figure 1 The circular BPV-I genome. Nucleotide numbers are noted within the map. E and L designate the early and late open reading frames, respectively; promoters are indicated by arrows. LCR indicates the long control region. A_E and A_L represent the early and late polyadenylation sites, respectively and MME indicates the minichromosome maintenance element.

Seven transcriptional promoters have been identified in the BPV-1 genome, of which one (the presumptive late promoter) is expressed only in productive warts. The activities of the six early promoters are regulated by host factors and the virally encoded E2 proteins. There are three E2 proteins encoded by BPV-1 (E2TA, E2TR and E8/E2) that are the result of expression from multiple promoters and alternative RNA splicing. All three have sequence-specific DNA binding and dimerization activities whereas the third (E2TA) has, in addition, a transcriptional activating domain. E2TA stimulates viral promoters by binding to multiple 12 bp palindromic sequences in E2-specific

enhancers within the LCR. This activity is modulated by the E8/E2 and E2TR proteins which antagonize the functions of E2TA.

E6 is a zinc binding protein found in the nucleus and nonnuclear membranes. It is capable of transforming certain mouse cells. The E7 protein is unable to tranform cells alone but both E6 and E7 expression are required for the full transformed phenotype. The E6 and E7 proteins of the HPVs are known to bind to the cellular p53 and pRB tumor suppressor proteins but the BPV-1 and CRPV proteins do not have analogous activities. However, BPV-1 E6 protein can bind the cellular focal adhesion protein, paxillin, a clathrin adaptor complex and a calcium binding protein, E6-BP. These interactions may be important for its transforming activity. The E6 protein has also been shown to have transcriptional activating activity in a heterologous assay system.

The BPV-1 E5 protein plays a central role in transformation of established mouse cell lines and, at 44 amino acids, is the smallest known transforming protein. E5 is a membrane protein localized to the Golgi apparatus and plasma membrane and is well conserved among the animal PVs that cause fibropapillomas. Acute expression of E5 results in rapid morphological transformation of mouse cells indicating that E5 is sufficient for transformation and that no secondary cellular event is required. The E5 protein is thought to function by activating the β type receptor for platelet-derived growth factor (PDGF). It is also able to interact with a vacuolar H(+)-ATPase. This appears to block acidification of endosomes which may in turn prolong growth factor receptor stimulation by inhibiting receptor degradation and promoting receptor recycling. E5 is highly expressed in the basal cells of a BPV-1 fibropapilloma and this may result in increased proliferation of these cells. Enhanced replication of basal cells may be important to increase the population of infected cells and to provide a suitable environment for establishment of a productive lesion.

E4 is a cytoplasmic phosphoprotein which is poorly conserved among the PVs. It is thought to be a late-associated protein since it is found in high concentration in the productively infected cells of the wart. Its function in productive infection is unknown and it is not required for viral transformation or DNA replication.

E1 is a nuclear phosphoprotein required for replication of the viral DNA. The E1 protein is an ATP-dependent helicase that specifically binds and unwinds the origin of replication. The E2TA protein is also required for DNA replication and the E1 and E2TA proteins cooperatively bind to the origin. Viral replication also requires host replication factors such as the host DNA polymerase. A second protein translated from the E1 ORF is called the E1M protein. It contains only the N-terminal region of the E1 ORF but its function is unknown. Transient BPV-1 DNA replication requires the E1 and E2TA proteins and the replication origin but long-term episomal maintenance of viral genomes requires an additional *cis* element from the LCR that contains multiple E2 binding sites. This has been designated a minichromosome maintenance element (MME). The E2TA protein and the viral genomes are attached to mitotic chromosomes in dividing cells and this may be important for segregation of viral genomes.

Injection of rabbit skin with CRPV DNA results in papillomas and this system has been used to define which gene functions are required for the formation of warts. These studies have shown that the E1, E2, E6 and E7 genes are required but that the E5 protein is dispensible for papilloma formation.

Evolution

All human and animal PVs sequenced to date have a similar genomic organization with the exception of the B subgroup of bovine papillomaviruses (BPV-3, -4, -6). These viruses have no E6 ORF but instead have an ORF homologous to E5 in the position between the LCR and the E7 gene. This suggests that genomic rearrangements may have occurred during the evolution of the B subgroup of BPVs. The papillomaviruses are evolving very slowly and diversification has occurred over millions of years. It has been estimated that the most variable parts of PV genomes change at a rate of 0.25% per 10 000–20 000 years. For example, the DNA sequence of two different isolates of BPV-1, one isolated in the US and the other in Sweden, differ only by five nucleotides in 8000. The relationship between different papillomaviruses can be established by sequence comparison and represented by a phylogenetic tree, as shown in **Fig. 2.** Within a single species, multiple, minimally related serological papillomavirus types exist. This implies that PVs have evolved in response to pressures from the host immune system, especially since regions of the capsid proteins that are not exposed to the immune system have remained conserved. Papillomas can be infected with more than one viral type, yet there is little or no evidence that recombination occurs among papillomavirus genomes.

Serological Relationships and Variability

Until recently, the study of the serological relationships among papillomaviruses based on antibody

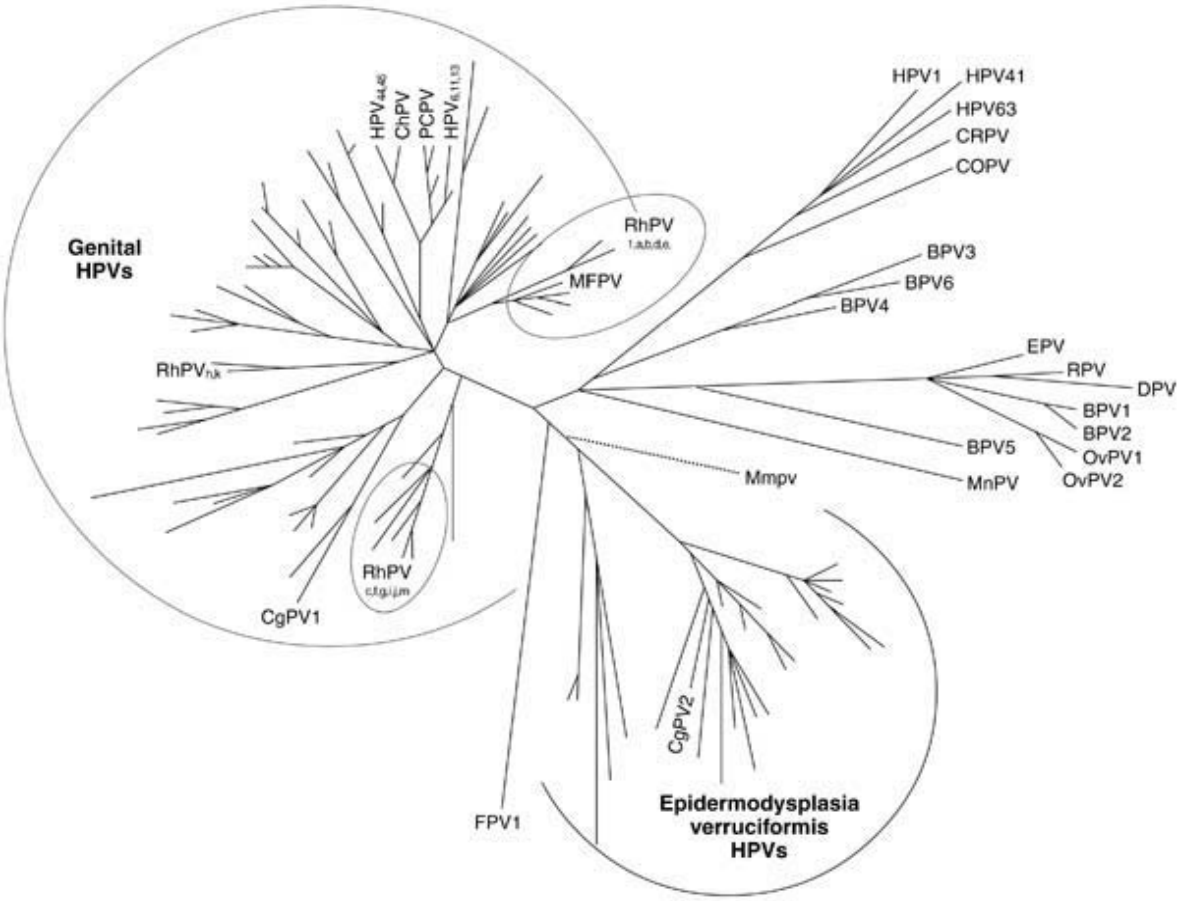

Figure 2 The evolutionary relationship between animal and human papillomaviruses is represented by a phylogenetic tree. (Adapted from Bernard H-U and Chan S-Y (1997) Animal papillomaviruses. In: *Human Papillomavirus*. Los Alamos National Laboratories, *http://hpv-web.lanl.gov/*)

recognition of viral capsids was limited because of the difficulties in obtaining virion particles. However, virus-like particles (VLPs) can be produced by expressing recombinant L1 and L2 proteins and used for antigenicity studies. All types of papillomaviruses (PV) share common, so-called group antigenic determinants. The cross-reactive epitopes are clustered in two regions of the L1 capsid protein. In general, antisera prepared against intact virions of one type are specific to that virus type. However, antisera to detergent-disrupted virus particles reveal internal, genus-specific antigenic determinants that are broadly cross-reactive against the spectrum of PVs. These cross-reactive sera have been used successfully to screen tissue from papilloma-like lesions for the presence of PV antigens.

Transmission and Tissue Tropism

Animal PVs predominantly infect cutaneous epithelium although some show specificity for the mucosal epithelium (e.g. ROPV, COPV, BPV-4). Unlike human PVs, animal PV infections can result in both papillomas and fibropapillomas in which hyperplastic growth is evident in both the infected epithelial cells and the underlying fibroblasts. For example, BPV types 1 and 2 predominantly induce fibropapillomas on the skin of cattle although lesions may also be found on the less keratinized epithelium of the rumen. BPV-3 induces true papillomas on the skin of adult cattle; BPV-5 is associated with 'rice-grain' lesions on the teat whereas BPV-6 causes true papillomas also in association with the teat. BPV-4 is associated with papillomas of the mucosal epithelium of the alimentary tract. Although BPV-4 can be experimentally transmitted to the soft palate, bovine skin is apparently refractory to BPV-4 infection.

BPV infection is readily transmitted in herd animals through direct contact of abraded skin. Natural infection of horses with BPV often occurs after placing the horses in stalls previously housing infected cattle. Some sexual transmission of venereal warts in cattle apparently occurs since such lesions are rare in animals that are artificially inseminated. PV virions

have also been detected in milk suggesting that mammary epithelium may also be susceptible to infection, and represent a potential route for vertical transmission.

CRPV infection is restricted to the cutaneous epithelium of rabbits and lesions can be experimentally induced on the head, neck, back and abdomen. Naturally infection of wild rabbits is most often observed to occur on the head or around the ears suggesting transmission may occur through grooming or fighting, or spread by biting insects such as rabbit ticks. The susceptibility of tissue to virus infection is often stringent. CRPV will only infect hair-bearing skin and is unable to infect epithelium of the tongue, gums, conjunctiva, genitals or mammary glands. Recent evidence suggests that the primary target of experimental CRPV infection may be the epithelial stem cells associated with the hair follicles.

Infection requires direct access to the basal layer of the epithelium that typically occurs through wounding. As a consequence of wounding, a regenerative healing process is initiated which is accompanied by a localized reactivation of cell division. This transient hyperplasia associated with tissue repair may be a critical step in the establishment of stable replicating viral genomes in the nuclei of infected host keratinocytes. Although episomal PV DNA is maintained in the basal cells of the epithelium and in the dermal fibroblasts of BPV-induced fibropapillomas, virus particle production is restricted to the overlying, terminally differentiated cells of the epithelium. It is thought that under certain conditions, a reservoir of latently replicating PV genomes are maintained at a low copy number in the basal cells of the epithelium; and that the latently infected cells can give rise to macroscopic lesions in response to appropriate physical or chemical stimuli.

The factors responsible for the characteristic tissue tropism of animal PVs are not yet fully understood. Tissue specificity could result in part from selective expression of a cell-type specific virus receptor in the basal cells of the epithelium. Recent data suggest that the glycoprotein, α_6 integrin, may serve as a virus receptor for infection. Interestingly, the $\alpha_6\beta_4$ integrin heterodimer has been observed to be selectively expressed in basal keratinocytes where PV infection is thought to occur, and is downregulated in differentiating keratinocytes.

At least on the surface, viral DNA replication does not appear to require tissue-specific factors that are exclusively expressed in epithelial cells. Studies have shown that origin-specific replication of PV DNA is dependent on the expression of two viral proteins, E1 and E2, and the host replicative machinery (e.g. DNA polymerase, topoisomerases, and DNA binding proteins) that are typically found in all actively growing cells. In infected tissues *in vivo*, however, the virus may utilize two different modes of DNA replication: latent replication and vegetative replication. Latent replication in the basal cells of the epithelium refers to the stable maintenance of a small number of copies of the viral genome, which replicate once per cell cycle. Vegetative replication (amplification) occurs exclusively in the more differentiated layers of the epithelium and is thought to be regulated through specific factors expressed (or turned off) during terminal differentiation.

In addition to the host factors involved in virus entry and genome replication, tissue-specific viral gene expression appears to rely heavily on cellular transcription factors. The control of PV transcription is very complex due to the presence of multiple promoters, alternate RNA splicing and polyadenylation, and differential mRNA production. For BPV-1, more than 20 different mRNA species have been described in transformed mouse cells and infected bovine tissue. At least six different promoters are active in productively infected fibropapillomas including the major late promoter (P_L) that is found to be activated in infected keratinocytes. Differential regulation is evident in the stratification of mRNA expression in different layers of BPV-infected warts. The LCR contains a number of binding sites for host transcription factors that act as *cis* regulatory elements in the control of viral gene expression. Clearly, tissue tropism, in part, results from an obligatory and complex pattern of coordinate gene expression that is exclusively found in actively differentiating epidermis.

Pathogenicity

In animals, PV infection causes benign epithelial neoplasms commonly called warts. Individual or clusters of benign papillomas can persist for many months or years or may regress spontaneously. Localized warts do not generally represent a significant threat to the health of the host animal although severe, disseminated outbreaks of warts in wild animals may result in an increased susceptibility to predation or secondary infections.

In a subset of infected animals, benign warts can progress to malignant carcinoma. Carcinogenic progression of benign warts has been relatively well-studied in CRPV and BPV-4 infected lesions. Progression of virus-induced benign tumors to carcinoma is a multifactorial process in which PV infection alone, although necessary, is not sufficient for malignant transformation. Progression is thought to require multiple secondary events in the infected host cells

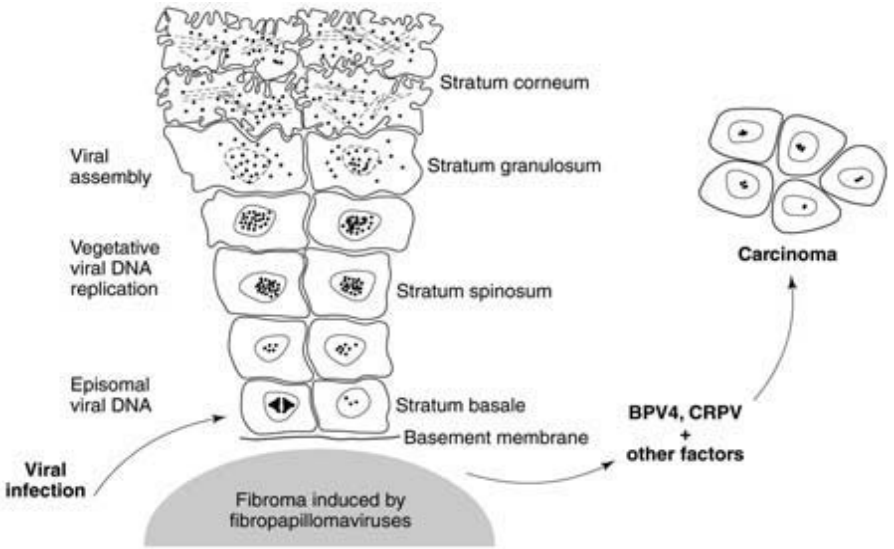

Figure 3 Life cycle of PVs. The diagram shows a model of stratified epithelium. The stages of the viral replicative life cycle that occur in each cell layer are indicated. Fibropapillomaviruses also infect fibroblasts in the dermis and this results in a fibroma. Papillomas infected with certain PV types will often progress to carcinomas.

which can result from the interplay between virus expression, genetic determinants of the host, and external, nutritional or environmental cofactors.

BPV-4 infection is associated with benign papillomas in the alimentary tract of cattle. It was noted some years ago, that an unusually high proportion of cattle in certain regions of Scotland had developed alimentary carcinomas in association with BPV-4 infected benign tumors. Alimentary papillomas were observed to become malignant in areas where cattle grazed on bracken fern which are known to contain various radiomimetic and immunosuppressive agents particularly when grown in specific geographic regions. Therefore, it is only within these specific regions that the consumption of bracken fern by cattle can act synergistically with BPV-4 infection to promote malignant transformation.

CRPV infection of rabbits was reported almost 70 years ago to induce benign cutaneous warts that could progress to malignant carcinomas. In addition to virus infection, several other factors were observed to be important determinants for progression. For example, the genetic background of the host is important; infection of domestic rabbits induces benign warts which will progress to carcinomas at a rate that is roughly three times higher than similar lesions in wild rabbits, the natural host. In addition to host-specific effects, progression to carcinoma is a relatively slow process occurring in both wild and domestic rabbits over the course of 1–2 years. As noted above with BPV-4, cocarcinogenic effects have been observed with CRPV-induced lesions. The topical application of methylchloranthrene will both increase the proportion of benign tumors which will progress and will reduce the time required for progression to as little as 6 months.

Clinical Features of Infection

PV infection is not associated with overt, systemic clinical symptoms. In cattle, exposure often occurs in young calves who will develop protective immunity subsequent to regression of the benign fibropapillomas. Such prior exposure presumably accounts for the relatively low incidence of disease in adult animals.

During natural outbreaks, BPV infected lesions arise in 101–126 days after exposure and can regress spontaneously between 18 and 173 days after warts become visible. At present, little is understood about clinically inapparent or latent infection. Several studies of CRPV and rabbit oral papilloma virus (ROPV) have indicated that viral DNA can be detected in clinically normal epithelium although the pathological consequences are not well understood.

Pathology and Histopathology

BPV-1 associated fibropapillomas in cattle occur either singly or as multiple nodules and may reach several centimeters in size. They may appear sessile or pedunculate and lobate, fungiform or verrucate. Other bovine PVs cause flat or filiform teat papillomas and BPV-4 causes alimentary papillomas that can progress to carcinomas. CRPV-induced papillomas occur as multiple, gray or black, well-keratinized

masses. They range in size from 0.5 to 1 cm in diameter and can reach several centimeters in height resulting in cutaneous 'horns'. The associated carcinoma appears as a raised, fungoid or eroding lesion.

Fibropapillomas show a marked proliferation of the underlying fibroblasts within a dense matrix of collagen. Fibroplasia occurs within the first week after infection whereas hyperplasia of the epithelia may not be visible before 4–6 weeks. This long delay in the appearance of epithelial changes is similar to that observed with the strictly epithelial PVs such as CRPV where it may take 3–8 weeks for a papilloma to appear.

The PV life cycle is exquisitely attuned to the progressive vertical differentiation that occurs during maturation of the epidermis (see **Fig. 3**) and the study of the PVs has been hampered because of the difficulties in reproducing such a system in cell culture. Papillomavirus infection results in a number of changes in the epidermis. The rate of division of the epidermal cells is increased and this results in acanthosis (thickening), papillomatosis (folding) and hyperkeratosis (increase in the horny layer). Vacuolation of cells (koilocytosis) occurs in the stratum spinosum and granulosum and abnormal keratohyalin granules are produced. PVs infect the basal layer of a stratified epithelium. The $\alpha 6\beta 4$ integrin protein, that is expressed exclusively in this cell layer, probably acts as the receptor for virus binding and entry. Damage to the superficial skin or mucosa is presumed necessary to allow access of virus to the basal layer. Within basal cells, the viral genome is thought to be amplified to a low copy number and maintained as an episome. In a bovine fibropapilloma, the E5 protein is expressed in the basal cells and this may increase proliferation of these cells. The basal cells differentiate and move upwards to form the stratum spinosum and granulosum. These cells no longer divide and are committed to terminal differentiation which includes progressive keratinization and enucleation. In the stratum spinosum, expression of the viral E2 proteins is greatly increased and vegetative DNA replication begins. In the HPVs the E7 protein is required at this stage to induce cells to enter S-phase and synthesize cellular replication proteins. However, this disruption of cell cycle control in differentiating cells can cause cells to undergo apoptosis (programmed cell death to eliminate damaged cells) and one function of the E6 protein may be to prevent this. Presumably the animal PV proteins have similar functions. Viral-induced hyperplasia is believed to be induced by the viral early gene products, and results from both increased division of the basal cells and delayed maturation of the committed keratinocytes of the spinous layer (acanthosis). Expression of the viral capsid proteins, L1 and L2, is first detected in cells of the stratum spinosum and virus-specific cytopathic effects are most pronounced in the stratum granulosum. Virions are assembled in the upper differentiated layers of the papilloma and are found throughout the nuclei, frequently organized into paracrystalline arrays.

Immune Response

Both humoral and cell-mediated immune responses can develop in papillomavirus infections. Infection results in benign proliferative lesions that usually regress spontaneously through a cell-mediated immune response. Infected animals demonstrate a typical primary response to antigen, with the development of a full IgG response by 6 weeks. However, bovine and rabbit papillomas continue to grow in the presence of circulating antibodies and only regress following leukocyte infiltration. Once regression of a single wart begins all papillomas begin to regress, indicating that the mechanism of immunity is systemic. The immune system is the major determinant of regression since animals which have had their immune system suppressed by methylprednisolone show almost a 20-fold reduction in regression frequency. This regression leaves the host immune to reinfection with the same PV type and this protection is thought to be due to the production of neutralizing antibodies against the capsid proteins.

Regressing warts contain a mononuclear cell infiltrate. Leukocytes are present near the basement membrane but do not coincide with the areas of reduced cell proliferation, suggesting that soluble lymphokine-like substances are involved. Lymph node cells from regressor and nonregressor rabbits inhibit *in vitro* colony formation by papilloma- and carcinoma-derived cells. However, nonregressor sera can specifically block the inhibitory effect of lymph node cells, suggesting that immunosuppressive humoral factors may contribute to the persistence of tumors. These results also suggest that a cell-mediated response may be the primary factor for regression.

In rabbits, cattle and dogs, papillomavirus neutralizing antibodies (Ab) generated against either the capsid proteins or VLPs protect the animal from reinfection and have been the basis of very successful prophylactic vaccines. When Ab neutralization of inoculated virus is avoided by transplantation of infected skin or by transfection with viral DNA, papillomas occur in animals with persistent warts but not in those where the warts have regressed, again suggesting cell-mediated immunity is the primary factor in rejection. Although neutralizing antibodies

are not sufficient to bring about tumor rejection, vaccination with CRPV-derived tumor cell preparations has been shown in some cases to increase the rate of regression. Regression and immunity to subsequent PV infections may result from a cell-mediated reaction against a tumor associated antigen as opposed to a virus-specific antigen; however, such a cellular determinant has not been identified.

Prevention and Control

Treatment of papillomas in animals is not routinely prescribed. Typically the disease is self-limiting although of variable duration. Unlike HPV infection of humans, there is little economic impact resulting from PV-associated disease in animals. Infection of cattle primarily affects the hide with little or no consequence to the quality or harvest of beef. Benign warts or sarcoids in thoroughbred show horses or race horses can however reduce the commercial value of the animals. In contrast however, models of PV infection in animals have seen extensive use in the evaluation of prophylactic and therapeutic modalities prior to human clinical trials against HPV.

Inoculation with homogenized, autologous wart tissue has been used with some success to stimulate regression of CRPV-induced warts. Aromatic retinoids known to affect epithelial differentiation have also been used to treat CRPV-induced lesions. In these studies, up to 60% of the rabbits treated with retinoids showed complete and permanent regression of well-established tumors. BPV-1 transformed mouse cells have been shown to respond therapeutically to murine β-interferon, reducing or eliminating viral DNA in the transformed cells. Cells cured of BPV DNA are no longer morphologically transformed, and they fail to induce tumors in athymic mice. Various photodynamic therapies have been preclinically evaluated against CRPV-induced benign warts. Hematoporphyrin derivatives (HPD) are preferentially retained in wart tissue over the surrounding normal tissue. When activated by exposure to light, HPD is toxic to cells resulting in localized eradication of warts.

Prophylactic vaccination has been used successfully in cattle with a commercially available, formalin-inactivated homogenate of bovine fibropapillomas that is injected intradermally in two doses. Vaccinated herds show a lower incidence of warts and cows are protected from experimental infection. Vaccination with purified capsid proteins, L1 and L2 has shown encouraging results. In one study, 12 of 13 calves were successfully protected from experimental challenge with BPV-1 following intramuscular vaccination with 5–10 mg of L1 protein expressed in bacteria. More recent work in which the L1 and L2 proteins have been expressed to high levels in insect cells, yeast, or from vaccinia vectors has shown that self-assembly into 'virus-like particles' (VLPs) can occur in the absence of viral DNA. VLPs are currently being evaluated for use in prophylactic vaccination of humans against HPV infection. Vaccination of dogs with VLPs derived from COPV was recently used to determine whether prophylactic modalities would result in the generation of immunity to PV infection at mucosal sites. These experiments in dogs were of particular importance since genital and oral HPV infection afflicts the mucosal epithelium which is somewhat remote from systemic immunity.

Perhaps one of the most interesting vaccine technologies currently under investigation is the use of naked DNA capable of expressing various viral gene products. In a typical PV infection, virus particles and capsid antigens are present only in the more superficial regions of the epithelium that may not be readily accessible to circulating antibodies. A more useful target for therapeutic vaccination may be the early proteins that are expressed in the proliferating cells of the basal layer. DNA vaccination offers an opportunity for expression of early proteins, and for natural proteolytic processing of viral antigens by the immune system, which is thought to be critical to the generation of cell-mediated immunity. Again it has been animal models such as CRPV infection, which has offered proof of principle for the potential applications of this technology. In the future, primate models of PV infection may see substantial use in the preclinical evaluation of both prophylactic and therapeutic treatments for HPV infection.

Future Perspectives

Many questions remain to be answered, including which viral and host factors are responsible for malignant progression and what is the basis for the differences in tissue tropism exhibited by the many viral types. Our understanding of the mechanisms by which viral gene expression is regulated by keratinocyte differentiation is not well understood. More also needs to be learned about the interaction of the virus with the host immune system, especially as it relates to regression. Is there a role for latency in the virus life cycle and what signals might activate latent virus?

The lack of a productive *in vitro* system for passaging virus has severely hindered the study of PVs but in recent years the use of organotypic cell culture techniques, xenografts on immunocompromised animals and methods of introducing viral DNA to the intact epithelium of animals has enabled viral particles to be produced from cloned viral DNA.

These systems are continually improving and should allow a detailed genetic analysis of the complete viral life cycle.

The ability to generate VLPs has revolutionized papillomavirus research. These VLPs are very useful for serological studies and have been the basis of very successful prophylactic vaccines in cattle, dogs and rabbits. These animal systems should also prove useful for developing efficient therapeutic vaccines and for testing antiviral drugs that may be used in treatment of PV infections in humans.

BPV-1 continues to serve as the molecular prototype for the study of papillomavirus DNA replication and transcriptional regulation. The ability of this viral genome to efficiently and stably replicate extrachromosomally will prove to be very useful in understanding the mechanisms by which extrachromosomal elements stably replicate and segregate their DNA. Such studies may also lead to improved gene transfer vectors based on papillomavirus genomes. BPV-1 genomes packaged in heterologous VLPs have been used in neutralization studies because of the ability of BPV-1 genomes to quantitatively transform certain mouse cells. This property of BPV-1 should continue to prove useful for many different studies.

PARAINFLUENZA VIRUSES (*PARAMYXOVIRIDAE*)

Contents

Human

Animal

Human

Allen Portner, Department of Virology and Molecular Biology, St Jude Children's Research Hospital, Memphis, USA

Introduction

The human parainfluenza viruses (PIVs) are an important cause of respiratory disease in infants and children. Four types were discovered between 1956 and 1960. PIV-1, PIV-2 and PIV-3 were first isolated from infants and children with lower respiratory tract disease and subsequently shown to be a major cause of croup (types 1–3) and pneumonia and bronchiolitis (type 3). PIV-4 was initially isolated from young adults and has been associated with mild upper respiratory tract disease of children and adults. Other viruses antigenically and structurally related to the human paramyxoviruses have been isolated from animals. Sendai virus, a natural pathogen of mice and not of humans, was the first PIV isolated and is antigenically related to human PIV-1. Simian virus (SV)5, recovered from primary monkey kidney cells, causes croup in dogs and is a subtype of human type 2, and bovine shipping fever virus is a subtype of type 3.

Taxonomy and Classification

The PIVs belong to three genera, *Respirovirus*, *Rubulavirus* and *Morbillivirus*, of the subfamily *Paramyxovirinae* in the family *Paramyxoviridae*. Some other species found in the *Rubulavirus* are

General Features

Gérard Orth, Unité des Papillomavirus, INSERM U. 190, Institut Pasteur, Paris, France

History

The recognition of different clinical types of warts and the suspicion of the venereal transmission of anogenital warts date from as early as the Greco-Roman times. The infectious nature of warts was substantiated in the 1890s. Skin wart transmission to humans by cell-free wart extracts demonstrated their viral etiology (Ciuffo, 1907). Rabbit skin papillomas and derived carcinomas induced by the cottontail rabbit papillomavirus (Shope, 1933) provided the first model of viral carcinogenesis in mammals. This led to such concepts as virus masking in tumors and synergy between viruses and chemical carcinogens in the development of cancers. The study of papillomaviruses has been hampered by the lack of tissue culture systems allowing their propagation. It has long been admitted that all types of warts in humans are due to a single papillomavirus, the human wart virus, and that differences in wart morphology and clinical evolution are determined by local conditions. The plurality of human papillomavirus (HPV) was demonstrated in the late 1970s, as a consequence of advances in DNA technology. It was proposed then that the diversity of papillomavirus-associated lesions reflected distinct biological properties of the different HPV types. The first evidence for the role of HPVs in human cancer was provided by the specific association of HPV type 5 (HPV5) with the skin cancers of epidermodysplasia verruciformis (EV), a rare genetic disease. In the mid-1970s, koilocytes in cervicovaginal smears had been recognized as HPV-infected cells, revealing the frequent HPV infection of sexually active women. The frequent association of morphologic signs of infection and features of cervical dysplasia suggested a role of HPV in the carcinogenesis of the uterine cervix. Specific HPV types (HPV16, HPV18) were found associated with invasive cervical cancer in the early 1980s. More than 100 HPV genotypes have been identified, so far. The high prevalence of sexually transmitted genital HPV infections and the central role played by some HPV types in the development of cervical carcinoma, the second most common cancer in women worldwide, explain the present wide interest in these viruses.

Taxonomy and Classification

Papillomaviruses constitute a genus of the *Papovaviridae* family. They are characterized by a naked icosahedral capsid of 55 nm diameter, composed of 72 pentameric capsomeres (**Fig. 1**). Their genome is a double-stranded, covalently closed, circular DNA molecule of 7500–8000 bp. The genetic information is located on one DNA strand and consists of at least eight open reading frames (ORFs). The viral genome is divided into three parts: (1) a noncoding region, the long regulatory region (LRR) (7–11% of the genome length); (2) the early (E) region (about 50% of the genome length) which encodes proteins capable of interacting with cellular proteins negatively regulating cell division (E6, E7, E5), and proteins involved in the replication and transcription regulation of the viral genome (E1, E2) or expressed late in the viral cycle (E4); and (3) the late (L) region which encodes

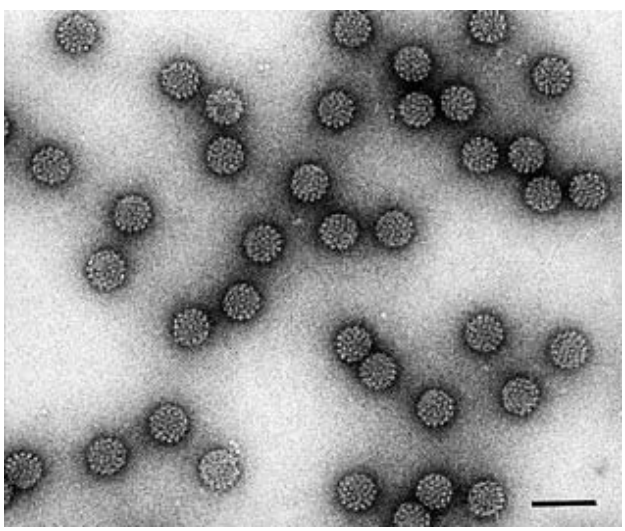

Figure 1 Human papillomavirus type 1 particles purified from plantar warts. Bar = 100 nm.

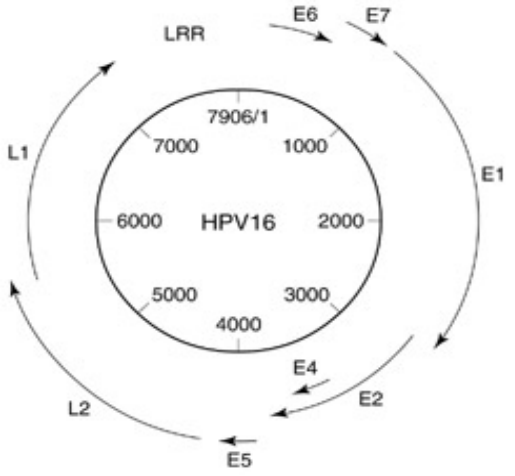

Figure 2 Genetic map of HPV16.

the capsid proteins, the major L1 protein constituting the capsomeres and the minor L2 protein (**Fig. 2**).

HPVs are classified into genotypes. Types were first defined on the basis of a crosshybridization between viral genomes less than 50%, in the most stringent hybridization conditions. According to an almost equivalent recent definition, genotypes should share less than 90% identical nucleotides in the L1 ORF. HPV isolates sharing a DNA sequence identity in the range of 90–98% correspond to subtypes, while isolates with more than 98% DNA sequence identity are considered as variants. Genotypes are designated by a number and subtypes by a letter, following the chronological order of their characterization. To date, at least 80 HPV genotypes have been cloned and the complete nucleotide sequence is available for almost all of them. The most distantly related HPV1 and HPV41 and the closely related HPV6 and HPV11 display 47% and 82% identical nucleotides, respectively.

DNA heteroduplex analysis and sequence comparison have revealed the existence of conserved regions between the viral genomes, mainly localized in the 3′ part of the E1 ORF and in the L1 ORF. These conserved sequences have allowed the design of consensus or degenerate primers for the detection of a broad range of HPV DNA sequences in cutaneous and genital lesions, using polymerase chain reaction (PCR) techniques. By sequencing the PCR amplification products, more than 50 putative novel HPV types have been identified. This indicates that the total number of HPV genotypes largely exceeds 100.

Geographic and Seasonal Distribution

HPV infections have a worldwide distribution, as illustrated by skin warts and genital warts, their well-known clinical manifestations. All around the world, HPV5 and HPV16 are the types most frequently associated with EV skin cancers and cervical carcinomas, respectively. Differences in geographic distribution have been noted for some HPV types. A higher prevalence of cervical cancer associated with HPV45 has been reported in Africa, and with HPV52 or HPV58 in China and Japan. HPV13 and HPV32 cause an oral disease mostly restricted to Central and South America, Alaska and Greenland.

Host Range and Virus Propagation

HPVs are highly host specific and humans are not susceptible to infection by animal papillomaviruses. It has been shown, however, that papillomaviruses bind a widely expressed and evolutionarily conserved cell surface receptor. HPV capsids agglutinate mouse erythrocytes and oncogenic genital HPVs are capable of transforming established rodent cell lines. Routine propagation of HPVs *in vitro* has not yet been achieved. A major reason for this is that HPVs are strictly epitheliotropic and replicate exclusively in terminally differentiating keratinocytes of the benign and premalignant lesions they induce. Upon grafting under the renal capsule of athymic mice, human foreskin chips infected *in vitro* with a particular strain of HPV11 form condylomatous cysts that produce large amounts of infectious virus. Progress in the ability to express late papillomavirus functions *in vitro* has recently been achieved by using keratinocyte cultures on collagen rafts at an air–liquid interface, that is in conditions that allow terminal differentiation of keratinocytes. Viral particles were produced from condyloma explants containing the HPV11 Hershey strain or from a keratinocyte line derived from a cervical intraepithelial neoplasia that harbored episomal HPV31 DNA. Oncogenic genital HPV types 16, 18, 31 and 33 are capable of immortalizing human keratinocytes. In such cell lines, the viral genome is integrated into the cell genome, an event that is not part of the virus life cycle and precludes virus multiplication. It has been shown recently, however, that cell lines harboring viral episomes could be obtained by transfecting cloned HPV18 or HPV31 DNA together with a drug resistance marker into primary keratinocyte cultures, and that viral particles were produced by growing these cells in raft cultures.

Genetics

Nucleotide sequence variability in the LRR and the E6, E7, L1 and L2 ORFs has been studied extensively for the oncogenic HPV5 associated with EV, for HPV

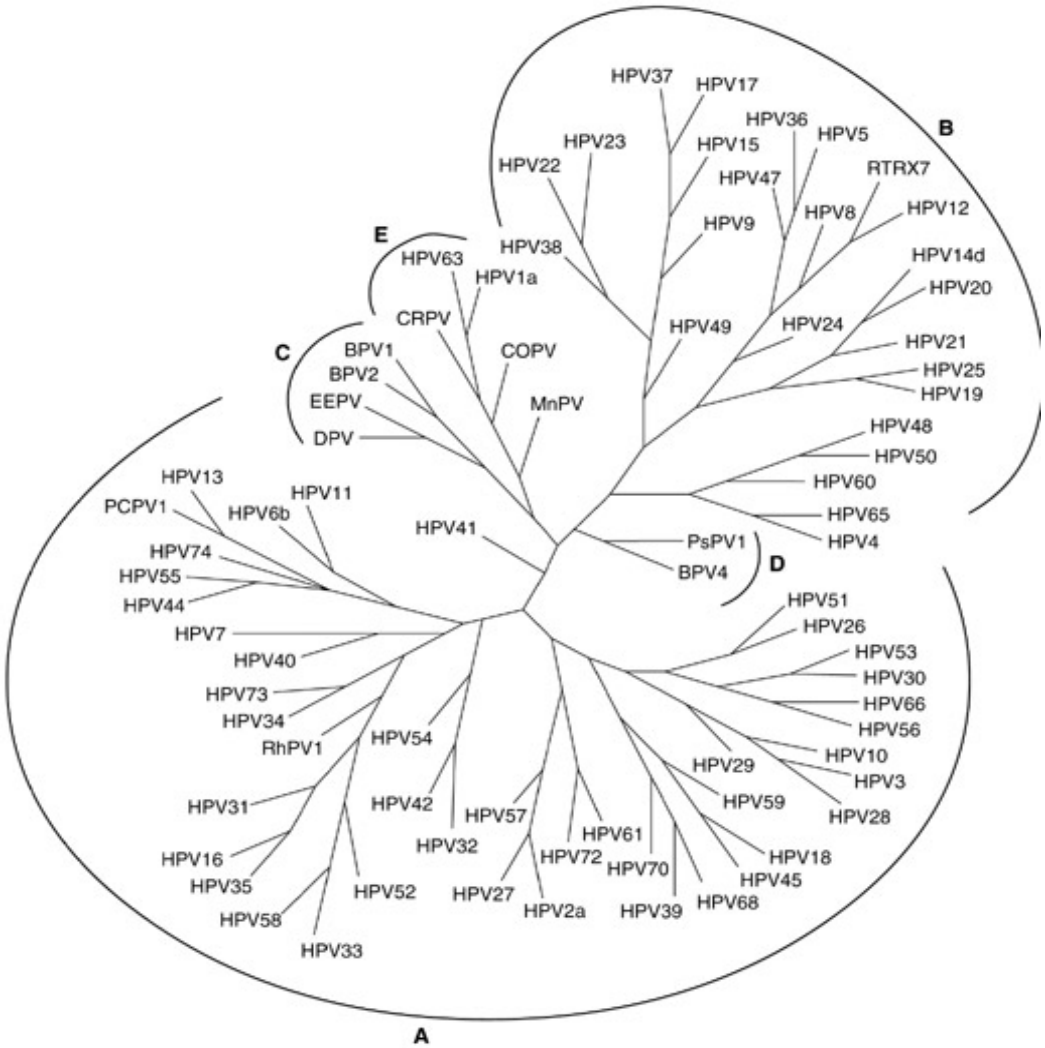

Figure 3 Phylogenetic tree of human and animal papillomaviruses based on the amino acid sequence of the L1 protein. (Adapted from Chan SY, Delius H, Halpan AL and Bernard HU (1995) *J. Virol* **69**: 3074.)

types 6 and 11 associated with condylomata acuminata, and for HPV types 16, 18 and 45 associated with genital cancers. For genital HPVs, the intratype variability does not exceed 2% in the coding region and 5% in the LRR. In contrast, an unusually high degree (about 10%) of intratypic variability has been observed in the LRR and the E6 and L1 genes of HPV5, leading to the identification of three HPV5 subtypes. To what extent this genetic variability affects the biological properties of the viral proteins is still poorly understood. HPV6 variants with short sequence duplications in the regulatory region and HPV5 variants with large deletions within the genes encoding capsid proteins have been identified in Buschke–Loewenstein tumors and EV carcinomas, respectively. It is not known whether such rearrangements play a role in tumor progression.

It has to be stressed that, despite their amazing multiplicity, HPV types, subtypes and variants are stable entities, most probably because HPVs use the cellular machinery for replicating their genome. Furthermore, there is no evidence for inter- or intratypic recombinations.

Evolution

Computer analysis of the sequences of the E6 and L1 genes has distributed the human and animal papillomaviruses into five phylogenetic supergroups and in groups that reflect tissue tropism and pathogenicity (**Fig. 3**). HPVs are distributed into supergroups A, B and E. Supergroup A contains mucosotropic potentially oncogenic genotypes (HPV types 16, 18, 31, 33, etc.) or nononcogenic genotypes (HPV types 6, 11, etc.) and some cutaneous types occasionally infecting mucous membranes (HPV types 2, 3, 7, 10, 28, 57,

etc.). Supergroup B contains 20 HPV genotypes specifically associated with EV, as well as a few other skin genotypes (HPV types 4, 48, 50, 60 and 65), while supergroup E comprises only cutaneous HPV types (HPV types 1 and 63). Phylogenetic grouping of HPV16 DNA variants has allowed identification of African, European, Asian and Asian-American lineages. The greater genetic heterogeneity of African isolates has led to speculation that HPV16 emerged in Africa 200 000 years ago and coevolved with the human races.

Serologic Relationships and Variability

Genital lesions usually contain very low amounts of virions, and purified particles are only available for some cutaneous HPV types (mostly HPV1 from plantar warts) and for the HPV11 Hershey strain. A limitation in the use of bacterial fusion capsid proteins and synthetic peptides as antigens is that only linear epitopes are presented, whereas natural human antibodies and hyperimmune antisera obtained with virions are mostly directed against native conformational epitopes. When produced in various eucaryotic expression systems, the L1 protein is able to self-assemble into virus-like particles (VLPs), with a morphology similar to that of virions. When L2 is coexpressed with L1, it is stably incorporated into the capsids. HPV16 L1/L2 VLPs produced in cells that maintain bovine papillomavirus (BPV) type 1 genome as high copy autonomous replicons are able to incorporate viral DNA. These HPV16 virion pseudotypes are able to transform murine C127 cells, thus providing a means of analyzing antigenic determinants and neutralizing epitopes.

Early studies on cutaneous HPV types 1–5 led to the identification of type-specific and group-specific (type-common) antigens. Monoclonal antibodies raised against VLPs have allowed the identification of both conformational, usually type-specific epitopes, and surface or cryptic linear epitopes that show various levels of cross-reactivity when analyzed by an ELISA test using intact or denatured VLPs.

When the serological relatedness of genital HPV types 6, 11, 16, 18, 31, 33 and 45 was assessed using rabbit antisera and L1/L2 VLPs in a hemagglutination inhibition test, only the closely related HPV types 6 and 11 or HPV types 18 and 45 (more than 85% L1 amino acid identity) exhibited detectable cross-reactions. However, HPV6 and HPV11 were found to have antigenically distinct, strongly immunogenic, conformationally dependent neutralizing epitopes in an athymic mouse xenograft infectivity assay. So far, the existence of distinct serotypes of the different genital HPV genotypes has not been reported but it has been shown that L1 VLPs of the three HPV5 subtypes have distinct antigenic properties.

Type-common epitopes are masked in intact particles. They are detected in sections of formalin-fixed lesions, using antisera raised against disrupted particles of HPV1 or BPV1 or against L1 fusion proteins. Such antibodies are not usually detected in human sera. Type-common epitopes have been mapped to the middle part of the L1 protein, which contains an amino acid sequence remarkably conserved among papillomaviruses.

Epidemiology

It has long been known that HPV infections are widespread from the high prevalence of skin warts among schoolchildren and young adults (about 10%) and among immunosuppressed patients. Epidemiologic studies have proven difficult because of the multiplicity of HPV types and the late recognition of many of them, and because of methodologic problems. HPV detection methods currently used for research purposes can be classified into HPV DNA test methods without amplification (Southern blot hybridization), signal-amplified hybridization assays (hybrid capture test) and DNA amplification methods (PCR-based assays). The PCR-based tests are the more sensitive, allowing the detection of as little as 10–100 viral DNA molecules, and provide a means to screen for the whole spectrum of HPV infections (from latent or inapparent infections to clinical manifestations). Sequencing PCR products allows the identification of HPV DNA variants. Degenerate MY09/MY11 or general $GP5^+/GP6^+$ L1 primer PCR-based tests and the liquid RNA-DNA hybridization hybrid capture test are presently the most widely used methods for epidemiological studies on genital HPV infections. Depending on the probes used to detect PCR products, PCR-based assays allow the detection of a whole broad range of genotypes or of subgroups comprising low-risk or high-risk (cervical cancer-associated) HPV genotypes, or the identification of specific genotypes. The hybrid capture test allows the chemiluminescent detection of low-risk or high-risk HPVs, using two probe cocktails. The seroepidemiological approach is only of recent use and is based on ELISA using L1 or L1/L2 VLPs.

Prevalence studies indicate that genital HPV infections are very common in sexually active young women, and that most of these infections are asymptomatic and transient. HPV DNA has been detected in cervical cell samples from about one-third of normal women in their teens and early twenties, and at tenfold lower rates in women over 50 years. Cytologic signs of overt infection, including koilocy-

totic atypia, are observed in cervicovaginal smears at tenfold lower rates, with the same age dependence. Only a minority of women exposed to genital HPVs will show persistent infection, and only some of these will develop high-grade cervical intraepithelial neoplasia, the immediate precursor of invasive carcinoma. The incidence of genital HPV infections appears to be similar for men and women. Sexual behavior, particularly multiple sex partners, is the major risk factor for HPV infection.

That immune factors play an important role in the control of HPV infections is shown by the high incidence of cutaneous and genital warts and of anogenital intraepithelial neoplasia among patients with genetic (Wiskott–Aldrich syndrome), iatrogenic (allograft recipients) or acquired (AIDS) cell-mediated immune deficiencies. Cervical HPV DNA detection is two- to fourfold more frequent in women infected with human immunodeficiency virus (HIV). Similarly, homosexual male AIDS patients have a high prevalence of anal HPV infection (about 50%). Genetic factors are prominently involved in two HPV-associated diseases affecting the oral mucosa and the skin. Oral focal epithelial hyperplasia, associated with HPV 13 and 32, is highly prevalent in American Indians and Eskimoes but rarely observed in Caucasians. EV is a genetically conditioned abnormal susceptibility to infection by a group of specific related HPV types and to the oncogenic potential of some of them, mostly HPV5. The reservoir of EV HPVs has long been searched for. By using highly sensitive PCR methods, most of these viruses and uncharacterized EV HPV-related types were detected in plucked hairs of about half of healthy volunteers and over 90% of immunosuppressed renal transplant recipients, pointing to the occurrence of widespread latent infections. As for HPV5, it has been shown recently that patients suffering from psoriasis are likely to constitute the reservoir of this oncogenic EV HPV.

The specific association of HPV7 with warts found in butchers and meat handlers remains to be explained.

Transmission and Tissue Tropism

HPVs are very stable viruses which are released from the desquamating superficial keratinocytes of the infected squamous stratified epithelia. Some HPVs infect the epidermis, while others infect the epithelia of the anogenital and oral mucous membranes. A major target for oncogenic genital HPVs is the transformation zone, at the squamocolumnar junction of the uterine cervix, where most cervical precancers and invasive cancers originate. Simple

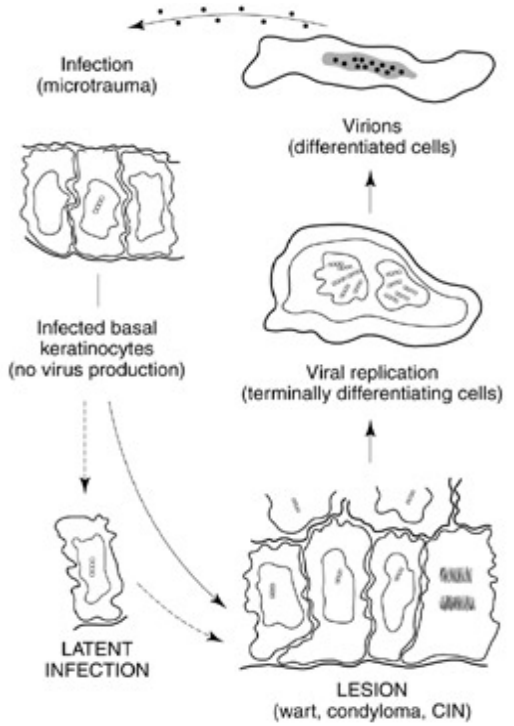

Figure 4 Life cycle of HPVs in keratinocytes.

epithelial cells or reserve cells of the endocervical glandular epithelium are likely to be susceptible to nonproductive HPV infection, which may result in the development of *in situ* or invasive adenocarcinomas. Esophageal, laryngeal, tracheobronchial, nasal, conjunctival and urinary epithelia are uncommon sites of infection with the known HPV types.

Transmission of cutaneous HPVs occurs through direct contact with an infected tissue or through indirect contact with contaminated objects or surfaces (swimming pools). Genital HPVs are sexually transmitted, as shown by partner tracing and epidemiologic studies. Transmission of HPV6 and 11 by passage through an infected birth canal is probably at the origin of laryngeal papillomatosis of young children. *In utero* infection with genital or EV-specific HPVs has been recently considered. Indirect transmission of genital HPVs may occur through contaminated fomites or instruments and by laser plumes.

The first stage of the HPV life cycle is the infection of basal keratinocytes, through minor abrasions (**Fig. 4**). The $\alpha 6$ integrin has been identified as a candidate receptor. Virus entry may result in a latent infection or in the development, within 1–3 months, of a lesion likely to result from the clonal expansion of infected cells. This proliferation is associated with the persistence of episomal viral genomes at low copy number and with the expression of the E1, E2, E5, E6 and E7 viral genes. Vegetative viral DNA replication

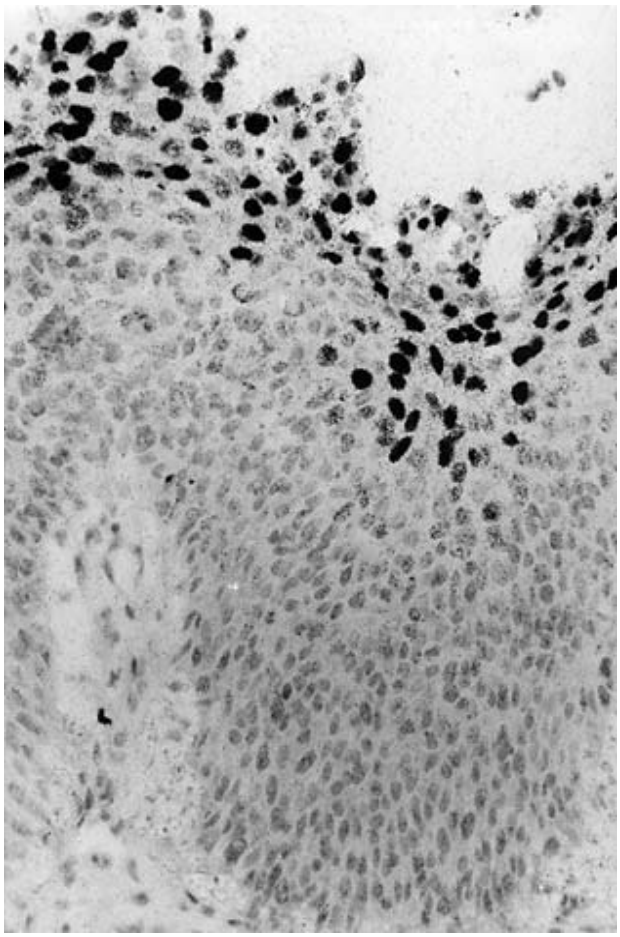

Figure 5 Vegetative replication of HPV16 DNA in the nuclei of superficial cells of a high-grade cervical intraepithelial neoplasia, as detected by *in situ* hybridization.

involving the sustained expression of early viral genes, expression of the E4 nonstructural protein, synthesis of L1 and L2 capsid proteins, and viral particle assembly take place successively in terminally differentiating host cells as they migrate towards the most superficial layers of the lesions (**Fig. 5**).

Pathogenicity

The spectrum of HPV infections includes asymptomatic latent infections, subclinical infections, and various clinical manifestations. HPV genotypes differ in their target tissue and their oncogenic potential, and each of them has a specific pathogenicity. A number of HPV types induce benign, self-limiting proliferations of the skin or the mucous membranes (**Table 1**). Such lesions usually regress, spontaneously or after treatment. Different clinical types of skin warts have been identified, and there is a strong preferential association between a particular HPV type and a clinical type of wart. For instance, myrmecia warts are associated with HPV1, common warts mostly with HPV2 and related types or, in meat handlers, with HPV7, and flat warts with HPV3 and related types. Anogenital warts are usually caused by HPV types 6 and 11. Although these two viruses are found associated with the rare anogenital Buschke–Loewenstein tumors and single cases of carcinoma of the respiratory tract, they are among those genotypes that are associated with low-grade cervical disease and never detected in invasive cervical carcinoma. They are considered as low-risk viruses.

Other HPV types are associated with the development of invasive carcinomas (**Table 1**) and are considered as high-risk viruses. The first example has been provided by the squamous cell carcinomas (SCCs) of the skin observed in about 50% of EV patients. Contrasting with the many HPV types associated with EV benign lesions, only a few of them (mostly HPV5) are found in EV SCCs. Viral genomes are maintained as episomes and transcripts of the E6 and E7 genes are easily detected. The role of HPVs in the etiology of nonmelanoma skin cancers in non-EV patients is still a matter of speculation. If one excepts periungual SCCs, HPV DNA sequences are only rarely detected by Southern blot hybridization in premalignant lesions (actinic keratoses, Bowen's disease) and in basal cell carcinomas (BCCs) and SCCs of the skin from immunosuppressed or immunocompetent patients. The detection limit of this technique is about 0.2 copy of the viral genome per tumor cell, which corresponds to the size of a subgenomic fragment encompassing the LRR and E6 and E7 genes (**Fig. 2**). By using single-step or nested PCR methods and various sets of degenerate primers, numerous known HPV types or putative novel types were detected in up to 90% of the precancerous lesions and invasive carcinomas of immunosuppressed renal allograft recipients and in about one-third of the specimens from immunocompetent patients. Results indicate that EV HPVs and related putative types are the most prevalent, that HPV5 is seldom detected, and that more than one genotype is found in about one-third of the specimens. There are no data available yet on the expression of the viral sequences. It remains to be determined whether PCR detection of HPV sequences identifies passenger viruses or etiologic agents that could act synergistically with ultraviolet radiation, the major known risk factor for skin cancer.

It is now well established that specific, sexually transmitted HPV types play a central role in anogenital carcinogenesis, especially in invasive carcinoma of the uterine cervix, on the basis of virologic, epidemiologic and experimental data. Cervical carcinoma is a progressive disease that begins with a

noninvasive intraepithelial lesion, designated as squamous intraepithelial lesion (SIL) or cervical intraepithelial neoplasia (CIN). Most low-grade intraepithelial lesions regress; some remain unchanged; 10–15% will progress into high-grade CIN (moderate or severe dysplasia; carcinoma *in situ*). A proportion of high-grade CIN may arise *de novo*. High-grade CIN may evolve into invasive cancer after years or decades. More than 40 known HPV genotypes or putative novel types have been found associated with up to 90% of low-grade CIN. Only some of these HPVs are detected in high-grade CIN and invasive carcinoma. Twelve genotypes were identified in a large worldwide survey of cervical cancers in which 93% of the specimens were found to be HPV positive by a PCR method. HPV16, found in 50% of the cases, HPV18 and HPV45 were the most prevalent and the other genotypes (HPV types 31, 33, 35, 39, 52, 56, 58, 59 and 68) accounted for 1–5% of positive cases. As a rule, HPV16 predominates in SCCs and HPV18 in adenocarcinomas. That HPV was the long sought sexually transmitted infectious cause of cervical neoplasia has been shown by recent epidemiologic studies. Key risk factors for cervical neoplasia (multiple sexual partners, early age at first coitus, etc) were found to be strongly associated with HPV infection. Case–control studies have demonstrated a strong association between the detection of high-risk HPV DNA and high-grade CIN and invasive cervical cancer, with odds ratios usually ranging from 20 to 75. Cohort studies have shown that the risk for progression of a low-grade lesion into a high-grade CIN is closely linked to persistent infection with high-risk HPV types. Experimental studies also strongly suggest that high-risk HPVs play a part in the whole process of cervical carcinogenesis. They point to the central role of the E6 and E7 viral oncoproteins. The E6 and E7 proteins complex and inactivate cellular proteins, such as p53 protein (E6) and pRB protein (E7), that are involved in the negative regulation of the cell cycle and in the control of the cell genome integrity. The development of cervical cancer is a multistep process that remains little understood.

Both immunologic and genetic factors are likely to play a prominent role in the persistence and progression of CIN. Cervical intraepithelial lesions are more frequent and of higher grade, persist at higher rates, and progress more rapidly in HIV-infected women. An immunogenetic control of cervical neoplasia has been suggested by the positive or negative associations of CIN and/or invasive carcinoma with certain HLA class II alleles or haplotypes, some of them showing HPV type-specificity. Among the other factors which may affect the risk of persistence and progression of CIN are hormones (pregnancy, oral contraception),

coinfections (herpes virus, chlamydia), smoking and dietary factors.

Oncogenic genital HPV types, mostly HPV16, are also found in lesions with features of intraepithelial neoplasia (Bowenoid papules, Bowen's disease) and in invasive SCCs of the vulva, penis and anal region. HPV16 and HPV33 are also associated with a high proportion of tonsillar carcinomas. A minority of CIN and cervical carcinomas and a significant number of carcinomas of the external genitalia do not contain detectable HPV sequences and may not be etiologically related to HPV infection. As for HPV sequences detected in 5–25% of carcinomas of the upper aerodigestive tract and urethra, their etiologic role is still unclear.

Clinical Features of Infection

Warts occur predominantly in children over 5 years and in young adults. At least two-thirds of the warts regress spontaneously within 2 years. Palmoplantar myrmecia warts are deep and painful. Common warts are exophytic, hyperkeratotic and located mainly on the hands, fingers and knees. Flat warts are usually multiple, slightly raised, with a flat and smooth surface and are localized mainly on the hands and face. EV is a lifelong disease, characterized by disseminated cutaneous flat wart-like lesions and macules. It may have an autosomal recessive mode of inheritance. Most patients with EV have an impaired cell-mediated immunity. Some benign lesions convert to intraepithelial neoplasia (actinic keratosis, Bowen's disease) and invasive carcinoma in about half of the patients, usually on light-exposed areas, about 20 years after the onset of the disease.

Genital HPV-associated lesions represent the most commonly diagnosed viral sexually transmitted disease. Condylomata acuminata and Bowenoid papules are found mostly in young adults, on the external genitalia and in the anal region. Condylomata acuminata are soft exophytic proliferations, Bowenoid papules are flat or somewhat elevated, often pigmented, usually multiple. In spite of their usual association with HPV16 and their features of intraepithelial neoplasia, they have a rather benign clinical course, in contrast to solitary lesions of genital Bowen's disease affecting individuals over 50 years. Subclinical macules or papules can be detected on the penis and vulva under magnification, after the application of 5% acetic acid. Anal lesions with a variety of morphological appearance and with features of intraepithelial neoplasia are found at the anorectal junction in HIV-infected males. HPV infection of the cervix results mostly in flat aceto-whitening areas corresponding to low-grade CIN, including flat condyloma. Cytologic evidence of HPV infection (SIL) is found in cervicovaginal smears of 2–3% of women in mass screening programs. Infection with genital HPVs are often multiple, and associated diseases are often multicentric. They can affect the entire anogenital region and even the oral mucosa.

Oral focal epithelial hyperplasia, the only disease associated with HPV types that exclusively infect the oral mucosa, is found in children and adults. It is characterized by multiple elevated papules which never undergo malignant transformation. Laryngeal papillomatosis is a rare recurrent disease that can occur at any age. The most frequent site affected is the vocal cords. Trachea, lung, oral and nasal cavities can also be involved. Respiratory papillomatosis may be life-threatening by obstructing airways but rarely progresses to cancer.

Pathology and Histopathology

Benign HPV-induced lesions are characterized by variable degrees of hyperplasia of the different epithelial layers (acanthosis, hyperkeratosis), parakeratosis (retention of nuclei in differentiated superficial cells) and papillomatosis (hypertrophy of dermal papillae). Some features may reflect distinct biological properties of the different HPV types. For instance, the growth pattern is endophytic for HPV types 1 or 4 and exophytic for HPV types 2, 6, 7 or 11. The extent of papillomatosis is prominent for HPV types 1, 2, 4, 6, 7 or 11, much less pronounced for HPV types 3 or 10, and often absent for EV HPVs.

Anogenital lesions with features of intraepithelial neoplasia (IN) are characterized by a disorganized architecture of the squamous epithelium, abnormal mitotic figures and nuclear atypia. Abnormalities restricted to the lower third of the epithelium and well-preserved maturation define low-grade IN (also named mild dysplasia or IN grade I). High-grade IN includes lesions with abnormalities up to two-thirds of the epithelium (moderate dysplasia, IN grade II) or the whole epithelium (severe dysplasia and carcinoma *in situ*, IN grade III). The Bethesda System nomenclature for the evaluation of cervicovaginal smears (Pap smears) has introduced low-grade SIL, which covers CIN I and condyloma, and high-grade SIL, which covers CIN II and CIN III. Features specific to Bowen's disease, especially dyskeratotic cells (individual cell keratinization), are observed in Bowenoid papules and EV lesions undergoing malignant conversion.

HPV replication interferes with the terminal differentiation of the host cells and provokes a cytopathic effect which can manifest in various forms, such as the accumulation of cytoplasmic inclusions

pathognomonic of HPV1-induced myrmecia (containing the E4 viral protein) or the perinuclear cavity that characterizes the koilocytotic cells of genital warts and CIN.

Immune Reponse

The immunobiology of HPV infections is far from being fully understood. Strong immune responses are not usually generated because HPVs most often induce latent infection or chronic disease, and productive infection does not lead to host-cell lysis. A major problem has been the unavailability of native HPV antigens, adequate target cell systems and well-characterized assays.

In natural infection, humoral responses are essentially directed against conformational epitopes borne by intact viral particles. Low levels of antibodies reacting against HPV1 virions are found in patients with skin warts or in nonselected individuals, with a frequency that varies from 10% to 100%, according to the method used, the age group and the type of warts. Antibodies neutralizing HPV11 infectivity assayed in the nude mouse xenograft system have been detected in patients with genital warts or laryngeal papillomas. Owing to the availability of VLPs and the design of sensitive VLP-based ELISA tests, the evaluation of serological responses to HPV infection has recently entered a new era. When using HPV6 or HPV11 L1 VLPs, IgG antibodies have been found in about half of the patients with genital warts. IgG and IgA humoral responses to HPV16 L1/L2 VLPs have been detected in 50–75% of women with HPV16-associated CIN. Antibodies are found in 15–25% of women showing no current signs of HPV infection, probably revealing past infections. Seropositivity to HPV16 L1/L2 VLPs has been shown to be a suitable marker of sexual behavior and a relatively sensitive indicator of persisting cervical HPV16 infection. Antibodies to native HPV16 E6 or E7 oncoproteins are rarely detected in patients with premalignant cervical lesions and are found in about 50% of patients with late-stage invasive HPV16-associated cervical carcinomas. They constitute virus type- and cancer-specific markers but have no prognostic value.

It is most likely that cell-mediated immunity (CMI) plays a major role in the control of HPV infections. A high incidence of cutaneous and anogenital HPV-associated diseases is observed among patients with genetic, acquired or iatrogenic CMI deficiencies. Infiltrates of CD4+ helper and CD8+ cytotoxic T lymphocytes and macrophages are observed in regressing flat warts, genital warts and CIN. This suggests that cytotoxic T lymphocyte (CTL) responses and delayed-type hypersensitivity reactions are important in the regression of HPV-induced lesions. Nonstructural viral proteins are likely to be targets. Helper T lymphocyte and CTL responses against HPV16 E6 and E7 oncoproteins have been demonstrated in murine models. Several HLA-restricted CTL and helper T cell epitopes have been identified in HPV16 E6 and E7 proteins. Occasional memory cytotoxic T cell responses against an HPV16 E7 encoded epitope have been demonstrated in patients with CIN or invasive carcinoma. There is some evidence for a shift from type 1 (IL-2, IFNγ) to type 2 (IL-4, IL-10) cytokine production by helper T cells in patients with extensive genital intraepithelial disease or with invasive cervical carcinoma. Natural killer cells are also likely to be involved in the immunologic surveillance of HPV-associated disease.

HPV-harboring keratinocytes may modify immune responses by secreting various cytokines which could influence local immune responses. Moreover, an altered expression of HLA class I and class II antigens has been observed in a substantial proportion of CIN and cervical carcinomas. Downregulation of HLA class I antigens may provide tumor cells with a means of evading immune surveillance by altering the interaction with cytotoxic CD8+ lymphocytes. Upregulation of HLA class II molecules may turn keratinocytes into nonprofessional antigen-presenting cells which may result in T cell anergy.

Prevention and Control

Education on prevention of sexually transmitted diseases should include appropriate information on HPV infections. Behavior likely to prevent infection (use of condoms, partner examination) should be promoted and the potential consequences of HPV infections should be monitored (routine cervicovaginal smears).

There is at present no vaccine available to prevent HPV infections. The two strategies would be to induce either neutralizing antibodies to prevent virus infection or CMI responses against viral proteins to eliminate HPV harboring keratinocytes. A virus type-specific protection against challenge has been obtained in different animal models (rabbit, cattle, dog) by vaccination with L1 or L1/L2 VLPs. Vaccination against nonstructural proteins has not been found protective but an enhanced rate of regression has been observed in rabbits immunized against the E1, E2 or E6 proteins of the cottontail rabbit papillomavirus and in cattle vaccinated against the E7 or L2 proteins of bovine papillomavirus type 4, indicating that this approach could be used for therapeutic purposes. To date, phase I/II trials of prophylactic HPV vaccines

are currently ongoing or planned. They are based on HPV11 or HPV16 L1 VLPs and on chimeric HPV16 VLPs consisting of the L1 protein plus the E7 protein fused to the L2 protein or constructed by replacing the C-terminal end of the L1 protein by parts of the E7 protein. Therapeutic vaccines are aimed at inducing CTL responses and are based on the use of recombinant vaccinia viruses expressing the HPV16 and HPV18 E6 and E7 proteins, defined HPV16 E6 and E7 peptides or a HPV6 L2-E7 fusion protein. Clinical trials are currently underway to test these vaccines in patients with recurrent late-stage invasive cervical cancer or, as an adjuvant to surgery and radiation therapy, in patients with early-stage cervical cancer, in young women with preinvasive genital disease or in patients with genital warts.

Reliable detection tests of oncogenic genital HPV genotypes have been progressively designed. Ongoing multicentric studies, involving large series of women, are aimed at evaluating their sensitivity, specificity, predictive values and cost-effectiveness in the clinical management of patients or in screening programs.

Since there are no specific anti-HPV therapeutic agents, treatment modalities are mostly aimed at destructing or removing lesions. Conventional treatments involve topical application of caustic agents (salicylic acid, trichloracetic acid, podophyllin), physical destruction (cryotherapy, electrocautery, laser vaporization), surgical removal (including cervical conization) or chemotherapeutic agents (5-fluorouracil, podophyllotoxin). Immune response modifiers could be of value. Interferon has been used successfully for refractory genital warts and, less successfully, in association with surgery, to prevent recurrence of laryngeal papillomatosis.

Future Perspectives

Progress might be expected in the understanding of the intracellular and immunologic mechanisms that control the transition from latent infection to clinically overt infection, the evolution towards regression, and the progression of persistent intraepithelial lesions towards malignancy. Allelic polymorphism or mutations in the genes involved should contribute to the identification of individuals at risk for HPV-associated cancers.

The etiological role of HPVs in cervical cancer should result in new approaches for the early diagnosis and prevention of precursor lesions. An important goal is to determine the proportion of CIN and cervical carcinomas which may be unrelated to HPV infection. It can be anticipated that the association of HPV detection tests to cervicovaginal cytology will permit an increase in the detection rate of high-grade CIN and constitute a means for the adequate management of women with minor cytologic abnormalities. It is also likely that immunoprevention and immunotherapy of HPV-induced genital lesions will be available in the near future. Progress is also expected in the design of therapeutic agents that specifically interfere with viral DNA replication and transcription or with the interactions involving virus-encoded proteins. All these strategies should contribute to the control of invasive carcinoma of the uterine cervix, a major worldwide disease.

Another important achievement will be to understand the biological significance of the frequent PCR detection of HPV DNA sequences in premalignant or malignant tumors at nongenital sites, such as the skin, or in other diseases, such as psoriasis. This may lead to a broadening of the spectrum of HPV-associated diseases.

Basic Description

Human papillomaviruses (HPVs) infect epithelial cells lining the skin and/or genitalia. Infection leads to the formation of warts, or papillomas. The viral life cycle takes place within these warts and is tied to the differentiation of the infected host epithelial cells. Warts are self-contained benign tumors that by and large do not progress to frank malignancy. A subset of the HPVs that infect the anogenital tract, however, are also associated with malignant tumors, specifically cervical cancer in women and penile cancers in men. This entry describes the basic molecular biology of HPVs, their life cycle, and their contribution to human cancer. General features of HPVs are described in the preceding entry.

Genomic Organization

Papillomaviruses contain a double-stranded circular DNA genome of approximately 8000 bp. Many HPV genomes have been cloned and sequenced; the overall genomic organization among these HPVs is very similar. Ten translational open reading frames (ORFs) are found present among all HPV genomes sequenced. These ORFs are located on a single DNA strand and their relative position is highly conserved among human and animal papillomaviruses. The papillomaviral genome has been divided into three regions, the long control region (LCR), and the early (E) and late (L) coding regions (**Fig. 1**). This division was originally based on the biological properties of bovine papillomavirus type 1 (BPV-1). The LCR contains regulatory sequences that act in *cis* to control the transcription of viral genes and the replication of the viral DNA genome. The early region contains eight ORFs (E1–E8) and was originally defined as the coding portion of BPV-1 that is sufficient to transform rodent cells in tissue culture. The early region is now recognized to contain all of the viral genes expressed in the early 'nonproductive' phase of the viral life cycle (see below). These genes contribute to the regulation of viral transcription and viral DNA replication, and affect the growth of host cells. The late region contains two ORFs which encode the two structural proteins (L1 and L2) that constitute the viral capsid. The late genes are expressed selectively in the late or 'productive' phase of the viral life cycle. In addition there is one gene (E1^E4) residing in the 'early' region of the viral genome that actually is expressed only in the productive phase of the life cycle. By and large, the functions of the individual viral gene products are highly conserved, though apparently important differences in the function and regulation of expression of specific viral genes are seen among the different HPV genotypes.

Papillomaviral Life Cycle

The HPV life cycle is tied to the differentiation of stratified squamous epithelia (**Fig. 2**). The papillomavirus is thought to gain entry to the basal layer of the epithelium at sites of wounding, attaching to the cell via interaction with an integrin, the candidate papillomavirus cell-surface receptor. In this poorly differentiated cell the viral genome establishes itself as a low copy number nuclear episome. A subset of viral genes (the early genes) are selectively expressed at low levels; these genes contribute to the regulated expression of viral genes, viral DNA plasmid replication and cell growth. The initially infected cell is induced to proliferate at a faster rate than the neighboring, uninfected cells, resulting in its clonal expansion and thereby the formation of a papilloma. These events are collectively known as the early or nonproductive stage of the viral life cycle because the infected,

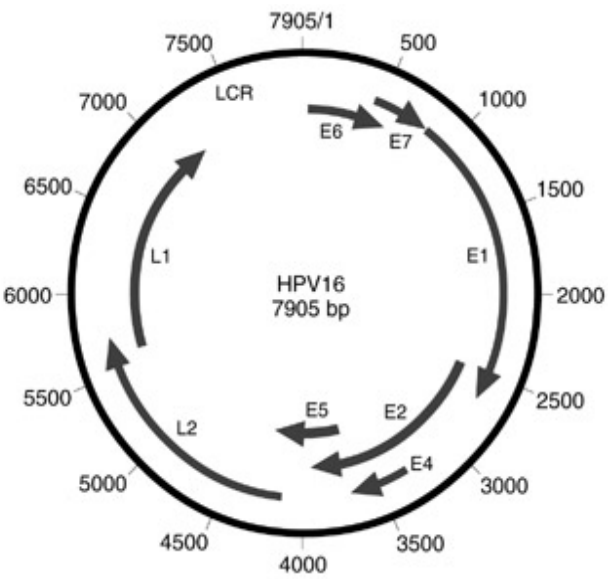

Figure 1 Genomic organization of HPV16. Shown is the circular map of HPV16 double-stranded DNA genome. Early (E) and late (L) translational ORFs are indicated (arrows). The long control region (LCR), also known as the upstream regulatory region, contains transcriptional enhancers and the viral origin of DNA replication.

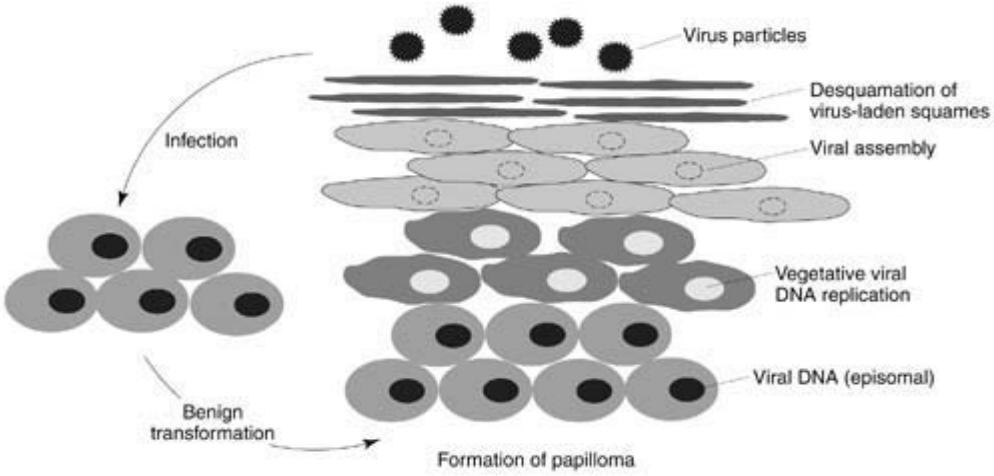

Figure 2 Life cycle of HPVs. The schematic depicts the cross-section of the infected epithelium within a papilloma. The round cells at the bottom represent undifferentiated basal epithelial cells. The flattened cell layers towards the top represent the differentiating suprabasal compartment including the spinous, granular and, most superficially, the corneal layers. Indicated at right are the different events in the viral life cycle occurring in the nonproductively infected undifferentiated and productively infected differentiated cells.

undifferentiated cell population does not produce progeny virus. Following cell division a subset of daughter cells undergo terminal differentiation, as normally occurs in stratified squamous epithelial tissues. As these infected cells progress through the terminal differentiation program, the viral DNA is amplified to high copy number and the full repertoire of viral genes, including the structural genes L1 and L2, are expressed in the spinous and granular layers of the epithelium. Viral assembly occurs in the granular layer. As the squames are sloughed off of the surface of the epithelium, progeny virus particles are released into the environment where they are then available to infect new hosts or new sites on the same host. The papillomaviral life cycle likely allows the virus to evade detection by the host immune system as the higher levels of viral gene expression and progeny virus production occur within the terminally differentiating layers of the stratified squamous epithelia where immune-surveillance is thought to be limiting.

Viral Gene Expression

HPVs have a strict tissue tropism for epithelial cells. This tropism appears to be at the level of viral gene expression. Transcription of papillomaviral genes is dependent upon epithelial specific transcriptional enhancers present in the viral LCR. The regulation of expression of HPV genes within epithelial tissue is complex. Multiple promoters direct transcription of subsets of viral genes. The activities of these promoters are differentially regulated by viral and cellular transcription factors with certain promoters (those directing transcription of early genes) active in both poorly and highly differentiated epithelial cells and others (directing expression of late genes) preferentially active in the highly differentiated cells. Transcripts are differentially spliced, giving rise to mature mRNAs with different coding capacities. These splice events can lead to the fusion of multiple ORFs, thereby generating fusion proteins. One example is the aforementioned E1^E4 gene product which arises from translation of an mRNA in which the E1 ORF is spliced in frame to the E4 ORF. Modulation of gene expression also appears to occur at the level of mRNA stability; mRNA instability elements have been identified in the 3′ untranslated region (UTR) of both the early and late transcripts.

Viral transcription is regulated by viral as well as cellular transcription factors. The viral E2 ORF encodes a family of gene products that possess transcriptional regulatory properties. The full-length E2 gene product, termed the E2 transactivator (E2TA), binds to the viral DNA genome at multiple sites that have the conserved sequence, $ACCN_6GGT$. These sites are primarily located in the LCR. Depending upon the promoter and the amount of E2TA present, binding of E2TA leads to activation or repression of transcription. Based on studies on BPV-1, E2TA-mediated activation results at least in part from the capacity of E2TA to bind cellular transcription factors TFIID and TFIIB. When present at high levels, E2TA can also repress transcription of the HPV promoter positioned directly upstream of the E6

ORF. By binding to DNA binding sites just upstream of this promoter, E2TA is thought to sterically hinder the binding of TBP and SP1 to their cognate sites positioned nearby to the promoter-proximal E2 binding sites. Additional gene products are translated from the E2 ORF through differential splicing or use of internal ATG codons. Originally identified in BPV-1, these E2 proteins act in a dominant-negative manner to inhibit transcriptional transactivation by E2TA. Because they retain the capacity to bind the same $ACCN_6GGT$ motif, they can also repress the promoter that is upstream of E6.

Multiple cellular transcription factors have been shown to bind to the HPV genome primarily within the LCR and to modulate HPV gene expression. These include positively acting (SP1, nuclear factor I (NFI), activator protein 1 (AP-1), AP-2, transcriptional enhancer factor 1 (TEF-1), TEF-2, and enhancer binding factor 1 (PEF-1)) as well as negatively acting (e.g. YY1, Oct-1, c-EBPα and CDP) transcription factors. A subset of the positively acting factors (including cell type-specific members of the NF-1 family) may confer the epithelial specificity in viral gene expression. The negatively acting factors are potentially responsible for the tight regulation of gene expression in the poorly differentiated epithelial cells within the wart, and their reduced abundance in highly differentiated cells may permit heightened expression of viral genes in the productive phase of the life cycle.

Replicative HPV Life Cycle

Papillomaviral DNA replication is dependent on the host DNA replication machinery (DNA polymerase α/primase, DNA polymerase δ/PCNA, replication protein A (RPA) and topoisomerases I and II) and viral proteins, E1 and E2TA. E1 is an ATPase-dependent DNA helicase that is thought to assemble the host DNA replication machinery on the viral genome. E1 binds the viral genome at a specific site positioned at the 3′ terminus of the LCR. E1 also binds to the host DNA polα. E2TA associates with E1 and is thought to help tether E1 to the viral genome through its ability to bind $ACCN_6GGT$ motifs located nearby to the E1 DNA binding site. In basal epithelial cells that are nonproductively infected and harbor the viral genome as a nuclear plasmid, DNA synthesis occurs through Cairns (theta) structures and initiates close to or at the DNA binding site for E1. The viral genomes replicate on average once per cell cycle. Inheritance of the viral genomes to daughter nuclei requires E2TA, which has been postulated to cause the association of viral genomes with host chromatin during mitosis.

In the productively infected epithelial cells of the wart the viral genome is amplified to high copy number for packaging into progeny virions. This amplification appears to occur through a rolling circle mode of replication which is distinct from the theta mode seen in the nonproductively infected basal epithelial cells. Whereas in theta mode of replication reinitiation is required for every round of replication, in rolling circle DNA replication, one initiation event leads to the generation of multiple daughter molecules. Thus, by switching to a rolling circle mode of replication, viral DNA amplification may be facilitated. Little is known as to how this switch in the mode of DNA replication occurs.

Whereas the poorly differentiated basal epithelial cells are mitotically active and produce the necessary factors for DNA replication, the highly differentiated suprabasal epithelial cells are no longer cycling. Thus it is expected that cellular factors necessary for DNA replication are no longer produced in the context of normal, suprabasal stratified squamous epithelia. Because the papillomavirus DNA replication depends on the availability of these factors, the virus must overcome these barriers in the differentiated cells of a wart. One way it may overcome these barriers is by the aforementioned switch in mode of DNA replication. By switching to a rolling circle mode of replication, limiting replicational machinery may be more optimally utilized. The virus may also utilize viral gene products, specifically E6 and E7, to overcome further the unfavorable environment of the highly differentiated suprabasal epithelial cell. E7 protein can bind to and inactivate the retinoblastoma tumor susceptibility locus gene product, pRb, thereby liberating the cellular transcription factor E2F to activate genes necessary for DNA synthesis, including dhfr, DNA polα, PCNA (**Fig. 3**). This activity of E7 may facilitate viral DNA replication. In some cell types, the re-engagement of differentiated cells into a DNA synthesis competent state may lead to the coincident induction of apoptosis. The viral E6 protein can inhibit this apoptosis in part through its ability to bind to and inactivate the p53 tumor suppressor gene product (**Fig. 3**). In addition, E6 may itself affect the proliferative and differentiated character of epithelial cells and thereby independently alter the DNA synthesis competence of the cell. Together E6 and E7 may create a DNA synthesis competent environment in the terminally differentiating layers of the epidermis. This putative role of E6 and E7 is in addition to their likely role in inducing the proliferation of the infected basal epithelial cells that leads to their clonal expansion and consequent formation of the papilloma; and as described below their omni-important role in the association of papillomaviruses with frank cancer.

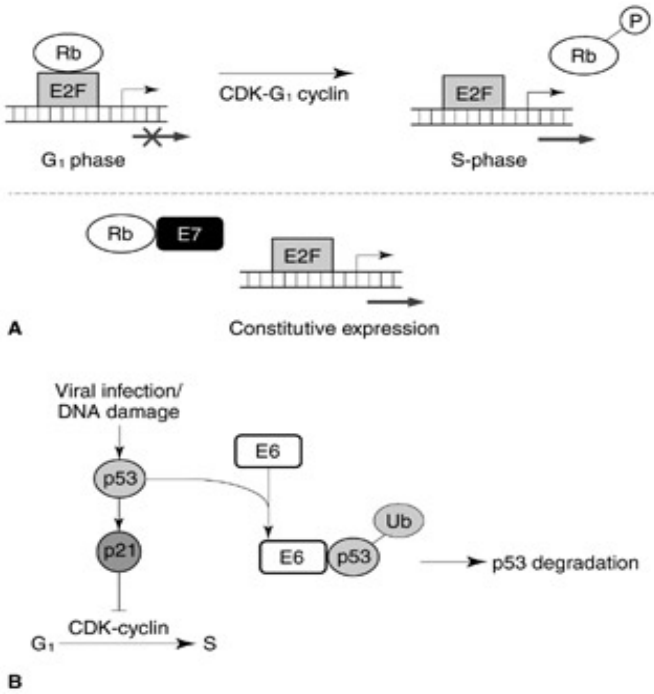

Figure 3 Interactions of high-risk HPV E6 and E7 gene products with cellular tumor suppressors. Shown are macromolecular interactions between the E7 (**A**) and E6 (**B**) gene products and specific cellular tumor suppressors. Note that both E6's interaction with p53 and E7's interaction with pRb leads to increased turnover of the tumor suppressor protein. In the case of E6, the interaction with p53 is mediated by E6-AP, a ubiquitin-ligase that causes the ubiquitination of p53 leading to p53's degradation via the ubiquitin-mediated proteolysis pathway. In the case of E7, its interaction with pRb appears direct through the pocket domain of pRb; this interaction directly interferes with pRb's interaction with E2Fs. The exact mechanism by which E7 induces the degradation of pRb is at present unknown but may involve the ubiquitin mediated pathway as well.

Virus Structure and Assembly

Papillomaviruses (PVs) are nonenveloped icosahedral viruses of about 55 nm in diameter containing the viral genome as circular double-stranded DNA associated with cellular histone proteins. The icosahedral capsids are arranged on a $T = 7$ icosahedral lattice and consist of 72 capsomers ($10T + 2$, $T = 7$), of which 60 are six-coordinated (hexavalent) $10 \times (T - 1)$) and 12 five-coordinated (pentavalent) pentameric capsomers. All capsomers have a fivefold axial symmetry suggesting that they are pentamers of the major capsid protein.

The capsid appears to be composed of 360 copies of the major capsid protein, L1, and 12 copies of the minor capsid protein, L2. The major capsid protein, L1, with a molecular weight of about 55 kDa, is the most highly conserved of the PV proteins. The overall amino acid homology reaches 50% between different PV L1 proteins. The C-terminus of the L1 protein of HPV16 contains two basic sequences which may be responsible for the nuclear localization of the L1 protein. The L1 protein is found only in the nuclei of the terminally differentiated, granular layer of the epithelium. When expressed in heterologous hosts, including bacteria, yeast, insect cells or mammalian cells, L1 protein can self-assemble into virus-like particles (VLPs). VLPs are empty PV capsids consisting of the structural proteins but lacking the viral genome. These VLPs have structural similarity to infectious virus particles and are currently being tested in prophylactic vaccine strategies owing to their ability to induce immunological protection against infection in animal model experiments. The minor capsid protein L2 has a molecular weight of 76–78 kDa. The N-terminal domain of the L2 protein is highly conserved among different PVs. The L2 proteins of fibropapilloma-producing (DPV, BPV-1), cutaneous (CRPV, HPV1a), and mucosal (HPV6, 11, 16) PVs have homologous sequence stretches within each group. This may reflect the tropism of the respective viruses for the skin, the mucosa and fibroblasts. The L2 protein is incorporated into the capsids when L1 and L2 are coexpressed in cells. The exact location of the L2 protein in the capsids is not known; however, it has been speculated that the L2 protein may be located in the center of a pentavalent

capsomer. Immunological studies support the premise that at least the N-terminal portions of L2 are exposed on the surface of the virion. The exact role of L2 protein in the viral life cycle is unclear but it has been suggested to play a role in: (1) correct assembly of the capsid proteins into icosahedral capsids (VLPs composed of L1 only are more heterogeneous in size and shape than capsids where both L1 and L2 are present); (2) selective encapsidation of PV DNA in viral capsids (viral genomes can be packaged in VLPs composed of both L1 and L2 more efficiently than in capsids composed of L1 alone); and (3) infectivity of PV virions. L2 can induce the relocalization of E2, L1 and the viral DNA to promyelocytic leukemia oncogenic domains (PODs). The significance of this subnuclear localization is not yet appreciated; however, it is interesting that components of other viruses (adenoviruses, herpesviruses) can also be found in POD domains.

Association of HPVs with Human Cancers

Certain types of HPVs, such as type 16, 18, 31 and 33, are associated with human anogenital cancers, and are referred as high-risk HPVs. These cancers include cervical cancers in women and penile cancers in men. The advent of Pap smears, which provide early detection of cervical cancer precursor lesions in women, has led to a significant decrease in deaths due to cervical cancer in countries where there is good access to health care. Nevertheless, cervical cancer remains a leading cause of death by cancer among women. More than 95% of cervical cancers are associated with infection by the sexually transmitted, high-risk anogenital PVs. HPV DNA can be detected in these cancers and cells derived from these cancers. The viral DNA is commonly found to be integrated into the cellular genome. The sites of integration appear relatively random with regard to the host genome, but specific with regard to the viral genome. Integration leads to the disruption of the 3′ portion of the viral early region encoding the E1 and E2 genes. In these cervical cancers there is a preferentially increased expression of two viral genes, E6 and E7. This may result in part from the derepression of the viral promoter directing expression of these genes (which can be repressed by high levels of E2 proteins) and in part from increased stability of the E6 and E7 specific mRNAs owing to the disruption of a mRNA instability element in the 3′ UTR of the early region. The presence of transcripts for E6 and E7 in cancer cells suggested these two genes may play an important role in the HPV-associated carcinogenesis. Studies outlined below have clearly proven E6 and E7 to be potent oncogenes that can cause the transformation of cells in tissue culture and induce tumor formation in animal models.

E7 is a nuclear protein of 98 amino acids that is well conserved among different HPVs. E7 protein has several regions that share homology to conserved regions (CRs) in the adenoviral transforming protein E1A. The N-terminal half of E7 protein contains two domains, CR1 and CR2, which are required for E7's transforming and tumorigenic properties. The CR2 domain contains the amino sequence that is necessary for binding pRb, the product of the retinoblastoma tumor susceptibility locus. The CR1 domain appears crucial for E7's ability to induce the degradation of pRb. pRb is a master regulator of cell cycle in the G_1 phase. Normally it is regulated in its activity by phosphorylation by cyclin associated kinases. Hypophosphorylated pRb associates with the cellular transcription factor E2F, blocking the latter's transcriptional transactivation activity. As mentioned earlier, E2F upregulates many genes required for DNA synthesis. Phosphorylation of pRb by cyclin-associated kinases leads to the disruption of the pRb:E2F complex. The active E2F thereby leads to the transition of the cell into S phase. Functional inactivation of pRb leads to unrestrained cell growth and cancer. In humans, mutational loss of pRb causes retinoblastoma in the eye, Wilms' tumor in kidney, and bone tumors. Binding of E7 to pRb results in disassociation of pRb from E2F protein and destabilization and degradation of pRb (**Fig. 3**). Thus the trans-dominant effects of E7 on pRb has been likened to the effects of mutational inactivation of pRb seen in some tumors. Recent evidence indicates that E7 also binds to other cell cycle regulating proteins, such as certain types of cyclin-dependent kinases (CDKs), and CDK inhibitors p21 and p27. These activities of E7 likely also contribute to its capacity to disrupt the control of the cell cycle.

E7 is a potent transforming protein in cell culture. Alone, it can transform established fibroblast cell lines and immortalize primary epithelial cells, as demonstrated in human mammary and cervical epithelial cells. In cooperation with another oncogene, activated H-*ras*, it can efficiently transform baby rat kidney cells. E7 also can abrogate normal cellular responses to DNA damaging agents, including radiation as well as drugs like actinomycin D. This capacity of E7 maps to its ability to bind and inactivate pRb and pRb-like proteins. Direct evidence of the tumorigenic activity of E7 comes from the analysis of E7 transgenic mice. Expression of E7 in the mouse epidermis, driven by human keratin 14 promoter, induces significant skin hyperplasia and tumor formation. E7-induced tumors include skin papillomas, carcinomas and sebaceous epitheliomas.

E7 appears to play primarily a role in the 'promotion' phase of carcinogenesis, reflective of its capacity to induce cell proliferation.

E6, a protein of 151 amino acids, is also a nuclear protein. The characteristic structural feature is the formation of two hypothetical zinc fingers. Each of the fingers contain a motif of two cysteines (Cys-X-X-Cys) at its base. Although the functions of these fingers are not clear, they seem to be necessary structures in the stability of E6 protein and transforming functions of E6. An important function of E6 in tumorigenesis is its binding to and inactivation of p53 (**Fig. 3**). p53 is the tumor suppressor gene most frequently mutated in human cancers. Wild-type p53 can induce cell cycle arrest and/or cell death in response to cell stress including DNA damage. Mutations in p53 contribute to immortalization and transformation of cells in tissue culture. Loss of p53 function in both human and animals causes early development of multiple types of malignant tumors. E6 protein from high-risk HPVs can bind p53 through another cellular protein, E6 associate protein (E6-AP), a 100 kDa ubiquitin-protein ligase. Association of E6, E6-AP and p53 leads to ubiquitination and thereby the subsequent degradation of p53. Analysis of E6 mutants has demonstrated that its ability to bind and inactivate p53 is necessary but not sufficient for E6 to immortalize and transform cells. Though yeast two-hybrid studies have led to the identification of multiple potential cellular targets for E6, including paxillin, E6 binding protein 1, and the human homologue of the drosophila discs large tumor suppressor protein, the p53-independent mechanisms of action of E6 that contribute to its role in cancer have yet to be elucidated.

Oncogenic activities of E6 include, in tissue culture, the immortalization of primary epithelial cells and transformation of baby rat kidney cells in cooperation with activated ras oncogene, and *in vivo*, the induction of tumors in E6 transgenic mice in which expression of E6 is directed from the human keratin 14 promoter. The tumors that arise in these mice are primarily malignant carcinomas. Studies suggest that E6 contributes not only to the 'progression' stage of carcinogenesis, but also earlier stages involved in the formation of benign lesions. The mechanisms of E6 transformation and tumorigenesis may be a combination of many activities on the cells. First, E6 induces cellular genome instability, as indicated by aneuploidy in the E6 transformed cells. Second, E6 can modulate DNA damage responses both in cell culture and in animal studies. Following DNA damage, the cells or tissues expressing E6 show an abrogation of apoptosis, cell cycle arrest, and the induction of p53. Modulation of DNA damage responses may contribute to genetic errors in E6-transformed cells. Third, E6 may modulate differentiation/apoptosis of epithelial cells and/or induce their proliferation.

E6 and E7 act synergistically to induce tumors *in vivo*; transgenic mice expressing both E6 and E7 have increased incidence and earlier onset of tumors compared to the mice transgenic for the individual genes. This synergy can also be detected in tissue culture experiments that score for the immortalization or transformation of cells. In sum, studies to data clearly implicate in carcinogenesis the two viral genes found expressed in cervical cancer.

Future Perspectives

Recombinant DNA technology offers new opportunities in the development of PIV vaccines. The HN gene of PIV-3 inserted into a baculovirus vector is expressed on the surface of infected insect cells, is biologically active and cell lysates protect cotton rats. Vaccinia virus recombinants expressing HN and F are also protective in cotton rats, suggesting that live attenuated recombinant viruses may be a feasible approach in the development of vaccines to human PIVs. Finally, cold-adapted mutants and F-altered cleavage-site mutants offer additional strategies for live virus vaccines.

Besides vaccines, antiviral drugs may be designed that curtail viral replication or prevent viral spread. Knowledge of the three-dimensional structure of HN and F, especially those regions involved in viral attachment, penetration and release, will be important in drug design.

Animal

Kailash C Gupta, Department of Immunology/ Microbiology, Rush Medical College, Chicago, Illinois, USA

Introduction

In the past fifty years several animal parainfluenza viruses (PIV) have been identified. Their hosts range from mice to cattle. Like the human parainfluenza viruses, animal parainfluenza viruses primarily cause the upper respiratory tract diseases. Pathogenic parainfluenza viruses for cattle, dogs and sheep have been isolated. The first outbreak of an animal parainfluenza virus disease, the 'shipping fever' caused by bovine PIV-3 (BPIV-3) was recognized in cattle in 1959. Sendai virus, a mouse virus, has been used as a model animal parainfluenza virus for research. Newcastle disease virus (NDV), a virus taxonomically related to parainfluenza viruses, is a scourge of chickens. The term 'parainfluenza' virus has been loosely used to classify the group of paramyxoviruses that are similar to influenza viruses and cause respiratory diseases.

Taxonomy and Classification

Recently the International Committee on the Taxonomy of Viruses (ICTV) has divided family *Paramyxoviridae* into two subfamilies: *Paramyxovirinae* and *Pneumovirinae*. All the known animal parainfluenza viruses fall in two (*Respirovirus* and *Rubulavirus*) of the three genera of the subfamily *Paramyxovirinae* (**Table 1**). The parainfluenza viruses are characterized by the presence of hemagglutinating and neuraminidase activities by virtue of the virus envelope glycoprotein, HN. In contrast to parainfluenza viruses, the third genus (*Morbillivirus*) of *Paramyxovirinae* has the hemagglutinating activity only. This chapter presents the characteristics of *Respirovirus* and *Rubulavirus* genera. The unifying theme of the *Paramyxovirinae* is the similar number of genes and their expression strategy. These viruses belong to the superfamily *Mononegalvirales* that is characterized by single-stranded RNA genome of negative polarity.

Host Range and Virus Propagation

Animal parainfluenza viruses have been isolated from several different animal species ranging from mice to cattle. However, many experimental animals such as hamsters, mice and guinea pigs have been used as hosts. Some parainfluenza viruses, particularly, Sendai virus and BPIV-3 grow well in the amniotic cavity of embryonated chicken eggs. Many viruses have been adapted to grow in primary and established cell cultures of different host origin. For example, simian virus 5 (SV5) grows well in Madin–Darby bovine kidney (MDBK) cells and BPIV-3 in baby hamster kidney (BHK) cells. Cytopathology varies depending on the virus strains and cell types used. For efficient growth, some viruses need trypsin or α-chymotrypsin in the medium for cleavage activation of the virus fusion protein, F.

Properties of Virion and Proteins

Virions are spherical yet pleomorphic in nature and range in size from 150 to 250 nm in diameter. The virions comprise a distinct lipid bilayer envelope with two types of glycoprotein (HN and F) spikes as

Table 1 Some members of the subfamily *Paramyxovirinae*

Genus	*Common name*	*Acronym*	*Genome length (nt)*
Respirovirus	Sendai virus (murine parainfluenza virus type 1)	SNDV	15 384
	Bovine parainfluenza virus type 3	BPIV-3	15 480
	Human parainfluenza virus type 1	HPIV-1	
	Human parainfluenza virus type 3	HPIV-3	15 480
Rubulavirus	Simian virus 5 (Canine parainfluenza virus type 2)	SV5	15 246[a]
	Simian virus 41	SV41	
	Mumps virus		
	Newcastle disease virus (Avian paramyxovirus type 1)	NDV	
	Canine parainfluenza virus 5	CPIV-5	
	Human parainfluenza virus 2	HPIV-2	
Morbillivirus	Dolphin morbillivirus	DMV	
	Equine morbillivirus	EMV	
	Porpoise morbillivirus	PMV	
	Canine distemper virus	CDV	15 616
	Phocid distemper virus	PDV-1	
	Baikal seal morbillivirus	PDV-2

observed under the electron microscope (**Fig. 1A** and **2**). These glycoproteins are crucial for virus attachment, entry and release. HN binds to sialic acid-containing cell surface molecules. The HN protein possesses both hemagglutinating and neuraminidase activities and the F protein possesses fusion activity. The neuraminidase activity of HN cleaves sialic acid from virions and cell surfaces and prevents virus aggregation during budding. Both glycoproteins traverse the entire lipid bilayer once. HN is a type II integral membrane protein which is anchored in the membrane by its hydrophobic domain at the N-terminus. It occurs as a tetramer consisting of a pair of disulfide-linked dimers. In contrast to HN, the F protein is a type I integral membrane protein in that it is anchored in the membrane by the hydrophobic domain at the C-terminus. The F protein also occurs as an oligomer, but it is not known whether it occurs as a trimer or a tetramer. However, the overwhelming evidence is in favor of a trimer. The F protein is synthesized as a precursor (F_0) which is processed by host proteolytic machinery in the *trans* Golgi network to generate two disulfide-linked fragments, F_1 (large) and F_2 (small). Furin, a protease localized in the *trans* Golgi appears to be the protease responsible for cleavage of F_0. However, in the respiratory tract, a protease secreted by the Clara cells of the bronchial epithelium appears also to be involved in F cleavage. Cleavage of F is important for its fusogenic activity necessary for infection. The N-terminus (20 residues) of F_1 is highly hydrophobic and is termed the fusion peptide domain. Fusion peptide sequences among parainfluenza viruses are highly conserved (70–90% identity). It is hypothesized that the fusion domain is masked by two coiled triple α-helices formed due to heptad repeats; one coiled region is adjacent to the fusion peptide and the other at the C terminus. The fusion domain is somehow exposed by a conformational change during infection.

Encased in the envelope is a single strand of RNase-resistant helical nucleocapsid, a ribonucleoprotein complex consisting of a single molecule of virus RNA genome and about 2500 molecules of the viral nucleocapsid protein (N or NP) (**Figs 1B, 1C** and **2**). NP is the most abundant viral protein. Associated with nucleocapsids are viral polymerase proteins, the phosphoprotein (P) and the large protein (L). P and L together form an RNA-dependent RNA polymerase complex. The functional domains of P and L proteins are not well defined, although several polymerase domains based on sequence similarities have been recognized in the L protein. The characteristic of P protein to be phosphorylated is highly conserved, but the functional role of phosphorylation is yet to be defined. The viral matrix (M) protein underlies the inner surface of the virus envelope. It is a basic protein. It appears to form a bridge between the nucleocapsid and the cytoplasmic tails of the envelope

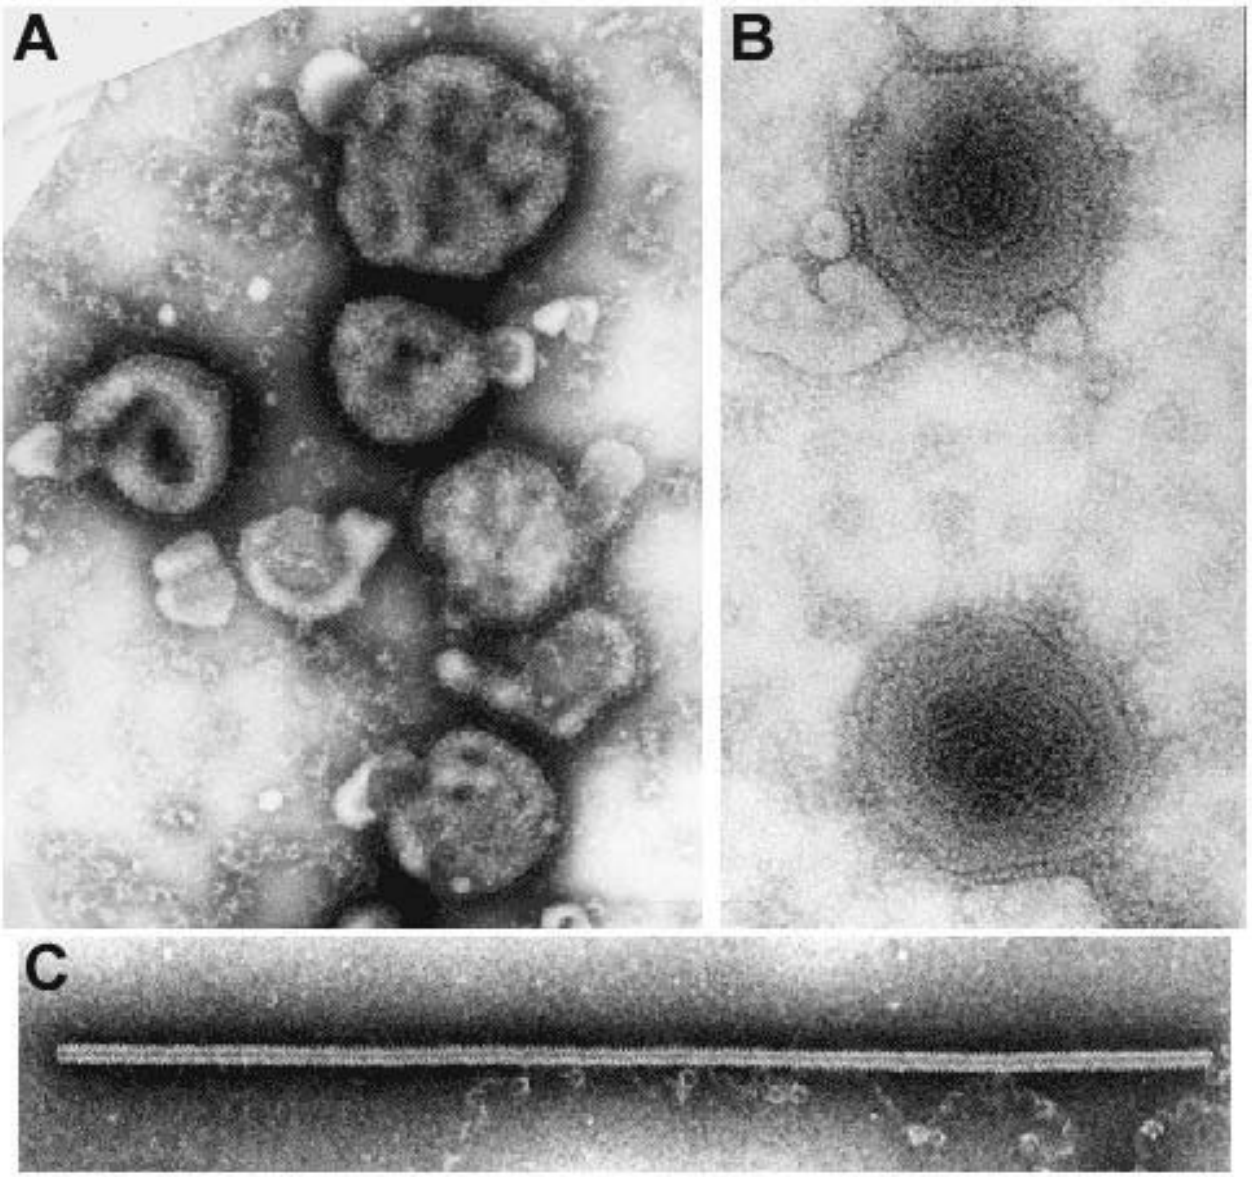

Figure 1 Electron micrographs of Sendai virus and its nucleocapsid. (**A**) Negatively stained virions: spherical and pleomorphic nature is clear. Magnification ×148 000. (**B**) Partially ruptured virions have allowed penetration of the stain into virion: the highly folded nucleocapsid inside the virion and an outer coat of spikes are evident. Magnification ×254 000. (Courtesy of Dr Gopal Murti, St Jude Children's Research Hospital, Memphis.)

proteins. It is involved in virus maturation, assembly and budding.

In addition to the viral structural proteins, certain virus-encoded accessory proteins (V and C) are found in infected cells. Interestingly, both these proteins are encoded in the P gene. Although almost all parainfluenza viruses encode V protein, only those of the *Respirovirus* genus encode the C protein. The C protein is synthesized from a +1 reading frame which overlaps the P and V reading frames. C protein is a basic protein. During transcription, mRNAs from the *P* gene are edited with certain frequency by insertion of one or several G residues at a specific site downstream from the C reading frame. This results in a frameshift in the edited mRNA starting at the insertion site. This strategy of expression allows synthesis of two proteins, P and V, each from a different mRNA. The N-termini of these proteins are identical but the C-termini are different. The C-terminus of V is highly conserved, cysteine-rich and can bind zinc. Both C and V proteins appear to have a role in virus replication. Recently V of Sendai virus

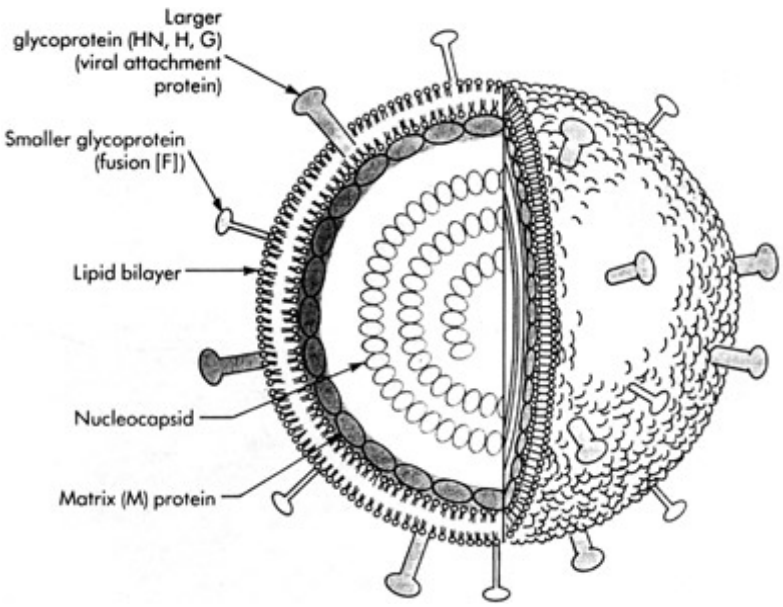

Figure 2 Schematic representation of a paramyxovirus particle. A single helical nucleocapsid is shown inside the virion. The lipid envelope is shown consisting of two types of spikes (HN and F) on the outer surface and the matrix (M) protein lining the inner surface. Not drawn to scale. has been shown to be important for pathogenesis. However, more definitive studies for C and V functions are needed.

Genome

The genomes of parainfluenza viruses contain approximately 15 500 nucleotides. Complete nucleotide sequence of several of these viruses have been completed (**Table 1**). A unique feature of their genomes is that the number of nucleotides occur in multiples of six. Approximately 50–60 noncoding nucleotides at each terminus of the genome are important for virus replication and are to a large extent complementary to each other. Apparently, viral polymerase binding and NP binding signals reside in these regions. The gene order in the genome is: *NP-P/C/V-M-F-(SH)-HN(H)-L*, in the 3′ to 5′ direction. The coding sequence of each gene is flanked by noncoding regions. The start and end of each gene is characterized by consensus sequences. Between the end of one and the start of the other is the intergenic region (IR). The IR comprises only three nucleotides in *Respirovirus*, but is of variable length (1–31) in *Rubulavirus*. Some rubulaviruses (e.g. SV5) encode an additional small hydrophobic (SH) protein which is an integral membrane protein. In addition to the fully mature virions, defective interfering (DI) particles are observed when virus is grown at high titers. DI RNAs are essentially internal deletion mutants which retain the terminal sequences essential for their replication. DI RNAs capitalize on the coding capacity of the full-length genome and, therefore, they interfere in the growth of mature virions.

Replication and Virus Assembly

All parainfluenza viruses replicate exclusively in the cytoplasm (**Fig. 3**). They can replicate in enucleated cells. The virus infection cycle begins by its attachment to cell receptors by HN. Various receptors such as sialic acid, gangliosides, and other cell surface proteins are used. Subsequent to attachment, the virus envelope fuses with the plasma membrane releasing the nucleocapsid into the cytoplasm. Recent studies have shown that both F and HN are required for efficient fusion. Parainfluenza viruses can cause cell–cell fusion, generating multinucleated cells (syncytia). Upon entry the nucleocapsid initiates the primary transcription of the virus using associated polymerase complex of P and L proteins. It is the nucleocapsid and not the naked viral RNA that acts as a template for the viral polymerase. The nucleocapsid can reversibly change its configuration (coiling) in response to ionic conditions. It is likely that the pitch of the coiling is modulated during viral RNA synthesis for the polymerase to function. The transcription products are primarily monocistronic mRNAs that are capped, methylated and polyadenylated. However, as described above, the *P* gene is transcribed into alternate mRNA species by cotranscriptional editing. In addition to these mRNA species, a small leader

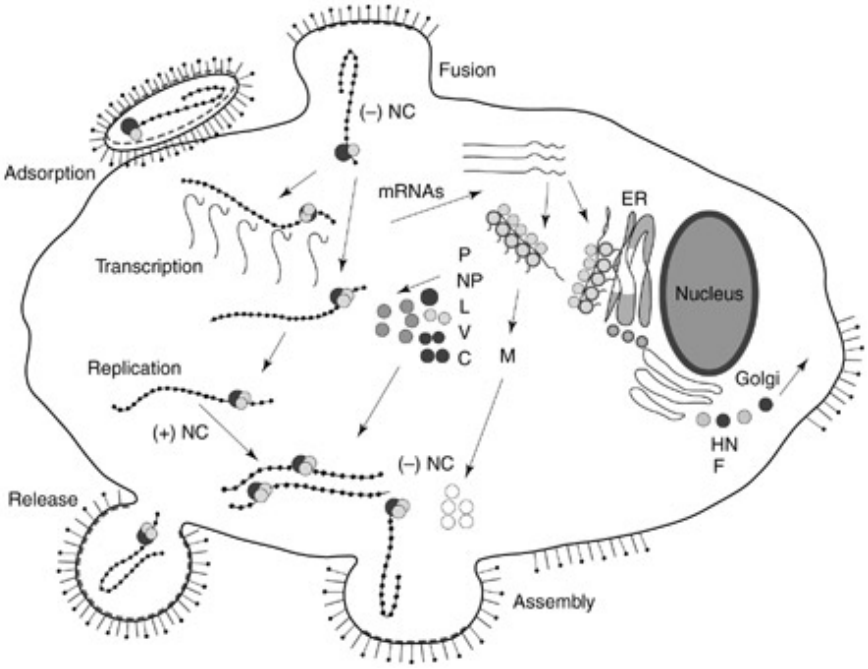

Figure 3 Representation of a paramyxovirus replication. The virus is adsorbed to cell surface by sialic acid containing receptors. Fusion of the virus envelope with the plasma membrane follows the adsorption. Transcription and replication occurs in the cytoplasm. Glycoproteins are transported to plasma membrane through rough endoplasmic reticulum (ER) and Golgi bodies. The M protein helps in virus assembly and perhaps in budding from the plasma membrane.

RNA (1) complementary to the 3′ of the genome is synthesized. The transcription is polar and consequently generates mRNAs in the following gradient: l>NP>P/C/V>M>F>(SH)>HN>L. The transcriptional polarity most likely arises through transcription initiation at the 3′ terminus of the viral genome and transcription termination at the end of each gene. The polymerase then reinitiates with subsequent lower frequency at the start of the next gene. Later in virus infection, when enough virus proteins have been synthesized from these mRNAs, the polymerase replicates the entire genome length RNA (**Fig. 3**). The first step is to synthesize the antigenome nucleocapsid (NC+) which is used as a template to synthesize the progeny of genomic nucleocapsids (NC−). Since more genomic nucleocapsids are synthesized than the antigenomic ones, it is believed that the promoter in the antigenomic nucleocapsid is more efficient than that in the genomic one.

It is assumed that the NP protein in the cytoplasm binds the nascent viral RNA chain initiating the assembly of viral nucleocapsid. It is likely that the accumulation of viral NP protein causes the polymerase from transcriptive mode to replicative mode. Perhaps the binding of NP to nascent RNA causes the polymerase to ignore gene start and end signals allowing genome-length RNA synthesis. Apparently P keeps the NP protein in a solubilized status and transports it to the nucleocapsid assembly site. Association of the polymerase protein complex (P + L) occurs during the nucleocapsid assembly. Subsequently the nucleocapsid is transported to the plasma membrane. It is possible that the M protein helps nucleocapsids to associate with the plasma membrane patches where viral glycoproteins have accumulated. F and HN proteins are processed through endoplasmic reticulum (ER) and Golgi bodies and then transported to the plasma membrane (**Fig. 3**). In polarized epithelial cells, the glycoproteins are transported to the apical surface of the cells. The final assembly and budding of the virus occurs at the plasma membrane.

Genetic Manipulation

Purified nucleocapsids associated with P and L proteins are capable of initiating virus infection. Recently, success has been achieved in constructing nucleocapsids from synthetic RNA and viral proteins *in vitro*. These nucleocapsids contained a reporter gene flanked by 5′ and 3′ termini of the regulatory virus genome sequences. These RNA minigenomes were rescued on transfection of virus-infected cells. Similarly, cDNA minigenomes were rescued on cotransfection with NP, P and L genes. Now infectious virus cDNA clones have been produced. Mutant virus can be derived from these clones. These

experimental approaches make it possible to alter specifically the virus gene or regulatory sequences to define their function more precisely and to create virus strains that could be potentially useful for vaccine development.

Genetics and Evolution

The entire genome sequence of several parainfluenza viruses is known (**Table 1**). Although the gene organization is very similar in these viruses, divergence of individual protein sequence is variable. P protein is the most variable. Interestingly, the V protein encoded in the same gene is relatively conserved at the C-terminus. NP and M are relatively less variable. L protein has four to five regions of significant amino acid conservation. These regions are believed to be important for a number of enzymic activities putatively associated with the L protein.

BPIV-3 is most closely related to human PIV-3 (HPIV-3). Sendai virus is more closely related to HPIV-1. SV5 is more closely related to HPIV-2 and canine PIV-5 (CPIV-5). It is possible that CPIV-5 and SV5 are the same virus. Several strains of NDV from various birds have been isolated. It is likely that the closely related viruses originated from a common stock and diverged due to host adaptation.

Serologic Relationships and Variability

The parainfluenza viruses that have been observed to show strong serological relationship were later found to have strong sequence homologies at the amino acid level. The viruses which show a high degree of antigenic similarities are: Sendai virus and HPIV-1, BPIV-3 and HPIV-3, SV5 and HPIV-2.

Epidemiology

BPIV-3 was isolated from a respiratory disease epidemic in cattle. It is often isolated from bovine respiratory disease, shipping fever, which occurs during or after cattle transport. Interestingly, Sendai virus, a mouse pathogen, was prevalent before 1961 in the pig population of Japan. Sendai virus causes acute epizootic in experimental rodents. NDV has been isolated from both domestic and free-living birds. Several epidemics of NDV infection have occurred in the past killing thousands of chickens. The most recent NDV outbreak was in 1995 in Taiwan. In general, parinfluenza viruses do not show strong host specificity.

Transmission and Tissue Tropism

Almost all parainfluenza viruses primarily infect epithelial cells of the respiratory tract. The mode of transmission is most likely aerosol inhalation. Rarely, these viruses cause viremia and infection of subepithelial cells. However, the presence of virus in the intestinal tract, aborted fetuses and milk indicate that contact transmission is also involved to a lesser extent. Since the receptors of parainfluenza viruses appear to be present on most of the host cells, virus infection to respiratory cells is most likely limited by the presence of cellular protease(s) that cause cleavage activation of the F protein. It has been shown that a pantropic mutant of Sendai virus, whose F is susceptible to cleavage by ubiquitous host proteases, causes systemic infection in mice. Cleavage activation of F allows cell-to-cell spread of the virus.

Pathogenicity

Most of the parainfluenza viruses cause upper respiratory tract diseases, such as cough, croup and bronchiolitis. These conditions could lead to lower respiratory tract infection and pneumonia. In contrast, avian paramyxoviruses (NDV) replicate in the intestinal tract. NDV strains range from avirulent to highly virulent strains. Virulent strains are highly lethal to chicken populations.

Immune Response

Parainfluenza viruses elicit both humoral and cellular immunity. Envelope glycoproteins, HN and F, are primarily responsible for the humoral response whereas NP and M proteins are antigens for cellular response. Mucosal immunoglobulin (Ig) A to HN is responsible for protection from further infection. However, animals become susceptible to reinfection several months after antibody development. The role of cellular immunity is not clear.

Prevention and Control

Live attenuated and killed vaccines have been developed for BPIV-3. Live vaccines are better than the killed ones. Vaccines developed for intranasal use induce effective nasal IgA antibodies. It is very important to keep experimental mice free from Sendai virus. Mice colonies can be freed of virus by maintaining them under pathogen-free conditions after cesarean birth. Several live attenuated and killed vaccines for NDV have been developed. Recent studies with DNA vaccines indicate their considerable potential in effectively controlling spread of NDV.

Future Perspectives

Parainfluenza viruses cause human suffering and

economic losses. A better understanding about their replication and host–virus interactions is essential in order to combat the diseases caused by them. Progress in the basic knowledge of parainfluenza viruses was stymied due to constraints on the manipulation of negative-sense virus genome. With the success of reverse genetics for manipulation of these viruses, a surge of knowledge is expected. This approach will be helpful in the in-depth understanding of the replication strategies of parainfluenza viruses and in designing efficient antivirals and vaccines against them.

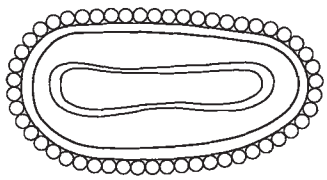
PARAPOXVIRUSES (*POXVIRIDAE*)



Andrew Mercer, University of Otago, Dunedin, New Zealand

David Haig, Moredun Research Institute, Edinburgh, UK

History

There are numerous historical references to diseases of domesticated animals such as sheep and cattle that we would now suspect to be the result of infection by parapoxviruses. These references include Jenner's 'spurious' cowpox which is likely to have been caused by the parapoxvirus, pseudocowpox virus. If a little poetic license is permitted it is easy to believe that when, in 1520, Pope Leo X wrote a letter deploring the actions of Martin Luther and stated that 'we cannot suffer the scabby sheep longer to infect the flock', he was making an analogy which indicates knowledge of the disease caused by orf virus and of its infectious nature.

In the latter part of last century reports appeared in the scientific literature which recognized the distinct identities of the diseases caused by members of this genus. Following an extensive study of contagious pustular dermatitis of sheep, Aynaud produced a report in 1923 which included the observation that the disease could be transmitted by a 'filterable' agent. The isolation of each of the viruses in cell culture was reported in the period from 1957 to 1963. Detailed reports of the transmission of each disease to humans appeared in 1933 (orf virus), 1963 (pseudocowpox virus) and 1967 (bovine papular stomatitis virus). The first molecular analyses of parapoxvirus genomes appeared in 1979 with publication of restriction endonuclease cleavage site maps and reports of G+C contents. These were followed, in 1989, by the first description of the DNA sequence of a region of a parapoxvirus genome.

Taxonomy and Classification

The *Parapoxvirus* genus belongs to the family *Poxviridae*, subfamily *Chordopoxvirinae*. The type species of the genus is orf virus and the other species recognized as members are bovine papular stomatitis virus, pseudocowpox virus and a recently identified member, parapoxvirus of red deer in New Zealand. Synonyms by which these viruses have been known include contagious pustular dermatitis virus and contagious ecthyma virus for orf virus and Milker's nodule virus and paravaccinia virus for pseudocowpox virus. Tentative species of this genus are Auzduk

These systems are continually improving and should allow a detailed genetic analysis of the complete viral life cycle.

The ability to generate VLPs has revolutionized papillomavirus research. These VLPs are very useful for serological studies and have been the basis of very successful prophylactic vaccines in cattle, dogs and rabbits. These animal systems should also prove useful for developing efficient therapeutic vaccines and for testing antiviral drugs that may be used in treatment of PV infections in humans.

BPV-1 continues to serve as the molecular prototype for the study of papillomavirus DNA replication and transcriptional regulation. The ability of this viral genome to efficiently and stably replicate extrachromosomally will prove to be very useful in understanding the mechanisms by which extrachromosomal elements stably replicate and segregate their DNA. Such studies may also lead to improved gene transfer vectors based on papillomavirus genomes. BPV-1 genomes packaged in heterologous VLPs have been used in neutralization studies because of the ability of BPV-1 genomes to quantitatively transform certain mouse cells. This property of BPV-1 should continue to prove useful for many different studies.

PARAINFLUENZA VIRUSES (*PARAMYXOVIRIDAE*)

Contents

Human

Animal

Human

Allen Portner, Department of Virology and Molecular Biology, St Jude Children's Research Hospital, Memphis, USA

Introduction

The human parainfluenza viruses (PIVs) are an important cause of respiratory disease in infants and children. Four types were discovered between 1956 and 1960. PIV-1, PIV-2 and PIV-3 were first isolated from infants and children with lower respiratory tract disease and subsequently shown to be a major cause of croup (types 1–3) and pneumonia and bronchiolitis (type 3). PIV-4 was initially isolated from young adults and has been associated with mild upper respiratory tract disease of children and adults. Other viruses antigenically and structurally related to the human paramyxoviruses have been isolated from animals. Sendai virus, a natural pathogen of mice and not of humans, was the first PIV isolated and is antigenically related to human PIV-1. Simian virus (SV)5, recovered from primary monkey kidney cells, causes croup in dogs and is a subtype of human type 2, and bovine shipping fever virus is a subtype of type 3.

Taxonomy and Classification

The PIVs belong to three genera, *Respirovirus*, *Rubulavirus* and *Morbillivirus*, of the subfamily *Paramyxovirinae* in the family *Paramyxoviridae*. Some other species found in the *Rubulavirus* are

mumps virus, which causes disease in humans; Newcastle disease virus (NDV) of chickens; SV5 in dogs; and in the *Respirovirus* genus Sendai virus in mice. The third genus which completes the subfamily is *Morbillivirus* (measles virus, canine distemper virus, rinderpest virus). A second subfamily, *Pneumovirinae*, has two genera, *Pneumovirus* (respiratory syncytial virus) and *Metapneumovirus* (turkey rhinotracheitis virus). The *Paramyxoviridae* family belongs to the order *Mononegavirales*, the distinctive feature of which is a negative-stranded RNA genome and a similar strategy of replication, suggesting that all negative-stranded viruses evolved from an archetypal virus.

Virion Structure, Genome Organization and Protein Composition

The PIVs are roughly spherical, lipoprotein enveloped particles 150–250 nm in diameter with an internal helical nucleocapsid containing the single-stranded RNA genome. Projecting from the surface of the virion are the hemagglutinin–neuraminidase (HN) and fusion (F) glycoproteins. These glycoproteins are anchored to the plasma membrane of the infected cell or the virion envelope by a hydrophobic transmembrane region. In paramyxoviruses the transmembrane domain of HN is located near the N-terminus of the molecule and F near the C-terminus. Extending into the cytoplasm of the infected cell or inside the virion membrane is a short hydrophilic tail region, thought to play a role in viral assembly through its interaction with the matrix (M) protein, which lines the inner surface of the plasma membrane and itself interacts with the nucleocapsid. Inside the lipid bilayer of the viral particle is the RNA nucleocapsid which houses the nonsegmented negative-stranded RNA genome. The genomes of PIV-1, PIV-2 and PIV-3 are approximately 15 000 nucleotides and PIV-4 is certain to fall in this range once the sequencing is complete. The RNA genome serves as a template for transcription of mRNAs specifying six virion structural proteins linked in tandem in the order of 3′-nucleoprotein (NP)–polymerase-associated protein (P/V)–matrix protein (M)–fusion protein (F)–hemagglutinin-neuraminidase (HN)–large protein (L)-5′. The P gene alone is unique in its capacity to express, in addition to the P protein, various other proteins by utilizing internal initiation codons in the same or different reading frames or by RNA editing of the P gene mRNA through insertion of nontemplated G residues. Besides P, these other proteins have been designated V, C, D and X, depending on the PIV. The helical nucleocapsid is 18 nm in diameter, contains approximately 2000 molecules of NP bound to the RNA genome, about 200 P and 20 L molecules. The P protein, which forms a polymerase complex with L, is essential for the enzymatic processes of viral RNA transcription and replication including the 3′ addition of poly(A), modification of the 5′ end, and nucleotide polymerization of viral transcripts.

The approximate molecular weights of the PIV proteins as exemplified by PIV-3 are: NP, 58 000; P, 68 000; M, 40 000; F, 63 000; HN, 72 000; L, 256 000.

Attachment Protein

The process of infection is initiated by the action of the HN glycoprotein, which binds the virion to sialic acid-containing receptors on the host cell surface. The same process is responsible for the hemagglutination of avian and mammalian erythrocytes. HN also causes the enzymatic (neuraminidase) cleavage of sialic acid residues from the carbohydrate moiety of glycoproteins and glycolipids, which functionally serves to prevent the self-aggregation of virus during release from infected cells. Besides attachment, HN provides an unknown function that is either essential or enhances the fusion activity of the F protein. It is believed that HN directly interacts with F, possibly altering its conformation, thereby stimulating the fusion activity of F.

The morphology of HN-based studies of Sendai virus is envisioned as an N-terminal stalk region of approximately 130 amino acids anchoring a large N-glycosylated hydrophilic globular head region to the viral envelope. A small uncharged hydrophobic peptide located near the N-terminus spans the viral envelope, and a small hydrophilic domain is internal to the membrane. The globular head contains the active site for virus attachment, neuraminidase activity and antigenic determinants that induce neutralizing antibodies for PIV-1 and Sendai virus. HN exits on the surface of the virion as disulfide-linked homodimers or tetramers.

Fusion Protein

Following virus attachment, F, the other surface glycoprotein, mediates the fusion of the virion and host cell surface membranes, which allows the nucleocapsid to be deposited in the cell cytoplasm where gene expression begins. F expressed on the surface of infected cells also mediates fusion, allowing the extension of infection to uninfected cells.

All F proteins are synthesized as inactive precursors (F0) which are post-translationally cleaved by a host cell trypsin-like protease to form the biologically active molecule. For the paramyxoviruses in general, the cleavage site is located about 100 amino acids

from the N-terminus of F0. The cleavage site is characterized by a short span of basic amino acids on the amino side of the site and a longer stretch of about 30 hydrophobic residues on the carboxyl side. The number and location of basic amino acids on the amino side of the cleavage site varies with individual PIVs. PIV-1 and Sendai virus have one basic amino acid immediately adjacent to the cleavage site (Arg), whereas PIV-2 and PIV-3 have two (Arg-Lys) and SV5 has five (all Arg). The motif of paired basic amino acids at the cleavage site increases the efficiency of cleavage, host and tissue tropism and pathogenicity, as the dibasic motif is recognized by a ubiquitous protease, whereas the enzymes that cleave at a monobasic site are found in a limited number of tissues. Cleavage of F0 results in two disulfide-linked fragments; the larger one, F1, forms the new hydrophobic N-terminus, which causes membrane fusion. The smaller product, F2, is the original approximately 100 N-terminal residues of F0.

M Protein

The M protein lines the inner surface of the viral envelope and is thought to play a role in virus maturation by interacting with the surface proteins and the nucleocapsid.

Transcription, Translation and Replication

The negative-strand strategy of viral replication involves the synthesis of unique mRNA species of each paramyxovirus gene during infection. After introduction of the infecting nucleocapsid into the host cell, transcription is the first step in gene expression. Transcriptional regulation of mRNA abundance is determined by the gene order; the closer the gene is to the 3′ end of the genome, the more efficient is the transcription. Thus, the abundance of paramyxovirus proteins is determined mainly by the polarity of the genome. Once protein synthesis is underway, replication of the genome begins, which provides additional templates for transcription and replication.

Recent development of 'reverse genetics' systems for SV and PIV-3, in which the RNA genomes of these viruses are expressed from a DNA template, are likely to facilitate our understanding of PIV protein structures and function, virus assembly, regulation of RNA transcription and replication and viral pathogenesis.

Geographic and Seasonal Distribution

All of the PIV types 1–4 have a wide geographic distribution. PIV-1–PIV-3 have been identified in most areas where facilities are available for the study of childhood respiratory tract diseases. PIV-4 has been isolated in fewer areas but this is likely to be due to the difficulty of isolation and it is probably widely distributed.

Host Range and Viral Propagation

The four PIV types were originally isolated from humans: they cause disease in humans and humans are the primary host. Other laboratory animals can serve as experimental hosts: hamsters, guinea pigs and ferrets can be infected with PIV-1, PIV-2 and PIV-3 but these infections are usually asymptomatic. PIV-3 can also infect cotton rats, rhesus and patas monkeys and chimpanzees, but these animals are not good model systems for studying disease caused by PIVs.

Embryonated hens' eggs can support the growth of some strains of PIV-1, PIV-2 and PIV-3, but are much less sensitive than monkey kidney cells for primary isolation. Sendai virus, a murine subtype of PIV-1, is an exception in that it grows exceedingly well in eggs.

All four PIV types grow well in primary monkey or human kidney cells, which are also used in the isolation of virus from clinical samples. LLC-MK2, a rhesus monkey kidney cell line, offers an efficient system for the isolation of PIVs and an experimental tissue culture system. PIV-2 and PIV-1 require trypsin in the medium to cleave the F glycoprotein for cell growth, but not PIV-3 strains. Viral infection of tissue culture can be detected by hemadsorption with guinea pig erythrocytes and the cytopathic effects produced by the viruses.

Genetics and Evolution

The entire genomic sequences of PIV-1, PIV-2 and PIV-3 have been completed. The genomes of other members of the *Paramyxovirus* and *Rubulavirus* genera (Sendai virus, NDV, SV5) have been sequenced as well. In general, the genome organization is remarkably similar, but differences exist in sequence, intergenic regions and nonstructural proteins expressed from the P gene. Sequence and immunological analyses suggest that human PIV-1 and Sendai virus are closely related type 1 PIVs, as is PIV-3 of human and bovine origin. PIV-1 and -3 are more closely related to each other than to PIV-2, SV5, mumps virus and NDV, which in turn show a closer evolutionary relationship to each other. Evolutionary divergence of PIV-3 and PIV-1 is greatest for the P protein (a phenomenon of paramyxovirus P proteins in general),

less for the HN and F glycoproteins, and least for M, NP and L. Similarly, PIV-1 and Sendai virus, and human and bovine PIV-3, show the greatest divergence in the P protein and least for NP.

Serologic Relationships and Variability

Early serologic studies have established that related antigenic determinants are present on PIV-1–PIV-3. Besides these interrelationships, the closest antigenic relationships are exhibited between human PIV-1 and Sendai virus, human PIV-2 and canine PIV-3 (SV5) and human PIV-3 and bovine PIV-3. During primary infection, the antibody response to HN is specific for the infecting serotype, while reinfection is more crossreactive. Recent studies have established that variation occurs in HN and F neutralizing epitopes but these do not involve progressive accumulation of changes with time because changes detected in early isolates may not be detected in later isolates. It appears therefore that random mutation is responsible for the observed heterogeneity which is not under strong immunologic selective pressure.

Epidemiology and Transmission

The PIVs are an important cause of respiratory tract disease in children and infants. Infection with PIV-1, -2 and -3 can result in an inapparent infection or life-threatening lower respiratory tract disease. Most children have been infected with PIV-3 by 4 years of age and PIV-1 and -2 by 5 years. PIV-3 can cause illness during the first month of life, whereas infection is rare with PIV-1 and PIV-2 during the first 4 months of life. Over the past 10 years, epidemics of PIV-3 have occurred in the early spring and PIV-1 and PIV-2 in the fall of odd-numbered years. PIVs can be a problem in hospitals, causing infection in children admitted with other illnesses.

Infection and reinfection is by rapid person-to-person spread, with PIV-3 being the most efficient and PIV-1 and PIV-2 less so.

Pathogenicity

Viral and host properties responsible for determining the severity and localization of human PIV disease are not clear. However, recent studies have identified some factors that may play an important role in the pathogenicity: (1) susceptibility of the F glycoprotein to cleavage by host cell protease, which in turn is determined by the number and alignment of basic amino acids at the cleavage site; (2) whether the host tissues have the cleavage enzymes; and (3) the immune status of the host.

Clinical Features of Infection

The most common type of illness in children is characterized by rhinitis, pharyngitis and bronchitis, often with fever. Cough, hoarseness and fever are common initial symptoms, with fever lasting 2–3 days. When croup develops, children recover in about 24–48 h; in some cases, however, airway obstruction may occur. Bronchiolitis or pneumonia may also develop, in which the fever and cough persist.

Pathology

The mucous membranes of the nose and throat are the initial tissues involved in PIV infection. Some limited involvement of the bronchi may occur with mild disease. In more severe infections with PIV-1 and PIV-2, involvement of the larynx and upper trachea may result in croup; this may extend to the lower trachea and bronchi and result in pneumonia. PIV-3 may also cause severe disease characterized by bronchopneumonia, bronchiolitis or bronchitis.

Immune Response

Pre-existing serum neutralizing antibodies to PIV-3 in children and infants have correlated with resistance to infection and illness; however, resistance is only partial. Upon reinfection, however, a previous immunity results in a milder infectious course.

In adults, resistance to PIV-1 and PIV-2 correlates mainly with local nasal secretory IgA neutralizing antibodies, while in infants these antibodies are of little consequence. Serum antibodies may partially protect infants from infection with PIV-1, PIV-2 and PIV-3, while being ineffective in adults. Infection with PIVs stimulates antibodies to the surface glycoproteins, HN and F. Antibodies to HN neutralize by preventing viral attachment to host cells, while F antibodies may prevent viral penetration and cell-to-cell spread. Cytotoxic T cells may also be an important component in immunity to PIVs in their role in recovery from infection.

Prevention and Control

Currently, no effective vaccines exist for PIVs. Inactivated vaccines have been prepared for PIV-1, PIV-2 and PIV-3 in tissue culture and embryonated eggs but these vaccines have failed to provide protection. The inactivation of the F glycoprotein in these preparations and the failure to stimulate local nasal IgA antibodies may have contributed to the ineffectiveness of these vaccines.

Future Perspectives

Recombinant DNA technology offers new opportunities in the development of PIV vaccines. The HN gene of PIV-3 inserted into a baculovirus vector is expressed on the surface of infected insect cells, is biologically active and cell lysates protect cotton rats. Vaccinia virus recombinants expressing HN and F are also protective in cotton rats, suggesting that live attenuated recombinant viruses may be a feasible approach in the development of vaccines to human PIVs. Finally, cold-adapted mutants and F-altered cleavage-site mutants offer additional strategies for live virus vaccines.

Besides vaccines, antiviral drugs may be designed that curtail viral replication or prevent viral spread. Knowledge of the three-dimensional structure of HN and F, especially those regions involved in viral attachment, penetration and release, will be important in drug design.

Animal

Kailash C Gupta, Department of Immunology/ Microbiology, Rush Medical College, Chicago, Illinois, USA

Introduction

In the past fifty years several animal parainfluenza viruses (PIV) have been identified. Their hosts range from mice to cattle. Like the human parainfluenza viruses, animal parainfluenza viruses primarily cause the upper respiratory tract diseases. Pathogenic parainfluenza viruses for cattle, dogs and sheep have been isolated. The first outbreak of an animal parainfluenza virus disease, the 'shipping fever' caused by bovine PIV-3 (BPIV-3) was recognized in cattle in 1959. Sendai virus, a mouse virus, has been used as a model animal parainfluenza virus for research. Newcastle disease virus (NDV), a virus taxonomically related to parainfluenza viruses, is a scourge of chickens. The term 'parainfluenza' virus has been loosely used to classify the group of paramyxoviruses that are similar to influenza viruses and cause respiratory diseases.

Taxonomy and Classification

Recently the International Committee on the Taxonomy of Viruses (ICTV) has divided family *Paramyxoviridae* into two subfamilies: *Paramyxovirinae* and *Pneumovirinae*. All the known animal parainfluenza viruses fall in two (*Respirovirus* and *Rubulavirus*) of the three genera of the subfamily *Paramyxovirinae* (**Table 1**). The parainfluenza viruses are characterized by the presence of hemagglutinating and neuraminidase activities by virtue of the virus envelope glycoprotein, HN. In contrast to parainfluenza viruses, the third genus (*Morbillivirus*) of *Paramyxovirinae* has the hemagglutinating activity only. This chapter presents the characteristics of *Respirovirus* and *Rubulavirus* genera. The unifying theme of the *Paramyxovirinae* is the similar number of genes and their expression strategy. These viruses belong to the superfamily *Mononegalvirales* that is characterized by single-stranded RNA genome of negative polarity.

Host Range and Virus Propagation

Animal parainfluenza viruses have been isolated from several different animal species ranging from mice to cattle. However, many experimental animals such as hamsters, mice and guinea pigs have been used as hosts. Some parainfluenza viruses, particularly, Sendai virus and BPIV-3 grow well in the amniotic cavity of embryonated chicken eggs. Many viruses have been adapted to grow in primary and established cell cultures of different host origin. For example, simian virus 5 (SV5) grows well in Madin–Darby bovine kidney (MDBK) cells and BPIV-3 in baby hamster kidney (BHK) cells. Cytopathology varies depending on the virus strains and cell types used. For efficient growth, some viruses need trypsin or α-chymotrypsin in the medium for cleavage activation of the virus fusion protein, F.

Properties of Virion and Proteins

Virions are spherical yet pleomorphic in nature and range in size from 150 to 250 nm in diameter. The virions comprise a distinct lipid bilayer envelope with two types of glycoprotein (HN and F) spikes as

economic losses. A better understanding about their replication and host–virus interactions is essential in order to combat the diseases caused by them. Progress in the basic knowledge of parainfluenza viruses was stymied due to constraints on the manipulation of negative-sense virus genome. With the success of reverse genetics for manipulation of these viruses, a surge of knowledge is expected. This approach will be helpful in the in-depth understanding of the replication strategies of parainfluenza viruses and in designing efficient antivirals and vaccines against them.

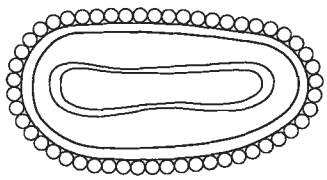
PARAPOXVIRUSES (*POXVIRIDAE*)



Andrew Mercer, University of Otago, Dunedin, New Zealand

David Haig, Moredun Research Institute, Edinburgh, UK

History

There are numerous historical references to diseases of domesticated animals such as sheep and cattle that we would now suspect to be the result of infection by parapoxviruses. These references include Jenner's 'spurious' cowpox which is likely to have been caused by the parapoxvirus, pseudocowpox virus. If a little poetic license is permitted it is easy to believe that when, in 1520, Pope Leo X wrote a letter deploring the actions of Martin Luther and stated that 'we cannot suffer the scabby sheep longer to infect the flock', he was making an analogy which indicates knowledge of the disease caused by orf virus and of its infectious nature.

In the latter part of last century reports appeared in the scientific literature which recognized the distinct identities of the diseases caused by members of this genus. Following an extensive study of contagious pustular dermatitis of sheep, Aynaud produced a report in 1923 which included the observation that the disease could be transmitted by a 'filterable' agent. The isolation of each of the viruses in cell culture was reported in the period from 1957 to 1963. Detailed reports of the transmission of each disease to humans appeared in 1933 (orf virus), 1963 (pseudocowpox virus) and 1967 (bovine papular stomatitis virus). The first molecular analyses of parapoxvirus genomes appeared in 1979 with publication of restriction endonuclease cleavage site maps and reports of G+C contents. These were followed, in 1989, by the first description of the DNA sequence of a region of a parapoxvirus genome.

Taxonomy and Classification

The *Parapoxvirus* genus belongs to the family *Poxviridae*, subfamily *Chordopoxvirinae*. The type species of the genus is orf virus and the other species recognized as members are bovine papular stomatitis virus, pseudocowpox virus and a recently identified member, parapoxvirus of red deer in New Zealand. Synonyms by which these viruses have been known include contagious pustular dermatitis virus and contagious ecthyma virus for orf virus and Milker's nodule virus and paravaccinia virus for pseudocowpox virus. Tentative species of this genus are Auzduk

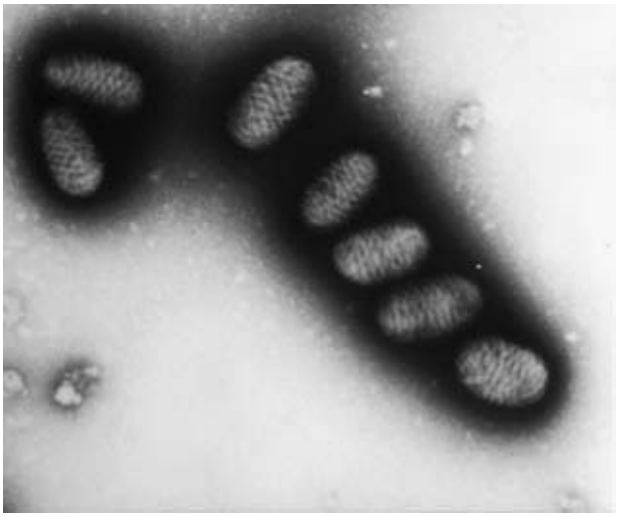


Figure 1 Electron micrograph of a cluster of five negatively stained orf virus particles.

disease virus (camel contagious ecthyma virus), chamois contagious ecthyma virus, sealpox virus and a virus that infects red squirrels.

The three original members of the genus were classified as separate species on the basis of the host animal and/or the pathology of the disease. Likewise, the observation of a parapox-like virus in red deer first suggested that this might represent another species. These separations have been supported by later studies which employed DNA/DNA hybridization, restriction endonuclease profiling or serology.

Properties of the Virion

Parapoxvirus particles are ovoid in shape and measure 220–300 nm × 147–170 nm. In these characteristics they resemble other poxviruses except that parapoxviruses are a little smaller than most other *Chordopoxvirinae* which are also more commonly described as brick-shaped rather than ovoid. A distinctive feature of parapoxvirus virions is their 'ball-of-yarn' appearance when negatively stained specimens are viewed by electron microscopy (**Fig. 1**). This results from a single 10–20 nm wide thread arranged as a spiral coil around the particle. This unique morphology remains the most practical means of confirming a suspected parapoxvirus infection. Such surface tubular elements are seen with other poxviruses but they lack the ordered helical array seen with parapoxviruses. It should be noted that in the case of vaccinia virus it has been suggested that these surface tubules might represent a shrinkage artefact resulting from dehydration during preparation for electron microscopy.

Analysis of thin sections of virions has revealed a lipoprotein bilayer surrounding a biconcave core and two associated lateral bodies. Some particles have an external membranous structure. It seems likely that this is equivalent to the Golgi-derived membrane which forms the outer layer of the extracellular enveloped form of vaccinia virus.

Properties of Viral Proteins

SDS–polyacrylamide gel electrophoresis analyses of orf virus and pseudocowpox virus virions have detected 30 to 40 polypeptides ranging in size from 10 to 220 kDa. Controlled degradation of the virions into core and surface fractions indicated the presence of 10–13 surface polypeptides. Prominent among these were a polypeptide of 39 kDa (orf virus) or 42–45 kDa (pseudocowpox virus) which was suggested to be the subunit of the virion surface tubule protein and a 15 kDa polypeptide. The 39 kDa orf virus polypeptide appears to be a dominant antigen and several independently derived monoclonal antibodies are directed against it.

DNA sequencing of regions of the orf virus genome has allowed the mapping of more than 60 genes. The majority of these are also found in vaccinia virus. Proteins with roles in DNA replication and gene expression are often similar to their vaccinia virus counterparts, with amino acid sequence identities of around 50%. These proteins include DNA polymerase, RNA polymerase subunits, poly(A) polymerase subunits, topoisomerase, dUTPase, RNA helicase and transcription factors. Related viral core and envelope proteins have also been identified. A smaller number of genes do not have counterparts in vaccinia virus and in some cases have no obvious matches in protein sequence data banks. A partial genetic profile of orf virus is listed in **Table 1**.

The genes encoding two major structural proteins of orf virus have been identified. One of these is a 42 kDa protein with strong amino acid sequence similarity to the vaccinia virus protein encoded by gene *F13L*. This vaccinia virus polypeptide is the major, nonglycosylated, 37 kDa protein specific for the extracellular enveloped form of the virus. Cloning and expression of the orf virus gene has shown that both antibody and T cell responses are directed against this protein during infection by orf virus. A second orf virus protein, p10k is a homolog of the vaccinia virus 14 kDa fusion protein encoded by gene *A27L*. This vaccinia virus protein has a surface location and is associated with intracellular mature virus but is required for the formation of extracellular enveloped virus.

Table 1 A partial genetic profile of orf virus.
Each orf virus (strain NZ2) gene is indicated by its location, expressed in kb from the left end of the genome. The orientation of each gene is indicated by an 'R' or 'L' representing transcription toward the right or left genome terminus, respectively. The coordinate given for each gene represents (a) the predicted initiation codon, (b) the termination codon or an internal restriction site. The homologous vaccinia virus genes listed are from strain Copenhagen except for '5k' which is present in strain WR but not in Copenhagen. The listed characteristics are for the vaccinia virus gene products except where no such homolog has been detected. Two genes are located within the inverted terminal repetition (ITR).

Properties of the Genome

The parapoxvirus genome is a single linear double-stranded DNA molecule of about 140 kbp with inverted terminal repeats of about 3.5 kbp in the case of orf virus. The ends of the genome are crosslinked. The G+C content of the genome is high (64%). Restriction endonuclease cleavage site maps have been produced for each of the parapoxviruses except that infecting red deer. These revealed some variability between isolates of the same species, but conserved patterns, consistent with the classification of the genus, were apparent.

DNA sequence derived from numerous points on the orf virus genome, and totalling nearly 30 kbp, has been published. This has revealed a general pattern of genomic organization that is similar to that seen in those orthopoxviruses that have been entirely sequenced. A central region of approximately 90 kbp is highly conserved between the two genera, encoding homologous genes in the same relative order and orientation. Terminal regions show less similarity to other poxviruses and at one end a region of up to 20 kbp appears unlike the DNA sequence reported for any other poxvirus. DNA/DNA hybridization studies suggest that this region may also differ between individual parapoxvirus species.

Passaging of orf virus in cell culture has resulted in genomic rearrangements. A detailed study of one such rearranged isolate showed that 19.3 kbp from the right end of the genome had been duplicated and replaced 6.6 kbp at the left end. This recombination occurred between nonhomologous sequences and caused the deletion of three genes. These alterations to the genome attenuated the growth of the virus in sheep skin. Similar rearrangements have been observed in other isolates.

Physical Properties

Parapoxviruses are resistant to desiccation and in a dried state such as within scab material the viruses retain infectivity for extended periods. Under laboratory conditions infectivity may be maintained over many years. UV light, γ irradiation or heating at 56°C for 1 h cause inactivation of parapoxviruses.

Replication

As with all poxviruses, the replication of parapoxviruses occurs in the cytoplasm of infected cells. Studies in cell culture have shown very similar patterns in the replication of orf virus and pseudocowpox virus. DNA replication begins 4–8 h post-infection (p.i.) and reaches a plateau between 25 and 30 h p.i. The first viral or viral-induced polypeptides appear from 10 h p.i. Viral particles appear 16–24 h p.i. and continue to be produced until at least 40 h p.i. Viral replication is accompanied by inhibition of host DNA and protein synthesis. Some orf virus genes have been shown to be transcribed when infection occurs in the presence of an inhibitor of DNA synthesis and therefore fit the definition of early poxvirus genes. The transition between early and late replication events occurs about 8–10 h p.i. The presence in orf virus of genes with homology to vaccinia virus intermediate genes encoding late gene transactivators suggests that expression of orf virus genes follow a regulated cascade (early – intermediate – late) similar to that reported for vaccinia virus.

Transcription

Transcriptional analyses of 14 orf virus genes have been published. Ten of these genes are expressed early, three late and one at both early and late times. The identification of transcriptional start points of early genes highlighted adjacent sequences which are very similar to sequences shown to act as transcriptional promoters in vaccinia virus. The three late genes are preceded by a TAAAT transcriptional initiation motif typical of vaccinia virus late genes and all the early genes are followed by a TTTTTNT motif which in vaccinia virus induces termination of early transcripts. The 3′ ends of transcripts derived from one early orf virus gene were mapped to a region 24–32 nucleotides (nt) downstream of a TTTTTNT sequence. These data indicate that A/T-rich transcriptional control sequences characterized in vaccinia virus function in very similar ways in parapoxviruses. The common nature of transcriptional regulation was confirmed by analyzing the transcription of three early genes encoded on a 4.4 kbp fragment of orf virus DNA carried by a vaccinia virus recombinant. The vaccinia virus transcriptional machinery recognized the orf virus promoters and specific transcripts were initiated from the same points as were recorded for these genes in RNA from orf virus-infected cells. Analysis of expression of orf virus antigens expressed from vaccinia virus recombinants carrying large multigene fragments of orf virus DNA suggests that orf virus late genes are also faithfully transcribed from their own promoters by vaccinia virus.

Host Range and Virus Propagation

Natural infection by orf virus has been reported in domestic, bighorn and thinhorn sheep, domestic and Rocky Mountain goat, chamois, Himalayan thar, musk-ox, reindeer, steenbok and humans. Experi-

mental inoculations have shown that monkeys are susceptible to orf virus but a wide range of other animals including mouse, rabbit, dog, cat and domesticated chickens are resistant. Bovine papular stomatitis virus and pseudocowpox virus both establish infection in cattle and humans but all other species tested, including sheep, are resistant. The parapoxvirus of red deer induces only very mild lesions on sheep and has not been tested in other species. The parapoxvirus of seals has been reported in a range of seals and sea lions. Parapoxviruses do not produce lesions on the chorioallantoic membrane of developing chick embryo.

The most widely used cell culture systems have been primary ovine or bovine cells derived from sources such as testis, skin biopsy and embryonic kidney, lung and muscle. There have also been reports of orf virus isolates adapted to growth in established cell lines. Yields of infectious orf virus from cell culture tend to be 10- to 100-fold lower than that achieved with vaccinia virus.

Serologic Relationships

Parapoxviruses show extensive antigenic crossreactivity, although monoclonal antibodies have been able to distinguish each of the species. There are also antigens shared with other poxvirus genera but there is no crossprotection between parapoxviruses and either orthopoxviruses or capripoxviruses.

Epidemiology

The parapoxviruses of cattle and sheep are found throughout the world, essentially wherever their host animal occurs. The viruses are maintained in populations by a combination of chronic infection, frequent reinfection and the environmentally resistant nature of the viruses.

Orf virus shed in scab material can remain infective for lengthy periods and infection of naive animals by virus persisting in heavily contaminated areas such as barns, yards and sheep camps is likely to play a major role in maintaining the disease. One study has shown that if the scab material is ground up so as to release the virus then exposure to field conditions quickly results in inactivation of orf virus. Several studies have shown that a productive infection can be established in animals which have recovered from a previous infection. Such reinfections result in lesions that are smaller and resolve more quickly than primary infections. This short-lived immunity is likely to contribute to the persistence of the disease.

In the case of pseudocowpox virus, it is apparent that infection can be spread within dairy herds by contamination of milking machinery and milkers' hands. The introduction of procedures which reduce damage to teats and improve general hygiene at milking time can control the spread of the disease.

Figure 2 Orf virus lesion on a human face.

Clinical Features

Parapoxviruses cause proliferative lesions that are confined to the skin and oral mucosa with no evidence of systemic spread. Infection is initiated in abrasions and generally proceeds through an afebrile, self-limiting lesion that resolves within 3–9 weeks without leaving a scar. Orf virus lesions are most generally seen around the mouth and nares, hence the infection is commonly referred to as scabby mouth or sore mouth. Lesions are also observed on other parts of the body, for example, the coronet, udder or vulva. Following experimental inoculation of scarified skin, lesions progress through erythema, papule, vesicle, pustule and scab before resolving. Very large, proliferative, tumor-like lesions have been observed. It is likely that these are a result of an immune impairment of the host animal.

Lesions around the mouth can interfere with feeding or suckling and especially in young animals result in failure to thrive. Teat lesions can have similar effects through the inhibition of suckling. Lesions on growing deer antler can affect antler growth and severely affect marketability of the product.

It is probable that all parapoxviruses are able to infect humans, although a human case of the parapoxvirus of red deer has not been reported. Transmission to humans occurs readily although there is little evidence of human to human transmission. Progression of the lesions is essentially as seen in sheep and cattle such that the infection is benign and confined to pustular lesions on the skin at the points of infection (**Fig. 2**). More severe progressive disease

can occur in immune compromised individuals. Severe reactions have also been recorded in otherwise normal individuals in cases of burns and in cases of atopic dermatitis. Erythema multiforme reactions in the form of rashes on the backs of the hands and on the legs and ankles are common.

Histopathology

The histological sequence of events in the skin of sheep after orf virus infection is similar in primary and reinfection lesions, in spite of differences in the magnitude of the lesions and the time to resolve. Antibodies to orf virus envelope proteins have been used to detect orf virus antigen in epidermal keratinocytes, particularly those regenerating the damaged skin. Basal keratinocytes at the root of hair follicles can also contain virus. Some infected cells show evidence of a ballooning-like degeneration. There is no evidence that orf virus infects other, nonepithelial cell-types *in vivo*. Orf virus lesions often exhibit epidermal downgrowths (rete formation) into the dermis. This is particularly marked in primary lesions. Another characteristic feature is extensive capillary dilation and proliferation.

Orf virus lesions contain a dense accumulation of immune and inflammatory cells underneath and adjacent to virus-infected cells. These include neutrophils, lymphocytes (T and B cells) and dendritic cells that stain intensely with major histocompatibility complex (MHC) class II antigens. This dense network of dendritic cells is characteristic of orf lesions in sheep. The function of these cells is not known. The accumulating cells increase and decrease in number in parallel with the presence of virus in epidermal cells. The histology of human orf virus lesions is generally similar to that described in sheep. Comparison of orf virus and pseudocowpoxvirus lesions in humans has not detected any histopathological differences.

Immune Response

Parapoxviruses, in common with other poxviruses, stimulate a vigorous immune and inflammatory response in their hosts, and have evolved to replicate in the presence of this response. In sheep experimentally infected with orf virus, studies in the skin and lymph draining into (afferent lymph) and out of (efferent lymph) local lymph nodes have demonstrated that activated $CD4^+$ (helper) and $CD8^+$ (cytotoxic) T cells, B cells and antibodies are generated as part of the sheep acquired immune response to infection. The cytokines generated in lymph in response to virus reinfection are typical of type 1 antiviral cell-mediated immune responses and include interleukin (IL)-1β, IL-2, tumor necrosis factor (TNF)-α, granulocyte–macrophage colony-stimulating factor, interferon (IFN)-α and IFN-γ. Studies of orf virus reinfection in sheep depleted of specific lymphocyte subsets or treated with the immunosuppressant drug cyclosporin A indicated that at least $CD4^+$ T cells and interferons are important components of the host protective response against infection. These studies also indicated that the cutaneous damage sustained during orf virus infection is due in large part to the virus rather than host immune-mediated.

Sheep infected with orf virus mount detectable antibody responses to a small number of viral antigens but there is considerable individual qualitative and quantitative variation in the response. There is no apparent correlation between antibody titers and severity of viral lesions and passive transfer of antibody does not confer protection against virus challenge.

Pathogenic Determinants

In general, parapoxvirus infection is mild and localized with more severe disease only occurring in stressed or otherwise immune impaired individuals. An intriguing feature of parapoxviruses is the ability to repeatedly infect animals despite an apparently typical antiviral immune response to infection. This may in part be a result of the action of viral-encoded immune modulators. Such factors have been characterized in orthopoxviruses and include decoy receptors for IFN-γ, IL-1 and TNF-α, interferon resistance factors, complement-binding proteins and a viral epidermal growth factor. Parapoxviruses have not been analyzed in the same depth but several possible virulence genes of orf virus have recently been identified.

The first of these to be reported was a homolog of mammalian vascular endothelial growth factor (VEGF). The viral VEGF is expressed early and shows 16–27% amino acid sequence identity to mammalian VEGFs. All isolates of orf virus examined have a single copy of the gene but two major forms of the gene have been detected. Each form of the gene is located in the same relative region of the viral genome and each has a similar level of relatedness to mammalian VEGF, but the two genes are unexpectedly different from one another (only 41% amino acid identity). Mammalian VEGF (also known as vascular permeability factor) is a secreted homodimeric glycoprotein that has specific mitogenic effects on endothelial cells and has a primary role in normal and pathological angiogenesis, including the vascularization of solid tumors. Extensive capillary proliferation

and dilatation is a feature of orf virus lesions and it seems likely that the viral VEGF is involved in generating these features. A number of possible roles for the VEGF-like gene in orf virus biology can be imagined. For example, it may act indirectly to enhance proliferation of the epithelium, the growth substrate for orf virus. Alternatively it might induce vascular leakage and thereby promote the extensive scab formation which is typically seen and which acts as a type of 'spore coat', enabling the virus to persist in the environment. The report that human VEGF can inhibit the functional maturation of dendritic cells hints at a possible immune-modulating role for the viral VEGF.

A second potential pathogenic determinant of orf virus is the recently discovered homolog of interleukin-10 (IL-10). The viral IL-10 is an early gene and the predicted protein is very similar to ovine IL-10 (80% amino acid sequence identity). In a murine thymocyte proliferation assay the viral IL-10 showed the same activity as ovine IL-10. IL-10 suppresses cytokine production by T cells via effects on antigen-presenting cells such as macrophages. The orf virus IL-10 may act to suppress the immune response directed at the viral lesion and thereby delay its clearance. It may also have a role in the short-lived nature of immunity to reinfection.

Neither a VEGF or an IL-10-like gene has been reported in any other poxvirus, although homologs of IL-10 have been discovered in Epstein–Barr virus and equine herpesvirus 2. A pathogenic determinant of vaccinia virus which does have a homolog in orf virus, is the vaccinia virus *E3L* gene which plays a part in the resistance of that virus to interferon. This gene encodes a double-stranded RNA binding protein which inhibits the activation of a double-stranded RNA-dependent protein kinase and thereby prevents the phosphorylation of eukaryotic translation initiation factor 2 and the subsequent inhibition of protein synthesis. An orf virus gene encodes a protein which has 31% amino acid sequence identity to vaccinia virus E3L and conserves the double-stranded RNA binding domain.

Prevention and Control

Orf virus vaccines have been available for many years and are widely used to protect lambs against the debilitating effects of natural infection. These vaccines consist of live and essentially nonattenuated virus which is applied to a scratch on the skin of a leg. The ensuing infection does not interfere with feeding and provides significant protection against infection for some months. However, scab derived from vaccination lesions is likely to contaminate the environment and contribute to the perpetuation of the disease. New vaccines that induce protection but do not shed infectious virus are highly desirable. This might be achieved by deleting genes encoding viral virulence determinants or by delivering in an appropriate way the protective antigens of the virus.

Humans may be infected by parapoxviruses following contact with animal lesions or scab. The viruses in scab associated with animal products such as wool or farm equipment can remain infectious for lengthy periods. Care should be taken to avoid contact between any skin wound and potentially contaminated material.

Future Perspectives

Current studies with orf virus have raised the possibility of developing a vaccine able to protect animals against infection by this virus without generating significant amounts of infectious virus. Such a vaccine would also be likely to reduce the frequency of human infections. It is hoped that in the near future the complete DNA sequence of at least one strain of orf virus will be completed. The completed sequence is likely to provide insights into the pathogenesis of parapoxviruses and may well uncover novel virulence genes.

An area of study with parapoxviruses that is likely to see rapid development is the use of orf virus and perhaps other parapoxviruses as vaccine vectors. It is known that recombinant orf viruses can be constructed using approaches similar to those successfully used with other poxviruses. Several features of orf virus may be advantageous in its development as a vector. These include the restricted host range, the acute lesion that remains localized even in immune suppressed individuals and the long history of inoculating sheep with live orf virus.

PARTITIVIRUSES – FUNGAL (*PARTITIVIRIDAE*)

Said A Ghabrial, Department of Plant Pathology, University of Kentucky, Lexington, Kentucky, USA

Bradley I Hillman, Department of Plant Pathology, Rutgers, The State University of New Jersey, New Brunswick, New Jersey, USA

History

Viruses that occur naturally and multiply in fungi 'mycoviruses' were first discovered about 35 years ago. Interest in an antiviral activity associated with two *Penicillium* species led to the discovery of dsRNA-containing virus particles in fungi. It is now believed that viruses, mainly dsRNA viruses, are of common occurrence in fungi. The isometric dsRNA viruses with divided genomes, currently classified as belonging to the family *Partitiviridae*, were among the first mycoviruses to be studied and characterized. The main reason for the belated discovery of fungal viruses is that they are mostly associated with symptomless infections of their hosts. Because of similarities in biological properties and genome organization, the International Committee on Taxonomy of Viruses (ICTV) has recently grouped together the fungal partitiviruses (family *Partitiviridae*) and the plant cryptoviruses (family *Cryptoviridae*) into one family (*Partitiviridae*) and the family name *Cryptoviridae* was dropped.

Typically mycoviruses, including those in the family *Partitiviridae*, do not lyse their fungal host cells, and there is no evidence that they have an extracellular phase to their life cycles. For viruses with multiple dsRNA segments, the lack of conventional infectivity assays makes it difficult to ascertain the number of dsRNA segments required for infectivity. To elucidate the genome organization of these viruses thus requires that the complete nucleotide sequence of the dsRNA segments be known. To date, only a single virus, *Atkinsonella hypoxylon* virus 1 (AhV-1), in the genus *Partitivirus* has been completely sequenced.

Taxonomy and Classification

The family *Partitiviridae* includes four genera, *Partitivirus*, *Chrysovirus*, *Alphacryptovirus* and *Betacryptovirus*. Viruses in the first two genera infect fungi, those belonging to the other two genera infect plants. The partitiviruses that infect plants (cryptoviruses) are discussed in a separate chapter. Members and tentative members of the genera *Partitivirus* and *Chrysovirus* are listed in **Table 1**. Because the names of the genus *Partitivirus* and the family *Partitiviridae* have the same root, and to avoid confusion, the term 'partitiviruses' will be used in this article to refer to all members of the family and the term 'fungal partitiviruses' will be used to refer to viruses in the genera *Partitivirus* and *Chrysovirus*. The plant partitiviruses will be referred to as 'cryptoviruses'.

Viruses belonging to the family *Partitiviridae* have bipartite genomes composed of two monocistronic dsRNA segments that are usually similar in size. The complete nucleotide sequence of only one partitivirus (AhV-1) is available; partial sequences for some cryptoviruses including the RNA-dependent RNA polymerase (RDRP) sequence of the beet cryptic cryptovirus (BCV) are also available. The RDRP sequence of AhV-1 was more closely related to BCV than to any other dsRNA virus (or (+) strand RNA virus) justifying the grouping together of the plant cryptoviruses and fungal partitiviruses. The RDRP sequences from these two viruses (AhV-1 and BCV), however, were more closely related to viruses in the family *Totiviridae* than to any of the (+) strand RNA viruses. A phenogram showing the relationships among RDRP sequences of several dsRNA viruses including the two partitiviruses is shown in **Fig. 1**.

Transmission

There are no known natural vectors for viruses in the family *Partitiviridae*. The fungal partitiviruses are transmitted intracellularly during cell division and sporogenesis (serial or vertical transmission), and following cell fusion between genetically compatible host strains (lateral or horizontal transmission). The hosts of viruses in the genera *Partitivirus* and *Chrysovirus* belong to the higher fungi classes, Basidiomycotina and Ascomycotina and their anamorphs. The hyphae are septate and grow by extension of the hyphal tip. Virus transmission during vegetative growth occurs as virus particles which accumulate in the peripheral growth zone (the region of the mycelium where septal pores remain unplugged) are translocated with the flow of protoplasm towards the tip. New growth continues to be virus-infected as long as the septal pores connecting the apical hyphal compartment with virus-containing compartments in the peripheral growth zone remain open.

Transmission through asexual spores is highly

Table 1 Members and tentative members in the genera *Partitivirus* and *Chrysovirus*

Members	*Abbreviation*	*Tentative members*	*Abbreviation*
Partitivirus			
Agaricus bisporus virus 4	AbV-4	Diplocarpon rosae virus	DrV
Aspergillus ochraceous virus	AoV	Penicillium stoloniferum virus F	PsV-F
Atkinsonella hypoxylon virus	AhV	Phialophora radicicola virus 2-2-A	PrV-2–2-A
Gaeumannomyces graminis virus 019/6-A	GgV-019/6-A		
Gaeumannomyces graminis virus T1-A	GgV-T1-A		
Penicillium stoloniferum virus S	PsV-S		
Rhizoctonia solani virus	RsV		
Chrysovirus			
Penicillium brevicompactum virus	PbV	Helminthosporium victoriae 145S virus	Hv145SV
Penicillium chrysogenum virus	PcV		
Penicillium cyaneo-fulvum virus	Pc-fV		

efficient as 90–100% virus transmission into single conidial isolates of the fungal hosts can be achieved. Transmission via spores plays an important role in virus dissemination, as fungi produce many types of propagules and often in great profusion. The presence of virus particles in conidiospores has been demonstrated for a number of fungi including those infected with PsV-S, PsV-F, PcV and PbV (see **Table 1** for abbreviations of virus names). The presence of virus particles in the sexual spores (basidiospores) of the cultivated mushroom *Agaricus bisporus*, possibly including the partitivirus AbV-4, has been demonstrated by electron microscopy in thin sections of basidiospores. Unlike the basidiomycetes, the sexual spores (ascospores) of virus-infected filamentous ascomycetes, including *Gaeumannomyces graminis* (which is a host for several viruses in the genus *Partitivirus* including the type species GgV-019/6-A), are virus-free. There is no evidence that virus infection of fungal spores, whether mitotic or meiotic, has any deleterious effects on their viability.

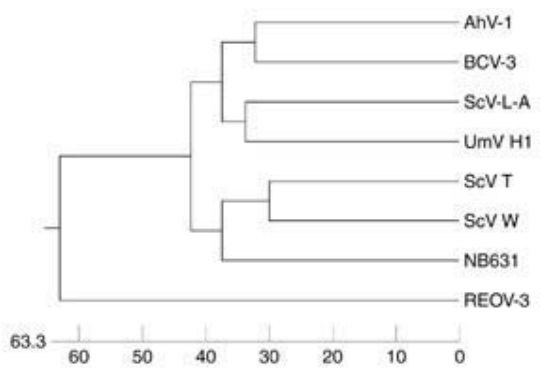

Figure 1 Phenogram summarizing relationships among core RDRP amino acid sequences of several dsRNA viruses including two members of the family *Partitiviridae* (AhV-1 and BCV-3), two members of the family *Totiviridae* (ScV-L-A = Saccharomyces cerevisiae virus L-A and UmVH1 = Ustilago maydis virus H1), and three unclassified nonsegmented dsRNA fungal viruses with genome sizes similar to the largest partitivirus segment (ScVT = Saccharomyces cerevisiae virus T; ScVW = Saccharomyces cerevisiae virus W; NB631 = dsRNA from *Cryphonectria parasitica* isolate NB631). The core polymerase sequence of reovirus-3 (REOV-3) was the outgroup.

Partitiviruses are transmitted intraspecifically from one fungal strain to another via hyphal anastomosis/heterokaryosis. Fungi are known to have a potential for plasmogamy and cytoplasmic exchange during extended periods of their life cycles. Because of vegetative incompatibility, hyphal anastomosis is limited to individuals within a species or within very closely related species. Transmission of several viruses including PsV-S, PsV-F, and PcV, by heterokaryosis has been demonstrated using auxotrophic and colored mutant fungal strains.

Host Range

With the exception of some members of the family *Hypoviridae*, there are no known experimental host ranges for mycoviruses in general including those in the genera *Partitivirus* and *Chrysovirus*. The reason for this is the lack of reliable conventional infectivity assays. The recent availability of infectious RNA transcribed from full-length cDNA to some hypovirus dsRNA has made it possible to extend slightly the host range of hypoviruses. Due to vegetative incompatibility, natural host ranges are restricted to individuals within the species known to be naturally infected with the virus in question. The finding that different fungal species belonging to widely divergent genera may harbor identical or closely related viruses, e.g. the serologically related partitiviruses PsV-S, AoV and DrV which infect *Penicillium stoloniferum*, *Aspergillus foetidus* and *Diplocarpon rosae*, respectively, raises

the question of the presence of vectors or means of transmission other than hyphal anastomosis.

Mixed infections of fungi with two or more unrelated mycoviruses are of common occurrence. Examples of mixed infections involving viruses in the genus *Partitivirus* include GgV-F6-B and GgV-F6-C in *G. graminis* and PsV-S and PsV-F in *P. stoloniferum*.

Virus–Host Relationships

Ultrastructural studies carried out with a number of the fungal partitiviruses including PsV-S, PcV and PbV, indicated that the virus particles accumulate in the cytoplasm of the hyphal compartments and in conidia. Particles often occur as free aggregates or enclosed in single or double-membrane bound vesicles. Whereas the apical hyphal compartments generally contain a small number of particles, virus replication occurs at higher levels in the lower hyphal compartments, particularly in the older plugged compartments which no longer contribute to host growth.

Like other fungal viruses, the partitiviruses generally do not have deleterious effects on their hosts. Because of their intracellular mode of transmission, fungal viruses have probably evolved along with their hosts as persistent subcellular particles. Thus, latency is the rule with mycovirus infections, and viral mutations that lead to pathogenic effects and lysis of host cells are expected to be self-eliminating because of the lack of extracellular mode of transmission.

Particle Properties

The sedimentation coefficients $s_{20,w}$ (in Svedberg units) for members of the genus *Partitivirus* are in the range of 101S to 145S. Buoyant density in CsCl = 1.35–1.36 g cm^{-3}. With some viruses, e.g. PsV-S, purified preparations contain, in addition to the mature virions (termed V1 and V2, respectively, for particles which separately encapsidate the bipartite dsRNA genome of 1.6 and 1.4 kbp, **Fig. 2**), sedimenting and density components that represent empty particles and intermediate components in the replication cycle. The latter include particles encapsidating single stranded (ss) RNAs, presumably the messenger sense strands of V1 and V2 dsRNAs, respectively; and intermediate particles containing both ss- and dsRNA (**Fig. 2**).

Particle Structure and Composition

The fungal partitiviruses have isometric particles, 30–35 nm in diameter, with icosahedral symmetry. The capsids are single-shelled composed of a single major polypeptide. The protein shell consists of 120 subunits of molecular mass in the range of 56×10^3–73×10^3 (for members of the *Partitivirus* genus), or 60 subunits of molecular mass of 125×10^3 (for members of the *Chrysovirus* genus) arranged in $T = 1$ lattices. The virions of members of the genus *Partitivirus* contain two unrelated segments of dsRNA, in the size range 1.3–2.2 kbp, one encoding the capsid polypeptide and the other an unrelated polypeptide, probably the virion-associated RNA polymerase. The two segments are usually of similar size, e.g. the sizes of the two dsRNAs (kbp) of GgV-019/6-A, GgV-T1-A, AbV-4, and RsV-717 are (1.7, 1.8), (2.1, 2.2), (2.0, 2.2) and (2.0 and 2.2), respectively. PsV-F and PrV-2-2-A each contain three dsRNA segments with sizes (kbp) of: 1.5, 1.3, 0.67 and 1.9, 1.8, 1.5, respectively. Sequence analysis of AhV-1 revealed that the three segments have sizes of 2180 (RDRP), 2135 (capsid protein) and 1790 bp. With the exception of the termini, the three segments are unrelated to each other. The absence of any long ORF on either strand of segment 3 (1790 bp) of AhV-1 and its unrelatedness to segments 1 or 2 suggest that it is a satellite segment, not required for virus replication. An unrelated *Partitivirus* of *A. hypoxylon*, AhV-2, contains two dsRNA segments of 2.2 and 1.6 kbp. A comparison of the two serologically closely related viruses GgV-019/6-A and GgV-38-4-A reveals that whereas the former has two dsRNA components, dsRNA1 and dsRNA2, the latter has three segments dsRNA1, 2 and 3. The dsRNA1 from GgV-019/6A and the corresponding one from GgV-38-4-A show a high degree of sequence similarity, as indicated by T1 oligonucleotide fingerprinting analysis and saturation hybridization assays. This is also true for dsRNA 2 from the two viruses. On the other hand, dsRNA3 from GgV-38-4-A has little or no sequence similarity to dsRNA1 or 2 from either virus suggesting that it is probably not required for replication, and may be regarded as satellite dsRNA. Why so many of these viruses contain satellite or defective dsRNA segments is an open question.

The particles of viruses in the genus *Chrysovirus* contain three unrelated dsRNA components with sizes in the range 2.8–3.5 kbp. Thermal denaturation and electron microscopy heteroduplex studies suggest that each dsRNA segment of PcV contains unique sequences. The three segments are separately encapsidated, and each is probably monocistronic. Some virus isolates encapsidate additional segments, which are probably satellite or defective dsRNAs.

Antigenic Properties

The fungal partitiviruses are efficient immunogens. Members and possible members which are serologically related, e.g. PsV-S, DrV and AoV, may be strains of a virus species.

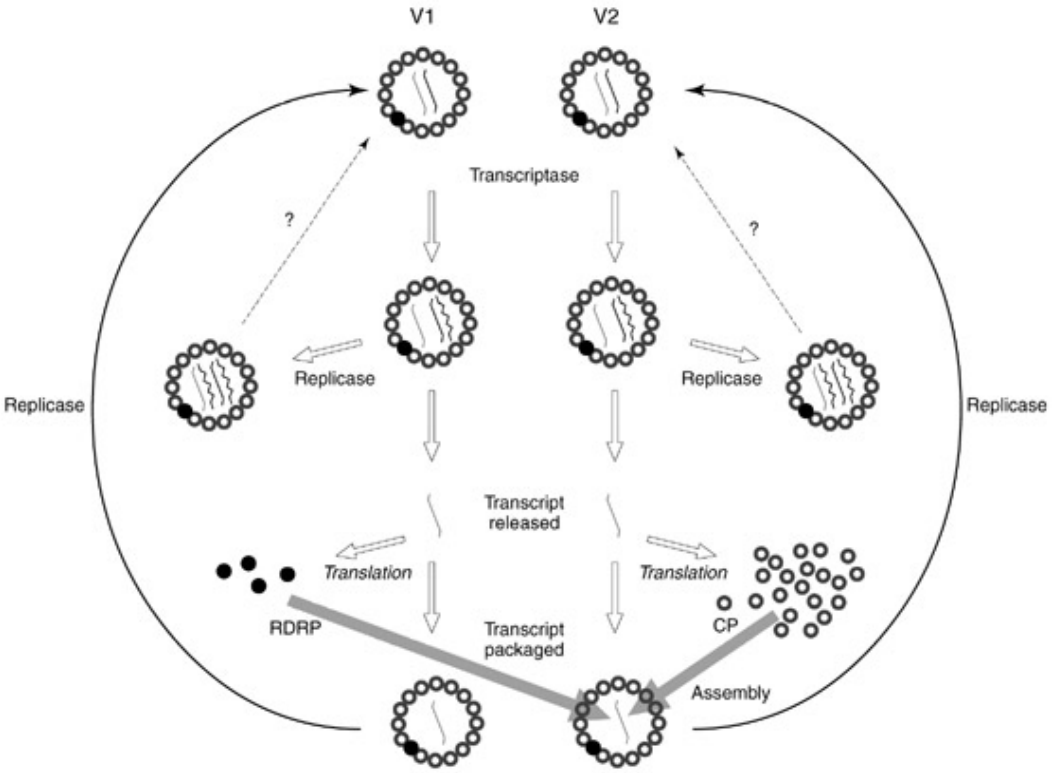

Figure 2 Model for replication of *Penicillium stoloniferum* S virus (PsV-S). The open circles represent capsid protein subunits and the closed circles represent RNA polymerase subunits. Solid lines represent parental RNA strands whereas wavy lines represent newly synthesized progeny RNA strands.

Transcription/Translation

All fungal partitiviruses so far examined have been shown to possess virion-associated RNA polymerase activity. The RNA polymerases associated with GgV 09/6-A and GgV 38-4-A are transcriptases which catalyze the synthesis and release of ssRNA copies of one of the strands of each of the virus template dsRNA molecules. Present evidence favors the idea that the *in vitro* transcription reaction occurs by a semi-conservative mechanism. Thus, the released ssRNA represents a displaced strand of the parental dsRNA and the newly synthesized strand becomes part of the dsRNA duplex.

In a rabbit reticulocyte lysates system, the ssRNA transcripts of GgV-38-4-A dsRNA1, 2 and 3 have each been shown to direct the synthesis of a major polypeptide, with molecular mass 62, 55 and 52 kDa, respectively. The three polypeptides are unrelated, as revealed by peptide mapping. The capsid polypeptide of the virus is encoded by dsRNA2 since the *in vitro* translation product of the ssRNA2 transcript co-migrates with the authentic virus capsid protein. The close serological relationship of GgV-38-4-A and GgV-019/6-A (the type species of the family *Partitiviridae*), coupled with the known sequence similarity of dsRNA2 from the two viruses, indicates that dsRNA2 of GgV-019/6-A also codes for the capsid polypeptide. Because GgV-O19/6-A has only two genome segments and requires the entire coding capacity of dsRNA2 for the capsid polypeptide of molecular mass 60 kDa, dsRNA1 probably encodes the virus RDRP. The dsRNA1 segments from GgV-38-4-A and that from GgV-019/6-A show extensive sequence similarity suggesting that the sequence of the putative RDRP sequence is highly conserved between these two strains. Lack of cross-hybridization of similar-sized dsRNA segments 1 or 2 from the two different partitiviruses infecting *A. hypoxylon*, coupled with the absence of serological cross-reactivity of their particles, supports the idea that the viruses are only distantly related. Relationships of the *A. hypoxylon* viruses to other partitiviruses are unknown.

Virus Replication

Current knowledge on how the fungal partitiviruses replicate their dsRNAs are derived from *in vitro* studies of virion-associated RNA polymerases and the isolation from naturally infected mycelium of particles that represent various stages in the replica-

tion cycle. The fungal partitivirus PsV-S serves as an example (**Fig. 2**). As indicated earlier, purified virus preparations are known to contain several classes of particles: the mature virions V1 and V2 which are composed of the two genomic dsRNA segments separately encapsidated in identical capsids; a small proportion of particles contain ssRNAs corresponding to the (+) strand of the genomic dsRNAs. Furthermore, purified virus preparations still contain a large proportion of a heterogeneous population of more dense particles than the mature virions. These particles represent various stages in the replication cycle which include: (1) particles containing the individual genomic dsRNAs with ssRNA tails of varying lengths; (2) particles with one molecule of dsRNA and one molecule of its ssRNA transcript; and (3) particles with two molecules of dsRNA. In *in vitro* reactions, only the particles with one molecule each of ds- and ssRNA exhibit RNA polymerase activity even though the capsid protein compositions of all three particle types are identical: all contain 120 molecules of the 56 kDa capsid polypeptide and one molecule of another polypeptide, presumably the RDRP. The reasons for lack of RDRP activity *in vitro* by particles containing only dsRNA or ssRNA are not known. The *in vitro* RDRP activity present in the particles with dsRNA + ssRNA is a replicase activity directing the completion of all the intermediate stages of the replication reaction to form particles with two molecules of dsRNA. The replication reaction occurs semiconservatively, as can be demonstrated by density labeling experiments, and probably takes place in two stages. In the first stage, the newly synthesized (+) strand displaces a parental strand of the same polarity and becomes part of the duplex. In the second stage, the displaced parental strand serves as a template for the synthesis of dsRNA. It is believed that the RDRP protein acts both as a transcriptase and a replicase. The transcriptase activity catalyzes the synthesis of (+) strand on parental dsRNA templates followed by the displacement of the parental (+) strand; the replicase activity catalyzes synthesis of (−) strand on the displaced parental (+) strand. There is no evidence for release of newly synthesized dsRNA from particles with two molecules of dsRNA.

PARVOVIRUSES (*PARVOVIRIDAE*)

Contents

General Features

Caroline R Astell, Department of Biochemistry and Molecular Biology, University of British Columbia, Vancouver, Canada

Taxonomy and Classification

The family *Parvoviridae* includes a group of small, single-stranded viruses that infect a wide range of animals, causing severe disease in many. The family consists of two subfamilies, the vertebrate viruses, members of the *Parvovirinae*, which this article deals

observed with other parvoviruses. These small mRNAs were shown to express a 7.5 kDa protein and a family of three 11 kDa proteins (**Fig. 2**) in transfected and infected cells. The proteins are both proline-rich. The functions of the 7.5 kDa and 11 kDa proteins have not been determined.

Replication

The autonomous viruses (e.g. MVM and B19) replicate in dividing cells. For MVM the normal lab host cell is mouse LA9 fibroblast cells. B19 virus requires fresh peripheral blood cells. The virus replicates in erythroid progenitor cells. A few cultured cells permit very limited replication, hence B19 virus has not been studied as extensively as MVM or AAV2.

AAV2 requires a helper virus for replication – normally adenovirus, which is believed to alter the intracellular environment providing conditions suitable for AAV2 replication. Recent studies indicate that the ORF 6 product from the adenovirus E4 region is required. Cells exposed to chemical carcinogens or UV light also allow replication in the absence of helper virus.

Gene Therapy

One novel aspect of AAV2 replication is that, in the absence of helper virus, the AAV genome can integrate into the host DNA. This occurs predominantly at a relatively specific site on the q arm of human chromosome 19. The integrated DNA often occurs as tandem integrated copies. Superinfection with adenovirus can rescue integrated AAV2 viral genomes.

The integration process requires at least one terminal hairpin and transient expression of the Rep protein. The phenomenon of integration of AAV2 has led to this virus being engineered as a gene therapy vector. The obvious advantages are site-specific integration plus a virus that apparently does not cause disease. Although the virus can only package ~5000 nt of DNA, much larger DNA sequences coupled to an inverted terminal repeat sequence from AAV2 can be transfected into cells using lipid vesicles. Hence, the packaging size limitation of parvoviruses does not appear to be a major problem. More recently, MVM vectors, although nonintegrating. are being developed for special uses (e.g. as anticancer or antiviral (HIV) agents).

Future Perspectives

The role of parvoviruses in gene therapy (as well as anticancer and antiviral agents) underscores the need to elucidate the molecular mechanisms of parvovirus gene expression and replication, in order that vectors can be optimized for their specific uses. Each virus is sufficiently novel that further studies are justified. When a productive cell line is identified for the human B19 parvovirus, molecular studies with this human pathogen will be important.

Cats, Dogs and Mink

Colin R. Parrish, James A Baker Institute for Animal Health, College of Veterinary Medicine Cornell University, Ithaca, USA

History

The parvoviruses affecting carnivores have a variety of histories. Feline panleukopenia virus (FPV) has been known as an infectious agent of cats since before 1900, and was shown to be a filterable virus during the 1920s. The disease of cats was originally described by a variety of names (e.g. feline distemper, feline infectious enteritis), and during the 1930s several studies showed that those diseases were caused by the same virus. A similar viral disease of raccoons was described during the 1940s, and it appears that the raccoon parvovirus (RPV) is very similar to or identical with FPV. During the 1960s FPV was shown to be the etiologic agent of feline cerebellar ataxia.

Mink enteritis virus (MEV) was first recognized during the late 1940s as the cause of an outbreak of enteric disease amongst mink in Fort William, Ontario, Canada. Initially called Fort William disease, and later mink viral enteritis, the disease was recognized throughout the USA and Europe during

the next decade. Both FPV and MEV were isolated in tissue culture cells during the 1960s, once the requirement of the viruses for rapidly dividing cells for replication was recognized.

Canine parvovirus (CPV) was first recognized as the cause of new diseases in dogs during 1978, and the virus was isolated from dogs in Europe, the USA, Australia and many other countries throughout the world during that year. Serological studies indicate that CPV was a new virus of dogs that was probably first widespread among dogs in Europe around 1974–1976, and which became globally distributed during 1978.

Canine minute virus or minute virus of canines (MVC) was first identified during the 1960s when it was isolated from the feces of clinically normal dogs. Recent evidence indicates that MVC can cause reproductive disease in dogs, and may also be associated with some cases of canine enteritis. Disease caused by MVC appears to be rare, however, and the limited number of cultured cells permissive for the virus means that the virus is rarely isolated or identified.

Aleutian mink disease, caused by Aleutian mink disease virus (AMDV), was first recognized around 1956 in ranch mink of the Aleutian genotype (see below). It was recognized later that all types of mink could develop Aleutian disease. The virus was identified during 1975, and its identity as a parvovirus confirmed during 1980.

Taxonomy and Classification

FPV, CPV, MEV and AMDV are all classified among the autonomous parvoviruses in the genus *Parvovirus*, within the subfamily *Parvovirinae*, in the family *Parvoviridae*.

CPV, FPV and MEV are host range variants of the feline parvovirus. RPV has not been classified, but available evidence suggests that it is similar to or identical with FPV. MVC is classified as a possible parvovirus. CPV, FPV, MEV and RPV are all very closely related antigenically, and isolates differ by <2% in DNA sequence, while AMDV is <50% similar in DNA sequence to the other viruses. The precise relationship of MVC to the other viruses has not been established, but preliminary DNA sequence analysis indicates that there is not obvious homology between MVC and CPV, and the most similar virus appears to be bovine parvovirus. No serological relationship has been described between MVC and any other parvovirus.

Geographic and Seasonal Distribution

CPV, FPV and the related viruses, as well as AMDV, are distributed as widely as their hosts. Limited studies indicate that in most countries the viruses are endemic, although vaccination has partially controlled reported clinical disease by CPV, FPV and MEV amongst many domesticated animal populations. Serological studies indicate that MVC is widely distributed amongst dogs in the USA. The virus has been isolated in the USA, Germany and Italy but its distribution has otherwise not been extensively studied. A seasonal distribution with greatest incidence of disease in the summer has been described for FPV in cats, most likely related to seasonal breeding patterns. The incidence of disease may be related to the population density of the susceptible host – in endemically infected areas, these are mostly young seronegative kittens or puppies. MEV disease is observed mostly during the summer, again due to the densities of susceptible kits, as mink breed and whelp once per year. Incidence of disease appears to be related to the density, immune status and size of the susceptible population. Acute interstitial pneumonitis caused by AMDV is seen only after infection of newborn mink, and therefore is observed only in spring and summer.

Host Range

CPV, FPV, MEV and RPV

The broad host ranges of these viruses have been defined primarily on the observations of disease. All susceptible hosts appear to be members of the order Carnivora, the various viruses causing disease in many species of large and small cats, most members of the family *Canidae*, including wolf-like canids, Asiatic raccoon dogs (*Nyctereutes procyonoides*), Arctic foxes (*Alopex lagopus*) and probably red foxes (*Vulpes vulpes*), common raccoons (*Procyon lotor*), mink (*Mustela vison*) and ringtail coatis (*Nasua nasua*). Ferrets (*Mustela putorius*) do not appear to be naturally susceptible, but cerebellar disease can be induced by experimental infection of neonatal kits. CPV infects wolf-like canids, as well as South American canids and Asiatic raccoon dogs. As well as cats and raccoons, FPV appears to infect foxes. Although FPV and MEV can both infect mink, only MEV isolates appear to be virulent for mink, and it appears that MEV isolates are differentiated from the other viruses by their ability to cause enteric disease in mink.

MVC

MVC is known only in the domestic dog, and the host range has not been investigated.

AMDV

Disease caused by AMDV has been observed mostly in mink, although ferrets are also susceptible to infection and disease. Other carnivores including raccoons, skunks (*Memphitis memphitis*), and martens (*Martes* spp.) are susceptible to infection, but disease has not been described.

Virus Propagation

CPV, FPV, MEV and RPV

Although these viruses replicate only in a limited number of tissues in the older host animal, this is at least partly due to the dependence of viral replication on cellular DNA replication. These viruses can grow in most primary cells or cell lines of feline origin. Only CPV grows well in canine cells in culture. Some cells may not propagate the viruses (e.g. some variants of the MDCK cell line appear to be not susceptible to CPV).

AMDV

Wild-type AMDV isolates grow poorly or not at all in most tissue culture cells, although certain viral strains have been adapted to feline tissue culture by passaging at lower temperature (~31.8°C). The viral strains propagated in tissue culture often do not replicate in mink. AMDV isolates will replicate in mitogen-stimulated mink lymphocytes (primarily B cells) in culture.

Structure

CPV

The atomic structure of the CPV capsid has been solved by X-ray crystallography (**Fig. 1**). This shows that the capsid shell is assembled from 60 copies of the region of the structural proteins common to VP1 and VP2. The exterior of the capsid is 22.4 nm and 28 nm at its narrowest and widest diameters, respectively.

Features observed on the capsid include a prominent 2.2 nm high by 7 nm wide 'spike' at the threefold axis of rotational symmetry. A hollow cylinder around the fivefold axis apparently allows the DNA genome or the N-terminal sequences of some copies of VP2 to pass through in full (DNA-containing) particles. There is a canyon surrounding the fivefold cylinder and a depression or dimple on the twofold axis. DNA is seen to be associated with the interior of the protein coat – at least 11 bases of single-stranded (ss)DNA with each VP2 equivalent.

Neutralizing epitopes are primarily affected by mutations of residues on the surface of the threefold spike, and mutations which affect hemagglutination of CPV are adjacent to the twofold dimple, indicating that is the site of sialic acid binding.

AMDV

Virus recovered from tissues of persistently infected adult mink is degraded to a number of lower molecular weight forms. Particles prepared from tissue culture or from acutely infected neonatal mink contain intact proteins. Monoclonal antibody analysis shows that there are antigenic epitopes specific for the degraded or intact forms of the proteins.

Genetics

CPV, FPV and the closely related viruses contain ssDNA of about 5200 bases, encapsidating the negative-sense strand (complementary to the mRNA). The AMDV genome is about 4750 bases of ssDNA. The structural proteins (VP1 and VP2) are encoded towards the right-hand end of the genome, while the nonstructural proteins are encoded towards the left-hand end. The CPV/FPV-like viruses are thought to express genes from two promoters (at 4 and 40 genome map units), and alternative splicing gives rise to messages for VP1 and VP2, and two nonstructural proteins (NS1 and NS2) (**Fig. 2**). NS2 shares its N-terminal region with NS1, but has a different C-terminal region derived by alternative mRNA splicing. The NS1 protein plays several important roles in DNA replication, but the function of NS2 is not known for CPV.

Mapping of host range differences between CPV and FPV by genetic recombination analysis shows that the canine host range of CPV is determined by a combination of as few as two surface-exposed amino acid residues within the capsid protein, one of which also determines a CPV-specific antigenic epitope. Feline host range differences are seen between FPV and the original strain of CPV. Those were also due to differences in the capsid protein, and the differences mapped to one region of the capsid structure.

The AMDV genome contains two promoters, and encodes two structural proteins (VP1 and VP2), as well as two or three nonstructural proteins. The structural proteins are derived from the same mRNA by differential use of translation start codons, probably by ribosome scanning. The various NS proteins are derived by differential splicing. There are two polyadenylation sites in the AMDV genome, one in the middle of the genome which is used for some NS protein gene messages, while the poly(A) addition site near the 5′ end of the genome is used for the structural and some of the nonstructural gene messages.

Infectious plasmid clones which contain almost

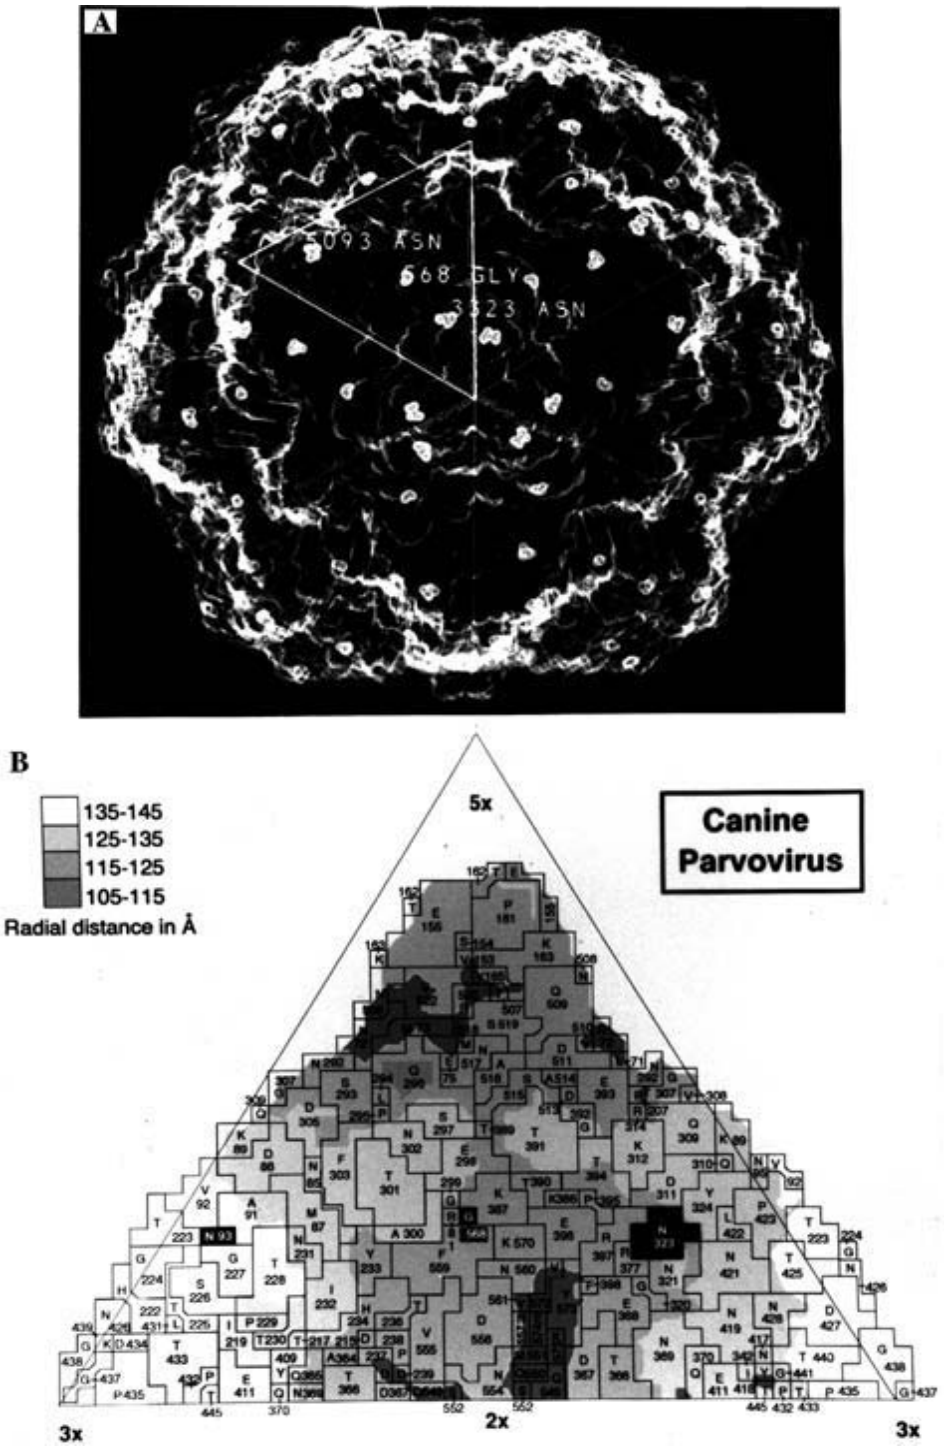

Figure 1 (**A**) The surface-exposed differences between CPV and FPV shown on the structure of the CPV particle which was determined by X-ray crystallography, as described by Tsao J *et al* (1991). (The three-dimensional structure of canine parvovirus and its functional implications. *Science* 251: 1456). The particle model is shown by grid-mesh surfacing, and the view is along the threefold axis of symmetry. The particle is comprised of 60 copies of VP2 (or the very similar VP1). The icosahedral face of the virus indicated by the triangle is comprised of portions of various symmetry-related VP2 molecules. Of the three variant amino acid residues shown on the surface (residues 93, 323 and 375 in the VP2 sequence), residues 93 and 323 are contributed from either the fivefold-related VP2 protein (5093) or the threefold-related protein monomer (3323). (**B**) One icosahedral unit of the virus capsid showing a 'road map' of the surface-exposed amino acids of CPV. Surface-exposed residues which vary between CPV and FPV are indicated by shading. The contours indicate the surface features, including a 'canyon' surrounding the fivefold axis of symmetry and a 'dimple' spanning the twofold axis of the virus. (Figures prepared by Jean-Yves Sgro, Institute for Molecular Virology, University of Wisconsin, Madison, WI, USA.)

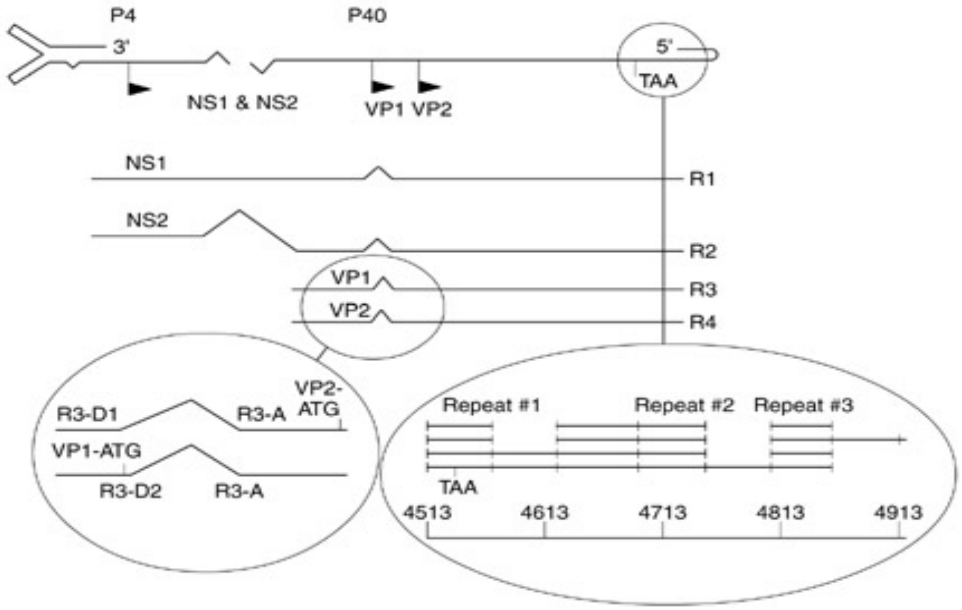

Figure 2 The genetic structure of the genome of CPV and FPV. The ssDNA genome is about 5200 nucleotides in length, and has terminal palindromes of about 150 bases at the 3′ and 5′ ends. Promoters at genomic map units 4 and 40 give rise to messages (R1–R3) for the nonstructural proteins (NS) and capsid proteins (VP), respectively. NS1 and NS2, and VP1 and VP2 are formed by alternative splicing from the same mRNA. Three sequences in the 5′ end of the genome may be present as single or multiple copies.

complete genome sequences have been prepared from CPV, FPV, MEV and AMDV. After transfection of susceptible cells the virus genomes resolve from the plasmids by specific nicking reactions, and infectious viruses are recovered which are indistinguishable from the original viruses.

The DNA sequence of MVC that has been determined indicates that it has a similar genetic organization to the other autonomous parvoviruses.

Evolution

The viruses vary at relatively low rates in nature, and less than 2% of their VP1/VP2 gene sequences over several decades. Sequence analysis shows that the FPV, MEV and RPV isolates are all closely related and comprise one phylogenetic cluster, while CPV isolates form a distinct cluster (**Fig. 3**). The CPV isolates have evolved in a step-wise fashion over time, with a progression of sequences from CPV type 2 to CPV type 2a to CPV type 2b. In contrast, the FPV strains do not show any progressive evolution, and appear to be in evolutionary equilibrium.

Serological Relationships and Variability

By conventional serological techniques (hemagglutination inhibition (HI), serum neutralization), CPV, MEV, FPV and other closely related viruses are difficult to distinguish. Some differences can be revealed by carefully controlled HI and plaque neutralization tests, but the differences are too small to be used for diagnostic purposes.

However, monoclonal antibody analysis readily reveals differences between CPV isolates and the other viruses, there being at least one epitope on all CPV isolates which is not present on any of the other viruses. There is also one (sometimes two) FPV-specific epitope on FPV, MEV and RPV isolates. A virus isolated from an Arctic fox appears very similar to FPV or MEV by DNA sequence analysis and monoclonal antibody typing, and it is quite distinct from CPV isolates.

Monoclonal antibody analysis has revealed variation in antigenic type among MEV isolates collected during the 1970s and 1980s in the USA and Scandinavia. The prevalence of those MEV antigenic variants was not related to the year of isolation, suggesting that these strains are not replacing each other. No difference between the strains was seen in crossprotection studies of animals when vaccinated mink were challenged with the various antigenic types of virus.

Two antigenic variants of CPV have emerged since that virus was observed in 1978. The first variant strain (designated CPV type 2a) emerged around 1979, and by 1981 had replaced the original virus type (designated CPV type 2) in the USA, Denmark, Japan

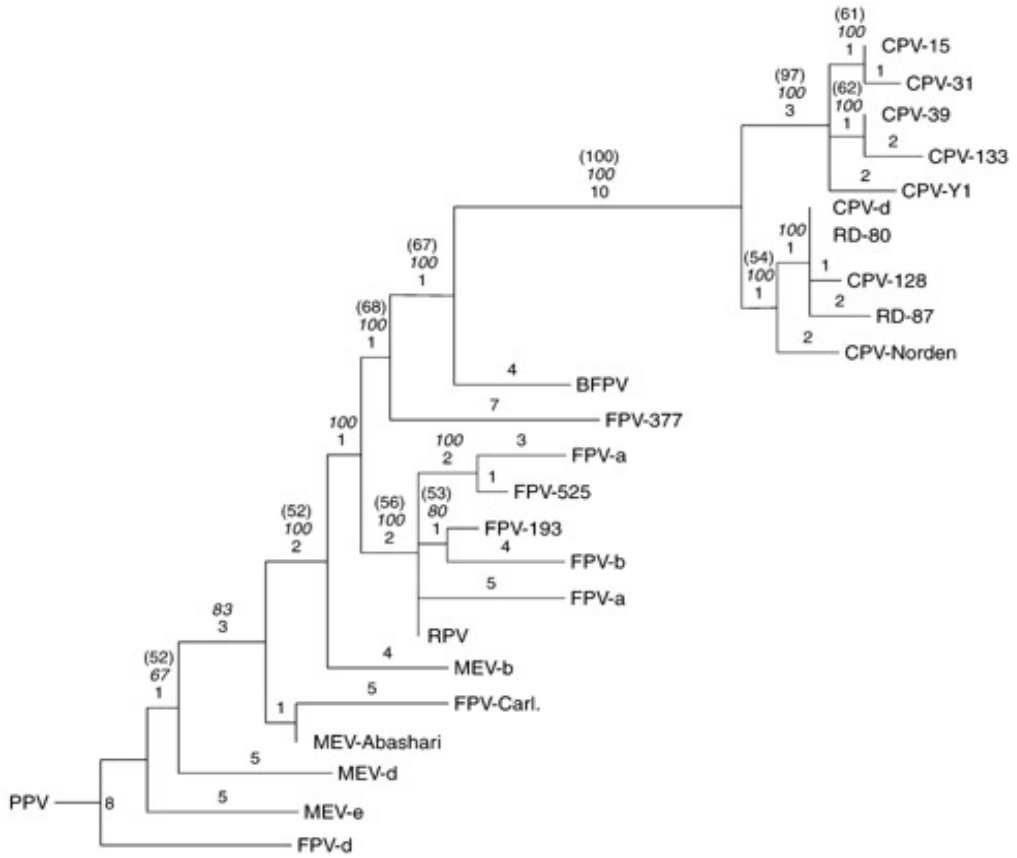

Figure 3 Phylogeny of the DNA sequences of the capsid protein genes of various isolates of dogs and Asiatic raccoon dogs (CPV and RD), cats (FPV), mink (MEV), raccoons (RPV) and Arctic (blue) foxes (BFPV). The numbers shown are the number of nucleotide differences which are present in each branch, the percentage of alternative trees which had that branching order (in italics), and the bootstrap support for that branching order (in parentheses). The tree was rooted using the PPV capsid protein gene sequence as an outgroup. (From Truyen *et al.* 1995 with permission.)

and Australia. A further antigenically variant strain (designated CPV type 2b) emerged around 1984, and by 1988 had become the predominant virus type isolated from dogs in the USA. The CPV-2a and CPV-2b strains each differ from the previous virus type in reactivity of one or two epitopes in the capsid. The variation in virus type was also correlated to the feline host range of the virus. The earliest CPV type (CPV-2) did not replicate in cats, whereas the later strains (CPV-2a and CPV-2b) readily infected cats and caused clinical disease.

Naturally-variant strains of AMDV have been defined antigenically by typing with monoclonal antibodies. The various AMDV isolates differ in virulence for mink. Variation of AMDV has also been shown in the DNA isolated from viruses within AMDV preparations, probably representing mixed virus preparations in tissues used for inoculation. The nucleotide sequences varied by up to 5% between the three principal types of virus sequence (designated types 1, 2 and 3) but the significance of that variation has not been defined.

Epidemiology

CPV, FPV and MEV are shed in high titers in the feces of infected animals, and transmission is via the fecal–oral route. The viruses are highly resistant to inactivation, and may survive in the environment for up to several months. Animals that recover from infection appear to be protected for life from reinfection. Animals born to immune females are protected from infection by maternally derived immunity, and so the susceptible cohort is generally young animals (8–16 weeks of age) with waning maternal immunity. Vaccination is able to protect animals efficiently, but effective immunization is also blocked by maternal immunity.

Spread of the viruses can be very rapid even over long distances; indeed, during 1978, CPV spread

around the world within a few months, even into countries such as Australia and New Zealand with strict quarantine for dogs and cats.

The role of antigenic variation in the epidemiology of these viruses is poorly understood. Antigenic variants of MEV all appear to cocirculate in mink. Variation of CPV has involved the sequential replacement of one viral type by the next, giving rise to the CPV-2a and CPV-2b antigenic types. The selection for the new types is presumably at least in part for the antigenic differences between the viruses, although other epidemiological advantages of the replacing strains may also be present, such as stability of the virus, or increased ability to infect or shed from dogs.

AMDV is shed in the feces, urine and saliva, and as such is readily spread between animals. However, the virus can be eliminated from mink ranch populations by serological testing and subsequent culling of antibody-positive animals, indicating that infected animals do not continuously shed virus.

Pathogenicity

CPV and FPV

Natural differences in virulence of CPV, MEV, RPV and FPV in their normal hosts have not been defined. However, viruses from the various hosts may show differences in virulence when infected into a heterologous host species. For example, although FPV isolates replicate in mink, they do not cause enteric disease, whereas MEV isolates cause severe clinical disease in mink. Attenuated strains of FPV, CPV and MEV have been derived by passage of the viruses in tissue culture, and AMDV and CPV strains which have lost the ability to infect their natural hosts have also been derived by passaging in culture.

The viral factors that result in attenuation of the viruses have not been defined, and the pathobiological basis of the attenuated phenotype is not known. However, some attenuated CPV vaccine viruses are shed at lower titers in the feces, suggesting a reduced replication in the intestinal epithelial cells.

AMDV

The pathogenesis of AMDV disease is at least partly dependent on the genotype of the mink infected. Aleutian mink (named after the Aleutian blue foxes, which have a similar coat color) are most susceptible to clinical disease; these mink suffer from a lysosomal abnormality similar to human Chédiak–Higashi syndrome. However, normal mink also suffer from a similar disease after infection by at least some strains of AMDV. Variation of the virulence of AMDV strains has also been described.

Clinical Features of Infection

Dogs, cats, mink and raccoons affected by CPV, FPV, MEV or RPV respectively suffer from similar enteric diseases. In animals older than about 5 weeks at the time of infection, the first clinical sign is pyrexia between 3 and 5 days after infection, and shortly thereafter virus is shed in the feces. The animals become depressed and lethargic, and may show a panleukopenia (cats) or a relative lymphopenia (dogs). In a proportion of infections (generally fewer than 20%) the animals may develop severe enteritis, with diarrhea and sometimes vomiting. Feces may be mucoid, liquid and flecked with blood. The severity of the disease depends on the condition of the animal – food deprivation prior to infection gives a more severe clinical disease. Animals may become severely dehydrated and die, possibly as a result of the dehydration and also to endotoxemia due to the destruction of the intestinal epithelium. Virus shedding stops once the immune response develops, and surviving animals recover without apparent long-term sequelae. It has been suggested that co-infections with other viral or parasitic agents may give a more severe disease owing to increased replication of crypt epithelium cells of the small intestine.

A number of different syndromes have been described after infection of neonatal or fetal animals. Ataxia may be seen after FPV infection of kittens or ferrets, where the virus replicates in the external germinal cerebellum, resulting in cerebellar hypoplasia. Puppies may develop a multifocal necrosis of the myocardium as a result of CPV infection. The animals die of acute heart failure days to weeks after infection. Many of the clinical signs observed, such as lethargy and dyspnea, are a consequence of the heart failure. Electrocardiographically the pups show a variety of subclinical abnormalities, and death results from ventricular fibrillation.

AMDV

The various clinical syndromes recognized for AMDV infection depend on the age, immune status and genotype of the mink. Infection of mink during pregnancy can result in fetal death or abortion. Kits born to AMDV noninfected dams are susceptible to developing interstitial pneumonia after neonatal AMDV infection, with clinical signs being observed 9–20 days after inoculation. Affected kits suffer from respiratory distress and lethargy, and most die within 24 h of the first observation of clinical signs.

Kits from immune dams or older (immunocompetent) animals develop a chronic disease which, after infection with a highly virulent strain, leads to death of a high proportion of infected animals due to

immune complex-mediated diseases. Affected animals often show few obvious clinical signs until shortly before death due to renal failure or to the rupture of inflamed arteries or enlarged spleens.

AMDV disease is characterized by a hypergammaglobulinemia with circulating immune complexes. The IgG concentration can reach very high levels and in a proportion of affected animals there is a restricted heterogeneity of the IgG produced, suggesting a clonal expansion of some B cell populations. Much of the antibody response is directed against the structural and nonstructural proteins of the virus. In addition, viral replication has been demonstrated in the kidney tubular cells, along with T lymphocytes, indicating that cell-mediated destruction of the kidney tubular cells is probably also occurring.

Pathology and Histopathology

CPV, FPV and MEV diseases

The pathogenesis of these viruses in their respective hosts is determined by the requirement of the parvoviruses for dividing cells for their replication. In fetal or neonatal animals viruses may replicate in a wide variety of tissues. In older animals the viruses replicate primarily in the lymphoid tissues and the intestinal epithelium.

Initial replication after oronasal infection occurs in the tonsils and in the regional or mesenteric lymph nodes, and subsequently in the thymus. Between 4 and 6 days after infection the virus infects the intestinal epithelial cells, and high titers of virus are shed in the feces. The loss of the regenerating epithelial cells results in a flattened attenuated epithelium and shortened intestinal villi. These changes may lead to loss of osmoregulation, resulting in diarrhea. Lymphoid tissues show lymphocytolysis and cellular depletion, followed by tissue regeneration and cellular repopulation in surviving animals. The spleen and bone marrow may be affected with a marked decrease in cellularity and decreases in cells of the myeloid, erythroid and megakaryocytic series. Whether these effects are due to direct viral replication or secondary effects, perhaps to endotoxemia, are unknown at present.

Feline ataxia results from viral replication in the external germinal epithelium of the developing cerebellum of newborn kittens, resulting in cerebellar hypoplasia.

In puppies which develop myocarditis there is a diffuse nonsuppurative myocarditis and often a mononuclear cell infiltration. Myocardial cells often contain Feulgen test-positive amphophilic inclusion bodies. Edema of the lungs is secondary to the acute heart failure.

AMDV

In seronegative newborn mink an interstitial pneumonia results from virus infection of alveolar type II cells of the lung, resulting in decreased surfactant production and causing the observed hyaline membrane disease and respiratory distress. In immune or older animals the virus replicates in various lymphoid tissues, particularly in follicular dendritic cells and macrophages. Probably as a result of infection of such antigen-presenting cells, and also due to the chronic infection and antigen expression by the virus, mink develop very high levels of antibody, and immune complexes are deposited in the kidney tubules and arteries.

Immune Responses

CPV, FPV and MEV

Antibodies appear to play the major role in the active immunity to and recovery from these parvovirus infections. Pups or kittens that acquire antibody from their immune dam are protected against infection until their circulating antiviral antibodies fall to very low levels. Parenterally transferred antibodies will likewise protect dogs against infection by CPV, the antibody acting to prevent systemic replication and spread of the virus. Any role for cellular immunity or secretory antibody is unknown at present. Virus may replicate locally in the gut of passively immunized animals, although at lower levels than in nonimmune animals.

AMDV

Effective protective immunity against AMDV infection, or immunity leading to virus clearance, has not been reported. Although AMDV replication is restricted in mink in the presence of high titers of circulating antiviral antibodies, the virus is not neutralized. The lack of neutralization is due to apparent protection of the virus by a coating of phospholipids or by viral aggregation, and AMDV virus is readily neutralized by antiviral antibody after detergent or organic solvent treatment.

Whereas vaccination with recombinant AMDV capsids had no effect or even enhanced disease, vaccination with the major nonstructural protein NS1 resulted in milder disease, suggesting a role for cell-mediated immunity in the control of the infection in animals.

Prevention and Control of Virus Infection

CPV, FPV and MEV

Vaccination efficiently protects animals against infection by CPV, FPV and MEV. Both inactivated virus and modified live virus vaccines are efficacious, although repeated doses are required to give long-lived protection with inactivated virus vaccines. Maternal immunity will prevent successful vaccination of animals. It appears that wild-type virus from the environment can infect animals with maternal antibodies at an earlier time than the same animals can be successfully vaccinated by parenteral routes. The cause of this 'window' of susceptibility to wild-type virus is not understood.

The control of virus spread between animals is difficult as the viruses are long lived in the environment, and also are shed in high titers in the feces. However, the virus may be inactivated with dilute hypochlorite solutions.

AMDV

No vaccine is available against AMDV, as the immune response is inextricably involved in the pathogenesis of the disease. Control measures involve the identification and culling of infected animals through serological testing, and control of reinfection by quarantine.

Future Perspectives

In future studies the basis of the host range and virulence differences between CPV, FPV and MEV will be defined, and the common features defined, at least in part, in terms of changes in the viral structure. The possible ancestors of CPV amongst the other carnivores should be defined by phylogenetic studies. The restricted but persistent replication of AMDV in mink will be examined, and the roles of the specific immune responses in the restricted replication will be defined. The viral and cellular factors that control replication in mink and in tissue culture cells should also be defined.

Introduction

Parvoviruses are among the smallest and sturdiest viruses known and the only viruses with linear single-stranded (ss) DNA genomes. Due to their limited coding capacity and inability to induce cellular replication, the infection by parvoviruses requires rapidly dividing cells which provide proteins necessary for the infection. Consequently, their pathogenicity is restricted to permissive cells of that nature such as fetal tissue, epithelium and transformed cells.

History

Rat virus (RV) was first isolated from 1959, when Kilham and Olivier were searching for a rat papovavirus in rat embryo cell cultures followed rapidly by the isolation of H-1 virus from cell filtrates. The minute virus of mice (MVM) was isolated in 1966 by Crawford from laboratory stocks of mouse adenovirus. More recently, MPV was identified during the

tion cycle. The fungal partitivirus PsV-S serves as an example (**Fig. 2**). As indicated earlier, purified virus preparations are known to contain several classes of particles: the mature virions V1 and V2 which are composed of the two genomic dsRNA segments separately encapsidated in identical capsids; a small proportion of particles contain ssRNAs corresponding to the (+) strand of the genomic dsRNAs. Furthermore, purified virus preparations still contain a large proportion of a heterogeneous population of more dense particles than the mature virions. These particles represent various stages in the replication cycle which include: (1) particles containing the individual genomic dsRNAs with ssRNA tails of varying lengths; (2) particles with one molecule of dsRNA and one molecule of its ssRNA transcript; and (3) particles with two molecules of dsRNA. In *in vitro* reactions, only the particles with one molecule each of ds- and ssRNA exhibit RNA polymerase activity even though the capsid protein compositions of all three particle types are identical: all contain 120 molecules of the 56 kDa capsid polypeptide and one molecule of another polypeptide, presumably the RDRP. The reasons for lack of RDRP activity *in vitro* by particles containing only dsRNA or ssRNA are not known. The *in vitro* RDRP activity present in the particles with dsRNA + ssRNA is a replicase activity directing the completion of all the intermediate stages of the replication reaction to form particles with two molecules of dsRNA. The replication reaction occurs semiconservatively, as can be demonstrated by density labeling experiments, and probably takes place in two stages. In the first stage, the newly synthesized (+) strand displaces a parental strand of the same polarity and becomes part of the duplex. In the second stage, the displaced parental strand serves as a template for the synthesis of dsRNA. It is believed that the RDRP protein acts both as a transcriptase and a replicase. The transcriptase activity catalyzes the synthesis of (+) strand on parental dsRNA templates followed by the displacement of the parental (+) strand; the replicase activity catalyzes synthesis of (−) strand on the displaced parental (+) strand. There is no evidence for release of newly synthesized dsRNA from particles with two molecules of dsRNA.

PARVOVIRUSES (*PARVOVIRIDAE*)

Contents

General Features

Caroline R Astell, Department of Biochemistry and Molecular Biology, University of British Columbia, Vancouver, Canada

Taxonomy and Classification

The family *Parvoviridae* includes a group of small, single-stranded viruses that infect a wide range of animals, causing severe disease in many. The family consists of two subfamilies, the vertebrate viruses, members of the *Parvovirinae*, which this article deals

with, and the invertebrate viruses, members of the *Densovirinae*. The subfamily *Parvovirinae* consists of three genera: *Parvovirus*, *Erythrovirus* and *Dependovirus*. Although all members of the *Parvoviridae* are similar in structure (single-stranded DNA genome surrounded by a nonenveloped icosahedral protein coat), they differ in detail in host range, pathogenesis and clinical symptoms, as well as in their gene expression and replication (described in *Parvoviruses, Molecular Biology*).

Members of the genus *Parvovirus* are autonomously replicating viruses which require cellular functions associated with the S phase of mitosis in order to replicate. Many *parvoviruses* characterized infect domestic animals: FPV (feline parvovirus or feline panleucopenia virus), CPV (canine parvovirus), BPV (bovine parvovirus), ADV (aleutian mink disease virus), MEV (mink enteritis virus) and PPV (porcine parvovirus), to name a few. These viruses often cause death in fetal or newborn animals, and widespread infection of susceptible animals can have significant financial consequences. There are also many rodent parvoviruses (e.g. MVM, minute virus of mice; H-1, a rat parvovirus; RV, rat parvovirus), and for others the natural hosts are still uncertain (e.g. LuIII, RA1).

Erythrovirus, a relatively new genus, includes human B19 parvovirus plus three distinct primate viruses, SPV (simian parvovirus from cynomolgus monkeys), PTMV (pig-tailed macaque virus) and RMV (rhesus macaque virus). These viruses replicate autonomously in erythroid progenitor cells, causing a transient depression in erythrocytes. In humans with genetic-based hemolytic diseases (e.g. sickle-cell disease, thalassemia, hereditary spherocytosis) that result in reduced red cell half-life, infection by B19 can cause a life-threatening aplastic crisis. This virus can also cross the placenta and infect fetuses, sometimes leading to hydrops fetalis. B19 parvovirus is also responsible for a transient polyarthropathy in ~50% of infected adults.

The third genus, *Dependovirus*, includes several viruses isolated in association with adenoviruses, hence the name adeno-associated viruses or AAV. These viruses include several human serotypes (AAV2, AAV3 and AAV5). AAV5 was isolated from penile cells and, in contrast to all other dependoviruses which require a helper adenovirus (or herpesvirus) for replication, it has been reported to replicate without a helper virus. Other AAV serotypes have been isolated from primates, cattle, dogs and birds.

Geographic and Seasonal Distribution

Parvoviruses have been isolated from infected animals worldwide and new viruses are being reported each year. Seasonal occurrence of parvoviruses has not been well documented; however, in a few studies B19 infections were found to cluster in late spring or early summer. It is difficult to rationalize why this is the case. These viruses are all very stable to inactivation and there are no known (insect or animal) vectors. B19 outbreaks often affect schoolchildren; hence, close association with infected individuals is required for aerosol transmission. With other viruses, seasonal incidence has been noted for FPV, correlating with the age at which kittens lose their maternal protective antibodies. MEV shows a seasonal (summer) occurrence.

Host Range and Virus Propagation

Parvoviruses are noted for their species specificity. MVM infects mice, whereas a closely related virus, H1 (97% sequence identity), infects rats. Within the host, the cells infected are almost always those that are actively dividing (e.g. fetal cells, cells lining the gastrointestinal tract, or cells of the hematopoietic system). In cell culture the species specificity is normally retained. An example of the fastidious nature of these viruses is B19 parvovirus. This virus infects human erythroid progenitor precursors, and in cell culture there is no permissive cell line known, including the erythroleukemia cell lines. Primary isolates of bone marrow cells, fetal liver cells and erythropoietin-stimulated peripheral blood cells will support replication and a few megakaryoblast cells will permit very limited replication. In contrast, the AAV viruses replicate in a number of cell lines when supplied with a helper adenovirus.

Genetics and Evolution

The genomes of the family *Parvoviridae* all consist of single-stranded DNA approximately 4600–6000 nt in length. Members of the genera *Parvovirus* and *Dependovirus* encode both structural and nonstructural proteins on one strand, referred to as the 'positive' or 'plus' strand. (Some members of the *Densovirinae* have their nonstructural and structural proteins encoded on opposite strands.) These viruses vary in their genome packaging strategies. For example, AAV and B19 package both plus and minus strands (in separate particles) in a ratio of 1:1. However, many parvoviruses package predominantly negative strands (e.g. MVM packages 99% minus strands), whereas others (e.g. BPV) package a variable percentage of minus strands from >90% to approximately 70–80%, depending on the host cell. No parvovirus has been characterized that packages predominantly plus strands.

The complete sequence of a number of parvovirus genomes has been reported over the past 18 years. The relatedness of these genomes ranges from >90% to <30%. However, the overall organization of each genome includes terminal inverted repeat sequences (100–300 nt in length) at the ends of the genomes. The remainder of the genome consists of large open reading frames (ORFs) encoding the nonstructural and structural genes. (Note that for viruses that package minus strands, the complement of the genomic DNA encodes the large ORFs.)

Regarding virus evolution, interest has been generated with respect to three closely related viruses, FPV, MEV and CPV. Infection by feline parvovirus has been recognized for more than 100 years. Mink enteritis virus was recognized by the middle of the twentieth century (~1950) and, more recently, CPV (a 'new' dog parvovirus) was recognized in the 1970s. It is believed that CPV evolved from FPV. One hypothesis has suggested that CPV evolved from vaccine strains of FPV, while more recently it has been suggested that the canine virus moved from cats to dogs via an intermediate host such as the fox. Although DNA viruses mutate at a much slower rate than RNA viruses, changes do occur. Studies to map the residues critical to determining the host range of CPV indicate that a very few key amino acid changes in the major capsid protein VP2 are responsible. Similar results have been obtained for MVMp and MVMi, as well as two strains of PPV. MVMp replicates in mouse fibroblasts; MVMi replicates in murine cells of lymphoid origin. This tropism has also been attributed to several amino acid differences in VP2. In each case, the tropism is not exerted at the level of receptor binding but at an, as yet, poorly defined intracellular step in the replication cycle.

Receptors

Over the past decade, a number of cellular receptors for many viruses have been identified. So far, however, few parvovirus receptors have been identified. B19 parvovirus binds to globoside (P-antigen of the P blood group system) on the surface of erythroid progenitor cells. AAV2, which infects a broad range of cell type, uses membrane-associated heparin sulfate proteoglycan as a receptor. Binding of MVM to mouse cells is blocked by neuraminidase, implicating a sialylated membrane protein as the receptor; however, this protein has not been identified.

Epidemiology

Because parvoviruses are very stable to inactivation, they undoubtedly contaminate living areas and can be easily transmitted to other immunologically naive animals. The major routes of transmission are aerosols, oral–fecal, venereal (PPV) and transplacental. Many parvoviruses are endemic in the population, with newborn animals protected by maternal antibodies. Many viruses also appear to exist in a persistent or latent form, causing little illness in adults.

Outbreaks in mink can result in severe disease, especially on mink farms. MEV causes a severe enteritis, while the distinct ADV virus kills young animals as a result of a massive humoral response to both the capsid and noncapsid viral proteins. Most animals die from immune complex glomerulonephritis resulting in kidney failure. PPV, another virus that can have a serious effect on nonimmune animals, causes significant reproductive failure.

B19 virus was identified as the causative agent of erythema infectiosum or fifth disease as recently as the early 1980s. Up to 80% of adults in the population are seropositive. Children are normally exposed during their school years, but if they fail to seroconvert as a child, there is a second wave of seroconversion of parents of school-age children. Immune compromised individuals are at risk of developing a persistent B19 infection.

Pathogenesis

While parvovirus infections are often subclinical, or symptoms are very minor, disease can be significant and death of the host can occur. It has been presumed that disease results from virus replication causing lysis of susceptible cells. Because of the need for actively cycling cells, replication is normally restricted to cells lining the gastrointestinal tract and cells of the hematopoietic system. In fetal animals, many more cells are actively dividing; hence, more types of cells are potentially susceptible. Whether infected cells are killed as a result of cell lysis, toxicity of the major nonstructural protein or induction of apoptosis is as yet unclear. It is generally accepted that the major NS protein of several parvoviruses is very toxic to cells, and recently evidence has been presented that the B19 NS protein is capable of inducing apoptosis.

In one case, disease and death of the infected animals are not the result of virus replication. Aleutian disease in mink causes a relatively mild infection. Death occurs from a massive immune response to both the structural and nonstructural proteins, resulting in immune complex glomerulonephritis and subsequent kidney failure. The characteristic 'slapped cheek' rash observed with B19 infection is also due to immune complexes, as is the associated transient polyarthropathy.

Clinical Features of Several Parvovirus Infections

Feline parvovirus (feline panleukopenia virus)

When FPV is introduced into a susceptible population of cats, all will become infected, although many will have subclinical symptoms. Kittens are especially at risk, with mortality on average ~50%. Perinatal infections can result in cerebellar hypoplasia, and if the infected animal survives it will display a distinctive ataxia that normally lasts for the lifetime of the animal. FPV also causes panleukopenia, a marked depression of all white cells. In addition, enteritis and gastroenteritis are common.

Mink enteritis virus

When MEV is introduced into a susceptible population, the virus spreads rapidly by the fecal–oral route. By 4–7 days postinfection (p.i.) the mink stop eating and develop a severe diarrhea and become dehydrated. Mortality is usually 20–50%. Surviving animals are immune. A vaccine is available, as once a mink ranch has experienced an MEV outbreak, the virus, being so stable, will likely always be present.

Canine parvovirus

CPV infects pups and nonimmune adults. While subclinical infections are common, a severe enteritis or myocarditis can occur and often the animals die. Animals that survive the enteritis recover, with no long-term effects. Puppies are especially susceptible to CPV-induced myocarditis, with a 50% mortality rate. Survivors normally have life-long heart-related problems. There is no treatment for this disease and vaccination of pups is standard in developed countries.

Aleutian disease virus

ADV is distinct from MEV. Both infect mink and are especially troublesome on mink ranches, where thousands of animals are housed in close proximity. Whereas MEV causes severe enteritis within a few days of infection, ADV is associated with persistent, low-level replication. There is a strong immunological response with elevated gammaglobulinemia by 30 days p.i. (3–11 times normal). Infectious immune complexes are readily detected in the serum, and immune complex glomerulonephritis is the cause of death. A recent comparison of both mink parvoviruses in cell culture has shown the MEV virus elicits high levels of viral capsid mRNA and produces large amounts of capsid proteins (80%) compared with NS proteins. In contrast, ADV has a lower level of transcription and 84% of mRNAs encode NS proteins.

Bovine parvovirus

BPV appears to be a common infection in cattle, with 50–90% of animals seropositive. BPV infection causes mild to severe enteritis within 1–2 days. The severity of the disease is increased in animals co-infected with other pathogens. There is some evidence that the virus can cause fetal death.

Adenoassociated virus

Infection with AAV2 continues to be unassociated with any clinical illness. This feature is one of several reasons why AAV vectors designed for use in gene therapy are considered to be preferable.

Human B19 parvovirus

B19 parvovirus is the only pathogenic human parvovirus. Infection is very common, with up to 80% of adults seropositive. This virus is responsible for erythema infectiosum or fifth disease, a relatively minor febrile illness with associated 'slapped cheek' rash. Clinical symptoms are often mistaken for rubella. A small number of infected children may also experience transient joint stiffness. Those who escape infection during their childhood years are again at increased risk as parents of young schoolchildren. In adults, the disease is normally a relatively minor febrile illness; however, as many as 50% (especially women) may develop a mild to severe transient polyarthropathy, normally lasting a few weeks to a few months.

B19 infection of those with an underlying genetic-based hemolytic anemia (e.g. sickle cell disease, thalassemia, hereditary spherocytosis) experience a life-threatening transient aplastic crisis which requires blood transfusion. Also, some fetuses develop hydrops fetalis due to transplacental infections, although the majority of newborns from B19-complicated pregnancies appear to be unaffected in any way. Individuals who are immunocompromised (e.g. human immunodeficiency virus (HIV)-positive, those with hereditary immunodeficiency diseases and acute lymphatic leukemia patients) can also experience aplastic crises and develop a relapsing anemia. These individuals are treated with immune globulin.

It is noteworthy that three additional erythroviruses also replicate in erythroid progenitor cells (all isolated from primates). The best characterized is simian parvovirus (SPV), which replicates in cynomolgus monkeys.

RA1 virus

Around the mid-1980s, RA1 parvovirus was reported as a possible agent of rheumatoid arthritis. It was obtained by multiple passages of synovial tissue

isolate from an individual with rheumatoid arthritis in rodent cells. With time, many have come to suspect RA1 is a rodent virus picked up during passage in rodents. The sequence of RA1 has yet to be published but is reported to be most closely related to BPV.

Detection of Parvovirus Infections

While many parvoviruses elicit distinctive cell morphology in the infected cells, diagnosis of parvoviruses (and many other viral infections) by microscopy has largely given way to immunological and molecular polymerase chain reaction (PCR)-based tests. There are many kits available commercially to detect viral antigens and PCR detection of viral DNA can be extremely sensitive.

Prevention and Control

Vaccines have been available for many parvoviruses that affect domestic animals (e.g. FPV, CPV, PPV) for a number of years. Also, in the mink industry in Denmark, success has been attained by eliminating infected mink. On 'ADV-free' ranches, the litter size is higher and loss due to ADV is significantly reduced.

A vaccine for human B19 virus is being developed. This vaccine will be especially useful for certain groups (e.g. those with hemolytic anemias) that are especially at risk.

Future Perspectives

Over the past decade, many new parvoviruses have been identified. It seems likely that many more will be identified in the next decade due to the use of PCR to detect new viruses. While these new viruses may persist in animals without obvious disease, it is worrisome that they are present as they may be having a subtle yet significant effect.

Note Added

A new human parvovirus has been identified within the past year. This virus is associated with post-transfusion hepatitis of unknown etiology and is referred to as TTV or transfusion transmitted virus.

Structure of Virus Particles

Members of the family *Parvoviridae* are small non-enveloped DNA viruses with particle sizes of 20–26 nm. These viruses are sufficiently small that the structure of the protein capsid of several viruses has been determined by x-ray diffraction. Canine parvovirus (CPV) was the first structure to be described. CPV contains 60 capsomers of predominantly VP2, the major capsid protein (with minor amounts of VP1 and VP3 structurally related proteins). The symmetry of the icosahedral particles is $T = 1$. The three-dimensional structure of VP2 is similar to other viral capsid proteins which include a central core of eight antiparallel β sheets. Overall the particles have a prominent protrusion at the threefold axis and a cylindrical structure at the fivefold axis which is surrounded by a deep canyon-like depression.

Over the past eight years the structures of feline parvovirus (FPV), minute virus of mice (MVM) and recombinant B19 have been reported, although resolution of the B19 crystals was only at 8 Å (0.8 nm), and provided less detail. These structures are in general very similar to the CPV particles with notable differences (e.g. B19 lacks the protrusion at the threefold axis and instead has a depression at this position). When the structure of CPV was completed, it was predicted that, by analogy with the rhinoviruses, the attachment site for cellular receptors may be within the canyon-like depression surrounding the fivefold axis. However, the receptor for B19 has been shown to bind to the depression at the threefold axis.

The parvoviruses contain a linear single-stranded DNA molecule ranging in size from 4600 to 6000 nucleotides (nt). Many viruses package exclusively the negative-sense strand (complementary to the coding strand) whereas some package predominately minus strands. Adeno-associated viruses (AAV), B19 and a

Structure of Virus Particles

Members of the family *Parvoviridae* are small non-enveloped DNA viruses with particle sizes of 20–26 nm. These viruses are sufficiently small that the structure of the protein capsid of several viruses has been determined by x-ray diffraction. Canine parvovirus (CPV) was the first structure to be described. CPV contains 60 capsomers of predominantly VP2, the major capsid protein (with minor amounts of VP1 and VP3 structurally related proteins). The symmetry of the icosahedral particles is $T = 1$. The three-dimensional structure of VP2 is similar to other viral capsid proteins which include a central core of eight antiparallel β sheets. Overall the particles have a prominent protrusion at the threefold axis and a cylindrical structure at the fivefold axis which is surrounded by a deep canyon-like depression.

Over the past eight years the structures of feline parvovirus (FPV), minute virus of mice (MVM) and recombinant B19 have been reported, although resolution of the B19 crystals was only at 8 Å (0.8 nm), and provided less detail. These structures are in general very similar to the CPV particles with notable differences (e.g. B19 lacks the protrusion at the threefold axis and instead has a depression at this position). When the structure of CPV was completed, it was predicted that, by analogy with the rhinoviruses, the attachment site for cellular receptors may be within the canyon-like depression surrounding the fivefold axis. However, the receptor for B19 has been shown to bind to the depression at the threefold axis.

The parvoviruses contain a linear single-stranded DNA molecule ranging in size from 4600 to 6000 nucleotides (nt). Many viruses package exclusively the negative-sense strand (complementary to the coding strand) whereas some package predominately minus strands. Adeno-associated viruses (AAV), B19 and a

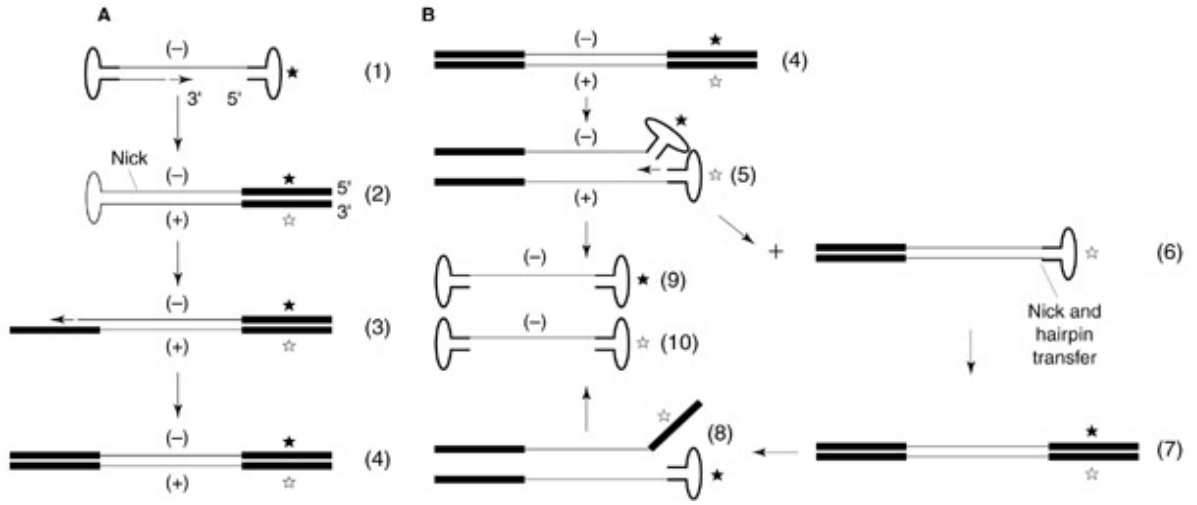

Figure 1 Simplified replication scheme for parvovirus. **A.** Incoming single-stranded genomic DNA (1) is converted into parental RF by strand extension (2). A nick is introduced opposite the site of initiation of strand extension and synthesis of a fully extended, double-stranded monomer RF is achieved (3, 4). **B.** Monomer RF (4) undergoes displacement synthesis (5), displacing a single-stranded progeny strand (9) and generating a covalently closed RF structure (6) which is again converted into a fully extended, double-stranded monomer RF (7) by nicking and hairpin transfer. In diagram (8), displacement synthesis of (7) again generates a single-stranded progeny genome (10). Note that the original genome sequence had a unique sequence denoted by a filled star (1) and the progeny strand (9) has the same sequence. However, repeated hairpin transfer results in two sequences at the end, the filled star (original sequence) (9) and the closely related, inverted complement (10). Hence, in a population of molecules, the hairpin termini exist as two sequences. DNA sequencing studies have shown that two sequences exist at both ends of the AAV genome. MVM, however, has a unique sequence at the left end. The model described is simplified. Both AAV2 and MVM generate dimer RF molecules and resolution of the dimer to monomer length duplex molecules is complex and the mechanism is not fully understood. The result is the left hairpin of MVM DNA contains a unique sequence.

few other viruses package equal amounts of minus and plus strands. No parvovirus packages predominately plus strands.

The structure of the icosahedral capsid results in virus particles which are extremely stable. These particles are resistant to heat inactivation (50° for 30 min) as well as moderate pH ranges (3–11). However, they are inactivated by high pH (>11), formalin, UV radiation, autoclaving, and β-propiolactone.

The DNA Genome

There are two striking features of the parvovirus DNA genome: it is largely a single-stranded DNA molecule and it has terminal hairpin structures at both ends. The ends of the linear genome contain inverted nucleotide sequences (116 to >300 nt in length). This allows the ends to fold back into double-stranded hairpin structures. In addition, within these terminal inverted repeats there are often smaller inverted repeat sequences that result in the termini existing in what has been described as T- or Y-shaped structures.

The viral genomes that have been characterized exist as molecules in which the 5′- and 3 terminal hairpin sequences are unrelated (in sequence) (e.g. MVM,) or they are closely related if not identical (e.g. AAV-2,). The significance of this remains to be determined.

Current models for parvovirus DNA replication propose that incoming parental DNA is converted into a double-stranded molecule using the 3′-OH of the terminal hairpin as a primer. A site-specific nick is introduced opposite the initial site of extension and the parental DNA strand is extended to yield a fully extended (double-stranded) molecule. This process of nicking inboard of the hairpin and strand extension is referred to as 'hairpin transfer' (**Fig. 1A**). Because the terminal sequences are not perfect inverted repeats, hairpin transfer results in two end sequences that are related but the inverted complement of each other. The sequences at the ends of viral DNAs have been sequenced from a population of replicated molecules with replication initiated from a cloned, infectious plasmid DNA (both AAV2 and MVM). Hence, replication began with a single unique sequence at the hairpin ends and two sequences were present in the replicated progeny strands (**Fig. 1B**). These data strongly support the 'hairpin transfer' mechanism for replication of the ends.

Deletion studies have shown that almost all of each hairpin terminus is necessary for efficient replication. Although some nucleotide changes are tolerated, the

overall hairpin structure is necessary. Also, specific binding sites for the viral nonstructural proteins are important. The role of the nonstructural proteins (Rep for AAV2 and NS1 for MVM) is to bind to the hairpin region overlapping the nick site and execute nicking. For MVM it has been established that a cellular DNA binding protein is required in addition to NS1 for nicking to occur. This protein binds distally to the DNA adjacent to NS1. Other cellular proteins involved in replication are presumably most of the host cell DNA replication complex. It is not clear which cellular DNA polymerase is involved.

Studies with MVM have shown that in addition to the hairpin termini, an internal replication sequence (IRS) inboard of the right hairpin is required for efficient replication of recombinant genomes. How the IRS sequence affects replication is unknown, however, it has been suggested that it facilitates initiation of replication at the right hairpin end.

Expression of Viral Polypeptides

The major portion of parvovirus genomes (excluding the hairpin termini) contains two large open reading frames (ORFs). These ORFs are by definition on the plus strand and transcription proceeds in a left to right direction (**Fig. 2**). Using this orientation, the left half of the DNA encodes the NS or Rep proteins while the right half encodes VPs. The pattern of gene expression varies depending on the number of promoters (1–3 promoters).

B19 has a single promoter at map unit 6. Transcription initiates at P6 and proceeds to the opposite end of the DNA. Complex alternate splicing and use of two polyadenylation sites (one in the middle of the genome and one at the right hand end) results in at least nine transcripts which encode NS and VP proteins as well as novel small proteins, the 7.5 and 11 kDa proteins (**Fig. 2**). Of interest is that all nine B19 transcripts contain a common 56 nt leader sequence. Although the B19 transcript map and use of one promoter seemed unusual when it was first discovered, the transcript map for bovine parvovirus is very similar.

MVM is an example of a virus that uses two promoters, P4 for expression of NS proteins and P38 for expression of VPs. All transcripts terminate at the far right of the genome and alternate splicing generates mRNAs that encode two nonstructural proteins (NS1 and NS2) and two VP proteins (VP1 and VP2).

AAV uses three promoters, P5, P19 and P40. The first two initiate transcripts that encode two large and two smaller Rep proteins whereas the P40 promoter generates mRNAs encoding three viral proteins: VP1, VP2 and VP3 (**Fig. 2**).

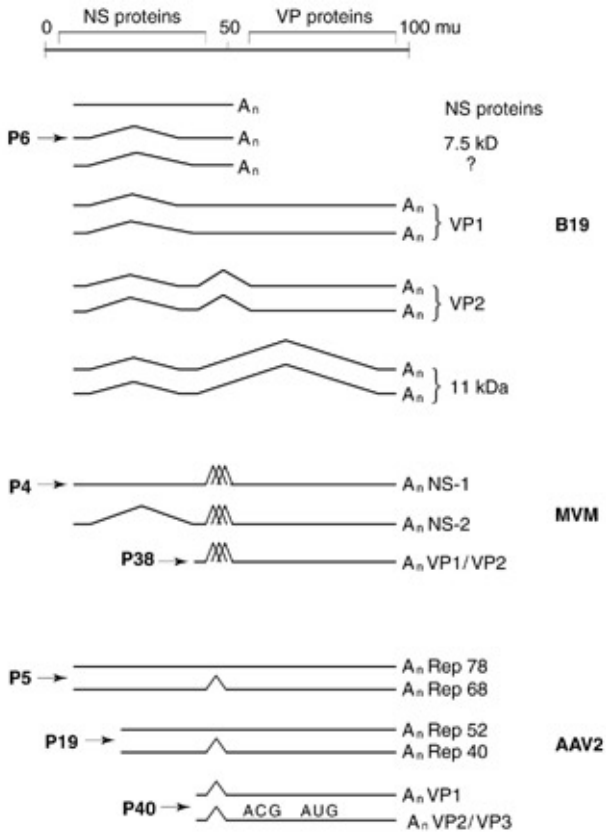

Figure 2 Transcription map of MVM, AAV-2 and B19. Nonstructural proteins (NS) are encoded on the left half of the DNA and structural proteins (VP) on the right half. Exons are represented by horizontal lines joined by brackets (introns). For B19, the nine transcripts that have been mapped are illustrated. All mRNAs contain a 56 nt leader sequence. For MVM the small 'middle' intron can be spliced in three different ways, hence, for each mRNA shown there are three different forms (total of nine mRNAs). All three transcripts coding for the NS-1 protein have the same coding potential as the small intron is 3′ to the stop codon for NS-1. The middle transcript also has three different versions of this small splice and results in three slightly different NS-2 proteins differing in the carboxy terminal residues. Of the three forms of the capsid protein mRNA, one splice allows initiation of synthesis of VP1 ahead of the small splice. The other two RNAs remove this ATG start codon and, thus, VP2 initiation begins to the right of the small splice. For AAV2, there are two mRNAs generated from transcripts initiated at each of the three promoters. The small splice generating the VP1 mRNA has a different splice acceptor from that generating VP2/VP3. VP3 is the major coat protein which initiates at the first AUG codon whereas VP2, a minor coat protein initiates at low frequency at an upstream ACG codon. The promoters for each virus are shown at the left (P6 →, etc.) and the names of the proteins encoded by each mRNA are shown on the right.

The processing of transcripts from all viruses is complex. The selection of intron donor and acceptor sites results in variable amounts of transcripts. For

example, in MVM and AAV, use of alternate splice acceptor sites results in synthesis of low levels of the largest coat protein (VP1) and high levels of the smaller, major coat protein, VP2 and VP3, respectively.

Regulation of gene expression for multiple promoter viruses is controlled by *cis*-acting sequences and transacting factors (both viral and cellular). The major NS proteins of MVM (NS1) upregulates expression of both the P38 and P4 promoters. NS1 binds to $(ACCA)_n$ repeats located upstream of the transcription start sites. An Sp1 motif and TATA box also function in upregulating the P38 promoter and studies have shown that NS1 and SP1 can interact on the absence of the promoter sequence.

Analysis of the DNA sequence near established promoters in many viruses has identified multiple motifs known to bind cellular transactivators. Although many of these motifs are present near parvovirus promoters, in most cases involvement of the cognate transactivator has not been demonstrated. An exception is YY1 which enhances expression of the B19, P6 promoter. It also binds to the +1 region of the AAV2 P5 promoter and allows basal level transcription from this promoter.

For AAV2, the Rep protein stimulates transcription of the P40 promoter, however, the response of the P5 and P19 promoters to Rep varies depending on conditions within the host cell. In the absence of helper virus, Rep protein normally downregulates P5 and P19.

The temporal regulation of early and late gene expression has been studied in MVM and BPV. There is evidence that NS encoding transcripts are expressed earlier than VP encoding transcripts. However, there is not as clear a demarcation between early versus late transcripts, as is seen with some DNA viruses.

Viral Nonstructural and Structural Proteins

Nonstructural proteins (NS, Rep)

The left ORF of parvoviruses encodes nonstructural proteins. MVM makes two NS proteins; a large 80 kDa protein (NS1) is required for replication and gene expression. Alternate splicing also generates a mRNA encoding the NS2 proteins (24 kDa) which exists as three closely related proteins with minor differences in amino acid sequence at the C-terminal as a result of three splicing variations of the small intron near the middle of the genome. The role of NS2 is uncertain. It appears to contribute to viral pathogenesis and also affects folding of viral structural proteins. The AAV2 virus expresses two versions of a large Rep protein (78 and 68 kDa) and two versions of a smaller Rep protein (52 and 40 kDa) depending on the promoter used (P5 or P19) (**Fig. 2**).

The NS1 protein of MVM and two larger Rep proteins of AAV function in gene expression and DNA replication. These proteins have been overexpressed and purified. They contain an intrinsic helicase, ATPase, and site-specific nickase. They also have a transactivation domain, nuclear localization signals and DNA binding domain. The *cis*-acting sequences required for binding the NS proteins have been mapped. Also, the binding sequences within the terminal hairpin structures have been identified. The function of the ATPase is likely associated with the helicase which functions in strand displacement synthesis. Both the large Rep proteins of AAV2 and NS1 of MVM have been shown to be covalently attached to the 5′ end of the genome. This occurs during nicking of the DNA. The attached NS protein is usually removed from packaged viral genomes (presumably by nucleolytic trimming of the 5′ end of the genome). However, particles with NS1 external to the capsid and covalently linked to the 5′ end of the genome have been characterized. Both the large Rep protein and NS1 have also been shown to multimerize and this is likely important for the replication function of these proteins.

As mentioned above, the NS1 protein of MVM interacts with Sp1. Recent reports have identified two other cellular proteins that also appear to interact with the NS1 of MVM and of H1 (a closely related rodent parvovirus). One protein is a novel hnRNP-like protein and it may be involved in regulating mRNA biogenesis.

Structural proteins

Parvovirus capsids are composed of two and in some cases three viral proteins. The coding of these proteins is entirely overlapping. A minor VP1 protein is expressed in addition to a major (shorter) VP2 protein generated from an alternately spliced transcript. MVM has a small amount of a third capsid protein, VP3, which results from proteolytic cleavage of VP2. AAV-2 also has two minor capsid proteins, VP1 and VP2. VP2 is translated from an alternately spliced mRNA using an internal ACG inititating codon at low frequency. The major coat protein, VP3, is expressed from the same spliced mRNA at a downstream AUG codon (**Fig. 2**).

Small proteins

When the transcripts for human B19 parvovirus were characterized it was recognized that there were two classes of small, abundant, spliced RNAs, so far not

observed with other parvoviruses. These small mRNAs were shown to express a 7.5 kDa protein and a family of three 11 kDa proteins (**Fig. 2**) in transfected and infected cells. The proteins are both proline-rich. The functions of the 7.5 kDa and 11 kDa proteins have not been determined.

Replication

The autonomous viruses (e.g. MVM and B19) replicate in dividing cells. For MVM the normal lab host cell is mouse LA9 fibroblast cells. B19 virus requires fresh peripheral blood cells. The virus replicates in erythroid progenitor cells. A few cultured cells permit very limited replication, hence B19 virus has not been studied as extensively as MVM or AAV2.

AAV2 requires a helper virus for replication – normally adenovirus, which is believed to alter the intracellular environment providing conditions suitable for AAV2 replication. Recent studies indicate that the ORF 6 product from the adenovirus E4 region is required. Cells exposed to chemical carcinogens or UV light also allow replication in the absence of helper virus.

Gene Therapy

One novel aspect of AAV2 replication is that, in the absence of helper virus, the AAV genome can integrate into the host DNA. This occurs predominantly at a relatively specific site on the q arm of human chromosome 19. The integrated DNA often occurs as tandem integrated copies. Superinfection with adenovirus can rescue integrated AAV2 viral genomes.

The integration process requires at least one terminal hairpin and transient expression of the Rep protein. The phenomenon of integration of AAV2 has led to this virus being engineered as a gene therapy vector. The obvious advantages are site-specific integration plus a virus that apparently does not cause disease. Although the virus can only package ~5000 nt of DNA, much larger DNA sequences coupled to an inverted terminal repeat sequence from AAV2 can be transfected into cells using lipid vesicles. Hence, the packaging size limitation of parvoviruses does not appear to be a major problem. More recently, MVM vectors, although nonintegrating. are being developed for special uses (e.g. as anticancer or antiviral (HIV) agents).

Future Perspectives

The role of parvoviruses in gene therapy (as well as anticancer and antiviral agents) underscores the need to elucidate the molecular mechanisms of parvovirus gene expression and replication, in order that vectors can be optimized for their specific uses. Each virus is sufficiently novel that further studies are justified. When a productive cell line is identified for the human B19 parvovirus, molecular studies with this human pathogen will be important.

Cats, Dogs and Mink

Colin R. Parrish, James A Baker Institute for Animal Health, College of Veterinary Medicine Cornell University, Ithaca, USA

History

The parvoviruses affecting carnivores have a variety of histories. Feline panleukopenia virus (FPV) has been known as an infectious agent of cats since before 1900, and was shown to be a filterable virus during the 1920s. The disease of cats was originally described by a variety of names (e.g. feline distemper, feline infectious enteritis), and during the 1930s several studies showed that those diseases were caused by the same virus. A similar viral disease of raccoons was described during the 1940s, and it appears that the raccoon parvovirus (RPV) is very similar to or identical with FPV. During the 1960s FPV was shown to be the etiologic agent of feline cerebellar ataxia.

Mink enteritis virus (MEV) was first recognized during the late 1940s as the cause of an outbreak of enteric disease amongst mink in Fort William, Ontario, Canada. Initially called Fort William disease, and later mink viral enteritis, the disease was recognized throughout the USA and Europe during

Prevention and Control of Virus Infection

CPV, FPV and MEV

Vaccination efficiently protects animals against infection by CPV, FPV and MEV. Both inactivated virus and modified live virus vaccines are efficacious, although repeated doses are required to give long-lived protection with inactivated virus vaccines. Maternal immunity will prevent successful vaccination of animals. It appears that wild-type virus from the environment can infect animals with maternal antibodies at an earlier time than the same animals can be successfully vaccinated by parenteral routes. The cause of this 'window' of susceptibility to wild-type virus is not understood.

The control of virus spread between animals is difficult as the viruses are long lived in the environment, and also are shed in high titers in the feces. However, the virus may be inactivated with dilute hypochlorite solutions.

AMDV

No vaccine is available against AMDV, as the immune response is inextricably involved in the pathogenesis of the disease. Control measures involve the identification and culling of infected animals through serological testing, and control of reinfection by quarantine.

Future Perspectives

In future studies the basis of the host range and virulence differences between CPV, FPV and MEV will be defined, and the common features defined, at least in part, in terms of changes in the viral structure. The possible ancestors of CPV amongst the other carnivores should be defined by phylogenetic studies. The restricted but persistent replication of AMDV in mink will be examined, and the roles of the specific immune responses in the restricted replication will be defined. The viral and cellular factors that control replication in mink and in tissue culture cells should also be defined.

Rodents, Pigs, Cattle and Waterfowl

Peter Tijssen, Mohamed Laakel, Zoltán Zádori and **Benoît Hébert**, Institut Armand-Frappier, Université du Québec, Laval, Canada

Introduction

Parvoviruses are among the smallest and sturdiest viruses known and the only viruses with linear single-stranded (ss) DNA genomes. Due to their limited coding capacity and inability to induce cellular replication, the infection by parvoviruses requires rapidly dividing cells which provide proteins necessary for the infection. Consequently, their pathogenicity is restricted to permissive cells of that nature such as fetal tissue, epithelium and transformed cells.

History

Rat virus (RV) was first isolated from 1959, when Kilham and Olivier were searching for a rat papovavirus in rat embryo cell cultures followed rapidly by the isolation of H-1 virus from cell filtrates. The minute virus of mice (MVM) was isolated in 1966 by Crawford from laboratory stocks of mouse adenovirus. More recently, MPV was identified during the

mid-1980s due to differences in hemagglutinating properties between MVM and this new agent.

Bovine parvovirus (BPV) was isolated by Abinanti and Warfield in 1961. Originally, this virus was known by its acronym HADEN ('hemadsorbing enteric') which indicated the ability of infected cells to adsorb erythrocytes and the isolation of the virus from gastrointestinal tracts. BPV is endemic and is mainly associated with enteritis and respiratory infections in association with other agents.

Porcine parvovirus (PPV) is a major disease-causing agent in pigs. Although the major syndrome known as SMEDI (stillbirths, mummification, embryonic death and infertility) was described by Dunne and co-workers in the mid-1960s, PPV was isolated and differentiated from the enterovirus agents for the first time in 1975. PPV strains have been isolated from different sources and have also been associated with other syndromes such as respiratory infections, dermatitis, enteritis and rhinitis.

The goose parvovirus (GPV) was first isolated among the waterfowl parvoviruses (WFPs). GPV causes a highly contagious and fatal disease of goslings and muscovy ducklings which emerged in the middle of the 1960s and was known under different names: goose influenza (Hungary), infectious myocarditis (Italy), hepatonephritis ascites (France), viral enteritis (former USSR), goose plaque (The Netherlands) and goose hepatitis (Germany). The working group of the World Poultry Scientific Association named it Derzsy's disease after the late Domokos Derzsy. In 1971, Schettler isolated the causative agent and showed it to be a parvovirus.

Muscovy duck parvovirus (MDPV) and GPV are closely related to each other. MDPV was isolated in France in the late 1980s from an epidemic which was 80% fatal among young muscovy ducks. The third waterfowl parvovirus emerged in Taiwan in 1989 during an epizootic duckling disease. The disease affected all breeds of ducks including their hybrids but geese were spared. The epizootic was diagnosed as a co-outbreak of duck parvovirus (DPV) infection and duck viral hepatitis virus. Inoculating the DPV alone in all duck breeds reproduced the high mortality and symptoms of the disease.

Taxonomy and Classification

All known viruses with a linear ssDNA genome belong to the *Parvoviridae* family which is further divided into two subfamilies: the *Parvovirinae* of vertebrates and the *Densovirinae* of invertebrates. The *Parvovirinae* subfamily comprises three genera: *Parvovirus*, *Erythrovirus* and *Dependovirus*. The three genera in the *Densovirinae* subfamily are: *Densovirus*, *Iteravirus* and *Brevidensovirus*. Phylogenetic analysis of the *Parvovirinae* subfamily reveals different associations which are more biologically relevant in terms of genome organization. For example, while *Parvovirus* members are autonomous, helper viruses can increase their replication substantially. On the other hand, *Dependovirus* members can sometimes replicate autonomously. The parvoviruses discussed here are, in the current taxonomy, all classified in the *Parvovirus* genus. Although the porcine and the rodent parvoviruses are very similar, BPV is quite different, as are the WFPs. The WFPs are genetically closely related to viruses in the *Dependovirus* genus (e.g. AAV) and not to others in the *Parvovirus* genus. Comparison of nonstructural and structural proteins of the WFPs suggests that the AAVs and the WFPs may have evolved from a common ancestral virus.

Properties of the Virion

Parvoviruses are among the most stable viruses. Nonpurified virus has been shown to withstand 2 h at 80°C, although purified viruses are not as stable (e.g. resistant for 1 h at 56°C). Most parvoviruses are also stable within the pH range 2–11. Sonication (without heating) does not affect the virus but it is sensitive to UV irradiation. Resistance to organic solvents, such as butanol and chloroform, and enzymes, such as DNase, RNase and various proteases has been noted. Capsids can also withstand many detergents, although they are dissociated in sodium dodecylsulfate (SDS) solutions. Their compact arrangement of the isometric nonenveloped particles is responsible for these properties.

Parvovirus capsids possess icosahedral symmetry with an approximate external radius of 14 nm and a buoyant density in CsCl of about 1.40 g ml^{-1} (full particles) or 1.30 g ml^{-1} (empty particles). The sedimentation coefficient is approximately 120S for full particles and 60S for empty particles. The capsid contains three to four different proteins (**Table 1**) and a total of 60 protein molecules per virion. The 60 kDa structural proteins found in full, mature particles of BPV, MVM and PPV are proteolytic cleavage products 64–62 kDa proteins. The major structural proteins are produced by a nested set of genes and have identical C-terminal sequences. Although the structural proteins are not glycosylated, they have been shown to be the target for phosphorylation, at least in MVM, and this form appears to be involved in morphogenesis.

The structure of MVM was determined in 1997 whereas structures of empty cpasids of PPV, GPV and MDPV are still being elucidated. The MVM structure

Table 1 Viral gene products (kDa)

Proteins	*MVM, H-I*	*PPV*	*BPV*	*GPV/MDPV*

Molecular masses of NS2/NS3 of PPV and of GPV REP are deduced from amino acid sequences.

is closely related to the CPV structure and contains an internal antiparallel β-barrel and external threefold spikes. Differences are mostly found on the surface in the twofold depression where a protrusion is located on a dimple-like structure.

Viral Genome and Molecular Biology of Replication

The rodent and porcine parvoviruses encapsidate virtually only the negative-strand (complementary to mRNA) although about 1% of viral DNA has positive polarity. Genome lengths reported for these viruses are 5085/5149 nucleotides (nt) for MVMi/MVMp, 5176 nt for H-1, 5517 nt for BPV, 5106 nt for GPV, 5132 nt for MDPV and 5075/4948 nt for PPV NADL2/Kresse (GenBank accession numbers are listed in **Table 2**). The genomic organizations are almost identical for these viruses. Interestingly, the nonviremic strains MVMp and PPV-NADL2 differ from the viremic strains by a repeated sequence at the 5′ end of the viral genome.

The viral strand is, concomitant with synthesis, excised from the replicative form and encapsidated from the 5′ end in (pro)virions (1.44 g ml^{-1} particles containing only VP1 and VP2). The VP2 are partially converted by proteolysis into VP3 which leads to a decrease in the density to 1.40 g ml^{-1} ('mature' particles). NS1 is still attached to the viral genome to the outside of the capsid and is often removed just before or during infection.

Approximately 10% of BPV virions contain the 5517 nt positive-strand DNA molecule, whereas the remainder contains negative-strand DNA. The genome hairpin termini differ from those of the rodent and porcine viruses in several respects. They lack any sequence homology and are 150 (left) and 121 (right) nucleotides long. The left-hand hairpin (3′ end of negative-strand) has both flip and flop orientations, with a 10-fold excess of flip, whereas the right-hand hairpin contains both orientations in equal amounts.

The WFPs encapsidate the opposite polarity strands in equal amounts. The genome lengths of the GPV and MDPV are 5106 and 5132 nt, respectively, each including long inverted terminal repeats (ITRs) of 444 and 457 nt, respectively. The coding regions of MDPV and GPV do not contain insertions or deletions when compared to each other but differences in length can be attributed to short deletions in the ITRs of GPV and to a 5′ nucleotide deletion in the GPV genome shortly after the first stop codon of the capsid gene.

Table 2 GenBank Accession numbers of parvoviruses of rodents, pigs, cattle and waterfowl

Strain/Isolate	*GenBank Accession number*
MVMi	X02481
MVMp	J02275
MPV-1	U12469
H-1	X01457
RPV-1a	AF036710
PPV NADL-2	L23427
PPV Kresse	U44978
GPV	U25749
MDPV	U22967
BPV	M14363

Accession numbers given are those considered with the least number of errors.

Transcription and Translation

Porcine and rodent parvoviruses have two genes, each coding for several products (**Table 1**). Their genomic organizations are almost identical. The genes are transcribed from two promoters (P4 and P38 for MVM; P4 and P40 for PPV) and the transcripts coterminate near the 5′ end of the negative-strand. The P4 transcripts code for the nonstructural proteins (left half of the transcripts) and P38/P40 codes for the structural proteins. A peculiarity of the transcripts originating from P4 is that both the nonspliced and the spliced transcripts are translated (NS1 and NS2/NS3, respectively). Whereas MVM has different

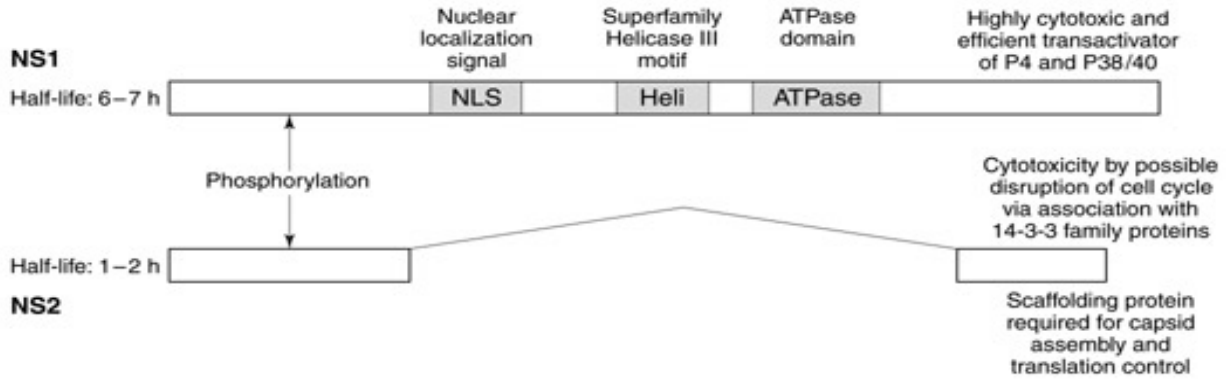

Figure 1 Properties and roles of NS proteins.

forms of NS2, we observed a third transcript of a potential nonstructural protein for PPV, NS3, which has the same N-terminal domain as NS1 and NS2 but the reading frame of the C-terminal domain overlaps the open reading frames (ORFs) of the structural proteins. The role of this protein is unknown. The N-terminal sequences of NS1 and NS2/NS3 are identical whereas the C-terminal sequences differ (overlapping ORFs). The intron removed to generate the NS2/NS3 transcript contains a nucleoside triphosphatase (NTPase) (probably ATPase), a *trans*-activation response element, which upregulates expression from P4, and the P38/P40 promoter elements (**Fig. 1**).

Splicing in parvoviruses is governed often using nonconsensus donor or acceptor sequences. The relative abundance of the spliced transcript (steady-state ratio) has been shown, for MVM, to be dependent on sequences located within the large and small introns. Sequences within the NS2-specific exon itself are required for its inclusion in the mature transcript. As described for MVM, the efficient excision of the upstream large intron (within NS1) from P4-generated mRNAs depends on at least the initial presence of sequences within the downstream small intron.

The start codon for VP1 of the various rodent and porcine parvoviruses is located almost immediately after the stop codons of NS1/NS2. There are small introns at about 40 map units in all P4 transcripts. The donor sites for these small introns are just upstream or just downstream of the VP1 start codon. When the upstream site is used, the start codon is removed and another start codon, almost 800 nt downstream, is used resulting in VP2 (**Fig. 2**).

The strategy used by BPV is different: for example, there are three major ORFs (left, mid and right) instead of two. Analysis of the genome suggests three promoters, P4, P13 and P38. Again, P38 is responsible for the production of capsid proteins. Unlike the rodent and porcine parvoviruses, BPV codes for two large proteins and two smaller proteins. BPV shares

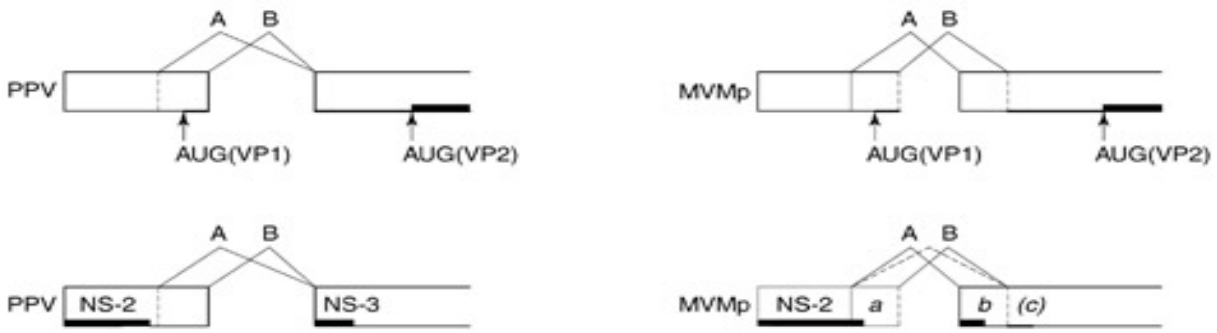

Figure 2 Comparative alternate splicing of NS transcripts in MVM and PPV. MVM has two splicing acceptor sites in the capsid gene ORF, but PPV has only one. Nonetheless, the expression strategy remains unaffected by the divergence in splicing patterns. The strategy of NS2 expression differs considerably between MVM and PPV. The MVM genome is organized to yield a maximum of three different NS2 which differ solely at their C-terminal. Normally, only two forms are detected. Although another (fourth) combination would be possible, it is undetectable due to distance constraints of the splicing machinery. In contrast, PPV NS2 terminates upstream from the VP splicing sites and a separate NS3 is generated by splicing the NS2 donor site to the VP acceptor site. (Adapted from Tijssen P, Bergeron J, Dubuc R and Hébert B *Seminars in Virology* 6(5): 321.)

with all autonomous parvoviruses a glycine-rich region (a stretch of 10–20 G) near the proteolytic cleavage site to generate the smallest capsid protein. This G-run could distort the α-helix structure and make it susceptible to proteolysis. Three BPV NS proteins have been detected (**Table 1**). The 83 and 75 kDa proteins share with NS1 of PPV and rodent parvoviruses the property that they are expressed before the capsid proteins [8 vs 14 h postinfection (p.i.)]. The NS1A and NS1B proteins of BPV may differ in the degree of phosphorylation, although both products can be detected after *in vitro* translation (suggesting primary translation products).

Gel-retardation assays demonstrated that both capsid and NS proteins bind to the left end of the BPV genome and may play different roles in replication and packaging. The right end of the genome does not compete with the left end for these proteins. Cellular proteins, particularly during S-phase, also form a specific complex with the DNA.

Recent work on the genetic analysis of WFP has demonstrated an organization similar to that of the AAVs and, similarly, three promoters, P9, P19 and P41 have been identified. Again, P41 is responsible for the production of capsid proteins whereas P9 and P19 are the transcriptional activators for the REP protein. It is noteworthy that whereas VP1 and VP3 are initiated from conventional AUG codons, VP2 is initiated from an ACG codon. Alternative splicing regulates the synthesis of the various capsid proteins as VP1 is bracketed between two alternative acceptor splicing sites. VP1 is synthesized when the upstream acceptor is used whereas VP2 and VP3 are made when splicing occurs at the downstream acceptor site.

Viral Morphogenesis

Parvoviruses lack the ability of most other DNA viruses to stimulate resting cells to DNA synthesis. The first steps during infection, i.e. absorption, penetration and uncoating in the cell, do not require viral functions but normal cellular processes. Mature (containing VP1, 2 and 3) and immature particles (VP1 and 2) compete equally well for receptors. Internalization through coated pits has been observed. It has been postulated that the virus is transported actively to the nucleus by the signal carried on the first ten amino acids of VP1. Uncoated DNA is not observed in the cytoplasm. The S-phase-dependent event appears to be the synthesis of the complementary strand from the 3′ end of the negative-strand. The resulting duplex can then serve as a template for transcription and expression. It should be noted that for MVMi and MVMp, in A9 cells, the steps up to transcription are equally efficient but that transcription and translation differ significantly. Transcription thus depends on developmentally regulated host-cell factors and is not merely a reflection of the presence of duplex DNA. An attenuation site located ~145 nucleotides downstream from the P4 promoter has been identified. This block could be alleviated by specific cellular factors. Moreover, the promoter for the capsid proteins is activated by NS1.

Parvoviruses interact with host nucleoli. Viral DNA replicates in the host nucleoli and nucleolar protein as well as small nuclear ribonucleoproteins are recompartmentalized. Replicative form DNA is exclusively nuclear-matrix bound early during infection but accumulates later in the soluble fraction. The DNA–matrix interactions are, at least in part mediated by the viral terminal proteins. ssDNA is encapsidated by the (pro)virion, as described above, usually from the 5′ to 3′ direction. This process is probably mediated by NS1 and the virus is ready for a new round of infection after the proteolytic maturation step.

Geographic and Seasonal Distribution

All parvoviruses described here have been isolated worldwide, wherever the host is present. However, some strains may have a wider distribution than others. For example, PPV strains involved in the SMEDI syndrome have been detected throughout the world, whereas strains causing vesicular lesions or enteritis have only been reported sporadically. Interactions of PPV with other porcine viruses are still poorly understood.

It is not known whether similar differences exist for the rodent parvoviruses. Early work showed that many strains differ in serology or hemagglutinating properties from the laboratory strains. A serologic survey from 10 European countries indicated that MVM was among the most prevalent murine viruses in colonies surveyed in the mid- to late 1980s. It has been circulating in mouse colonies for at least 20 years. Retrospective testing indicated that the prevalence of MPV approached 40% in the early 1970s whereas only 7% of tested sera contained anti-MVM antibodies. Similarly, several BPV strains have been compared and serology and hemagglutinating differences have been noted. Caution is warranted since comparisons are often not under identical or standardized conditions. For example, different donors of erythrocytes could be responsible for subtle variations.

Seasonal distributions are related to the age distribution of the host if infection occurs at a certain age. For example, GPV usually infects goslings younger than 1 month, although latent infections

can be established in older animals. Thus, domesticated or wild geese are usually infected in the spring. Similarly, BPV infects calves but latent infections may develop in older animals. The birthing pattern of the host thus contributes to the seasonality of the infections.

Host Range and Viral Propagation

In general, parvoviruses have a narrow host range, probably due to their high dependence on particular host cell functions. Although parvoviruses accumulate mutations at a very slow rate, it has nonetheless been extensively documented that small genomic variations or mutations may lead to phenotypic differences in antigenicity, tissue tropism, host range, virulence or properties such as hemagglutination. It is unknown if these mutations are random or if they appear due to environmental pressures.

The natural host of RV and MVM are rats and mice, respectively, as supported by serology and infection studies. All rodent viruses can induce an osteolytic syndrome after perinatal inoculation of hamsters. This syndrome is characterized by dwarfism, mongoloid features, abnormal teeth and fragile bones because of infection of osteogenic tissues.

About 40 PPV isolates have been obtained from different cell cultures (KBSH from KB cells is the prototype) and it has been suggested that these viruses were introduced with porcine trypsin used in passaging. Field isolates of PPV cluster within four pathogenic groups but, when the region qualified as the allotropic determinant is sequenced, two major groups can be identified. This pattern mainly segregates pathogenic from nonpathogenic isolates whereas other noncharacterized residues or noncoding changes may account for the observed pathologies. Sequencing of the capsid protein gene of isolates originating from Europe and Canada indicate that variations in residues outside the allotropic determinant vary geographically.

Cattle are the natural reservoir of BPV, but goats and possibly horses, may also be a source since many animals are seropositive. Crossreactivity with until now unisolated viruses cannot be ruled out. Canine, monkey and human sera may also be seropositive, by immunofluorescence, but very low titers are obtained when they are assayed for neutralizing activity. Some crossreactivity therefore seems more likely. Domesticated and wild geese as well as Muscovy ducks are susceptible to GPV. Chickens and ducks are resistant.

Parvoviruses are most often propagated in cell culture. GPV is usually replicated in embryonated eggs. The reproduction of parvoviruses in tissue cultures can be dependent on the passage number, temperature or the nature of the strain of the same parvovirus. For instance, lymphotropic and fibrotropic strains have been described for MVM, and restricted temperature ranges for different PPV strains (some only at low temperatures, others at 37°C and still others at 39°C). PPV-NADL2 replicates most efficiently in PFT cells at passage 75–100 and hardly, or not at all, above 200.

Genetics and Evolution

Rodent and porcine parvoviruses are so closely related that they have probably evolved from a common ancestor. Their relatedness with BPV, *Dependovirus* or *Densovirus* is low and decreases in this order, with one noteworthy exception. The amino acid sequence 10–50 of the VP1 capsid protein is also found in the structural protein of many densoviruses (about 90% homology).

Evolution of parvoviruses is evident even in the short time span in which they have been studied. For example, canine parvoviruses evolved, most probably indirectly, from feline parvoviruses. Many of the newly discovered strains with different tropisms may have evolved very recently since only a few (two to three) amino acids are involved in the tropic determinant. It can be speculated that, after a change to a new tropism through one of these amino acids, other mutations may rapidly accumulate until the optimal reproduction rate is obtained.

Parvoviruses have been sequenced to predict the way the genome functions. Subsequently, these predictions were confirmed or rejected by transcription studies and by site-directed mutagenesis of genetic elements (see below). A virulence determinant is also emerging. NS2 nonstructural protein and repetitive elements (at the 5′ end of the negative-strand) seem to be involved. For PPV, we have isolated strains with one, two or four repetitive elements (from mummified embryos almost all have one repetitive element; unpublished results).

Transmission and Epidemiology

Parvoviruses can be transmitted horizontally by the fecal–oral route, respiratory exudates, dust, gloves, clothing and food, provided that the susceptibility of the host and the dosage of the virus are sufficiently high. They can also be transmitted vertically. Toolan noted two types of infection, one that is temporary and produces low levels of antibody which disappear within months and a second type of infection which is latent or permanent leading to high antibody titers, maintained throughout life. The latter type is exemplified by neonatal and latent infections. Similar

patterns can be observed for all parvoviruses discussed in this entry. PPV- or BPV-seronegative herds are sometimes found. In most herds, most animals are seropositive but some asymptomatic long-term virus excretors may be present, mostly because of continuous replication in susceptible gut cells.

Horizontal transmission is most common but vertical transmission has been shown for BPV, GPV and PPV. Vertical transmission of the virus leads to the abortion or resorption of the fetus. A few long-term PPV excretors seem to be less efficient in horizontal transmission in age-segregated herds. However, the resistance of parvoviruses to environmental inactivation is believed to be more important than chronic carriers in the epidemiology by horizontal transmission.

The morbidity and mortality rates depend on the susceptibility of the host and the immune status of the herds. Viral infections can range from completely symptomless to mortality rates that, for GPV, may be close to 100%. Again, the strain of the parvovirus is important.

Tissue Tropism and Pathogenicity

The replication of parvoviruses depends on cellular functions, transiently expressed during late S or early G2 phase of mitosis. Thus, cell division is an essential requirement and parvoviruses infect mitotically active tissues such as those from the fetus, intestinal epithelium and hemopoietic systems. The viruses are considered 'mitolytic', hence their oncosuppressive activities. Additional cellular factors, expressed during differentiation, are also required. Cell division is not the only determinant, and parvoviruses are therefore not truly pantropic. A tropic determinant has been identified in the capsid protein of MVM and in the corresponding region of PPV structural proteins.

The complex set of factors involved in viral pathogenicity is still poorly defined. At a molecular level, much of the current attention is focused on the (until now unknown) role of the viral-encoded NS2 protein and noncoding genetic elements. Both seem to be involved in pathogenesis or virulence. It is not clear yet whether tropism factors can be completely separated from virulence factors. Curiously, RV, H-1 and MVMp are not pathogenic for their native hosts. Only under experimental conditions, such as intracerebral inoculation of rats with virulent RV, does a disease become apparent. RV and H-1 when isolated, were associated with tumors, and MVM has been isolated from oncogenic adenovirus stocks. All rodent parvoviruses have been shown to suppress carcinogenesis, whether spontaneous, virus-induced or carcinogen-induced. In contrast, MVMi, most PPV strains, BPV and GPV are pathogenic. Mixed infections with other pathogens are common and a role for these parvoviruses in certain diseases is emerging.

There is a striking resemblance between MVM and PPV with respect to tropism and pathogenesis. The nonpathogenic PPV-NADL2 and MVMp are nonviremic whereas the pathogenic PPV-NADL8, PPV-Kresse and MVMi are viremic (i.e. high virus titers in blood circulation).

PPV infections are often harmless to the adult animals except for some PPV strains associated with severe dermatitis or enteritis. Nonviremic strains are considered harmless unless inoculated *in utero* prior to immunocompetence where they will cause abortions. Some PPV strains cause embryonic and fetal infections of various degrees through postviremic transplacental infection during the first 70 days of gestation usually without any manifestation of maternal clinic signs since the adult mounts an immune response but the maternal antibodies do not cross the placenta to protect the fetuses. The infection or death of fetuses after immunocompetence is attained around 70 days and is only observed in highly pathogenic isolates such as Kresse and IAF-A54 which are usually associated with necrotic skin lesions in the dams.

The generalized infection of hematopoietic cells, lymphocytes and capillary endothelium leads to bilateral infarcts of the solitary renal papilli for MVMi and fetal infection for PPV. It needs hardly to be emphasized that laboratory diagnosis should distinguish the strains for reliable epidemiological surveys and herd management, instead of mere detection of virus.

Most BPV isolations are from samples from calves with diarrhea, but BPV is increasingly associated with respiratory disease and reproductive failure. Viremia can be established (in leukocytes), and, during the symptomatic phase, different targets become infected (intestinal tissue, brain, heart muscle, adrenal gland, thymus and lymph nodes). Fetal infection after viremia is particularly acute in the first trimester (particularly cerebellum). Active immunity develops in the second half of pregnancy, and a fetus infected in the third trimester usually recovers from the infection.

According to available *in vitro* data, cell tropism relates to the strain properties (capsid amino acids). Different tropisms among variant strains are also a striking feature of other parvoviruses. An example is the sudden appearance of canine parvovirus in the late 1970s probably due to mutations in a feline parvovirus (*See also:* **Parvoviruses (Parvoviridae): Cats, Dogs and Mink**). This flux in parvovirus strains and

properties makes them very important, both in disease prevention and fundamental research.

Clinical Features and Pathology

Except for MVMi, natural infections of rodents are clinically inapparent. Experimental infections of rodents may produce (1) an acute lethal disease in newborn animals, (2) an osteolytic syndrome, (3) cerebellar ataxia or (4) hemorrhagic encephalitis. Successive passaging of H-1 or RV in newborn hamsters can increase the pathogenicity in newborn animals to close to 100% mortality. After 4–10 days, infected animals suddenly become sluggish, gasp for breath and die. Necropsy often reveals hemorrhage of the gut and congestion of the liver. In contrast, no liver damage is observed with the RT strain, but intestines often contain a sanguineous exudate.

Infected newborn rats become apathic just before dying. Intranuclear inclusions are found in cells of almost all organs of the animals.

Hamsters surviving RV or H-1 infections usually develop mongoloid features due to osteolytic activity of the parvoviruses [in rodents, osteogenic activity (osteoblasts, odontoblasts) is high]. Cerebellar ataxia can only be introduced by intracerebral inoculation of hamsters younger than 4 days (and is apparent after a month). The HER agent induces hemorrhagic encephalitis in rats after cyclophosphamide treatment. Upon necropsy, hemorrhage and necrosis are observed in brains or spinal cords of these rats.

The most common feature of an outbreak of PPV reproduction failure is the appearance of mummified fetuses. The litter may contain both mummified and stillborn fetuses. The PPV strain associated with equine abortion has not been reproduced experimentally. Interestingly, this virus also seems to be fetotropic in rabbits. Clinical features of BPV infections, mostly in calves (1–12 months), include enteritis, respiratory disease and conjunctivitis. The severity of the clinical symptoms is usually increased by coinfection with other pathogens and may only be apparent in their presence.

GPV-infected goslings or Muskovy ducklings (at day 1) stop eating after about 3 days, are reluctant to move, remain near a heat source and usually die after a week. Those that survive are usually severely retarded and may become featherless. These animals may also develop a transient leg weakness. When older animals are infected, a symptomless carrier state may be obtained. Birds that succumb in the acute phase after GPV infection have characteristic lesions in the liver and heart muscle. The hyperemic liver contains small grayish-white areas. The apex of the enlarged heart can be rounded off and the myocardium may show a discoloration. Accumulation of fluid in the pericardium and abdominal cavity is often observed.

Immune Response and Prevention

A strong active immunity depends to a large degree on viral multiplication in tissues of the infected organism. The equilibrium between virus produced during latency and the production of circulating antibodies can lead to high antibody titers over long periods. A single injection with cyclophosphamide (immunosuppressive) was shown to be sufficient to convert a latent RV infection into an apparent disease. Toolan observed that infection of pregnant hamsters with H-1 did not yield any antibodies, neither did subsequent inoculations. The reason for this tolerance is not clear.

Passive immunity (maternally acquired antibodies) may protect the fetus against infection in rodents. However, immunoglobulins do not pass through the multilayer placenta (epitheliochorial) in pigs. Production of antibodies in neonatal piglets is the result of active immunity (embryos are immunocompetent from about 70 days on). After birth, pigs can contain high concentrations of PPV antibodies from colostrum while nursing seropositive dams. A similar pattern is observed for BPV; second- and third-trimester fetuses yield an immunoglobulin (Ig)M response that is maximum after about 10 days and is gradually replaced by IgG with maximum titers about 5 months after infection. Calves deprived of colostrum from seropositive cows may develop severe diarrhea upon infection.

Viral strains that do not produce viremia can often be used as live vaccines. The NADL2 strain of PPV, but also others such as the HT strain of PPV (no viremia), can be used. Some workers have been able to induce high antibody titers to PPV with inactivated virus. An early management method for PPV was the back-feeding of fecal material or fetal tissues from PPV-infected sows. Infections with BPV are widespread and are clinically inapparent in adults. BPV vaccines are not yet available nor has the need for vaccination been demonstrated.

Conclusion

Initially, parvoviruses attracted attention since it was felt that these small viruses would be simple and easier to understand than most other viruses. It has become clear, however, that they depend more on cellular functions which are more difficult to study.

Recent knowledge about parvovirus structures has enabled researchers to focus on the role of structurally conserved motifs during infection and their implication in tropism and host range. The extent of knowledge on MVM made it an excellent model especially since more is known about the genetic make-up of the mouse than other vertebrates. Other parvoviruses generate increasing interest due to their role in disease and as models in host–virus relationship and structure–function studies.

Animal Viruses

Kenneth L Tyler, Neurology, University of Colorado Health Sciences Center, Denver, Colorado, USA

Introduction

The term pathogenesis is derived from two Greek words which can be translated to mean, 'the origin of disease'. The study of viral pathogenesis thus concerns itself with understanding the process by which a virus produces disease in the host. It is important to recognize that a virus can enter and replicate in a host, and even induce an immunologic response, without producing overt signs or symptoms of disease. For many viruses, the majority of infections, under normal circumstances, are asymptomatic. Infection may be of short duration and self-limited (acute) or may be long-term (chronic) or even persist for the life of the host. For many viruses, such as influenza, acute infection is followed by viral clearance and subsequent lifelong immunity against reinfection by the same viral strain. In other cases, exemplified by infection with herpes simplex virus, acute infection is followed by persistence of virus in a noninfectious latent state from which there is periodic reactivation and shedding. A third pattern involves acute infection followed by continuous shedding of virus from infected tissues. By definition, in such cases the host immune response fails to completely clear virus. This may result from strategies which allow viruses to successfully evade host immune responses including restricted expression of viral genes, limitation of infection to immunologically privileged sites, rapid evolution of viral antigenic variants, or virus-induced suppression of or interference with host cellular, humoral, or cytokine-mediated immunological defenses.

In the classic model of acute virus infection, injury to cells occurs as a direct result of the replication and release of viral particles. However, it has become increasingly recognized that viruses may also produce disease through a variety of other mechanisms. They can promote the induction of neoplasia (oncogenesis), suppress the immune system and even alter specific cellular functions without killing the target cell.

Viral pathogenesis can be analyzed in terms of a series of interactions between the virus and the host. Although the specific steps in this process may differ for individual viruses and particular hosts, the general outline remains true for most cases. A virus must survive in the environment, enter a susceptible host, multiply to increase its inoculum, and spread from the site of entry to target tissues, where it produces disease as the result of infection and injury to particular organs or populations of cells. Finally, virus must be shed into the environment and transmitted to

Introduction

The term pathogenesis is derived from two Greek words which can be translated to mean, 'the origin of disease'. The study of viral pathogenesis thus concerns itself with understanding the process by which a virus produces disease in the host. It is important to recognize that a virus can enter and replicate in a host, and even induce an immunologic response, without producing overt signs or symptoms of disease. For many viruses, the majority of infections, under normal circumstances, are asymptomatic. Infection may be of short duration and self-limited (acute) or may be long-term (chronic) or even persist for the life of the host. For many viruses, such as influenza, acute infection is followed by viral clearance and subsequent lifelong immunity against reinfection by the same viral strain. In other cases, exemplified by infection with herpes simplex virus, acute infection is followed by persistence of virus in a noninfectious latent state from which there is periodic reactivation and shedding. A third pattern involves acute infection followed by continuous shedding of virus from infected tissues. By definition, in such cases the host immune response fails to completely clear virus. This may result from strategies which allow viruses to successfully evade host immune responses including restricted expression of viral genes, limitation of infection to immunologically privileged sites, rapid evolution of viral antigenic variants, or virus-induced suppression of or interference with host cellular, humoral, or cytokine-mediated immunological defenses.

In the classic model of acute virus infection, injury to cells occurs as a direct result of the replication and release of viral particles. However, it has become increasingly recognized that viruses may also produce disease through a variety of other mechanisms. They can promote the induction of neoplasia (oncogenesis), suppress the immune system and even alter specific cellular functions without killing the target cell.

Viral pathogenesis can be analyzed in terms of a series of interactions between the virus and the host. Although the specific steps in this process may differ for individual viruses and particular hosts, the general outline remains true for most cases. A virus must survive in the environment, enter a susceptible host, multiply to increase its inoculum, and spread from the site of entry to target tissues, where it produces disease as the result of infection and injury to particular organs or populations of cells. Finally, virus must be shed into the environment and transmitted to

a new susceptible host to begin its life cycle anew. Each of these stages is considered separately.

Entry

The most common routes of viral entry are through the skin, respiratory tract, gastrointestinal tract, urogenital tract and conjunctiva.

Skin

Under normal circumstances the skin poses an effective barrier to the entry of viral pathogens. The dead keratinized cells of the outer skin layer (stratum corneum) do not support viral replication. Infection can be initiated when a virus enters the host through breeches in skin contiguity such as cuts, abrasions or wounds. Viruses can also be mechanically transported across the stratum corneum by an insect or animal bite or with human-made implements such as hypodermic needles. The layer of the epidermis below the stratum corneum (stratum Malpighii) contains living cells but is essentially devoid of blood vessels, lymphatics and nerves. Viruses that enter this layer, such as the papillomaviruses, typically induce local pathology (e.g. dermal warts), but only rarely disseminate to produce systemic disease. In the case of papillomaviruses, infection occurs initially in basal cells adjacent to the basement membrane separating the overlying epidermis from the deeper dermal layer. Virus maturation parallels keratinocyte differentiation and proceeds as the cells migrate from the deep epidermal layers toward the stratum corneum. Virion assembly occurs predominantly in keratinocytes in the upper spinous layers of the epidermis and mature virions are found in cells in the granular layers and are shed when the stratum corneum is sloughed.

Deep inoculation through the epidermis may introduce virus into the dermis, with its luxurious supply of vessels, lymphatics and nerves, or even into the underlying subcutaneous tissue and muscle. These tissues often provide fertile ground for viral multiplication and subsequent dissemination. Infection of the dermis may occur when virus is transmitted by a deep bite, as occurs with rabies virus.

The host's dermal barrier is not impervious to invasion. It is penetrated by the openings of the respiratory, alimentary and genitourinary tracts, and modified in areas such as the conjunctiva of the eye.

Respiratory tract

Some viruses that initiate infection via the respiratory tract replicate almost exclusively within the cells of the mucosal surface (e.g. influenza, parainfluenza), whereas others spread systemically after an initial phase of replication in respiratory mucosa (e.g. mumps, measles). Entry of both groups of viruses is typically initiated by means of infected droplet aerosols generated by coughing or sneezing, by nose to hand to nose transmission of infected nasal secretions or by exchange of infected saliva through kissing or sharing of drinking glasses, toothbrushes or other utensils. The fate of inhaled viral droplets is influenced largely by physicochemical factors including particle size, temperature and humidity. Large particles are generally trapped in the nasal turbinates and sinuses, and may initiate upper respiratory infections. Particles smaller than 5 μm can reach the alveolar airspaces to produce lower respiratory infection (pneumonia).

Host defenses against the initiation of viral infection through the respiratory tract are complex. Filtration by the nose reduces the number of particles in certain size categories. Mucociliary clearance further impedes particle entry. Mucus is secreted by goblet cells, and propelled upward in the oropharynx by the coordinated beating of ciliated epithelial cells. Viruses trapped in mucus are efficiently propelled out of the respiratory tract. Viral infection may be facilitated by factors that compromise mucociliary clearance including cigarette smoking, atmospheric pollutants, in-dwelling tubes or certain inherited disorders.

The immune system of the respiratory tract has not been as extensively studied as that of the gastrointestinal tract (see below). The respiratory immune system includes bronchus-associated lymphoid tissue (BALT) and the lymphoid tissue of the tonsils and adenoids. IgA is present in the upper respiratory tract, and its deficiency may increase the risk of developing upper respiratory infections. IgG that is derived from the systemic circulation contributes to antiviral defenses in the lower respiratory tract. Cellular immunity is mediated by intraepithelial lymphocytes and resident alveolar and bronchial macrophages.

Gastrointestinal tract

Viruses that infect the host through the gastrointestinal (GI) tract must be able to survive the acidity of the stomach, the bile salts and proteolytic enzymes of the small intestine, and the mucus coating of the gut. They must also avoid inactivation by secretory IgA and the action of lymphoid cells and macrophages.

Enteric viruses can induce either symptomatic or asymptomatic disease. One determinant of this outcome is the degree of enterocyte injury. Viruses which fail to induce significant gastrointestinal symptoms may still spread to produce systemic infections, as exemplified by poliovirus. Despite the absence of local disease many enteric viruses are shed in high titer and for prolonged periods in feces. The target cells for

enteric viruses include the mature enterocytes of the intestinal villi and the immature dividing cells in the villus crypts. Some viruses including reoviruses, rotaviruses, picornaviruses, retroviruses, astroviruses and toroviruses can also infect M cells, which are specialized epithelial cells overlying collections of small intestinal lymphoid tissue (Peyer's patches). Although most enteric viruses initiate infection in the small intestine there are exceptions to this rule. For example, human immunodeficiency virus (HIV), introduced from infected semen during anal intercourse, may infect dendritic and epithelial cells of the colon and rectum. Rectal and large intestinal infection may also occur in immunocompromised individuals infected with cytomegalovirus (CMV) and herpes simplex virus (HSV). These viruses can also infect the upper gastrointestinal tract producing esophagitis.

Local gastrointestinal symptoms occur when viral infection involves villus epithelial or crypt cells. Destruction of the villus enterocytes results in malabsorption, and the resulting intraluminal osmotic load can induce diarrhea. Infection of the crypt cells, which develop into absorptive cells, ultimately results in loss of absorptive capacity and leads to diarrhea. Another mechanism of diarrhea production may be through the action of viral proteins that act as secretory toxins. For example, the rotavirus NSP4 protein has toxin-like actions that stimulate enterocyte hypersecretion and subsequent diarrhea. Another important consequence of enterocyte infection is the shedding of large amounts of virus in the stool. This fecal shedding is the predominant source of transmission of many enteric viruses with new cycles of infection being initiated by fecal–oral spread.

The first barrier faced by viruses entering the upper alimentary tract is the acidity of the stomach. Viruses must be extremely acid stable to survive this environment. The differing effects of acidity on virions are dramatically illustrated by different species of picornaviruses. For example, rhinoviruses are acid labile and lose infectivity at low pH. Under acidic conditions the viral outer capsid is disrupted, and viral RNA escapes, leaving noninfectious empty capsids. As expected, rhinoviruses do not produce enteric infections. By contrast, other members of the picornavirus family including polio- and coxsackieviruses are resistant to degradation under acidic conditions. They are extremely successful at initiating enteric infections, a fact recognized by their inclusion in the Enterovirus functional group.

Viruses that initiate infection through the enteric route must also resist inactivation by the proteolytic enzymes secreted by gastric and pancreatic cells. In fact, proteolytic digestion actually increases infectivity of several enteric viruses. For example, partial cleavage of the rotavirus spike protein, VP4, by intestinal proteases enhances the direct penetration of virus into enterocytes. In the case of reoviruses, proteolytic cleavage of outer capsid proteins results in the production of infectious subviral particles (ISVPs). ISVPs appear to play a critical role in the initiation of subsequent intestinal infection (see below). Thus, as a general principle, viruses that produce or initiate infection in the intestinal tract are not inactivated by intestinal proteolytic enzymes. In fact, quite the converse appears to be true, as in many cases proteolytic processing of viral capsid proteins seems to trigger conformational changes in the virus particle or expose new functional determinants on specific proteins which in turn facilitate specific events (receptor binding, membrane fusion, cell entry, transcriptional activation) in the viral life cycle.

Bile salts are another important factor in inhibiting viral entry through the intestinal tract. Viral envelopes are particularly susceptible to digestion by bile salts. Before direct ultrastructural visualization of virions was routinely possible, the capacity of bile salts to destroy viral infectivity was taken as prima facie evidence for the presence of a lipid envelope. With the solitary exception of coronaviruses, viruses that initiate infection through the intestinal tract are all nonenveloped.

The enteric immune system provides another important host defense against viral infection. Enteric viral infection typically induces rapid production of intestinal antibody, composed predominantly of secretory IgA. Enteric viruses also induce specific cytotoxic T cells (CTLs) and helper T (Th) cells. These cells form part of the gut associated lymphoid tissue (GALT) system which includes regional collections of lymphoid tissue in the small intestine (Peyer's patches). Cellular immunity (e.g. CD4+ and CD8+ T cells) plays a key role in clearing enteric infection.

The cellular events that underlie the initiation of systemic infection by enteric viruses are becoming better understood. Reoviruses and polioviruses initially bind to the luminal surface of specialized epithelial cells (M cells) which overlie regional aggregates of intestinal lymphoid tissue (Peyer's patches). Virions are then transported in vesicles across the M cell cytoplasm and discharged into the subepithelial lymphoid tissue where primary replication can occur in lymphoid cells and macrophages.

Genitourinary system

A number of human viruses including HIV, herpes simplex and papillomaviruses are venereally transmitted. Small tears or abrasions in the epithelial lining of the rectum, urethra or vagina may occur during

sexual activity and permit entry of virus. Host factors that inhibit viral entry through these routes include cervical mucus, the pH of vaginal secretions, the chemical composition and cleansing action of urine and the presence of secretory IgA.

Conjunctiva

Although viral conjunctivitis is common, and occurs either as an isolated illness or in association with certain systemic infections (e.g. measles), the conjunctiva only rarely serves as a site of entry of viruses into the host. Local infection may be initiated by direct inoculation of virus following ophthalmologic procedures (tonometry, foreign body removal) or in the process of swimming ('swimming pool conjunctivitis'). The offending viruses include adenoviruses and enteroviruses. Most such infections remain localized. Enterovirus 70 (E70) appears to be an important exception to this rule. E70 commonly produces acute hemorrhagic conjunctivitis, and on extremely rare occasions (perhaps 1 in 10 000 cases) spreads from the eye to the nervous system to produce cranial nerve palsies, myelitis or encephalitis.

Spread in the Host

For viruses that produce localized infections, the major steps in pathogenesis are entry into the host and subsequent primary replication in cells and tissues in proximity to the site of infection. In many local infections, virus spread is predominantly by cell-to-cell spread in a contiguous fashion. The brunt of injury is confined to the epithelial layer, although local lymphoid tissues may also be involved. This type of circumscribed infection is typical of uncomplicated upper respiratory diseases caused by coronaviruses, rhinoviruses and influenza, and the acute diarrheal disease induced by rotaviruses. More generalized symptoms (fever, chills, myalgia, malaise, fatigue, anorexia) can accompany these infections, but are generally the result of cytokine production or through the action of other circulating mediators induced as a result of the local infection.

The factors that restrict some viruses to local sites while allowing others to invade the host are poorly understood. They include the direction of viral release from infected cells, the distribution of viral receptors and the effects of differences between core body and epithelial surface temperature.

Release of certain enveloped viruses occurs preferentially from either the luminally facing apical surface (e.g. para- and orthomyxoviruses) or the subepithelially facing basolateral surface (e.g. rhabdoviruses) of infected epithelial cells. The pattern of release is determined by the site in the cell membrane at which viral envelope glycoproteins are inserted. This is in turn influenced by specific amino acid signal sequences within the viral protein. This type of polarized release may be an important factor in either limiting or favoring systemic invasion. For example, release of virus only toward the lumen of the respiratory or GI tract would facilitate local infection of the epithelial surface but would inhibit invasion of deep subepithelial tissues. Conversely, release of virus from the basolateral cell surface would facilitate invasion of the subepithelial mucosa, and the subsequent dissemination of virus through lymphatics, blood vessels, or nerves (see below).

Spread through the bloodstream

Direct entry of virus into the bloodstream without any preceding replication in the host ('passive viremia') is a rare event. It can occur in association with intravenous drug abuse or during transfusion of infected blood or blood products. The bite of an arthropod vector may also allow direct entry of virus into the bloodstream. More commonly, viremia follows an initial phase of virus replication in the host ('active viremia'). Important sites of primary replication include subcutaneous tissue, brown fat, skeletal muscle, endothelial cells and regional lymphatic tissue. Virus enters the bloodstream from these sites ('primary viremia'), and is further disseminated to reticuloendothelial organs (bone marrow, liver, spleen) and endothelial cells. Additional replication is followed by a 'secondary viremia', which is typically of longer duration and higher magnitude than the initial viremia. This sequence of events was originally described for experimental mousepox (ectromelia) infection. Distinct phases of primary and secondary viremia are often difficult to identify in human viral infections.

Virus in the bloodstream may travel free in the plasma or in association with cellular elements. For example, enteroviruses and togaviruses are frequently found free in plasma. HIV, HTLV-1 and the human herpesviruses HHV 6 and HHV 7 infect subsets of T-lymphocytes, Epstein–Barr virus (EBV) infects B lymphocytes and Colorado tick fever virus (CTFV) infects erythrocyte precursors which subsequently mature and enter the circulation. It is important to recognize that plasma and cell-associated viremias need not be mutually exclusive. For example, HIV is found free in plasma as well as in association with CD4+ T-lymphocytes and monocytes. Finding a virus in association with cellular elements may also result from binding or adsorption without associated active replication (e.g. the hemadsorption of influenza to erythrocytes).

Termination of viremia is often abrupt and may coincide with the appearance of neutralizing antibodies. However, a variety of host defenses in addition to antibodies act to clear virus from the bloodstream. The magnitude of viremia is determined by the balance between the entry of virus into the circulation and its subsequent clearance by host defenses. The average time which a viral particle spends in the circulation ('transit time') is generally less than one hour. Larger virus particles and particles coated with antibody or complement are cleared with far greater efficiency than small nonopsonized particles, and may have transit times of only a few minutes. Additional factors that influence clearance and transit time include the net charge of the virion particle and the composition of the viral capsid or envelope. Host factors may also influence the efficiency of clearance. Experimentally, agents such as thorotrast or silica, which decrease the phagocytic capacity of macrophages and other reticuloendothelial phagocytes, enhance the magnitude and duration of viremia induced by some viruses. Differences in the capacity of macrophages from immature animals to clear virus compared to their adult counterparts may be one mechanism contributing to differences in age-related susceptibility to certain viral infections (e.g. herpes simplex). Macrophages derived from different strains of mice vary in the efficiency with which they clear specific viruses (e.g. mouse hepatitis virus, MHV), and this may explain some strain-specific differences in susceptibility to certain viruses. Finally, recent evidence has suggested that different strains of the same virus may show striking differences in their capacity to replicate in macrophages, and that this in turn may be associated with distinct patterns of organ-specific tropism and virulence.

Uptake of virus by phagocytes does not always result in their inactivation. Many viruses including HIV, lentiviruses, and certain toga-, corona-, arena- and reoviruses are capable of replicating in macrophages. The various outcomes possible when viruses infect macrophages are exemplified by the interaction of viruses with hepatic Kupffer cells. Kupffer cells may inactivate virus and limit subsequent spread of infection. Conversely, virus may either actively replicate in or be passively transported through these cells to subsequently enter the bloodstream through the hepatic sinusoids or following biliary excretion. Macrophages contain receptors for the Fc portion of antibody molecules, and in some cases uptake of virus is facilitated by the presence of antiviral antibody [antibody-mediated enhancement' (AME)]. This uptake may either lead to viral inactivation or conversely, may facilitate productive macrophage infection. AME plays an important role in the pathogenesis of dengue and certain other viral infections.

As would be expected, there is a general correlation between the magnitude of viremia generated by blood-borne viruses and their capacity to invade tissues such as the central nervous system (CNS). Conversely, the failure of some attenuated viruses to generate a significant viremia may also account for their lack of invasiveness. For example, certain neurotropic bunyaviruses are fully virulent after direct intracerebral inoculation, but avirulent after peripheral inoculation because they fail to generate sufficient viremia to allow neuroinvasion. It is important to recognize that viremia *per se* does not automatically equate with the capacity to invade tissues from the bloodstream. This has been elegantly demonstrated by certain mutants of Semliki Forest virus (SFV) which have lost the capacity to invade the CNS while retaining the capacity to generate a viremia equivalent in duration and magnitude to that induced by their neuroinvasive wild-type counterparts.

The steps by which blood-borne viruses exit the bloodstream to enter tissues remain poorly understood. In come cases, the viruses appear to directly infect endothelial cells, and then are transported across these cells into the underlying parenchyma. In other cases, viruses may enter tissues inside migrating cells that are capable of emigrating across capillaries (diapedesis). Transendothelial transport of virus inside infected cells has been colorfully referred to as the 'Trojan Horse' mechanism of entry. This type of process may be important in the pathogenesis of lentivirus and HIV infections. Factors that alter vascular permeability (e.g. vasogenic amines) can be shown experimentally to facilitate tissue invasion by certain viruses. This suggests that endothelial permeability may also play a role in determining tissue invasion by blood-borne viruses. Endothelial cells in most organs are joined by tight junctions (zona occludens). However, in certain regions (e.g. the choroid plexus in the brain) capillary endothelial cells lack tight junctions. These areas of fenestrated capillary endothelium may be the site of entry for viruses into perivascular tissue.

Spread through nerves

Many viruses including herpes simplex (HSV), varicella zoster (VZV), rabies and certain strains of poliovirus, reovirus and coronavirus can spread through nerves in the infected host. This pathway of spread is particularly important for viruses that invade the CNS, but theoretically also provides a route for infection of virtually any organ. Neural

spread to sites other than the CNS is exemplified by the spread of rabies virus to salivary glands and VZV and HSV to the skin.

The exact mechanism(s) of neural transport of viruses have not been established, although certain basic principles have emerged. Although spread of many neurotropic viruses along nerves can occur by cell-to-cell spread through nonneural cells (e.g. Schwann cells), the more important mode of viral spread is through the axoplasm of neurons. In the case of enveloped viruses, transport appears to involve predominantly the nucleocapsid rather than the enveloped virion. Neurally spreading viruses appear to all utilize the intraneuronal system of microtubule-associated fast axonal transport. This has been established by studying the kinetics of transport and through the use of selective pharmacologic inhibitors of fast and slow axonal transport. The mechanism by which viruses access axoplasmic transport systems and the form in which they are transported (e.g. free or within vesicles), has not yet been established. Taken as a group, neurally spreading viruses provide examples of spread through motor, sensory and autonomic nerve fibers, and in both the anterograde and retrograde direction. In some cases, individual strains of particular viruses (e.g. HSV) may preferentially travel in only one direction. Similarly, studies with reassortant viruses and viral mutants including rabies virus, pseudorabies virus and reovirus suggest that changes in either the viral envelope or capsid proteins, or in some cases in nonstructural proteins (e.g. HSV), may alter the capacity of viruses to spread through nerves, or even through specific neural pathways.

Viruses that spread within neurons also have the capacity to spread from nerve cell to nerve cell (transneuronal transport). In some cases this appears to occur specifically at synapses (trans-synaptic transport). The factors that influence the release of virus from presynaptic nerve terminals and facilitate their uptake postsynaptically are unknown.

Specific viral proteins play a critical role in determining whether viruses spread through the bloodstream or through nerves in the infected host, and even the specificity of the neural pathways utilized. For example, the principal pathway spread of reovirus type 1 Lang (T1L) from muscle to CNS is through the bloodstream, and for type 3 Dearing (T3D) through nerves. The viral S1 gene, which encodes the outer capsid protein sigma 1, determines this difference. As noted earlier, certain rabies and pseudorabies virus variants with single amino acid substitutions in the envelope glycoproteins, have altered neural spread properties when compared to their wild-type counterparts.

Nonstructural proteins may also influence the efficiency with which viruses infect and spread within the nervous system. However, in most cases this appears to be due to their effect on viral replication rather than due to direct effects on capacity for neural spread. For example, nonneuroinvasive HSV strains often replicate poorly in peripheral sensory ganglia, suggesting that this, rather than an inability to be neurally transported, accounts for their lack of neuroinvasiveness. These nonneuroinvasive strains remain capable of spreading from the site of inoculation, through nerves, to the sensory ganglia, but their spread is arrested at this stage. Genetic studies of recombinant herpesviruses containing portions of the genome derived from both invasive and nonneuroinvasive viruses indicate that the viral DNA polymerase may determine the capacity of certain viruses to replicate in sensory ganglia and subsequently invade the CNS.

Tropism

The capacity of a virus to selectively infect certain populations of cells in particular organs is referred to as 'tropism'. Viral tropism can depend on a variety of viral and host factors, several of which are discussed in detail in the sections which follow.

Receptors

Viruses must bind to target cells prior to initiating infection. Entry may be the result of the interaction of virus with a specific cellular receptor followed by receptor-mediated endocytosis. Alternatively, some viruses are capable of fusing directly with the plasma membrane (e.g. certain alphaviruses), which allows the nucleocapsid to enter the cell cytoplasm through a nonendocytosis-mediated pathway. Viruses that utilize receptor-mediated endocytosis to enter target cells may have receptors that are found on only certain types of cells (e.g. CD4 receptor for HIV), and thus receptor distribution may play an important role in determining viral tropism. In other cases the viral receptors appear to be ubiquitously distributed [e.g. sialic acid receptors for influenza, heparan sulfate glycosaminoglycans for HSV, gangliosides or phospholipids for rhabdoviruses, intercellular adhesion molecule (ICAM) 1 for rhinoviruses], and other factors must account for the specificity in the pattern of viral infection.

A number of principles have emerged from studies of viral receptors. Many of these proteins are membrane glycoproteins. These glycoproteins vary in structure and subserve a variety of different functions in the host. Putative viral receptors include receptors for neurotransmitters, growth factors,

cytokines, complement and laminin. Other viral receptors include integrins, MHC molecules, intercellular adhesion molecules, lymphocyte surface antigens (e.g. CD4, CD46, CD55) and members of the carcinoembryonic antigen (CEA) family. Some receptors have enzymatic or transport functions including aminopeptidase N, the sodium-dependent phosphate transporter, and the cationic amino acid transporter. In many cases, putative viral receptors are glycoproteins whose normal cellular function is unknown. A second major group of viral receptors includes sialic acids, glycosaminoglycans and glycolipids. These compounds are generally ubiquitously distributed across a wide variety of cells and tissues.

It should be emphasized that controversy surrounds some viral receptor assignments. This may result from the fact that viruses can infect cells lacking the putative receptor, indicating that the particular protein is either not the viral receptor or that other mechanisms of entry into the cell (additional receptors, nonreceptor-mediated processes) exist. Many viruses have the capacity to use alternate receptors in different cells, different tissues, and across different animal species. For example, HIV appears to be able to utilize both CD4 and galactosyl ceramide as a receptor. Productive infection subsequently requires the presence of additional 'co-receptor' molecules such as the chemokine receptors including CKR2, CKR3, CKR5 and fusin. Other recently identified putative co-receptors include HVEM, a member of the tumor necrosis factor (TNF) receptor superfamily for HSV, and CD55 (decay accelerating factor) for coxsackievirus A21. Some viruses appear to bind distinct receptors through different proteins or using different regions of the same protein. For example, binding of type 3 reoviruses to sialic acid residues appears to be mediated by a portion of the sigma 1 protein that is distinct from the region utilized for binding to nonsialyated receptors.

In the case of viruses which utilize a widely distributed membrane component such as sialic acid or glycosaminoglycans as a receptor, this may facilitate initial interaction between the viral envelope and the cell membrane ('loose association'), which is then followed by more specific interactions between additional virion proteins and the cell membrane or by virion envelope–cell membrane fusion. Herpesviruses exemplify this pattern. Many members of this family interact via specific envelope glycoproteins (e.g. gB of HSV and HHV 7) with heparan sulfate or related cell surface glycosaminoglycans. Subsequent virus–cell interaction is mediated by a complex process involving a variety of additional envelope glycoproteins.

Different strains of the same virus may use different receptors, and conversely, entirely unrelated viruses may share the same receptor. For example, human rhinoviruses (HRV) 1A, 1B, 2, 49 (the minor group) bind to the low density lipoprotein receptor, whereas HRV14 and all other rhinoviruses (the major group) bind to ICAM-1. Coxsackieviruses B1–6 and adenovirus 2 compete with each other for binding to certain cells, suggesting that they may share a common receptor, despite the fact that they belong to totally unrelated and completely distinct viral families.

It is important to recognize that although the presence of the appropriate viral receptor on a cell may be necessary for infection it is often not sufficient. For example, cultured mouse cells transfected with cDNA encoding the HIV receptor, and expressing the receptor protein, remain insusceptible to HIV infection. Similarly, expression of the human poliovirus receptor in intestinal epithelial cells of mice is not sufficient to allow poliovirus replication in the mouse gut. However, some cell lines that are resistant to infection with viruses including EBV, HIV and polio become fully susceptible when they are made to express the appropriate receptor, indicating that lack of receptor can be the only barrier to susceptibility.

Viral cell attachment proteins

The interaction of a virus with its cellular receptor is typically mediated by one or more cell surface proteins. Among the proteins playing a primary role in cell attachment are envelope glycoproteins (e.g. influenza HA, E2 for togaviruses, G1 for bunyaviruses, SU for retroviruses, gp120 for HIV, G for rhabdoviruses, VP1 for polyomaviruses, penton fiber protein for adenovirus, gp350/220 for EBV). Capsid proteins play a similar role in nonenveloped viruses (sigma 1 for reoviruses, VP4 for rotaviruses, VP1 for polio, large S for HBV). For HSV, more than one envelope glycoprotein may be required for different phases of cell attachment.

High-resolution three-dimensional crystal structures of the influenza HA and of several picornaviruses [HRV14, poliovirus, mengovirus, encephalomyocarditis (EMC), Theiler's] has provided atomic and even subatomic level structural information about viral receptor-binding sites. The sialic acid-binding domain of the influenza HA lies in a small depression near the distal tip of the molecule. The receptor-binding site of picornaviruses typically forms a depression in the virion surface that has been variously described as a canyon (HRV14), a valley (poliovirus) or a pit (mengovirus). Conversely, the receptor-binding site for foot and mouth disease virus (FMDV), a member of the aphthovirus group of

picornaviruses, is located on a prominent outward-facing antigenic loop of the VP1 protein.

For enveloped viruses the close approximation of the viral envelope with the host cell plasma membrane may be followed by fusion of viral and cellular membranes. This interaction may occur independent of the presence of specific viral receptors, or may be dependent on the presence of viral receptors which facilitate the close approximation of the viral envelope and the plasma membrane. Virus proteins with fusion activity may be the same as or distinct from virion cell attachment proteins. Fusogenic activity is typically triggered by a conformational change in the virion fusion protein. This in turn may be triggered by a specific proteolytic cleavage of this protein or by changes occurring consequent to receptor binding. When proteolytic cleavage occurs it may depend on intra- or extracellular host proteases or be dependent on virus encoded proteins or autocatalytic events.

Tissue-specific promoters, enhancers and transcriptional activators

Although the binding of a virus to its receptor may be a necessary initiating event in most viral infections, a number of other host and viral factors influence tropism. Viruses may contain distinct genetic elements, referred to as promoters or enhancers, that may enhance the transcription of certain genes in a cell-, tissue- or even species-specific manner. When mouse embryos are injected with the early region of JC virus (JCV) DNA, pathology is limited to oligodendrocytes within the CNS, despite the presence of viral genome in virtually all cells. The JCV genome contains a region that allows expression of the viral large T antigen only in oligodendrocytes and not other cells. An important role for viral enhancer elements in determining cell-type-specific gene expression has also been described for polyomaviruses, papillomaviruses and hepatitis B virus. It has recently been suggested that a cell-type-specific enhancer region may be contained within the HIV long terminal repeat (LTR), and that differences in this LTR sequence may account for differences between the neurotropism/monocyte-tropism compared to T-lymphoid tropism of some HIV isolates.

Site of entry and pathway of spread

The site of entry of virus into the host may influence its tropism. This has been clearly documented for neurally spreading viruses, whose neural spread is limited by the nature of the pathways available at the site of entry. Variations in the distribution of pathology, infectious virus or viral antigen following different sites or routes of viral inoculation have been clearly demonstrated experimentally with polio, rabies, herpes simplex viruses, reovirus, coronaviruses and the neurotropic (NWS) influenza virus strain. Obviously it has been harder to document this point in human infections, although clinical studies of rabies infection and polio suggest that an identical process occurs in humans. For example, patients who developed paralytic polio after being inadvertently immunized with improperly inactivated lots of poliovirus (the 'Cutter incident') showed a preponderance of paralysis involving the inoculated limb. Similarly, with rabies infection, the site of the bite (e.g. face versus leg) influences prognosis, the initial symptomatology, the incubation period and the probability of subsequent development of clinical disease.

It has also been suggested that the site of viral entry may influence the subsequent tropism of blood-borne as well as neurally spreading viruses. This was initially suggested after clinical observations suggested that local trauma to a muscle (e.g. an injury, an injection, strenuous overexertion) increased the likelihood of this muscle becoming paralyzed during a subsequent attack of paralytic polio ('provoking effect'). This effect could be reproduced experimentally if monkeys were given muscle damaging intramuscular injections followed by intracardiac inoculation of poliovirus type 1. Virus introduced into the bloodstream through the intracardiac route appeared to preferentially induce paralysis in muscles damaged by the preceding intramuscular inoculation. The mechanism of the provoking effect has never been satisfactorily established. It was suggested that local trauma could alter the vascular permeability in the region of the spinal cord innervating the traumatized site, and the increased permeability could result in an increased likelihood that blood-borne poliovirus would localize in that segment of the spinal cord. This phenomenon does not appear to have attracted recent attention, and its existence and mechanism must be considered speculative. Nonetheless, the possibility that local factors can influence the tropism of blood-borne viruses remains intriguing.

Host Factors

It is important to recognize that host factors may play a critical role in determining the outcome and many aspects of the pathogenesis of viral infections. Although a comprehensive discussion of the role of host factors in infection is beyond the scope of this review, several of the more important ones are worthy of emphasis. Among these are age, sex, genetic background, immune status and nutritional state.

The importance of host factors in determining the

outcome of viral infection is dramatically illustrated when populations of individuals are exposed to the same pathogen. Inadvertent experiments of this type have resulted from immunization of large populations with yellow fever virus vaccine contaminated with hepatitis B and with incompletely inactivated lots of poliovirus vaccine. In both cases, those vaccinated showed a wide spectrum of outcomes ranging from no obvious ill effects to severe disease (hepatitis, paralytic polio). These results occurred despite apparent uniformity in the nature of the pathogen, and its dose and route of administration. Epidemics of neurotropic arthropod-borne virus (arbovirus) infection provide a less controlled illustration of the same point. Among infected individuals there is a wide variety of clinical manifestations ranging from asymptomatic seroconversion to lethal encephalitis.

The role of genetic factors in determining the outcome of viral infection has been extensively investigated using inbred strains of mice. Human genes conferring resistance or susceptibility to viral infection have not yet been identified, although one can presume that they will ultimately be shown to exist. By comparing the severity of a particular viral infection in different strains of inbred mice, it can be shown that genetic determinants of viral resistance and/or susceptibility exist for almost all groups of viruses. Genetic factors that determine susceptibility to one virus are typically unique, and differ from those involved with other viruses. In addition, there are clearly multiple mechanisms by which genetic differences lead to differences in viral susceptibility. Among those that have been characterized are differences in immune responses [cytomegalovirus (CMV), murine leukemia viruses], in the expression of viral receptors in target tissues (coronavirus) and in interferon-induced expression of antiviral proteins (influenza virus).

The importance of differences in the age and sex of the host in determining the outcome of viral illness can be seen in a variety of human and animal viral infections. For example, viruses such as varicella, EBV, mumps, polio and hepatitis A typically produce milder infections in children than adults, whereas the opposite is true for viruses such as rotavirus and Rous sarcoma virus (RSV). Studies of experimental viral infection suggest that age-related differences in viral susceptibility have multiple mechanisms. Among those frequently cited are the maturation of the immune system, changes in the nature and distribution of populations of mitotically active cells, or on the state of cellular differentiation. Examples of host factors operating at a cellular level include the requirement of retroviruses that host cells undergo mitosis for integration of proviral DNA into their chromosomes. Other examples include viruses that only replicate efficiently when cells are in specific phases of the cell cycle. This may reflect a requirement for host proteins whose level of activity varies during different phases of the cell cycle such as polymerases or transcription factors.

Differences in the susceptibility of males and females to particular viral infection may be due to differences in the risk of exposure or the mechanism of viral transmission. For example, in the US, HIV infection is far more common in men than women. Similarly, the risk of transmission appears higher when the infected sexual partner is male rather than female. In some cases, sex-related differences in susceptibility cannot be accounted for by obvious epidemiologic factors such as exposure risk or mode of transmission. For example, neurologic complications of mumps infection are two to three times more common in boys than girls. Similarly, following exposure to hepatitis-B-virus-contaminated blood during hemodialysis, men are twice as likely to become chronic HB carriers as women. Striking differences in the nature of and susceptibility to viral infection also occur during pregnancy. These may be related to differences in levels of sex or steroid hormones or to pregnancy-related immunosuppression. Among the infections that are more severe during pregnancy are those caused by polio, hepatitis and herpes simplex viruses. There is also a higher rate of re-activation of latent viruses including polyomaviruses, CMV and herpes simplex viruses.

Exogenously administered hormones, including steroids and thyroid hormone can worsen the course of certain experimental viral infections. Steroids are often believed to exacerbate infections due to viruses such as herpes simplex, although definitive studies on the effects of steroids on human viral infections are lacking.

Transmission and Shedding

The successful propagation of a virus in nature requires that it be able to spread from the infected host to other susceptible individuals. The first step in this process is shedding from the initial host. There are several routes for viral shedding. Enteric viruses are characteristically shed in high titer and for prolonged periods of time in feces. Some respiratory viruses are shed in aerosols generated by coughing or sneezing. Other respiratory viruses are found in saliva or nasal secretions and are transmitted by direct contact with these secretions or by spread from nose to hand to objects which are subsequently contacted by susceptible hosts. Viruses which infect the genital tract are frequently present in genital secretions.

Sexual transmission through infected semen plays an important role in the transmission of HIV and certain other viruses. Virus contained in milk or colostrum may be responsible for initiation of certain perinatal infections including those caused by CMV. Although many viruses are present in urine ('viruria'), this is rarely an important source of viral transmission. An important exception to this rule may be arena- and Hanta-viruses for which rodent urine appears to be a source for shedding virus, and contact with this dried aerosolized urine may initiate human infection.

For certain viruses exposure to virus-infected blood or tissues may be an important source of transmission. Viral infections transmitted by this route include HIV, HTLV, CMV and hepatitis B and C. This route of infection is facilitated by modern medical practices (e.g. transfusion of blood or blood products, surgical procedures including organ transplantation), and certain cultural practices (e.g. tatooing, body piercing, intravenous drug use). In the case of arboviruses, transmission from a viremic host to uninfected individuals by arthropod vectors is an essential part of the natural life cycle of the virus. In this case the likelihood of transmission is affected by the duration and magnitude of viremia and various factors specific to the vector including the degree of viral replication in the vector and its feeding habits and seasonal life cycle. Transmission of infection from blood contaminated material is also an integral part of the life cycle of many viruses that produce hemorrhagic fever syndromes.

Plant Viruses

James N Culver, Center for Agricultural Biotechnology, University of Maryland Biotechnology Institute, College Park, Maryland, USA

Introduction

Viruses depend on their hosts for the cellular machinery needed to complete their life cycles. This level of dependency necessitates precise interactions between virus and host components. For plant viruses, these interactions allow the virus to uncoat its genetic information, express its gene products, replicate its nucleic acid, move cell-to-cell, and spread long distances throughout the plant. Similar types of interactions may also occur between a virus and its vector to permit plant-to-plant movement. Still other types of specific virus–host interactions may result in the activation of host defense responses that arrest disease development. In general, any of these interactions may affect virus pathogenesis.

The ability to identify pathogenesis determinants involved in different virus–host interactions has been greatly expanded as a result of recombinant DNA technologies. Due to the small genome size of many plant viruses molecular approaches to identify viral determinants have proven extremely successful. In particular, the ability to clone and manipulate virus genomes using bacterial plasmid systems that can be used to generate infectious virus nucleic acid has allowed the mapping of multiple virus components involved in disease and resistance responses. In contrast, efforts to identify interacting host genes has, for the most part, been limited to classical genetic approaches. However, the development of screening methods to identify host mutations defective in a specific interaction along with genome sequencing projects for both crop and model plant systems such as *Arabidopsis thaliana* has significantly facilitated our ability to identify interacting host genes.

Other factors, such as the environment or host physiology can also affect virus pathogenesis. However, this article focuses primarily on the interactions between specific virus and host genes that are known to affect the outcome of an infection. The consequences of these interactions range from resistance to severe disease and plant death. What follows are several specific examples of virus–host interactions in which the virus component, host component, or both are known. These interactions have been grouped according to Matthew's definitions of virus–host responses.

Plant Viruses

James N Culver, Center for Agricultural Biotechnology, University of Maryland Biotechnology Institute, College Park, Maryland, USA

Introduction

Viruses depend on their hosts for the cellular machinery needed to complete their life cycles. This level of dependency necessitates precise interactions between virus and host components. For plant viruses, these interactions allow the virus to uncoat its genetic information, express its gene products, replicate its nucleic acid, move cell-to-cell, and spread long distances throughout the plant. Similar types of interactions may also occur between a virus and its vector to permit plant-to-plant movement. Still other types of specific virus–host interactions may result in the activation of host defense responses that arrest disease development. In general, any of these interactions may affect virus pathogenesis.

The ability to identify pathogenesis determinants involved in different virus–host interactions has been greatly expanded as a result of recombinant DNA technologies. Due to the small genome size of many plant viruses molecular approaches to identify viral determinants have proven extremely successful. In particular, the ability to clone and manipulate virus genomes using bacterial plasmid systems that can be used to generate infectious virus nucleic acid has allowed the mapping of multiple virus components involved in disease and resistance responses. In contrast, efforts to identify interacting host genes has, for the most part, been limited to classical genetic approaches. However, the development of screening methods to identify host mutations defective in a specific interaction along with genome sequencing projects for both crop and model plant systems such as *Arabidopsis thaliana* has significantly facilitated our ability to identify interacting host genes.

Other factors, such as the environment or host physiology can also affect virus pathogenesis. However, this article focuses primarily on the interactions between specific virus and host genes that are known to affect the outcome of an infection. The consequences of these interactions range from resistance to severe disease and plant death. What follows are several specific examples of virus–host interactions in which the virus component, host component, or both are known. These interactions have been grouped according to Matthew's definitions of virus–host responses.

Immune Interactions

The majority of virus–host combinations result in an immune or nonhost response. In most cases, immunity is likely due to a nonfunctional or missing interaction between virus and host components needed for replication. In practice, this response is observed as the inability of a virus to replicate efficiently in protoplasts.

An example of such an interaction involves the *Tm-1* gene from *Lycopersicon* (tomato) and the replicase gene from tomato mosaic tobamovirus (ToMV). Whole plants and protoplasts from tomato lines that are homozygous for the *Tm-1* gene do not support ToMV RNA or protein synthesis. However, inhibition of virus replication is less effective in cells that are heterozygous for the *Tm-1* gene and absent in cells lacking *Tm-1*. Okada and colleagues have isolated and characterized a ToMV strain, Lta1, that overcomes *Tm-1* resistance. The ability to overcome *Tm-1* resistance was mapped to amino acid alterations in the helicase domain of the Lta1 viral replicase. Further mutagenesis studies suggest that the ability of Lta1 to overcome *Tm-1* resistance is the result of conformational changes in the replicase protein. This indicates that the *Tm-1* gene may encode a host component that must properly associate with the viral replicase before replication can proceed. Two other plant genes that confer a similar type of resistance are the *Ry* gene from *Solanum tuberosum* (potato) and the et^a gene from *Capsicum annuum* (pepper) which direct resistance against potato potyvirus Y (PVY) and tobacco etch potyvirus (TEV), respectively. Both *Ry* and et^a prevent the accumulation of viral RNA in protoplasts and plants. However, the viral components involved in these responses have not been identified.

The induction of host responses may also result in the inhibition of virus replication in the initially infected cell. The *Rx* resistance from potato confers immunity against most strains of potato potexvirus X (PVX). *Rx* resistance usually results in extremely low levels of virus replication in protoplasts and no detectable accumulations of virus in plants. Baulcombe and colleagues have determined that the ability of PVX strain HB to overcome *Rx* resistance is the result of mutations in the virus coat protein. In particular, a single amino acid substitution, Thr to Lys, at position 121 in the coat protein confers the ability to overcome *Rx* resistance. Evidence indicating that *Rx* resistance is the result of a host defense response comes from studies in which protoplasts were co-inoculated with PVX strains that were either avirulent, not capable of overcoming *Rx* resistance, or virulent and able to escape the resistance. Results from these studies demonstrated that in co-infected *Rx* protoplasts there was a significant reduction in the replication and accumulation of both avirulent and virulent PVX strains. Reduction in replication was not observed in similar protoplasts infected with only the virulent PVX strain. Time-course studies using protoplasts also indicated that measurable reductions in virus accumulations occurred only at later time points. This time delay suggests that the accumulation of a threshold level of coat protein is required to activate a resistance response that inhibits further virus replication. These studies demonstrate that plant disease resistance mechanisms can respond rapidly enough to limit virus replication at the single cell level.

Resistance Interactions

Virus localization to initially infected cells can be the result of either nonproductive host interactions that prevent virus movement from initially infected areas or the result of host defense mechanisms that rapidly limit virus spread to tissue surrounding the initial site of infection (**Table 1**). These types of interactions usually produce no visible disease symptoms, or in the case of resistance responses, produce necrotic local lesions at the sites of virus infection as shown in **Fig. 1**.

Single cell or subliminal infections

In general, plant viruses carry genes, such as the 30 kDa protein of tobacco mosaic tobamovirus (TMV), that allow for cell-to-cell movement through intercellular plasmodesma openings. These viral genes, termed movement proteins, have been shown to bind viral nucleic acid and are closely associated with plasmodesmata and cellular networks of microtubules. Movement proteins have also been shown to alter or gate the size of plasmodesmata to allow larger molecules to pass through these intercellular openings. In addition, mutant viruses with defective movement proteins replicate normally in initially infected cells or protoplasts but cannot move to adjacent non-infected cells. These movement-defective viruses can often be complemented by the transgenic expression of a functional virus movement protein. On the host side, genes in pepper and potato have been shown to limit the cell-to-cell movement of PVY in plants but not affect levels of replication in protoplasts. It is clear from these findings that specific interactions between virus movement proteins and host components are required for efficient virus spread and pathogenesis.

Table 1 Virus and host genes involved in resistance

Virus	*Virus gene*	*Host gene*	*Host*	*Level of resistance*
Tomato mosaic tobamovirus	130/180 kDa replicase	*Tm-1*	Tomato	Replication
Potato potexvirus X	Coat protein	*Rx*	Potato	Replication/HR
	Coat Protein	*Nx*	Potato	HR[a]
Tobacco mosaic tobamovirus	Coat Protein	*N'*	Tobacco	HR
		L^1, L^2, L^3	Pepper	HR
		?[b]	Eggplant	HR
	30 kDa cell-to-cell movement protein	*Tm2, Tm2*[b]	Tomato	HR
	Replicase	*N*	Tobacco	HR
Cauliflower mosaic caulimovirus	Gene VI	?	Tobacco/*Datura*	HR
Tomato bushy stunt tombusvirus	p19 and p22	?	Tobacco	HR

[a] Hypersensitive resistance response.
[b] Corresponding resistance gene has not been identified.

Localized infections

Nonproductive virus–host interactions may also result in the limitation of systemic virus movement. At this level of inhibition, the virus is able to replicate and move cell-to-cell normally, but cannot efficiently move through the plant's vascular system (bundle sheath cells to phloem parenchyma to sieve elements). In general, the slow pace of cell-to-cell movement ($\mu m\ h^{-1}$) versus that of long-distance movement ($cm\ h^{-1}$) dictates that viruses incapable of phloem transport cannot establish an infection at the plant's growing apex and are therefore limited to the initially infected tissue. Several different virus proteins have been linked to long distance movement. The coat proteins of TMV and red clover necrotic mosaic dianthovirus are clearly required for long distance movement. Mutations that disrupt the ability of either coat protein to assemble into virus particles interfere with long distance movement. However, it has been shown that replacement of the TMV coat protein open reading frame with that of ondontoglossum ringspot tobamovirus (orchid strain) resulted in a chimeric virus that produced assembled particles but was debilitated in systemic movement in tobacco. This finding suggests that determinants for host specificity in long distance movement also reside on the TMV coat protein. Still other virus proteins, such as the tombusvirus p19 or the potyvirus HC-Pro have been shown to play a role in long distance movement. On the host side, recessive alleles in soybean and tobacco have been shown to limit the systemic movement of cowpea chlorotic mottle bromovirus and TEV, respectively.

Hypersensitive responses

The hypersensitive response (HR) is an active pathogen defense mechanism that occurs in most higher plants. HR induction is dependent on a gene-for-gene recognition event that occurs between plant-encoded resistance gene products and pathogen-encoded molecules termed elicitors (**Table 1**). Recognition results in the induction of a cascade of host defense responses that include: oxidative bursts of H_2O_2, hydrolytic enzymes, callose and lignin precursors, pathogen related proteins etc. These defense responses lead to the rapid localized necrosis of tissue at the site of infection and prevent further virus spread (**Fig. 1**). Interestingly, similar HRs are observed against viruses, bacteria, fungi and nematodes. This implies that specificity for the HR does not involve the defense responses that confine the pathogen, but rather the recognition of the pathogen elicitor. In addition, analysis of cloned plant resistance genes indicate that they share similar characteristics including leucine rich repeats, protein kinase motifs and nucleotide binding sites. Taken together, this information indicates that plants utilize a common defense mechanism against pathogen invasion.

Many different viral proteins have been shown to act as specific elicitors of the HR. For example, the coat protein of TMV elicits HRs encoded by the *N'* gene from *Nicotiana sylvestris* (tobacco; **Fig. 1**), the *L* alleles from *Capsicum* spp. (pepper), and an uncharacterized gene from *Solanum melongena* (eggplant). The involvement of viral process and gene products other than coat protein have been eliminated from these interactions. The structural properties of coat protein required for *N'* gene recognition have been investigated. It has been demonstrated that recognition required a correctly folded coat protein and that amino acid residues along the right face of the coat protein's four helical bundle were critical for HR induction. These findings are consistent with the presence of a receptor binding site that confers *N'* gene recognition. Interestingly, this recognition site is

Figure 1 Hypersensitive resistance response between the *N'* gene of *Nicotiana sylvestris* and the coat protein of tobacco mosaic tobamovirus (TMV). The photograph was taken five days postinoculation and displays necrotic local lesions developing at the sites of TMV infection. This active host defense confines the virus to the area of the lesion and prevents its further spread.

conserved among all tobamoviruses and is even present in TMV strains that overcome N' gene resistance. However, mutations that disrupt the normal aggregating ability of coat protein and lie outside the recognition site can confer N' gene recognition to coat proteins that normally overcome this HR. Thus, strains of TMV that break N' gene resistance have apparently evolved a quaternary configuration that masks this site from host recognition.

The PVX coat protein also acts as an elicitor of *Nx* resistance in potato. It has been shown that the ability of some PVX strains to break *Nx* resistance resides within the coat protein. Specifically, a single coat protein amino acid exchange, Glu78 to Pro, was all that was required to overcome this resistance. It has also been demonstrated that a second site mutation of Ile62 to Val restored host recognition of the Pro78 coat protein. Based on the proposed PVX coat protein structure, the resistance breaking Glu78 mutations may interfere with the structure of a recognition site whereas the second-site Val62 mutation presumably restores the structure of the site. These findings provide another example of how subtle structural changes can result in dramatically different host responses.

Other plant-derived hypersensitive responses have been shown to target virus proteins other than coat protein. It has been shown that the HR conferred by the *N* gene from *Nicotiana glutinosa* is likely elicited by the replicase gene of TMV. Mutations that lead to the induction of the *N* gene HR by TMV-Ob, a strain that normally breaks this resistance, were mapped to the helicase domain of the virus replicase. However, it has not yet been determined if the replicase acts alone to elicit this HR or in combination with other viral components or processes. In addition, the *N* gene is currently the only plant virus resistance gene to be molecularly cloned and characterized. It has been shown that the *N* gene encodes a protein that contains a cytoplasmic domain similar to the *Drosophila* Toll protein, a nucleotide binding site, and a region of leucine rich repeats. The *N* gene product also appears to be cytoplasmic with no discernible membrane spanning domain. This indicates that recognition of the virus occurs within the cell, which is consistent with the location of TMV replication.

In tomato, two genes, *Tm2* and $Tm2^2$, have been identified as conferring an HR-like resistance against TMV. Both genes provide resistance only at the level of the plant and not at the level of protoplasts. TMV mutants that overcome either *Tm2* or $Tm2^2$ resistance have been identified. Meshi and colleagues determined that the *Tm2* resistance-breaking abilities of two independent TMV mutants, Ltb1 and C32, resided with specific amino acid substitutions (Glu52 to Lys, Cys68 to Phe, or Glu133 to Lys) in the virus 30 kDa movement protein. Similarly, Weber and colleagues identified the ability of a ToMV strain capable of breaking $Tm2^2$ resistance also resided with a different set of specific amino acid substitutions (Ser238 to Arg and Lys244 to Glu) in the 30 kDa movement protein. In addition, the transgenic expression of the ToMV 30 kDa movement protein in $Tm2^2$ tomato resulted in a necrotic HR phenotype. This demonstrated that the virus movement protein alone was sufficient to induce this resistance response.

The ability of barley stripe mosaic hordeivirus (BSMV) to induce necrotic local lesions on *Chenopodium amaranticolor* has been investigated. Different strains of BSMV were found to vary in their ability to induce lesions. For example, strain ND18 induced necrotic lesions within three to four days of inoculation whereas the type strain induced chlorotic

lesions at 14 days postinoculation. A genetic analysis of the virus determinants responsible for these lesion phenotypes indicated that they mapped to RNA-γ. RNA-γ is one of three BSMV genomic RNAs and encodes two protein products, γ-a and γ-b. Molecular studies of this RNA revealed that a short open reading frame present in the type strain 5′ leader of RNA-γ was responsible for the attenuated chlorotic local lesions. Translational studies indicated that this leader sequence decreases the production of γ-a protein *in vitro*. Thus, lower levels of γ-a protein may account for the attenuated lesion phenotype. However, a single amino acid substitution, Pro to Leu, in the γ-b protein of RNA-γ was also found to convert lesion phenotype from chlorotic to necrotic, suggesting that factors in addition to γ-a protein accumulation can also affect lesion formation. A third effect on the lesion phenotype of BSMV in *C. amaranticolor* was also found to reside in the composition of the other two BSMV genomic RNAs. For example, the rapid lesion-forming phenotype (4 days versus 14 days) occurred only when the type strain RNA-β was present. Taken together these findings illustrate the ability of multiple virus determinants to influence a host response.

Susceptible Responses

Susceptible host responses are generally associated with the appearance of systemic disease symptoms. This implies that the interactions between virus and host components needed for replication, cell-to-cell movement, and systemic spread are functional. The observed disease responses, which include effects on growth, development and output, are likely the result of numerous factors related to the affects of these interactions on the homeostatic balance of the plant.

Sensitive responses

Disease responses vary dramatically depending on the virus–host combination under investigation. The type of response, for example chlorotic versus necrotic symptoms, is generally dependent on the genetic makeup of both the plant and the infecting virus. However, environmental factors such as the availability of micronutrients, nitrogen, water and light can also have significant effects on the severity of the observed disease. Additionally, the developmental stage of a plant or leaf at the time of infection can also determine the type of disease response. For example, Matthews and colleagues determined that for tobacco leaves infected with TMV the critical leaf size at which mosaic symptoms develop is at or below 1.5 cm in length. Leaves that were developmentally larger when inoculated failed to display the mosaic symptom. This finding likely reflects a requirement for active virus replication at the time of cell differentiation. However, other disease responses, such as vascular necrosis, appear to develop independently of the developmental stage of the plant.

Chlorosis

Chlorosis of green plant tissue is one of the most common disease symptoms associated with virus infection and generally results from a decrease in chlorophyll content due to perturbations in chloroplast structure and function. Chlorosis associated with systemic mosaic disease likely involves the disruption of chloroplast development in the leaf primordium. In some systems the development of a mosaic disease pattern appears to reside with the expression of a single virus gene. For example, gene VI from cauliflower mosaic caulimovirus when expressed transgenically in tobacco has been shown to induce chlorotic mosaic-like symptoms. In another system, detailed mapping of symptom determinants in TMV strains that confer mild mosaic symptoms has shown that specific amino acid substitutions in the viral replicase gene control the severity of the mosaic response. These mutations do not affect the expression of other viral proteins but do reduce the rate of phloem-dependent virus accumulation. However, the rate of TMV accumulation did not strictly correlate with the severity of the mosaic response. Some replicase mutants accumulated poorly but still induced severe mosaic symptoms. Thus, factors other than the rapid early accumulation of virus within the merstematic tissue of the plant appears to be responsible for this mosaic symptom, suggesting that a direct replicase–host interaction may be involved. Similarly, mutations in the replicase genes of cucumber mosaic cucumovirus and barley stripe mosaic virus have also been shown to affect the pathogenicity of these viruses in zucchini and oats, respectively.

The severity of chlorotic symptoms can also be affected by other viral genes. In particular, specific amino acid substitutions in the coat proteins of TMV and cucumber mosaic virus have been shown to enhance the severity of mosaic symptoms (**Fig. 2**). The precise effects of these coat proteins on symptom development have not been determined, however, many of the TMV coat protein mutants that confer severe mosaics also produce a brighter chlorosis on mature leaves compared to that induced by the wild-type virus (**Fig. 2**). This suggests that these coat proteins disrupt the function of developed chloroplasts. In addition, TMV mutants that do not produce coat protein still induce systemic mosaic symptoms that are indistinguishable from the wild-type virus.

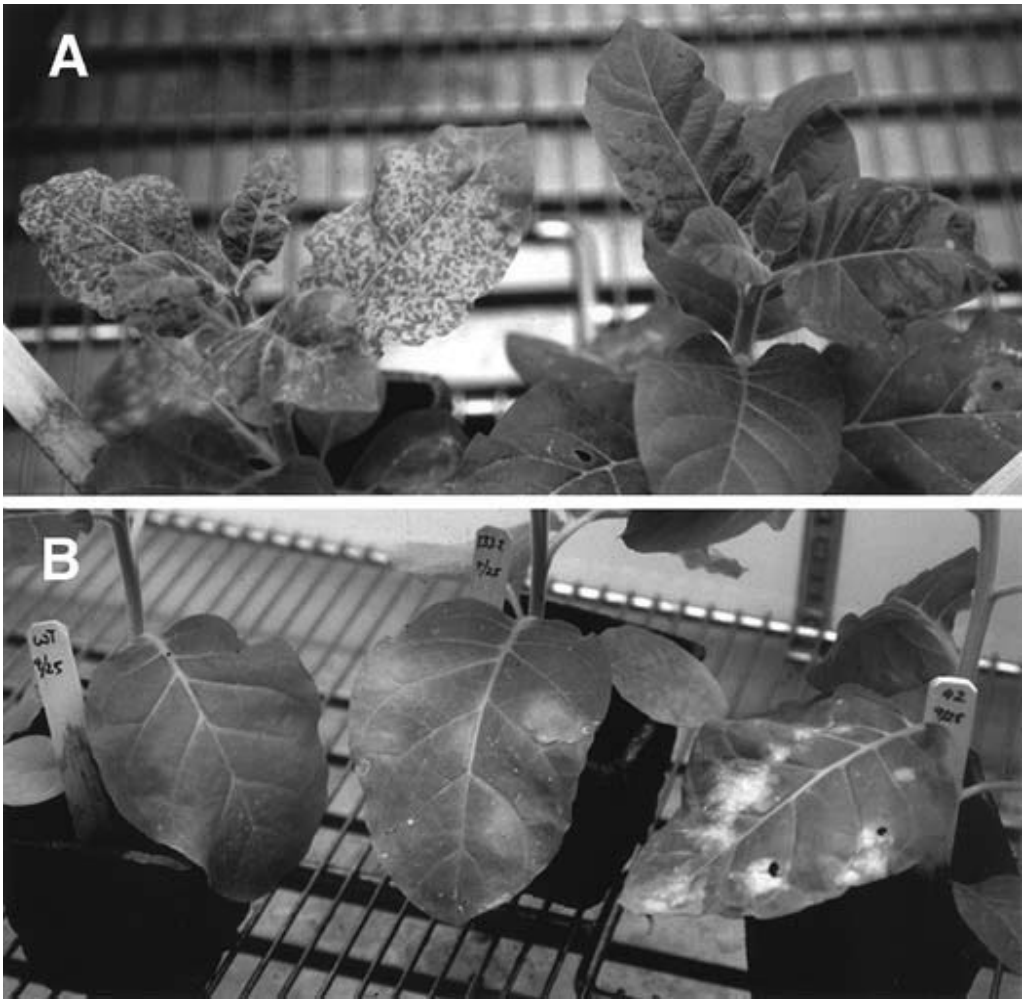

Figure 2 Symptom variations resulting from single amino acid substitutions in the coat protein of tobacco mosaic tobamovirus (TMV). (**A**) Left, Xanthi tobacco systemically infected with a TMV coat protein mutant F67L; right, Xanthi tobacco systemically infected with wild-type TMV. (**B**) Xanthi tobacco leaves inoculated with: left, wild-type TMV showing no symptoms; center, TMV coat protein mutant L133P showing chlorosis at the sites of infection; and right, TMV coat protein mutant T42R showing necrosis at the sites of infection.

Thus, severe mosaic symptoms can be the result of both the developing mosaic and the enhanced chlorosis caused by coat protein. One possible mechanism by which coat protein enhances chlorosis involves the direct accumulation of coat protein within the chloroplasts. Evidence for this comes from the purification of TMV coat protein and virions from chloroplast fractions. In addition, a positive correlation has been found between the level of TMV coat protein associated with photosystem II in chloroplasts and the severity of the observed mosaicism. In another system, the PVY coat protein was targeted to chloroplasts by fusing it to a chloroplast transit peptide. Tobacco plants transformed with the PVY coat protein plus transit peptide produced white mosaic symptoms whereas plants transformed with only the unfused PVY coat protein showed no symptoms. This further suggests that the ability of a coat protein to move into chloroplasts can directly effect the severity of the observed disease. Additional evidence also suggests that coat protein may affect chloroplast function and structure indirectly by interfering in the synthesis or transport of proteins into and out of the chloroplasts. Electron microscopy studies have shown that various coat protein mutants of TMV produce dark staining coat protein bodies (aggregates of unassembled coat protein) within the cytoplasm. The presence of these bodies was correlated with dramatic disruptions in the structures of mature chloroplasts. However, these coat proteins did not accumulate within the chloroplasts, suggesting that their affect on chloroplast structure occurs indirectly from the cytoplasm.

The effects of turnip yellow mosaic tymovirus

(TYMV) replication on chloroplast structure have been well documented. In addition, it has been shown that a single amino acid substitution in the TYMV movement protein was found to confer more severe and uniform systemic chlorotic symptoms. This mutation also correlated with increased virus yields in systemically infected tissue. Alteration of the TYMV movement protein may enhance the ability of the virus to move into the leaf primordium at a time or in a concentration that results in a more uniform and thus more severe systemic infection.

Viral nucleic acid, such as single- or double-stranded RNA, contains a high-degree of secondary structure involved in viral replication, protein translation and virion assembly. Thus, it is not surprising that alterations in disease symptoms have been mapped to RNA segments that do not encode a protein product. One example has come from studies on the satellite RNAs of cucumber mosaic virus (CMV). The induction of chlorosis has been mapped to specific nucleotide sequences present in several satellite RNAs (satRNAs). This region, termed 'chlorosis domain' (nucleotides 97–191 of the B-5 satRNA of CMV) was found to contain a number of specific nucleotides that when altered led to changes in the type of chlorosis (white versus yellow) or the host specificity of the chlorosis (tobacco versus tomato). In addition, the type of induced chlorosis was found to be dependent on the strain of helper virus. This implies that the satellite sequences involved in chlorosis may indirectly affect chloroplast function and symptoms via interactions with specific helper virus components.

Systemic necrosis

Necrosis of systemically infected tissue often results in the most severe form of disease. These necrotic responses can be displayed as either sporadic necrotic areas within a mosaic symptom or widespread necrosis resulting in vascular collapse and plant death. One type of systemic necrosis results from the weak induction of the plant hypersensitive defense response. For TMV, mutants that weakly elicit the *N′* or *Tm2* HRs are not fully localized and can move systemically through the plant. However, as these viruses move they continually trigger the necrotic HR, eventually resulting in plant death. Additionally, a number of different single amino acid substitutions in the coat protein of TMV have been shown to confer necrosis at the site of infection or intermixed patches of necrosis and mosaic in systemically infected tissue (**Fig. 2**). This type of patchy necrosis appears to be independent of any host defense response. Exactly what causes this type of necrosis is not known.

Necrotic responses have also been mapped to the satellite RNAs of CMV. Chemical and enzymatic modifications were used to compare the structural features of CMV satRNAs that vary in their ability to confer necrosis. These studies have identified one helix and two tetraloop regions in the satRNA that correlated with necrosis, suggesting the importance of specific RNA structures in this disease response.

Tolerance

In a tolerant interaction the virus infects the host systemically and can reach high titers, but the infection produces few if any detectable symptoms. A number of host genes that confer tolerance have been described including r_{m1} and r_{m2} in tobacco, conferring tolerance to TMV, and *TTR1* in *A. thaliana*, conferring tolerance to tobacco ringspot nepovirus. Virus components that specifically affect tolerance have not been specifically described, although many components that enhance or attenuate disease symptoms without affecting virus replication and movement have been described (see the above sections).

PEA ENATION MOSAIC VIRUS (*LUTEOVIRIDAE*)

Jihad S Skaf, **Steven A Demler** and **Gustaaf A de Zoeten**, Department of Botany and Plant Pathology, Michigan State University, East Lansing, Michigan, USA

Taxonomy and Classification

The genus *Enamovirus* (*Luteoviridae* family) comprises a single member, pea enation mosaic virus (PEMV). PEMV is characterized by a single-stranded, plus-sense, bipartite RNA genome encapsidated in two morphologically distinct isometric particles. Some isolates contain a third, nonessential satellite RNA. The distinguishing features of PEMV include the ultrastructural alterations of infected cells and viruliferous aphids. Also, virus titer in infected plants is much higher compared to related luteoviruses, perhaps because of the true systemic infection that can be established by PEMV. The following text reviews the current state of knowledge concerning PEMV and compares and contrasts PEMV with other viruses. Also highlighted is the symbiotic nature of the PEMV complex that is analogous to that described for helper-dependent, aphid-transmitted virus complexes involving members of the genera *Luteovirus* and *Umbravirus*.

Virus Structure and Composition

Virions of PEMV consist of two isometric nucleoprotein components with estimated $S_{20,w}$ values ranging from 91 to 106S for the top component and 107 to 122S for the bottom component. There is no evidence of empty viral shells in purified PEMV virion preparations. In general, the bottom component is the dominant species, although the amount of top component is highly variable and a variant strain in which the top component dominates has been reported. Particle molecular weights are in the ranges $5.4 \times 10^6 - 5.6 \times 10^6$ for the bottom component and $4.4 \times 10^6 - 4.7 \times 10^6$ for the top component, with an estimated RNA content of *c.* 28–33%. Purified virions display a bimodal diameter distribution of approximately 25 and 28 nm. It has been proposed that the bottom component is composed of 180 subunits arranged in a $T = 3$ icosahedron, whereas the top component is composed of approximately 150 subunits lacking quasi-equivalence. The top component is also less stable (particularly under high salt conditions) than the bottom component, a possible result of the irregularity in virion composition.

Virions of aphid-nontransmissible strains of PEMV contain a single coat protein (CP) of 21 kDa. In contrast, aphid-transmissible strains also contain a second minor protein of 54 kDa. Repeated mechanical inoculation of aphid-transmissible PEMV strains often leads to the elimination of the 54 kDa protein and aphid transmissibility.

Electrophoretic examination of intact virions of aphid-nontransmissible isolates of PEMV reveals two bands, corresponding to the top and bottom components. In contrast, aphid-transmissible isolates display a complex banding pattern attributed to incremental size differences between particles.

Serology

PEMV is moderately immunogenic, with titers of up to 1:1024 attainable by standard methods. Antisera against aphid-transmissible strains of PEMV contain two antibody populations whereas antisera generated against the aphid-nontransmissible strain contain only a single population. There are no reports of serological crossreaction between PEMV and any other virus.

Genome Structure

The genome of PEMV consists of two and sometimes three plus-sense RNAs of molecular weight 1.9×10^6, 1.4×10^6 and 0.23×10^6. The nucleotide sequence of all three species has been determined. The RNAs are not polyadenylated and nonaminoacylatable.

There has been considerable controversy as to the infectivity and particle distribution of the viral RNAs of PEMV. Part of this discrepancy is due to the inability of centrifugation and electrophoretic techniques to adequately separate the bottom and top components to homogeneity, as well as to the uncertain existence and particle affiliation of RNA3 (and its effect on particle density). The favored model suggests that the bottom component encapsidates RNA1 and the top component RNA2, with both components mandatory for wild-type (WT) infection. An alternative proposal argues that RNA1 and RNA3 are encapsidated in the bottom component, with RNA2 encapsidated in both the top and bottom components.

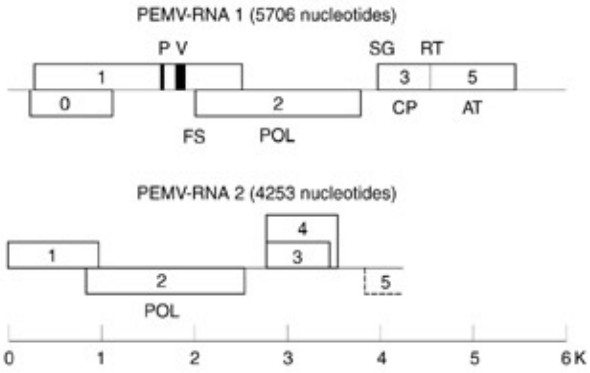

Figure 1 Schematic representation of the genome structure of wild-type PEMV RNAs 1 and 2. Numbered hollow boxes indicate open reading frames. AT, aphid transmission; CP, coat protein; FS, frameshift; POL, polymerase; SG, subgenomic; RT, readthrough; P, conserved 3C-like protease motif; V, genome-linked protein (VPg).

RNA1: the luteovirus component

RNA1 of PEMV (5706 nucleotides) bears strong organizational and sequence similarity to the RNAs of subgroup II luteoviruses encompassing beet western yellows (BWYV), potato leafroll (PLRV) and the NY-RPV isolate of barley yellow dwarf virus (NY-RPV BYDV). RNA1 is composed of five predominant open reading frames (ORF, **Fig. 1**). The first ORF (ORF 0) encodes a protein of 34 kDa of unknown function or relationship to other viruses. ORF 1 encodes an 84 kDa protein and overlaps (out of frame) 90% of ORF 0. *In vitro* translation analysis of RNA1 generated products of 36 and 88 kDa, suggesting that expression of the ORFs 0 and 1 products occurs by independent translational initiation. Sequence analysis has identified a 3C-like protease core sequence within the 84 kDa protein, suggesting that proteolytic processing may be involved in the expression of the viral genome. The central region encompassing this protease motif is conserved in luteoviruses. Similar to other subgroup-II luteoviruses, the genome-linked protein (VPg) of PEMV is encoded by ORF 1 of RNA1 downstream of the putative protease motif (**Fig. 1**). It is not known at this time if this VPg is covalently linked to all three viral RNAs. Protease treatment does not abolish infectivity suggesting that the VPg is not required for the initial translation of viral RNA.

ORF 2 encodes a protein of 67 kDa and overlaps (in a unique frame) the C-terminal 23% of ORF 1. This 67 kDa protein is characterized by RNA polymerase- and helicase-like motifs, and is postulated to represent the core of the viral RNA-dependent RNA polymerase. Sequence comparisons have established a strong relationship between this protein and those of comparable ORFs of subgroup II luteoviruses. *In vitro* translation analysis suggests that this protein is expressed as a fusion of the 84 kDa and 67 kDa protein reading frames by translational frameshift.

ORF 3 encodes the 21 kDa viral CP, and is immediately followed in the same reading frame by ORF 5 (encodes a 33 kDa protein). The amino acid sequence of both the coat and 33 kDa proteins bears strong sequence homology to their counterparts in the 3′-terminal ORFs described in luteoviruses. In addition, the 41-amino acid intergenic region between the opal stop codon of the CP and the first true start codon of the 33 kDa protein contains a proline-rich region also conserved within luteoviruses. The 33 kDa protein is expressed as a translational readthrough fusion with the 21 kDa CP. The resulting 54 kDa minor protein is associated with aphid transmitted isolates of PEMV and is dispensable for infectivity but its presence is mandatory for aphid transmission. In response to a specific selection pressure (mechanical transmission), PEMV suppresses aphid transmissibility via a number of mechanisms including the generation of genotypes lacking the 33 kDa protein or the downregulation of the expression of the translational readthrough protein.

Deletions in the CP ORF do not inhibit the systemic movement of PEMV or alter the accumulation of truncated viral RNA (compared to WT isolates). Pea plants infected with CP-less mutants exhibit wilting and severe necrosis that appear earlier and are more severe than observed in WT infections. Interestingly, the absence of the CP (and hence virions) from cells infected with CP deletion mutants does not affect the formation of replication complexes or the double-membrane bound vesicles characteristic of PEMV infection (see the cytopathology section below). The association of these vesicles, whose production is controlled by RNA1, with viral RNA-dependent RNA-polymerase, viral single stranded- (ss-) and double stranded- (ds)RNA, as well as plasmodesmata and phloem tissue suggests their involvement in virus movement throughout the plant. This CP-independent movement of PEMV is in sharp contrast to the absolute necessity of the CP for the movement of luteoviruses. This contrast may be due to functions provided in *trans* by RNA2 to PEMV complex.

One of the imperfections in the analogy between PEMV and luteoviruses is the lack in PEMV-RNA1 of a 17–19 kDa ORF 4 nested within the luteovirus CP genes. This ORF 4 has been implicated as a possible participant in cell-to-cell luteovirus movement. However, silencing ORF4 of BWYV reduced the level of viral RNA accumulation but did not abolish the systemic movement of the virus.

Neither the coat nor the 33 kDa protein are expressed in *in vitro* translation of RNA1. There is evidence from northern blot analysis of polysomal and total RNA isolation from infected tissue for an 1800 nucleotide RNA specific to the 3′ terminal region of RNA1. These data suggest that expression of these two proteins occurs from a single subgenomic messenger.

RNA1 is perfectly capable of replicating in isolated protoplasts but cannot establish systemic infections in plants on its own regardless of the inoculation method used.

RNA2: the umbravirus component

Unlike all known multicomponent viruses, there is a surprising lack of sequence homology (especially at the 5′ and 3′ termini) between RNA2 and RNA1 of PEMV. The only exception is a region that immediately precedes ORFs hypothesized to be expressed from subgenomic mRNAs (ORFs 3 and 5 of RNA1 and ORFs 3 and 4 of RNA2). The first ORF (ORF 1) of RNA2 can potentially encode a 33 kDa protein of unidentified function. Introducing specific frameshift and or deletion mutations into ORF 1 does not affect the infectivity of RNA2 or PEMV. ORF 1 overlaps (out of frame) the first 37 amino acids of the 65 kDa ORF 2. ORF 2 contains sequence motifs typical of RNA polymerases and bears a strong taxonomic relationship to those of carmo-like viruses encompassing subgroup I luteoviruses. The polymerase encoded by RNA2 is unrelated to the polymerase encoded by RNA1. ORF 2 is followed by two largely overlapping (in unique reading frames) ORFs (ORFs 3 and 4) potentially encoding 26 kDa and 27 kDa proteins. Circumstantial as well as experimental evidence indicate that both cell-to-cell and systemic movement, mechanical transmissibility and the relaxation of phloem limitation of the luteovirus component of PEMV are mediated by ORFs 3 and 4 and by their P26 and P27 products. This evidence includes sequence homology between P27 and other viral movement proteins. In addition, specific changes (both natural and experimental) in ORFs 3 and 4 halt the *in planta* movement of PEMV but not the replication of RNA2 in pea protoplasts. ORFs 3 and 4 are followed by a 293 nucleotide noncoding region leading to a potential fifth ORF (15 kDa) that lacks a conventional stop codon. The pronounced sequence heterogeneity may be indicative of the degenerative nature of this region. The loss of this region in some clones confers no distinctive phenotype in pea or in *Nicotiana benthamiana*.

Serological screening with anti-PEMV antibodies has failed to identify a CP encoded by RNA2.

In vitro translation analysis of RNA2 has demonstrated only a single product of 45 kDa with no evidence of the larger frameshift product postulated above.

RNA2 is mechanically transmissible and can establish a systemic infection in whole plants in the absence of RNA1.

RNA3: the satellite component

In addition to the two genomic components, some isolates of PEMV possess a third, 717 nucleotide RNA (RNA3), with features characteristic of B-type mRNA satellite RNAs (although there is no evidence of translational activity associated with this RNA). RNA3 is not infectious on its own and was long considered an artefact of virus purification. However, recent molecular methods permitted the cloning and further analysis of this RNA. RNA3 has no measurable impact on the symptoms induced by PEMV in pea plants, although its presence results in symptom attenuation in *N. benthamiana*. RNA3 is encapsidated in the CP encoded by RNA1 and replicated by the polymerase encoded by RNA2 (the first 13 and 8 nucleotides at the 5′ and 3′ termini, respectively, are identical between RNAs 2 and 3). In return, RNA3 may have an effect on virion stability which can be advantageous to the two genomic RNAs. This trilateral interaction between RNA3 and the genomic components of PEMV is reminiscent of that described for the satellite RNA of groundnut rosette virus (GRV). Indeed, both satellite RNAs share considerable sequence homology and can be interchangeably replicated and encapsidated by their counterparts' helper luteoviruses. In contrast with the GRV satellite, RNA3 is dispensable for the infectivity of PEMV, although its prevalence and role in natural infections has not been determined.

Host Range

PEMV has a narrow host range, limited mainly to the family Leguminosae, and includes members of the genera *Anthyllis, Astragalus, Cicer, Lathyrus, Lens, Lotus, Lupinus, Medicago, Melilotus, Phaseolus, Pisum, Glycine, Trifolium* and *Vicia*. Nonleguminous hosts include *Gomphrena globosa, N. benthamiana, Nicotiana clevlandii, Nicotiana tabacum* and members of the genus *Chenopodium* (*C. quinoa, C. amaranticolor* and *C. album*) which serve as local lesion hosts.

Transmission

Similar to other luteoviruses, PEMV is transmitted by aphids in a circulative nonpropagative manner. A

notable distinction, however, is the additional capacity of PEMV for effective mechanical transmission. Eight species of aphid have been reported as vectors of PEMV, with the pea aphid *Acyrthosiphon pisum* (Harris) being both the most effective and most significant in the field. There is considerable variability in the literature concerning the dynamics of vector transmission of PEMV, a reflection of variability in both the viral isolate and aphid biotype examined. In general, acquisition periods range from 15 min to 3 h, with a mandatory latent period of approximately 10–18 h, consistent with a circulative transmission pattern. Following the latent period, *A. pisum* was able to transmit PEMV following test feeding probes of less than 60 s, suggesting that inoculation of nonphloem tissues was adequate to transmit the virus. Nymphs are more efficient than adults at virus transmission. Virus particles are retained through moults, and aphids remain viruliferous in excess of 30 days. There is no concrete evidence of viral replication occurring in aphid tissues.

Extended mechanical propagation of PEMV isolates can lead to the loss of vector transmissibility. There are no reports at this time of such aphid-nontransmissible isolates occurring under field conditions, or the reversion of these laboratory strains to aphid transmissibility.

Symptomology

Symptoms attributed to PEMV vary considerably, depending on the viral isolate, the age of the host plant and environmental conditions. Symptom expression in pea seedlings inoculated prior to the unfolding of the first true leaves (*c.* 7–10 days after sowing) is manifested by a downward curling of the uppermost leaves 5–7 days postinoculation. This is followed (7–10 days postinoculation) by a marked vein-clearing and the development of both irregular chlorotic flecks and small irregular translucent lesions (often described as windows) along the leaf surface. From 10 to 14 days after inoculation, the aerial portions of the plant become severely stunted, epinastic and rugose, with continued amplification of foliar symptoms. Apical dominance is often lost, with proliferation of severely distorted axillary buds. In severe cases, top and bud necrosis is also observed. The diagnostic symptom of this virus, the enation, is evident on the lower leaf vein and stipule surfaces as hypertrophic undifferentiated outgrowths. These tend to form late in infection, approximately 2–3 weeks after inoculation. Although infected plants will successfully set pods, their yield, size and quality is significantly reduced. Pod symptoms consist primarily of wart-like protuberances along the outer pod surface, although pod enations have also been observed. In older plants and tolerant varieties, symptoms are often less severe, consisting mainly of the foliar mosaic symptoms with fewer growth abnormalities.

Symptoms on *Chenopodium* species consist of small chlorotic local lesions emerging 3–10 days after inoculation. The reproducibility of *Chenopodium* species as a local lesion host is highly variable and greatly influenced by environmental conditions.

Virus Epidemiology and Control

PEMV was initially described in 1935 by Osborn to occur in *Vicia faba* in New York State. The virus occurs predominantly in northern temperate climates, but has also been reported as far south as Iran and Sicily. Economically, PEMV is considered the most significant viral disease in commercial pea production. In addition, significant disease losses have also been described in commercial chickpea, broadbean and lentil production.

Annual and perennial leguminous host and weed species serve as overwintering reservoirs for both PEMV and its aphid vector. Aphid migration from these overwintering hosts in spring and early summer results in the dissemination of the virus into adjacent areas. Therefore, one method of reducing the incidence of PEMV is to control the aphid vector in both the overwintering host as well as in the secondary crop host. It has also been suggested that control of leguminous weed species and avoidance of perennial legumes, adjacent to production fields may assist in reducing the available virus and vector reservoirs.

Resistance to PEMV in *Pisum sativum* is controlled by a single dominant gene designated *En* derived from USDA PI No. 40295 originating in Iran. Similar tolerance has also been uncovered in *Lens culinaris* accessions PI Nos. 472547 and 472609 originating in India and in Iran, respectively.

PEMV, like several members of the luteovirus group, can serve as a partner in a disease complex with an unrelated aphid-nontransmissible virus. The bean yellow vein banding complex (BYVBV) consists of a helper-dependent association between PEMV (the helper) and BYVBV (the dependent). This affiliation results in an increase in yield loss over that associated with PEMV infection alone. In this complex, BYVBV, which is normally mechanically transmitted, is dependent on PEMV for aphid transmission. Bean leafroll luteovirus also serves as a substitute helper virus in this complex.

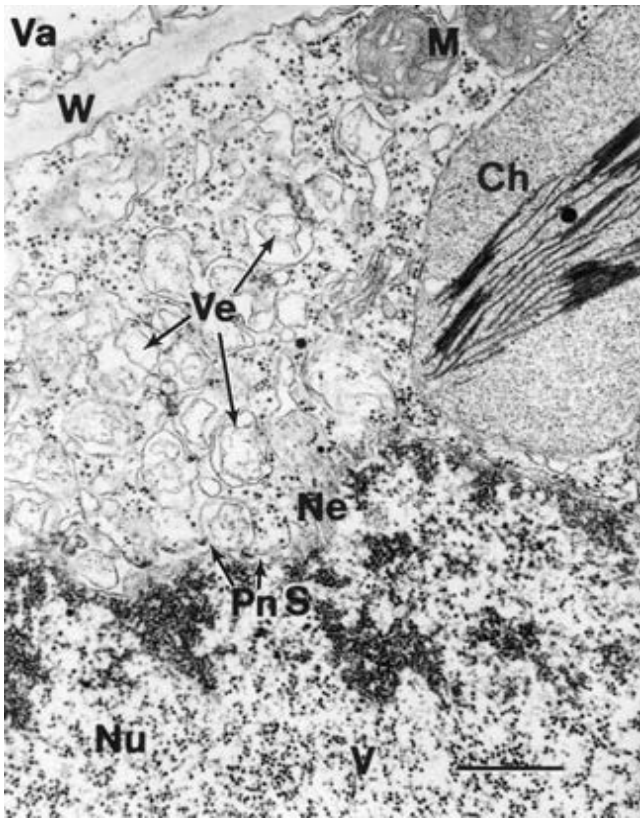

Figure 2 A PEMV-infected pea mesophyll cell. Note the cytoplasmic vesiculation (Ve) representing the replication complex of the virus. The vesicles are formed in the perinuclear space (PnS) of nuclei sustaining virus replication. In many cases, nuclei of infected cells contain assembled virions (V). Ch, chloroplast; M, mitochondrion; Ne, nuclear envelope; Nu, nucleus; Va, vacuole; W, cell wall. Magnification ×31 000; scale bar = 0.5 μm.

Cytopathology

Infections by PEMV are characterized by distinctive ultrastructural alterations of tissues of both plant host and aphid vector (**Fig. 2**). These alterations have strong parallels with those observed in luteovirus infections. Perhaps the most distinguishing characteristic of PEMV infection is the intimate association with the host cell nucleus and with vesicular structures originating from the nucleus. Virions are found throughout the nucleus as well as in the cytoplasm and vacuoles, either scattered or in loosely packed clusters. A proliferation of fibril-containing vesicular structures is evident in infected tissue, including all parenchymatic cell types and particularly in phloem tissues. In time-course studies, these vesicles were shown to originate from the inner nuclear membrane and are deposited into the perinuclear space from which membrane-bound groups of vesicles are extruded into the cytoplasm. *In situ* hybridization studies demonstrated that both the nuclei and fractions enriched for these vesicular structures contained both the negative- and positive-sense strand of PEMV RNA, implicating these structures as the site of viral replication. Supporting this view, PEMV-induced RNA-dependent RNA polymerase activity was also localized to both the vesicular and nuclear fractions. Indeed, isolated healthy pea nuclei were also demonstrated to support replication of PEMV RNA in *in vitro* assays. Combined, these data support the assignment of these membranous vesicles as the replicative complex of PEMV.

In addition to their role in viral replication, these vesicles are also found associated with, or traversing through plasmodesmata of mesophyll, phloem parenchyma, sieve element and fully developed sieve tubes. The systemic mobility of these complexes coupled with their demonstrated polymerase activity suggests a possible role for these structures in the systemic spread of PEMV infection. In addition, transient, electron-dense, dagger-like structures protruding into the cytoplasm of healthy and necrotic companion cells and sieve elements, can often be found associated with plasmodesmata. It is not clear whether this structure is of viral origin or a possible defense reaction of the host. An additional cytopathic feature characteristic of PEMV infection is the presence of elongated feather-like crystalline inclusions in epidermal cells. These anomalous inclusions are always surrounded by membranes and are rich in ribosomes and polyribosomes. They are often associated with the perinuclear space or with the vesicular membranes derived from the perinuclear space. Occasionally these structures are evident in apparently healthy tissue, and may reflect a stress-related response by the host. Their functional significance and origin are currently unknown.

In viruliferous aphids, PEMV virions were identified in the gut lumen, fat bodies, epithelium and muscle cells of the midgut, in hemocytes and in electron-dense viroplasm-like structures hypothesized to be part of the lysosomal apparatus. Electron microscopic analysis of aphid salivary systems demonstrated an association of PEMV virions with the basal lamina and plasma-membrane complex of the accessory salivary gland, establishing a directional membrane-mediated shuttling of virions from the hemocoele to the stylet. In contrast, there was no evidence of similar association of virions of the aphid-nontransmissible isolate of PEMV with these salivary structures. These observations are consistent with similar observations described for luteoviruses.

Future Perspectives

Symbiosis is rarely used to describe interactions between plant viral genomes. One reason is that most of those interactions take place either between distinct and independent viruses in a mixed infection (leading to various degrees of mutualism), or between the components of a virus with a multipartite genome. Extensive analysis of the molecular biology of PEMV suggests that the interactions between its genomic components are actually a combination of both scenarios. Thus, in this curious partnership of the RNAs of PEMV, the vital functions currently lost from each RNA are provided in *trans* by the other component resulting in a highly infectious entity. Now that the sequence and the genomic organization of both viral RNAs is determined, the contribution of various ORFs to the infection cycle of PEMV can be further delineated. The mechanical transmissibility and the high virion yield of PEMV provide additional advantages to the use of PEMV to answer lingering questions related not only to this virus but possibly to related luteoviruses and umbraviruses.

For example, the isolation and further characterization of the VPg will provide important insights into the replication strategies utilized by PEMV.

In addition, the involvement of RNA2 (ORFs 3 and 4 in particular) in spreading the infection of PEMV beyond the phloem tissue raises questions about the mechanism involved and whether RNA2 can indeed change the phloem restriction characteristic of other luteoviruses.

History

Pecluviruses are viruses so far found in Africa and the Indian Subcontinent that are responsible for the disease called 'clump' in crops of groundnut (= peanut, *Arachis hypogaea*). Clump disease is one of the many biotic and abiotic stress factors that have been shown to contribute to low yields of groundnut. It has been estimated to cause annual losses on a global scale of about 38 million US dollars.

Clump disease was first reported in 1927 in groundnut crops in India. Subsequently, in 1931, a similar disease was reported from West Africa. The economic importance of this disease was recognized following systematic surveys in the Indian subcontinent as well as in parts of West Africa.

Taxonomy and Classification

In taxonomic parlance, pecluviruses comprise the genus *Pecluvirus*. The genus contains two species, *Peanut clump virus* (PCV) and *Indian peanut clump virus* (IPCV). The genus is a relatively recent taxonomic construction and has not been assigned a family. Previously, the two species were considered to

be strains of a single species (PCV) that was classified as a furovirus together with other fungus-transmitted viruses with rod-shaped particles. Recent molecular data concerning these viruses have revealed much heterogeneity and several new genera have been created to accommodate the variety of molecular characters.

The current classification does not seem to be very robust because the extent of the sequence variation among the three serotypes of IPCV is as great as is the variation between any serotype and the one isolate of PCV sequenced to date. The only clear feature that distinguishes PCV from IPCV at present is the geographical location in which an isolate is found.

Virion, Genome and Protein Properties

The structural and molecular features that distinguish pecluviruses from other viruses with rod-shaped particles are (1) particles with lengths of about 245 nm and 190 nm and diameters of about 21 nm, (2) genomes that contain a triple gene block that encodes proteins thought to be involved in virus movement, (3) genomes that lack an open reading frame (ORF) expressed by readthrough suppression of the coat protein gene termination codon. IPCV particles are rod shaped, 24 nm in diameter, with two predominant lengths of 249 and 184 nm. PCV particles contain two predominant lengths 245 and 190 nm. Both PCV and IPCV contain a single capsid protein of 24 kD. For more detail see Molecular Biology Section.

Geographic Distribution

In the Asian subcontinent, clump disease has been reported from the Indian States of Andhra Pradesh, Gujarat, Punjab, Rajasthan and Tamil Nadu, and from Pakistan in the states of Sindh and Punjab. In Africa it has been found in Burkina Faso, Niger Republique (Sadore, Maradi and Tarna), Mali, Côte d'Ivoire, Gambia and in Sénégal (Bambey, Kirene, Mbour, N Diongo, Pout, T Kaymor).

Symptoms and Host Range

Diseased plants are conspicuous because of their severe stunting and dark green appearance. They often occur in patches in fields and the disease recurs in more or less the same position in the field in successive peanut crops. Symptoms appear on young leaflets as mottling, mosaic and chlorotic rings. However, when these leaflets mature, they turn dark green with or without faint mottling. Plants infected when relatively young become severely stunted; although the infected plants can produce flowers, any pods that are formed are not well developed. Plants infected at a later stage also become stunted with shortened internodes, and have dark green leaflets. Yield losses up to 60% have been recorded from such late-infected plants.

IPCV and PCV have extremely wide host ranges, which include monocotyledonous and dicotyledonous plants. They include such economically important crops as peanut, wheat, barley, maize, sorghum, pearl millet, finger millet and pigeonpea. The symptoms induced by various IPCV isolates differed in several hosts, namely in *Canavalia ensiformis, Nicotiana clevelandii, N. benthamiana* and the hybrid *N. clevelandii* × *N. glutinosa*. The symptoms induced in *Chenopodium amaranticolor* by various PCV isolates collected from Senegal, Burkina Faso and Niger were shown to differ markedly.

Serological Relationships

Tests conducted with polyclonal antisera using ELISA and immunosorbent electron microscopy have shown that IPCV isolates can be grouped into three serotypes, namely IPCV-Hyderabad (IPCV-H), IPCV-Durgapura (IPCV-D) and IPCV-Ludhiana (IPCV-L). All IPCV isolates are serologically distinct from PCV isolates, and vice versa. By using tests with monoclonal antibodies, a number of PCV isolates have been placed in five distinct groups. None of seven monoclonal antibodies produced against PCV reacted in triple antibody sandwich ELISA with one of the Indian isolates related to IPCV-D.

Transmission

All IPCV and PCV isolates can be transmitted by mechanical sap inoculation with sap from infected plants. However, extracts of infected plants of some hosts, e.g. peanut, were difficult to transmit mechanically. PCV and IPCV can be transmitted through peanut seed. IPCV was also shown to be transmissible in seed of infected plants of pearl millet, finger millet, foxtail millet, wheat and maize. IPCV has been shown to be transmitted by *Polymyxa* sp. However, direct evidence for transmission of PCV by *Polymyxa* has so far not been reported.

Life Cycle

The life cycle of IPCV/PCV and the vector *Polymyxa* sp. is given in **Fig. 1.** Dicotyledonous hosts do not permit multiplication of *Polymyxa* sp. and are therefore considered as fortuitous hosts that will not contribute to perpetuation of virus inoculum. Indeed virus-infected peanut roots or virus-infected peanut seed could not transmit or establish the disease.

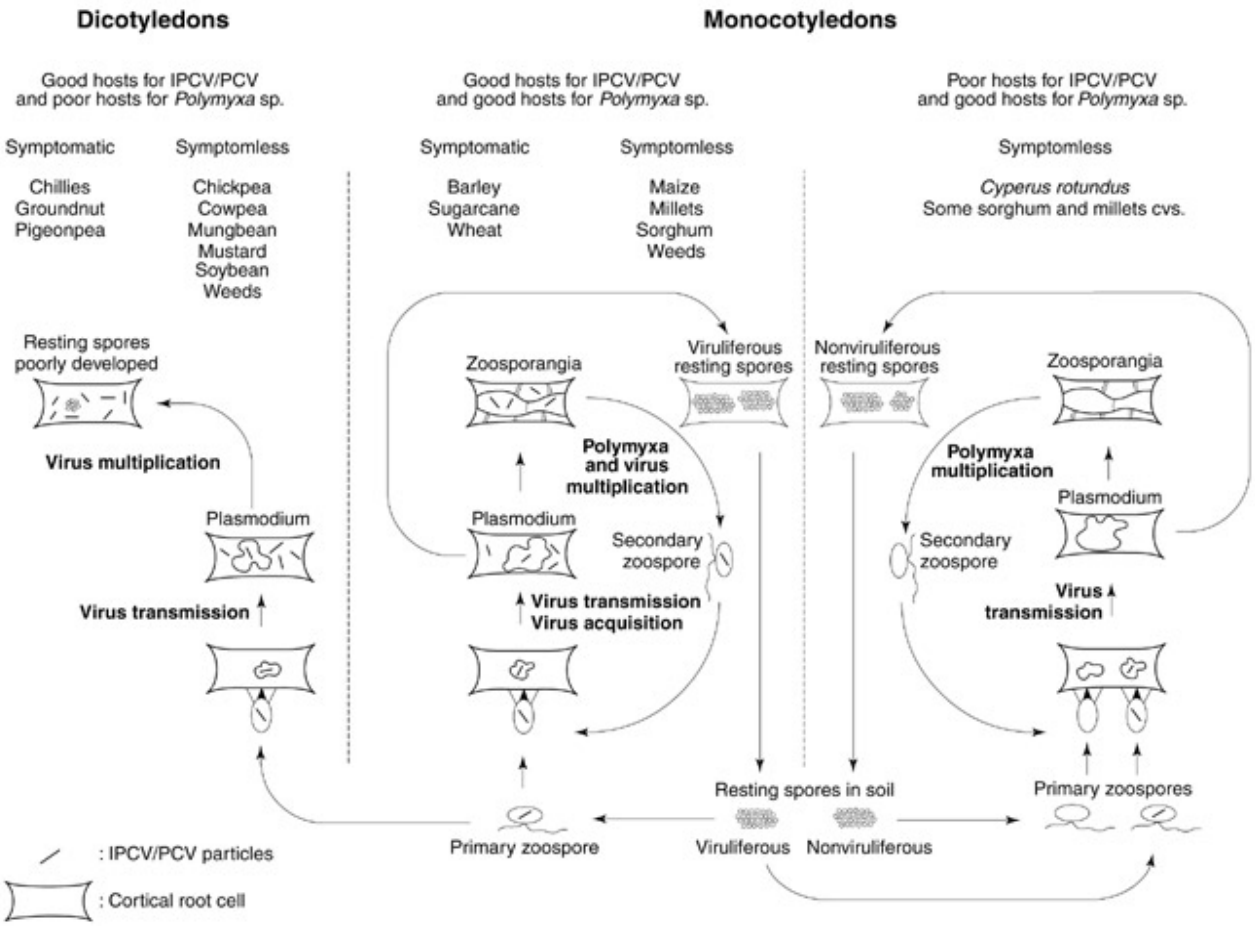

Figure 1 Life cycle of IPCV/PCV and the vector *Polymyxa* sp.

Monocotyledonous hosts were found to be the preferred hosts for multiplication of *Polymyxa* sp. They contribute to building up of *Polymyxa* sp. inoculum potential in the soil. Seed of millets, maize and wheat and rhizomatous grasses such as *Cynodon dactylon* are likely to contribute to the establishment of the disease in new areas by supporting both virus and fungus multiplication. Certain monocotyledonous weeds, e.g. *Cyperus rotundus*, and some sorghum and millet cultivars, although excellent hosts for *Polymyxa* sp., were found to be poor hosts for IPCV. They are likely to contribute to reduction of clump disease.

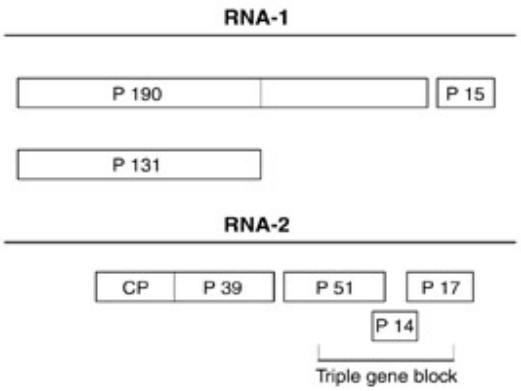

Figure 2 Genome organization of IPCV/PCV.

Molecular Biology

The single-stranded (ss) RNA genome of pecluviruses consists of two components each encoding more than one polypeptide. **Figure 2** illustrates the genome of PCV, that of IPCV is identical in arrangement.

Coding sequences

The 5′-most ORF of RNA-1 encodes a large polypeptide (c. 130 kDa). The ORF is followed immediately by another that is in frame with the termination codon of the 131 kDa polypeptide and which is expressed by readthrough of the UGA termination codon to generate a fusion polypeptide of c. 190 kDa

that contains the c. 130 kDa polypeptide at its 5′ end. A third ORF that encodes a c. 15 kDa polypeptide is downstream of the 190 kDa ORF and separated from it by a noncoding region of about 60 nucleotides. The amino acid sequence of the c. 190 kDa polypeptide contains domains with sequences similar to proteins with methyltransferase, helicase and RNA-dependent RNA polymerase activities (see **Fig. 2**). No function can be inferred from the sequence of the 15 kDa polypeptide.

RNA-2 is more complex. It encodes five polypeptides, each of which is expressed directly, apparently with no readthrough. The 5′-most ORF encodes the coat protein. The following ORF is expressed by leaky scanning by ribosomes of the c. 1 kb leader. The remaining three ORFs form a triple gene block and the encoded polypeptides (c. 51 kDa, c. 14 kDa and c. 17 kDa) are thought to play a role in virus movement within infected plants. No function can be inferred from sequence comparisons involving the 39 kDa polypeptide, although it is thought that the protein may be involved in the transmission of pecluviruses by *Polymyxa* sp.

Terminal noncoding sequences

The terminal noncoding sequences of pecluvirus RNA-1s are about 130 (5′) and 350 (3′) nucleotides in length. Those of RNA-2 are more diverse, between c. 390 and c. 500 nucleotides in length. There is no marked 5′ sequence feature common to all pecluviruses. RNA-1 and RNA-2 have similar 5′ noncoding region (NCR) for six to seven nucleotides and these sequences are shared between pecluvirus species. The 3′ NCR are c. 300 nucleotides in length and the c. 100 terminal nucleotides are almost identical among all pecluvirus RNAs sequenced so far. This sequence similarity has enabled the development of a hybridization probe that consists of the 3′-terminal 700 nucleotides of the sequence of IPCV-H serotype. It can detect any of the currently known IPCV serotypes as well as an isolate of PCV.

Sequence comparisons

The polypeptides encoded by pecluvirus RNA-1 are between 75% (P15) and 95% (readthrough part of P191) identical between species and show significant similarities with other viruses previously classified as furoviruses (e.g. 56% identity with polymerase of soil-borne wheat mosaic virus). The polypeptides encoded by RNA-2 are 39% (P39) to 89% (P14) identical between the species. The coat proteins are c. 60% identical and also show a significant similarity (c. 30% identity) with the coat protein of barley stripe mosaic virus (genus *Hordeivirus*). The triple gene block proteins resemble those of potato mop-top virus (genus *Pomovirus*) more than those of viruses in any other genera.

Control

After confirming the soil-borne nature of clump disease, initial experiments were centered on application of soil biocides and soil solarization. Although both the treatments were effective in reducing disease incidence, they were not economical to adopt and also the biocides that proved effective were known to be hazardous. Resistance to IPCV has so far not been located in cultivated or wild *Arachis* species. Therefore efforts have been concentrated on understanding the epidemiology of clump disease with the hope of devising cultural methods of control. These studies included identification of alternative hosts of the virus and the vector, and of factors that contribute to survival and spread of inoculum. As a result, the following measures have been recommended for controlling IPCV:

- Early planting before the onset of the monsoon and under judicious irrigation;
- Trap cropping with pearl millet, i.e. sowing a pearl millet crop at a high density and then two weeks after germination ploughing the entire crop into the soil and then planting with peanut;
- Avoiding rotation with such highly susceptible cereal hosts as maize or wheat;
- Continuous cropping with dicotyledonous hosts to reduce substantially the inoculum in the soil and thus contribute to low incidence of disease.

The methods recommended are ecofriendly and economical and are applicable even under smallholder farming conditions.

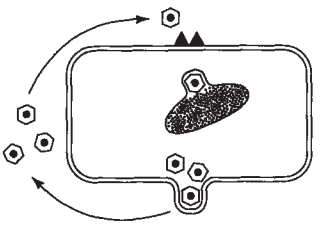
PERSISTENT VIRAL INFECTION

Maryann T. Puglielli and **Rafi Ahmed**, Emory University Vaccine Center, Atlanta, Georgia, USA



Introduction

Persistent viral infections have been and continue to represent significant health problems to the human population. Millions of people worldwide are chronically infected with pathogens such as human immunodeficiency virus (HIV-1 or -2), hepatitis B virus (HBV) and hepatitis C virus (HCV). **Table 1** illustrates the variety of viruses that can cause persistent infections in humans. This group of viruses is not limited solely to DNA-based types but includes several RNA-based viruses as well. These long-term infections have serious disease consequences with a diverse range including tumor formation, autoimmune diseases such as hemolytic anemia and arthritis, and immune system collapse as seen in acquired immune deficiency syndrome (AIDS). However, it is important to acknowledge that not all persistent viral infections lead to disease. There may be genetic and environmental factors at work; for example nasopharangeal carcinoma is found in unusually high rates in Chinese populations and Burkitts Lymphoma (BL), also an Epstein–Barr virus (EBV) associated cancer, has a high correlation with the incidence of malaria in areas of Africa. Persistent infections are categorized into two main types: chronic and latent infections. Chronic viral infection, as exemplified by HBV, is characterized by active, constant replication of virus progeny throughout the life span of the host. Latent infection occurs when the viral genome is present in host cells in the absence of virion production. An essential component of true latency is the ability for the virus genome to reactivate and reestablish virion production. Otherwise, in the absence of reactivation, latency becomes a dead-end in the life cycle of the virus. Herpes simplex virus (HSV), an alpha herpesvirus, often serves as the prototype for the study of latency and expresses nontranslated transcripts called latency associated transcripts (LATs) whose function remains unknown.

Several viruses, however, incorporate into their life cycle a combined strategy of latency and chronic infection. EBV, a gamma herpesvirus, initially infects epithelium of the oropharynx where viral replication is permissive. At this site B lymphocytes come into contact with EBV and become latently infected. Three different latency transcription programs that express different combinations of viral transcripts have been identified *in vivo*. Group I latency is likely the least visible to anti-EBV cytotoxic T lymphocytes (CTLs) as it involves expression of one viral protein, EBNA 1, which is necessary for genome maintenance in the host cell as an episome. Two small RNAs, EBERs, are also expressed during all forms of EBV latency whose effects on the immune response are discussed later. It has been proposed that this pool of latently-infected B cells come in contact with epithelium of the oropharynx where EBV actively replicates to produce infectious virions in the saliva 15–20% of the time for spread to new hosts. HIV-1 is another well-known example of a virus that combines latency with chronic infection. HIV-1 actively infects and replicates in CD4 T lymphocytes and monocytic macrophages. In some instances during the replication process, the DNA genome intermediate of this retrovirus is incorporated into host chromosomes where it lies dormant depending on the activation state of the cell.

Antiviral Immune Responses

The greatest adversary a virus must face during its replication life cycle is the host's immune response. To understand these selective pressures, it is worth-

In some instances during the replication process, the DNA genome intermediate of this retrovirus is incorporated into host chromosomes where it lies dormant depending on the activation state of the cell.

Antiviral Immune Responses

The greatest adversary a virus must face during its replication life cycle is the host's immune response. To understand these selective pressures, it is worth-

Table 1 Viruses that persist in humans[a]

Virus group	*Site of persistence*	*Consequence*
DNA viruses		
Adenovirus	Adenoids, tonsils, lymphocytes	None known
Cytomegalovirus	Kidneys, salivary glands, lymphocytes?, macrophages, stromal cells	Pneumonia, retinitis
Epstein–Barr virus	Pharyngeal epithelial cells, B cells	Infectious mononucleosis, Burkitt's lymphoma, nasopharyngeal carcinoma, non-Hodgkin's lymphoma, oral hairy leukoplakia
Herpes simplex virus 1 and 2	Sensory ganglia neurons	Cold sores, genital herpes, encephalitis, keratitis
Human herpesvirus 6	Lymphocytes	Exanthem subitum
Human herpesvirus 8	PBMC? Endothelial spindle cells?	Kaposi sarcoma
Varicella zoster virus	Sensory ganglia neurons and/or satellite cells	Varicella, zoster
Hepatitis B virus	Hepatocytes	Hepatitis, hepatocellular carcinoma
Hepatitis D virus	Hepatocytes	Exacerbation of chronic HBV infection
Papillomavirus	Epithelial skin cells	Papilloma, carcinomas
Parvovirus B19	Erythroid progenitor cell in bone marrow	Aplastic crisis in hemolytic anemia, chronic bone marrow deficiency
Polyomavirus BK	Kidney	Hemorrhagic cystitis
Polyomavirus JC	Kidney, oligodendrocytes in CNS	Progressive multifocal leukoencephalopathy
RNA viruses		
Hepatitis C virus	Hepatocytes	Hepatitis, hepatocellular carcinoma
Measles virus[b]	Neurons and supporting cells in CNS	Subacute sclerosing panencephalitis, measles inclusion body encephalitis
Rubella virus[b]	CNS	Progressive rubella panencephalitis, insulin-dependent diabetes?, juvenile arthritis?
Human immunodeficiency virus	CD4 T cells, monocytes/macrophages, microglia	AIDS
Human T-cell leukemia virus I	T cells	T-cell leukemia, tropical spastic paraparesis, polymyositis
Human T-cell leukemia virus II	T cells	None known

[b] Measles and rubella viruses typically cause acute infections. However, in rare instances, these viruses have been shown to persist in the CNS.
AIDS, autoimmune deficiency syndrome; CNS, central nervous system; PBMC, peripheral blood mononuclear cells.

while reviewing the components of the antiviral immune response, as shown in **Table 2**. T lymphocytes and antibodies are the two main antigen-dependent defenses against a viral infection. T lymphocytes are composed of two populations, CD8 and CD4. A major function of virus-specific CD8 T cells is to kill an infected cell by one of two mechanisms. (1) Perforin monomers and granzymes (serine proteases) are released onto the target cell surface where pore-like perforin polymers assemble and punch holes in the target cell membrane. This hole punching and the action of granzymes ultimately leads to apoptosis of the infected cell. (2) Upon activation of the CD8 T cell, Fas ligand (FasL) is upregulated on the T cell surface and binds to Fas on the surface of the infected cell. This crosslinking of FasL and Fas also leads to apoptosis of the infected cell. Of these two killing pathways, the dominant mechanism for virus control *in vivo* appears to be perforin-mediated killing due to the faster kinetics of target cell destruction as compared to the Fas/FasL pathway. In addition, some cells do not express Fas and as such would be resistant to Fas/FasL-mediated apoptosis. Of equal importance to direct killing of infected cells is the ability of CD8 T cells to produce and secrete antiviral cytokines such as interferon gamma (IFN-γ) and tumor necrosis factor (TNF). An absolute requirement for the initiation of these antiviral effector responses is the interaction of the T cell receptor (TCR) on the T lymphocyte with a major histocompatability complex (MHC) molecule presenting a processed viral peptide on the surface of the infected cell. CD8 T lymphocytes recognize peptides associated with MHC class I molecules whereas CD4 T lymphocytes recognize viral peptides associated with MHC class II molecules. These target

Table 2 Components of antiviral immunity

Effector system	*Recognition molecule*	*Mechanism of viral control*
Specific immune response		
Antibody	Surface glycoproteins or outer-capsid proteins of virus particles	Neutralization of virus
	Viral glycoproteins expressed on membrane of infected cells	Antibody-complement mediated killing and antibody-dependent cell-mediated cytotoxicity (ADCC) of virally infected cells
CD4+ T cells	Viral peptides (10–20-mers) presented by MHC class II molecules. The peptides can be derived from any viral protein internal or surface. The limiting factor is the ability to bind MHC.	Release of antiviral cytokines (IFN-γ, TNF) and activation of macrophages. Killing of virally infected cells? Optimize antibody responses to virus. Optimize CD8 T cell function.
CD8+ T cells	Viral peptides (9-mers) presented by MHC class I molecules of infected cells. The peptides can be derived from any viral protein, the main limiting factor being the processing and binding affinity of the peptide for MHC molecules.	Killing of virally infected cells. Release of antiviral cytokines (IFN-γ and TNF) and activation of macrophages
Innate immune response		
Natural killer cells	Not known	Release of IFN-γ, participation in ADCC, direct lysis of virus infected cells?
IFN-α/β	Not applicable	Inhibition of virus replication, induction of NK activity

peptides are derived from all proteins of the virus, both internal and external.

CD4 T lymphocytes are known as helper T cells because they enhance CD8 T cell and B cell functions. Like CD8 T cells, CD4 T cells also produce antiviral cytokines. For poorly understood reasons, depending on the viral infection, CD4 T lymphocytes have a varying degree of importance in supporting the CD8 T cell (CTL) response. Acute lymphocytic choriomeningitis virus (LCMV) infection can be controlled initially in the absence of CD4 T cells. However, CTL responses to vesicular stomatitis virus (VSV), influenza and herpes simplex virus (HSV) are much more dependent on these helper cells. In addition, more recent evidence suggests a crucial role for CD4 T cells in maintaining CD8 T cell responses to sustained chronic viral infections such as LCMV and HIV-1. This may be due to interleukin 2 (IL-2) production by CD4 T cells that leads to the survival of CD8 T cells over time or perhaps by the CD4 T cells stimulating the infected cell to increase expression of costimulatory molecules on the infected cell. Clonal expansion and differentiation of virus-specific B cells is oftentimes, but not always, dependent on CD4 T cell function. Likewise, it has been demonstrated that antibody responses to viral infections are greatly compromised in the absence of CD4 T cells.

B lymphocytes, through production of antibodies, are involved in the recognition and elimination of free virus and virus infected cells whereas T lymphocytes are adapted solely for destruction of virally infected cells via the TCR/MHC interactions described above. Antibodies serve to limit viral spread by neutralizing the virus directly by opsonization of viral particles or by tagging a virus-infected cell for destruction by antibody-dependent cell-mediated cytotoxicity (ADCC). Antibodies against viral glycoproteins tend to be more effective at neutralizing and eliciting ADCC than those against more internal viral proteins. Antiviral antibodies can remain in blood serum for years after infection and serve as a first line of defense against secondary infections.

During the time it takes to organize and mount an adaptive, virus-specific immune response, the innate immune response provides the initial line of defense for first exposure to a virus. Natural killer (NK) cells are the main component of this branch of the immune system. These cells produce IFNγ (type 2 interferon) and take part in ADCC. They may also directly lyse infected cells although it is not known how they distinguish virus-positive from virus-negative cells. A second component of the innate immune response is manifest in the ability of virally infected cells to produce antiviral type 1 interferons such as IFN α/β.

Evasion of Host Immune Responses

Given the complexity of an antiviral immune response, there are many ways in which a virus can subvert this defense and persist in the host. **Table 3** provides an outline of these strategies. As described above in EBV group I latency, HSV latency and HIV-1

Table 3 Viral strategies for evading the immune system[a]

Escape mechanism	*Example*[b]
Restricted gene expression; virus remains latent in the cell with minimal to no expression of viral proteins	HSV and VZV in latently infected neurons, EBV in B cells, HIV in resting T cells.
Infection of sites not readily accessible to the immune system	HSV, VZV, measles, and rubella persistence in neurons/CNS. CMV, polyomaviruses BK and JC in the kidney. EBV and CMV in the salivary gland. Papillomaviruses in the epidermis.
Inhibition of NK function	CMV protein UL18 is a MHC class I homologue that inhibits NK activity.
Antigenic variation; virus rapidly evolves and mutates antigenic sites that are critical for recognition by antibody and T cells	Antibody escape variants in lentiviruses. CTL escape variants in HIV, EBV, and HBV. T-cell receptor antagonism by HIV and HBV variants.
Suppression of cell-surface molecules required for T-cell recognition	Suppression of MHC class I molecules by adenoviruses, CMV, HSV, and HIV. Decreased expression of cell adhesion molecules LFA-3 and ICAM-1 by EBV. Suppression of MHC class II molecules by CMV, HIV, and measles.
Interference with antigen processing and presentation	HSV ICP47 protein and CMV U6 protein interfere with TAP to inhibit MHC class I antigen presentation. EBV protein EBNA-1 contains Gly-Ala repeats that confer resistance to proteasome mediated degradation and subsequent MHC class I presentation. CMV protein pp65 phosphorylates the CMV immediate early protein and inhibits its processing/presentation.
Viral defense molecules that interfere with the function of antiviral cytokines and chemokines	Adenovirus proteins E3 and E1B protect infected cells from lysis by TNF. Adenovirus VA RNA, EBV EBER RNA, HIV TAR and TAT RNA, K3L and E3L of vaccinia virus, NS5A of hepatitis C virus, NSP3 of porcine group C rotavirus, and σ3 of reovirus inhibit function of interferon. EBV protein BCRF1 (a homologue of IL-10) blocks synthesis of cytokines such as IL-2 and IFN-γ.
Immunologic tolerance	Clonal deletion/anergy of virus-specific CTLs in HBV carriers, HIV(?).
Cell-to-cell spread by snycytia	SSPE caused by measles.

[b] Only examples of viruses known to persist in humans are cited.
HSV, herpes simplex virus; VZV, varicella zoster virus; EBV, Epstein–Barr virus; CNS, central nervous system; CMV, cytomegalovirus; MHC, major histocompatability complex; NK, natural killer; CTL, cytotoxic T lymphocytes; HIV, human immunodeficiency virus; HBV, hepatitis B virus; TAP, transporter associated with antigen processing; IL, interleukin; IFN, interferon.

latency, viruses can restrict the repertoire of genes they express or even become transcriptionally quiescent. This strategy renders the pathogen effectively invisible to the immune system.

Viruses can also attack areas of the body that are immune privileged. The central nervous system (CNS) is targeted by several viruses among them HIV-1, LCMV, HSV, varicella zoster virus (VZV) and measles. At least two factors favor viral persistence in the CNS: the presence of the blood–brain barrier which limits lymphocyte trafficking through the CNS and the presence of neurons which express little to no MHC class I and no class II molecules therefore preventing T cell recognition. Another organ often targeted is the kidney. Though T cells commonly move through this organ, it is thought that infected epithelial cells are not accessible due to the presence of a continuous basement membrane and vascular endothelium covering them. Similar anatomical blockades are at work in epithelial surfaces of secretory glands (e.g. the salivary gland) and the epidermis with its protective basement membrane.

Mutations often happen during the replication of viral genomes via the error propensity of reverse transcriptase, RNA based RNA polymerases and to a lesser extent, DNA polymerases. Though many of these mutations are nonbeneficial, a small number result in the alteration of a T cell or antibody epitope. This alteration prevents recognition of the mutant antigen and therefore of the virus by antibodies and T cells that would recognize the parental epitope. This 'antigenic drift' phenomenon has been observed in HIV-1, EBV, HCV and HBV infections. However, it should be noted that although these variants have a selective advantage over the parental strain, they do not always become the predominant population in the

host. There have also been cases of TCR antagonism reported with variants arising from HIV-1 and HBV infections. Mutant antigens from these viruses are recognized by CD8 T cells, but instead of delivering an activation signal, an antagonistic signal renders the T cell nonfunctional. TCR antagonism would allow for the continued survival of parental, nonmutated strains of virus by deactivating CTLs that would recognize them.

Antigen presentation is a necessity for the preservation of T cell effector function. Viruses have also tapped into this vital requirement in two ways: (1) by suppressing cell surface molecules needed for T cell recognition such as MHC class I and class II and (2) by interfering with the processing and transportation of viral antigens to the cell surface. Human adenoviruses and human cytomegalovirus (HCMV) have evolved to block terminal glycosylation of viral antigens and thus their proper processing, block the transport of mRNA encoding MHC class I, retain MHC class I molecules in pre-Golgi complexes, and promote rapid degradation of newly synthesized MHC class I molecules. Likewise HCMV, HIV-1 and measles virus have been shown to interfere with MHC class II by blocking IFN-γ-mediated upregulation of MHC class II mRNA transcription. HSV ICP47 gene product is a classic example of attacking antigen transport. It binds to the transporter associated with antigen processing (TAP) and prevents antigen transport to the endoplasmic recticulum. EBV EBNA-1, the only protein expressed during group I latency, has been shown to be resistant to antigen processing in the proteasome due to a series of gly-ala repeats. Though low numbers of EBNA-1 specific CTLs can be found *in vivo*, their presence is due to cross-priming via exogenous processing of EBNA-1. Viruses have also evolved the capacity to interfere with the expression of adhesion molecules that are necessary for prolonged T cell contact with target cells and optimal activation. EBV infection has been demonstrated to decrease expression of ICAM-1 and LFA-3 allowing some BL cell lines to escape CTL killing.

Lastly, cytokines and chemokines are important messengers for the coordination and orchestration of the immune response. TNF is targeted for example by poxvirus T2 protein that acts as a TNF receptor homologue. Secretion of this protein from infected cells results in the quenching of free TNF from the bloodstream. EBV BCRF-1, a homologue of IL-10, can block the synthesis of IFN-γ and IL-2. Adenovirus VA RNA, HIV TAR RNA, and EBV EBER RNA can block the antiviral function of IFN-α/β. There are several additional examples one could add to this list of well-defined anticytokine viral proteins as well as many more viral proteins with suspected, though unconfirmed, homologies to chemokines and their receptors.

Challenges for the Future

Virology and immunology are but two sides of the same coin. Viruses have done well to identify for immunologists important components of the immune response to these pathogens. The mechanisms described here for evading the host's immune response are diverse. Unfortunately, persistent viruses commonly employ several of these tricks as exemplified here. However, the role that these strategies play in persistence *in vivo* is still unclear. Most of the experiments that led to the discovery of these anti-immune response mechanisms were done *in vitro*. To date, antigenic shift, MHC class I suppression, and cytokine interference have not been demonstrated to directly affect persistence of viruses *in vivo*.

Prophylactic vaccines have proven to be very effective against acute infections such as polio, measles, mumps, rubella and smallpox. There is also a very effective prophylactic vaccine for HBV, a normally chronic infection. This vaccine, based on HBV surface antigen, does not work therapeutically for individuals with established HBV infections. The lack of an effective treatment to eliminate pre-existing persistent infections represents a significant gap in the physician's arsenal of weapons against viral infections. Treatment strategies targeting antigen presentation by dendritic cells may also prove helpful. Candidate vaccines, drugs, or combination treatments for the elimination of established chronic viral infections will need to be as sophisticated as the viruses themselves by allowing for countermeasures to T cell suppression, cytokine function suppression and latency. Until treatments for established persistent viral infections exist, these pathogens will continue to present a significant problem for human health worldwide.

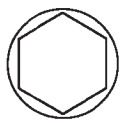
PHAGE ϕ6 (CYSTOVIRIDAE)



Dennis H. Bamford, Institute of Biotechnology, University of Helsinki, Biocenter, Finland

Discovery and Classification

Investigation of bacteriophages of phytopathogenic pseudomonads led to the discovery of a virus (ϕ6) which was extremely sensitive to organic solvents and detergents. The first reports in 1973 described two unique features: this spherical virus had a lipid envelope and the genome was composed of double-stranded RNA (dsRNA). Phage ϕ6 was, until very recently, the only member of the family *Cystoviridae*, genus *Cystovirus*. It appears now that ϕ6-like viruses can be isolated from sources such as degrading plant material. The host range of this virulent phage is restricted to pseudomonads. The largest number of sensitive strains is found among *glysinea*, *phaseolicola*, *syringae*, *tabaci* and *viridiflava* species.

Virus Particle

The overall diameter of the virus is about 85 nm. The spike protein extends from the membrane surface and the membrane is approximately 6 nm thick. The nucleocapsid has a diameter of 58 nm and the polymerase complex about 45 nm (**Fig. 1**). The mass determined for the virion is about 99 000 kDa and that for the nucleocapsid 40 000 kDa. The sedimentation values for these particles are 406S and 298S respectively. The density of the virion in Cs_2SO_4 is 1.22 g ml^{-1} and the corresponding value for the nucleocapsid is 1.33 g ml^{-1}. The virion is composed of approximately 70% protein, 20% lipid and 10% RNA. The spike protein P3 is associated with the integral membrane protein P6 to form an adsorption fusion complex. There are three additional hydrophobic membrane-associated proteins (P9, P10, P13). Between the membrane and the nucleocapsid, in close contact with the nucleocapsid surface protein P8, is a lytic enzyme (P5). Inside the shell of P8 is the icosahedral polymerase complex composed of four protein species (P1, P2, P4, P7). P1 forms the structural dodecahedral framework upon which the rest of the polymerase complex proteins are attached. P2 contains an RNA-dependent RNA polymerase active site. P4, a potent unspecific nucleoside triphosphate phosphohydrolase, provides the energy for RNA packaging. P7 is necessary for stable RNA

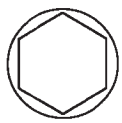
PHAGE ϕ6 (CYSTOVIRIDAE)



Dennis H. Bamford, Institute of Biotechnology, University of Helsinki, Biocenter, Finland

Discovery and Classification

Investigation of bacteriophages of phytopathogenic pseudomonads led to the discovery of a virus (ϕ6) which was extremely sensitive to organic solvents and detergents. The first reports in 1973 described two unique features: this spherical virus had a lipid envelope and the genome was composed of double-stranded RNA (dsRNA). Phage ϕ6 was, until very recently, the only member of the family *Cystoviridae*, genus *Cystovirus*. It appears now that ϕ6-like viruses can be isolated from sources such as degrading plant material. The host range of this virulent phage is restricted to pseudomonads. The largest number of sensitive strains is found among *glysinea*, *phaseolicola*, *syringae*, *tabaci* and *viridiflava* species.

Virus Particle

The overall diameter of the virus is about 85 nm. The spike protein extends from the membrane surface and the membrane is approximately 6 nm thick. The nucleocapsid has a diameter of 58 nm and the polymerase complex about 45 nm (**Fig. 1**). The mass determined for the virion is about 99 000 kDa and that for the nucleocapsid 40 000 kDa. The sedimentation values for these particles are 406S and 298S respectively. The density of the virion in Cs_2SO_4 is 1.22 g ml^{-1} and the corresponding value for the nucleocapsid is 1.33 g ml^{-1}. The virion is composed of approximately 70% protein, 20% lipid and 10% RNA. The spike protein P3 is associated with the integral membrane protein P6 to form an adsorption fusion complex. There are three additional hydrophobic membrane-associated proteins (P9, P10, P13). Between the membrane and the nucleocapsid, in close contact with the nucleocapsid surface protein P8, is a lytic enzyme (P5). Inside the shell of P8 is the icosahedral polymerase complex composed of four protein species (P1, P2, P4, P7). P1 forms the structural dodecahedral framework upon which the rest of the polymerase complex proteins are attached. P2 contains an RNA-dependent RNA polymerase active site. P4, a potent unspecific nucleoside triphosphate phosphohydrolase, provides the energy for RNA packaging. P7 is necessary for stable RNA

Table 1 Protein functions and proposed stochiometry

Protein	Molecular weight (kDa)	Molecules/virion (estimated)	Functions
P1	85.0	120	Core skeleton
P2	74.8	12	RNA polymerase
P4	35.0	120	Packaging NTPase
P7	17.2	60	Needed for packaging (+)-strand synthesis fidelity
P8	15.9	600	Nucleocapsid coat
P5	24.0	120	Membrane penetration lytic enzyme
P9	9.5	1200	Vesicle formation
P10	4.3	ND	Lysis factor
P13	7.6	ND	?
P6	17.2	60	Membrane fusion
P3	69.2	60	Cell attachment
P12	20.3	NA	Membrane assembly
P14	6.8	NA	?

NA, not applicable; ND, not determined.

encapsidation. The polymerase complex encloses three polycistronic genome segments, small (S, 2948 bp), medium (M, 4061 bp) and large (L, 6374 bp). The membrane phospholipids (8% cardiolipin, 35% phosphatidylethanolamine, and 57% phosphatidylglycerol) are derived from the host pool. The amount of lipid in the virus is enough to cover about half of the necessary surface area, the rest being protein.

Table 1 summarizes the protein functions and proposed stoichiometry.

Genome and Genetics

Phage ϕ6 has a high mutation rate. Temperature-sensitive mutants are found at a frequency of about 0.5%. In order to establish a genetic system for ϕ6 a nonsense suppressor host system was developed using a *Pseudomonas pseudoalcaligenes* strain. Nonsense, thermosensitive, missense or deletion mutants are available for all the genes. The mutants could be placed in three linkage groups consistent with the observation of three genomic dsRNA segments. All the genome segments are polycistronic. The nonsense mutants were assigned to the genes through analysis of phage-directed protein synthesis in the nonsuppressor host.

The entire genome is cloned and sequenced and the genes localized by the N-terminal analysis of the viral proteins (**Fig. 2**). The genes are organized so that the L segment codes for the viral polymerase complex proteins P1, P2, P4 and P7, as well as a small protein P14 of unknown function. The M segment codes for the attachment–fusion complex proteins P3 and P6, and two small membrane-associated proteins P10 and P13. The S segment codes for the nucleocapsid surface protein P8, the major membrane protein P9 and the

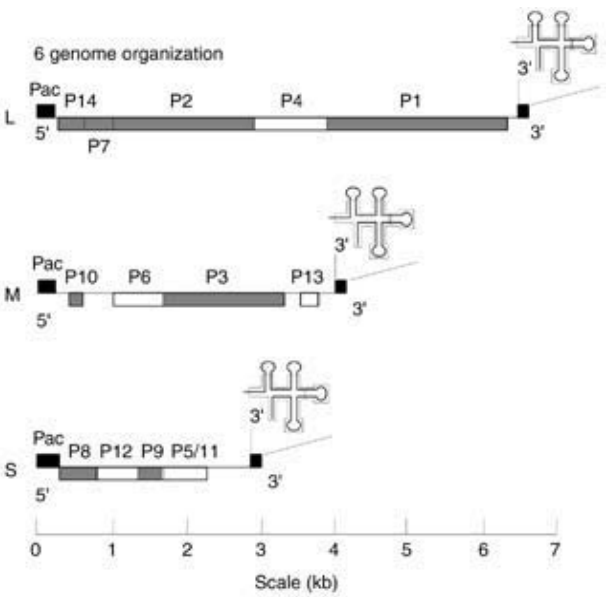

Figure 2 Map of the ϕ6 genome. S, M, L indicate the small, medium and large dsRNA genome segments respectively. The gene number corresponds to the protein number it encodes. (Courtesy of Mikko Frilander, Biocenter, University of Helsinki.)

lytic enzyme P5, as well as the nonstructural protein P12 needed in membrane assembly.

Each genome segment has noncoding regions of a few hundred base pairs at each end. There is a high degree of similarity between the ends of the three segments. The 3′ ends are identical for 17 bp and the similarity gradually diminishes and disappears at about position 80. At the 5′ end there is an identical block of 18 bp with no further similarity. However, the second base in the L segment differs from that in the M and S segments. The 5′ end contains the packaging (pac) site and the plus-strand synthesis start signal, whereas the 3′ end encodes the functions needed for the minus-strand synthesis initiation.

Life Cycle

Figure 3 depicts the life cycle of ϕ6. Protein P3 mediates the adsorption of the ϕ6 particle to the receptor, the host pilus. It is suggested that the pilus retraction brings the virus particle into contact with the host outer membrane (OM). Protein P6 mediates the fusion of the virus membrane with the OM, exposing the peptidoglycan layer to the virion-associated lytic enzyme (P5). The peptidoglycan is locally digested, allowing the nucleocapsid (NC) to face the cytoplasmic membrane (CM). The NC penetrates the CM via a mechanism which seems to be analogous to endocytosis and driven by acidification of the NC surface protein P8. The formed vesicle and the NC surface proteins (P8) are disassembled upon entry into the cell cytoplasm. The viral transcriptase starts the early transcription via a semiconservative mechanism. Approximately equal amounts of full-length transcripts of all the genome segments are synthesized. However, only the L message is actively translated. This leads to the assembly of polymerase complexes (procapsids) inside the cell. These particles package one of each type of messenger molecule. The packaging is followed by minus-strand synthesis (replication), leading to the dsRNA genomic segments inside the procapsid. These particles direct the late type of transcription where the majority of the transcripts originate from the M and S genome segments. The M and S messages are then translated, leading to the synthesis of the late proteins. The synthesis of the NC shell protein P8 leads to its assembly on to the polymerase complex, silencing its transcription activity. With the aid of the assembly factor P12, the NC is enveloped inside the cell with a virus-specific membrane derived from the

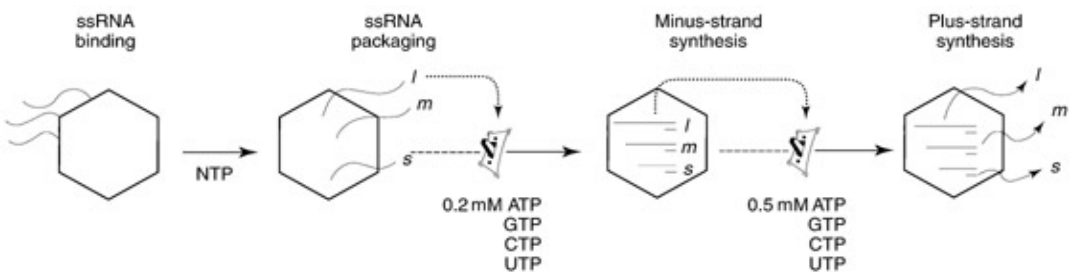

Figure 4 *In vitro* replication cycle of the purified procapsid. *s*, *m* and *l* indicate the single-stranded (ss) genome segments. The *l*-segment acts as a switch to turn on the next step.

host CM. The P3 spikes are assembled on the particle and the mature viruses are released by cell lysis. The cell lysis is caused by the phage-specific lytic enzyme P5 accompanied by the membrane protein P10.

In Vitro Assembly

Several recent technical developments in the $\phi 6$ system have generated an *in vitro* assembly pathway. The expression of the polymerase complex genes in *Escherichia coli* leads to the formation of empty procapsids, which are competent for *in vitro* packaging of the plus-strand transcripts. The packaged particles can replicate the single-stranded RNAs to the double-stranded form. Purified NC shell protein P8 can be assembled on to these particles. The nucleocapsids formed this way can infect $\phi 6$ host cells with partially removed outer membrane. Although these cells do not divide any more, they support one life cycle of the virus, leading to the formation of infective enveloped virus particles. The current focus is on assembling a functional polymerase complex from its four constituent proteins. This will accomplish the *in vitro* reconstitution of an infective complex dsRNA particle using purified structural components (**Fig. 4**).

These techniques are powerful in elucidating, in more detail, the assembly, packaging and replication signals and mechanisms operating in this virus. The nucleocapsid infection system allows the *in vivo* testing of the new constructs obtained. The availability of structural information of the virus and its subassemblies together with the assembly information will extend our understanding of the biology of dsRNA viruses.

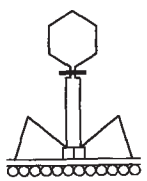
PHAGE ECOLOGY, EVOLUTION AND SPECIATION



Allan M Campbell, Stanford University, Stanford, California, USA

Ecology

Where are phages found in nature, and what impact do they have on their surroundings? Phages infecting most of the major groups of bacteria and archaea have been identified and observed in the diverse natural habitats of their hosts. Meaningful quantitation of phage densities is complicated by the fact that plaque counts enumerate only those phage plating on a specific host (generally with unknown efficiency), whereas electron microscopic counts may include many inactive particles. Concentrations of phage-like particles can be as high as 10^8 per ml in natural aquatic habitats (both fresh and salt water) and 10^{10} per ml in sewage. Plaque counts on specific hosts are generally orders of magnitude lower. A concentration of 10^8 active phage particles per ml could have a substantial effect on bacterial densities and the recycling of bacterial biomass.

Compared with plasmids, phages generally have

host CM. The P3 spikes are assembled on the particle and the mature viruses are released by cell lysis. The cell lysis is caused by the phage-specific lytic enzyme P5 accompanied by the membrane protein P10.

In Vitro Assembly

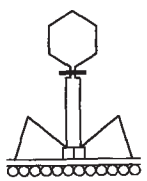
PHAGE ECOLOGY, EVOLUTION AND SPECIATION



Allan M Campbell, Stanford University, Stanford, California, USA

Ecology

Where are phages found in nature, and what impact do they have on their surroundings? Phages infecting most of the major groups of bacteria and archaea have been identified and observed in the diverse natural habitats of their hosts. Meaningful quantitation of phage densities is complicated by the fact that plaque counts enumerate only those phage plating on a specific host (generally with unknown efficiency), whereas electron microscopic counts may include many inactive particles. Concentrations of phage-like particles can be as high as 10^8 per ml in natural aquatic habitats (both fresh and salt water) and 10^{10} per ml in sewage. Plaque counts on specific hosts are generally orders of magnitude lower. A concentration of 10^8 active phage particles per ml could have a substantial effect on bacterial densities and the recycling of bacterial biomass.

Compared with plasmids, phages generally have

rather narrow host ranges, frequently being restricted to one bacterial genus or to a few strains within that genus.

Temperate phages have been identified for many hosts, and molecular probes show that natural bacteria frequently retain remnants of prophages acquired in past infections. For example, the K-12 strain of *Escherichia coli* harbors (in addition to λ itself) four λ-related defective prophages, and most natural isolates of *Escherichia* and related genera contain λ-related sequences. In K-12, λ and its defective relatives comprise about 3% of the bacterial genome.

Prophages sometimes affect the phenotype of their hosts. The ϵ-prophages of *Salmonella* encode enzymes that modify the polysaccharide of the cell envelope, changing the antigenic specificity and rendering the bacteria resistant to infection by other phages of the same type. A number of phages affect the ability of pathogenic bacteria to cause disease. Sometimes a phage gene is directly involved in pathogenesis, as in diphtheria, where the toxin is encoded by a phage. Other phages have ancillary effects, as with bacteriophage λ, which bears genes that increase the serum resistance (and therefore potential pathogenicity) of *E. coli* hosts.

Evolution

Phages can be classified into numerous groups. Of the common coliphages T2, T3, λ, P1, f1, Mu-1, MS-2 and ϕX174, each has several known relatives. Within a group, different phage types can be distributed nonuniformly among local habitats and geographical areas, e.g. the ubiquitous F-specific isometric RNA coliphages are present in sewage from most parts of the world, generally at concentrations of about 10^3 PFU ml^{-1}, but different serotypes are more common in India than in Japan and in the feces of humans versus those of domestic animals. No good molecular phylogeny relates the various groups to one another. Hierarchical taxonomic schemes have been proposed (usually based on type of nucleic acid and virion morphology) but none has gained wide acceptance or carries any claim to phylogenetic significance. As with many animal virus groups, an independent origin of the different groups from host nucleic acid is as plausible as derivation from one ancestral virus. Within a group, a molecular phylogeny can of course be constructed for any one gene, but the phylogenies for different genes are not congruent, indicating frequent natural recombination. It is questionable whether the members of a group are better considered as different species rather than as members of the same species drawn from a common gene pool (see below, under Speciation).

At least for the larger DNA phages, current thinking generally assumes a chimeric origin, with different segments of the phage genome derived from different parts of the host genome, or from different hosts, or from plasmids, transposons or other phages. Even for the phylogeny of the major groups, the pattern of ancestry may therefore be reticulate rather than arboreal. Within a group, the conservation of gene order suggests descent from a common ancestor of that group.

Population Biology

Whatever the evolutionary origin of a given phage, one may ask how the phage population maintains itself over long periods of time. Mathematical analysis and chemostat experiments agree that a virulent phage can persist in permanent equilibrium with its host. Depending on the values of such parameters as adsorption rate, latent period, burst size and host growth rate, the equilibrium may either be stable or unstable with respect to undamped oscillations in phage and host numbers. Theory also indicates that the ability to impart a selective advantage to the host should be an important factor in the survival of temperate phage. The possible advantage might be felt by either the individual bacterium or the bacterial population.

Advantage to the individual in its natural surroundings should be intermittent, otherwise the phage genes imparting the advantage should by now have been incorporated into the host genome. Laboratory situations can be contrived where a prophage gene promotes bacterial survival; for example, some λ-related phages and prophages contain a gene *nmpC* which encodes an outer membrane protein able to substitute for the host OmpC protein; similarly, the recombination genes of lambdoid prophages can replace the *recBCD* genes of the host to impart resistance to DNA damage. In the appropriate bacterial mutant and environment, these phage genes can thus confer a selective advantage on the host. It is frequently assumed that some of the phage genes affecting bacterial pathogenesis are likewise beneficial to the host, although the exact advantage of being pathogenic remains elusive.

At the populational level, phage can transduce genes from one cell to another. Sequence comparisons of homologous DNA regions from natural isolates of related bacteria indicate that recombinational substitution of DNA from other strains is common. Whether this recombination benefits the bacteria remains to be established, as does the magnitude of the phages' contribution to the natural process.

Speciation

In sexual eucaryotes, a species is generally defined as a group of individuals that share a common gene pool because of interbreeding. Until recently, the concept was generally considered inapplicable to either bacteria or viruses. However, molecular data have encouraged reconsideration. The basic fact (cited above) that, within a group, trees based on different genes are not congruent rules out the textbook expectation for asexual organisms related to one another by purely clonal propagation without genetic exchange. The different lambdoid phages appear related to one another by numerous exchange events, suggesting that the entire group is best viewed as a single species.

Classical speciation entails the establishment of barriers to interbreeding so that the gene pools of distinct species cannot mix. The phage equivalent of that process is undefined. If each phage group has an independent origin, classical speciation may not exist. What can be asked is whether, or to what degree, the gene pools of various phage groups are isolated from one another (and from the gene pools of the hosts they infect). When an answer is sought through sequence comparisons, the question overlaps that of viral origins (discussed above, under Evolution).

There are some well-documented cases of homologies between viral genes and their host counterparts. For example, whereas the λ replication protein gp*P* interacts with the host *dnaB* helicase, in at least one lambdoid phage (P22) the N-terminus of the analogous protein is fused to a C-terminal *dnaB*-related segment, and replication does not require *dnaB*. Similarly, homologies have been detected between genes of T4, P2 and λ whose products contribute to attachment of phage to the cell surface or which are closely linked to genes for attachment proteins. In both cases, the genes are clearly of a common origin but not a very recent one. Within a group, homologous genes are also highly diverged in some cases but much more similar in others. Thus some past exchanges have occurred between distantly related phages and between phage and host. If such exchanges were frequent and recent, the concept of distinct species with separate gene pools would have little use. The examples known at present can be reasonably viewed as rare lateral transfers across species boundaries.

PHAGE PRD1 (*TECTIVIRIDAE*)

Dennis H Bamford, Institute of Biotechnology, Biocenter, University of Helsinki, Finland

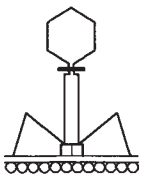
Discovery and Classification

Bacteriophage PRD1 belongs to a group of very closely related phages isolated from different parts of the world. Other members of this group are PR3, PR4, PR5, LI7 and PR772. These viruses are lytic, infecting a vast variety of Gram-negative cells harboring a P-, N- or W-type conjugative plasmid. Among the hosts are *Escherichia coli, Salmonella typhimurium* and *Pseudomonas aeruginosa*. PRD1 is the type virus of the family *Tectiviridae*, genus *Tectivirus*. This virus family also includes members infecting Gram-positive hosts. PRD1 and PR4 are the most thoroughly studied phages in this group. Since these viruses are almost identical, the description of this phage system uses information from both of them. The discovery (1973–1979) was associated with studies of antibiotic-resistant plasmids. In further studies it was observed that they have an internal lipid membrane and a linear double-stranded DNA (dsDNA) genome with 5′-covalently-linked terminal proteins.

Properties of the Virion

The viral particle (**Fig. 1**) has an outer diameter of approximately 65 nm. The outer protein layer sur-

PHAGE HOMOLOGOUS RECOMBINATION



Kenneth N Kreuzer, Department of Microbiology, Duke University Medical Center, Durham, North Carolina, USA

Introduction

For about half a century, bacteriophages have provided very productive systems for analyzing recombination mechanisms, and fundamental advances continue to emerge from these model systems. As described below, every phage that has been studied in detail uses multiple pathways of homologous recombination catalyzed by different combinations of host- and/or phage-encoded proteins.

A typical consequence of genetic recombination is the generation of a progeny genome with a combination of genetic markers different from either parental genome. However, recombination also plays central roles in the life cycles of many bacteriophages, even when considering solo infections in which reassortment of genetic material is not possible. For example, homologous recombination is important in phage DNA replication, repair of damaged phage DNA, and the maintenance of phage genomic structure (e.g. recombination of terminal redundancies). This entry summarizes homologous recombination in a few well-studied phage systems, considering the process of recombination in the context of the phage life cycle. Mechanistic aspects of recombination are also considered, and a closing section attempts to draw parallels. Recent reviews in the Further Reading list should be consulted for more comprehensive descriptions of homologous recombination and for literature citations. Bacteriophages also provide extremely productive systems for analyzing mechanisms of site-specific and transpositional recombination, but these will not be considered here.

Single-stranded DNA Phages

Unlike many other phage systems, recombination is not very important in the life cycle of the single-stranded DNA (ssDNA) phages (e.g. ϕX174, S13, f1). Indeed, ssDNA phage recombination is so infrequent that it is difficult to detect in the absence of agents (e.g. UV) that stimulate the process.

In spite of its low frequency, genetic analyses of ssDNA phage recombination revealed basic characteristics that are shared by many phage systems. For example, a variety of experiments established that the products of ssDNA phage recombination are usually nonreciprocal, eliminating simple break–rejoin models. The preponderance of nonreciprocal products in phage recombination forces recombination models that include one or more of the following features: (1) information from one parental molecule is destroyed during the reaction; (2) mismatch repair of heteroduplex DNA produces unequal recovery of alleles; (3) DNA replication copies information from one homologue so that two products of a single event carry the same allele.

A second characteristic of ssDNA phage recombination shared by many other phage systems is the existence of multiple recombination pathways. A majority of the recombination in ssDNA phages requires the host-encoded *recA* gene product. This is a well-studied bacterial recombination protein which catalyzes the invasion of a single-stranded region of one DNA into a duplex homologue. In most bacterial recombination, the host RecBCD enzyme is responsible for generating the ssDNA for RecA-promoted strand exchange. Surprisingly, however, RecA-dependent recombination of ϕX174 is not significantly reduced by host *recBC* mutations. Perhaps RecA catalyzes strand invasion using the infecting viral ssDNA of one phage and the duplex replicative form of a coinfecting phage.

An alternative means of generating ssDNA is apparently available near the phage replication origin, which acts as a strong hotspot for RecA-dependent recombination. This finding led to a model in which initiator protein-induced nicking of the origin in duplex replicative form DNA sometimes creates a single-stranded tail that participates in RecA-promoted strand invasion, leading to recombination events that are localized to the origin region. The recombination hotspot activity of the replication origin provides one interesting linkage between the processes of phage DNA replication and recombination.

While most ssDNA phage recombination requires RecA, a significant fraction does not. The mechanism of RecA-independent recombination is uncertain, but could involve the annealing of two complementary single strands. RecA-independent recombination is further reduced by about an order of magnitude in a *recB*$^-$ mutant host, implying a requirement for the RecBCD enzyme. Again, this is a surprising result, because all other known modes of RecBCD-promoted recombination require the RecA protein. The genome

of ϕX174 contains a χ site (5′-GCTGGTGG-3′), which is the activation sequence for RecBCD, but it is not known whether this χ site is necessary for RecA-independent recombination.

The RecA-independent recombination of ϕX174 is abolished in phage gene *A* mutant infections, which are blocked for all DNA replication after the initial conversion of infecting viral DNA to a duplex circle. This result strongly suggests that RecA-independent recombination requires phage DNA replication, and provides a second interesting linkage between DNA replication and recombination. How could DNA replication provoke RecA-independent recombination? If ssDNA annealing is central to this mode of recombination, then replication presumably generates ssDNA. Perhaps breakage of a replicative intermediate provides a duplex end that serves as an entry site for the RecBCD enzyme, which can actively denature a duplex to produce recombinogenic ssDNA (see below). Alternatively, perhaps replication generates ssDNA regions on the lagging strand or occasional ssDNA products that have not undergone complementary strand synthesis. In any case, if two complementary single strands are necessary for RecA-independent recombination, one of the participating molecules could once again be the viral strand of one infecting phage (which has not yet been converted into a duplex circle).

Phage λ

Recombination in phage λ has been analyzed in exquisite detail, using combinations of genetic, physical and biochemical approaches. λ recombination is intertwined with phage DNA replication and packaging, and therefore the roles of phage and host recombination proteins in all three processes must be considered.

The packaging of phage λ DNA into infectious particles involves double-strand DNA cleavage at the *cos* site by the terminase enzyme complex. DNA cleavage requires a multimeric DNA substrate, either in the linear or circular form, and cannot occur with monomeric circles. In wild-type λ infections, phage DNA replication proceeds by both the bidirectional (θ) and rolling-circle (σ) modes, the latter producing the linear multimers that are substrates for DNA packaging. In contrast, when the infecting phage is mutant in a gene called *gam*, the rolling-circle mode is blocked by the host RecBCD enzyme. The major function of the Gam protein in wild-type infections is to protect the rolling-circle intermediates from the action of the host RecBCD enzyme, which can degrade linear DNA. Consistent with this function, the Gam protein has been shown to bind to RecBCD enzyme and block all known activities of the enzyme *in vitro*. In spite of the fact that *gam*$^-$ mutants cannot produce linear multimers via rolling-circle replication, such mutants are normally viable. This is due to the fact that recombination between circular monomers can produce circular multimeric DNA and thereby provide a suitable substrate for DNA packaging. Thus, recombination is essential for growth of phage λ *gam*$^-$ mutants, and host- and/or phage-encoded recombination proteins can participate in recombination during the λ infective cycle (see below).

In addition to Gam, phage λ encodes several other proteins involved in homologous recombination, most notably the products of the *red* genes. The *red* genes encode two proteins, an exonuclease (Red α) that can generate single-stranded 3′ tails at duplex breaks and an ssDNA-binding protein (Red β) that can facilitate renaturation of complementary ssDNA *in vitro*. The Red proteins play a major role in phage λ recombination (see below). Red may also play a direct role in λ DNA replication, because *red* mutations reduce the rate of phage DNA replication. It has been proposed that the Red system participates in the rolling-circle mode of λ DNA replication by catalyzing a break–copy mechanism of recombination, much like that used by phage T4 (see below). Nevertheless, *red*$^-$ mutant infections produce concatemeric DNA, presumably via rolling-circle replication, and therefore the Red system is not solely responsible for generating rolling circles. The mechanisms that generate λ rolling circles, either in the presence or absence of Red function, are not understood.

The influence of phage and host recombination proteins on phage λ DNA metabolism can thus be summarized as follows. In λ$^+$ infections, rolling-circle replication generates linear DNA multimers that are the normal substrate for DNA packaging, and the λ Red pathway may be responsible for generating some of the rolling circles. In λ *gam*$^-$ infections, rolling-circle replication is prevented by the host RecBCD enzyme. In this case, recombination by phage- and/or host-directed pathways is essential for survival, because multimeric circular DNA must be produced by recombination to allow DNA packaging.

Phage λ recombination can be directed by several different pathways depending on the genotype of the phage and the host. A single mutation in the host *recA* gene has little effect on the frequency of recombination during a λ infection, but a mutation in the phage *red* genes reduces recombination by several fold. A combination of both mutations essentially abolishes

recombination, except in the genetic interval that is subject to site-specific recombination by the phage-encoded Int system. The simple interpretation is that a majority of λ recombination is catalyzed by the Red pathway, and a minority by one or more host pathways that require RecA protein. An important complexity, however, is that the RecA protein is apparently utilized, in conjunction with the Red proteins, during infection of wild-type *Escherichia coli*. This can be inferred because the qualitative nature of *red*$^+$ λ recombination changes dramatically when the host RecA protein is mutationally inactivated (even though the frequency of recombination does not change much; also see below).

The host recombination pathways that are active during λ growth are difficult to study when the phage Red system is active, because the Red system predominates. However, these pathways can be readily analyzed by inactivating Red. As mentioned above, all Red-independent λ recombination requires the host RecA protein (except for site-specific recombination by Int). In addition, RecBCD is normally required for most λ *red*$^-$ (*gam*$^+$) recombination, because phage recombination is 3- to 10-fold lower in a *recBC*$^-$ host than in a wild-type host. There are several important factors to consider with respect to RecBCD pathway recombination during λ *red*$^-$ infection. First, RecBCD contributes to λ recombination in spite of the production of Gam protein, perhaps during the time when Gam has not yet reached high levels. Nevertheless, the production of Gam clearly reduces RecBCD activity in the λ infection, because λ *red*$^-$ recombination increases several fold (to nearly wild-type levels) if Gam is mutationally inactivated. Second, during infection by such a *red*$^-$ *gam*$^-$ double mutant of λ, active RecBCD enzyme prevents rolling-circle replication but, together with RecA protein, allows sufficient recombination to generate packagable DNA in the form of multimeric circles. Third, wild-type λ contains no χ sites, which act as hotspots for RecBCD-promoted recombination. Mutants of λ containing χ sites utilize the RecBCD pathway more efficiently, and χ-less wild-type λ presumably recombine by the RecBCD pathway using pseudo-χ sites that deviate slightly from the consensus sequence.

Phage λ can also utilize the host RecF and RecE pathways when these pathways are activated by the appropriate host mutations (*sbcBC* and *sbcA*, respectively). One interesting feature of λ's use of the RecF pathway relates to the protein requirements. The host genes *recO*, *recR* and *recF* are not required for λ recombination by the RecF pathway but are necessary for host conjugal recombination by the same pathway. The solution to this puzzle was recently uncovered. λ encodes a protein, Orf, that substitutes for the three host functions, and a mutation that inactivates the *orf* gene results in a requirement for the three host genes. Recombination of λ by the RecE pathway of *E. coli* closely resembles recombination by the λ Red pathway, because the RecE pathway is dependent on the Red-like functions of a cryptic prophage in the genome of some *E. coli* strains.

By using appropriate combinations of host and phage mutations, it is possible to limit λ recombination to any one of the above-mentioned pathways (Red, RecBCD, RecF, RecE). This, together with other advantages of λ, has allowed the λ infective cycle to become a fertile testing ground for models of recombination. The mechanistic details of the two major pathways of λ recombination (Red and RecBCD) will be considered here, and reviews in the Further Reading list should also be consulted for mechanistic descriptions of these and the RecE and RecF pathways.

The Red pathway of λ recombination appears to be primarily, if not exclusively, triggered by double-stranded breaks (DSBs). In the absence of DNA replication, Red-promoted recombination is focused on sites of double-strand breakage, including the natural DSBs created by terminase cleavage at *cos* and engineered DSBs generated by restriction enzyme cleavage. When replication is allowed, Red-promoted recombination occurs throughout the genome. Nonetheless, DSBs appear to be responsible for initiating Red-promoted recombination even in the presence of replication, because such recombination is prevented by production of a protein that blocks double-strand ends. Presumably, replication generates randomly located DSBs, including the tips of rolling-circle intermediates.

Stahl and his colleagues have presented evidence that Red-promoted recombination can occur by at least two mechanisms, depending on whether the host RecA protein is available. In both mechanisms, the 5′ exonuclease activity of the Red α protein (λ exonuclease) generates a single-stranded 3′ tail after production of a DSB by one of the routes listed above. In the presence of RecA, this tail invades homologous duplex DNA to establish a recombination intermediate. Subsequent steps are not entirely clear, and may depend on whether DNA replication can occur (break–copy recombination, as mentioned above). In the absence of RecA, a large fraction of Red-promoted recombination appears to involve the annealing of complementary single strands by the Redβ protein.

The general features of RecBCD-promoted λ recombination now seem clear, based on a convergence of genetic and enzymological approaches. As

with Red-promoted recombination, DSBs are important for activation of recombination, but RecBCD-promoted recombination does not occur at the site of the break. Genetic analyses demonstrated that RecBCD activates recombination whenever at least one of the participating DNAs contains a χ site and a DSB. As mentioned above, wild-type λ contains no χ sites, but recombination is thought to be activated by sequences that closely resemble the χ consensus. In most genetic analyses of RecBCD-promoted λ recombination, a single χ site is introduced into the λ genome, a *gam* mutation is used to allow maximal RecBCD activity, and the natural DSB is provided by terminase-promoted cleavage at the *cos* site. After *cos* cleavage, terminase remains bound to one of the two newly formed DNA ends, resulting in only a single unblocked DNA end (the right end on the standard λ genetic map). With this configuration, RecBCD greatly enhances recombination near and beyond a properly oriented χ site, regardless of the distance between the *cos*-promoted break and the χ site. The localization of recombination suggests that the RecBCD enzyme requires a duplex break to enter, but that it does not stimulate recombination until it encounters a χ site. The genetic information between the right end of the genome and the χ site is lost during the process of recombination, arguing that the RecBCD enzyme destroys DNA prior to its encounter with a χ site. The genetic results just described have recently been duplicated and analyzed at a biochemical level. In an *in vitro* system with purified proteins, RecBCD degrades the DNA between the free end and the χ site, and stimulates (RecA-promoted) recombination at and beyond the χ site. Passage through a χ site grossly alters the properties of the RecBCD enzyme, converting it from a degradative nuclease to a recombinative helicase. The mechanism of this alteration is not known, but has been hypothesized to involve the loss of the RecD subunit of the enzyme.

Phage T7

Unlike the cases described above, phage T7 is largely independent of host recombination functions. Mutations in the host *recA* or *recBC* genes do not affect T7 recombination, even when the infecting T7 carries mutations that reduce recombination. Phage T7 also induces its own replication proteins, making T7 DNA metabolism independent of that of the host.

One of the central themes of T7 DNA metabolism is the close coupling between replication and recombination. An electron microscopic analysis of DNA from T7-infected cells indicated that the largest number of joint molecules (presumptive recombination intermediates) are present at the time of maximal DNA replication. Furthermore, a mutation in the gene that encodes the viral DNA polymerase (gene *5*) or helicase/primase (gene *4*) abolishes DNA replication and greatly reduces recombination. The close coupling of replication and recombination can be explained in at least three ways: (1) replication increases the DNA copy number, leading to more recombination; (2) the products of genes *4* and *5* play important roles in both processes independently; and/or (3) some replicative intermediate is a substrate for recombination.

Although DNA copy number may affect recombination frequency, the first explanation alone is not sufficient to explain the coupling of T7 replication and recombination. In the first place, a mutation in gene *1* (encodes T7 RNA polymerase) or 2 (encodes inhibitor of host RNA polymerase) greatly reduces replication but does not affect recombination. Likewise, the presence of a host DNA gyrase inhibitor (nalidixic acid) or the absence of DNA ligase reduces replication but not recombination. Second, a sensitive direct physical assay of infecting viral DNA failed to detect recombinant products during infections that were deficient in gene *4* or *5*. Third, active plasmid replication apparently stimulates T7-promoted plasmid–phage recombination, even when the plasmid copy number increases only slightly.

There is very good reason to believe that T7 recombination and replication require common proteins. In general, most models for genetic recombination include at least one replicative step and therefore implicate DNA polymerase and associated proteins in recombination. More specifically, the gene *4* helicase and the gene 2.5-encoded ssDNA-binding protein both promote important steps during *in vitro* replication and recombination reactions (see below). An *in vitro* system using crude extracts from T7-infected cells shows a tight coupling between recombination and replication. This *in vitro* system is capable of very extensive DNA replication and recombination, with about 20% of progeny DNA being recombinant. The coupling is particularly evident when a substrate DNA contains a double-strand gap. The break is efficiently repaired, using homologous intact DNA as template for the DNA synthesis necessary to cross the gap.

It also seems very likely that T7 DNA replication generates recombinogenic structures. The frequency of marker rescue from UV-damaged phage T7 genomes is greatest for markers near the primary replication origin, which is also the region of the genome that preferentially replicates after UV treatment. Thus, partially replicated DNA molecules may be preferential substrates for recombination, perhaps

because they contain single-stranded regions or because they are prone to break.

One unusual recombination event is critical for maintaining the genome of phage T7 and is probably directly coupled to DNA replication. The T7 genome is packaged in phage particles as a linear DNA molecule. Because DNA polymerases replicate DNA in the 5′ to 3′ direction and cannot initiate chains *de novo*, the 3′ ends of the T7 viral genome should remain single-stranded after replication from the internal origin. Without a remedy, the ends of the genome would be progressively lost with subsequent rounds of DNA replication. T7 solves this potential problem with 160 bp terminal repeats in its genome. Replication of the infecting viral DNA presumably creates daughter molecules that each contain one single-stranded end (the 3′ end of the parental strand). Because the opposite ends of the genome carry the same sequence, the single-stranded 3′ ends in the two daughters will be complementary, and thus single strand annealing can produce a dimeric molecule with one copy of the repeat in the middle. Subsequent rounds of replication followed by end annealing can produce longer multimers, again with only one copy of the repeat forming the junction between any two genomes. The regeneration of viral genomes prior to DNA packaging therefore requires the duplication of the terminal repeat, which apparently occurs by means of a special replication reaction.

The generation of dimers and higher multimers is a form of recombination from a physical viewpoint. However, from a genetic viewpoint, this recombination event does not lead to recombinant progeny. Even if dimerization is biparental, subsequent cleavage at the concatemeric joint resegregates the markers of the two parents from each other. This formation of dimer T7 DNA molecules forms an interesting model for a presumed ssDNA annealing recombination reaction. Unfortunately, the gene products required for dimer formation have not been directly determined. The ssDNA-binding protein of T7 (product of gene 2.5) mediates a similar annealing reaction *in vitro*, arguing that this protein may be critical for dimer formation *in vivo*. Although the reaction is thought to be normally coupled to DNA replication, a strand-specific exonuclease (see below) could also generate complementary single strands at the genome ends and perhaps obviate the need for DNA replication.

In addition to the T7 helicase/primase, DNA polymerase and ssDNA-binding protein, two T7-encoded nucleases are important in phage recombination. Out of all T7 genes, mutations in gene 6 cause the most dramatic reductions in phage recombination (greater than 100-fold). The gene 6 protein is therefore necessary for virtually all T7 recombination. Even in the absence of other T7 replication/recombination proteins (products of genes 3, 4 and 5), gene 6 protein apparently provides a minor pathway of recombination. Biparental joint DNA molecules resembling Holliday junctions can be detected from cells infected by a multiple $1.3^-\ 2^-\ 3^-\ 4^-\ 5^-$ mutant but not a $1.3^-\ 2^-\ 3^-\ 4^-\ 5^-\ 6^-$ mutant.

In spite of the importance of the gene 6 protein, its precise role in T7 recombination has not been elucidated. Gene 6 encodes the major T7 exonuclease, which generates 3′ single-stranded tails at duplex DNA ends, and also has RNaseH activity. The generation of ssDNA is presumed to be the key to recombination promoted by the gene 6 exonuclease. Perhaps the high level of recombination that is coupled to DNA replication is caused by occasional breakage of the replication fork, followed by gene 6 exonuclease processing of the broken DNA. In any case, once ssDNA regions are created, the T7 ssDNA-binding protein (gene 2.5 product) presumably facilitates an annealing reaction to generate joint molecules.

Recent *in vitro* experiments indicate that a more complete recombination reaction can be achieved using the gene 4 helicase. When a single-stranded circular DNA was incubated with a homologous linear duplex that contained a short single-stranded region at one end, the gene 2.5 protein promoted annealing of the complementary single-stranded regions and the gene 4 helicase then catalyzed a branch migration reaction into and through the duplex region. Thus, a complete strand exchange reaction occurred, generating duplex circular and ssDNA linear products.

The second T7-encoded recombination nuclease is the product of gene 3, T7 endonuclease I. Endonuclease I plays a key role in recombination, namely the resolution of Holliday junctions. An early study indicated that branched dimeric DNA molecules were detected from infections by $2^-\ 3^-\ 4^-$ triple mutants, but hybrid monomers were found with a $2^-\ 4^-$ double mutant. More recently, the endonuclease was shown to cleave branched DNA molecules *in vitro*, and cloned gene 3 protein was shown to substitute, during phage T4 infections, for T4 gene 49 protein (T4 endonuclease VII; resolves DNA branches during T4 DNA packaging; see below).

Pulling together the demonstrated functions of these various T7-encoded proteins, a reasonable (though untested) model for T7 recombination can be formulated as follows. The initiating lesions would be DNA ends, generated by replication fork breakage, random genomic breaks (e.g. nuclease induced), DNA damage (e.g. chemical or radiation induced) and/or

natural genome ends. Gene 6 exonuclease would resect the ends to create single-stranded regions, and the T7 ssDNA-binding protein would then promote annealing of two complementary strands. Subsequent events could include branch migration into duplex regions by the gene *4* helicase and/or *de novo* replication events in which invading 3′ ends are used to trigger localized or extensive DNA synthesis. Finally, endonuclease I would resolve any remaining branches to produce simple linear DNA products.

Phage T4

Viral genetic recombination was first demonstrated using infections with T4 and the closely related T-even phages. T4 recombination has since been extensively studied and has provided key advances in our understanding of recombination mechanisms, for example, the earliest evidence for DSB-directed recombination. An advantage of the T4 system is that the phage encodes its own recombination proteins, most of which have been purified and analyzed biochemically. Furthermore, recombination is extremely active in T4, with the average progeny DNA having experienced between 10 and 20 recombinational exchanges during the infective cycle.

Phage mutations that reduce recombination have profound effects on phage growth, and therefore recombination is very important in the T4 life cycle. As in the case of phages λ and T7, the importance of T4 recombination reflects the intimate connections between phage recombination, DNA replication and packaging. Infecting T4 phage DNA is a terminally redundant linear molecule, and recombination of the genomic ends is required to generate multimeric DNA forms that are necessary for packaging. During a solo infection, recombination at the ends could generate a circular form if recombination precedes replication or a linear dimer if recombination follows replication. Other DNA forms are possible during a coinfection by two or more phages. Because packaging creates circularly permuted genomes, the end of one phage DNA may be homologous to a middle of another coinfecting phage DNA, and therefore Y forms can be generated. As replication produces multiple genome copies during the course of the infection, all T4 DNA within a single infected cell becomes enmeshed in a large, complex concatemeric structure with numerous recombinational joints.

Mutations that reduce T4 recombination also abolish one of the two major modes of T4 DNA replication. At early times of infection, T4 replication origins direct genomic replication regardless of the presence or absence of recombination proteins. However, the origins become repressed as the infection proceeds, and recombination-dependent DNA synthesis becomes the only significant replication mode at late times. T4 mutations that reduce recombination thereby cause a 'DNA-arrest' phenotype. Mosig and her colleagues presented a model for recombination-dependent DNA synthesis in which recombination intermediates are converted into replication forks. In this model, a single-stranded 3′ end invades a duplex homologue, forming a Y-structure with a D-loop at the point of invasion. The single-stranded ends may arise from the incomplete replication of genomic ends (see above), or by exonuclease action, perhaps directed by the T4-encoded gp46/47 nuclease. After formation of the recombination intermediate, the invading 3′ end is proposed to serve as primer for leading-strand DNA replication, and Okazaki fragment synthesis on the lagging-strand completes the replication fork. Note that the two strands of the invaded duplex serve as the template strands for DNA replication.

A variety of results support this general model for T4 recombination-dependent replication. *In vivo* experiments have provided the following evidence: (1) both recombination and late replication are reduced or blocked by mutations in phage genes *uvsX*, *uvsY*, *46*, *47* and *59*; (2) the ends of infecting T4 DNA are highly recombinogenic, and the characteristics of the recombinants are consistent with replication often initiating at the recombination junction; (3) electron microscopy of early replicating DNA has revealed the proposed Y form intermediates; (4) recombination-dependent replication does not require specific DNA sequences (replication origins), but does require homologous DNA sequences to allow formation of recombination junctions; and, (5) an artificial DSB introduced into one DNA can trigger replication of homologous DNA during T4 infection.

T4 recombination-dependent replication has been reproduced *in vitro*. The properties of the *in vitro* system provide strong support for the general model described above, and also reveal important mechanistic details of the reaction. The *in vitro* system utilizes a linear ssDNA fragment and a linear or circular duplex homologue. Strand invasion is catalyzed by the phage-encoded UvsX protein, a functional analogue of the *E. coli* RecA protein, together with the T4 ssDNA-binding protein gp32 and the phage-encoded UvsY protein. UvsY is a prototype for a class of proteins that facilitate the loading of a strand-exchange protein on to ssDNA coated with ssDNA-binding protein. In the presence of appropriate T4 replication proteins, the invading 3′ single-stranded end primes DNA replication, using the duplex homologue as template. In the most complete

reactions, the product of T4 gene *59* facilitates the binding of the T4 helicase/primase complex to the invaded duplex DNA. Thus, gp59 apparently assists leading-strand replication by providing the replication-fork helicase and assists lagging-strand replication by providing the primase for Okazaki fragment synthesis.

Genetic analyses indicate that T4 recombination proceeds by multiple pathways which are dependent only on phage-encoded proteins. The mechanistic details of these recombination pathways are not understood, except that one pathway is identical to the recombination-dependent replication pathway described above. Surprisingly, mutations that inactivate the T4-encoded strand exchange protein (UvsX) reduce phage recombination by only a few fold, regardless of the presence or absence of the host RecA protein. Thus, a significant portion of T4 recombination is independent of any known strand exchange protein. Based on electron microscopic analysis of DNA from replication-blocked coinfections, Broker and his colleagues proposed that the annealing of complementary ssDNA accounts for some fraction of T4 recombination, perhaps explaining recombination in the absence of UvsX. The generation of ssDNA in the absence of replication required the function of gp46/47, which is thought to be an exonuclease, and the ssDNA annealing was apparently promoted by the T4 ssDNA-binding protein, gp32. Although ssDNA annealing has not been demonstrated to contribute to recombination during replication-allowed infections, it would provide a suitable explanation for the large amount of recombination in the apparent absence of *bona fide* strand exchange proteins. Alternatively or in addition, perhaps a T4-encoded helicase is able to drive branch migration into duplex regions after an initial ssDNA annealing reaction, as described above for the phage T7 system.

Many of the recombination proteins encoded by phage T4 provide important prototypes for biochemical analyses of recombination. As implied above, the T4 UvsX protein catalyzes strand-invasion reactions *in vitro,* assisted by the phage-encoded UvsY protein and gp32. In addition, the gene *59* protein loads helicase/primase on to recombination intermediates and the gene *49* product (endonuclease VII) is the best-studied enzyme that resolves Holliday junctions and other structural aberrations in DNA.

Recombination in phage T4 is very closely coupled to DNA replication. As described above, a major mode of T4 DNA replication is triggered from recombination junctions. In addition, T4 DNA replication stimulates recombination by at least two distinct mechanisms. First, the ends of an infecting phage DNA are activated for recombination by DNA replication, presumably because replication leaves 3′ single-stranded termini in the parental DNA. Second, T4 replication origins activate the major hotspots for genetic recombination (following UV damage) by an unknown mechanism.

The linkage of T4 replication and recombination can be analyzed by measuring the integration of a plasmid into the phage genome. The integration of a plasmid that contains a T4 DNA insert but no replication origin strictly requires the UvsX and UvsY proteins. However, the addition of a phage replication origin to the plasmid causes a large stimulation in the recombination that occurs in the absence of UvsX or UvsY (also independent of RecA). Thus, plasmid replication apparently activates a recombination pathway that is independent of strand exchange proteins. Similar to the cases discussed above, replication of the plasmid may generate recombinogenic structures (e.g. ssDNA or DSBs). A clue to the mechanism of this recombination is provided by an analysis of protein requirements. A mutation in either gene *46* or *32* essentially abolishes recombination between the origin-containing plasmid and the phage genome. Thus, generation of ssDNA regions by the gp46/47 exonuclease and ssDNA annealing by gp32 are likely steps in this recombination pathway. This model is very reminiscent of that suggested by the electron microscopic analyses of phage DNA recombination (see above).

DSB-promoted recombination was first inferred in the phage T4 system, based on the facts that the ends of the infecting T4 genome are essentially DSBs and are very active in recombination. Thus, it is appropriate that T4 now provides one of the best-developed systems for studying the mechanism of DSB-promoted recombination. Two self-splicing group I introns of phage T4 encode endonucleases that trigger the highly efficient process of intron mobility. In each case, the endonuclease specifically recognizes an intronless copy of the cognate gene and induces a DSB in that DNA. DSB repair, using the intron-containing DNA as template, results in a unidirectional gene conversion event that essentially transfers a copy of the intron into the intronless gene. The characteristics of this DSB repair event are very closely related to those of recombination-dependent DNA synthesis. Indeed, recent experiments suggest that these two processes are just two manifestations of the same biological reaction.

Drawing parallels

Very diverse mechanisms are clearly responsible for generating the substrates for recombination in differ-

ent phage systems. Specific DNA signals such as packaging sites, genome ends, replication origins and χ sites have all been shown to stimulate recombination, and the action of each of these signals is unique to a particular phage system. Nonetheless, these varied DNA signals may generate just one or a small number of DNA structures that trigger recombination, for example ssDNA tails and/or DSBs. These DNA signals generally stimulate recombination locally or at least in restricted regions of the genome. What then stimulates the background level of recombination that occurs throughout a phage genome? In the case of replication-allowed infections of phage λ, most Red-promoted recombination apparently depends on randomly located DSBs, which are produced by an unknown mechanism that involves replication. Indeed, DSBs may be the major cause of recombination during infections by many phages. Random DNA nicks in phage genomes may also contribute to background recombination, as judged by the fact that the ssDNA phage replication origins are sites of nicking and stimulate local recombination. The pathway of recombination from a DNA nick could involve either local DNA replication (e.g. as in the Meselson–Radding recombination model) or exonucleolytic generation of an ssDNA gap.

Moving beyond the initial stages of generating recombinogenic structures, the formation of the joint (biparental) molecule is the essence of recombination. Much attention has focused on DNA pairing mediated by strand exchange proteins, which involves the invasion of a single strand into a duplex homologue. There is no doubt that this mode of pairing plays a large role in recombination. Mutations in the *E. coli recA* gene abolish most recombination in the bacterial host and during ssDNA phage infections, and *uvsX* mutations in T4 eliminate 70–80% of phage–phage recombination. Numerous biochemical studies have now been performed on both RecA- and UvsX-promoted strand-invasion reactions, revealing a highly detailed view of a central step in genetic recombination. This is not a complete picture, however. Every phage system described above also appears to generate at least some recombinants without the help of a RecA-like protein. In most or all cases, this mode of recombination is activated by replication. A common explanation for the dependence on replication is that replication generates ssDNA regions, perhaps at the sites of DSBs, that serve as substrates for recombination. Judging from the involvement of λ Red β protein and T4 gp32, protein-promoted annealing of two ssDNA regions seems likely to be a critical step, perhaps followed by helicase-mediated branch migration into duplex regions. Naively, ssDNA annealing might be thought of as a pathway peculiar to phage systems, where the genome copy number can be very high. However, recent studies of DSB repair in repeated genes of eukaryotes have led to virtually identical models involving protein-promoted annealing of complementary ssDNA from adjoining copies of the repeated sequence.

The activation of recombination by replication is common to all phage systems that have been studied in detail. Replication may generate recombinogenic DSBs, although the mechanism for generating such breaks is not known. Clearly, phages are very tolerant of DSBs, presumably in part because phages maintain a high genome copy number for most of the infective cycle. Programmed double-strand cleavage of the genomes of many phages occurs during DNA packaging, and the maintenance of genome structure requires efficient DSB repair of some type in the next infective cycle. DSB-promoted recombination was first detected in phage systems, and is now believed to play a dominant role in a wide variety of recombination pathways. Using bacteriophage systems such as λ and T4, the detailed molecular steps in DSB-promoted recombination are currently under intense investigation.

Introduction

In 1915 and 1917, Twort in London and d'Hérelle in Paris independently described agents which destroyed bacteria. D'Hérelle named his agent bacteriophage ('eater of bacteria'), which became shortened to phage, and began studies on the nature of phages which led to modern virology.

D'Hérelle believed there was only one species of phage and that strain diversity was due to extensive variation within this single species. Subsequent workers showed that, whereas different phage strains did indeed vary in their properties (e.g. antigenic specificity, and resistance to inactivation by physical and chemical agents), the properties of any one strain were fairly constant during repeated subculturing and cloning. This demonstrated that there were different phages and, as more phages were isolated, the need for their systematic classification arose.

As with animal and plant viruses, early efforts at phage taxonomy concentrated on groupings based on properties such as antigenic relationships, plaque morphology, particle size by ultrafiltration and heat resistance. Modern viral taxonomy began in 1962 when Lwoff, Horne and Tournier proposed a classification system based on properties of the virion and its nucleic acid. Procedures for viral taxonomy and nomenclature became organized in 1966 with establishment of the International Committee for Taxonomy of Viruses (ICTV). Since then, the ICTV has developed an internationally agreed nomenclature and taxonomy for viruses, through regular meetings and communications among virologists. A complete ICTV Report on virus taxonomy is published every few years: at present, there are 13 families and one unassigned genus of bacterial viruses (**Table 1**). 'Bacterial virus' is used here as a generic term for viruses infecting hosts in the domains *Bacteria* and *Archaea*.

The ICTV Universal System of Virus Taxonomy

Virus classification is based on structural, physicochemical and replication properties. Some of these criteria have been used since the earliest days of virology (e.g. antigenic relationships) and others have been developed only recently (e.g. nucleic acid sequencing). The taxa in virology are order, family, genus and species. Each taxonomic level is defined by a specific subset of properties. For example, virion morphology and size, and genome type and strandedness are high-level properties and define taxa at the order and/or family level, whereas nucleotide sequence and protein properties are low-level properties and define taxa at the genus and/or species level.

In practice, a virus strain (i.e. the progeny virus from a single isolation) is usually classified from the 'top down'. Classification generally begins with data on virion morphology and the nature of the genome to determine the order and/or family. Additional data are then used to determine the genus, and finally whether the strain is a new species. However, in

Speciation

In sexual eucaryotes, a species is generally defined as a group of individuals that share a common gene pool because of interbreeding. Until recently, the concept was generally considered inapplicable to either bacteria or viruses. However, molecular data have encouraged reconsideration. The basic fact (cited above) that, within a group, trees based on different genes are not congruent rules out the textbook expectation for asexual organisms related to one another by purely clonal propagation without genetic exchange. The different lambdoid phages appear related to one another by numerous exchange events, suggesting that the entire group is best viewed as a single species.

Classical speciation entails the establishment of barriers to interbreeding so that the gene pools of distinct species cannot mix. The phage equivalent of that process is undefined. If each phage group has an independent origin, classical speciation may not exist. What can be asked is whether, or to what degree, the gene pools of various phage groups are isolated from one another (and from the gene pools of the hosts they infect). When an answer is sought through sequence comparisons, the question overlaps that of viral origins (discussed above, under Evolution).

There are some well-documented cases of homologies between viral genes and their host counterparts. For example, whereas the λ replication protein gp*P* interacts with the host *dnaB* helicase, in at least one lambdoid phage (P22) the N-terminus of the analogous protein is fused to a C-terminal *dnaB*-related segment, and replication does not require *dnaB*. Similarly, homologies have been detected between genes of T4, P2 and λ whose products contribute to attachment of phage to the cell surface or which are closely linked to genes for attachment proteins. In both cases, the genes are clearly of a common origin but not a very recent one. Within a group, homologous genes are also highly diverged in some cases but much more similar in others. Thus some past exchanges have occurred between distantly related phages and between phage and host. If such exchanges were frequent and recent, the concept of distinct species with separate gene pools would have little use. The examples known at present can be reasonably viewed as rare lateral transfers across species boundaries.

PHAGE PRD1 (*TECTIVIRIDAE*)

Dennis H Bamford, Institute of Biotechnology, Biocenter, University of Helsinki, Finland

Discovery and Classification

Bacteriophage PRD1 belongs to a group of very closely related phages isolated from different parts of the world. Other members of this group are PR3, PR4, PR5, LI7 and PR772. These viruses are lytic, infecting a vast variety of Gram-negative cells harboring a P-, N- or W-type conjugative plasmid. Among the hosts are *Escherichia coli, Salmonella typhimurium* and *Pseudomonas aeruginosa*. PRD1 is the type virus of the family *Tectiviridae*, genus *Tectivirus*. This virus family also includes members infecting Gram-positive hosts. PRD1 and PR4 are the most thoroughly studied phages in this group. Since these viruses are almost identical, the description of this phage system uses information from both of them. The discovery (1973–1979) was associated with studies of antibiotic-resistant plasmids. In further studies it was observed that they have an internal lipid membrane and a linear double-stranded DNA (dsDNA) genome with 5′-covalently-linked terminal proteins.

Properties of the Virion

The viral particle (**Fig. 1**) has an outer diameter of approximately 65 nm. The outer protein layer sur-

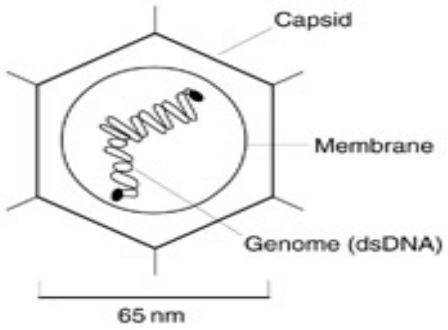

Figure 1 Major structural components of the PRD1 particle.

rounds the viral membrane. The viral genome resides inside this membrane vesicle. The virion is composed of approximately 70% protein, 15% DNA and 15% lipid. The outer protein layer is composed of the major coat protein P3 and the minor coat protein P5, as well as a small protein P30. P3 is a homotrimer. Protein P5 contains a $(Gly\text{-}X\text{-}Y)_6$ motif which is found in collagens and is cleavable with collagenase. Proteins P31, P5 and P2 together form adsorption spikes extending from the fivefold symmetry vertices. There are several proteins associated with the DNA injection (P11, P14, P16, P18) and DNA packaging (P9, P20, P22). In addition to these proteins, the membrane contains several small integral membrane proteins with, as yet, no described function. Protein P8 is covalently linked to the 5′-terminal nucleotides of the linear dsDNA genome. The membrane composition is approximately half protein, half lipid. The membrane phospholipids are composed of approximately 56% phosphatidylethanolamine, 37% phosphatidylglycerol, 5% cardiolipin and 2% neutral lipids. The fatty acid composition of the phospholipids is identical to that of the host.

Properties of the Genome and Genetics

Isolated nonsense mutants form 19 genetic complementation groups. Most of these are assigned to a virion protein. At least eight gene products are known to be nonstructural. The amber mutants can be complemented with cloned genomic fragments and thus the genes are located on the physical genome map determined from the restriction enzyme fragments.

Sequencing of the entire genome revealed 110 bp inverted terminal repeats at both ends of the 14 925 bp linear dsDNA (**Fig. 2**). The early genes for DNA replication and for transcription control are located at both ends of the genome. The genome terminal protein gene VIII and DNA polymerase gene I are at the left, and two genes coding for DNA-binding proteins at the right (genes XII and XIX). The latter two are so far the only genes transcribed from left to right. Gene XV codes for the phage lytic enzyme, the synthesis of which begins before that of the late gene products. The late genes are located in the 'upper' genome strand. Genes X, XVII and XXXII code for nonstructural assembly factors, whereas the rest of the late genes code for structural proteins. A gene designated with a roman numeral (for example I) produces an identified protein with the same arabic number (P1), whereas localized genes with as yet no identified gene product are designated with lower case letters (for example, gp o).

Life Cycle

The PRD1 life cycle is illustrated in **Fig. 3.** The phage adsorbs to the plasmid-encoded receptor. In optimal conditions, up to 50 phage particles can attach to one cell. The phage membrane forms a tube-like structure during the DNA injection event. The early transcrip-

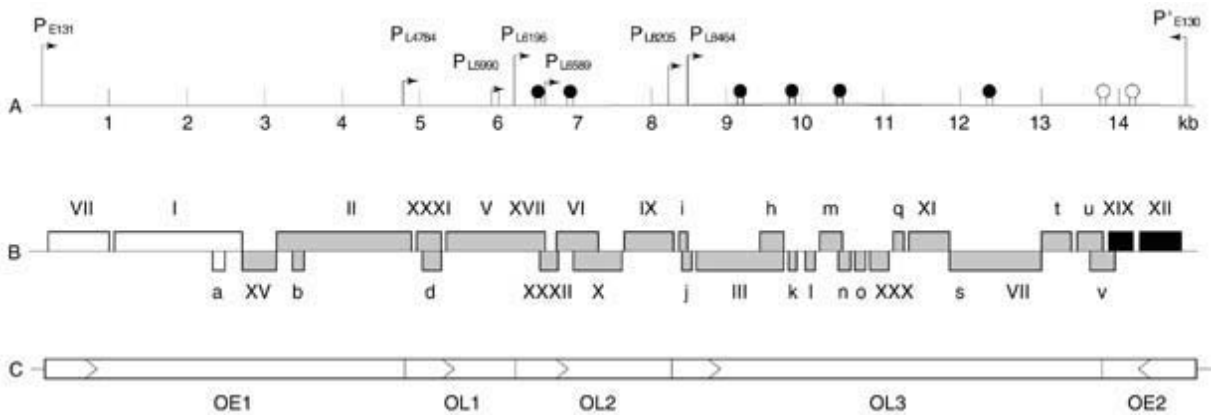

Figure 2 PRD1 genome. Genes with identified protein products are designated with roman numerals. Other localized genes are designated with lower case letters. For details see the text. membrane behind. DNA replication and protein synthesis begins. The major capsid proteins are formed as soluble multimers, whereas membrane proteins are associated with the host membrane. Upon translocation of the membrane and its associated proteins, empty particles are formed. DNA packaging results in the formation of mature virions. Mature viral particles are released after cell lysis. R, replication; T, transcription.

tion leads to the synthesis of the genome terminal protein (P8) and the DNA polymerase (P1), which can initiate the replication from each genome end. The initial reaction is the formation of a phosphodiester bond between Tyr190 in the terminal protein and dGMP destined to become the third 5′-terminal nucleotide of the synthesized strand. Replication initiation from both ends leads to two identical molecules. However, initiation from only one end produces one displaced single-stranded DNA (ssDNA) molecule in addition to the complete dsDNA genome. The displaced ssDNA molecule can either initiate replication using paired inverted terminal repeats, or pair with another single strand with opposite polarity. The late protein synthesis leads to accumulation of coat protein (P3 and P5) multimers in the cytoplasm as well as to insertion of membrane proteins into the host plasma membrane.

Empty virus particles are formed in a process that is absolutely dependent at least on the major coat protein multimers and two assembly factors P10 and P17. In this membrane translocation event, the virus-specific membrane is removed from the host plasma membrane and placed inside the virus protein coat. The empty virus particles are located in the nucleoplasm area where DNA packaging takes place. The mature virus particles are preferentially located in the cell periphery prior to cell lysis. Cell lysis liberates several hundred virus particles, 10–15% of which are empty DNA-less particles.

Future Perspectives

Bacteriophage PRD1 is the only known protein-primed DNA-replication system operating in *E. coli*. An *in vitro* replication system with purified components produces full-length PRD1 DNA allowing a detailed study of the DNA synthesis. The DNA replication mechanism, trimeric coat protein arrangement and the presence of spikes are features sheared with adenovirus. The atomic resolution structure of the PRD1 coat protein trimer also reveals similarities with the adenovirus. This functional relationship will be under detailed study. The PRD1 membrane system is also potentially valuable in understanding membrane biogenesis and translocation.

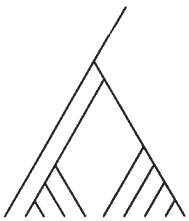
PHAGE TAXONOMY AND CLASSIFICATION



Jack Maniloff, Department of Microbiology and Immunology, University of Rochester, Medical Center, Rochester, New York, USA

Hans-Wolfgang Ackermann, Département de Biologie Médicale, Université Laval, Faculté de Médecine, Cité Universitaire, Québec, Canada

Audrey Jarvis, New Zealand Dairy Research Institute, Palmerston North, New Zealand

Introduction

In 1915 and 1917, Twort in London and d'Hérelle in Paris independently described agents which destroyed bacteria. D'Hérelle named his agent bacteriophage ('eater of bacteria'), which became shortened to phage, and began studies on the nature of phages which led to modern virology.

D'Hérelle believed there was only one species of phage and that strain diversity was due to extensive variation within this single species. Subsequent workers showed that, whereas different phage strains did indeed vary in their properties (e.g. antigenic specificity, and resistance to inactivation by physical and chemical agents), the properties of any one strain were fairly constant during repeated subculturing and cloning. This demonstrated that there were different phages and, as more phages were isolated, the need for their systematic classification arose.

As with animal and plant viruses, early efforts at phage taxonomy concentrated on groupings based on properties such as antigenic relationships, plaque morphology, particle size by ultrafiltration and heat resistance. Modern viral taxonomy began in 1962 when Lwoff, Horne and Tournier proposed a classification system based on properties of the virion and its nucleic acid. Procedures for viral taxonomy and nomenclature became organized in 1966 with establishment of the International Committee for Taxonomy of Viruses (ICTV). Since then, the ICTV has developed an internationally agreed nomenclature and taxonomy for viruses, through regular meetings and communications among virologists. A complete ICTV Report on virus taxonomy is published every few years: at present, there are 13 families and one unassigned genus of bacterial viruses (**Table 1**). 'Bacterial virus' is used here as a generic term for viruses infecting hosts in the domains *Bacteria* and *Archaea*.

The ICTV Universal System of Virus Taxonomy

Virus classification is based on structural, physicochemical and replication properties. Some of these criteria have been used since the earliest days of virology (e.g. antigenic relationships) and others have been developed only recently (e.g. nucleic acid sequencing). The taxa in virology are order, family, genus and species. Each taxonomic level is defined by a specific subset of properties. For example, virion morphology and size, and genome type and strandedness are high-level properties and define taxa at the order and/or family level, whereas nucleotide sequence and protein properties are low-level properties and define taxa at the genus and/or species level.

In practice, a virus strain (i.e. the progeny virus from a single isolation) is usually classified from the 'top down'. Classification generally begins with data on virion morphology and the nature of the genome to determine the order and/or family. Additional data are then used to determine the genus, and finally whether the strain is a new species. However, in

Table 1 Taxonomy of viruses of *Bacteria* and *Archaea*

Order	*Family*	*Genus*	*Type species*	*Host (Domain: taxa)*
Double-stranded DNA viruses				
Caudovirales	*Myoviridae*	'T4-like viruses'	Coliphage T4	*Bacteria:* entero- and related bacteria
		'P1-like viruses'	Coliphage P1	*Bacteria:* entero- and related bacteria
		'P2-like viruses'	Coliphage P2	*Bacteria:* entero- and related bacteria
		'Mu-like viruses'	Coliphage Mu	*Bacteria:* enterobacteria
		'SPO1-like viruses'	Bacillus phage SPO1	*Bacteria: Bacillus*
		'ΦH-like viruses'	Halobacterium phage ϕH	*Archaea: Halobacterium*
	Siphoviridae	'λ-like viruses'	Coliphage λ	*Bacteria:* enterobacteria
		'T1-like viruses'	Coliphage T1	*Bacteria:* enterobacteria
		'T5-like viruses'	Coliphage T5	*Bacteria:* enterobacteria, *Vibrio*
		'L5-like viruses'	Mycobacterium phage L5	*Bacteria:* mycobacteria
		'c2-like viruses'	Lactococcus phage c2	*Bacteria: Lactococcus*
		'ψM1-like viruses'	Methanobacterium phage ψM1	*Archaea: Methanobacterium*
	Podoviridae	'T7-like viruses'	Coliphage T7	*Bacteria:* entero- and related bacteria
		'P22-like viruses'	Enterobacteria phage P22	*Bacteria:* enterobacteria
		'ϕ29-like viruses'	Bacillus phage ϕ29	*Bacteria: Bacillus, Kurthia, Streptococcus*
	Tectiviridae	*Tectivirus*	Polyvalent phage PRD1	*Bacteria:* proteobacteria, *Bacillus, Thermus*
	Corticoviridae	*Corticovirus*	Alteromonas phage PM2	*Bacteria: Alteromonas, Vibrio*
	Plasmaviridae	*Plasmavirus*	Acholeplasma phage L2	*Bacteria: Acholeplasma* (mycoplasma)
	Lipothrixviridae	*Lipothrixvirus*	Thermoproteus virus TTV1	*Archaea: Thermoproteus, Desulfurolobus*
	Rudiviridae	*Rudivirus*	Thermoproteus virus TTV4	*Archaea: Thermoproteus, Sulfolobus*
	Fuselloviridae	*Fusellovirus*	Sulfolobus virus SSV1	*Archaea: Sulfolobus*
		Unassigned genus SNDV	Sulfolobus virus SNDV	*Archaea: Sulfolobus*
Single-stranded DNA viruses

		Plectrovirus	Acholeplasma phage L51	*Bacteria: Acholeplasma, Spiroplasma* (mycoplasma)
	Microviridae	*Microvirus*	Coliphage ϕX174	*Bacteria:* enterobacteria
		Spiromicrovirus	Spiroplasma phage SpV4	*Bacteria: Spiroplasma* (mycoplasma)
		Bdellomicrovirus	Bdellovibrio phage MAC-1	*Bacteria: Bdellovibrio*
		Chlamydiamicrovirus	Chlamydia phage Chp1	*Bacteria: Chlamydia*
Double-stranded RNA viruses				
	Cystoviridae	*Cystovirus*	Pseudomonas phage ϕ6	*Bacteria: Pseudomonas*
Positive-sense, single-stranded RNA viruses				
	Leviviridae	*Levivirus*	Enterobacteriophage MS2	*Bacteria:* enterobacteria
		Allolevirus	Enterobacteriophage Qβ	*Bacteria:* enterobacteria

principle, taxa are defined from the 'bottom up', because the species is the fundamental taxonomic unit in biological systematics. Genera are then defined in terms of species, families in terms of genera and orders in terms of families.

Virus species

The ICTV definition of a virus species is: 'A virus species is a polythetic class of viruses that constitutes a replicating lineage and occupies a particular eco-

logical niche.' This means that members of a species must have a number of properties in common, but no single property need be shared by all members of the species. This definition involves subjective decisions because some virus species contain strains with greater phenotypic and/or genetic diversity than others. Species are given English vernacular names.

The criteria used to define phage species are properties such as virion morphology (e.g. fine structure, protein composition and serological relationships), DNA homology, sequence similarity and physiology (e.g. host range and burst size). These generally are adequate to identify a virus or group of viruses as distinct from other groupings. However, as for other viruses, there is an element of judgment in deciding whether a particular bacterial virus should be considered a species or a strain.

Virus genera

The ICTV definition of a virus genus is: 'A virus genus is a group of species sharing certain common characters.' Like the species definition, this involves subjective judgments, so there is significant diversity among genera in different families. Genus names end in *-virus*.

A variety of criteria have been employed to define phage genera. Properties related to DNA replication and packaging have been used for defining tailed phage genera. Other useful properties are presence of protein covalently linked to DNA 5′ termini, virus-encoded type A (Pol I) or B (Pol II) DNA polymerase and/or RNA polymerase, occurrence of unusual DNA bases, DNA replication via transposition, temperate infection with the provirus either integrated into the host chromosome or persisting as a plasmid, genome organization and host range.

A species for which considerable data are available is designated the type species of a genus, although this may not be the virus most typical of the properties of all species in a genus.

Virus families

The ICTV definition of a virus family is: 'A virus family is a group of genera sharing certain common characters.' Family names end in *-viridae*, and are defined by high-level criteria, such as virion morphology and the nature of the genome.

Virus orders

The ICTV recently introduced the taxonomic category of 'order', defined as 'a group of families sharing certain common characters'. Order names end in *-virales*. The first two orders were established for groups of animal virus families, based on similar genome organization and replication strategies. The third order, *Caudovirales*, was established in 1998 for the three families of tailed phages with linear double-stranded (ds) DNA genomes: *Myoviridae* (phages with contractile tails), *Siphoviridae* (phages with long noncontractile tails), and *Podoviridae* (phages with short tails). These families are grouped in a single order based on a set of properties involving morphology, replication, assembly and infection cycle.

Description of New Phages – The ICTV Process

The major organizational units of the ICTV are subcommittees for viruses infecting different hosts: i.e. Bacterial, Fungal, Plant, Invertebrate and Vertebrate Virus Subcommittees. At present (mid-1998), the Bacterial Virus Subcommittee consists of 19 virologists, from ten countries, with expertise in all bacterial virus families and most important bacterial host groups. *Ad hoc* study groups are formed as needed.

Over the years, the ICTV has evolved rules for virus nomenclature and procedures for establishing new taxa. New taxonomic proposals are usually initiated by subcommittee study groups, but can also be submitted by individual virologists, and require approval by the appropriate subcommittee, the ICTV Executive Committee, and finally an ICTV Plenary Session. The process is highly interactive between organizational levels within the ICTV, in an effort to assure clarity and uniformity in viral nomenclature and taxonomy.

Description of Phage Families

The most recent literature survey of phages was completed in 1995 and covered 4551 phage descriptions: 96% were tailed phages and 4% were isometric, filamentous or pleomorphic phages. The 4389 tailed phages are classified into three families, whereas the 162 other phages form ten families and one unassigned genus (**Table 1**). Hence, each tailed phage family contains many members, with significant diversity in morphology and other characteristics.

The three tailed phage families, grouped in the order *Caudovirales*, are distinguished by tail structure. Each tailed phage family contains many species, with sufficient data on a small number to enable them to be grouped into genera. There have been 1073 descriptions of phages with contractile tails (family *Myoviridae*); 2708 of phages with long, noncontractile tails (family *Siphoviridae*); and 608 of phages with short tails (family *Podoviridae*).

The taxonomy, major characteristics, and host

range of the 13 phage families and one unassigned genus are summarized below. A complete listing of the members in each taxon is in the seventh ICTV Report.

Myoviridae

Taxonomy

Family: *Myoviridae*
Genus: 'T4-like viruses'
Genus: 'P1-like viruses'
Genus: 'P2-like viruses'
Genus: 'Mu-like viruses'
Genus: 'SPO1-like viruses'
Genus: 'ΦH-like viruses'

Characteristics *Myoviridae* have contractile tails and contain linear dsDNA. Virions have a relatively large head and a long, thick, complex, contractile tail (80–455 nm × 16–20 nm), consisting of a central tube surrounded by a contractile sheath and ancillary structures (e.g. tail fibers). Heads, tails and (when present) tail fibers are assembled by separate pathways.

'T4-like viruses' (type species: coliphage T4) have elongated heads (111 × 78 nm) and tails with long, kinked fibers. The genome is about 170 kb dsDNA, circularly permuted and terminally redundant, typically containing 5-hydroxymethylcytosine and encoding a type B DNA polymerase. The genetic map is circular, and progeny DNA is packaged by a headful mechanism from concatemers formed via recombination. Infection is virulent. Host range: enterobacteria and other proteobacteria.

'P1-like viruses' (type species: coliphage P1) have icosahedral heads about 85 nm in diameter. The genome is about 100 kb dsDNA, with limited circular permutation and terminal repeats. Concatemers are formed from Θ structures by rolling circle replication and progeny DNA is packaged from concatemers by a headful mechanism from *pac* sites. Infection is temperate and prophages generally persist as plasmids. Host range: enterobacteria and other proteobacteria.

'P2-like viruses' (type species: coliphage P2) have icosahedral heads about 60 nm in diameter. The genome is about 33 kb dsDNA, with cohesive ends (*cos* sites). Infection is temperate and prophages are integrated into host chromosomes by site-specific recombination. DNA replication is via Θ structures to form covalently closed circular DNA, and progeny DNA is packaged from covalently closed circular molecules cleaved at a *cos* site. Host range: enterobacteria and other proteobacteria.

'Mu-like viruses' (type species: coliphage Mu) have icosahedral heads about 60 nm in diameter. The genome is about 43 kb dsDNA, consisting of the viral genome with variable host DNA sequences at both ends. Infection is temperate and prophages integrate into host chromosomes by site-specific recombination. DNA replication is via replicative transposition of phage genomes to random sites in the host chromosome, and progeny DNA is packaged from integrated phage DNA. Host range: enterobacteria.

'SPO1-like viruses' (type species: *Bacillus* phage SPO1) have icosahedral heads about 94 nm in diameter. The genome is 140–160 kb dsDNA, with short terminal repeats, containing hydroxymethyluracil, and encoding a type A DNA polymerase. Infection is virulent. DNA replication is via concatemer formation, and progeny DNA is assumed to be packaged by headful packaging from concatemers, with site-specific cleavage and DNA synthesis to duplicate terminal repeats. Host range: *Bacillus*.

'ΦH-like viruses' (type species: *Halobacterium* phage ΦH) infect archaebacteria. Virions have icosahedral heads about 64 nm in diameter. The genome is about 59 kb dsDNA, with limited circular permutation and terminal repeats, and containing methylcytosine. Infection is temperate and prophages persist as plasmids. Early transcription is regulated by viral antisense mRNA. DNA replication results in concatemer formation and progeny DNA is packaged from *pac* sites. Host range: *Halobacterium*.

Other members of the *Myoviridae* A large number of unassigned species have been described infecting a wide range of bacteria.

Siphoviridae

Taxonomy

Family: *Siphoviridae*
Genus: 'λ-like viruses'
Genus: 'T1-like viruses'
Genus: 'T5-like viruses'
Genus: 'L5-like viruses'
Genus: 'c2-like viruses'
Genus: 'ψM1-like viruses'

Characteristics *Siphoviridae* have long, thin, noncontractile tails (65?–825 × 7–10 nm) and contain linear dsDNA. Heads and tails are assembled separately.

'λ-like viruses' (type species: coliphage λ) are temperate, with the prophage integrated into the host chromosome by site-specific recombination. The genome is about 49 kb dsDNA, with *cos* sites. DNA replication is via Θ structures followed by rolling circle replication to produce concatemers, with progeny DNA cut and packaged from concatemers at *cos* sites. Host range: enterobacteria.

'T1-like viruses' (type species: coliphage T1) have

extremely flexible tails. The genome is about 49 kb dsDNA, with limited circular permutation and terminal repeats. DNA replication is via concatemers formed by recombination, and progeny DNA is packaged from concatemers by headful packaging from *pac* sites. Infection is virulent. Host range: enterobacteria.

'T5-like viruses' (type species: coliphage T5) have large heads and long, kinked tail fibers. The genome is about 125 kb dsDNA, with terminal repeats and single-strand gaps, and encodes a type A DNA polymerase. DNA injection is by 2-step transfer process; concatemers are formed. Infection is virulent. Progeny genomes may be packaged by a headful mechanism from concatemers, with site-specific cleavage and DNA synthesis to duplicate terminal repeats. Host range: enterobacteria, *Vibrio*.

'L5-like viruses' (type species: *Mycobacterium* phage L5) are temperate, with the prophage integrated into host chromosome by site-specific recombination. The genome is about 52 kb dsDNA with *cos* sites, encoding a type A DNA polymerase. Host range: *Mycobacterium*.

'c2-like viruses' (type species: *Lactococcus* phage c2) have prolate heads. The genome is about 22 kb dsDNA with *cos* sites, possibly encoding a type B DNA polymerase. Infection is virulent. Host range: *Lactococcus*.

'ψM1-like viruses' (type species: *Methanobacterium* phage ψM1) produce virulent infections in archaebacteria. The genome is about 30 kb dsDNA, circularly permuted and terminally redundant. Host range: *Methanobacterium*.

Other members of the *Siphoviridae* A large number of unassigned species have been described infecting a wide range of bacteria.

Podoviridae

Taxonomy
Family: *Podoviridae*
Genus: 'T7-like viruses'
Genus: 'P22-like viruses'
Genus: 'ϕ29-like viruses'

Characteristics *Podoviridae* have short, noncontractile tails, about 20 × 8 nm, and contain linear dsDNA. Heads are assembled first, DNA is packaged, and tail subunits assembled on the completed head.

'T7-like viruses' (type species: coliphage T7) produce virulent infections. The genome is about 40 kb dsDNA with short terminal repeats, encoding a type A DNA polymerase and RNA polymerase. Concatemers are formed by annealing 3′ termini of daughter molecules. DNA packaging is from concatemers via site-specific cleavage and DNA synthesis to duplicate terminal repeats. Host range: enterobacteria and other proteobacteria.

'P22-like viruses' (type species: enterobacteria phage P22) are temperate, with the prophage integrated into host chromosome by site-specific recombination. The genome is about 43 kb dsDNA, with limited circular permutation and terminal repeats, and encoding a type A DNA polymerase. DNA replication is via Θ structures followed by rolling-circle replication to produce concatemers, and packaging is from *pac* sites in concatemers. Host range: enterobacteria.

'ϕ29-like viruses' (type species: *Bacillus* phage ϕ29) produce virulent infections. The genome is about 19 kb dsDNA, with short inverted terminal repeats and encoding a type B DNA polymerase. Virus-encoded protein is covalently linked to DNA 5′ termini, to prime DNA replication from both termini to produce linear monomeric daughter molecules with protein covalently linked to 5′ termini. Host range: *Bacillus, Kurthia, Streptococcus*.

Other members of *Podoviridae* A large number of unassigned species have been described infecting a wide range of bacteria.

Tectiviridae

Taxonomy
Family: *Tectiviridae*
Genus: *Tectivirus*

Characteristics Tectiviruses (type species: polyvalent phage PRD1) are lipid-containing dsDNA phages. Virions are nonenveloped icosahedral particles, about 63 nm in diameter with spikes at the vertices. The protein capsid encloses an inner, DNA-containing, lipoprotein vesicle. Virions are normally tailless, but produce tail-like tubes, about 60 × 10 nm, upon adsorption or after chloroform treatment. The genome is about 15 kb linear dsDNA, with inverted terminal repeats and protein covalently linked to DNA 5′ termini, and encoding a type B DNA polymerase. DNA replication is protein-primed and proceeds from both termini by strand displacement. Infection is virulent. Host range: phage PRD1 and relatives infect proteobacteria with P, N, or W incompatibility plasmids (*Acinetobacter*, enterobacteria, *Pseudomonas, Vibrio* and possibly others); phage P37-14 and relatives infect *Thermus*; phages AP50, NS11 and relatives infect *Bacillus*.

Corticoviridae

Taxonomy
Famsgml_outily: *Corticoviridae*
Genus: *Corticovirus*

Characteristics Corticoviruses (type species: *Alteromonas* phage PM2) are lipid-containing dsDNA phages. Virions are nonenveloped icosahedral particles about 60 nm in diameter, consisting of two protein shells separated by a lipid bilayer and spikes at the vertices. The inner protein shell contains a transcriptase. The genome is about 9 kb covalently closed, superhelical, circular dsDNA, encoding a transcriptase. Infection is virulent. DNA replication proceeds unidirectionally. Inner protein shells of progeny virions are assembled first, filled with DNA, and completed by progressive addition of lipids, the outer shell and spikes. Host range: *Alteromonas*; an unassigned species in the family infects *Vibrio*.

Plasmaviridae

Taxonomy
Family: *Plasmaviridae*
Genus: *Plasmavirus*

Characteristics Plasmaviruses (type species: *Acholeplasma* phage L2) are dsDNA phages that infect mycoplasmas. Virions are quasi-spherical, slightly pleomorphic, enveloped particles, about 80 nm (range 50–125 nm) in diameter. No capsid is detectable. Size range is due to virion heterogeneity; at least three distinct virion forms are produced during infection. The genome is 12 kb circular, superhelical dsDNA. Infection includes both a nonlytic cytocidal productive infectious cycle and a lysogenic cycle in each infected cell. Noncytocidal infection involves progeny virus released by budding from the host cell membrane, with the host surviving as a lysogen. Lysogeny involves integration into a unique site in the host chromosome. Host range: *Acholeplasma*.

Lipothrixviridae

Taxonomy
Family: *Lipothrixviridae*
Genus: *Lipothrixvirus*

Characteristics Lipothrixviruses (type species: *Thermoproteus* virus TTV1) are dsDNA phages that infect archaebacteria. Virions are thick, enveloped, rigid rods, about 400 nm long and 40 nm in diameter. The genome is about 16 kb linear dsDNA. Infection results in virus production with lysis or establishment of a carrier state. Pieces of TTV1 DNA may be integrated into host genomes. Host range: *Thermoproteus*; an unassigned species in the family infects *Desulfurolobus*.

Rudiviridae

Taxonomy
Family: *Rudiviridae*
Genus: *Rudivirus*

Characteristics Rudiviruses (type species: *Thermoproteus* virus TTV4) are dsDNA phages that infect archaebacteria. Virions are stiff, nonenveloped, rod-shaped particles, 26–30 × 500–950 nm. The genome is 17–33 kb linear dsDNA. Host range: *Thermoproteus, Sulfolobus*.

Fuselloviridae

Taxonomy
Family: *Fuselloviridae*
Genus: *Fusellovirus*

Characteristics Fuselloviruses (type species: *Sulfolobus* virus SSV1) are dsDNA phages that infect archaebacteria. Virions are lemon-shaped, 60 × 100 nm, and slightly flexible in appearance with short tail fibers attached to one pole. The virion envelope consists of host lipids and two virus-encoded proteins; a third protein is DNA-associated. The genome is about 15 kbp circular, positively supercoiled dsDNA and, after infection, is integrated into a tRNA gene in the host chromosome. UV induction results in large numbers of particles which are released without lysis. Host range: *Sulfolobus*.

Sulfolobus Virus SNDV

Taxonomy
Unassigned genus: *Sulfolobus* virus SNDV

Characteristics *Sulfolobus* virus SNDV is a dsDNA phage that infects archaebacteria. Virions are 80 × 180 nm droplet-shaped particles. The genome is about 20 kb circular, covalently-closed dsDNA. Host range: *Sulfolobus*.

Inoviridae

Taxonomy
Family: *Inoviridae*
Genus: *Inovirus*
Genus: *Plectrovirus*

Characteristics *Inoviridae* are single-stranded (ss)DNA phages with helical symmetry. Virions are nonenveloped, rod-shaped or filamentous particles, with virion length determined by the size of the genome. The genome is circular, positive-sense ssDNA, usually in the range 5–10 kb. Productive

infection involves conversion of parental ssDNA into replicative form (RF) dsDNA, semiconservative RF replication, synthesis of progeny ssDNA by a rolling circle mechanism, and membrane-based progeny virus assembly and extrusion without cell lysis. Infected host cells survive in a carrier state. However, there are lysogenic *Vibrio* and *Xanthomonas* inovirus strains that encode integrases and viral sequences are found integrated at several host chromosome sites. Vibrio phage CTX encodes the two subunits of cholera toxin, which are expressed on conversion of the lysogen into nonlytic productive infection.

Inovirus (type species: coliphage Ff, where Ff is the collective designation for coliphages M13, f1, and fd) particles are 700–2000 × 6–8 nm, with genomes of 6–9 kb. Host range: entero- and other proteobacteria, *Thermus*.

Plectrovirus (type species: *Acholeplasma* phage L51) particles are 70–90 × 14–16 nm for *Acholeplasma* phages and 230–280 × 10–15 nm for *Spiroplasma* phages, with genomes about 4.5 kb for *Acholeplasma* phages and 8 kb for *Spiroplasma* phages. Host range: *Acholeplasma, Spiroplasma* (mycoplasmas).

Microviridae

Taxonomy
Family: *Microviridae*
Genus: *Microvirus*
Genus: *Spiromicrovirus*
Genus: *Bdellomicrovirus*
Genus: *Chlamydiamicrovirus*

Characteristics *Microviridae* are isometric ssDNA phages. Virions are nonenveloped, 22–33 nm in diameter (depending on the orientation chosen for measurement), with icosahedral symmetry. The genome is 4.4–5.4 kb circular, positive-sense ssDNA. Infection is virulent and involves adsorption to cell walls (cell membranes for *Spiromicrovirus*), parental ssDNA conversion into circular RF DNA, synthesis of progeny ssDNA from RF DNA, and progeny virus release by cell lysis (by a nonlytic cytocidal mechanism for *Spiromicrovirus*).

Microvirus (type species: coliphage ϕX174) can be divided into three major groups based on their host enzyme requirement for viral DNA replication. Host range: enterobacteria.

Spiromicrovirus (type species: *Spiroplasma* phage SpV4) infects mycoplasmas and, therefore, adsorbs to and is released from wall-less bacteria. Also, like their host cells, viruses use TGA as the tryptophan codon instead of as the 'universal' stop codon. Host range: *Spiroplasma*.

Bdellomicrovirus (type species: *Bdellovibrio* phage MAC-1) has not been extensively characterized, but is distinguished by its host. Host range: *Bdellovibrio*.

Chlamydiamicrovirus (type species: *Chlamydia* phage Chp1) replicates in *Chlamydia* reticulate bodies, and transmission is via infection of extracellular *Chlamydia* elementary bodies. Host range: *Chlamydia*.

Cystoviridae

Taxonomy
Family: *Cystoviridae*
Genus: *Cystovirus*

Characteristics Cystoviruses (type species: *Pseudomonas* phage ϕ6) are dsRNA phages. Virions are about 85 nm in diameter, consisting of an envelope enclosed 58 nm icosahedral capsid. The capsid contains RNA polymerase and three linear dsRNA molecules. The three dsRNA genome segments are 2.9, 4.1 and 6.4 kb. Infection is virulent and involves adsorption to pili, which retract bringing the virion into contact with the host outer membrane. After fusion of viral and cellular outer membranes, the capsid enters the periplasmic space. Viral RNA replication is semiconservative with viral-encoded RNA polymerase to produce progeny dsRNA. Virus release is by cell lysis. Host range: *Pseudomonas*.

Leviviridae

Taxonomy
Family: *Leviviridae*
Genus: *Levivirus*
Genus: *Allolevivirus*

Characteristics *Leviviridae* are nonenveloped, icosahedral particles about 26 nm in diameter, containing ssRNA. The genome is linear, positive-sense ssRNA, either about 3.5 kb or 4.2 kb. Infection is by adsorption to pili determined by a wide variety of different plasmids. Viral replication is via a virus-encoded replicase, which requires host translation factors as cofactors. Release is by cell lysis.

Levivirus (type species: enterobacteriophage MS2) particles contain shorter genomes (about 3.5 kb) and have a separate gene for cell lysis, which partly overlaps the replicase coding region in the +1 reading frame. Overlap with the coat protein gene is variable. Synthesis of the lysis protein is dependent on translation of the coat protein gene. Host range: enterobacteria.

Allolevivirus (type species: enterobacteriophage Qβ) particles contain longer genomes (about 4.2 kb). The extra RNA encodes a carboxy-terminal extension of the coat protein, which is expressed by occasional suppression of the coat gene termination

codon. There is no separate lysis gene. Host range: enterobacteria.

Other members of *Leviviridae* There are unassigned species infecting *Acinetobacter*, *Caulobacter* and *Pseudomonas*.

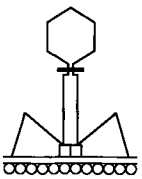
PHAGE TOXINS AND DISEASE



Randall K Holmes and **Michael G Jobling**, Department of Microbiology, University of Colorado Health Sciences Center, Denver, Colorado, USA

Michael P Schmitt, Laboratory of Bacterial Toxins, Center for Biologics Evaluation and Research, Food and Drug Administration, Bethesda, Maryland, USA

Introduction

Bacteriophages are associated with most bacteria, including pathogenic bacteria. Many bacterial pathogens produce toxic proteins that function as virulence factors and cause characteristic signs or symptoms of disease in humans or animals. The ability of some pathogenic bacteria to produce toxins is determined by specific temperate phages. When a nontoxinogenic bacterium becomes toxinogenic as a consequence of infection or lysogenization by a specific phage, the process is called phage conversion (or lysogenic conversion). Phenotypic characteristics other than toxinogenicity can also be determined by phage conversion.

Some nonconverting phages are highly homologous to converting phages, except that the determinants for toxin production are absent or nonfunctional in the nonconverting phages. The determinants for toxinogenicity in converting phages are usually not essential either for lytic growth or for lysogeny. Converting phages are similar to specialized transducing phages, except that the origin of genes that determine toxinogenicity is unknown.

Toxins that are produced as a result of phage conversion include diphtheria toxin in *Corynebacterium diphtheriae*, Shiga toxins in *Escherichia coli*, pyrogenic exotoxins in *Streptococcus pyogenes*, enterotoxins in *Staphylococcus aureus*, botulinum toxins in *Clostridium botulinum*, and cholera toxin in *Vibrio cholerae*. The converting phages in these pathogenic bacteria contain the structural genes for the corresponding toxins, but the various toxins differ greatly in biochemical structure, immunogenicity, mode of action and toxicity. This chapter emphasizes the characteristics of phage-encoded toxins that are important for pathogenesis of diseases in humans.

Diphtheria Toxin

Diphtheria is a local infection of the upper respiratory tract or skin that is caused by *C. diphtheriae* and spread from person to person by respiratory droplets or intimate contact. The characteristic lesion in the respiratory tract is a pseudomembrane that can sometimes cause obstruction of the airway. Diphtheria toxin produced at the site of local infection is distributed systemically and can cause myocarditis, polyneuritis and other complications. Respiratory diphtheria is usually caused by toxinogenic strains of *C. diphtheriae*, but cutaneous diphtheria is often caused by nontoxinogenic strains. The primary treatment for diphtheria is parenteral administration of diphtheria antitoxin to neutralize toxin that has not yet entered target cells. Antibiotics are used to eradi-

codon. There is no separate lysis gene. Host range: enterobacteria.

Other members of *Leviviridae* There are unassigned species infecting *Acinetobacter*, *Caulobacter* and *Pseudomonas*.

Introduction

Bacteriophages are associated with most bacteria, including pathogenic bacteria. Many bacterial pathogens produce toxic proteins that function as virulence factors and cause characteristic signs or symptoms of disease in humans or animals. The ability of some pathogenic bacteria to produce toxins is determined by specific temperate phages. When a nontoxinogenic bacterium becomes toxinogenic as a consequence of infection or lysogenization by a specific phage, the process is called phage conversion (or lysogenic conversion). Phenotypic characteristics other than toxinogenicity can also be determined by phage conversion.

Some nonconverting phages are highly homologous to converting phages, except that the determinants for toxin production are absent or nonfunctional in the nonconverting phages. The determinants for toxinogenicity in converting phages are usually not essential either for lytic growth or for lysogeny. Converting phages are similar to specialized transducing phages, except that the origin of genes that determine toxinogenicity is unknown.

Toxins that are produced as a result of phage conversion include diphtheria toxin in *Corynebacterium diphtheriae*, Shiga toxins in *Escherichia coli*, pyrogenic exotoxins in *Streptococcus pyogenes*, enterotoxins in *Staphylococcus aureus*, botulinum toxins in *Clostridium botulinum*, and cholera toxin in *Vibrio cholerae*. The converting phages in these pathogenic bacteria contain the structural genes for the corresponding toxins, but the various toxins differ greatly in biochemical structure, immunogenicity, mode of action and toxicity. This chapter emphasizes the characteristics of phage-encoded toxins that are important for pathogenesis of diseases in humans.

Diphtheria Toxin

Diphtheria is a local infection of the upper respiratory tract or skin that is caused by *C. diphtheriae* and spread from person to person by respiratory droplets or intimate contact. The characteristic lesion in the respiratory tract is a pseudomembrane that can sometimes cause obstruction of the airway. Diphtheria toxin produced at the site of local infection is distributed systemically and can cause myocarditis, polyneuritis and other complications. Respiratory diphtheria is usually caused by toxinogenic strains of *C. diphtheriae*, but cutaneous diphtheria is often caused by nontoxinogenic strains. The primary treatment for diphtheria is parenteral administration of diphtheria antitoxin to neutralize toxin that has not yet entered target cells. Antibiotics are used to eradi-

cate C. *diphtheriae*, eliminate the convalescent carrier state, and prevent spread of infection to susceptible contacts. Active immunization with diphtheria toxoid is highly effective in preventing diphtheria. Diphtheria is now rare in the United States and most developed countries, but it re-emerged as an epidemic disease in the early 1990s in the New Independent States of the former Soviet Union as a consequence of inadequate implementation of immunization programs during a period of severe socioeconomic disruption.

Toxinogenic conversion in C. *diphtheriae* was discovered in 1951, and in 1971 the structural gene for diphtheria toxin was shown to be phage-encoded. C. *ulcerans* and C. *pseudotuberculosis*, animal pathogens that occasionally cause disease in humans, can also carry tox^+ corynephages and produce diphtheria toxin. Phage β, the best characterized of the tox^+ corynephages, is an inducible, temperate phage with a polyhedral head and a long noncontractile tail. It has a linear, double-stranded, 34.7 kbp DNA genome with cohesive ends. On the vegetative map the genes for head and tail components are located at opposite ends, and the *tox* gene is located centrally between the immunity region *imm* and the host range marker *h*. The phage integrates into the host chromosome by means of site-specific recombination between the phage locus *attP* and an homologous bacterial locus *attB*. The prophage map is a circular permutation of the vegetative phage map, and the *tox* gene in the prophage is adjacent to the attachment site. This location suggests that an ancestral *tox* gene located on the bacterial chromosome may have been acquired by the phage by illegitimate recombination during prophage excision. Several tox^+ corynephages that vary with respect to virion morphology, antigenicity, and immunity specificity have homologous genomes, indicating that they constitute a family of related corynephages.

Diphtheria toxin (DT) is produced by C. *diphtheriae* as a secreted, extracellular protein of 535 amino acid residues. DT is cleaved by a protease such as trypsin or furin into an amino-terminal fragment A (21 kDa) and a carboxyl-terminal fragment B (37 kDa) that remain linked by a disulfide bond. The receptor-binding (R) domain of fragment B interacts with a receptor (heparin-binding EGF-like growth factor precursor) on susceptible cells and mediates entry of DT by endocytosis. Following acidification of the endosomes, the transmembrane (T) domain of fragment B inserts into the endosomal membrane and mediates translocation of fragment A into the cytoplasm. Fragment A catalyzes ADP-ribosylation of the unique diphthamide residue of EF-2, causing inactivation of EF-2, inhibition of protein synthesis and cell death. One molecule of fragment A in the cytoplasm can kill a susceptible eukaryotic cell. Exotoxin A from *Pseudomonas aeruginosa* ADP-ribosylates EF-2 in the same manner as DT, but it interacts with a different cell surface receptor and therefore differs from DT in its species and tissue specificity.

Production of diphtheria toxin by C. *diphtheriae* is regulated by iron, and maximal toxin production occurs during late log or stationary phase in iron-depleted medium. Transcription of the *tox* gene is repressed under high-iron growth conditions by the diphtheria toxin repressor (DtxR), an Fe^{2+}-activated global regulatory protein that also controls production of corynebacterial siderophore, utilization of ferric siderophore complexes, and probably other functions in C. *diphtheriae*. DtxR binds to promoter/operators that have a 19 bp core homologous to the palindromic consensus sequence TTAGGTTAGCC-TAACCTAA. The function of DtxR in C. *diphtheriae* is similar to that of the ferric uptake regulator (Fur) protein in *E. coli*, but DtxR and Fur bind to different consensus sequences and are therefore specific for different operators.

Shiga Toxins of *Escherichia coli*

Shigella dysenteriae type 1 causes bacillary dysentery and produces the classical Shiga toxin (Stx). Some pathogenic *E. coli* that produce disease in humans or animals produce toxins (currently designated Stx1 and Stx2) that are closely related to Stx. These *E. coli* Shiga toxins were previously called Shiga-like toxins (SLT) or Vero toxins (VT). *E. coli* that cause hemorrhagic colitis and hemolytic uremic syndrome in humans (enterohemorrhagic *E. coli* [EHEC]) typically produce moderate to large amounts of Stx1, Stx2, or both, and *E. coli* that cause edema disease in pigs produce a variant of Stx2 called Stx2e.

Classification of Shiga toxins is based on their antigenicity, amino acid sequences, and biochemical properties. Stx1 and Stx are antigenically indistinguishable and differ by a single, conservative amino acid substitution. Stx2 and Stx2e do not crossreact antigenically with Stx/Stx1, but they exhibit partial antigenic crossreactivity with each other. The amino acid sequences of Stx2 and Stx2e are more homologous with each other than with Stx/Stx1. Additional variants of Stx2 designated Stx2c and Stx2d have been characterized. The biological activity of Stx2d, but not that of Stx2, Stx2c and Stx2e, is activated by incubating the toxin in the presence of human intestinal mucus.

The operons that encode Stx1 and Stx2 are located on different phages in EHEC, and individual EHEC

strains can produce Stx1 only, one or more variants of Stx2, or both Stx1 and Stx2. The operons for Stx in *S. dysenteriae* type 1 and for Stx2e in *E. coli* are located on the bacterial chromosome. The synthesis of Stx by *S. dysenteriae* type 1 and Stx1 by *E. coli* is inhibited by high concentrations of iron in the growth medium, and this iron-dependent repression is mediated by Fur. In contrast, the synthesis of Stx2 and Stx2e by *E. coli* is not regulated by iron.

The prototype converting phages for Stx1, designated H19A and H19B, were isolated from EHEC strain H19 (O26:H11), which was obtained from an infantile diarrhea outbreak in Great Britain. Morphologically these phages have a noncontractile, flexible, long tail and a hexagonal head. DNA hybridization revealed that phage H19B is partially homologous with coliphage lambda. In phage H19B the genes that encode Stx1 are located far from the phage attachment locus. The prototype converting phage for Stx2, designated 933W, was isolated from EHEC strain 933 (O157:H7), which produces both Stx1 and Stx2. Phage 933W is morphologically distinct from the H19 phages and has a very short, noncontractile tail. A converting phage for Stx1 designated 933J, originally reported from EHEC strain 933, is indistinguishable from phage H19A, and subsequent attempts to recover phages from strain 933 in two laboratories yielded only 933W-like phages. Hybridization experiments demonstrated that EHEC strain 933 contains sequences that are homologous with DNA from phage H19A, raising the possibility that a EHEC strain 933 may contain a defective converting phage for Stx1 related to phage H19A.

Stx and the Shiga toxins of *E. coli* are all oligomeric proteins with one A polypeptide and five identical B polypeptides. Exposure of toxin to trypsin and reduction of an intrachain disulfide bond converts the A polypeptide into fragments A1 and A2. The B polypeptides bind to specific glycosphingolipid receptors in the plasma membranes of susceptible cells. The preferred receptor for Stx, Stx1 and Stx2 is globotriaosylceramide (Gb3), whereas the preferred receptor for Stx2e is globotetraosylceramide (Gb4). Binding of toxin to these specific glycolipids triggers receptor-mediated endocytosis, uptake via coated pits, and retrograde transport of toxin to the Golgi and endoplasmic reticulum. The A1 fragment is translocated to the cytosol, probably from the endoplasmic reticulum, by a mechanism that does not depend on acidification of endosomes. The final step in intoxication is inhibition of protein synthesis, which is caused by removal of a specific adenine residue from 28S rRNA in 60S ribosomal subunits by the highly specific RNA *N*-glycosidase activity of fragment A1. The intracellular action of the A1 fragment of Stx and the *E. coli* Shiga toxins is identical to that of ricin, and the active sites of these toxins have homologous structures. X-ray crystallography also demonstrated conserved three-dimensional folding between the B polypeptides of Stx/Stx1 and the heat-labile enterotoxin of *E. coli* despite lack of amino acid sequence homology.

The role of Shiga toxin in the pathogenesis of dysentery is unclear. *S. dysenteriae* type 1 and other species of *Shigella* cause bacillary dysentery, characterized by bloody, mucoid diarrhea and colonic inflammation, although dysentery caused by *S. dysenteriae* type 1 in humans or monkeys is typically more severe than that caused by *S. dysenteriae* type 1 mutants or other shigellae that produce little or no Shiga toxin. These findings suggest that Shiga toxin is not essential for the pathogenesis of dysentery but that it contributes to the severity of the disease.

Epidemiologic evidence clearly identifies EHEC as a cause of hemorrhagic colitis, but the roles of Stx1 and Stx2 in the pathogenesis of that disease are not clearly defined. Similarly, hemolytic uremic syndrome is clearly a sequela of infections caused by *E. coli* that produce high levels of Stx1, Stx2 or both, but an animal model that precisely replicates the pathology observed in humans with hemolytic uremic syndrome is not yet available. An emerging consensus from numerous studies on bacillary dysentery, hemorrhagic colitis, and hemolytic uremic syndrome, however, is that damage to endothelial cells of the vasculature in the colon and in the kidneys caused by Stx or related toxins of *E. coli* is an important aspect of the pathogenesis of these diseases. In the case of edema disease, injection of purified Stx2e into pigs mimics the naturally occurring disease. The data are compelling, therefore, that Stx2e has a direct and dominant role in the pathogenesis of edema disease.

Pyrogenic Exotoxins of *Streptococcus Pyogenes* and *Staphylococcus Aureus*

The streptococcal pyrogenic exotoxins (also known as erythrogenic toxins or scarlatinal toxins) are produced by *S. pyogenes* and cause the rash of scarlet fever. The enterotoxins of *S. aureus* cause the symptoms of staphylococcal food poisoning, and toxic shock syndrome toxin of *S. aureus* is responsible for many manifestations of toxic shock syndrome. These toxins share antigenic properties, amino acid sequences, and biological activities including pyrogenicity, enhancement of sensitivity to endotoxins of Gram-negative bacteria, and various immunomodulatory effects. They are all superantigens as described below.

Phage conversion for streptococcal pyrogenic exotoxin A (SpeA, 221 amino acids) production was demonstrated after lysogenization of *S. pyogenes* strain $T25_3$ with the temperate phage T12. Phage T12 is a double-stranded DNA phage with a 36 kbp genome that is circularly permuted and terminally redundant. The *speA* structural gene in the phage T12 genome is adjacent to *attP*. There are at least 10 different SpeA-converting phages that differ serologically and in host range. DNA sequences homologous with *speA* and with phage T12 sequences distinct from *speA* were present and physically linked in other SpeA-producing strains of *S. pyogenes* from which converting phages could not be recovered. These findings suggest that some SpeA converting phages are defective or that appropriate indicator strains for detecting them were not available.

The production of streptococcal pyrogenic exotoxin C (SpeC, 208 amino acids) by *S. pyogenes* is also controlled by phage conversion, and the genome of the SpeC converting phage CS112 is also circularly permuted with *speC* closely linked to *attP*. The genetic control of streptococcal pyrogenic exotoxin type B (SpeB, 253 amino acid mature protein) production in *S. pyogenes* is not yet clearly defined. DNA hybridization studies show that all strains of *S. pyogenes* have one copy of the *speB* gene, although only half of the strains produce detectable SpeB. Previous suggestions that SpeB production is controlled by phage conversion have not been confirmed.

In recent years there has been a resurgence of serious group A streptococcal infections and the recognition of a streptococcal toxic shock syndrome (strepTSS) that resembles staphylococcal toxic shock syndrome. Early studies in the United States showed that most isolates of *S. pyogenes* from patients with strepTSS produced SpeA, whereas isolates from most strepTSS patients from Europe and Canada produced SpeB and SpeC. Recent studies suggest that other streptococcal superantigens designated SpeF and SSA may also contribute to strepTSS. The importance of specific streptococcal superantigens in the pathogenesis of strepTSS and severe invasive streptococcal infections remains under active investigation.

The pyrogenic toxins of *S. aureus* include enterotoxins A, B, C1, C2, C3, D, E and G (228–239 amino acids) as well as toxic shock syndrome toxin 1 (TSST-1, 234 amino acids). The staphylococcal enterotoxins (designated SEA, SEB, etc.) are classified serologically, with C1, C2 and C3 representing minor serological variants. The genes that encode these toxins have been sequenced, and allelic variants have been identified for some of them. Analysis of amino acid sequences demonstrated homologies among the staphylococcal enterotoxins and SpeA, as well as homologies between SpeA and SpeC. SEA, SED, and SEE formed one closely related subgroup, whereas SEB, SEC, SEG, and SpeA formed a second closely related subgroup. SpeB and TSST-1 did not have significant amino acid sequence homology with the other toxins. X-ray crystallographic studies of these toxins are progressing rapidly and are identifying common structural motifs important for their function as superantigens.

Production of the staphylococcal enterotoxins SEA and SEE is controlled by phage conversion. Phage PS42-D has a linear 42 kbp genome with cohesive ends that encodes the *sea* gene, but *sea* in PS42-D is not immediately adjacent to *attP*. Phage PS42-D has a preferred site of integration in the *pur-ilv* region of the chromosome of *S. aureus*, and integration of PS42-D results in insertional inactivation of the gene that encodes β-hemolysin. A family of phages related to PS42-D has been identified, some of which contain the *sea* gene and some of which lack it. The *see* gene may be part of a defective phage that is related to the *sea*-containing phages. There is no evidence that the other staphylococcal pyrogenic exotoxins are phage-encoded. The *sed* gene is located on a 27.6 kbp penicillinase plasmid. The genes *seb*, *sec* and *tst* (which encodes TSST-1) are located on discrete but not well characterized genetic elements within the bacterial chromosome; they may possibly be mobile genetic elements similar to the 'hitchhiking transposons' described in other strains of *S. aureus*.

Pyrogenic exotoxins function as superantigens because they can interact with two different classes of receptors on cells of the immune system and activate large populations of T cells. They bind simultaneously to major histocompatibility complex (MHC) class II molecules on antigen-presenting cells (APC) and to T cell receptors (TCR) that express specific β chain variable regions. The resulting ternary complexes are unconventional, however, because the superantigens are not processed by the APC; they interact with the MHC class II molecules at positions that are distinct from those used for presentation of processed peptide antigens; and they interact with the TCR at positions that are distinct from those used for recognition of complexes of processed peptide antigens with MHC class II molecules. If appropriate costimulatory signals are present, the result is activation of T cells that express the appropriate Vβ chains. Superantigens can activate 5–20% of T cells, whereas the response to traditional antigens activates only 0.0001–0.01% of T cells. The activated T cells produce large amounts of several mediators, including interleukin-2, γ-interferon (IFN-γ), and tumor necrosis factor α (TNF-α), which are responsible for many of the observed biological effects. Superantigens

can induce T cell anergy if they engage TCR without delivery of appropriate costimulatory signals, and they can induce apoptosis and cause deletion of specific T cell lineages if they engage TCR on T cells that are already activated by exposure to high levels of cytokines such as IFN-γ or TNF-α. There is also evidence that the emetic action of the staphylococcal enterotoxins can be dissociated from their ability to activate T cells and might involve stimulation of mast cells to release leukotrienes.

Botulinum Toxins

Botulinum toxins are produced primarily by *C. botulinum* and cause the paralytic symptoms of botulism. Seven serologically different neurotoxins, designated A, B, C1, D, E, F and G, have been identified, and all appear to be structurally and functionally similar. Types A, B, E and F cause botulism in humans. Types C1 and D are the primary causes of animal botulism. Type G is produced by an environmental isolate of *C. botulinum*.

C. botulinum is a Gram-positive, spore-forming, anaerobe that is classified into groups I–IV based on biochemical, physiological and serological characteristics. Spores of *C. botulinum* are highly resistant to heating and boiling and can persist in the environment for years. Production of toxin requires germination of spores and anaerobic growth of the bacteria. Some strains of *C. botulinum* produce more than one type of botulinum toxin. Some isolates of *C. butyricum* and *C. baratii* have also been shown to produce botulinum toxin.

Three forms of botulism are recognized. Food-borne botulism, which involves the ingestion of preformed toxin, is the classical form in adults and is now rare. Wound botulism, which is associated with infection by *C. botulinum* at the site of an injury, is extremely rare. Infant botulism, which is usually caused by ingestion of *C. botulinum* and production of toxin within the intestinal tract, occurs more frequently, but the incidence of infant botulism in the United States is less than 100 cases per year. Infant botulism has received much attention because of a possible association with a small proportion of cases of sudden infant death syndrome.

Botulinum toxin affects the peripheral cholinergic nervous system, resulting in neuromuscular paralysis. The symptoms of botulism are quite variable and depend on the amount of toxin present. Symptoms typically begin approximately one day after ingestion of toxin, but in severe cases death may occur within 24 h. Early symptoms include weakness, double vision or inability to focus, impaired speech and difficulty swallowing, and death may result from respiratory paralysis. Treatment involves administration of antitoxin and supportive care as needed, including assisted ventilation.

Phage conversion of botulinum toxin production has only been proved for type C1 and D botulinum toxins. The C1 and D converting phages share some morphological similarities with the *E. coli* T-even phages. Electron microscopy indicates that they have hexagonal heads and long flexible tails surrounded by contractile sheaths. A study examining the DNA from five tox^+ phages that encode either the C1 or D toxins established that the phages contained double-stranded DNA genomes of either 110 kbp or 150 kbp. Restriction endonuclease profiles and DNA hybridization experiments with genomic DNA from these phages indicated that all but one of the phage DNAs were similar.

One or more isolates of the structural genes for all seven serological types of botulinum toxin, and for the related clostridial neurotoxin tetanus toxin, have been cloned and sequenced. The botulinum toxins of different serotypes vary from 1251 to 1297 amino acids in size. Amino acid sequence identity between toxin isolates of different serotypes does not usually exceed 40%. In contrast, the amino acid identity of toxin isolates within serotypes is much higher (74–100%), and the greatest differences are observed when the serologically similar toxins are produced by *C. botulinum* isolates from different groups (I–IV) or by *C. barati*.

Botulinum toxin is synthesized as a single polypeptide of approximately 150 kDa. After secretion, the toxin is typically cleaved into two components, a 100 kDa heavy chain and a 50 kDa light chain that are held together by a disulfide bond. Botulinum toxins are usually purified as high-molecular-weight complexes of the 150 kDa toxin with a 130–140 kDa protein (called the nontoxic–nonhemagglutinin component) plus a 33 kDa hemagglutinin protein; although the hemagglutinin is not present in purified botulinum toxins of types E and F. Other uncharacterized proteins are also present in some preparations of botulinum toxin. The high-molecular-weight complexes may protect the integrity of the botulinum toxins as they are exposed to gastric juices in the stomach.

Botulinum toxin blocks the release of acetylcholine from motor neurons at the myoneural junctions, resulting in flaccid paralysis. The heavy chain is believed to mediate receptor binding and translocation of toxin into the neuron, whereas the light chain acts intracellularly. The light chains of botulinum and tetanus neurotoxins were recently shown to be Zn^{2+}-dependent metalloproteases which cleave specific proteins of the neuroexocytosis apparatus at positions

that are characteristic for each toxin, thereby preventing release of acetylcholine from synaptic vesicles. The specific proteins that are targets for the action of these neurotoxins are VAMP/synaptobrevin for botulinum toxins B, D, F and G and tetanus toxin, SNAP-25 for botulinum toxins A and E, and syntaxin for botulinum toxin C1.

Cholera Toxin

Cholera is a profuse watery diarrhea produced by infection with *Vibrio cholerae* and caused mainly by the action of cholera enterotoxin (CT) on the intestinal epithelium. *V. cholerae* is a Gram-negative, motile, rod-shaped bacterium that is classified into over 140 serogroups based on O antigens. Only *V. cholerae* serogroups O1 and O139 cause epidemic cholera. *V. cholerae* O1 consists of two biotypes, classical and El Tor, that are differentiated by biochemical properties, polymyxin B resistance and bacteriophage sensitivity. The biotypes of strains that caused the first four recorded cholera pandemics (1817 through 1879) are unknown. Classical O1 strains caused the fifth and sixth cholera pandemics (1881 through 1923), and the O1 El Tor biotype has predominated in the seventh pandemic (1961 to present). *V. cholerae* O139, believed to have arisen from an El Tor strain by acquisition of novel O antigen determinants, was first identified as a cause of epidemic cholera in 1993.

V. cholerae produces toxin coregulated pili that enable it to colonize the small intestine, where it secretes CT. CT is composed of a single A polypeptide and a pentamer of five identical B polypeptides, and it is closely related to the type I and type II heat-labile enterotoxins (LT-I and LT-II) of *E. coli*. The A subunit is proteolytically nicked to generate disulfide-linked A1 and A2 peptides, and the A2 polypeptide links the A1 polypeptide to the B pentamer. Binding of B pentamer to the cell surface receptor ganglioside GM_1 triggers endocytosis of CT. The reduced A1 polypeptide is translocated to the cytoplasm, where it catalyzes the transfer of ADP-ribose from NAD to the $G_S\alpha$ subunit of a heterotrimeric regulatory G protein. This causes constitutive activation of adenylate cyclase, increases intracellular cAMP concentration, and leads to active secretion of chloride and diarrhea.

The genes for CT (*ctxA* and *ctxB*) are organized into an operon in a genetic element called CTX that is found at the same location in the chromosome of classical and El Tor biotypes of *V. cholerae*, and a second copy of the CTX element is present at an unlinked chromosomal location in the classical biotype. In both biotypes the CTX element can be present as tandemly repeated copies. Expression of the *ctx* operon and of toxin coregulated pili is positively regulated by the product of the *toxR* gene. The *ctxA* and *ctxB* genes are present in a core element, flanked by copies of 2.4–2.7 kbp repetitive sequences called RS elements. Unequal recombination between RS sequences is believed to generate the tandem duplications. The RS elements encode a site-specific recombination system capable of integrating into an 18 bp sequence in the *V. cholerae* chromosome called attRS1, which forms the junctions between RS elements and also between the CTX element and the chromosome in all *V. cholerae* strains. The core element also contains genes that were originally identified as potential virulence factors, such as *zot* (zonula occludens toxin), *ace* (accessory cholera enterotoxin), *cep* (core encoded pilin) and an unidentified gene (*orfU*).

Recent discoveries have identified the CTX genetic element as the genome of a novel, filamentous, single-stranded DNA bacteriophage (designated CTXΦ) related to coliphage M13. Among the major bacterial protein toxins, therefore, CT is the one most recently recognized to be produced as a consequence of phage conversion. The *zot* and *orfU* genes are required for phage morphogenesis, and *cep* is predicted to encode the virion capsid protein. The genes present in the RS element encode regulation, replication and integration functions. In *V. cholerae* strains possessing an attRS1 site, CTXΦ exists as an integrated prophage, but in attRS1-minus strains it can exist as an extrachromosomal, 7 kbp, double-stranded, circular prophage. This extrachromosomal prophage consists of the core element plus a copy of RS2 and attRS1, and it corresponds to the expected product of a chromosomal excision event between attRS1 sites flanking the core-RS2 element. CTXΦ is a 7 nm diameter filamentous phage with a single-stranded genome, and it uses the TCP pilus as a receptor.

CTXΦ is the first filamentous converting phage described. The *ctx* operon that encodes CT appears to be the only non-essential part in the viral genome. The coregulation of the toxin genes and the phage receptor TCP by *toxR* highlights the coevolution of phage and bacterial virulence determinants in *V. cholerae*. Only bacteria that express TCP can colonize the intestine, be infected by CTXΦ, acquire the ability to make CT, and in turn cause cholera.

Conclusions

The bacterial protein toxins described here share the characteristic that they are encoded by genes of temperate phages, but the toxins are otherwise heterogeneous in structure and function. These toxins have no essential roles in the life cycles of the

corresponding converting phages, and toxin production is regulated by mechanisms that are independent of the regulation of other phage genes. Typically, the toxin genes can be expressed from prophage, from lytically replicating phage, or from superinfecting, nonreplicating phage in bacteria with homologous lysogenic immunity.

The evolution of toxin converting phages is not well defined. Genes that encode bacterial toxins could presumably become incorporated into bacteriophage genomes by any of several mechanisms for genetic exchange. The fact that several toxin genes are located in phage genomes at sites adjacent to *attP*, however, suggests that imprecise excision of prophage and incorporation into the phage genome of segments of the bacterial genome that were originally contiguous to *attB* may be a fairly common mechanism for evolution of toxin converting phages.

In recent years the genes for many toxins and other virulence factors have been found on accessory genetic elements of bacteria such as phages, plasmids and transposons. Typically, virulence-associated genes encode nonessential functions that are advantageous for pathogenic bacteria in their animal hosts. The localization of multiple virulence-associate genes on accessory genetic elements has several potential advantages for pathogenic bacteria. The virulence genes can be maintained in the bacterial gene pool without being present in every member of the population, and appropriate groups of virulence genes can be disseminated rapidly by horizontal transfer of the accessory genetic elements within the bacterial population. The potential for successful intergeneric transfer of virulence-associated genes is also increased by their presence on accessory genetic elements that may have broad host range. Presumably, such advantages could provide the pressure for positive selection of converting phages that arose during the course of bacterial and bacteriophage evolution.

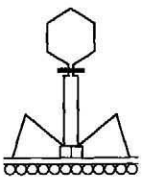
PHAGE TRANSDUCTION

Werner Arber, University of Basel, Basel, Switzerland,



Definition and Discovery of Transduction

Transduction is the phage-mediated transfer of genetic information from donor to recipient bacteria followed by the phenotypic expression of transferred genetic traits in the progeny of the recipient cell.

Transduction was first described in 1952 by Norton Zinder and Joshua Lederberg. These authors investigated the possibility that pairs of genetically distinct bacterial strains of *Salmonella typhimurium* could exchange genetic traits by conjugation, a phenomenon discovered a few years before with *Escherichia coli* K-12 and requiring intercellular contact. In the

corresponding converting phages, and toxin production is regulated by mechanisms that are independent of the regulation of other phage genes. Typically, the toxin genes can be expressed from prophage, from lytically replicating phage, or from superinfecting, nonreplicating phage in bacteria with homologous lysogenic immunity.

The evolution of toxin converting phages is not well defined. Genes that encode bacterial toxins could presumably become incorporated into bacteriophage genomes by any of several mechanisms for genetic exchange. The fact that several toxin genes are located in phage genomes at sites adjacent to *attP*, however, suggests that imprecise excision of prophage and incorporation into the phage genome of segments of the bacterial genome that were originally contiguous to *attB* may be a fairly common mechanism for evolution of toxin converting phages.

In recent years the genes for many toxins and other virulence factors have been found on accessory genetic elements of bacteria such as phages, plasmids and transposons. Typically, virulence-associated genes encode nonessential functions that are advantageous for pathogenic bacteria in their animal hosts. The localization of multiple virulence-associate genes on accessory genetic elements has several potential advantages for pathogenic bacteria. The virulence genes can be maintained in the bacterial gene pool without being present in every member of the population, and appropriate groups of virulence genes can be disseminated rapidly by horizontal transfer of the accessory genetic elements within the bacterial population. The potential for successful intergeneric transfer of virulence-associated genes is also increased by their presence on accessory genetic elements that may have broad host range. Presumably, such advantages could provide the pressure for positive selection of converting phages that arose during the course of bacterial and bacteriophage evolution.

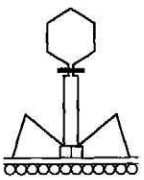
PHAGE TRANSDUCTION

Werner Arber, University of Basel, Basel, Switzerland,



Definition and Discovery of Transduction

Transduction is the phage-mediated transfer of genetic information from donor to recipient bacteria followed by the phenotypic expression of transferred genetic traits in the progeny of the recipient cell.

Transduction was first described in 1952 by Norton Zinder and Joshua Lederberg. These authors investigated the possibility that pairs of genetically distinct bacterial strains of *Salmonella typhimurium* could exchange genetic traits by conjugation, a phenomenon discovered a few years before with *Escherichia coli* K-12 and requiring intercellular contact. In the

experiments with *Salmonella,* hybrid recombinants were indeed obtained. However, these also appeared under conditions in which the two bacterial strains were inhibited by a membrane filter from undergoing close intercellular contact. The filterable agent responsible for the formation of recombinants was soon identified as the endemic bacteriophage P22.

Experimental Evidence for Transduction

The basic experimental strategy to identify transduction by a phage strain is as follows. The phage is propagated in a donor bacterium prototrophic for a few identifiable traits. The vegetative propagation can be initiated by either infection or induction of lysogens for the phage in question. The resulting phage lysate is carefully sterilized in order to inactivate any remaining viable donor bacteria. Recipient bacteria chosen to be auxotrophic for the considered genetic traits are then infected with the sterile phage preparation, ideally at a multiplicity of infection of about one phage per cell. The infected bacteria are exposed to selective medium in which the input recipient cells will not grow, but in which recipients having acquired one or several genetic traits of the donor strain can propagate. Growth of a usually low number of colonies indicates that the transfer of the traits under consideration from the donor into the recipient cells has been mediated by phage particles acting as gene vectors. Obvious control experiments include the determination of mutant reversion frequencies of the recipient to prototrophy as well as tests of the sterility of the phage lysate, the sensitivity of transduction to phage-inactivating antiserum and the insensitivity of transduction to nuclease treatment of the phage lysate.

The ability of a given phage strain to transduce and the particular mechanistic features of transduction largely depend on the life style of a virus. Because of the usually low frequency of transduction and because of the often aleatoric nature of each particular transduction event, the mechanistic investigation of transduction at the molecular level largely depends on evidence collected at the level of microbial populations. Individual events can hardly be looked at directly, nor are many of their features strictly reproducible. Nevertheless, satisfactory interpretations are available to explain transduction processes displayed by a small number of thoroughly investigated model systems, including the *Salmonella* phage P22 and the coliphages P1 and lambda (λ). While some of the mechanistic features unraveled with these phages may represent general rules, others may, rather, be specifically dependent on some particular viral trait. This should serve as a caveat to the reader of this general overview on transduction and its biological significance.

Generalized versus Specialized Transduction

In early experiments it was found that some phages transduced any tested donor gene with roughly similar, although low, frequencies. This phenomenon is called *generalized transduction,* and phages P22 and P1 represent prototypes of this transduction mode. In contrast, other phages such as λ transduce only a few particular donor genes, thus the term *specialized transduction.* It soon became clear that in specialized transducing phages, the transferred donor genes are covalently linked to the phage genome, so that they also become propagated as the virus propagates either vegetatively in bacteria sensitive to the phage or as prophage in lysogenic bacteria. This is usually not so in generalized transduction, in which normally a DNA segment of the donor genome is wrapped into a viral coat without undergoing hybridization with viral DNA. Its later propagation to the progeny of the infected recipient cell will thus usually depend on recombinational integration into the recipient genome. In the absence of such integration, unilinear inheritance of the transferred genetic information can occur. This phenomenon is known as *abortive transduction.* In particular cases, in which transferred DNA carries the appropriate genetic information for its autonomous replication, the establishment can be ensured by plasmid replication and maintenance.

Uptake of Cellular Genetic Information into Transducing Viral Particles

The mode of packaging progeny viral DNA into preformed viral coats is an important characteristic of the lifecycle of each phage strain. Some phages encapsulate a so-called headful of DNA (see section below). Other phages package precisely a viral genome, the ends of which are in these cases identified by specific nucleotide sequences (see section below).

Packaging: headful of DNA Together with the virulent T-even phages of *Escherichia coli* the classical transducing phages P22 and P1 use the headful strategy for the packaging of phage particles. In the course of DNA replication, the viral genomes of these phages form long concatemeric DNA molecules composed of several genome copies arranged in tandem. DNA packaging into viral particles is then initiated by the interaction of a specific viral protein with a particular nucleotide sequence within the

genome, the *pac* site, from which packaging of the DNA then proceeds linearly until the viral coat, called the phage head, is full. DNA is then cleaved and the protein which apparently remains attached to the end of the not yet packaged part of the concatemeric DNA molecule can immediately reinitiate the packaging of another phage particle. In this way, several phage particles become sequentially packaged from the same concatemeric DNA molecule. This explains why phages encapsulating their DNA by this headful mechanism form populations of particles with circularly permuted DNA molecules. The normal phage head has a capacity to take up somewhat more DNA than that corresponding to the length of the wild-type phage genome. Therefore, the phage DNA in these viral particles is also terminally redundant, which is a requirement for successful initiation of the next cycle of reproduction of the phage. As observed with phage P1, some phages produce populations of phage coats of different size, the smaller of which encapsulate less than a genome size of DNA. Consequently, these small-headed phages are not able to reproduce upon single infection.

Occasionally, DNA packaging becomes initiated on cellular DNA rather than on the specific *pac* site on a concatemer of phage DNA. Possibly, this occurs at host DNA sequences resembling the *pac* site of the phage. Packaging of cellular DNA can then proceed in the same way as with phage DNA. Several coats chosen randomly from populations of phage coats of different size, if relevant, thus become packaged with cellular DNA segments of lengths corresponding to the capacity of the heads. This is, for example, about 40 kb for P22 coats, about 100 kb for P1 heads of normal size and about 40 kb for small-headed P1 particles; 40 kb roughly corresponds to 1% of the host chromosome.

There are alternative possibilities by which packaging of cellular DNA can also occur. Some phages such as P1 encode for site-specific recombinases and they carry in their genomes crossing-over sites at which these enzymes can act. Recombination between such a phage site and a similar DNA sequence carried on the host chromosome can bring about the fusion of a copy of the viral genome with the cellular DNA. If DNA packaging then becomes initiated at the viral *pac* site of such a cointegrate, packaging may proceed into the regions of cellular DNA. If for example a single copy of the viral genome had fused with the bacterial chromosome, subsequent packaging as proposed will produce a first viral particle with hybrid DNA between the phage and the host chromosome, and all subsequent viral particles from this packaging chain will contain only host DNA. Fusion of the phage genome with cellular DNA can also occur either by transposition-mediated cointegration or more classically by general recombination acting at portable sequence homologies, as they are, for example, provided by inserted sequence (IS) elements carried both in the host genome (see below) and in some viral genomes.

Transducing phage particles originating by one of the possibilities described usually contain only host DNA and give generalized transduction. The frequency of such transducing phage particles in phage preparations is of the order of 1% of the total phage population, both for P22 and for P1.

Packaging: discrete genomes Bacteriophage λ and its relatives also normally package their DNA from concatemeric oligomers of the phage genome. However, a specific enzyme-mediated process selects discrete phage genomes for encapsulation. A specific nucleotide sequence, called the *cos* site, identifies the genome ends at which concatemers are cleaved upon packaging. Consequently, the linear DNA molecules carried in phage particles represent a uniform population of genomes; they are neither terminally redundant nor circularly permuted.

With these phages, DNA packaging only rarely originates within cellular DNA at a DNA sequence homologous to a *cos* site. Even so, it is quite unlikely that a second *cos* site would be carried at an appropriate distance from the first, so that the DNA segment contained between the two sites would roughly correspond to the length of the phage genome, a requirement to obtain phage particles able to infect a new host cell. Indeed, phage λ does not give measurable frequencies of transduction for most of the regions of the bacterial chromosome.

In contrast, phage λ transduces genes located near the site in the chromosome at which the λ genome is carried as prophage in λ-lysogenic bacteria. λ lysogeny is the result of an infection in which the vegetative phage reproduction is repressed at an early stage and the phage genome becomes integrated into the host chromosome by phage-mediated site-specific recombination between the phage *att*P sequence and the host *att*B sequence. The normal bacterial attachment site (*att*B) for the integration of prophage λ into the *E. coli* chromosome is located between the *gal* operon and the *bio* operon. When λ-lysogenic bacteria are induced (e.g. by UV irradiation) to vegetatively produce λ phage, the λ prophage is normally excised precisely at its junctions with the cellular DNA, i.e. at the *att* sites. With a frequency of about 10^{-4} per event, however, excision is not as precise and can occur more or less randomly by so-called illegitimate recombination. The result of such recombination occurring between phage sequences

and host sequences is a hybrid genome in which part of the phage genes have been replaced by bacterial genes, which can be either the *gal* or the *bio* genes. Consequently, such specialized transducing phages may have lost some of the genes essential for vegetative phage reproduction. Such phages are therefore defective and can only reproduce by complementation with functions provided by a normal phage genome serving as 'helper'.

A model drawn by Allan Campbell explains prophage excision with the formation of a figure eight of the λ-lysogenic *E. coli* chromosome followed by a single recombination event. In independent illegitimate excision events hybrid genomes are formed which differ with regard to the extent of both the deleted phage genes and the acquired host DNA. However, hybrids always carry their substitutions adjacent to the *att* site, in accordance with the Campbell model. In fact, the *att* site of the hybrid genomes also remains hybrid; it is one of the two junctions between the prophage and the host chromosome in λ lysogens.

In theory, hybrid DNA molecules of any length could be expected to result from illegitimate prophage excision. In practice, limits are naturally set to hybrid DNA molecules to be packaged into λ phage particles. The hybrid DNA must contain the *cos* site on the phage sequences and the length of the hybrid genome must allow the formation of an infective particle, i.e. its length can at most vary between 78% and 108% of the length of the wildtype λ genome length. This has to do with the size and the stability of the phage λ head. The stability is ensured only for genome sizes varying between about 36 and 51 kb.

Specialized transducing λ phages carrying *gal* or *bio* genes are only formed upon initiation of phage reproduction in lysogenic bacteria; they do not arise upon vegetative phage growth after infection. Occasionally, the λ prophage can integrate at other chromosomal locations than *att*B. In these cases, subsequent induction of phage reproduction can lead to the formation of specialized transducing phage derivatives transferring those bacterial genes located in the immediate vicinity of the prophage location, exactly as in the normal situation with the prophage located at *att*B.

Transposition as an Alternative Source of Specialized Transducing Phage Genomes

As we have already seen, the formation of specialized λ*gal* and λ*bio* transducing phages depends on recombinational events involving the hybridization of the λ phage genome with the bacterial chromosome. The resulting hybrids are autonomous replicons which, upon vegetative reproduction of the phage, can be encapsidated into phage particles. Upon infection of new hosts, the hybrid genomes can become established and give rise to transductants. These are derivatives of the infected recipient host expressing some of the genes carried in the transducing phage.

An alternative route to obtaining specialized transducing phage under natural conditions is transposition. Transposons are mobile genetic elements which are specific DNA sequences able to insert into any selected target on DNA molecules. In addition to the genetic information required for the transposition process, transposons carry one or more genes unrelated to the transposition functions. This contrasts with the structure of prokaryotic inserted sequence (IS) elements which are defined as mobile genetic elements carrying only genetic information for their own transposition. However, an IS element can be part of a transposon. Indeed, composite transposons are defined as IS-mediated transposons which carry genetic information unrelated to transposition sandwiched between two identical IS elements, at least one of which should exert transpositional activity. Therefore, in principle any segment of a bacterial chromosome may at one time or another become part of a composite transposon, when it becomes flanked by the consecutive insertion of an IS element to its left and right sides. Other transposons may have their structural origin in other types of DNA rearrangements.

Transposons can transpose from the bacterial genome into the genome of a vegetatively reproducing phage. Alternatively, a transposon can also become inserted into a prophage carried in lysogenic bacteria. The vegetative reproduction of such prophage can later become induced. Both cases can give rise to the formation of specialized transducing phages, provided that the following conditions are fulfilled. The insertion of the transposon must not have inactivated phage functions essential for vegetative reproduction, or at least such inactivated functions must be complemented by a helper phage present in the same host cell. Furthermore the size of the hybrid genome must not be excessively large. This condition again relates to the packaging mode of the phage strain. Phages packaging a genome length of DNA cannot accommodate insertions leading to a genome size larger than that corresponding to the volume available in the phage particles. In phage λ this is about 108% of the wild-type λ genome length. Phages packaging a headful of DNA such as P1 require some terminal redundancy for recircularization of the phage genome, a prerequisite for a new cycle of

vegetative reproduction or for prophage establishment. However, insertions of large transposons into the P1 genome have been observed, so that the phage could no longer package an entire genome per phage head. Such oversized hybrids can still reproduce and lysogenize their host, but only upon infection at high multiplicity, so that entire genomes can become reconstructed by recombination occurring after infection. Upon infection at low multiplicity, such transducing phages may only give rise to generalized transduction.

Not all phage strains limit the volume available for the uptake of nucleic acids. The filamentous bacteriophages represented by phage M13 are a good example. These phages package a precise genome length in the form of a circular single-stranded DNA molecule. Therefore the length of the filamentous phage directly reflects the size of its genome. The insertion of a transposon consequently results in the production of specialized transducing phages larger than particles with wild-type genomes.

Fate of Transferred Donor DNA upon Infection of a Recipient Host

According to the definition of transduction, transfer of donor DNA must be followed by the expression of donor genes in the recipient bacteria: expression of the acquired gene functions is the basis of the monitored phenotype of the transductants. To produce this phenotype, the donor DNA must be maintained and ideally also replicated in the transductant clone.

If the donor DNA finds some homology in the recipient chromosome, the homologous segments can undergo general recombination. This type of genetic conversion is often involved in generalized transduction. It can cause stable integration also of DNA segments carried in specialized transducing phages, e.g. *gal* genes in *λgal*.

Another way of propagating acquired donor DNA is autonomous replication. This requires appropriate replicon functions. These can be provided by the vector phage. An example is specialized transducing P1 carrying a transposon. Upon lysogenization of the recipient, this phage establishes its prophage as a plasmid.

Phage P1 is also able to give generalized transduction for entire plasmids unrelated to the P1 genome. Such plasmids can become established as independent replicons after their transfer into recipient bacteria.

Rather than relying on their own replication functions, genomes of specialized transducing phages can also integrate into the recipient chromosome and then become further propagated together with the latter. This is the case when *λgal* lysogenizes its host. Thereby the intact *λgal* hybrid genome integrates into the bacterial chromosome by site-specific recombination. Alternatively, integration of hybrid transducing genomes can also be obtained by other types of recombinational events, e.g. if the transducing phage carries an IS element which finds its homologous counterpart in the recipient chromosome, so that general recombination can provide a means for the production of cointegrates. Alternatively a transposon carried in a transducing phage has a low probability of transposing, after its transfer, into the recipient chromosome and this can ensure its further inheritance.

As discussed above, transferred donor DNA is not always propagated in the progeny of the infected recipient cell. It can indeed also be maintained intact without undergoing replication, possibly being protected against nucleolytic degradation by specific proteins. This then gives rise to abortive transduction, in which the acquired DNA is unilinearly inherited and the donor gene functions become expressed and subsequently diluted in the cytoplasm of the cells of the growing clone of the transductant.

Obviously, the survival of the infected recipient cells is a prerequisite for the detection of transductants. This condition is particularly relevant for virulent phage strains such as T-even and T1 phages. By applying particular infection conditions, it could be shown that lysates of these phages also contain phage particles packaged with host DNA and therefore can give transduction.

Natural Limits Keep the Probability of Acquisition of Foreign Genes by Transduction Low

Although transduction frequencies are usually low, both general and specialized transduction can readily be observed with many host–phage systems. Ideally, mechanistic studies are made with homologous donor and recipient strains which differ by only a few mutations which serve as genetic markers. However, transduction is also observed if donor and recipient strains are only distantly related. Obviously, both donor and recipient strains must belong to the host range of the phage. In this respect it is interesting to note that populations of specialized transducing phage, e.g. P1Cm in which a gene for chloramphenicol resistance is carried in a transposon, can serve to select for host range mutants of the phage: rare Cm^r transductants of a bacterial strain that normally does not serve as a host for phage P1 may prove to contain a mutant P1Cm prophage with extended host range.

A serious barrier against the acquisition of foreign

genetic information by phage-mediated transduction as well as by other means of gene transfer such as conjugation and transformation is brought about by restriction-modification (R-M) systems. R-M systems are very widely present in most bacterial strains, and many strains harbor more than one R-M system. These systems produce enzymes with the ability to distinguish entering DNA originating in other bacterial strains from the cell's own DNA molecules. The basis for the distinction usually resides in the methylation patterns of specific nucleotide sequences. Only rarely do two different bacterial strains provide the same methylation pattern. Restriction enzymes are part of R-M systems. They not only recognize invading foreign DNA as such, but they also endonucleolytically cleave it into fragments. Normally such fragments will eventually become exonucleolytically degraded. However, before this happens, some of the DNA fragments may become integrated into the recipient chromosome by recombination and thus be stabilized. Indeed, the original fragmentation may render the acquired DNA recombinogenic. Therefore R-M systems can have the following double function. They efficiently reduce the overall chance that invading foreign DNA becomes established in the recipient cell but they might stimulate the stable acquisition of short segments of foreign DNA. In this light, acquisition of foreign genetic functions is tolerated at a low rate, but only in small steps, i.e. only relatively short DNA segments are made available for uptake into the recipient genome.

Acquisition of foreign gene functions in small portions may appear a good natural strategy if one considers the risk inherent to gene acquisition in disturbing the harmony of biological functions of the recipient strain. Such a risk is likely to be relatively small if only one new function is acquired, but much higher if many functions are acquired at once. In fact, functional compatibility between residential gene functions and the newly acquired functions represents another criterion contributing to the limits naturally set to gene acquisition.

Applications of Transduction

Shortly after the discovery of transduction, microbial geneticists realized its usefulness as a tool in fine structure mapping of bacterial genes. Measuring cotransduction frequencies of genetic markers linked on the bacterial chromosome allows one to determine the degree of genetic linkage much more precisely than do conjugation experiments.

The availability of specialized transducing phages able to lysogenize the recipient bacteria opens up the interesting possibility for complementation tests between bacterial mutants for the same biological function. Indeed, lysogens for specialized transducing phages are partially diploid if the transduced genetic information finds homologous information already on the chromosome, which is often the case. If donor and recipient are independently mutated for a given biological function, restoration of the function by specialized transduction suggests that the two mutations affect different genes and thus undergo complementation. Absence of complementation indicates that the two mutations affect the same gene.

Another application of transduction in microbial genetics is localized random mutagenesis. The transducing phage lysate is submitted to treatment by a mutagen before infection of the recipient strain. A marker linked to the gene to be mutagenized can then serve for selection of transductants. Screening easily reveals cotransductants carrying a mutation in the linked gene under study which had been the actual mutagenesis target. This method ensures that after heavy mutagenesis treatment no chromosomal genes other than the transduced ones could have been affected by the mutagenesis treatment.

Transduction can also serve to transfer plasmids from a donor to a recipient strain.

Perhaps the most important 'application' of transduction in the wide fields of fundamental and applied research is the general use of the concept of the host–vector system which has emerged from the understanding of structure and functions of specialized transducing genomes. It became obvious around 1960 from work with λ*gal* and other specialized transducing phage genomes that phage replicons can undergo the insertion of host DNA segments to form genetically stable units. Such hybrid phages can propagate in the same way as wild type phages and the passenger genes can express their functions in recipient bacteria. This knowledge has stimulated scientists to reproduce this phenomenon *in vitro*. The attempts were successful around 1970 and soon gave rise to the *in vitro* recombinant DNA techniques. By this technology, molecular genetics, which was formerly mainly limited to microbial genes, has become accessible for application to the genes of any living organism.

Transduction is an Element of Biological Evolution

Gene acquisition is an important source for microbial genomes to obtain new or altered biological functions. It depends on a single evolutionary step. Therefore, the acquisition strategy is more efficient per step of mutation than most other types of spontaneous mutagenesis which occur in the DNA

of the residential genome. The high degree of efficiency resides, among other reasons, in the universality of the genetic code and in the similarity of basic biological functions exerted by widely different living organisms. Thus, a biological function developed in the course of evolution in a particular branch of the evolutionary tree is likely to have a fair chance of also being useful in another branch of that tree after its horizontal transfer. In bacteria, phage-mediated transduction can be considered as efficient a process of gene acquisition as conjugation involving a conjugative plasmid as a gene vector and as transformation in which free DNA is taken up by recipient bacteria. As compared with these latter mechanisms, phage-mediated transduction offers the particular advantage that phage particles are quite stable over prolonged periods of time. Thus, DNA of donor bacteria packaged in transducing phage particles can some later time be re-activated upon infection of a recipient host strain.

In view of these considerations bacterial viruses thus have their particular role as promoters of microbial evolution. This function is accomplished by more or less random uptake of donor DNA and its subsequent spreading to more or less randomly encountered recipient host strains. Thus, phage-mediated transduction makes essential contributions to the steady generation of genetic variety in bacterial populations which is a prerequisite for the progressive course of biological evolution.

Virus-mediated gene transfer in eucaryotes has been documented on many occasions, but whether this phenomenon plays as important an evolutionary role in higher organisms as in procaryotes remains to be elucidated. The answer to this question is of real concern in view of the biohazard debate about *in vitro* recombinant DNA work, in particular with regard to protocols that foresee the deliberate release of organisms with recombinant DNA. Besides this practical aspect, the concept of gene acquisition as an evolutionary strategy is *per se* of interest not only from the scientific point of view, but also with regard to its philosophical dimensions.

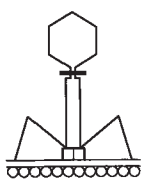
PHAGES AS CLONING VEHICLES

Noreen E Murray, Division of Biological Sciences, Institute of Cell and Molecular Biology, University of Edinburgh, Kings Buildings, Mayfield Road, Edinburgh, UK



Introduction

The genomes of three coliphages have been adapted as vector systems for the purification and amplification of segments of DNA in *Escherichia coli*, the host commonly used for molecular cloning. The general principles exemplified by these well-developed vectors will be stressed rather than the specific details of particular vectors for either *E. coli* or other bacteria.

Some years before recombinant molecules could be made *in vitro*, phage lambda (λ) was the prototype cloning vehicle for those genes close to the normal

prophage attachment site in the bacterial chromosome, but subsequently more generally for genes flanking a large number of secondary attachment sites distributed around the bacterial chromosome. The λ genome was therefore an obvious substrate for manipulation to produce receptor molecules, or vectors, to which DNA fragments from any source could be covalently linked *in vitro* by DNA ligase, recovered in bacterial cells and consequently amplified *in vivo*.

Any genome that is to serve as a vector must be isolated in a double-stranded form and have a target for the specific endonuclease that will be used to open the genome as a prerequisite to the insertion of foreign DNA. Insertion must not interfere with any essential vector functions; the recombinant molecule must replicate and yield either a plaque or a lysogenic colony. On the other hand, insertional inactivation of a nonessential gene associated with a recognizable phenotypic change can provide a screen or even a selection for recombinant phages.

λ Vectors

Three factors have greatly influenced the role of λ vectors. First, the efficient recovery of recombinant genomes following *in vitro* packaging, i.e. the encapsidation of recombinant genomes within phage heads and the addition of tails thereby permitting adsorption to bacterial receptors and the consequent injection of DNA into the recipient cell. Second, the large amounts of readily accessible DNA and proteins exposed in plaques permit very sensitive detection of either specific nucleotide sequences by their hybridization to appropriate probe sequences, or the protein domains by their binding to antibodies or other ligands including oligonucleotides. Third, the amenability of phage λ to genetic analyses, including the maintenance of its genome as a prophage, one copy per bacterial chromosome and the ready transfer of phage DNA from one *E. coli* strain to another. The first two factors are most relevant to the effective recovery and screening of genomic and cDNA libraries, the third to genetic analysis of cloned genes, particularly those of *E. coli*.

The cutting and packaging of λ DNA *in vivo* is directed by specific sequences (*cos*) in concatemeric (multimeric) λ genomes; cutting regenerates the cohesive ends of the linear λ genome. Although this process is sequence specific, it is influenced significantly by the distance between the specific (*cos*) sequences. These must be separated by a minimum distance, well below the optimum, and may be separated by some few kb of DNA above the optimum. Some vectors, therefore, offer efficient recovery of small fragments (up to 10 kb), others efficient recovery of large (~20 kb) DNA fragments. In general, the former are insertion vectors and the latter replacement vectors (see below), but in either case the size selectivity of *in vitro* packaging can be used to preferentially recover recombinant rather than vector molecules.

Since λ has a big genome (48.6 kb), making vectors usually requires not only the use of deletions to make space, but the removal of superfluous restriction targets so that cutting is confined to specific cloning sites. Targets can be removed by using known deletions or substitutions, and by specific mutations, sometimes selected *in vivo* but also *in vitro* using restriction enzymes to cut, and hence select against, genomes with restriction targets.

Insertion Vectors

These simple vectors are deleted for nonessential DNA (up to approximately 9 kb) and they retain single targets (cloning sites) for one or more restriction enzymes. Insertion of DNA fragments of appropriate length yields a recombinant molecule that is packaged in preference to a vector genome. Ideally, insertion of the DNA is associated with inactivation of a nonessential coding sequence and a recognizable phenotypic change. The most commonly used screen relies on insertional inactivation of a *lacZ* gene within the vector and the combined use of $lacZ^-$ bacteria and a substrate (X-gal) that when hydrolysed by the product of the *lacZ* gene (β-galactosidase) yields a nondiffusible blue pigment. Insertional inactivation of the *lacZ* gene correlates with a failure to hydrolyse X-gal and a white rather than a blue plaque. An alternative screen is provided by insertional inactivation of the gene encoding the phage repressor (*c*I) and the consequent 'clear' rather than 'turbid' plaque morphology. The use of a specific host (hfl^-) in which cI^+ phages establish repression and consequently fail to reproduce vegetatively provides a genetic selection for recombinant phages dependent on the insertional inactivation of the *c*I gene.

Insertion vectors are used for cloning cDNA or relatively short DNA fragments (<11 kb), vectors of larger genome length (~5 kb less than λ^+) being chosen for smaller inserts, those of shorter length (8–9 kb less than λ^+) for larger inserts.

Replacement Vectors

A λ genome deleted for all nonessential genes (40% of its genome) is too small to be packaged. It follows that full advantage of the cloning capacity of a λ vector requires a derivative with a dispensable

'stuffer' fragment. When the stuffer fragment is excised it must be replaced with a donor DNA fragment, if the genome is to be packaged. In some vectors the retention of a stuffer fragment can be detected by virtue of a genetic tag; a *lacZ* gene or phage genes (*red* and *gam*). Special selective hosts can discriminate against the vector genomes, although such genetic selections are not essential since a variety of enzymatic tricks can reduce or eliminate the background of vector genomes. Replacement vectors are used for cloning larger fragments of DNA, often in the range of 20 kb. The stuffer fragment is frequently flanked by synthetic nucleotide sequences including targets for a variety of restriction enzymes, and commonly by promoter sequences recognized only by their cognate RNA polymerases (e.g. phage T3 or T7). Efficient transcription of one strand of DNA can be driven *in vitro* by the addition of T3 RNA polymerase, that of the other by T7 RNA polymerase. Labeled transcripts of peripheral fragments of the insert provide probes to facilitate chromosome walking.

Screening of genomic libraries is usually achieved by hybridization of probe sequences to the DNA released in plaques following denaturation and transfer to nitrocellulose filters. An alternative screen uses genetically tagged plasmid probes, and homology-dependent *in vivo* recombination is recognized by acquisition of the genetic tag, commonly a short sequence specifying the *supF* tRNA.

Expression Vectors

The DNA fragments are often inserted within a coding sequence that has a good promoter and Shine–Dalgarno sequence so that efficient controlled expression of a fusion polypeptide can be achieved for in-frame insertions. Frequently expression vectors take advantage of the *lacZ* gene and its control sequences. The fusion polypeptides may not be enzymatically active, but nevertheless they are frequently stable, can be purified and provide antigenic substrates. Screening by radioimmunoassay is very effective. Phage λ can be adapted to amplify gene products, particularly prokaryotic gene products, using either a λ promoter or the promoter of the relevant gene. The recombinant genome can be maintained in the prophage state and amplification achieved following prophage induction.

M13 Vectors

M13 plaques, like those of λ, offer efficient screens by DNA hybridization, but M13 has the special virtue of yielding large quantities of single-stranded DNA. From very small volumes of M13 suspensions, sufficient DNA is quickly prepared to prime a variety of sequencing reactions. M13 is the preferred vector wherever single-stranded DNA is required, including not only DNA sequencing, but site-directed mutagenesis and the assay and analysis of mRNA. M13 genomes with large inserts are readily packaged but are at a replicative disadvantage, and therefore it is preferable to use M13 for cloning small DNA fragments.

Since the phage genome is single-stranded the replicative form of the virus is used as vector DNA. M13 has little surplus DNA but multiple cloning sites built into the 5′part of a *lacZ* coding sequence have been incorporated within an intergenic interval. The N-terminal, but incomplete, *lacZ* polypeptide is functional in interallelic complementation with a defective host-encoded β-galactosidase; the latter lacks some amino acids within the N-terminal portion of the polypeptide. The complementation between polypeptides defective in either the α or ω parts of their sequences is detected by hydrolysis of the usual chromogenic substrate (X-gal). Insertional inactivation of the α component encoded by M13 provides a ready screen for recombinant derivatives.

Phage P1

Most recently the molecular understanding of phage P1 has permitted the harnessing of the large cloning capacity of this phage. DNA fragments up to approximately 100 kb can be recovered. The long recombinant molecule, though linear on entering a bacterium, is converted into a circular plasmid by a site-specific recombinase, Cre (Cyclization *re*combination protein), acting to break and join the DNA identified by two target sites, *lox* (locus for crossing-over), one in each arm of the vector DNA.

The P1 Cre-*lox* system is now used to promote site-specific recombination *in vitro* and *in vivo* even in eukaryotic cells. *In vitro,* Cre-mediated recombination between one *lox* site in a terminally labeled, linear, double-stranded oligonucleotide and a second *lox* site in a circular plasmid molecule, converts the plasmid into a terminally labeled linear molecule. Alternatively, Cre can catalyze the reverse reaction and circularize the DNA flanked by two *lox* sequences. Similarly, *in vivo,* Cre can promote site-specific recombination to integrate a circular DNA substrate into another DNA molecule or it can excise, as a circular molecule, the DNA between two *lox* sites. In this way, for example, a plasmid sequence flanked by *lox* sequences can be excised from a phage vector or some other genome.

Hybrid Systems

Plasmid/phage

Cosmids are plasmids that include the specific sequence of λ (*cos*) which is essential for packaging DNA into λ phage particles. Since plasmids are generally small, a large insert (35–45 kb) sandwiched between two cosmid genomes can provide the necessary separation between two *cos* sequences to promote packaging of the plasmid and donor DNA. The concept is an extension of that used in λ replacement vectors, but cosmids do not require a stuffer fragment since the vector DNA is prepared as a plasmid. In theory the phage particle will only package recombinant genomes, and these are efficiently transmitted to *E. coli*. Within the bacterium the linear genome circularizes via the cohesive ends of the *cos* sequence, and is then maintained as a large plasmid. Cosmids, like plasmids, have small genomes, but they take advantage of *in vitro* packaging to facilitate the efficient cloning of large DNA fragments. In a similar way the most significant feature of M13, and its relatives fd and fl, can be bestowed on plasmid vectors to produce a 'phagemid'. The ability to produce and package single-stranded plasmid DNA following infection with the appropriate phage (M13 or a relative) is conferred by the insertion of the appropriate *cis*-acting elements.

Plasmid expression vectors frequently use a λ promoter as their means of achieving efficient transcription of a cloned gene. Control of transcription is provided by temperature-sensitive repressor encoded by the repressor gene of λ (*c*I). This gene may be within the expression plasmid, within a compatible plasmid or within the host chromosome. As previously mentioned, many λ vectors include other phage promoters, particularly those recognized by only their cognate RNA polymerase. Some plasmids also incorporate these promoters to elicit efficient transcription *in vitro* or as a component of an *in vivo* expression system.

Multicomponent phage vectors

Some vectors aim to take advantage of the best features of λ, M13 and plasmids. The first of these (λZAP) is an insertion vector commonly used to express fusion polypeptides. A combination of M13 and plasmid (phagemid) are carried in a λ vector. The phagemid can be excised *in vivo* from its carrier phage following superinfection with M13 (or f 1) because the plasmid sequence is suitably flanked by signals from phage f 1 for the initiation and termination of DNA synthesis. The single-stranded DNA is made and forms a circular molecule that replicates, and can be maintained in the plasmid form. Its presence is selected by addition of the appropriate drug. Because the excised phagemid incorporates an f 1 (M13-like) origin of replication, it can be recovered in single-stranded form on infection with an f 1 or M13 helper phage. λZAP, like any λ vector, offers the high efficiency of packaging *in vitro* and sensitive screening of plaques. It then allows the experimenter to separate the plasmid *in vivo* from its superfluous λ carrier DNA, thereby providing the virtues of both plasmids and M13. The particular multicomponent vector described has a variety of cloning sites within the α coding sequence of β-galactosidase and hence has a screen for recombinant phages. The cloning sites are flanked by phage T3 and T7 promoters and appropriate terminators to facilitate efficient *in vitro* transcription of either strand of cloned DNA.

Phage vectors for other bacteria

Phage vectors have been developed for only a minority of bacterial genera, particularly Streptomycetes, Bacilli and Mycobacteria. Most cloning of microbial genes has been done in *E. coli*. Both shuttle and promiscuous plasmids permit transfer of cloned sequences between *E. coli* and other bacteria. Cosmids based on promiscuous plasmids have been particularly valuable.

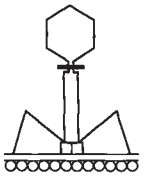
PHAGES IN INDUSTRIAL FERMENTATIONS



Mary Ellen Sanders, Dairy and Food Culture Technologies, Littleton, Colorado, USA

Introduction

Industrial fermentations rely on the growth and end-product formation of microbes. These processes include the production of many types of food, amino acids, organic acids and diverse, non-native proteins from recombinant microbes. Any interference with these processes is an economic liability.

Bacteriophage (or phage) can kill bacteria with astounding efficiency. A single phage may take only 60 min to complete its replication cycle, which could result in 200 new phages. Released into the environment, these new phages are free to find susceptible hosts and repeat the cycle. These kinetics suggest that, theoretically, one phage could yield over 1 billion phages within 4 h. (In contrast, a bacterium with a 30 min generation time, replicating via binary fission, would yield only 256 progeny in the same 4 h period.) Although not all phages replicate this dramatically it is apparent that phage can constitute a major threat to industries which rely on bacterial growth. Due to their biological nature, bacteriophage can be difficult to predict and to control, and as such can be the source of significant concern to industrial microbiologists.

Factors that Predispose Industries to Phage Problems

Certain industrial processes are more susceptible to bacteriophage problems than others. A combination of factors is responsible for this. Some production practices increase bacteriophage problems. However, it also seems that there may be poorly understood inherent biological factors that lead some bacteria to be more susceptible to destruction by phage than others. The following is a description of some factors that put a fermentation process at high risk for phage problems.

The process must rely on bacterial growth or metabolism. This may be the central process, such as lactic acid production in milk fermentations, but may also include secondary processes such as the malolactic fermentation in wine, the lactic acid production in sour dough bread, or diacetyl production in buttermilk.

There must be a means of contamination of the fermentation. Phage may enter a process either from external sources from air, equipment, or raw material or through the culture itself. The lysogenic or phage carrier states account for this avenue of phage entry, although modern starter culture production practices minimize the likelihood of this occurrence. Food fermentations are conducted with nonsterile raw materials and sometimes in exposed, open air fermentation vessels. Opportunities for phage contamination and dispersal abound in this environment. Other industrial fermentations including amino acid production or fermentations for recombinant DNA products can be more easily controlled by using sterile growth media, self-contained fermentation vessels, careful inoculation procedures, select production strains and contamination control. However, bacteriophage are difficult to keep out of even these systems due to their small size, especially if the fermentation requires input of oxygen. Therefore, even supposedly aseptic fermentations have reports of bacteriophage-induced failure.

The biological nature of the strains and phage present in a fermentation process dictate the speed and extent of phage destructiveness. Some phages develop to high levels very quickly, resulting in a rapid, thorough destruction of host populations. Others develop at a slow rate, detectable but insignificant to the overall bacterial metabolism and growth. This replication rate seems to be a result of both host and phage functions. Some industrial strains are known for developing devastating phages, and some phage types are known for rapid replication rates. Regardless, if phages are limited to slow development, little interruption of the fermentation process results.

The potential impact of destructive phage is augmented with some equipment and processes. In some processes, the scale-up of starter inoculum requires a commitment to the exact strains that will be used for fermentation several days in advance. A switch to a different production strain due to emerging levels of destructive phage is very difficult. If starter scale-up is not necessary (for example through the use of highly concentrated starter cultures) or can be done in less time, much more flexibility with strain substitution can be achieved, allowing effective response to detection of phage.

The necessity of adhering to an inflexible production schedule also amplifies the effects of phage on a

fermentation. Some fermentations are lengthy, and extending the time of fermentation can, under some circumstances, serve to overcome phage-induced 'slow downs' without significantly harming fermentation efficiency.

Production facilities designed with attention to personnel, material and product flow through the plant, air quality, separation of seed culture, and easily cleaned and sanitized equipment help reduce phage problems. Processes that do not produce aerosols, do not require excessive mixing, and lend themselves to adequate cleaning and sanitation can also effectively decrease the destructive effects of phage.

An industry that has a broad assortment of defined bacterial production strains has a greater chance of coping with phage problems than an industry with one, unique production strain. Strain substitution is an effective means of dealing with phage infections. The success of this approach, however, depends on the availability of suitable numbers of substitute strains that both resist current phage and carry out the desired metabolic transformation. It is not always a trivial matter to isolate these strains, and the genetic pool of available strains may not be extensive.

Processes that rely on a large number of bacterial strains seem to have a complementary large diversity of phage strains. The approach of the dairy industry to limit production strains to blends of well-characterized strains instead of mixtures of many undefined strains has worked to limit the phage populations and diversity in cheese plants.

Detection of Phage Problems

Not all fermentation delays are due to phage. The presence of chemical inhibitors, antibiotics, variability of physical parameters such as temperature, pH, dissolved oxygen and nutrient feed, and improper preparation of starter inoculum can all contribute to fermentation inhibition. The challenge is to differentiate these factors from true bacteriophage-induced fermentation failure.

The occurrence of starter failure is usually easy to detect. A drop in metabolic activity or growth is detected by whatever parameters are used to monitor the fermentation. Unfortunately, the root cause of starter failure is harder to determine, and the lack of technical resources of some industries impedes investigation into exact causes. The presence of a destructive bacteriophage can sometimes be especially difficult to determine due to inadequately defined detection methods. Results must then be differentiated from inhibition due to chemical inhibitors.

Since bacteriophage cannot be seen with the naked eye, alternative assays must be developed. Most commonly, phage are cultivated and their presence inferred from the results. Spot or plaque assays on agar plates and broth lysis are frequently used. However, laboratory assays for phage are dependent on the presence and concentration of cations, pH, temperature and media nutrients. Perhaps most importantly, purified, single-strain indicator bacteria must be available on which to assay the phage and these strains must be in the proper physiological state during assay. In some cases, mixed undefined, or multiple, defined strain combinations are used for fermentation. Production facilities may not have access to the component strains of these blends. In the case of commercially available defined strain blends, the strain manufacturer may be able to perform a meaningful assay for phage presence. However, in the case of undefined, mixed culture blends, even the culture producers may not know the strain composition of the blend. Assay for phage on a mixture of strains will often result in false-negative results, as phage against a single strain in the blend would likely be masked by growth of the other phage-insensitive strains. Furthermore, assay conditions may interfere with a definitive lytic response in the laboratory that may have been prevalent under production conditions. Therefore, it can be complicated to develop a consistent and reliable phage assay, especially for a phage population that may be continually changing. The ability of phage to replicate on hosts can also depend on a variety of environmental factors, which, when changed, may result in shifts in host range or efficiency of plating.

Even in the face of these difficulties, phage detection procedures have been developed for many phage and are regularly used during production.

Industries Affected by Phage Infection

Reliable data on the severity of phage infection of industrial fermentations are difficult to obtain. This is primarily because release of this information raises confidentiality concerns of private industry. Therefore, inference must be made from publications citing incidences (although not degrees) of phage infection or reporting developments to cope with phage problems. Such information suggests that phage problems are pervasive, although assignment of an accurate monetary value on lost or downgraded product is impossible. Phages have been responsible for disturbing industrial production of glutamic acid, butanol-acetone, natto (fermented soy beans), antibiotics, enzymes, casein, sausage, wine, sourdough bread, yogurt and cheese, as well as sewage treatment. Phage problems with industrial strains of *Clostri-*

dium, Bacillus, Lactobacillus, Lactococcus, Streptomyces, Escherichia, Streptococcus, Leuconostoc, Pseudomonas, Brevibacterium and *Corynebacterium* have been published.

The segment of the food industry that seems most seriously affected by phage is the fermented dairy foods industry. Scientific papers abound on the incidence and control of phage infecting dairy fermentations. Virtually all different types of fermented dairy products are involved, including hard cheeses, cottage cheese, yogurt and fermented milks. Phages infect the bacteria responsible for production of acid, diacetyl, extracellular polysaccharides and carbon dioxide. These factors are important to the final flavor, body and texture of different dairy products, and their absence decreases the value and, in the case of lactic acid, the safety of the food.

A relatively new aspect of the fermentation industry is the use of bacteria to produce proteins encoded by genes derived from other sources. Examples of eucaryotic proteins now produced by bacteria include chymosin, interferon, bovine somatotropin, insulin, human growth hormone, blood clotting factors and tissue plasminogen activator. This list is not complete and is expanding rapidly. Much effort has been placed on the development of efficient expression systems for these foreign genes, and inadvertent product loss through phage infection is troublesome. Although this industry is much better suited to control phage through using sterile production media, sterile air and aseptic fermentation technique, its reliance on single unique production strains increases susceptibility. Scientists involved with the scale-up of processes to production size should be aware of the threat of phage infection and design equipment, processes and production facility layout to provide a measure of defense against such problems.

Although not the process of choice today, acetone and butanol were once produced by the fermentation of molasses by some *Clostridium* species. Phage infection of this fermentation resulted in a significant decrease in process efficiency. The introduction of continuous fermentation compounded the problem. Phage-resistant mutants provided some relief, but host-range phage mutants evolved to attack newly released production strains. Finally, the rotation of phage unrelated strains brought the process into control.

Control of Phage in Industrial Fermentations

The control of phage in industrial processes is usually multifaceted. It frequently combines one or more of the following:

- *Sanitation* In considering equipment and processes, it is most important to accept that the single best intervention for preventing phage attacks is a properly sanitized production facility. This includes the valves, pipes, connectors, joints and other equipment areas that can harbor microbes of any type, including phage. Furthermore, any opportunity for crosscontamination of product containing replicating bacteria with product further upstream is an opportunity for phage to gain a foothold early in the process, in time to cause a fermentation problem.
- *Phage-resistant strain isolation or development* (see below).
- *Judicial starter use* Several approaches to starter use have been recommended, and the success of each seems to depend on the particular application. In some fermentations (especially foods), mixed, undefined blends of starter strains are used. A measure of phage control can be achieved with this approach as the bacterial populations are sufficiently diverse to allow bacterial components of the mixture which are resistant to infecting phage to carry out the fermentation. Some fermentation delay may result as these, perhaps minor, components of the strain mixture grow and become dominant. However, a totally dead fermentation is rarely experienced. In some cases during starter culture scale-up, starter cultures are deliberately contaminated with phage from the current production runs so that the phage-resistant populations can emerge. The problems with this approach are that fermentation times can be unpredictable and product characteristics dependent on bacterial metabolism can vary due to variation in the dominant strains executing the fermentations. Modern production facilities are frequently not willing to live with this lack of consistency.

An opposite approach is the isolation of production strains resistant to phages currently in the fermentation environment. Ideally, strains with broad-based resistance to phage are found or developed. These strains can then be used as single strains or as defined blends. They may be used repeatedly or may be rotated with other defined, phage-unrelated strains. Diligent analysis of phage in the fermentation environment helps predict which defined strains may suffer phage attack during production. The use of defined strains allows more predictability in product quality and process efficiency. Also, pure strains are available to assay for contaminating phage. The difficulty

with this approach is obtaining a suitable number and quality of strains to formulate the blends and to use as strain substitutes as phage appear. Also, since fewer strains are involved in executing the fermentation, the chances of complete starter failure increase.

Clearly, the starter system chosen for the fermentation must be managed carefully to control fermentation problems.

- *Use of phage-inhibitory media or other antiphage chemicals* Divalent cations such as Ca^{2+} and Mg^{2+} are required by many phage for adsorption to cell surfaces. These cations can be chelated by phosphates, citrates or oxalate. Other antiphage agents include nonionic detergents, antibiotics, spermine, ascorbic acid, phytic acid, glutathione and Fe^{2+}. Since these agents can also be inhibitory to production strains, an antiphage agent must have a more limited effect on host metabolism than on phage survival to be useful. Some industrial fermentation broths can be formulated to contain these agents. In the case of food fermentations, presence of these or other agents can be considered adulteration. Therefore, these agents may be added to starter propagation media to provide some control over phages developing in the starter scale-up process.
- *Phage detection* An ongoing program designed to detect phages against production strains can be very effective at identifying a phage problem before it builds to a truly destructive level.

Development of Phage-resistant Strains

The development of phage-resistant derivatives of production strains offers an approach to contend with phage infection of industrial strains. Diverse strategies have been taken throughout the fermentation industry, and efforts have met with different degrees of success. In a comprehensive approach, strain improvement efforts should be coupled with excellent sanitation and culture handling practices. In particularly phage-contaminated environments, the release of new, improved strains is not a permanent solution, but an intervention that will avert phage problems in the immediate future. It is a testament to the ability of phage to evolve and emerge that they can frequently, and with what seems to be creative ability, overcome many efforts to limit them.

In the laboratory, the isolation of mutants resistant to any particular phage is usually an easy task. Spontaneous mutation frequencies are sometimes as high as 1 in 10^4. Unfortunately, the resulting mutants are likely to have only shifted their phage sensitivity spectrum, and not broadened it. In addition, even though no genetic linkage may exist between phage resistance and fermentative characteristics, strains isolated as resistant to particular phages may suffer fermentative deficiencies. Therefore, isolation of mutants that possess resistance to a broad range of potentially lethal phage and still retain essential fermentative activities, is a challenge.

To develop a phage-resistant strain, the cell must be able to interfere with phage infection or proliferation at some point along the phage's lytic life cycle. Mutations in genes responsible for phage adsorption, passage of phage DNA into the host cell, transcription and translation of phage genes and expression of phage lysin could all interfere with phage development. Much larger changes in a cell's ability to resist phage could come from recombinant techniques, which would allow the introduction of entire gene systems, rather than relying on simple mutations, which would likely have a narrower effect. Bacterial systems that interfere with phage include abortive infection, a mechanism which greatly reduces the replication rates of phages and often destroys the bacterial cell prior to phage release, and restriction and modification, in which unmodified invading phage DNA containing recognized DNA sequences is cleaved and thereby destroyed.

A directed genetic approach has been successful for developing improved lactococci for dairy fermentations. In some lactococci, naturally occurring, self-transmissible plasmids were found to encode phage resistance genes. The phage resistance mechanisms included restriction and modification and abortive infection. When these plasmids were transferred into appropriately selected recipient strains, strains with improved, broad-spectrum phage resistance resulted. Although not resistant to all phages, these strains were significantly improved. Their phage resistance had a broader spectrum and fermentative activities were not diminished. This approach required characterized phage resistance genes, a method to introduce the genes into a host strain, a means to select the improved strain, and plasmid stability and gene expression in the new strain.

A different approach was taken to avert phage attack of a *Lactobacillus casei* strain used for fermentation of a dairy-based product. A troublesome lytic phage was found to be a lytic variant of a lysogenic phage carried by the production strain. The shift from lysogeny to virulence in the phage was caused by transposition of an insertion sequence from the *L. casei* strain to the phage. Prophage curing of the starter strain removed the threat of that phage from the fermentation.

In another case, phage problems were seen with a

strain of *Escherichia coli* used to produce insulin. Scientists averted problems by cloning genes for the restriction/modification system *Hha*II into the production strain. Expression of these genes decreased phage survival and permitted fermentations to proceed.

Strains used in the production of acetone and butanol, glutamic acid and fermented dairy products have been mutated to phage resistance in an effort to derive phage-resistant strains. In each case, mutants permitted only short-term freedom from phage attack.

A method of interfering with phage development has been tried with lactococci used in dairy fermentations. Expression of antisense mRNA targeted against a conserved phage gene has afforded some protection against phage in the laboratory. High copy numbers of the antisense mRNA strand presumably interfere with phage gene transcription. Although resistance levels were not very high, improvements in this strategy may possibly provide another method of developing cell-directed phage resistance to phage.

Summary

Phages abound where bacterial replication occurs. Phages have a dynamic ability to increase in numbers very rapidly at the expense of the host strain. This can lead to the rapid cessation of a bacterial viability and metabolic activity. Phages are ubiquitous and difficult to control. The isolation of phage-resistant mutants can provide temporary relief from phage problems, but the appearance of host range phage mutants usually undermines this approach. The introduction of whole gene systems and multiple levels of phage defense will more likely result in strains with a sustained ability to resist phage. Use of carefully developed defined strains, along with diligent sanitation efforts and careful process control, will usually result in control of phage.

Introduction

The soil presents a highly complex and variable environment for its microbial community. At the macroenvironmental level the activity and survival of bacteria is influenced by many factors, such as the amount and type of energy supplies and the gross abiotic factors, for example aeration, temperature and pH. Superimposed on these spatial and temporal variations are the even more subtle fluctuations at the microenvironmental level in the microbial growth sites within the soil mass. Thus, for example, it is well known that microsites for anaerobic bacterial metabolism (e.g. inside clay aggregates) occur even in grossly aerobic soils. The complexities of the soil environment have two major consequences for the microbial ecologist. Firstly, this habitat provides the greatest number and diversity of isolates. One gram of a fertile soil can provide viable counts of 10^9 bacteria and more than 100 different taxa. Even this is an

Introduction

The soil presents a highly complex and variable environment for its microbial community. At the macroenvironmental level the activity and survival of bacteria is influenced by many factors, such as the amount and type of energy supplies and the gross abiotic factors, for example aeration, temperature and pH. Superimposed on these spatial and temporal variations are the even more subtle fluctuations at the microenvironmental level in the microbial growth sites within the soil mass. Thus, for example, it is well known that microsites for anaerobic bacterial metabolism (e.g. inside clay aggregates) occur even in grossly aerobic soils. The complexities of the soil environment have two major consequences for the microbial ecologist. Firstly, this habitat provides the greatest number and diversity of isolates. One gram of a fertile soil can provide viable counts of 10^9 bacteria and more than 100 different taxa. Even this is an

understimate, as the number detected depends on the isolation procedure used and whether or not the bacteria are inherently culturable. Secondly, it is still difficult to differentiate between active and inactive propagules within the sample studied. Therefore, there are still many problems in determining the extent and sites of bacterial activity in soil.
