of TNFα of infected phagocytes by releasing a protease-sensitive inhibitor for the expression of this cytokine (Caron et al., 1996). Therefore, it is reasonable to speculate that intracellular *Brucella* uses this strategy to regulate the activation of phagocytic cells and promote in this manner its own survival within these cells. Since LPS is also released from bacteria inside host cells (Fig. 35) and this molecule is not degraded by peritoneal macrophages, it can be hypothesized that one additional form by which *Brucella* may contribute to immunosuppression is the release of LPS inside cells (Forestier et al., 1999b). In this respect, *Brucella* LPS, together with other molecules, may play a central role in the immunosuppression observed upon brucellosis infection and may account for the presence of anergic T cells in infected patients (Renoux and Renoux, 1977). Experiments have demonstrated that *Brucella* is capable of infecting small lymphocytes in the cortical zone of lymph nodes (Cheville et al., 1996a). The infected lymphocytes harboring intracellular bacteria within vacuolar compartments with no signs of degradation look normal (Fig. 30). At the present time, the implications of lymphocyte *Brucella* parasitism are not known. The fact that *Brucella* LPS complexes with MHC-II in these cells (Forestier et al., 1999a) opens the possibility that LPS released by intracellular *Brucella* could modulate antigen presentation in lymphocytes, as it does in macrophages (Forestier et al., 2000).

Control of the Infection

Strong humoral and cellular immune responses are generated during *Brucella* infection. Although the role of cell mediated immune response has been regarded as the essential mechanism for controlling the infection, antibodies may play a more or less relevant role, depending upon the specie of the infected animal. Comprehensive reviews can be found in references (Baldwin and Winter, 1994; Liautard et al., 1996; Nicoletti and Winter, 1990b; Oliveira, et al., 1998).

Antibody Response *Brucella* infections generate an elevated production of antibodies. The most relevant molecules involved in the humoral response of animals or humans infected or vaccinated with smooth strains are by far the LPS and the NH polysaccharides (Jones et al., 1980; Marín et al., 1999; Moreno et al., 1984a; Nielsen et al., 1988; Spink, 1956). Mainly at early stages of the infection (first month), it has been estimated that close to 80% of the antibodies against *Brucella* are directed toward the *O* chain and NH determinants, with the great majority of the immunoglobulins being against the C epitopes (in smooth strains) (Fig. 34). Moreover, most of the IgG_1 passively transferred through colostrum to newborn calves are directed against these two bacterial surface molecules (Antibody Detecting Tests in Infected Patients; Smooth-lipopolysaccharide Tests in Infected Animals). Antibodies recognizing core and lipid A determinants (Fig. 34) are not detected by conventional serological methods in the sera from infected or vaccinated bovines with smooth strains, unless purified antigens are used. In contrast, individuals infected or vaccinated with rough brucellae generate a strong antibody response against LPS core and lipid A determinants as well as toward Omps (Bowden et al., 1995; Gamazo et al., 1989; Riezu-Boj et al., 1990; Rojas et al., 1994). The most immunogenic proteins are the Omps of group 3 (Omp3a and Omp3b and Omp31), some of which are strongly bound to the LPS (Gamazo and Moriyón, 1987; Kurtz and Berman, 1986; Riezu-Boj et al., 1990; Rojas et al., 1994), and stress response proteins (GroEL, DnaK, Sod, PurE and HthA) (Protein Tests in Infected Patients; Protein Tests in Infected Animals). Antibodies against various cytoplasmic soluble proteins, ribosomal proteins, periplasmic proteins, outer-membrane lipoproteins and porins, as well as against peptidoglycan, have also been detected (Fig. 38). Most of the antibodies against proteins appear at later stages (after the third week) of the infection (Protein Tests in Infected Patients).

The immunoglobulin profiles of the anti-LPS response in newly infected bovines, humans, goats and mice measured by ELISA or discriminatory agglutination are characteristic of a T-dependent cell response (Fig. 39), despite the fact that *Brucella* LPS, as well as killed organisms, has been defined as a T-independent antigen (Kurtz and Berman, 1986; Moreno and Berman, 1979; Moreno et al., 1984b; Rennick et al., 1983; Tenay and Strober, 1985). The secondary antibody responses observed in antibiotic-treated individuals who have relapsed are also typical of a T-dependent response with strong generation of IgG_1 antibodies (Antibody Detecting Tests in Infected Patients; Smooth-lipopolysaccharide Tests in Infected Animals). Under natural conditions, IgG_1 antibodies may remain for life (Castañeda, 1961; Foz et al., 1954; Spink, 1956). This may be due to the persistence of the bacteria in tissues (Enright, 1990b; Enright, 1990a; Spink, 1956) or alternatively to the permanence of *Brucella* LPS within phagocytic cells for long periods. In support of this last statement are the findings of LPS within macrophages of infected mice after several months (Modulation of the Immune Response) and the detection of large quantities of apparently intact LPS in granulomatous lesions of individuals with

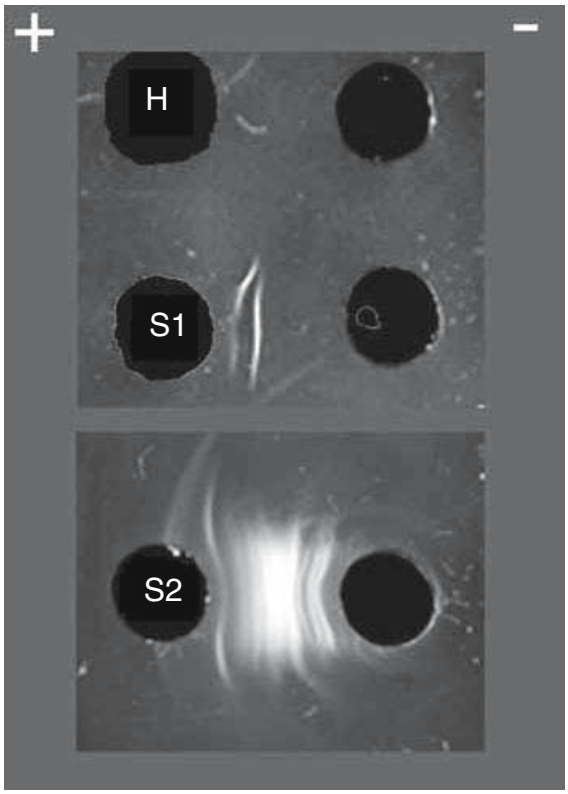

Fig. 38. Crossover immunoelectrophoresis with protein antigens for the diagnosis of brucellosis. The wells on the left contained the sera from a healthy donor (H) and from two patients after a brief (S1) or a prolonged (S2) period of infection before treatment. For reference of the antibody response to LPS see Fig. 39. Courtesy of R. Díaz, University of Navarra, Spain.

chronic brucellosis (R. Díaz, University of Navarra, Spain, personal communication).

The antibody response of mice immunized with purified LPS generates a non-typical T-independent response with relatively large quantities of IgG_3 against the *O* chain and moderate quantities of IgG_1 and IgM (Kurtz and Berman, 1986; Moreno et al., 1984b). In contrast to other types of LPS, *Brucella* LPS is immunogenic for the endotoxin-resistant C3H/HeJ mice and displays a strong IgG_1 adjuvant effect in this and other strains (Kurtz and Berman, 1986; Moreno and Berman, 1979; Moreno et al., 1984b).

The role of antibodies against *Brucella* infection has been a matter of controversy for many years. In mice, it is clear that antibodies play an important part in anti-*Brucella* immunity (Araya et al., 1989), mainly because of the exacerbation of the phagocytosis and bactericidal action mediated by professional phagocytes (Opsonization and Complement Susceptibility). Nevertheless, in other species of mammals, including humans, infections seem to course unaffected in the presence of large quantities of circulating antibodies (Ariza, 1998; Enright, 1990a; Enright, 1990b; Shuterland and Searson, 1990). However, maternal antibodies seem to play a role in protecting calves and piglets born within herds with prevalent brucellosis as demonstrated by experimental and field experience (Cunningham, 1977b; Halliday, 1968; Hoerlin, 1957; Plommet, 1977). In addition, whether antibodies to LPS, or to any other antigen, hamper the ability of the bacteria to infect animals under field conditions needs to be examined. The truth is, that despite the current opinion that antibodies do not play a role in human or ungulate infections, at the present this asseveration is not sustained by clear-cut experimental data. This doubt is not trivial and it has practical implications related to the use of vaccines derived from rough strains for controlling brucellosis (Samartino et al., 2000; Schurig et al., 1991). Finally, the role of anti-LPS immunoglobulins either as blockers of antigen recognition or as facilitators of cell invasion also needs to be re-examined in light of the recent advances in our knowledge of *Brucella* parasitism and intracellular trafficking of bacterial antigens.

T Cell Responses In a series of elegant investigations, Mackaness (1967) demonstrated more than three decades ago that acquired cellular resistance could be specifically induced by *Brucella* organisms or by other facultative intracellular parasites, but nonspecifically expressed for a given period of time. That means that, at some intervals after *B. abortus* invasion, the *Brucella*-infected mice will clear *Listeria* as though they have been immunized against this Gram-positive bacterium. The postulated cellular episodes mediated by lymphocyte cytokines capable of activating macrophages, that eventually could kill both organisms, were the basis for explaining the immunological events necessary to control *Brucella* inside macrophages (Mackaness, 1967). Passive transfer of CD_4^+, CD_8^+ cells and antibodies has clearly demonstrated the role of each of these elements in the control of murine brucellosis (Araya et al., 1989; Araya et al., 1990; Eze et al., 2000). It has been hypothesized that CD_8^+ cells, in addition to producing IFNγ, could lyse *Brucella* infected macrophages and downregulate the production of cytokines by Th2 cells, such as IL-10 and the cytokine-like CD_8^+ T cell antiviral factor (Oliveira et al., 1998). Despite the role played by antibodies and CD_8^+, it is generally accepted that the ultimate brucellacidal activity in most animals is based on CD_4^+ type-I immune response, through the generation of cytokines capable of activating macrophages (Baldwin and Winter, 1994; Liautard et al., 1996; Oliveira et al., 1998). In consequence, a more robust respiratory burst, a more powerful pro-

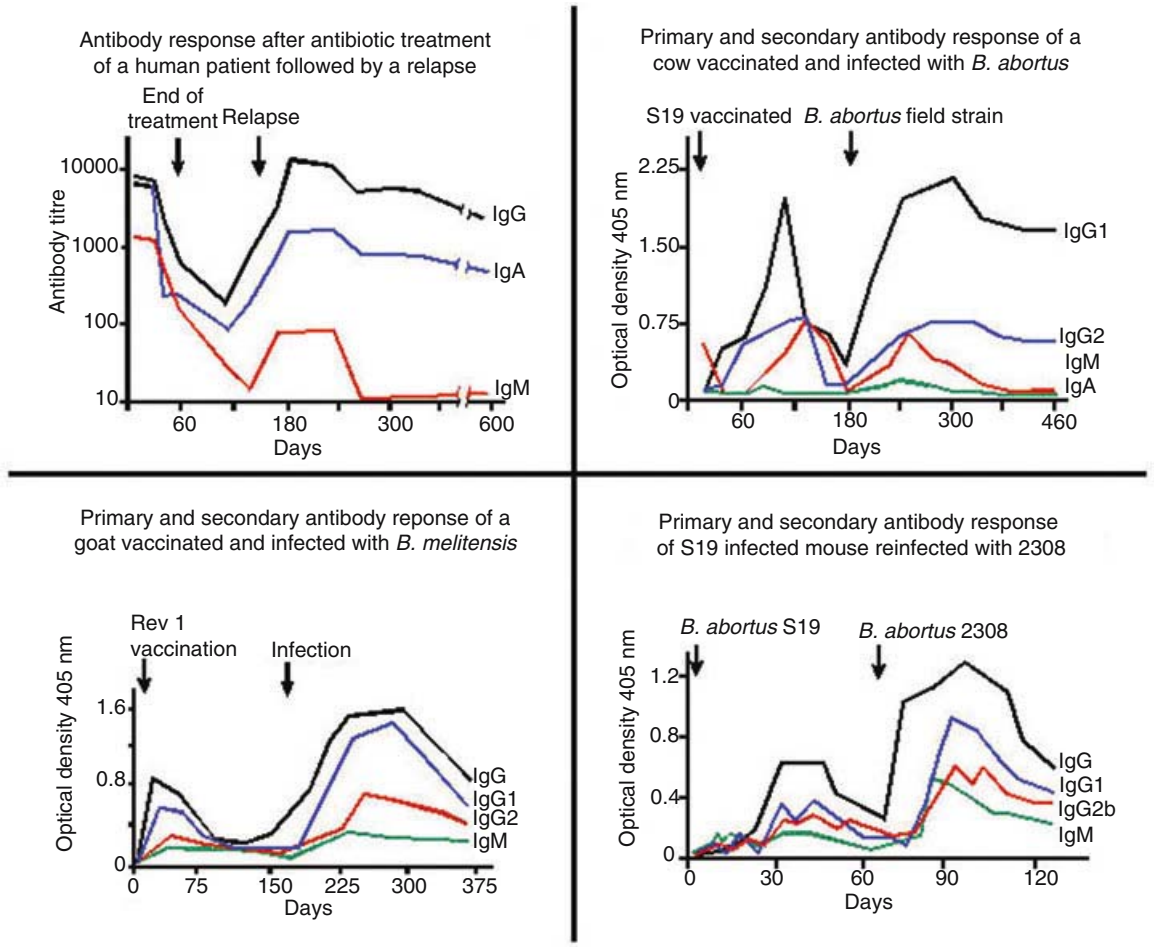

Fig. 39. ELISA immunoglobulin isotype reactivity against *B. abortus* LPS from humans and animals infected with *Brucella*. A) Antibody response (over time) of a human patient infected with *B. melitensis* after antibiotic treatment, followed by relapse. B) Primary and secondary antibody responses of a cow vaccinated with *B. abortus* S19 and infected with *B. abortus* 2308, respectively. C) Primary and secondary antibody responses of a goat vaccinated with *B. melitensis* Rev. 1 and infected with *B. abortus*, respectively. D) Primary and secondary antibody responses of a mouse infected with *B. abortus* S19 and reinfected with *B. abortus* 2308, respectively. Notice the strong IgG (IgG_1) response against *Brucella* LPS, characteristic of a type-2 T-dependent immune response. Since most of antibodies produced are directed against the common *Brucella* epitopes (Fig. 34), *B. abortus* LPS antigen bound to the ELISA plates serves its purpose, regardless of whether the individuals were infected or vaccinated with *B. abortus* or *B. melitensis*. The profile of the infected patient (panel A) was supplied by Dr. Javier Ariza, from the Infectious Disease Service, Hospital de Bellvitge, Barcelona, Spain.

duction of microbicidal reactive oxygen intermediates, and a more efficient phagosome-lysosome fusion are performed by the activated macrophages (Gross et al., 1998; Jiang and Baldwin, 1993a; Jiang and Baldwin, 1993b; Zhan and Cheers, 1995; Zhan and Cheers, 1996). As expected, the most relevant antigens involved in the T cell responses are bacterial proteins, as revealed by delayed-type hypersensitivity reactions in infected individuals with a mixture of protein extracts (Cell-mediated Immunity Tests). However, nonprotein antigens also may be involved in T cell responses (Bertotto et al., 1993; Ottones et al., 2000a; Ottones et al., 2000b; J.-P. Gorvel and E. Moreno, unpublished results).

Similar to what has been observed with other intracellular bacteria, such as *Mycobacterium*, *Listeria* and *Francisella*, the blood of humans infected with *Brucella* demonstrates an important increase in γδ T cells (Barnes et al., 1992; Bertotto et al., 1993; Jouen-Beades et al., 1997; Poquet et al., 1998). The T lymphocyte population that specifically expands is one carrying the Vγ9Vδ2 T cell receptor, suggesting that this subset of lymphocytes is generated in response to intracellular pathogens. The γδ T cell repertoire

responds to natural and synthetic low molecular weight nonpeptide ligands of diverse structure, complicating the nature of the recognition pattern carried out by this repertoire. For instance, when stimulated with isopentyl pyrophosphate from *M. tuberculosis*, Vγ9Vδ2 T cells polyclonally expand and secrete high levels of TNFα and INFγ, without stimulating αβ or Vγ1Vδ2 subsets. Similarly to other intracellular bacteria, *Brucella* stimulates the production of TNFα and INFγ by Vγ9Vδ2 T cells (Ottones et al., 2000a; Ottones et al., 2000b). It has been shown that *Brucella*-activated Vγ9Vδ2 lymphocyte subset is capable of impairing the intracellular multiplication. This effect seems to proceed by two different mechanisms. The first one is through the release of a low molecular weight soluble factor that stimulates the production of TNFα and INFγ cytokines, which activate the brucellacidal mechanisms of professional phagocytes. The second mechanism seems to take place by a direct contact-dependent cytotoxic effect on monocytic cells infected with *Brucella* organisms. The bactericidal activity mediated by this γδ lymphocyte subset during early stages of infections by intracellular bacteria, such as *Mycobacterium*, *Listeria* and *Brucella*, may explain, in part, why acquired cellular resistance could be specifically induced by one intracellular bacteria, but nonspecifically expressed for a given period of time, as indicated at the beginning of this subsection (Mackaness, 1967).

Interleukins in Brucellosis Several studies have highlighted the role of IFNγ, TNFα, interleukin (IL)-6, IL-1β, IL-10, IL-12, granulocyte macrophage colony-stimulating factor (GM-CSF), and granulocyte colony-stimulating factor (G-CSF) in host resistance against bacterial infections (Fernández-Lago et al., 1996; Flesh et al., 1994; Flynn et al., 1995; Liautard et al., 1996; Sarmento and Appelberg, 1996; Tanaka et al., 1995). Delayed-type hypersensitivity response of *Brucella*-infected animals and humans has been used as a diagnostic parameter for brucellosis, as well as an indicator for cell-mediated immune response and release of cytokines in brucellosis (Nicoletti and Winter, 1990b). Particularly, during *Brucella*-infection IFNγ, TNFα, IL-2, IL-10, and IL-12 seem to control the intracellular growth of *Brucella* strains within macrophages, whereas IL-1α, IL-4, IL-6 and GM-CSF do not have clear effects (Fernández-Lago et al., 1996; Jiang and Baldwin, 1993a; Ottones et al., 2000a; Ottones et al., 2000b; Zhan and Cheers, 1995). Among the various cytokines, IFNγ is the most relevant for generating macrophages with strong brucellacidal activity. Moreover, IL-2, IL-10 and IL-12, cytokines that influence the acquired cellular resistance and specifically contribute to control the brucellae multiplication, seem to work via the IFNγ-dependent pathway. It is known that *Brucella* LPS is a poor inducer of cytokine production, as well as an inefficient activator of phagocytic cells (Goldstein et al., 1992; López-Urrutia et al., 2000; Rasool et al., 1992). Similar to what has been observed with *Legionella* pneumophila LPS, it seems that the CD_{14} molecule does not serve as receptor for *Brucella* LPS (Neumeister et al., 1988; E. Moreno, unpublished observations), precluding the activation of macrophages by this mechanism. This coincidence between two LPS from phylogenetically distant intracellular bacteria does not come as a surprise, since the lipid A structures of these two molecules have co-evolved to the point that they chemically resemble each other (Fig. 7). As an overall conclusion, it seems unlikely that macrophage activation and secretion of IL-12 occur via the *Brucella* LPS molecule (Huang et al., 1999).

The role of TNFα in brucellosis is not completely clear. In contrast to what has been observed in murine macrophages, *Brucella* strains do not induce TNFα in human macrophages and live *Brucella* is capable of inhibiting the production of this cytokine (Caron et al., 1994b; Caron et al., 1996). However, pretreatment of human macrophages with exogenous TNFα significantly inhibits the rate of *Brucella* intracellular replication. TNFα may not be essential for the induction of acquired cellular resistance but it is likely to directly activate effector cells by limiting the multiplication of intracellular *Brucella* (Ottones et al., 2000a; Ottones et al., 2000b; Zhan and Cheers, 1996).

It has been demonstrated that bactericidal action of activated macrophages and expression of macrophage-specific cytokines depend upon the expression of NF-IL6 (Akira et al., 1990; Katz et al., 1993; Lowenstein et al., 1993; Scott et al., 1992; Tanaka et al., 1995). Upon activation of NF-IL6 knockout macrophages by IFNγ, induction of the transcription of TNFα, IL-6, IL-1β, GM-CSF, M-CSF, IL-10, and IL-12 is comparable to that observed in normal mice (Tanaka et al., 1995). Strikingly, no induction of G-CSF expression is observed in NF-IL6 knockout mice, being this defect is restricted to macrophages and fibroblasts (Tanaka et al., 1995). Moreover, NF-IL6 knockout mice display a high susceptibility to Salmonella and Listeria infections, suggesting that NF-IL6 plays a role in controlling intracellular parasites (Tanaka et al., 1995).

Attenuated *B. abortus* strain 19 is capable of replicating in NF-IL6 knockout murine macrophages. The levels are comparable to those observed in normal macrophages infected with the virulent *Brucella* strains (Pizarro-Cerdá et al., 1998c). The role of NF-IL6 in the inhibition of intracellular bacterial replication is related to

its control of endocytosis and membrane fusion between endosomes and *Brucella*-containing phagosomes. Addition of G-CSF, where production is impaired in NF-IL6 knockout macrophages, restores both endocytosis and the morphology of endosomes, together with the bactericidal activity. During *Brucella* infection, it has been observed that endocytosis but not recycling is affected in NF-IL6 knockout macrophages, suggesting that G-CSF promotes fusion events in early phagosomes (Pizarro-Cerdá et al., 1999a; Fig. 35).

In NF-IL6 knockout macrophages, NO synthetase is not impaired (Tanaka et al., 1995). The production of reactive oxygen intermediates is, however, lower in NF-IL6 than that in wildtype macrophages (Tanaka et al., 1995), suggesting that NF-IL6 may control the expression of other elements of the respiratory burst. Indeed, it is known that G-CSF enhances the respiratory burst in phagocytes (Yuan et al., 1993). The NO synthetase was found to be associated to intracellular membrane vesicles different from lysosomes and peroxisomes in murine macrophages (Vodovotz et al., 1995). These vesicles could translocate to *Brucella*-containing phagosomes in normal macrophages and be hampered in NF-IL6-deficient macrophages due to the lack of fusion between endosomes and phagosomes. Therefore, one hypothesis is that G-CSF, by completely restoring endosome-phagosome fusion, allows elements of the respiratory burst present in endocytic compartments to reach the *Brucella*-containing phagosomes and thus to partially re-establish the bactericidal activity of macrophages (Pizarro-Cerdá et al., 1999a). Under these conditions, attenuated *Brucella* could be targeted to lysosomes and killed, whereas virulent bacteria could still replicate but to a lesser extent than in resting macrophages (Jones and Winter, 1992).

Diagnosis

Brucellosis causes a great variety of clinical symptoms in humans, and although a thorough anamnesis (by questioning feeding habits, occupation and recent animal contacts) is very informative, a definite diagnosis cannot be made solely on these bases. A similar situation happens in animal brucellosis: abortion and infertility are the main symptoms, but they are not exclusively caused by *Brucella* and do not necessarily occur in all infected animals.

The laboratory diagnosis of brucellosis logically follows clinical or epidemiological suspicion of the disease and uses direct and indirect tests. Direct tests are those that show the presence of viable bacteria by bacteriological culture or of some molecules specifically produced by the pathogen. They have the advantage that, when positive, the diagnosis is conclusive. However, they often lack sensitivity (i.e., they yield false negative results) and are cumbersome to perform. Indirect tests are those that detect the presumed effects of *Brucella* infections, which means almost always an analysis of the adaptive immune response. Depending on the tests, they can be very sensitive. However, it has been proven that a proportion of infected animals born to infected mothers do not develop a detectable immune response immediately after birth and that animals that have been infected for a long time may have no significant levels of antibody to the commonly used *Brucella* antigens. Indirect tests may also lack specificity (i.e., they may produce false positive results). This is so because a positive result of immunological tests can mean not only an active infection, but also the existence of antibodies or memory cells persisting after vaccination or recovery, contact with *Brucella* not followed by disease, or exposure to immunologically crossreacting bacteria. Thus, without a good knowledge of the circumstances outlined in the previous paragraph, the results of laboratory tests are not always meaningful.

Direct Diagnosis of Human Brucellosis

Bacteriological Culture for Humans This is by definition the most specific diagnostic test, and since in human brucellosis it is mandatory to achieve a correct diagnosis for each individual, bacteriological cultures should be performed whenever possible. Moreover, owing to the problems posed by the serological diagnosis of *B. canis* (Immunological Diagnosis of Infections Caused by *B. ovis* and *B. canis*), culture is the best diagnostic tool when an infection by this species is suspected.

Brucella has been isolated from several tissues, articular and cerebrospinal fluids, and bone marrow, but the culture of aseptically taken blood in tryptic soy broth or similar media (Table 10) in a 10% CO_2 atmosphere is the simplest and most often used procedure. This is an enrichment procedure, and subcultures on agar media are necessary to identify the bacteria. However, blood debris prevents detection of growth by the appearance of turbidity, and unless special methods are adopted, repeated blind subculture is necessary until a successful isolation happens or the blood culture is discarded as negative. Because this procedure conveys a great risk of infection (Biosafety), Ruiz-Castañeda developed a biphasic system for *Brucella* in which one of the sides of the culture flask is layered with solid medium. After inoculation, the flask is tilted every three or more days so that the broth wets the agar briefly and colonies eventually

appear. In addition, automated methods have been developed over the last decade that detect the CO_2 resulting from aerobic bacterial growth, and they also make blind subculturing unnecessary.

When using the Ruiz-Castañeda method, blood cultures are seldom positive by the fourth day of incubation, the majority are positive between the seventh and twenty-first, and only 2% are positive after the twenty-seventh day. In this method, incubations should be carried out for at least 45 days before rejecting a blood culture as negative for *Brucella* (Díaz and Moriyón, 1989). The automated CO_2-detecting systems are advantageous in that they have a shorter average period of detection (usually less than five days). However, prolonged incubation is not completely avoided as some flasks do not become positive in less than three weeks. Moreover, cultures remaining negative after the first week of incubation do not always produce CO_2 above the positive threshold level, and it is advisable to do blind subculturing for maximum sensitivity (Ariza, 1999; Casas et al., 1994; Yagupsky et al., 1997).

The low numbers of *Brucella* cells in the sample (sometimes as low as 1–2 colony forming units per ml) are in all likelihood one of the reasons for prolonged incubations, and larger samples are advantageous (Zimmerman et al., 1990). It is, therefore, advisable to inoculate 5–10 ml in duplicate flasks, as it is also advisable to perform two or three independent blood samplings at adequate intervals (Díaz and Moriyón, 1989). Some studies have found that bacteriological detection can be improved by using the leukocyte lysis-concentration procedure (Gaviria-Ruiz and Cardona-Castro, 1995; Etemadi et al., 1984).

When blood samples are taken from febrile patients, isolation is successful in the majority of cases, and much lower rates are obtained from afebrile patients (68 versus 32% in the extensive comparative study of Rodríguez-Torres et al., 1977). This difference is also found in relapsed patients. Indeed, the probability of obtaining a successful culture is greatly reduced when antibiotherapy has started. Since the percentages of positive cultures reported for *B. melitensis* (about 70-80%) are usually higher than for *B. abortus* (about 50%), it has been suggested that the infecting species influences the likelihood of a successful isolation (Dalrymple-Champneys, 1960). Unless epidemiological data are necessary, or infection with the vaccine strain US19 or Rev. 1 is suspected (Treatment), identification to genus level is enough for medical purposes (Identification and Typing).

Molecular Tests for Humans A number of molecular tests have been proposed for human brucellosis, but PCR is the only one that has deserved significant attention. So far, amplification of DNA extracted from blood with primers taken from a 31-kDa *B. abortus* soluble protein (BCSP31) is the only protocol that has been evaluated (Matar et al., 1996; Morata et al., 1999a; Queipo-Ortuño et al., 1997). This protocol has been reported to have a diagnostic sensitivity of 92% or higher (with regard to the combined clinical, bacteriological and serological evidence) and a specificity of 93%. Modifications of the original protocol have been described in further work (Morata et al., 1998; Queipo-Ortuño et al., 1999), and the protocol reported to be successful in the evaluation of recovery and in the diagnosis of relapses (Morata et al., 1999b). However, other laboratories have not been able to reproduce the results (Navarro et al., 1999). If the findings are confirmed, the method would provide medical microbiologists with an exceedingly valuable diagnostic tool.

Direct Diagnosis in Animal Brucellosis

Bacteriological Culture for Animals Bacteriological culture, by definition, is the most specific diagnostic test in animal brucellosis, and when performed exhaustively, it allows the identification of over 90% of infected cattle, sheep and also possibly of other animal species. Unfortunately, performed in this way, it is cumbersome and expensive, and the processing of samples containing *B. melitensis*, *B. abortus* or *B. suis* requires special precautions (Alton et al., 1988) (Biosafety). Its use is, therefore, restricted to some circumstances, such as the unequivocal demonstration of the disease at herd level, the identification of vaccine shedders (Identification of Vaccine Strains; Epidemiology), the assessment of the performance of serological tests and vaccines, and the diagnosis of animals of high genetic value.

Samples used include vaginal swabs, semen, aborted fetuses (stomach contents, lung and spleen) and fetal membranes. Direct examination of smears of these materials stained by Stamp's method (Cellular and Colonial Characteristics) can be very informative, although other bacteria like *Chlamydia* are also Stamp positive and a cause of abortion (Fig. 10). Blood can also be used and hemocultures are recommended as a good diagnostic test for *B. canis* in dogs. Milk (cream and sediment from the four quarters) is very useful for identifying shedders. Materials that can be obtained at the abattoir or after necropsy include the udder and the uterus of pregnant or early postparturient animals and the male reproductive organs, but the best samples are the spleen and, in particular, the lymph nodes. Although mammary nodes yield *Brucella*

most often, all major lymph nodes (up to seventeen) should be examined for an exhaustive inquiry into the infectious state of a particular animal. In addition, any tissues showing inflammatory lesions and abscesses should be cultured (Alton et al., 1988).

Most samples require maceration (in a safety cabinet). All but blood or other normally sterile fluids (which can be processed in the same way as human blood cultures) are inoculated as abundantly as possible into an appropriate selective or enrichment medium (Table 11) and incubated in a 10% CO_2 atmosphere. Cultures are seldom clearly positive by the fourth day of incubation and should be incubated for at least 15 days. The number of bacteria in the organs can vary widely and plates can contain from very few to many *Brucella* colonies. An alternative to selective media is the inoculation of guinea pigs followed by the recovery of the bacteria from the appropriate tissues at necropsy and the demonstration of seroconversion (Alton et al., 1988; Ne'eman and Jones, 1963; Brucellosis in Guinea Pigs). This method, however, is only justified when dealing with very heavily contaminated specimens and after consideration of the ethical issues involved.

Molecular Tests for Animals Tests detecting *Brucella* cells or antigens by immunological methods have been described but they have not found a practical use in the diagnosis of brucellosis, and this is also true of tests detecting directly *Brucella* DNA with labeled probes (Mayfield et al., 1990). PCR has deserved much greater attention, but so far most research has been directed to the development of protocols under laboratory conditions (Table 4), and since studies on the actual diagnostic value are scarce, there is no established PCR protocol that could replace the bacteriological culture. An assessment of the possible practical value of the existing PCR protocols is complicated by the fact that an efficient DNA extraction from samples is critical for optimal diagnostic sensitivity. There are no specific studies on this problem, but it has been noted that even in culture, *Brucella* cells are resistant to conventional DNA extraction protocols (Romero and López-Goñi, 1999). Nevertheless, the few studies that have compared the diagnostic performance of PCR with that of standard bacteriological or serological tests suggest that PCR could be a valuable diagnostic test in animal brucellosis. In the examination of tissues, organs and stomach contents of *B. abortus* infected cattle, a PCR protocol with primers taken from a putative *B. abortus* Omp showed 98% sensitivity and 96% specificity as compared to bacteriological culture (Fekete et al., 1992a; Fekete et al., 1992b). In a study carried out to assess the ability to detect *Brucella* in the stomach contents of aborted sheep fetuses, PCR with 16S rRNA primers performed closely to bacterial cultures, albeit the number of samples studied was low (Cetinkaya et al., 1999). For obvious reasons, milk would be one of the samples of choice, and in one study, conventional PCR with 16S rRNA primers was found to have 100% specificity and 87.5% sensitivity with respect to bacteriological culture (ELISA showed 100% specificity and 98.2% sensitivity in the same samples; Romero et al., 1995b). Other possible uses of PCR in the diagnosis of animal brucellosis include the direct identification of *B. abortus* strain 19 vaccine shedders by using primers taken from the *ery* region (Identification of Vaccine Strains).

Immunological Tests for Brucellosis *Brucella* evokes a cell- and antibody-mediated immune response (Control of the Infection), and accordingly, immunological tests for brucellosis can be grouped into two categories: those that detect specific antibody and those that analyze cell-mediated immunity. Mainly protein antigens trigger the cell-mediated response, but also both LPSs and proteins elicit an antibody response. Thus, broadly speaking, antibody tests for brucellosis can be subclassified into two groups corresponding to each of these antigens. Although structurally related to the LPS *O*-polysaccharide, NH or polysaccharide B is measured by a third group of antibody tests.

To understand the immunological diagnosis of brucellosis, it is necessary to keep in mind 1) the differences in surface antigens existing between smooth and rough *Brucella* species (Response to Environmental Stress); 2) the close structural similarity of the LPS *O*-polysaccharides of the *Brucella* serotypes; 3) the presence of the smooth LPS in the most effective vaccines (Vaccines and Vaccination); 4) the existence of Gram-negative bacteria that, albeit phylogenetically distant, show *O*-polysaccharides similar to those of the smooth *Brucella* species; and 5) that significant immunological crossreactivities with *Brucella* proteins have been shown only for similar antigens of phylogenetically close relatives (Fig. 3). The implications of these facts can be summarized as follows:

A. LPS tests used to diagnose infections caused by *Brucella* rough species (*B. ovis* and *B. canis*) are different from those used to diagnose *B. melitensis*, *B. abortus* and *B. suis* infections.

B. If quality control of antigens is always important, dissociation of smooth *Brucella* cultures is a constant possibility. Thus, extreme care must be taken to make sure that the antigens used in smooth LPS tests are prepared

from nondissociated cultures (Colonies and Dissociation).

C. Antibodies to the smooth-LPS can be detected with whole smooth cells (Outer Membrane Topology) or LPS extracts. It is not necessary to use bacteria or LPS of the homologous serotypes. Thus, *B. abortus* biotype 1 cells (often *B. abortus* vaccine strain 19) can be used to obtain antigens for the diagnosis of infections caused by other smooth brucellae. This has been clearly shown for *B. melitensis* and *B. abortus* biotypes serologically different from biotype 1, and it is so because polyclonal responses contain a large proportion of antibodies that, because of combinations of titer and avidity, show overlapping reactivities with the A, M and C epitopes (Fig. 15). In the diagnosis, therefore, the C epitopes are largely dominant (Fig. 34; Response to Environmental Stress).

D. Smooth LPS tests have two main sources of nonspecificity: vaccination with *B. abortus* strain 19 or *B. melitensis* Rev. 1 (Vaccines and Vaccination) and infections with Gram-negative bacteria carrying perosamine-containing *O*-polysaccharides. Among the latter, *Y. enterocolitica* O:9 is the one showing the strongest crossreactivity due to the rather close similarity existing between its *O*-polysaccharide and the *O*-polysaccharide of *B. abortus* biotype 1 (Table 6).

E. Protein tests allow a differential diagnosis of brucellosis and infections caused by Gram-negative bacteria that carry perosamine-containing *O*-polysaccharides. They are also the antigens active in tests assessing the cell-mediated immunological response.

Practically all types of immunological assays available have been investigated as potential tests for the diagnosis of brucellosis. The most relevant antigens and, where appropriate, immunoglobulins involved in some commonly used or representative tests are summarized in Table 16.

Immunological Diagnosis of Human Brucellosis Caused by Smooth Brucella *Brucella melitensis*, *B. abortus* and *B. suis* are the *Brucella* species infecting humans most often (Brucellosis in Humans). *Brucella canis* is also pathogenic for humans, but it does not pose a threat to human health of the magnitude created by the first three species, and the few reported cases are not always confirmed by bacteriological cultures (Carmichael, 1990). The immunological diagnosis of *B. canis* infection is considered in a separate section (Immunological Diagnosis of Infections Caused by *B. ovis* and *B. canis*).

Antibody Detecting Tests in Infected Patients Tests detecting cell-mediated immunity are not used nowadays for the diagnosis of human brucellosis. On the other hand, antibody-detecting tests are performed routinely and they can be performed with blood serum and, when neurobrucellosis is suspected, with cerebrospinal fluid. Since serum samples are rarely taken early enough, seroconversions are seldom observed in human brucellosis. Serological tests are then useful not only to detect anti-*Brucella* antibodies, but also to evaluate the stage of evolution of the disease through an assessment of the classes of immunoglobulins involved in a given test or specifically detected by it. Obviously, a dominant IgM response is characteristic of the early stages (acute brucellosis), whereas IgG and IgA in the absence of IgM are characteristic of a brucellosis that was acquired some time before the test was performed. To detect changes in the immunoglobulin levels also can be useful to evaluate the possibility that a relapse had occurred (Fig. 39).

Smooth-Lipopolysaccharide Tests in Infected Patients At the early stages of infection, antibodies are directed almost exclusively against the *O*-polysaccharide of the smooth-LPS, and they are also those that persist longer after recovery (Fig. 39). Thus, changes in immunoglobulin profiles are best observed in smooth-LPS tests. Moreover, these are the most sensitive tests.

Agglutination tests are inexpensive, technically simple and informative. Thus, they are recommended for the diagnosis of human brucellosis in most situations. They include the classical serum tube agglutination test used to titrate the total amount of agglutinating antibody and modified tests aimed to roughly determine the amount of IgM versus IgG plus IgA by including reagents that preferentially (but not exclusively) inactivate IgM (e.g., the β-mercaptoethanol test; Table 16). The diagnostic titer in the classical tube agglutination test may vary depending upon the prevalence and other circumstances (Díaz and Moriyón, 1989). Agglutination tests for brucellosis also include the rose bengal test (and the card test), in which the use of an acid pH makes all antibodies show their intrinsic agglutinating activity. Although it is primarily a rapid slide agglutination screening test, the rose bengal can also be used in human brucellosis with serum dilutions to obtain a rough idea of the total amount of anti-smooth-LPS antibody, which is enough for most clinical purposes. Prozones are occasionally observed in the classical tube agglutination, but not in the rose bengal, and both tests have very few false-negative results.

The serum agglutination test can be adapted to measure the nonagglutinating (low affinity) IgG and IgA (Coomb's test; Table 16), which characteristically develop in brucellosis. In acute brucellosis, Coomb's titers are usually 4–16 times

Table 16. Some tests and antigens used in the diagnosis of brucellosis.

Tests	Antigen	Antibody	Comments	References
Agglutination				
Tube agglutination (and β-mercaptoethanol and rivanol) test	S-LPS (*B. abortus* cell suspension)	IgM, IgG and IgA	It can be adapted to the diagnosis of *B. canis*. To estimate the amount of IgM, the results of the standard tests are compared with those obtained in the presence of β-mercaptoethanol (or similar reagents)[a] or rivanol[b]	Alton et al., 1988
Rose bengal (and card) tests	S-LPS (stained *B. abortus* cell suspension in lactate buffer pH 3.65)	IgM, IgG and IgA[c]	Simple and inexpensive slide-agglutination type tests in which bacteria are stained with rose bengal. Used as screening tests	Alton et al., 1988
Coomb's	S-LPS (*B. abortus* cell suspension)	IgG and IgA	Detects nonagglutinating Ig that has reacted with the bacterial surface by using an anti-Ig serum that brings about the agglutination. It can, therefore, be used to specifically detect nonagglutinating IgG or IgA with an antiserum of the appropriate specificity	Otero et al., 1982
Milk ring test	S-LPS (stained *B. abortus* cell suspension in citrate buffer pH 4.0)	IgA (also IgM and IgG)	Ig in milk reacts with hematoxylin stained bacteria, and the complex attaches to the fat that ascends to form a ring on the surface of the reaction tube. Only adequate for cow milk	Alton et al., 1988 Sutra et al., 1986
Complement consumption				
Hemolysis in agar	S-LPS coated erythrocytes	IgG[d]	Sensitized erythrocytes are included with complement in an agarose gel and a radial immunodiffusion performed	Ruckerbauer et al., 1984
Complement fixation	S-LPS (*B. abortus* cell suspension) or R-LPS plus Omps (*B. ovis* hot saline extracts)	IgG[d]	A confirmatory test for *B. abortus* or *B. melitensis* animal brucellosis; also used in the diagnosis of *B. ovis*. Cumbersome to perform unless automated; some sera show anticomplementary activity	Alton et al., 1988
Precipitation				
Double immunodiffusion	Extracts containing S-LPS, S-LPS plus NH, or R-LPS plus Omps (*B. ovis* hot saline extracts)	IgG (also IgM)[e]	Used mostly for *B. ovis* and *B. canis* diagnosis with the R-LPS plus Omps extract; usually performed in hypertonic gels	Alton et al., 1988

Table 16. *Continued*

Tests	Antigen	Antibody	Comments	References
Reverse radial immunodiffusion (RID)	NH and polysaccharide B	IgG[f]	A confirmatory test for cattle, goat and sheep (*B. melitensis*) brucellosis. Performed in hypertonic gels	Jones et al., 1980 Díaz et al., 1981
Crossover immunoelectrophoresis	Soluble proteins of rough *Brucella* mutants	IgG	Useful for the diagnosis of human brucellosis. IgM to protein antigens is not detected in this assay	Díaz et al., 1976
Immunoenzymatic				
Indirect ELISA	Purified S-LPS, S-LPS *O*-polysaccharide, S-LPS rich extracts or extracts containing R-LPS plus Omps (*B. ovis* hot saline extracts). Purified proteins	Depends on conjugate specificity	In human brucellosis, ELISAs detecting anti-S-LPS antibodies could replace classical tests if adapted to measure IgM and IgG. For animal brucellosis, ELISAs are most often adapted to detect anti-S-LPS IgG	Nielsen et al., 1996 Alonso-Urmeneta et al., 1988 Marín et al., 1998 Rosetti et al., 1996 Goldbaun et al., 1992 Letesson et al., 1997
Competitive ELISA	S-LPS, S-LPS O-polysaccharide, or S-LPS rich extracts	Presumably all Ig classes	A mouse monoclonal antibody competes with low avidity (and low titer) antibodies for the S-LPS C epitopes; the monoclonal antibody bound is then detected with an immunoconjugate specific for mouse immunoglobulins	Gall and Nielsen, 1994
Fluorescence polarization	Fluorescein-labelled *O*-polysaccharide	Presumably all Ig classes	A promising test based on the change of fluorescence of labeled antigen upon antibody binding	Nielsen et al., 1996
Delayed type hypersensitivity	Soluble proteins of rough *Brucella* mutants	None	Most often performed as a simple skin test	Jones et al., 1973 Blasco et al., 1994 Saegerman et al., 1999
Lymphocyte blastogenesis	Complex antigenic mixture; soluble and outer mebrane proteins	None	Technically demanding	Baldwin et al., 1984
γ-interferon production	Soluble proteins of rough *Brucella* mutants	None	Technically demanding	Weynants et al., 1995

[a]At least human IgA has been shown to be sensitive to the concentrations of β-mercaptoethanol used in the test.
[b]2-Ethoxy-6,9-diamino-acridine (an IgM precipitating reagent).
[c]IgA activity in the rose bengal test has been shown with human sera.
[d]There are contradictory reports on the IgM ability to activate complement. At least in cattle, IgM does not activate guinea pig complement in the absence of homologous serum components.
[e]IgM is particularly active in the immunoprecipitation of LPS extracts (this molecule forms aggregates, and the reactions mimic a microagglutination).
[f]IgM precipitating NH has been shown in some human sera. At least in cattle, IgG_1 is the major immunoglobulin precipitating NH (and polysaccharide B) and accounting for the hypertonic conditions required in the assay.

higher than tube agglutination titers, whereas at later stages they are 16–256 times higher. Thus, comparison of the serum agglutination and the Coomb's tests allows the assessment of the stage of evolution of human brucellosis. This can also be achieved by using the complement fixation test: in over 90% of the human cases, serum agglutination and complement fixation are simultaneously positive, but after the fourth or the fifth week of evolution, complement fixation titers are higher than serum agglutination titers. At the very early stages of infection, serum agglutination is positive and complement fixation negative, and the opposite is true in patients that are recovered or are developing chronic or focal forms (Díaz and Moriyón, 1989).

The indirect enzyme-linked immunosorbent assay (i-ELISA) with smooth-LPS (or with smooth cells) is both very specific and sensitive for the diagnosis of human brucellosis. Using this assay, it has been clearly proven that the response to smooth-LPS in treated patients follows a classical pattern: IgM appears and decreases faster than IgA or IgG, and in relapses, IgG and IgA, but not IgM, increase over the levels observed when the first diagnosis was made (Fig. 39). The assay also shows that IgG is the more persisting immunoglobulin and that over 80% of the patients have high titers of IgG and IgA a year and a half after clinical recovery (Ariza et al., 1992; Pellicer et al., 1988). The correlation of the IgM or IgG i-ELISA with agglutination, Coomb's and complement fixation tests is the one expected from the immunoglobulin classes involved in the latter tests. It seems, therefore, possible to replace all classical serological tests by an i-ELISA with smooth-LPS and anti-IgM and IgG conjugates, but this would require not only standardization but also the definition of the equivalence between the i-ELISA results and those of the classical tests that clinicians are used to interpreting. There is one report on the use of the competitive ELISA (c-ELISA) in human brucellosis, and the assay was found also very specific and sensitive (Lucero et al., 1999). This test could be less sensitive to interference by crossreacting bacteria, but no definite studies with human sera have been published to date.

Protein Tests in Infected Patients Both indirect evidence and studies in experimentally infected animals show that antibodies to soluble proteins develop later than antibodies to the smooth-LPS. They are characteristic of an active brucellosis, and the longer the evolution of the disease before treatment, the higher the antibody levels and the diversity of proteins to which they are directed (Fig. 38). Antibodies to *Brucella* proteins can be found not only in blood serum but also in the cerebrospinal fluid of patients afflicted with neurobrucellosis. The protein antigens that have been used include the mixture of soluble proteins present in the hypertonic *Brucella* extracts also used in the skin test (Díaz et al., 1976; Cell-mediated Immunity Tests), BP26 (Rossetti et al., 1996) and an immunocaptured cytosolic protein (lumazine synthase; Goldbaum et al., 1992; Goldbaum et al., 1999). Antibodies to Omps also develop in brucellosis but they are more cumbersome to detect and their diagnostic value is less clear (Leiva-León et al., 1991). Tests that have been used include gel precipitation (either as double gel diffusion or as crossover immunoelectrophoresis), indirect ELISA and Western blot.

By gel immunodiffusion, it has been shown that over 80% of brucellosis patients have precipitating antibodies to one or several soluble proteins in hypertonic *Brucella* extracts. In one study, in which the sera of 173 patients with acute brucellosis and 39 with brucellosis having a long evolution were examined by crossover immunoelectrophoresis, 84.9% and 91.6% had developed anti-protein antibodies, respectively (Díaz et al., 1976). Using an indirect ELISA in which the antigen had been immunocaptured with a monoclonal antibody, 94% (33 of 35) of the brucellosis patients examined showed IgG to *Brucella* lumazine synthase (an 18-kDa antigen), as well as strong anti-smooth-LPS response. By contrast, individuals classified as having a "nonactive" brucellosis seldom showed anti-lumazine synthase antibody, even though most had various degrees of anti-LPS reactivity (Goldbaum et al., 1992). All these results strongly suggest that the presence of anti-protein antibodies is a useful criterion to decide whether low levels of anti-smooth-LPS antibodies are indicative of infection or simply of contact without the development of disease. Thus, these tests deserve further attention.

Antibody Detecting Tests in Recovered Patients After recovery, serum agglutination becomes progressively negative, usually six months to two years later. The complement fixation titers also decrease but they may also persist, always for longer times than those of serum agglutination titers. The last conventional test to become negative is the Coomb's test. When the results of these three classical tests are taken together, the serology seldom becomes negative by the third month, and positive results often persist after the eighth month of evolution. In the ELISA, IgM, IgA and IgG are negative by the first year in 65, 25 and 3% of recovered patients, respectively (Ariza et al., 1992). The problem of predicting a relapse based on the results of serological tests has not been satisfac-

torily solved. It has been suggested that persisting β-mercaptoethanol-resistant antibodies (IgG) correlate with the risk of relapse, but the ELISA studies show that IgG persists for a long time in the serum of fully recovered patients.

Immunological Diagnosis of Animal Brucellosis Caused by Smooth Brucella A major difference with the immunological diagnosis in humans is that, in animals, what is most often judged is whether there has been contact with *Brucella* and not the existence of an ongoing infection. This information is enough for eradication purposes, including control of animal movements and trade, and an assessment of the immunoglobulin profile or a comparison of the results of smooth-LPS and protein tests is not necessary. However, the use of vaccines complicates the diagnosis of animal brucellosis. Vaccination induces an immunological response that closely mimics that resulting from a true infection, and since even the best vaccines available do not afford 100% protection, distinction of infected and vaccinated animals becomes necessary.

For obvious reasons, the majority of the information on the performance of the immunological tests concerns cattle, sheep, goats and swine. Positive reactions in the classical blood serum tests have been recorded for other important domestic animals, such as camels, water buffalos and reindeer, and also for a variety of wild animals (Davis, 1990). However, since these observations have not been complemented by bacteriological studies, the actual performance of the tests in detecting *Brucella* infection in all these animals is not known and the results of the immunological tests can only be taken as presumptive. The discussion is limited here to the immunological diagnosis of brucellosis in domestic ruminants and swine.

Antibody Detecting Tests in Infected Animals The tests used are often the same as those used in human brucellosis (Table 16), and in fact, some, like the rose bengal test, were first developed for the diagnosis of animal brucellosis. The presence of antibodies to *Brucella* can be investigated in blood serum but also in the whole milk or whey of dairy animals.

Smooth-Lipopolysaccharide Tests in Infected Animals Like in human brucellosis, these are the tests used most often. Their application has been studied best in cattle. There are fewer studies in small ruminants, and the number of animals included is also comparatively reduced. Moreover, for classical tests, such as the rose bengal and complement fixation, most investigations in small ruminants have been performed with the tests standardized for the diagnosis in cattle, and these conditions do not result in optimal sensitivity (Blasco et al., 1994b). This standardization problem affects only the proportion of serum to antigen and not to the particular epitopic structure of the smooth-LPS used in the assay (Immunological Tests for Brucellosis). The results of selected studies in which this difficulty is taken into account, the sensitivity defined with respect to bacteriological culture, and the specificity determined in the absence of vaccination are presented in Table 17. They show that, under those circumstances, most tests perform with a remarkable high efficiency and that the i-ELISA and the rose bengal (or card) test come close to the ideal test. There is a long practical experience in the use of the rose bengal test, but the i-ELISA has been investigated thoroughly. It has been shown that purified smooth LPS, *O*-polysaccharide or NH preparations offer no advantage over relatively crude smooth-LPS extracts (Alonso-Urmeneta et al., 1988; Nielsen et al., 1995; Wright and Nielsen, 1990b). Conjugates based on monoclonal antibodies specific for ruminant IgG_1 or on the IgG-binding Streptococcus protein G allow the diagnosis of the three common domestic ruminants with a single reagent, improving the specificity and reducing the background reactivity caused by IgM (Alonso-Urmeneta et al., 1988; Wright et al., 1990b). Peroxidase conjugates and the chromogenic substrate 2,2′-azino-bis(3-ethylbenzthiazoline-6-sulfonic acid) (ABTS) have been shown to produce excellent results. Thus, this assay has been well-defined and the choice between the i-ELISA and the rose bengal test depends mostly on economical and logistic reasons. With regard to swine brucellosis, studies with well-defined sera are scarce but immunoenzymatic and fluorescence polarization assays seem to outperform the classical agglutination or complement fixation tests (Table 17). The latter tests have been reported to show low sensitivity and to be useful for diagnosis only on a herd basis (Alton, 1990a).

The specificity of the smooth-LPS tests becomes compromised when vaccination with *B. abortus* 19 or *B. melitensis* Rev. 1 is implemented (Vaccines and Vaccination). To overcome this problem (and also to reduce the restrictions in the application of the vaccines), a test that is able to distinguish infected from vaccinated animals (i.e., a test showing a high specificity in the context of vaccination) would be necessary. Ideally, such a test should also have a high sensitivity and be technically simple to facilitate large-scale testing. No classical test fulfils these requirements, and therefore a combination of a simple screening test (highly sensitive) and a confirmatory test (highly specific with respect to vaccinated animals) has been traditionally used. The rose ben-

Table 17. Performance of some antibody tests for the diagnosis of infections by smooth *Brucella* spp.

Abbreviations: RID-NH, radial immunodiffusion for antibody to native hapten polysaccharide; i- and c- ELISA, indirect and competitive enzyme-linked immunosorbent assay; and BPAT, buffered antigen plate agglutination test.

[a]Sensitivity = number of test-positive sera among culture-positive animals / total number of culture positive animals.

[b]Specificity = number of test-negative sera among *Brucella*-free (unvaccinated) animals / total number of *Brucella*-free (unvaccinated) animals.

[c]Depending on whether sera with anticomplementary activity are considered as positive or negative.

[d]BPAT, buffered plate agglutination test. This is a rapid agglutination test similar to the rose bengal test, but cells are stained with a mixture of crystal violet plus brilliant green. It may be slightly more sensitive than the rose bengal test.

gal and the complement fixation, respectively, have been the tests of choice for these purposes. The former test is simple, can be automated, and is very sensitive (Table 17), but it remains positive in a large proportion of vaccinated animals long after vaccination. The complement fixation test yields negative or weak titers six months after calfhood vaccination, but it requires careful and periodical standardization, and when adult vaccination is used, some animals may have titers persisting for a long time. Despite these problems, the efficacy of the combination of these two tests with calfhood vaccination is well established (MacMillan, 1990a), and they have been the reference in the serological diagnosis of animal brucellosis for years. Although it has been accepted that their performance in sheep and goats is adequate, they lack sensitivity when standardized according to current guidelines (Blasco et al., 1994b).

Several studies have shown that the i-ELISA is highly sensitive and, when properly standardized, also specific in differentiating infected from vaccinated animals, with reported specificities as high as 95–98% for cattle (Samartino et al., 1999). In experiments performed in sheep bled periodically after vaccination, the i-ELISA was less specific than the complement fixation, an immunoprecipitation test with NH (NH [and Polysaccharide B] Tests), and a competitive ELISA (c-ELISA; Marń et al., 1999). This last type of assay has been designed to prevent reactions below a given avidity threshold level set by the concentration of a competing monoclonal antibody specific for the *O*-polysaccharide C epitope(s) (Table 16). Since there is evidence that the antibodies remaining in serum several months after vaccination are in most cases of low avidity, the c-ELISA is an interesting approach to the differential diagnosis of infected and vac-

cinated animals. An additional advantage of this method is that it does not use a conjugate specific for the immunoglobulins in the tested serum, and therefore, it can be easily adapted to detect *Brucella* infections in different animal species. Like the i-ELISA, several protocols are possible with regard to antigen, monoclonal antibody, and other conditions. In a study performed in cattle, the sensitivity of a c-ELISA with monoclonal BM-40 was 100% in animals with bacteriologically proven infection, but its specificity in vaccinated calves was only 80% (76% for the complement fixation in the same animals; Macmillan et al., 1990b). However, an improved c-ELISA with monoclonal M48 showed 100% specificity in differentiating infected from vaccinated cattle (Nielsen et al., 1995). In a large study conducted to evaluate several i-ELISA and c-ELISA protocols with sera from animals of unknown bacteriological and vaccine status, the c-ELISA with smooth LPS and monoclonal M48 was found to be the best performing assay in terms of balanced sensitivity and specificity (97.5 and 96.5%, respectively) with respect to the combined results of rose bengal and complement fixation (Gall et al., 1998). In the analysis of sera from *Brucella*-free, vaccinated, and bacteriologically positive sheep, this same c-ELISA showed slightly lower sensitivity than the i-ELISA (96 and 100%, respectively) and better specificity (about 89%) in distinguishing infected from Rev. 1 vaccinated animals (Marín et al., 1999). In this same study, the c-ELISA was more specific (87–89%) than the complement fixation in vaccinated adults and in subcutaneously vaccinated young sheep (45–66 and 78%, respectively) but not in conjunctivally vaccinated young sheep (89% for the c-ELISA versus 100% for the complement fixation). Thus, when properly standardized, the c-ELISA seems a better test than the complement fixation but the influence of the route of vaccination deserves further research.

NH (and Polysaccharide B) Tests Immunoprecipitation tests with NH or polysaccharide B are very specific when cattle are vaccinated with *B. abortus* strain 19 and can replace the complement fixation test. For optimal sensitivity (up to 92%), precipitating antibodies are detected in a reverse radial immunodiffusion (RID) system, in which the serum is allowed to diffuse in a hypertonic gel containing the polysaccharide (Díaz et al., 1979; Díaz et al., 1981), but the more simple double gel diffusion procedure is also useful (Lord et al., 1989; Pinochet et al., 1989; Fig. 19). Calves vaccinated at 3–5 months of age are negative after 2 months of vaccination, and adult cattle vaccinated 4–5 months previously with the standard dose of *B. abortus* 19 do not give positive reactions unless the animals develop vaccine infections in the mammary gland and shed the vaccine in their milk (Jones et al., 1980). In a study carried out with the sera of 1,057 cattle from infected herds in which adult vaccination was implemented, the RID test outperformed the complement fixation in specificity (80 versus 66%, respectively) and showed acceptable sensitivity (88 versus 98%, respectively) despite the fact that vaccination and infection were superimposed (Jones et al., 1980). The RID test also shows better specificity than the complement fixation test in adult and young sheep vaccinated with Rev. 1, either subcutaneously or conjunctivally (Blasco et al., 1984a; Jiménez de Bagués et al., 1992). A remarkable characteristic of the RID test is that a positive result correlates with *Brucella* shedding. In addition to the evidence mentioned above on the strain 19 shedders, this has been shown in experimentally infected cattle (Jones et al., 1980) and also in naturally infected cattle undergoing antibiotic treatment (Jiménez de Bagués et al., 1991). Thus, the combined use of rose bengal, RID and strain 19 vaccination has been proven to be useful in achieving eradication (Asarta, 1989).

The NH (and polysaccharide B) and the LPS *O*-polysaccharides are structurally very similar (Fig. 16; Response to Environmental Stress). It is thus noteworthy that whereas both antigens yield very close results when used in the i-ELISA, immunoprecipitation with smooth LPS has a much lower sensitivity than immunoprecipitation with NH (Alonso-Urmeneta et al., 1988). These differences in sensitivity can be explained by the fact that the high epitopic density and disperse state of NH (versus the bulky micelle-like state of LPS) favor its immunoprecipitation when only low titers of antibody are present. Moreover, the comparatively high threshold antibody avidity required for a positive immunoprecipitation could account for the ability of the RID with NH to discriminate infected from vaccinated animals, since it has been observed that unless udder infections develop, vaccination only transiently induces the high avidity IgG that results from an active infection (B. Alonso-Urmeneta et al., unpublished observations). Comparative studies between immunoprecipitation with NH and c-ELISA show similar sensitivity (90 and 96%, respectively) and specificity in vaccinated animals (85–100% and 87–98%, respectively; Marín et al., 1999), supporting by this manner the interpretation that the former assay detects only high avidity antibodies. It seems likely that the subtle structural and epitopic differences existing between the NH (and polysaccharide B) and the *O*-polysaccharide could contribute to the peculiar immunoprecipitating properties of the former polysaccharide. In one study in which it was com-

pared with *B. melitensis* 115 polysaccharide B, the *O*-polysaccharide obtained directly by hydrolysis of the smooth LPS of *B. abortus* strain 19 (which is poor in NH) did not produce good results (Jones et al., 1980). Although the polysaccharides obtained by acid hydrolysis of smooth virulent *B. abortus* produce satisfactory results (Cherwonogrodzky and Nielsen, 1988), these whole cell extracts contain both NH and *O*-polysaccharide, and it is not possible to determine to what extent each of these two molecules accounts for the results.

Protein Tests in Infected Animals Tests detecting antibodies to *Brucella* proteins are receiving an increased attention in the hope of improving the differential diagnosis of infected and vaccinated animals. If sensitive enough, these tests would also be very useful to avoid false positive results caused by bacteria crossreacting with smooth *Brucella* at the LPS level. Early work carried out by crossover immunoelectrophoresis showed that extracts containing a mixture of soluble proteins were promising diagnostic antigens in sheep (Trap and Gaumont, 1982). On the other hand, a gel immunodiffusion test with a purified protein (protein α-2) showed only low sensitivity (55%), even though it was highly specific (99%) in differentiating infected from vaccinated cattle (Dubray, 1984). More recently, several cloned proteins have been tested in immunoenzymatic assays. Although cattle, goats and sheep infected by smooth *Brucella* develop antibodies to group 1 (89 kDa), Omp2 (porins), Omp3a (also known as Omp25), Omp19, Omp16 and Omp10, the response is of lower intensity and frequency than that to the smooth-LPS, and these Omps used individually would have no diagnostic use (Cloeckaert et al., 1992; Letesson et al., 1997; Zygmunt et al., 1994). Cytosolic or periplasmic proteins tested include GroEL (Lin et al., 1996), Cu^{++}-Zn^{++} superoxide dismutase (Tabatabai and Hennager, 1994), and a variety of soluble proteins of 9, 15, 17, 24, 28, 32, 39, 50 and 54 kDa (Letesson et al., 1997; Salih-Alj Debbarh et al., 1995), but lumazine synthase (an 18-kDa protein; Baldi et al., 1996) and BP26 (Arese et al., 1999; Rossetti et al., 1996; Salih-Alj Debbarh et al., 1996) seem to be the most promising reagents. It seems likely that for maximal sensitivity, several of these proteins would have to be combined in a single immunoenzymatic test.

Milk Tests In dairy cattle, milk and milk serum are suitable samples either for individual diagnosis or for monitoring the status of the herd by checking pooled milk. For these purposes, the milk ring test (Table 16) was originally developed. This test uses whole milk rather than serum, has been standardized and is highly sensitive and easy to perform. Moreover, the conditions of use for testing pooled milk (i.e., sensitivity with regard to numbers of animals and total volume of sample) have been well studied (Pietz, 1977). Unfortunately, as the test depends on characteristics such as the content and type of fat in the milk, it is not applicable to small ruminants.

Several i-ELISA protocols have been evaluated as alternatives to the milk-ring test in both cattle and small ruminants. Most authors have concluded that it is an excellent test for the examination of milk from individual animals (Bercovich and Taaijke, 1990; Heck et al., 1980; Mikolon et al., 1998; Romero et al., 1995b; Thoen et al., 1979; Vanzini et al., 1998). In addition, some studies have addressed the problem of determining the conditions under which the i-ELISA could be used to detect anti-*Brucella* antibody in bulk milk. In the analysis of a large number of farms, an i-ELISA with smooth-LPS showed better sensitivity than the milk-ring test when both were applied to bulk milk (Kerkhofs et al., 1990), and the sensitivity of the assay can be improved by concentrating the antibody in the whey (Forschner et al., 1989). Poorer results have been reported by some authors possibly owing to methodological differences, but it can be concluded that when properly standardized, the i-ELISA is a suitable method for monitoring the status of herds in *Brucella*-free areas (Knosel et al., 1991).

Cell-Mediated Immunity Tests The value of the demonstration of a delayed-type hypersensitivity response for the diagnosis of animal brucellosis has been analyzed repeatedly. The test is performed by injection of a suitable protein allergen into the skin, and the demonstration of a characteristic lesion 48–72 hours later is taken as a positive result. LPS-free antigens are necessary because the *O*-polysaccharide induces an Arthus-type reaction that obscures the interpretation of the test, and the toxicity of large quantities of the LPS lipid A also induces a local reaction, which obscures (without histological examination) a true delayed-type hypersensitivity response. Most often, the antigen used is a mixture of proteins extracted with NaCl from rough *B. melitensis* 115 (brucellin or brucellergene; Bhongbhibhat et al., 1970; Jones et al., 1973), and the use of the whole cytosolic fraction or of purified proteins does not offer advantages (Blasco et al., 1994a) nor seems to improve the sensitivity (Denoel et al., 1997b). It is accepted that the skin test is less sensitive than the serological tests, but also that it may be positive in infected animals that have serologically negative responses (Nicoletti and Winter, 1990b). In a recent study per-

formed in experimentally infected cattle, a sensitivity of 78–93% was reported depending on the time lapse after infection (Saegerman et al., 1999). In a study in naturally infected sheep, the skin test showed 97% sensitivity with respect to the findings of a thorough bacteriological search, but it was also positive in many animals from which *Brucella* was not isolated (Blasco et al., 1994a). Thus, although it seems that the skin test is not reliable for detecting individually infected animals, it may be useful as a herd test. Its use does not resolve the problem of the differentiation of infected and vaccinated cattle.

Other tests that correlate with cell-mediated immunity and that have been evaluated for diagnostic purposes are the lymphocyte stimulation assays and the determination of γ-interferon (Interleukins in Brucellosis). The former tests have not been successful in distinguishing infected from vaccinated animals (Nicoletti and Winter, 1990b), and as they are expensive and technically demanding, they are not used presently. The γ-interferon assay has been evaluated preliminarily in experimentally and naturally infected heifers (Weynants et al., 1995) and reported to be more sensitive than any combination of serological tests, but its specificity has been questioned (Kittelberger et al., 1997).

Immunological Diagnosis of Infections Caused by B. ovis *and* B. canis The main differences between the tests used in the diagnosis of infections by smooth *Brucella* and *B. canis* and *B. ovis* relate to their markedly different LPS structure (Response to Environmental Stress) and outer-membrane topology. Because rough *Brucella* cells do not form stable suspensions and are prone to autoaggregate, agglutination tests produce a high proportion of false-positive results. Although this problem can be overcome in a variety of ways, the absence of the *O*-polysaccharide in the rough *Brucella* spp. comparatively reduces the importance of the antibody response to the LPS and increases that to other surface antigens. This has been clearly shown in *B. ovis* ram epididymitis where the antibody response to Omps, in particular to those of group 3 (Outer Membrane Proteins), is more intense than in the infections caused by *B. melitensis* (Riezu-Boj et al., 1990). However, neither the LPS nor the Omps by themselves are effective diagnostic antigens (Ficapal et al., 1995; Kittelberger et al., 1998; Riezu-Boj et al., 1986). This explains why serological tests for rough *Brucella* spp. are most effective when the hot-saline extract (Myers and Siniuk, 1970) is used because it is enriched in both rough LPS and group 3 Omps (Riezu-Boj et al., 1990).

A large variety of assays have been proposed for the diagnosis of *B. ovis* sheep brucellosis (reviewed by Blasco, 1990). However, only the complement fixation test, a gel immunoprecipitation assay, and some i-ELISAs have been extensively used or tested. *Brucella ovis* antigens often show anticomplementary activity, and although the effect is reduced when the hot saline or similar extracts are used, it is still significant. A sensitivity of about 90% has been estimated for the complement fixation test, similar to that found for the gel immunoprecipitation with the same antigen. The i-ELISA has been studied with respect to the antigen (purified rough LPS, hot saline extract, cytosoluble proteins) and conjugate (polyclonal of heavy and light chain IgG specificity, anti-ruminant IgG monoclonal and protein G; Ficapal et al., 1995; Marń et al., 1989b, 1998; Vigliocco et al., 1997). In addition to the demonstration that hot saline extract is the best antigen in the i-ELISA, these studies have shown that the monoclonal or protein-G based conjugates reduce the background reactivity observed with the sera of healthy animals. The sensitivity of the i-ELISA has been found to be superior (Cho and Niilo, 1987; Spencer and Burgess, 1984) or equal to that of the gel immunoprecipitation or complement fixation, and there are no objective reasons to use these methods instead of the classical tests. However, since hot saline extracts are obtained in low yields and the i-ELISA uses much less antigen, it could be more practical. *Brucella melitensis* Rev. 1 is used to vaccinate sheep against both *B. melitensis* and *B. ovis* (Vaccines and Vaccination), and it elicits a strong antibody response to the *O*-polysaccharide, interfering in the smooth LPS tests. Moreover, it also elicits antibodies to the core and lipid A sections of the LPS, and these antibodies interfere in the serological tests for the diagnosis of *B. ovis*, owing to the shared epitopes of the inner LPS sections of *B. melitensis* and *B. ovis* (The Lipooligosaccharide of Rough *Brucella* Species). This interference is reduced in the case of the complement fixation and gel immunoprecipitation tests (Blasco, 1990) and more importantly in the i-ELISA, and this is probably due to the favorable exposure of the common epitopes after adsorption to polystyrene (Marń et al., 1998).

The immunological diagnosis of *B. canis* infections has been less investigated, and existing tests may provide a large proportion of false-negative and false-positive results. In experimentally infected dogs, blood cultures were positive several weeks before a positive result was obtained in any of the agglutination and gel immunoprecipitation tests available (Carmichael et al., 1984). False-positive results relate to the nature of the antigens, since the preparation of bacterial suspensions efficient in agglutination tests is even more difficult than in the case of *B. ovis*.

Brucella canis almost always produces mucoid colonies on standard media and bacteria strongly autoaggregate at pH below neutrality, a problem also existing with the hot saline extracts obtained from mucoid bacteria (Carmichael, 1990). The problem is partially solved using growth media and buffers at pH 7.4, and *B. ovis* and a nonmucoid *B. canis* variant have been used in an attempt to develop suitable agglutination tests (Carmichael, 1990). Moreover, it has been shown that a brief treatment with β-mercaptoethanol reduces the number of false-positive results. However, even under the best conditions, the demonstration of a specific immunological agglutination using *B. ovis* and *B. canis* cell suspensions is not obvious and requires some training (Carmichael and Shin, 1996). Agglutination can be examined in tubes by the serum dilution method or in a rapid slide test, and the interpretation has to take into account the possibility (25–50%) of a false-positive result. On the other hand, the test is accurate in identifying noninfected dogs when a negative result persists after several bleedings.

As an alternative to agglutination tests, gel immunoprecipitation has been investigated. When used in this assay, hot saline or sodium deoxycholate extracts suffer from the same problems of nonspecific reactions as do agglutination tests. On the other hand, cytoplasmic protein antigens do not produce false~~ne~~gative results and the method is considered to be highly accurate in detecting antibodies. Antibodies to proteins develop late after infection, and the sensitivity is low during the first months. However, these antibodies persist in chronically infected dogs at times when the other serological tests may have become negative (Carmichael et al., 1984).

Immunological Diagnosis of Brucellosis and Cross-Reacting Bacteria Smooth-LPS tests are susceptible to yield false-positive results when infections by Gram-negative bacteria with perosamine-containing *O*-polysaccharides occur (Table 6). But for those due to *Y. enterocolitica* O:9, crossreactivities are mild, and none is a significant problem in the diagnosis of human brucellosis when the clinical symptoms and the results of the anamnesis are considered. Indeed, in addition to some of the serological tests discussed in the following paragraphs, blood cultures are 100% specific. On the other hand, *Y. enterocolitica* O:9 infections in cattle can be troublesome, particularly in countries free from *B. abortus*, since the sporadic appearance of positive serological results among unvaccinated populations calls for an immediate differential diagnosis. Although orally acquired *Y. enterocolitica* O:9 seldom induces high levels of antibodies to smooth *Brucella* LPS and the responses are transient in cattle (Garin-Bastuji et al., 1999; Kittelberger et al., 1997; Mittal et al., 1985), titers in blood serum and milk may be higher and persistent when mammary infections occur (Mittal et al., 1985). The problem can also be a significant one in swine (Wrathall et al., 1993). So far, three different approaches have been followed to develop differential tests.

The demonstration of antibodies specific for the enterobacterial common antigen (Mittal et al., 1980b), *Y. enterocolitica* flagellar antigens (Mittal and Tizard, 1979) and *Yersinia* outer proteins (yops; Kittelberger et al., 1995b; Weynants et al., 1996a; Weynants et al., 1996b; Yersinia) has been proposed to identify with precision those cases suspected of *Y. enterocolitica* O:9 infection. However, antibodies to antigens shared by enteric bacteria are not uncommon in healthy cattle and titers of anti-flagella antibody are weak possibly because *Y. enterocolitica* is nonmotile at the host body temperature. Moreover, dual infections by *Yersinia* and *Brucella* do not seem uncommon in livestock, and this reduces the usefulness of the yops (Kittelberger et al., 1995b; Mittal and Tizard, 1980a). On the other hand, yops have been found clearly useful for the differential diagnosis in humans (Schoerner et al., 1990).

An alternative approach is based on the small differences existing between the LPS of *Y. enterocolitica* O:9 and smooth *Brucella* spp. at *O*-polysaccharide (Response to Environmental Stress) and core oligosaccharide levels. Early reports suggest that whereas the antigenic determinants involved in the crossreaction are resistant to periodate oxidation and borohydride reduction, the determinants specific for *Y. enterocolitica* O:9 LPS are sensitive and on this basis an i-ELISA with both treated and untreated LPS was proposed for the differential diagnosis of human infections (Lindberg et al., 1982). The differences at LPS level were also noted in competitive immunoassays (Granfors et al., 1981). Based on the results of experimental infections in cattle, the c-ELISA has been proposed as a specific diagnostic test that is able to discriminate antibody elicited by *Y. enterocolitica* O:9 (Nielsen, 1990a). A c-ELISA with a monoclonal antibody to the C/B epitope (shared by smooth *Brucella* spp. and absent from *Y. enterocolitica* O:9) has been tested with field bovine sera and found to improve the specificity of the rose bengal and complement fixation up to 70% (Weynants et al., 1996b; Weynants et al., 1996a).

Immunological crossreactivities with proteins of taxonomically unrelated bacteria seem limited to some highly conserved proteins, such as heat shock protein-65 (Dáz and Bosseray, 1974; Spencer et al., 1994). On the other hand, they

are extensive with the proteins of taxonomically related bacteria, but although they can be shown with sera from naturally infected hosts (Drancourt et al., 1997; Velasco et al., 1997), they do not seem to represent a relevant source of nonspecificity (Velasco et al., 1997) and can be easily discriminated by using smooth LPS tests. Thus, *Brucella* protein antigens are perhaps the most useful antigens for the differential diagnosis of brucellosis and yersiniosis. Although they have been used in some antibody (Baldi et al., 1996) and lymphocyte blastogenesis tests (Chukwu, 1987), the skin test with proteins saline extracted from rough *B. melitensis* 115 (brucellin or brucellergene; Bhongbhibhat et al., 1970; Jones et al., 1973) is very useful and relatively simple to implement (Chukwu, 1987; Saegerman et al., 1999). There are contradictory reports on the value of the γ-interferon in the differential diagnosis of brucellosis and yersiniosis in cattle (Kittelberger et al., 1997; Weynants et al., 1995).

Treatment

The ability of *Brucella* organisms to replicate within cell vacuoles is a determining factor in the chronic course of the disease and in the tendency to relapse. Within the intracellular niche, *Brucella* organisms are protected from a large number of antibiotics that cannot reach the intracellular milieu. Therefore, an appropriate therapy must use antibiotics capable of killing both extracellular and intracellular *Brucella* organisms (Ariza, 1999). Unfortunately, not a single antibiotic therapy achieves complete eradication of intracellular infection. In this respect, synergistic or additive effect by the use of two or more antibiotics for prolonged periods is required to cure and to reduce the frequency of relapses (Fig. 40). The possibility of enhancing the effectiveness of antibiotics showing good in vitro activity by including them into liposomes has been studied by several authors (Dees and Schultz, 1990; Vitas et al., 1997), but attempts to use some of these formulations in animals have been discouraging (Nicoletti et al., 1989). The development of antibiotic resistance by *Brucella* has never been demonstrated. For instance, the susceptibility of strains from human patients with relapses remains identical to that of strains isolated during the initial episode (Ariza et al., 1986); similarly, *Brucella* strains isolated from animals that did not clear the infection after the first antibiotic therapy show the same antibiotic susceptibility as that of the first isolates (Guerra and Nicoletti, 1986). The absence of plasmids (Genome Evolution) should be an important factor explaining, at least in part, the observation that the in vitro susceptibility of *Brucella* strains to antibiotics remains stable over time (Bosch et al., 1986).

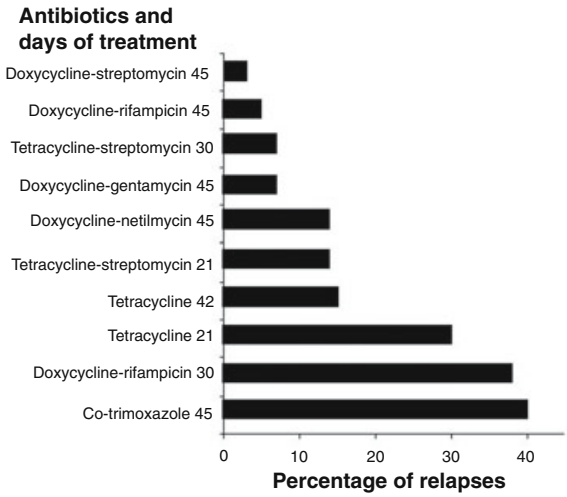

Fig. 40. Relapse rate after antibiotic therapy of human brucellosis. Patients, naturally infected with *Brucella* organisms, were treated with a combination of antibiotics for different periods (indicated on the vertical axis). The period between the end of treatment and relapse and the percentage of relapses were registered, accordingly. Bars indicate average values. Standard error was less than 10% in all cases, except in doxycycline plus rifampicin treatment for 45 days in which standard error was close to 30%. Dr. Javier Ariza, from the Infectious Disease Service, Hospital De Bellvitge, Barcelona, Spain, supplied this information.

Human Brucellosis The antibiotic treatment of human brucellosis has been recently reviewed (Ariza, 1999), and only the most significant facts are summarized here. Since there is no antibiotic therapy effective in the totality of human cases, a careful follow-up of the patients is important.

It is an established fact that tetracyclines are the most effective antibiotics in the treatment of brucellosis but also that by themselves they are not satisfactory and result in high rates (from 15–30%, depending on the duration of the treatment) of relapses. Monotherapy with other antibiotics, such as aminoglycosides, rifampicin, azithromycin, co-trimoxazol, or second generation fluoroquinolones has produced unsatisfactory results in laboratory models, human patients or both. Presently, a prolonged tetracycline-aminoglycoside combination (doxycycline 100 mg twice/day for 45 days and streptomycin 1 g/day [or 750 mg in patients older than 50 years] for 14 days) is the best treatment of the disease as judged by the comparatively low (3–5%) rates of relapse. Although aminoglycosides have low intracellular penetration, their synergy with tetracyclines is well established,

and in most cases, their effectiveness in this combination offsets the problems (parenteral administration and ototoxicity). Some aminoglycosides such as gentamycin have better in vitro activity against *Brucella* and show lower toxicity, and they are currently recommended as streptomycin substitutes. Because of its better tolerance, doxycycline is the tetracycline used. It has to be emphasized that the duration of the treatment with both antibiotics is essential to obtain the best results.

As an alternative to aminoglycosides, rifampicin can be used (900 mg in a single morning dose) along with doxycycline, both administered during 45 days. Although this treatment has no side effects and is better tolerated by the patient, its effectiveness is less than that of the doxycycline-aminoglycoside combination (the rate of relapses can be as high as 15%). It is, however, the therapy of choice when infections by *B. melitensis* Rev. 1 (Vaccines and Vaccination) occur or are suspected (Blasco and Díaz, 1993a). This sort of infection occurs most often in veterinarians and farmers, and there are also reports of accidental inhalation in vaccine-producing plants. In these cases, it is recommended that bacterial cultures be performed and the isolate typified or at least tested for streptomycin resistance.

Brucellosis in pregnant women and in children less than seven years old requires a different therapy because of the side effects of the antibiotics of the standard treatment. There is no established optimal therapy, but rifampicin for 8 weeks in the first case and rifampicin for 4–6 weeks plus gentamycin for the first 7–10 days in children are recommended. Recent reports suggest that gentamycin is less effective than streptomycin in children (Issa and Jamal, 2000). *Brucella* endocarditis is a dangerous form of the disease that also calls for a special treatment to ensure clearance of the infection. Doxycycline plus gentamycin, both for 3 weeks, plus rifampicin for at least 8 weeks is recommended.

Accidental inoculation or exposure to virulent *Brucella* in the diagnostic and research laboratories calls for a prophylactic antibiotic therapy. For this purpose, doxycycline alone is effective provided the treatment starts immediately. Although the duration of this treatment has not been determined, it is generally considered that the standard dose (doxycycline 100 mg twice/day) for 7–10 days is effective in preventing the development of the disease.

Animal Brucellosis Antibiotics have been rarely employed in animal brucellosis but they have been applied in some cases to treat animals of high genetic value or to prevent spreading of the disease in small dairy herds of highly valuable animals.

In cattle, monotherapy with either oxytetracycline or free or liposomal streptomycin (Nicoletti et al., 1985; Nicoletti et al., 1989) is very unsatisfactory. The combination of long-acting oxytetracycline (for example, 20 mg/kg administered intramuscularly every 3 days for 21 days) and streptomycin or dihydostreptomycin (for example 20 mg/kg administered intramuscularly daily for 10 days) is successful in eliminating milk shedding of *B. abortus* in 55–71% of treated animals (Jiménez de Bagüés et al., 1991; Milward et al., 1984; Nicoletti et al., 1985; Nicoletti et al., 1989). A more prolonged treatment (14 oxytetracycline and 8 streptomycin doses) accompanied by intramammary infusion with oxytetracycline for 4 days is reported to have a 100% rate of success (Radwan et al., 1993). In the noncured animals, the oxytetracycline and streptomycin therapy reduces the number of bacteria in milk or in tissues after necropsy (Jiménez de Bagüés et al., 1991; Milward et al., 1984; Nicoletti et al., 1985; Nicoletti et al., 1989) and when combined with adult vaccination with *B. abortus* 19, allows for control of the disease without eliminating the infected animals (Jiménez de Bagüés et al., 1991).

Antibiotic therapy also has been used in infections caused by *B. ovis* in rams. Like in human or cattle brucellosis, streptomycin or tetracyclines by themselves are not successful (Kuppuswamy, 1954; Marín et al., 1989a). On the other hand, combinations of aureomycin plus streptomycin (Kuppuswamy, 1954) or tetracyclines plus streptomycin have produced satisfactory results (Giauffret and Sanchis, 1974; Marín et al., 1989a). However, successful antibiotic therapy does not result in a clearance of the lesions characteristic of this disease (Marín et al., 1989a), and semen quality after treatment is reported to be poor (Kuppuswamy, 1954). Brucellosis in horses is quite severe and prolonged treatments are required. A mixture of oxytetracycline (20 mg/kg) and streptomycin (15 mg/kg) for at least 21 days is recommended.

Applications

Similarly to other intracellular parasites such as *Mycobacterium* species, *Brucella* organisms and their products have been used as adjuvants, antitumoral agents, antiviral components and immunological tools as well as vectors for delivering foreign antigens. In addition, most of the *Brucella* species are primary pathogens capable of infecting healthy hosts and in consequence candidates to be used as biological weapons.

Brucella Vaccines as Vectors for Delivering Foreign Antigens

Live bacterial vaccines are scarce and rather exceptional among useful vaccines. *Mycobacterium* BCG and attenuated *Brucella* vaccines developed more than 70 years ago are among the accepted vaccines currently in use. *Brucella* vaccines, such as *B. abortus* strain 19, *B. melitensis* Rev. 1 and *B. abortus* RB51, are the best known vaccines used in many countries for the control and eradication of bovine, caprine and ovine brucellosis. In contrast to the attenuated mycobacterial vaccine, the efficacy of which in open populations is controversial, *Brucella* vaccines have been efficiently used for many years (Vaccines and Vaccination). This recognized status makes *Brucella* vaccines good vector candidates for the expression and delivery of foreign antigens (Comerci et al., 1998; Vemulapalli et al., 2000). *Brucella abortus* strain 19 recombinant vaccine expressing a reporter repetitive protein of *Trypanosoma cruzi* induces good antibody responses against the alien protein in mice. In vitro and in vivo expression of this repetitive *Trypanosoma* antigen does not alter the *Brucella* growth pattern, nor does it generate a toxic lethal effect in the bacterium. Similarly, rough *B. abortus* RB51 vaccine has been used to express *Mycobacterium* heat shock protein 65. The foreign mycobacterial protein expressed in this vector vaccine induces a typical Th1-type immune response in mice, as indicated by the presence of IgG_2 and INFγ, without the production of IgG_1 or the secretion of IL^{-4}. The immunogenic properties and growth conditions of this recombinant vector *B. abortus* RB51 remain without change as compared to the parental strain.

The rationale for using *Brucella* vaccines as vectors for delivering foreign antigens is based on the assumption that these attenuated intracellular bacteria could successfully deliver antigens inside antigen-presenting cells (Splitter and Everlith, 1986; Splitter and Everlith, 1989). Since attenuated *Brucella* organisms follow the endocytic pathway (Escaping from the Endocytic Pathway), the prediction is that antigens delivered by this manner will follow the appropriate antigen processing route necessary for eliciting an efficient and protective immune response against foreign antigens. An important prediction would be that the expression of foreign antigens does not exclude the immune response to *Brucella*. In this respect, a double purpose vaccine would be developed.

Antitumoral and Antiviral Activity of *Brucella* Cells and Their Fractions

Live and killed bacteria and subcellular *Brucella* fractions have been used experimentally as antitumoral reagents in mice and humans (Chirigos et al., 1978; Dazord et al., 1980; Dazord et al., 1984; Schultz et al., 1978). Trials have demonstrated that live *Brucella* vaccines, killed bacterins or insoluble cellular extracts (mainly containing peptidoglycan, outer-membrane fractions and ribosomes) are capable of inducing the reduction of tumoral masses without causing unfavorable reactions. Although insoluble *Brucella* extracts exert antitumoral activity, better results are achieved when irradiated tumor cells and *Brucella* extracts are administered at the same time. The antitumoral activity mediated by *Brucella* vaccines can be understood within the context of the Mackaness effect (T Cell Responses), in which transitional acquired cellular resistance against invaders (e.g., cancer cells) could be nonspecifically induced by *Brucella* organisms or other intracellular parasites, such as *Mycobacterium*.

The logic behind the use of *Brucella*-human immunodeficiency virus (HIV) protein conjugates as vaccines is based on the property that *Brucella* bacterins have to behave as T-independent antigens (Antibody Response), which is a strategy to bypass the requirement for CD_4^+ cells in the antibody response of AIDS patients (Golding et al., 1995; Lapham et al., 1996). Killed *Brucella* bacterins conjugated with gp120 or V3 loop peptide derived from HIV induce neutralizing antibodies against HIV. *Brucella*-HIV protein conjugates mainly generate IgG_{2a} primary and secondary responses in mice, even after CD_4^+ depletion. This type of response also has been observed with other foreign "academic" antigens conjugated to *Brucella*, such as trinitrophenyl, indicating that it is a general behavior of *Brucella* bacterins (Sacks and Kilnman, 1997). Sera from mice immunized with *Brucella*-gp120 display more potent anti-HIV activity than sera from mice immunized with the *Brucella*-V3 loop peptide. In addition, killed *B. abortus* stimulates Th1-type immunity with the production of INFγ and generation of virus-specific cytotoxic T-lymphocyte response in both normal and CD_4^+-depleted mice. In addition to the T-independent properties of *Brucella* bacterin (Antibody Response), the antibody and T cell cytotoxic responses are linked to the adjuvant effect displayed by *Brucella* cells (*Brucella* Bacterins and Envelope Molecules as Adjuvants). *Brucella* also promotes the secretion of other cytokines, such as IL-12, a molecule that acts synergistically with IL-2 to induce Th1 activation and differentiation of cytotoxic cells (Huang et al., 1999). Of course, the low endotoxic activity displayed by *Brucella* LPS (Moreno et al., 1981; Rasool, 1992) is a factor that may favor the use of *Brucella* bacterin-conjugates as adjuvants.

Brucella Bacterins and Envelope Molecules as Adjuvants

In contrast to enterobacterial LPS, *Brucella* LPS behaves as a T-independent type 1 carrier that stimulates the production of high levels of IgG_2 and moderate levels of IgM in the endotoxin-resistant C3H/HeJ mice strain (Moreno and Berman, 1979; Moreno et al., 1984b; Kurtz and Berman, 1986). The primary and even the stronger secondary responses induced by the *Brucella* LPS adjuvant activity could occur without the assistance of T cells. By taking advantage of these properties, together with the low endotoxicity displayed by *Brucella* LPS (Moreno et al., 1981; Rasool, 1992), this molecule has been used as an adjuvant in foot-and-mouth disease, for enhancing the immune response against the virus (Berinstein et al., 1993; Betts et al., 1993), and to potentiate antibody production against snake venom toxins (Rucavado et al., 1996) and has been proposed as an adjuvant for HIV vaccines (Goldstein et al., 1992).

Murein-rich insoluble fractions have been experimentally used as adjuvant for generating antibodies against a variety of antigens, with variable success (Galdiero, 1995; Serre, 1982). It has been observed that these fractions induce quantitative and qualitative changes in the T and B lymphocyte population in mice, mainly with an initial increase of CD_4^+ and B cells, followed by an increase of CD_8^+ lymphocytes and a concomitant decrease of CD_4^+ and B cells.

Brucella Bacterins and Lipopolysaccharide as Immunological Tools

Brucella cells bind to human B cells and to certain leukemic cells of B origin, forming rosettes (Lee et al., 1983; Teodorescu et al., 1977). This quality has been used for diagnostic purposes in the differentiation of leukemic cells. The *Brucella* B cell receptor has been associated with the LPS, since the M serotype is more prone than the A serotype to bind to B lymphocytes (Fig. 15; O-polysaccharide). *Brucella* LPS and trinitrophenylated-*Brucella* bacterin have been extensively used as T-independent antigens in immunological studies (Betts et al., 1993; Moreno et al., 1984b; Kurtz et al., 1986; Rennick et al., 1983; Tenay and Strober, 1985). Moreover, trinitrophenylated-*Brucella* bacterin has been regarded as one of the classical T-independent type-1 antigens and used as an academic model for demonstrating this type of antibody response dependent on B lymphocytes.

Brucella as a Biological Weapon

Brucella species, particularly *B. melitensis* and *B. suis*, are potential agents of biological warfare. There are several properties that make these bacteria good candidates as biological weapons (Anonymous, 2000; Kaufmann et al., 1997). The main one is that members of the genus are primary pathogens inducing a debilitating and incapacitating severe disease that requires expensive and long-term treatment. It has been estimated that less than five bacteria of *B. melitensis* 16M are necessary to infect one human being. Alertness to suspected cases of biological terrorism with *B. melitensis* and investigations leading to integrated clinical, public health, and law enforcement against biological terrorism with *Brucella* strains have taken place in the United States. A model that compares the impact of *Brucella* melitensis released as aerosols in suburbs of a major city has been developed in this country. The model demonstrated that the economic impact of a bioterrorist attack in a populated area with *B. melitensis* could be close to $500 million per 100,000 persons. The model takes into account preventive measures, including rapid implementation of a post-attack prophylaxis program.

CHAPTER 3.1.17

Introduction to the Rickettsiales and Other Intracellular Prokaryotes

DAVID N. FREDRICKS

Introduction

In the past, any small bacterium that required an intracellular environment for growth could be classified as belonging to the order Rickettsiales (Moulder, 1974). It is now clear that bacteria from diverse phylogenetic groups have adopted the intracellular niche, an example of convergent evolution. Most eukaryotic cells have defenses that prevent prokaryotes from invading and establishing a parasitic existence. Once these defenses are breached, however, an intracellular existence has many advantages for the suitably adapted bacterium. Within a host cell, bacteria are free from competition with most other microbes and benefit from host defenses directed against external threats. Intracellular bacteria may have access to host substrates and enzymes for metabolism. Host behaviors, such as blood feeding in insects or locomotion in vertebrate hosts, may aid the spread of intracellular bacteria. Therefore, it should not be surprising that bacteria from different phylogenetic groups have evolved to take advantage of intracellular life in eukaryotic cells.

In this chapter, bacteria are organized into groups based primarily on phylogenetic inferences made from analysis of their 16S rRNA sequences (Fig. 1). Although criticized in some quarters (Pennisi, 1998), the use of 16S rRNA genes for inferring evolutionary relationships among bacteria has proven very reliable, though small subunit rRNA phylogeny may not resolve evolutionary relationships among organisms in the deepest branches of the tree of life (Woese, 2000). There is the potential for misclassification of organisms when one relies on a single gene for phylogenetic analysis. Gene insertions, deletions and transfers between organisms are possible (Nelson et al., 1999; Yap et al., 1999). However, the phylogenetic relationships suggested by analysis of 16S rRNA genes tend to be supported by phylogenetic analysis of other genes (Pace, 1997).

Bacteria that form a monophyletic group with the classical rickettsiae based on phylogenetic analysis of 16S rRNA gene sequences are listed here as belonging to the Rickettsiales. Other intracellular bacteria that have been classified traditionally as belonging to the Rickettsiales but do not cluster with this group of bacteria based on 16S rRNA analysis are listed under the Rickettsia-like prokaryotes. Figure 2 is a detailed phylogenetic tree of the bacteria described in this chapter, based on analysis of 16S rRNA. The role bacteria may play as endosymbionts of eukaryotic cells is illustrated with some examples, and the endosymbiotic hypothesis for the origin of mitochondria is discussed.

The Rickettsiales

The Rickettsiales can be organized into five major genogroups based on 16S rRNA phylogeny. These groups consist of the Rickettsiae, Ehrlichiae, Neorickettsiae, Wolbachiae and Holosporae. These bacteria form a monophyletic group within the α-proteobacteria. The traditional classification scheme for the Rickettsiales is listed in Table 1, as described in *Bergey's Manual of Systematic Bacteriology* (Weiss and Moulder, 1984). This chapter does not use the traditional classification scheme of families and tribes listed in Table 1 because the molecular phylogeny of these bacteria is at odds with that organizational structure.

The Rickettsia Group

The rickettsiae are small (0.3–0.5 × 0.8–2.0 μm), Gram-negative, aerobic, coccobacillary organisms that are obligate intracellular parasites (Saah, 2000a). They reside free in the cytoplasm or nucleus of eukaryotic cells where they divide by binary fission and metabolize glutamate via the citric acid cycle (Weiss and Moulder, 1984). They have cell walls but no flagella. The rickettsia have been propagated in the laboratory by cocultivation with eukaryotic cells, but have not been propagated using axenic media. These bacteria frequently have a close relationship with arthropod vectors that may transmit the

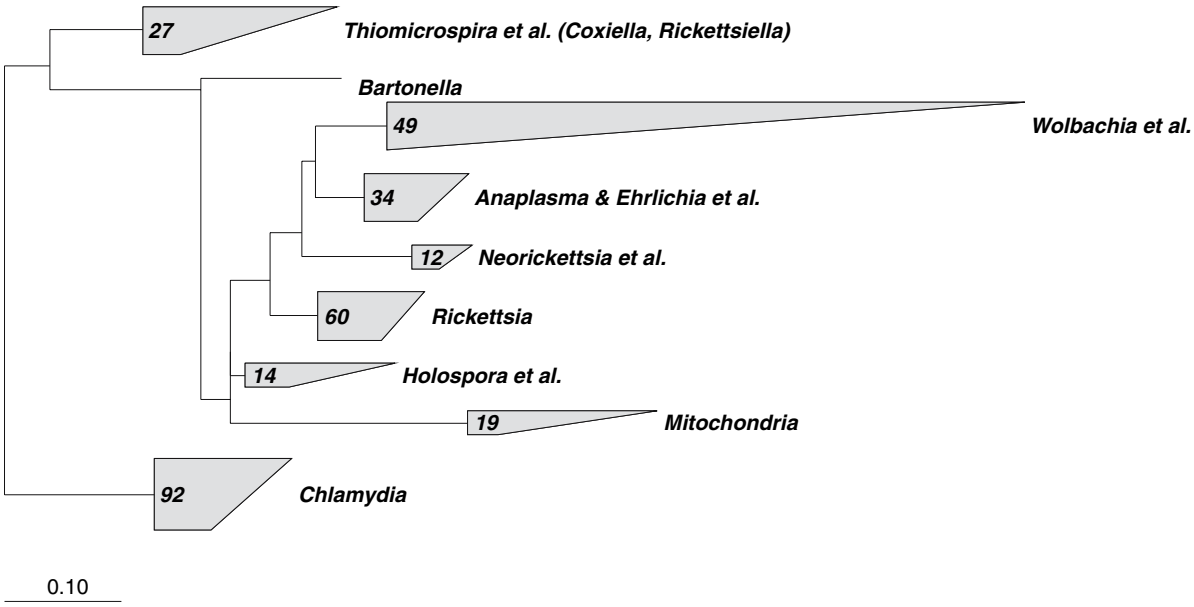

Fig. 1. Phylogentic tree containing the Rickettsiales and related intracellular bacteria as inferred from 16S rRNA sequence data. This tree shows the evolutionary relationships of the major bacterial groups to each other (http://www.arb-home.de, Technical University, Munich, Germany).

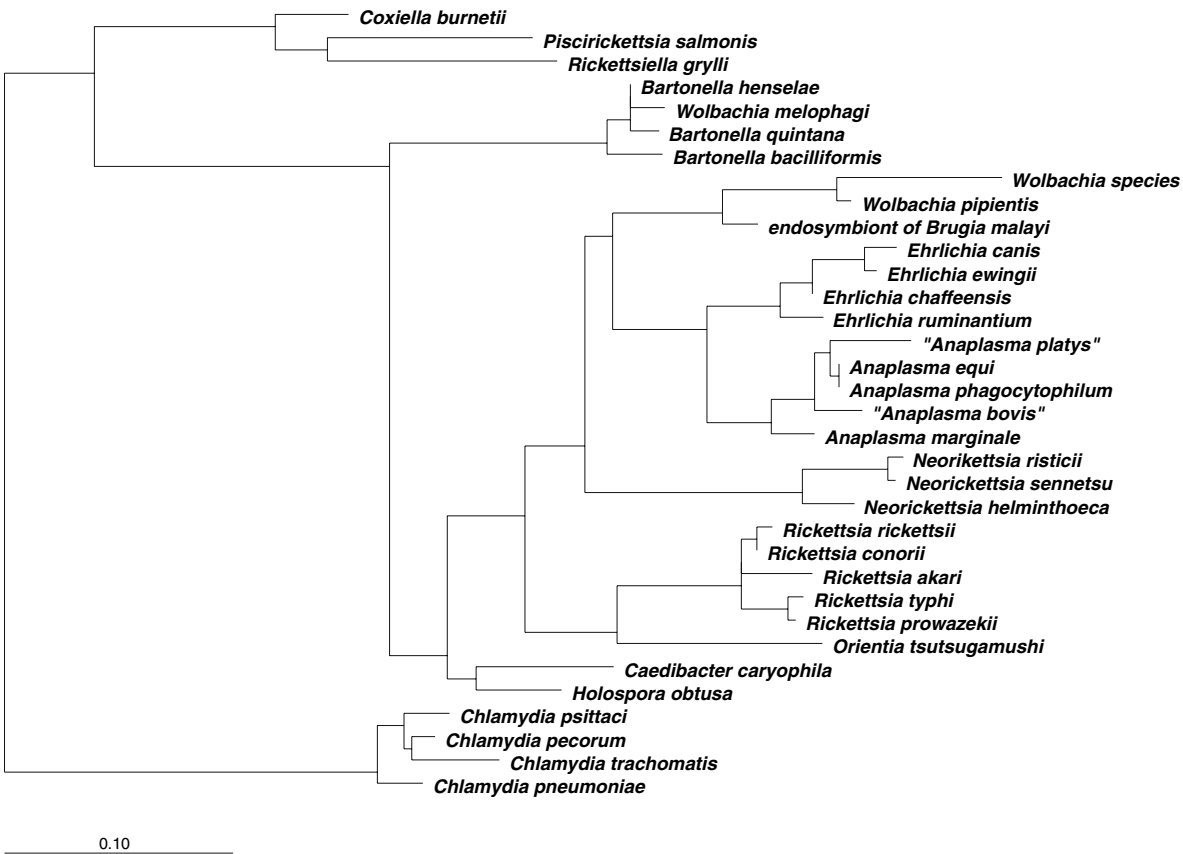

Fig. 2. A detailed phylogentic tree of selected intracellular bacteria as inferred from 16S rRNA sequence data. The bar represents 0.1 nucleotide substitutions per position and is a measure of evolutionary distance (http://www.arb-home.de, Technical University, Munich, Germany).

Table 1. The traditional classification scheme for the order Rickettsiales as described in *Bergey's Manual*.

Order	Family	Tribe	Genera
Rickettsiales	Rickettsiaceae	Rickettsieae	*Rickettsia*

			Coxiella
		Ehrlicheae	*Ehrlichia*
			Cowdria
			Neorickettsia
		Wolbachieae	*Wolbachia*
			Rickettsiella
	Bartonellaceae		*Bartonella*
			Grahamella
	Anaplasmataceae		*Anaplasma*
			Aegyptianella
			Haemobartonella
			Eperythrozoon

organism to mammalian hosts. The rickettsiae have very small genomes of about 1.0–1.5 million bases. The true rickettsiae can be subdivided into three major groups (spotted fever, typhus and scrub typhus groups) based on clinical characteristics of disease and phylogenetic relationships (Weisburg et al., 1989; Tamura et al., 1991).

Spotted Fever Group *Rickettsia rickettsii* is the cause of Rocky Mountain spotted fever (RMSF) and the prototypical bacterium in the spotted fever group of rickettsiae (McDade and Newhouse, 1986). This bacterium is found in the Americas and is transmitted to humans through the bite of infected ticks. *Rickettsia rickettsii* infects human vascular endothelial cells, producing a vasculitis. The possibility of RMSF should be considered in patients from endemic areas presenting with fever, headache, and a rash, particularly during the summer and late spring. The rash tends to start on wrists and ankles and spreads centripetally (Walker and Raoult, 2000b).

Other spotted fever group rickettsiae that produce human rickettsioses include *R. conorii*, *R. mongolotimonae* and *R. slovaca* (bouteonneuse fever and similar illnesses), *R. akari* (rickettsial pox), *R. japonica* (Japanese spotted fever), *R. sibirica* (North Asian tick typhus), *R. africae* (African tick bite fever), *R. helvetica* (perimyocarditis), *R. australis* (Queensland tick typhus) and *R. honei* (Flinders Island spotted fever; Raoult et al., 1997; Fournier et al., 2000a; Fournier et al., 2000b; Nilsson et al., 1999). The spotted fever rickettsiae have been found on every continent except Antarctica. Other spotted fever group rickettsiae, including *R. montana*, *R. rhipicephali*, *R. parkeri*, *R. massiliae* and *R. aeschlimannii*, have been detected in ticks, but have not been clearly linked to human disease (Walker and Raoult, 2000b).

Typhus Group *Rickettsia prowazekii* is the cause of epidemic or louse-borne typhus and is the prototypical bacterium from the typhus group of rickettsiae (Saah, 2000c). Like other members of the rickettsiae, *R. prowazekii* infects human vascular endothelial cells, producing widespread vasculitis. In contrast to RMSF, louse-borne typhus tends to occur in the winter, with the rash starting in the axillary folds and spreading centrifugally. Infection usually is transmitted from person to person by the body louse and, therefore, tends to manifest under conditions of crowding and poor hygiene. The southern flying squirrel appears to be a reservoir in the United States, but the vector involved in transmission from the flying squirrel to humans is currently unknown. The disease has a worldwide distribution. Latent human infection may occur with subsequent reactivation disease (Brill-Zinsser disease).

Other rickettsiae in the typhus group include *R. typhi* and *R. felis*. Murine typhus is caused by transmission of *R. typhi* from rats, cats and opossums to humans via a flea vector (Dumler and Walker, 2000). Murine typhus is found worldwide and is endemic to areas of Texas and southern California in the United States. *Rickettsia typhi* infects the gut epithelium and sometimes the reproductive tissues of the flea vector. Murine typhus manifests as a nonspecific febrile illness; rash occurs in only about 50% of patients, usually as a late finding. Although *R. felis* is phylogenetically more closely related to the spotted fever group of rickettsiae than to the typhus group, it shares antigens with *R. typhi* and produces a murine typhus-like illness. *Rickettsia felis* has been detected in cat fleas and opossums (Higgins et al., 1996).

Scrub Typhus Group *Orientia tsutsugamushi* is the cause of scrub typhus. Originally called *Rick-*

ettsia tsutsugamushi, this organism was given its own genus designation because it is phylogenetically distinct from the other rickettsiae, though closely related (Tamura et al., 1995). This bacterium has a thicker outer leaflet to its cell wall and a minimal outer slime layer, in contrast to the situation with the other genogroups of rickettsia (Weiss and Moulder, 1984). *Orientia tsutsugamushi* is transmitted to humans by the bite of trombiculid mites (chiggers), which are the vector and host (Saah, 2000b). Scrub typhus occurs throughout much of Asia and Australia. The clinical presentation of scrub typhus is a nonspecific febrile illness with headache and myalgias. An inoculation eschar and/or lymphadenopathy are helpful clues in its diagnosis.

The Ehrlichia Group

The ehrlichia are small, Gram-negative, pleomorphic bacteria. They can be divided into several groups based on 16S rRNA phylogeny, ultrastructural features of infected cells, and pathological features of disease (Walker and Dumler, 2000a). The bacteria *Ehrlichia risticii* and *Ehrlichia sennetsu* have been designated as ehrlichiae, but it is clear from the phylogeny of these organisms that they form a distinct group with *Neorickettsia helminthoeca* and belong in a different but related genus (Pretzman et al., 1995; Popov et al., 1998). In this chapter, *Ehrlichia risticii* and *Ehrlichia sennetsu* are classified as neorickettsiae (next section) while awaiting further taxonomic designation. The ehrlichiae are obligate intracellular bacteria. Like chlamydiae, they exist in membrane-bound vacuoles within the cytoplasm of eukaryotic cells. Bacteria are only 0.5–1.0 μm in diameter, but can be visualized by light microscopy when they form groups of bacterial cells within vacuoles, called "morulae." The ultrastructure of morulae formed by each genogroup of ehrlichia is distinct (Popov et al., 1998).

THE *E. CHAFFEENSIS-E. CANIS* GROUP The true ehrlichiae form two distinct phylogenetic clusters or genogroups of organisms. One cluster includes the agent of human monocytic ehrlichiosis (HME), *E. chaffeensis*, as well as *E. canis*, *E. ewingii* and *E. muris*. Widely found in the United States, HME is a vector-borne zoonosis transmitted by ticks of the Amblyomma and Dermacentor genus. Dogs and deer appear to be natural reservoirs of infection. *Ehrlichia chaffeensis* parasitizes circulating and tissue-bound macrophages. Unlike rickettsiae, ehrlichiae do not infect human endothelial cells or produce a vasculitis. The clinical presentation of HME is similar to RMSF. However, HME differs from RMSF in that a rash is found in less than half of HME cases, leukopenia may be present, and intracytoplasmic morulae occasionally may be detected on peripheral blood smear. Patients with HME may have multiple abnormalities evident on blood chemistry and hematology tests (Walker and Dumler, 2000a).

Ehrlichia canis and *E. ewingii* are closely related to *E. Chaffeensis*. Both bacteria have been reported to cause disease in humans but are primarily canine pathogens (Buller et al., 1999). *Ehrlichia canis* infects macrophages in dogs, whereas *E. ewingii* infects granulocytes in dogs. *Ehrlichia muris* is another ehrlichia that clusters phylogenetically with this group, and it has been found in Japanese mice (Kawahara et al., 1993). Ticks transmit all of these bacteria.

Cowdria ruminantium is an obligate intracellular bacterium that is the cause of heartwater disease, an illness of African and Caribbean ruminants. This bacterium is found within vacuoles in the cytoplasm of host endothelial cells (Moulder, 1974). Ticks of the Amblyomma genus transmit *C. ruminantium*. Phylogenetically, *C. ruminantium* falls within the *E. Chaffeensis-E. Canis* group of ehrlichiae and probably should be renamed *Ehrlichia ruminantium* (Pretzman et al., 1995).

THE *E. PHAGOCYTOPHILA-E. EQUI* GROUP Another genogroup of the true ehrlichiae includes the agent of human granulocytic ehrlichiosis (HGE), which appears similar or identical to *E. equi* and *E. phagocytophila* (Walker and Dumler, 2000a). The agent of HGE is transmitted to humans by ticks of the Ixodes genus and has been described in the United States and Europe. Small mammals, such as the white-footed mouse, appear to be major reservoirs of this bacterium. *Ehrlichia equi* causes equine granulocytic ehrlichiosis in horses in the United States (Bullock et al., 2000). The clinical presentation of HGE is again similar to that of RMSF, except less than 10% of patients have a rash. As with HME, patients with HGE may have laboratory test abnormalities including thrombocytopenia, leukopenia and elevated serum levels of hepatic enzymes. Patients with HGE frequently have visible morulae in circulating granulocytes, whereas morulae are rarely detected in circulating monocytes of patients with HME.

The phylogenetic cluster related to *E. phagocytophila* includes *E. platys* and *E. bovis*. *Ehrlichia platys* infects dogs and targets platelets and macrophages (Woody and Hoskins, 1991). The vector is unknown. *Ehrlichia bovis* infects cattle and buffalo.

Anaplasma marginale is an obligate intracellular bacterium that infects cattle (Moulder, 1974). Anaplasmosis is found worldwide and is transmitted by ticks such as *Dermacentor andersoni*.

The bacterium occupies vacuoles within erythrocytes. *Anaplasma marginale* clusters phylogenetically with the *E. phagocytophila-E. equi* group of ehrlichiae, though it occupies a deep branch in this cluster (Drancourt and Raoult, 1994). Based on 16S rRNA phylogeny, *A. marginale* should be considered an ehrlichia.

The Neorickettsia Group

Although related to the ehrlichiae and the rickettsiae, the neorickettsiae form a distinct phylogenetic cluster within the Rickettsiales. *Ehrlichia sennetsu* and *E. risticii* are phylogenetically very closely related organisms that do not group with the true ehrlichiae (Pretzman et al., 1995). These bacteria are closely related to *Neorickettsia helminthoeca* (Rikihisa, 1991). Unlike the ehrlichiae that are transmitted by tick vectors, the neorickettsiae are associated with trematode worm vectors.

Neorickettsia helminthoeca is a small, pleomorphic, intracellular bacterium that causes salmon poisoning disease in canids such as coyotes and dogs (Foreyt et al., 1987). *Neorickettsia helminthoeca* infects cells of the canine reticuloendothelial system. A fluke vector (*Nonophyetus salmincola*) that infests salmonid fish transmits the disease. Dogs acquire the bacterium by eating fish containing infected flukes.

Ehrlichia risticii is the cause of Potomac horse fever (PHF), a febrile colitis of horses found in North America and Europe (Palmer, 1993). It has also been associated with equine abortions. Also, PHF has been transmitted to horses by inoculation with infected trematode worms harvested from freshwater snails (Barlough et al., 1998). The natural mode of acquisition is not known, but horses may become infected by drinking or standing in trematode-infested water or by ingesting aquatic insects containing infected metacercariae. *Ehrlichia risticii* has been propagated in mice. There is considerable 16S rRNA sequence diversity amongst the bacteria classified as *E. risticii*, suggesting that there are several different strains (Wen et al., 1995).

Ehrlichia sennestu is a human pathogen that has been reported to occur in Japan and Malaysia (Rapmund, 1984). It causes sennetsu fever, a mild mononucleosis-like illness marked by fever, lymphadenopathy and atypical lymphocytosis that usually resolves spontaneously. The vector has not been described, but an excellent candidate would be a trematode worm.

Another bacterium related to the neorickettsiae has been detected in California rainbow trout and the trematodes infesting these fish. It is not known whether this bacterium, which has not been named as yet, causes disease in mammals (Pusterla et al., 2000).

An illness that was first thought to be due to *E. sennetsu* was later linked to another member of the neorickettsiae. People in western Japan developed an illness (Hyuga fever) after eating raw gray mullet fish (Fukuda and Yamamoto, 1981). The SF agent was isolated from the trematode worm *Stellantchasmus falcatus*, which infests gray mullet (Wen et al., 1996). Phylogenetic analysis of the 16S rRNA gene suggests that SF is very closely related to *E. risticii*.

The Wolbachia Group

The Wolbachiae

The Wolbachiae are small, Gram-negative, intracellular bacterial symbionts of invertebrate hosts, particularly arthropods (Dobson et al., 1999). These bacteria can infect reproductive cells and thus have the potential to be vertically transmitted by cytoplasmic inheritance. Horizontal transmission of Wolbachiae also may occur. Wolbachiae are known to affect host reproduction by inducing cytoplasmic incompatibility, parthenogenesis, male killing, feminization of genetic males, and increases in fecundity (McGraw and O'Neill, 1999; Hadfield and Axton, 1999; Hurst et al., 2000). These reproductive changes induced in host arthropods appear to promote the spread of Wolbachia endosymbionts. *Wolbachia pipientis* and numerous unnamed Wolbachia species make up this group (McGraw and O'Neill, 1999). *Wolbachia pipientis* multiplies by binary fission in host cell vacuoles.

Wolbachia persica was isolated from the tick *Argas persicus*, now called *Argas arboreus* (Moulder, 1974). Phylogenetic analysis of the 16S rRNA gene shows that this bacterium does not cluster with the Wolbachiae, but rather belongs to the *Francisella* genus (Forsman et al., 1994). If this phylogeny proves correct, the name should probably be changed to *Francisella persica*.

Other bacterial endosymbionts of arthropods have been described that cluster phylogenetically with the Wolbachiae, but have been named by describing the infected host. These bacteria include symbionts of Trichogramma (Genbank L02886), Bangasternus (M85266), Muscifidurax (L02882), Brugia (AF051145), *Rhinocyllus* (M85267), and several incompatibility symbionts (M84692, M84689, ARB [short for "arbor," or "tree," in Latin] database, Technical University, Munich, Germany).

Wolbachia melophagi groups with the *Bartonellae* and is described in that section.

Other Bacteria in the Wolbachia Group

Bacteria that cluster with the Wolbachia based

on 16S rRNA phylogeny include bacterial symbionts associated with the algae *Cosmocladium saxonicum* (X79497) and *Pleurastrum paucicellulare* (Z47997) and a symbiont associated with the tick *Haemaphysalis longcornis* (AB001520). Some bacteria that are very closely related to the symbionts of *Cosmocladium saxonicum* have been called "Wolbachia species" (X64266) (http://www.arb-home.de, Technical University, Munich, Germany).

The Holospora Group

Another group of bacteria within the Rickettsiales includes *Holospora obtusa*, *Caedibacter caryophila*, and many unnamed bacteria detected in such diverse environments as marine and rumen ecosystems. *Holospora obtusa* and *C. caryophila* are lethal symbionts of the ciliate *Paramecium caudatum* (Springer et al., 1993; Fujishima and Fujita, 1985). Another bacterial endosymbiont from this group has been implicated in causing necrotizing hepatopancreatitis in shrimp (Loy et al., 1996).

Rickettsia-Like Prokaryotes

The Bartonellae

Members of the *Bartonella* genus are small (0.4 × 1.5 μm), Gram-negative, aerobic rods with typical cell walls (Weiss and Moulder, 1984). They may invade erythrocytes and endothelial cells or can occupy an epicellular location. Some *Bartonella* have flagella. In 1993, the bacteria previously classified in the Rochalimea genus were grouped and renamed with the *Bartonella* genus (Breitschwerdt and Kordick, 2000). In 1995, bacteria previously in the Grahamella genus were similarly absorbed into the *Bartonella* genus. Bartonellae are α-proteobacteria that are phylogenetically distinct from the Rickettsiae and are related to bacteria in the *Rhizobium* genus. An intracellular environment is not required for growth, as these bacteria can be propagated on complex axenic media in the laboratory (Spach and Koehler, 1998). Although many of these bacteria appear to grow intracellularly, the extent of intracellular versus extracellular replication in animal host tissues is not clear.

Bartonellae are important human pathogens, particularly in the immunocompromised host. A list of Bartonellae and the diseases they produce includes *B. bacilliformis* (Oroya fever and verruga peruana), *B. henselae* (cat scratch disease, bacillary angiomatosis, peliosis hepatis, bacteremia and endocarditis), *B. quintana* (trench fever, bacillary angiomatosis, endocarditis and bacteremia), *B. elizabethae* (endocarditis), *B. clarridgeiae* (cat scratch disease), *B. vinsonii arupensis* (bacteremia), *B. washoensis* (cardiac disease) and *B. grahamhii* (neuroretinitis).

Nonhuman mammals appear to be the primary hosts for most *Bartonella* species. For instance, cats are frequently infected with *B. henselae*, and they may have prolonged bacteremia (Heller et al., 1997; Chomel et al., 1995). Nonhuman reservoirs have not been identified for *B. bacilliformis* and *B. quintana*. Vectors for transmission of these agents are known: *B. bacilliformis* can be transmitted between humans via the sand fly, and *B. quintana* can be transmitted via the body louse.

Other members of the *Bartonella* genus not presently associated with human disease include *B. taylorii*, *B. doshiae*, *B. alsatica*, *B. tribocorum*, *B. weissii*, *B. koehlerae*, *B. vinsonii berkhoffii*, *B. vinsonii vinsonii*, *B. talpae* and *B. peromysci* (Breitschwerdt and Kordick, 2000). A diversity of mammals and insect vectors show high rates of infection with these bacteria.

Of note, the bacterium *Wolbachia melophagi* (Genbank X89110) does not group phylogenetically with the Wolbachiae genus, but rather groups with the Bartonellae genus. *Wolbachia melophagi* is closely related to *B. henselae* using 16S rRNA sequence phylogeny and should probably be renamed *Bartonella melophagi*.

The Thiomicrospira

The Thiomicrospira are γ-proteobacteria that include the human and animal pathogen *Coxiella burnetii*, the fish pathogen *Piscirickettsia salmonis*, and insect symbionts, such as *Rickettsiella grylli* and several unnamed tick symbionts. These bacteria live within cytoplasmic vacuoles of host cells and are phylogenetically distinct from the Rickettsiae and the Bartonellae that are α-proteobacteria. The Thiomicrospira are closely related to Legionella.

Coxiella burnetii is a small (0.2–0.4 × 0.4–1.0 μm), Gram-negative, obligate intracellular bacterium that passively enters cells where it replicates in the acidic environment of the phagolysosome (Maurin and Raoult, 1999). *Coxiella burnetii* can form an endospore that is resistant to degradation in the environment. Human infection is produced by inhalation of bacteria, though natural infection in animal populations probably involves a tick vector. In humans, *C. burnetii* is the cause of Q fever. A wide spectrum of organisms can harbor the bacterium, including insects, birds, fish and mammals.

A bacterial pathogen of salmonid fish, *Piscirickettsia salmonis*, causes epizootics of disease called "piscirickettsiosis" (Mauel et al., 1999; Fryer et al., 1992). The reservoir, vector and

mode of acquisition for this bacterium are not known.

Rickettsiella grylli is another member of the *Thiomicrospira* and is not related to the Rickettsiae despite the association implied by its name (Roux et al., 1997; Frutos et al., 1994). *Rickettsiella grylli* has a cricket host. The bacterium enters a host cell vacuole where it divides. Like chlamydia, these bacteria undergo a developmental cycle consisting of stages, including a large particle that replicates and a small dense particle that is infectious. The bacteria may form disk shapes and condense into crystalline bodies. Other members of this taxonomic group include symbionts of Rhipicephalus and Ornithodoros ticks.

The Chlamydiae

Chlamydiae are small bacteria (0.2–1.5 μm) that replicate within the phagosome of eukaryotic cells. Whereas rickettsiae exit the phagosome after phagocytosis and multiply in the cell cytoplasm, the chlamydiae (and ehrlichiae) remain in the phagosome and prevent fusion with lysosomes (Weiss and Moulder, 1984). Chlamydia do not metabolize glutamate, in contrast to the rickettsiae. Chlamydiae have some structural features of Gram-negative bacteria, but their cell wall lacks peptidoglycan. Chlamydiae have a biphasic life cycle. The infectious stage is more compact and called "the elementary body," whereas the replicative stage is larger and called "the reticulate body." The chlamydiae form their own distinct phylogenetic group within the eubacteria (Everett, 2000) and are peripherally related to the planctomycetes, a group of aquatic and terrestrial bacteria that also lack peptidoglycan in their cell walls (Weisburg et al., 1986).

The currently defined species of chlamydia include *C. psittaci*, *C. pecorum*, *C. trachomatis* and *C. pneumoniae*. *Chlamydia pecorum* is exclusively an animal pathogen, whereas the other three chlamydiae can cause human disease. *Chlamydia psittici* causes disease in birds and mammals. Humans acquire the bacterium via inhalation of aerosols generated from infected animals, with resulting pneumonia (Vanrompay et al., 1995). Closely related to *C. psittici*, *C. pecorum* causes disease in animals such as ruminants, swine and marsupials (Fukushi and Hirai, 1993). In humans, *C. trachomatis* causes ocular (trachoma), genital disease (lymphogranuloma venereum) and, less commonly, other syndromes (Stamm, 1999). *Chlamydia pneumoniae*, exclusively a human pathogen producing respiratory disease (Kuo et al., 1995), has also been linked to atherosclerosis in humans.

Prokaryotic Endosymbionts of Eukaryotic Cells

The relationships between prokaryotic and eukaryotic cells are discussed in detail (see section on Symbiotic Associations in this Chapter). This section will give examples of how some intracellular prokaryotes have evolved with their eukaryotic hosts.

Wolbachia pipientis, a member of the Rickettsiales, is a common cytoplasmic symbiont of insects. This bacterium is widely distributed in host tissues and can be transmitted vertically in the cytoplasm of infected host eggs, though horizontal transmission may also occur. The numerous effects of *W. pipientis* on insect reproduction increase the number of female offspring while suppressing the number of male offspring (McGraw and O'Neill, 1999; Stouthamer et al., 1999). Because female insects can vertically transmit *W. pipientis* to their offspring, this strategy benefits the endosymbiont. One mechanism for producing this result is crossing incompatibility. Infected females can mate with infected or uninfected males, but uninfected females cannot mate with infected males. Another mechanism promoting female representation is the direct killing of male embryos by *W. pipientis*.

Buchnera aphidicola is an obligate intracellular symbiont of aphids that is vertically transmitted and colonizes specialized host cells called "bacteriocytes" (Clark et al., 2000). This bacterium is not a member of the Rickettsiales, but rather is a member of the γ-proteobacteria. The complete genome of *Buchnera* has been sequenced (Shigenobu et al., 2000). *Buchnera* has genes for the biosynthesis of essential amino acids required by the host, but lacks those for nonessential amino acids produced by the host, demonstrating complete biochemical interdependence. Indeed, eradication of bacteria from bacteriocytes is lethal for aphids.

Mitochondria: The Ultimate Prokaryotic Endosymbiont

Mitochondria are specialized aerobic energy producing organelles of eukaryotic cells. Like chloroplasts, mitochondria have unique genomes that are distinct from the nuclear genomes of their associated eukaryotic cells (Gray, 1993). When mitochondrial DNA from diverse eukaryotes are compared, there are striking differences in the size, organization and gene content of these genomes (Gray et al., 1999). Yet, phylogenetic analyses suggest that all mitochondrial genomes descended from a common ancestor related to the α-proteobacteria (Lang et al.,

1999). The most complete mitochondrial genome has been found in the flagellated protozoan *Reclinomonas americana* (Lang et al., 1997). This genome contains 97 genes, including genes for bacterial rRNA and genes encoding a eubacteria-like multicomponent RNA polymerase. Of the bacterial genomes that have been sequenced, that of *Rickettsia prowazekii* is most closely related to the mitochondrial genome (Andersson et al., 1998).

These data suggest a bacterial origin for mitochondria. According to the endosymbiont hypothesis (Gray and Doolittle, 1982), about 1.5–2.0 billion years ago an α-proteobacterium entered a proto-eukaryotic cell where it established an endosymbiotic relationship. Progressive gene loss and specialization of function led to the development of mitochondria as known today. Mitochondria allowed eukaryotic cells to generate energy without using the plasma membrane. The host cell provided substrates for energy production and a protected niche for replication. Regulation of the mitochondrial genome eventually shifted to nuclear control.

The hydrogen hypothesis is an extension of the endosymbiont hypothesis for the origin of mitochondria (Rotte et al., 2000; Bui et al., 1996). This theory holds that a hydrogen-requiring archaebacterium engulfed a hydrogen-producing α-proteobacterium. Specialization of function by the endosymbiont led to the formation of hydrogenosomes for anaerobic energy production in eukaryotic cells. Hydrogenosomes occur in early amitochondric eukaryotic cells, such as Trichomonads. Although lacking in DNA, hydrogenosomes have proteins (e.g., heat shock proteins) that are phylogenetically related to mitochondrial proteins (Bui et al., 1996; Dyall et al., 2000). These data suggest a common origin for hydrogenosomes and mitochondria, though it is not clear if there was a single endosymbiotic event leading to two different organelles or multiple introductions with closely related prokaryotes.

Mitochondria appear to have originated from the introduction of a single α-proteobacterial endosymbiont into a eukaryotic or proto-eukaryotic cell (Gray et al., 1999). Although theoretically possible, a model in which different endosymbiont bacteria formed mitochondria is not supported by the data. Mitochondria are most closely related to the rickettsiae. However, one cannot conclude that the mitochondrial ancestor also belonged to this genus. It is possible that an α-proteobacterial ancestor gave rise to both the rickettsiae and the mitochondrial endosymbiont. The rickettsial and mitochondrial genomes are quite small. Both genomes are likely to have sustained gene loss over evolutionary time related to their common intracellular niche. Thus, the extensive loss of mitochondrial genes does not necessarily imply a rickettsial origin.

If evolutionary success is measured by the ability to pass a genome to succeeding generations, then the mitochondrial endosymbiont has been fantastically successful. Mitochondria in eukaryotic cells provide evidence that the strategy of intracellular prokaryotic existence is ancient and durable.

CHAPTER 3.1.18

The Genus *Bartonella*

MICHAEL F. MINNICK AND BURT E. ANDERSON

Phylogeny

Bartonella species share many general characteristics. Members of the genus are small (approximately 0.3 μm × 1 μm), Gram-negative, pleomorphic coccobacilli. The bacteria are facultative intracellular pathogens, many of which employ hemotrophy (infection of erythrocytes) as a parasitic strategy. All members of the genus are notoriously fastidious and grow slowly in vitro. *Bartonella* species have been shown to infect a variety of mammalian hosts, and at least three species (*B. bacilliformis*, *B. henselae* and *B. quintana*) are relatively common human pathogens. Vector-mediated transmission is another common theme within the genus. *Bartonella* spp. are typically transmitted between mammalian hosts by arthropods, with each bacterial species transmitted by a particular insect vector. Reservoirs for *Bartonella* spp. include a diverse array of mammals.

Based on 16S rRNA gene sequence comparisons, members of the genus *Bartonella* fall into the α-2 subgroup of the *Proteobacteria* (O'Connor et al., 1991). The genera closest to *Bartonella* include *Brucella*, *Rhizobium* and *Agrobacterium*. In general, the current genus *Bartonella* is relatively homogeneous with members exhibiting greater than 95% identity among aligned 16S rRNA gene sequences, resulting in a somewhat tightly branched phylogenetic tree (Fig. 1). Phylogenetic relationships determined using other loci, including *gltA* (the citrate synthase gene; Birtles and Raoult, 1996), *ftsZ* (a gene specifying a cell division [tubulin-like] protein; Kelly et al., 1998; Ehrenborg et al., 2000), and the 17-kDa antigen gene (Sweger et al., 2000), have resulted in dendrograms similar to that derived from the 16S rRNA gene sequences.

Taxonomy

The genus *Bartonella* has recently undergone a major taxonomic reorganization. Since the description of *Bartonella bacilliformis* in 1909, this species was the only representative from the genus described by A. L. Barton (Barton, 1909). However, bacteria once constituting the genera *Rochalimaea* and *Grahamella* were reclassified into the genus *Bartonella* (Brenner et al., 1993; Birtles et al., 1995), increasing the number of potential species to 15. Three *Bartonella* species are etiologic agents of major emerging infectious diseases in humans (Table 1). An additional four species (and two subspecies) of *Bartonella* also have been associated with human disease or described as human pathogens in isolated case reports (Table 2). Finally, ten species have not been associated with human disease but have been found in a variety of animal hosts (Table 3). The group's potential impact on human health and their ubiquitous presence in animal reservoirs have fueled an interest in understanding the basic biology of these bacteria as well as the epidemiology, clinical presentation and natural history of the resultant diseases.

The *Bartonellaceae* family has been removed from the order *Rickettsiales*; a group that originally included the *Anaplasmataceae*, *Rickettsiaceae* and *Bartonellaceae*. Members of the family *Bartonellaceae* share some rickettsia-like characteristics such as small size (e.g., the "virus-like particles" of *B. bacilliformis*), its transmission to humans through an arthropod vector (sandflies), and its ability to live within host cells (Moulder, 1974). However, they are not true obligate intracellular parasites like the rickettsiae, and several phenotypic properties differ between members of *Bartonellaceae* and the rickettsiae. For instance, *Bartonella*, *Grahamella* and *Rochalimaea* species and a few species of *Wolbachia* were the only *Rickettsiales* members that can be cultured in vitro, whereas true rickettsiae are strictly obligate intracellular parasites of eukaryotic cells. In addition, *B. bacilliformis* was the only flagellated member within the order (Weinman, 1974). Recently obtained DNA relatedness data, mainly 16S rRNA gene sequences, have clearly shown that *Rochalimaea* and *Bartonella* are more closely related to each other than to any rickettsia and most closely related to members of the α-2 subgroup of the *Proteobacteria*

Table 1. The three major human pathogens in the genus *Bartonella*.

Species	Common manifestation(s)	Vector(s)	Reservoir(s)
bacilliformis	Oroya fever, verruga peruana	Sandflies	Humans
henselae	Cat-scratch disease, endocarditis, bacillary angiomatosis, bacillary peliosis, bacteremic syndrome	Cats, fleas	Cats
quintana	Trench fever, endocarditis, bacillary angiomatosis, bacteremic syndrome	Body louse	Humans

Table 2. *Bartonella* species associated with human disease.[a]

Species	Clinical manifestation	Vector	Reservoir(s)	Reference
clarridgeiae	Cat-scratch disease?	Cats	Cats	Kordick et al., 1997
elizabethae	Endocarditis	Unknown	Unknown	Daly et al., 1993
grahamii	Retinitis	Unknown	Rodents	Kerkhoff et al., 1999
vinsonii sub sp. *aurepensis*	Bacteremia	Ticks?	Domestic dog, rodents	Welch et al., 1999
vinsonii sub sp. *berkhoffii*	Endocarditis	Unknown	Unknown	Roux et al., 2000

[a]Includes species associated with disease through serology or single case reports of disease associated with isolation or detection.

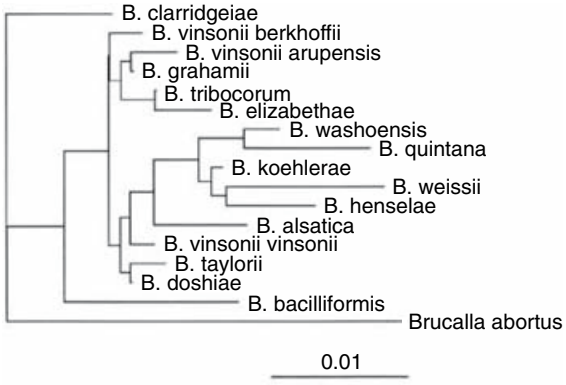

Fig. 1. Phylogenetic tree showing relationships of *Bartonella* spp. The 16S rRNA gene was aligned with over 1,272 bases. *Brucella abortus* is shown as an outgroup. Bar indicates a 1% nucleotide divergence. (From Breitschwerdt and Kordick, 2000, with permission.)

Table 3. *Bartonella* species that have not been demonstrated to be pathogenic for humans.

Species	Host(s)	Reference(s)
alsatica	Rabbits	Heller et al., 1999
doshiae	Rodents	Birtles et al., 1995
grahamii	Rodents, insectivores	Birtles et al., 1995
koehlerae	Domestic cat	Droz et al., 1999
peromysci	Rodents	Birtles et al., 1995
talpae	Moles	Birtles et al., 1995
taylorii	Rodents	Birtles et al., 1995
tribocorum	Rats	Heller et al., 1998
vinsonii sub sp. *vinsonii*	Voles	Weiss and Dasch, 1982
washoensis	Ground squirrels	Unpublished
weisii	Cats	Unpublished

class, especially the *Rhizobiaceae* (Birtles et al., 1991; O'Connor et al., 1991; Brenner et al., 1991; Relman et al., 1992). On the basis of these findings, *Rochalimaea* species were subsequently reclassified as *Bartonella*, and the *Bartonellaceae* family (containing both the *Grahamella* and *Bartonella* genera) was removed from the *Rickettsiales* order (Brenner et al., 1993). A subsequent study reclassified five *Grahamella* species as bartonellae based upon DNA relatedness data and phenotypic characteristics, thereby eliminating the *Grahamella* genus (Birtles et al., 1995).

The *Bartonella* genus presently contains the 18 species as listed in Tables 1–3. The phylogenetic relationship of *Bartonella* to other α-*Proteobacteria* indicates that the closest relatives to *Bartonella* include *Agrobacterium*, *Rhizobium* and *Brucella* species, the latter being the most closely related (Brenner et al., 1993). At first glance this grouping seems diverse, but its members do show similar natural histories. Specifically, all four genera have evolved towards a parasitic or mutualistic association with eukaryotic cells. *Bartonella* spp. and *Brucella* spp. are both intracellular parasites of mammalian cells, whereas *Agrobacterium* and *Rhizobium* species can parasitize or mutualistically associate with plant cells, respectively. None of these bacteria are obligate parasites, and all can be cultivated in vitro.

Interestingly, human diseases caused by *Brucella* and *Agrobacterium* spp. share superficial similarities with bartonelloses. Like with *Bartonella* spp., opportunistic infections with *Agrobacterium radiobacter* mainly occur in immunocompromised patients and can cause bacteremia and endocarditis (Edmond et al., 1993; Freney et al., 1985; Plotkin, 1980; Southern, 1996). In addition, some manifestations of brucellosis resemble the symptoms associated with

infection by *B. henselae* or *B. quintana*. For instance, brucellosis is a febrile illness characterized by granulomatous tissue in the lymph nodes, liver, spleen and bone and is accompanied by lymphadenopathy, bacteremia and occasionally endocarditis (Wilfert, 1992).

Habitat

Bartonella species have been isolated or detected in a wide range of animal species. Included in the list of potential animal reservoirs are cats, dogs, rodents, rabbits and cattle as well as a diverse group of wild animals including wildcats (bobcats, pumas and mountain lions), coyotes, deer, elk and foxes (for review, see Breitschwerdt, 2000). At least three species have been identified as major human pathogens (Table 1), and their disease syndromes are described below. An additional four species, including two subspecies, have been associated with human disease either indirectly or through isolated case reports (Table 2). However, their identification as major human pathogens awaits further reports associating them with human disease. Finally, currently eleven other species of *Bartonella* have only been isolated from animals (Table 3). It should be stressed that separation of individual species into human and animal agents is likely to change as specific diagnostic tests for all *Bartonella* species are developed and applied to testing human samples.

Transmission of *Bartonella* to humans occurs through an insect vector for most *Bartonella* species. The list of vectors associated with transmission includes flies, fleas, ticks, lice and mites (Tables 1 and 2). The possibility of direct mechanical transmission of *B. henselae* from cats to humans resulting in cat-scratch disease has been suggested. The role of the cat flea in this process seems likely and may involve the contamination of cat claws with infected flea feces. Transmission of *B. henselae* among cats appears to require the cat flea as a vector (Chomel et al., 1996). The epidemiological association of cat fleas with cases of human cat-scratch disease further supports the idea that contaminated flea feces is required for transmission (Zangwill et al., 1993).

Isolation

Isolation of *Bartonella* spp. from clinical specimens requires extended incubation times and specialized media. In addition, direct plating of specimens prepared by the lysis-centrifugation method (Wampole Laboratories, Cranbury, NJ) sometimes enhances isolation from blood (Slater et al., 1990). Alternatively, homogenized tissue can serve as the inoculum on blood plates or endothelial cell monolayers (Koehler et al., 1992). Blood or chocolate agar plates with a complex base medium (trypticase soy, heart infusion or Columbia agar) are used for culturing. The pH of the medium should be 7.0 to 7.5 for optimal growth. *Bartonella* spp. also require high humidity and, with the exception of *B. bacilliformis*, prefer 5% CO_2 within the growth chamber. The slow growth rate of these bacteria can compound primary isolation and often requires incubation times exceeding 3–4 weeks to visualize colonies. The combination of a slow growth rate and fastidious nature can make isolation and axenic culture of *Bartonella* spp. a challenging undertaking. In fact, endocarditis isolates of *B. henselae* were only recently obtained (Drancourt et al., 1996). Following isolation and pure culture of a strain, identification of the suspected *Bartonella* species can be accomplished using the techniques described below in "Identification."

Identification

In addition to a number of growth characteristics, structural, biochemical and genetic properties have been used to assist in the identification of *Bartonella* isolates. In general, polymerase chain reaction (PCR) amplification coupled with sequencing, restriction fragment-length polymorphism (RFLP) analysis or genetic probing recently has gained favor for rapid and definitive identification of isolates.

Colony Morphology

Bartonella colonies, typically small (1–3 mm diameter) and round, range from transluscent to opaque (white or cream) in color. Colonies may display a dry-to-mucoid phase variation with repeated passage. Colonies obtained from low-passage isolates typically adhere to and pit the medium, but this phenotype disappears following repeated passage in vitro. Colonies of *B. bacilliformis* freely interconvert between a small, transluscent round colony (T1) to a larger colony with an irregular edge (T2; Walker and Winkler, 1981). Colonies from primary isolates can take up to four weeks before becoming visible; however, growth is much more rapid (2–5 days) in subsequent passages. It has been suggested that this colony variation may correlate with antigenic phase variation seen with *B. henselae* and B. *quintana*, with fresh isolates being more highly reactive with human sera than isolates that have undergone extensive laboratory passaging (Regnery and Tappero, 1995).

Cell Morphology

Bartonella cells are Gram negative, non-acid fast, pleomorphic rods. *Bartonella* spp. stain poorly with safranin, but stain well with Giemsa or Gimenez stains. Cells are typically coccobacilli or slightly curved rods with a polar enlargement(s). Cells also can be coccoid, beaded, filamentous or in chains. Annular (ring forms) and autoaggregates also can occur. Cell size is uniformly less than 3 μm in the greatest dimension, with most cells measuring 0.5 μm × 1.0 μm. Figure 2 shows examples of the two basic cell morphologies observed in *Bartonella* spp. including a flagellated and nonflagellated cell.

Biochemical Tests

Bartonella spp. are nonfermentative aerobes with unremarkable physiology. For this reason biochemical tests are usually not conclusive for species identification. One potential problem with standard biochemical tests is that they do not include hemin for *Bartonella* growth, and therefore test results must be judged cautiously. If hemin is added to physiological test media, test results for acid production from carbohydrates (lactose, maltose and saccharose), hippurate hydrolysis, pyrazinamidase and Voges-Proskauer can be used to differentiate *B. henselae* from *B. quintana* (Drancourt and Raoult, 1993). RapID ANA panels (Innovative Diagnostic Systems, Inc., Norcross, GA; Daly et al., 1993; Clarridge et al., 1995), DNA hybridization (Regnery et al., 1991; Welch et al., 1992) and pre-formed peptidases (Welch et al., 1992) also have been used with varying success for the identification of *Bartonella* species.

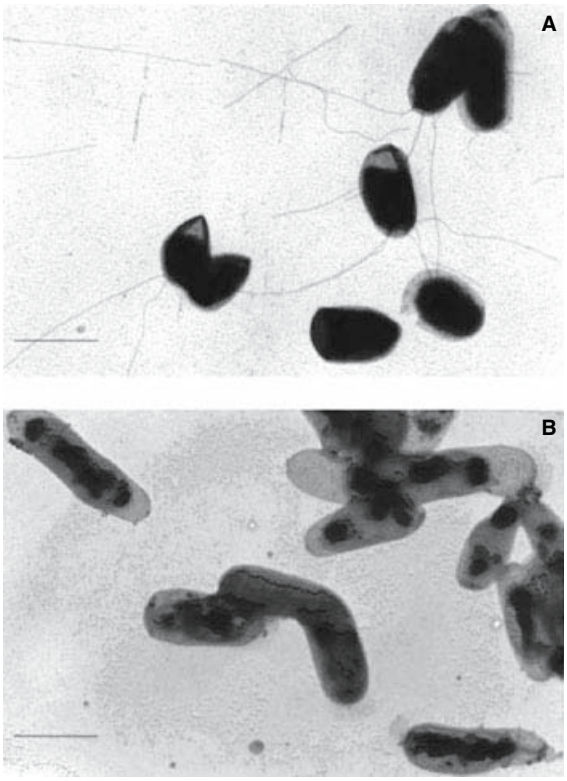

Fig. 2. Transmission electron micrographs showing the two basic cell morphologies observed in *Bartonella* species. Bacteria were grown by standard methods and stained with uranyl acetate. A) Flagellated cell morphology as exemplified by *B. clarridgeiae*, and B) a more typical, nonflagellated cell morphology as exemplified by *B. elizabethae* (Bars = 0.5 μm). (Courtesy of James A. Carroll.)

Polymerase Chain Reaction

The PCR is a sensitive and specific tool for identifying "non-culturable" *Bartonella* spp. in human samples or for confirming presumptive identification of isolates. Frequently, PCR has been used to amplify portions, or all, of the 16S rDNA gene from suspected *Bartonella* spp. The 16S rDNA PCR product is subsequently sequenced, and the data compared to known 16S rDNA sequences in GenBank to confirm presumptive identification (Relman et al., 1990; Regnery et al., 1992a; Koehler et al., 1992; Hadfield et al., 1993). To streamline identification, PCR strategies also have been devised using *Bartonella* genus-specific or species-specific targets. Targets have included the 16S rDNA gene (Dauga et al., 1996), a heat shock protein or stress endopeptidase *gene (htrA*; Anderson et al., 1993), the *gltA* gene (Regnery et al., 1991; Birtles and Raoult, 1996; Patel et al., 1999), the *ribC* gene (Bereswill et al., 1999), the *ftsZ* gene (Kelly et al., 1998), repetitive extragenic palindromic (REP) or enterobacterial repetitive intergenic consensus (ERIC) DNA sequences (Clarridge et al., 1995; Rodriguez-Barradas et al., 1995b) and the 16S-23S rDNA intergenic spacer (ITS; Minnick and Barbian, 1997b).

Restriction Fragment-Length Polymorphism

The RFLPs identifying *Bartonella* spp. employed rare-cutting restriction endonucleases together with genomic DNA (Slater et al., 1990; Maurin et al., 1994; Roux and Raoult, 1995), with PCR fragments of *gltA* (Norman et al., 1995), or with PCR products containing the 16S-23S rDNA intergenic spacer region (ITS; Matar et al., 1993; Roux and Raoult, 1995; Bergmans et al., 1996).

Cellular Fatty Acids

Cellular fatty acid (CFA) analysis also has been used to identify *Bartonella* spp. to the genus level. This technique is particularly useful, as *Bar-*

tonella spp. have an unusual fatty acid composition when compared to other bacteria. *cis*-11-Octadecanoate ($C_{18:1\ \omega7c}$; ~54%) and hexadecanoate ($C_{16:0}$; ~20%) are the predominant fatty acids of all *Bartonella* spp. *Bartonella elizabethae*, *B. henselae*, *B. clarridgeiae* and *B. quintana* contain considerable amounts of octadecanoate ($C_{18:0}$; ~23%), whereas *B. bacilliformis* contains very little (~2%). *Bartonella bacilliformis* also contains an unusually high quantity (~20%) of *cis*-11 hexadecanoate ($C_{16:1\ \omega7c}$) in contrast to most *Bartonella* species (<1%; Westfall et al., 1984; Slater et al., 1990; Daly et al., 1993; Clarridge et al., 1995; Kordick et al., 1995b).

Preservation

Bartonella spp. are highly resistant to freezing and freeze-thaw cycles (R. Regnery, personal communication). Strains can be stored indefinitely by adding glycerol to a final concentration of 12.5% (v/v) and storing at –70°C.

Physiology

Cell Structure

Bartonella cell walls are comparable to those of other Gram-negative bacteria (Kreier et al., 1991). Cellular fatty acids are unusual in composition, with greater than 50% being cis-11-octadecanoate ($C_{18:1\ w7c}$; see "Cellular Fatty Acids"). Motility has been observed in two pathogenic species (Table 3) and is conferred by unipolar lophotrichous flagella (*B. bacilliformis* and *B. clarridgeiae*; Scherer et al., 1993; Clarridge et al., 1995) or type IV pili (*B. henselae*; Batterman et al., 1995). There are no capsules or spore-like structures in any species. Spheroplasts of *Bartonella* can be made using lysozyme, and outer-membrane fractions can be prepared from these by cell lysis and collected by sucrose step-gradient centrifugation. The outer membrane of *B. bacilliformis* contains 14 outer-membrane proteins (OMPs) ranging from 11.2 to 75.3 kDa when analyzed by SDS-PAGE (Minnick, 1994). Further analysis of outer-membrane fractions by two-dimensional (2-D) SDS-PAGE suggests that the actual number of OMPs is closer to 50 (M. F. Minnick, unpublished observation). Nine surface proteins have been identified in *B. henselae* (Burgess and Anderson, 1998). The flagellin subunit (42 kDa) and a phage coat protein (31.5 kDa) are the major OMPs of *B. bacilliformis*. The outer membrane of *B. bacilliformis* contains a uniform lipopolysaccharide (LPS) molecule, migrating on SDS-PAGE at the equivalent of 5 kDa (Knobloch et al., 1988b; Minnick, 1994). A lack of multiple LPS bands suggests that only subtle differences exist in the O-side chains of *B. bacilliformis*. Early work on purified LPS from *B. quintana* showed that it contained 2-keto-3-deoxy-octonate and heptose and that it was reactive in chick embryo lethality, complement fixation and limulus amebocyte lysate tests (Hollingdale et al., 1980).

Growth and Metabolism

Excluding hemotrophy, the physiology of *Bartonella* spp. is not particularly exciting. Using standard tests, *Bartonella* spp. are strictly aerobic and do not utilize carbohydrates (no acid or gas) by preformed or de-novo enzymes. The oxidase test is usually negative for *Bartonella* spp., although variable and positive weak reactions have been reported for *B. quintana* and *B. vinsonii* (Daly et al., 1993; Kordick et al., 1996). Tests for catalase, indole production, nitrate reduction and urease activity are all negative (Clarridge et al., 1995; Birtles et al., 1995). In addition, tests for hippurate hydrolysis, alkaline phosphatase, tetrathionate reductase, pyrazinamidase, tributyrin, o-nitrophenyl-β-D-galactoside, esculin hydrolysis and arginine dihydrolase are all negative (Birtles et al., 1995). Voges-Proskauer tests are negative for all human pathogenic species, but positive for *Bartonella* spp. previously designated as *Grahamella* spp. (Birtles et al., 1995). Aminopeptidase hydrolysis of a variety of amino acids and peptides has been observed in the pathogenic *Bartonella* species, and hydrolysis of phenylalanine or trypsin might be useful for differentiation of some species (Clarridge et al., 1995; Kordick et al., 1995b; Birtles et al., 1995; Table 3). Utilization of succinate has been demonstrated for *B. quintana* (Weiss and Moulder, 1984).

Bartonellae are slow-growing bacteria with generation times of approximately 6 (i.e., 5.8–6.7) h under optimal conditions in vitro for *B. quintana* (Weiss and Dasch, 1982) and 6–8 h for *B. bacilliformis* (Benson et al., 1986). Because of long generation times, maximal colony size is only reached after several days of growth on plates. *Bartonella* spp. also can be cultivated in embryonated chicken eggs and tissue culture.

Extracellular Products

Only three extracellular products from *Bartonella* spp. have been described, including deformation factor (deformin), a defective bacteriophage, and hemolysin. A putative ABC transporter from *B. bacilliformis* has been cloned and sequenced (*txpA*; GenBank accession no. U68242) and shares homology with the ABC glucan exporter from *Agrobacterium tumefa-*

ciens. The TxpA protein may be involved in export from or import into *Bartonella* (for a review of ABC transporters see Fath and Kolter, 1993). Likewise, an operon encoding type IV secretion system genes with extensive similarity in sequence and gene arrangement to the *virB* operon of *A. tumefaciens* has been described for *B. henselae* (Schmiederer and Anderson, 2000; Padmalayam et al., 2000a). Notably, one gene (*virB5*) has been replaced by the gene encoding the 17-kDa antigen– previously described immunodominant protein of *B. henselae* (Anderson et al., 1995).

DEFORMATION FACTOR. *Bartonella bacilliformis* produces an extracellular protein termed "deformin" that can independently generate indentations and trenches in erythrocyte membranes. The pits and trenches produced with purified deformin are morphologically similar to those observed in infected cells (Benson et al., 1986; Fig. 3). The protein is actively secreted during growth of the bacterium and is a 130-kDa homodimer in its native state. Deformin is sensitive to heat (70–80°C) and proteases. Deformin activity is enhanced by pretreatment of the erythrocytes with trypsin or neuraminidase and abrogated if erythrocytes are pretreated with phospholipase D. Deformin-induced invaginations are reversible by vanadate, by dilauroylphosphatidyl choline (DLPC), or by increasing intracellular Ca^{2+} levels with ionophores (Mernaugh and Ihler, 1992; Xu et al., 1995). Whether other bartonellae produce deformin, or whether deformin is active against other cell types, is not known. The gene for deformin has not been characterized.

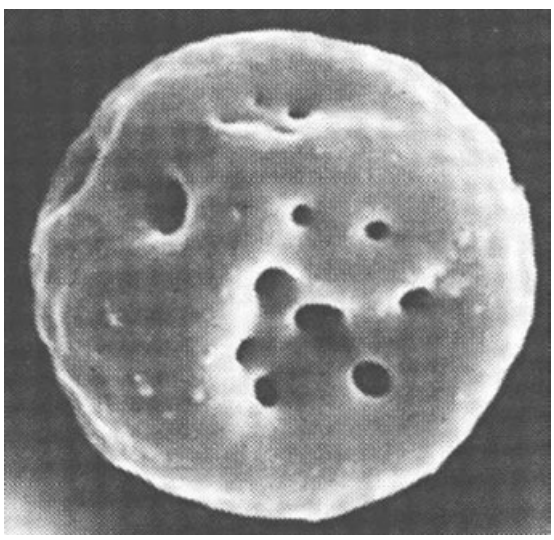

Fig. 3. Erythrocyte invaginations caused by *B. bacilliformis* deformation factor (deformin). Erythrocytes were treated with: trypsin, *B. bacilliformis* culture filtrate for 2 h, and purified deformin for 2 h. (From Xu et al., 1995, with permission.)

DEFECTIVE BACTERIOPHAGE. Uniform bacteriophage-like particles containing icosahedral heads (~40 nm in diameter) and a filamentous sheath-like tail structure (16 nm in length) were first observed in *B. bacilliformis* (Umemori et al., 1992). The authors suggested that the bacteriophage was temperate and that the *Bartonella* strains (KC583 and KC584) were lysogenic. In addition, observed decreases in *B. bacilliformis* yields with increased passage were thought to be due to bacteriophage infestation. Subsequent work showed that phage-like particles also can be obtained from *B. henselae*, but not *B. elizabethae* or *B. quintana*. Phages from *B. henselae* and *B. bacilliformis* consist of a heterogeneous, linear DNA of 14 kbp and at least three proteins (Anderson et al., 1994a). Two of the phage-associated proteins, Pap31 and PapA, have been characterized and are 31 and 36 kDa, respectively (Anderson et al., 1997b; Bowers et al., 1998). It is not currently known if this particle mediates transduction and genetic exchange among *Bartonella* spp, although packaging of a chromosomal marker has been demonstrated in the *B. bacilliformis* phage (Barbian and Minnick, 2000; Fig. 4).

HEMOLYSINS. These are produced by *B. bacilliformis* and *B. elizabethae*. Until recently, all literature on *B. bacilliformis* claimed that the bacterium was nonhemolytic. However, if *B. bacilliformis* cultures are plated on thin blood agar plates and cultured for at least four days, incomplete β-hemolysis can be observed. The hemolysin is extracellular and can pass through 0.2 μm filters into the underlying medium to produce a zone of hemolysis, which is limited to the outline of the colony (Minnick, 1997a). Likewise, an incomplete β-hemolysin with delayed appearance (four days growth) has been reported from *B. elizabethae* (Daly et al., 1993). The molecular nature of these hemolysins is not known.

Angiogenic Factor

The three major pathogenic *Bartonella* spp. produce a protein that stimulates angiogenesis and probably facilitates the generation of vascular lesions during infection. Fractions from *B. bacilliformis* containing the protein induce vascularization in vivo and can induce human umbilical vein endothelial cells (HUVECs) to proliferate in vitro (Garcia et al., 1990). Live *B. bacilliformis* (Garcia et al., 1992), *B. henselae* or *B. quintana* (Conley et al., 1994) stimulates endothelial cell proliferation when cocultured with HUVECs. The HUVECs also migrate towards bartonellae in cocultures (Conley et al., 1994). Mitogenicity

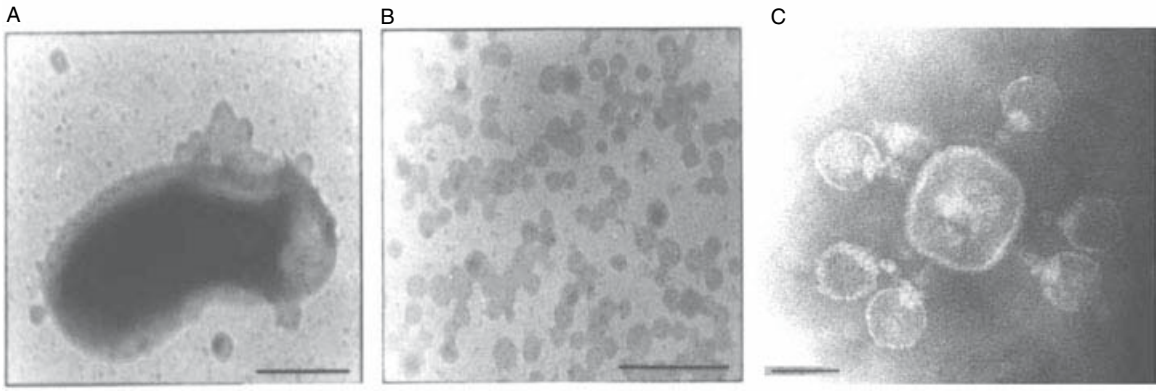

Fig. 4. Transmission electron micrographs showing: A) *B. bacilliformis* (strain JB585, a flagellin-minus mutant; Battisti and Minnick, 1999) infected with bacteriophage, B) purified bacteriophage from JB585 (Bars = 250 nm), and C) six bacteriophage with tails, infecting a bleb from *B. henselae*. (Panels A and B from Barbian and Minnick, 2000, with permission; Panel C courtesy of James A. Carroll.)

of the angiogenic protein is active on endothelial cells, but fibroblasts, smooth muscle or mesenchyme cells are unaffected (Garcia et al., 1990; Conley et al., 1994). In *B. bacilliformis*, the angiogenic factor has been shown to be a cytoplasmic protein (Garcia et al., 1990). The initial report for the angiogenic factor of *B. henselae* indicated that it was an insoluble membrane-associated protein (Conley et al., 1994); however, a more recent report indicated that it was a diffusible protein found in bacterial culture supernatants (Maeno et al., 1999). Thus, the bacterial localization of the angiogenic factor as well as the molecular nature of the protein and its mechanism of action remains unclear.

Enzymes

Few enzymes have been characterized and no exotoxins have been described from any *Bartonella* species. Seven putative *Bartonella* enzymes have been deduced from nucleotide sequences. These include several GltAs (citrate synthase species; Birtles and Raoult, 1996), HtrA (Anderson et al., 1996), FtsZ (Padmalayam et al., 1997), GroEL (Haake et al., 1997), alanyl tRNA synthetase (AlaS), leucyl tRNA synthetase (LeuS), and orotidine monophosphate decarboxylase (PyrF). Only four *Bartonella* enzymes have been characterized at both the nucleotide sequence and protein level: a carboxy-terminal protease that is autolytic (CtpA; Mitchell and Minnick, 1997a), the invasion-associated locus A protein (IalA), a nudix hydrolase (Cartwright et al., 1999), the gyrase B subunit (GyrB; Battisti et al., 1998), and inorganic pyrophosphatase (PPase; Mitchell and Minnick, 1997b). In keeping with Ppases from other prokaryotes, the *B. bacilliformis* enzyme displays maximal activity at a pH of 8.0 and demonstrates high thermostability in the presence of Mg^{2+} (highest activity at 55°C).

Pathogenesis

Hemotrophy is a striking aspect of the physiology of most *Bartonella* spp. Parasitism of erythrocytes is very unusual for bacteria and is undertaken by species from two other genera, *Anaplasma* and *Haemobartonella* (Kreier and Ristic, 1981). Hemotrophy undoubtedly fulfills the growth requirement for blood or hemin by all bartonellae. Heme uptake is employed by several pathogenic bacteria to acquire iron and porphyrin (Reidl and Mekalanos, 1996). Work done with *B. quintana* shows that a high concentration of heme (20–40 µg/ml), but not protoporphyrin, is essential for growth. In addition, serum is not a required growth factor (Myers et al., 1969). The gene encoding an outer-membrane, hemin-binding protein of *B. quintana* has been identified and characterized (Carroll et al., 2000). The protein appears to be a homolog of the phage-associated protein of *B. henselae*, Pap31 (Bowers et al., 1998).

Bartonella spp. are adapted to infect a variety of hosts (invertebrates and vertebrates) and several cell types (erythrocytes, epithelial and endothelial cells). Thus, these pathogens provide a splendid opportunity to investigate host-parasite interactions at the cellular and molecular level. Research on molecular pathogenesis primarily has been done using *B. bacilliformis* as a model system for the genus.

COLONIZATION OF THE HOST. *Bartonella* spp. are inoculated directly into the blood

by the bite or scratch of a contaminated arthropod or cat. Subsequent colonization of the host lymphatics and circulatory system is likely enhanced by blood flow and, if possible, bacterial motility. *Bartonella bacilliformis* and *B. clarridgeiae* (previously 94-F40), a novel *Bartonella* species recently isolated from cats (Clarridge et al., 1995; Kordick et al., 1997), are highly motile and employ peritrichous flagella. Twitching motility has been observed in low-passage isolates of *B. henselae* and is thought to be conferred by type IV bundle-forming pili (Batterman et al., 1995). Putative type IV pili also have been observed in *B. bacilliformis*, but probably play a subordinate role to flagella in motility (Minnick et al., 1996). *Bartonella bacilliformis* flagella have been biochemically characterized and consist of multiple 42-kDa flagellin subunits that are highly resistant to protease treatment (Scherer et al., 1993). The N-terminus for flagellin (Scherer et al., 1993) and the nucleotide sequence of the *fla* gene (GenBank accession no. L20677) have both been characterized. Recently, the gene encoding the flagellin subunit from *B. clarridgeiae* also was cloned and sequenced and displays extensive sequence similarity with the *fla* gene of *B. bacilliformis* (Sander et al., 2000).

ADHERENCE TO HOST CELLS. *Bartonella bacilliformis* and *B. henselae* show a correlation between colony morphology and adherence to host cells in in vitro assays. Adherence rates for *B. bacilliformis* obtained from colony type T2 (see "Colony Morphology") were nearly twice that of bacteria derived from colony type T1 (Walker and Winkler, 1981). Similarly, high-passage phase variants of *B. henselae* from mucoid colonies showed a decrease in adherence to Hep-2 cells relative to low-passage bacteria obtained from dry and embedded colonies (Batterman et al., 1995). Reduction in *B. henselae* adherence is believed to result from repeated-passage phase variation, causing the loss of expressed type IV bundle-forming pili (BFP) on the surface of the pathogen (Batterman et al., 1995). The recent discovery of a putative type-IV BFP on low-passage *B. bacilliformis* suggests that other *Bartonella* spp. employ these appendages as well (Minnick et al., 1996). Figure 5 shows a low-passage *B. henselae* cell expressing BFP on its surface.

Bartonella bacilliformis can associate with human umbilical vein endothelial cells (HUVECs) or epithelial cells (HEp-2) with equal binding efficiency, and the majority of adherence occurs within the first 60 min of a 3-h incubation period (McGinnis-Hill et al., 1992). This is in contrast to erythrocyte adherence, where maximal complexing occurs at approximately 6 h after incubation (Benson et al., 1986).

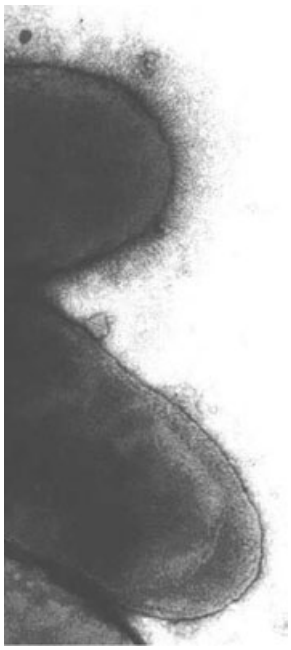

Fig. 5. Transmission electron micrograph showing piliated (upper) and non-piliated (lower) *B. henselae* cells from the same culture. (Courtesy of James A. Carroll.)

Disparate binding kinetics suggests that unique receptor-ligand interactions occur between each type of host cell and *Bartonella*. Adhesion to erythrocytes can be inhibited by reagents that inactivate proton-motive force (N-ethyl maleimide) or respiration (potassium cyanide; KCN), but is unaffected by pretreating the erythrocyte with inhibitors of glycolysis (sodium fluoride; NaF) or proton-motive force (N-ethyl maleimide). These observations suggest that adhesion is energy dependent (Walker and Winkler, 1981). However, it is believed that the red blood cell is passive during the process and cannot contribute to energy-dependent adhesion. The identity of the host cell receptor is not known. However, pretreating the erythrocyte with pronase or subtilisin enhances adhesion, whereas α- or β-glucosidase treatment decreases adhesion. Presumably, protease treatment of red cells exposes a glycolipid receptor that can be subsequently destroyed by glucosidase. It also is known that human erythrocytes are preferentially bound by *Bartonella* as compared to red blood cells from rabbits or sheep, suggesting that human red cells possess a more appropriate receptor or possess greater receptor density or accessibility than other types of erythrocytes possess (Walker and Winkler, 1981). Given the ability of *B. henselae* to infect cats and humans, it would be interesting to compare its binding efficiency with cat and human erythrocytes.

More recently, studies show that *B. bacilliformis* and *B. henselae* recognize five and six proteins, respectively, from human erythrocyte membranes (Iwaki-Egawa and Ihler, 1997).

Flagella also may serve as adhesins. A polar tuft of fibrous projections on *B. bacilliformis* was observed to make contact with the erythrocyte membrane during adhesion (Walker and Winkler, 1981). The fibrous tuft closely resembles the peritrichous flagella of the bacterium. It is also known that nonmotile bacteria bind poorly to erythrocytes, suggesting that an adhesin (flagella?) is missing in nonmotile bacteria or that nonmotile mutants have fewer bacteria-erythrocyte collisions (Benson et al., 1986). If *B. bacilliformis* is treated with rabbit anti-flagellin antiserum, there is a significant reduction (~41%) in bacterial association with red cells as compared to controls conducted with preimmune rabbit serum (Scherer et al., 1993). These data suggest that flagella may possess adhesive qualities and/or they increase the number of bacteria-host cell collisions.

The endothelial cell receptor for *Bartonella* spp. has not been characterized. The observation that *B. bacilliformis* binding to epithelial cells and endothelial cells displays a similar degree of efficiency suggests that the pathogen's apparent predilection for endothelial cells may actually be due to tissue site (e.g., circulatory system), rather than receptor-mediated constraints (McGinnis-Hill et al., 1992). In addition, binding data also suggest that both cell types contain a suitable, if not the same, receptor(s). The role of surface-exposed *Bartonella* polypeptides in adhesion is largely unknown. However, recent work with *B. henselae* has identified five biotinylated proteins (28–58 kDa) capable of binding to intact HUVECs. Of these, a 43-kDa polypeptide was identified as the major adhesin of the pathogen. It is significant to note that the 43-kDa protein also was recognized by reciprocal probing with biotinylated HUVEC surface proteins (Burgess and Anderson, 1998). The exact nature of the 43-kDa adhesin is currently under investigation.

INVASION OF HOST CELLS. Invasion of erythrocytes has been documented for *B. bacilliformis* (Benson et al., 1986), *B. henselae* (Kordick and Breitschwerdt, 1995a; Mehock et al., 1998), and *Bartonella* spp. previously classified as *Grahamella* species (Birtles et al., 1995; Table 2; Fig. 6). Host cell invasion by *B. quintana* and *B. elizabethae* has not been demonstrated, although both require blood or hemin for growth. In fact, *B. quintana* is believed to epicellularly associate with erythrocytes (Merrell et al., 1978). In addition to invasion of red blood cells, invasion of other host cell types (epithelial and endothelial cells) has been demonstrated for *B. henselae* (Batterman et al., 1995; Dehio et al., 1997b; Fig. 7) and *B. bacilliformis* (Garcia et al., 1992; McGinnis-Hill et al., 1992) and *B. quintana* (Brouqui and Raoult, 1996).

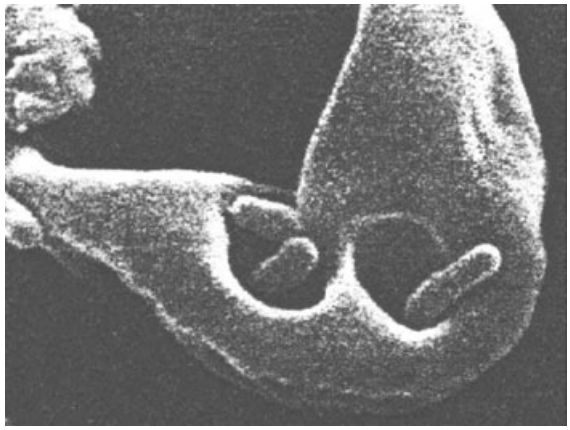

Fig. 6. Human erythrocyte being invaded by *B. bacilliformis*. (From Benson et al., 1986, with permission.)

Because *Bartonella* spp. can enter a variety of cells, molecular mechanisms for entry probably depend on the type of cell being invaded. Virulence studies with *B. bacilliformis*, together with cultured epithelial or endothelial monolayers, demonstrate that host cells can be induced by *Bartonella* to reconfigure the cytoskeleton, thereby enhancing bacterial uptake. Internalization is significantly reduced (~30% of controls) if actin filament formation is inhibited with cytochalasin D or if bacteria are pretreated with anti-*Bartonella* antiserum (McGinnis-Hill et al., 1992). These inhibition studies suggest that the bacterium is not passive during internalization and that the process involves a surface-borne molecule(s) that is accessible to antibody. Erythrocyte invasion by *Bartonella* spp. is very different because red cells are necessarily passive (non-endocytotic) and cannot contribute to bacterial uptake. Recent work by Dehio et al. (1997b) shows that *B. henselae* enters endothelial cells by a novel structure termed "an invasome" (Fig. 8). In in vitro models of infection, *B. henselae* cells are contacted and moved rearward to form an aggregate on the leading lamella of the endothelial cell. The "clumps" of bacteria are subsequently engulfed by membrane protrusions that are rich in cortical F-actin, intercellular adhesion molecule (ICAM-1), and phosphotyrosine. Based upon chemical inhibition studies, invasome activity is actin-dependent and microtubule-independent. Although most clinical strains of *B. henselae* were internalized via formation of the invasome, a natural mutant of *B. henselae* was internalized

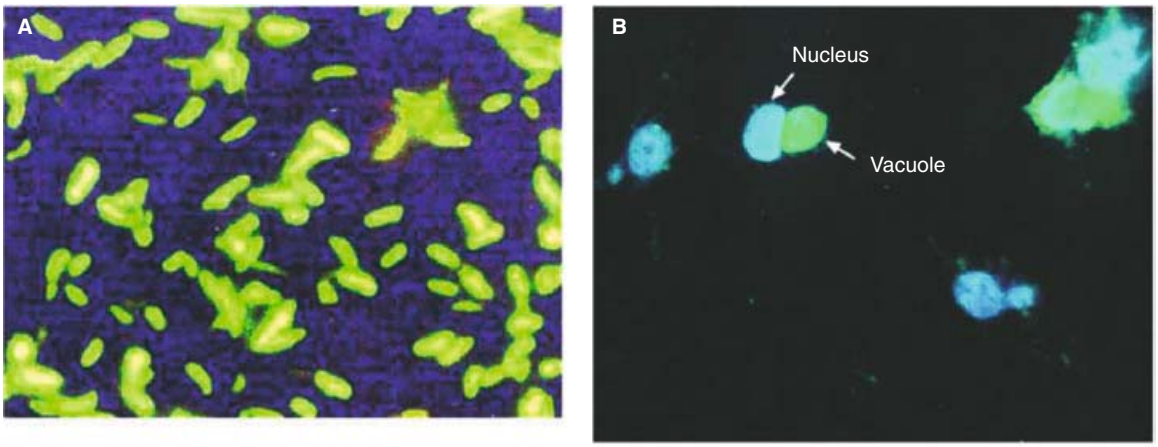

Fig. 7. Fluorescence microscopy showing a human microvascular endothelial cell with internalized *B. henselae*. A) *Bartonella henselae* expressing green fluorescent protein (GFP). B) A microvascular endothelial cell vacuole with numerous GFP-expressing *B. henselae* (green) in contrast to the nucleus (blue). (Magnification 400×; From Resto-Ruiz et al., 2000, with permission.)

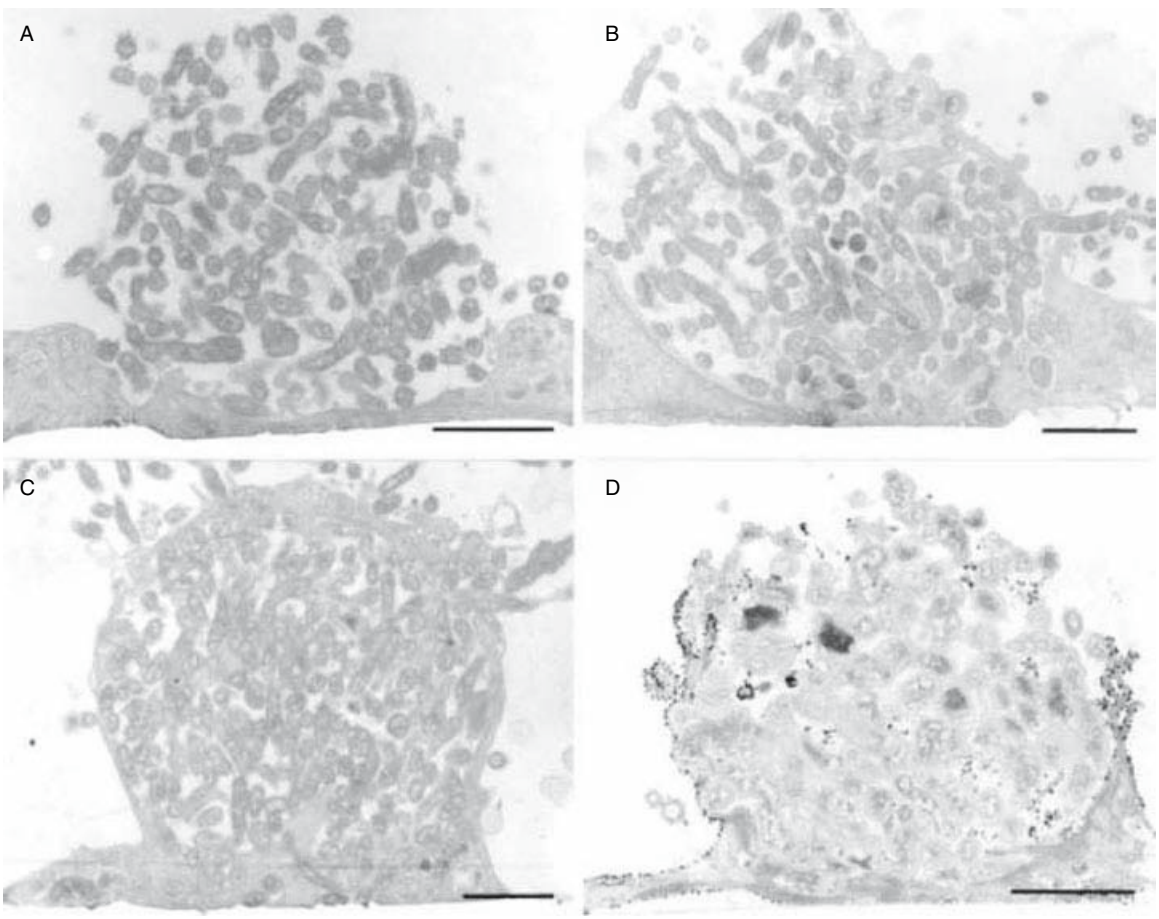

Fig. 8. Invasome structure observed when *B. henselae* is internalized by vascular endothelial cells. Transmission electron microscopy of: A) initial invasome structure, B) and D) engulfment of the bacterium, and C) internalization. Panel D shows immunogold labeling with mAbs to ICAM-1. Bars = 2 µm. (From Dehio et al., 1997b, with permission.)

via an alternate process and was ultimately located in a perinuclear phagosome. The authors hypothesized that invasome-mediated internalization may somehow interfere with the perinuclear phagosome formation. It is also possible that the mutant lacked the appropriate surface ligand for triggering formation of the structure.

Bartonella quintana was shown to invade epithelial cells in classical in vitro experiments using Hep-2 cells (Vinson and Fuller, 1961). More recent work has shown that the pathogen is also invasive for human endothelial cells in vitro and, more importantly, in cardiac valve tissue from endocarditis patients (Brouqui and Raoult, 1996). In vitro studies with *B. quintana* and human endothelial cells show that bacteria can become internalized within only one minute of coincubation. Concurrently, host cells exhibit ruffling and the bacterial cell wall becomes modified to produce surface appendages (20–40 nm wide by up to 500 nm in length). The appendages are apparently lost after adherence or internalization of the pathogen and are similar to those observed in *Salmonella typhimurium*. The authors hypothesize that the appendage is mediating or directing host cell adherence and endocytosis. Following host cell uptake, *B. quintana* multiplies in a vacuole, culminating in formation of morulae resembling those seen during infection by *Ehrlichia* spp. or *Chlamydia* spp. Older *B. quintana* and endothelial cell cocultures showed that morulae contain both bacteria and vesicle-like blebs presumably derived from the bacterial membrane. However, membrane blebs were not observed in cardiac tissue samples. It is interesting to note that *B. bacilliformis* (M. F. Minnick, unpublished data), *B. henselae* and *B. quintana* (Brouqui and Raoult, 1996) all produce blebs during in vitro growth, but their potential role in pathogenesis remains a mystery.

Three virulence determinants have been implicated in *Bartonella* invasiveness, including deformin, flagella, and proteins encoded by the invasion-associated locus of *B. bacilliformis*. Deformin-induced invaginations in the plasma membrane of erythrocytes (see "Extracellular Products") likely produce entry portals for colonizing the red cell. However, even with deformin, bacteria cannot enter the red cell cytosol unless they are motile (Mernaugh and Ihler, 1992). Perhaps *B. bacilliformis* swims into the trenches produced by deformin. If *B. bacilliformis* cells are treated with monospecific antibodies generated against the flagellin subunit, invasiveness of human erythrocytes is nearly abrogated in in vitro virulence assays (Scherer et al., 1993). Invasion of *B. bacilliformis* into Hep-2 cells is thought to require host cell tyrosine phosphorylation (Williams-Bouyer and Hill, 1999). In addition, invasion of human endothelial cells by *B. bacilliformis* requires host cell GTPase-Rho (Verma et al., 2000).

Recent work also shows that *B. bacilliformis* possesses an invasion-associated locus containing two genes, termed "*ialAB*" (Mitchell and Minnick, 1995; Fig. 9). The locus is approximately 1,500 bp and contains two ORFs (*ialA* and *ialB*) that confer an invasive phenotype on minimally invasive strains of *Escherichia coli* (strains HB101 and DH5α-) when combined with human red cells in vitro. Both genes are required to produce the invasiveness phenotype. The *ialA* gene codes for a (di)nucleoside polyphosphate hydrolase that may function to reduce stress-induced dinucleotide "alarmones" during host cell invasion and therefore enhance pathogen survival (Cartwright et al., 1999). The *ialB* gene codes for a protein with similar molecular mass and approximately 60% amino acid sequence similarity to the adhesion and invasion locus (Ail) protein of *Yersinia enterocolitica* (Miller et al., 1990) and the resistance to complement killing (Rck) protein of *Salmonella typhimurium* (Heffernan et al., 1994). Both Ail and Rck are implicated in host cell attachment, invasion and serum resistance. Whether the *Bartonella* invasion-associated locus mediates or facilitates the invasion of other cell types is unknown.

Characterization of genes that flank the *ialAB* locus suggests that *ialA* and *ialB* are components of a larger pathogenicity gene cluster. A gene encoding a carboxy-terminal protease, *ctpA*, lies upstream of *ialA* and *ialB* (Mitchell and Minnick, 1997a; Fig. 9). The encoded protease may be involved in *B. bacilliformis* virulence, espe-

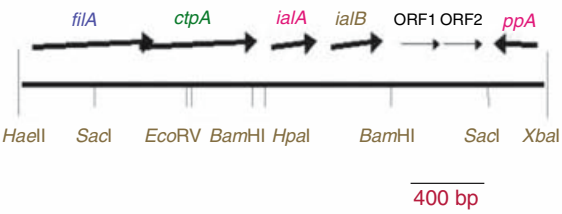

Fig. 9. The invasion-associated locus of *B. bacilliformis* plus flanking sequences characterized to date. Genes include *filA* (filament A gene), *ctpA* (carboxy-terminal processing protease gene), *ialA* (invasion-associated locus A gene), *ialB* (invasion-associated locus B gene), ORFs 1 and 2 (unknown function) and *ppA* (inorganic pyrophosphatase gene). The GenBank accession numbers are U73652, L37094, L25276 and L46591, respectively. Similar gene clusters have been found in *B. quintana* and *B. henselae*.

cially considering that the *prc* carboxy-terminal protease of S. *typhimurium* is involved in intracellular survival. The *prc* protease is thought to degrade abnormally folded stress-response proteins generated within the intracellular environment of the macrophage, thereby enhancing survival of S. *typhimurium* (Baumler et al., 1994). Though no evidence for CtpA involvement in invasion of human erythrocytes was found (Mitchell and Minnick, 1997a), the possible role that CtpA plays in *B. bacilliformis* intracellular survival is unknown.

Immediately upstream of the *ctpA* gene is a 1,200-bp ORF termed "*filA*" (M. F. Minnick and S. J. Mitchell, unpublished data). Characteristics of the predicted FilA polypeptide include: 1) a typical secretory signal sequence that follows the -3,-1 rule, 2) a 60% α-helical secondary structure, 3) a C-terminal hydrophobic domain that could anchor the protein in a membrane, 4) leucine-rich composition (12%) with numerous leucine repeats, a characteristic found in proteins that engage in protein-protein interactions (Kobe and Deisenhofer, 1995), and 5) amino acid similarity to a variety of filamentous proteins including smooth muscle myosin and the M1 protein of *Streptococcus pyogenes*, a virulence determinant involved in adhesion and invasion (Fischetti, 1989; Kehoe, 1994). The FilA polypeptide's similarity to M1 protein, the potential surface location and filamentous nature, plus the possibility that FilA provides for protein-protein interaction all suggest that the protein is a virulence determinant. The 3′ end of the virulence gene cluster is presumably demarcated by an inorganic pyrophosphatase (Ppase) gene (*ppa*) that is located 1,022 bp downstream of the locus (Mitchell and Minnick, 1997b). The Ppase is not involved in virulence because this enzyme plays an essential metabolic housekeeping role in many organisms.

DNA hybridization data suggest that *B. quintana* and *B. henselae* both possess homologues of *ialA*, *ialB* and *ctpA*, whereas *B. vinsonii*, an agent that does not infect humans, contains *ialA* and *ctpA* but may not contain an *ialB* homologue. *Bartonella elizabethae* showed very poor hybridization to any of the probes for the three genes (Mitchell and Minnick, 1997a). A homolog to the *ialAB* locus was recently cloned from *B. henselae* and was found to confer an invasive phenotype upon *E. coli* to approximately 100-fold over controls and possessed identical gene linkage with approximately 70–85% sequence identity to the *B. bacilliformis* locus (Murakawa, 1997). Likewise, invasiveness by *B. tribocorum* for rodent erythrocytes required the activity of IalB (Gille et al., 1999). Collectively, these data suggest that the invasion locus is conserved in most pathogenic *Bartonella* spp.

Genetics

Genome

The G+C content for *Bartonella* species is 40 + 1 mol%, with values ranging from 38.5 mol% for *B. quintana* (Tyeryar et al., 1973) to 41.1 mol% for *B. vinsonii* (Daly et al., 1993). In addition to a highly conserved G+C content, DNA hybridization results indicate a high degree of sequence homology (32–67% relatedness at 55°C) between the genomes of *Bartonella* species (Welch et al., 1992; Daly et al., 1993). The genome sizes of *B. bacilliformis* and *B. quintana* are approximately 1.6 and 1.5 Mbp, respectively (Krueger et al., 1995; Myers et al., 1979). Thus, the typical *Bartonella* genome is less than half the size of that from *E. coli*. Sequencing of the *B. henselae* genome is nearing completion and updated information from this project may be obtained. Genome sequencing projects for other *Bartonella* species are not currently in progress. An extrachromosomal, linear DNA band of 14 kbp is frequently observed in genomic DNA preparations from *B. henselae* and *B. bacilliformis*. The DNA is heterogeneous in nature and derived from a putative defective bacteriophage for bartonellae (Anderson et al., 1994a; Barbian and Minnick, 2000). Plasmids have not been described from any *Bartonella* spp.

Gene Structure

Because of their modest G+C content, genes in *Bartonella* spp. are biased for A or T in the second and third positions of their codons. For example, codon usage analysis of the 2,275-bp *gyrB* gene (gyrase B subunit) of *B. bacilliformis* (Battisti et al., 1998) or the 1,512-bp *htrA* gene (heat-shock antigen) of *B. henselae* (Anderson et al., 1996) shows an A or T 60% of the time in the second position and 77% of the time in the third position of their respective codons. However, a clear bias is not observed in the first position of the codons. Although promoters have never been characterized fully from a *Bartonella* species, all genes characterized are preceded by putative -35 and -10 hexamers with homology to the *E. coli* consensus promoter (McClure, 1985). Likewise, these genes are immediately preceded by a ribosomal binding site similar to that of *E. coli* (Gold et al., 1981). Indeed, the recent complementation of *E. coli* mutants with a cloned *ppA* gene (inorganic pyrophosphatase) and *gyrB* (gyrase B) from *B. bacilliformis* suggests that there is conservation of promoter sequence and function between the two bacteria (Mitchell and Minnick, 1997b; Battisti et al., 1998). The majority of the characterized *Bartonella* ORFs end

with a TAA stop codon, and putative transcriptional terminators have been observed downstream of the *ialA*, *ialB*, *ctpA* and *ppA* genes from *B. bacilliformis* (Mitchell and Minnick, 1995; Mitchell and Minnick, 1997a; Mitchell and Minnick, 1997b).

Genetic Systems

No naturally occurring systems for genetic exchange have been demonstrated for any *Bartonella* species. The presence of the bacteriophage particle in *B. henselae* and *B. bacilliformis* and the packaging and exportation of a diverse collection of chromosomal DNA fragments have raised the question about a possible role of this particle in transduction (Anderson et al., 1994a; Barbian and Minnick, 2000). The introduction of exogenous DNA into *B. bacilliformis* by electroporation (Batttisti and Minnick, 1999) and into *B. henselae* by transconjugation (Dehio and Meyer, 1997a; Lee and Falkow, 1998) and electroporation (Resto-Ruiz et al., 2000) has recently been reported.

Furthermore, the construction of specific mutants by the use of suicide plasmids and site-specific recombination recently has been demonstrated (Battisti and Minnick, 1999) and will undoubtedly prove valuable for a number of different types of studies.

Epidemiology and Control

Bartonellosis has been reported in rodents, insectivores, dogs, cats and humans (Breitschwerdt and Kordick, 2000). The pathogen usually is transmitted to mammals by arthropods. If chronically infected, the host may serve as a reservoir. Transmission also may be enhanced by persistent infection of the vector. For example, *Bartonella* (previously *Grahamella*) species (endemic in rodent populations) also infect the flea, thereby conferring the status of reservoir to the insect (Kreier and Ristic, 1981). Bartonelloses are usually sporadic and epidemic in nature, suggesting that infection of the vector or reservoir is cyclical, rather than continuous, in nature.

Bartonella bacilliformis The only known risk factor for *B. bacilliformis* infection is exposure to bites from phlebotamine sandflies (*Lutzomyia verrucarum*) in South America. The bacterium was once thought to be endemic to the high altitude regions of the Andes because its vector was restricted to that habitat. However, a recent review reports that related sandflies may serve as vectors for the agent and that numerous cases of Oroya fever have occurred in areas of much lower altitude (Alexander, 1995). Because of this, *B. bacilliformis* may be an emerging infectious agent in South America. The high carrier rate and seropositivity of individuals in endemic areas strongly suggest that these individuals serve as a reservoir for the pathogen. In addition, the sandfly vector is possibly infected by the bacterium (Hertig, 1942; Kreier and Ristic, 1981). The best control measure is insecticide application to eradicate sandflies. The use of antibiotics has produced a dramatic decline in the number of deaths caused by Oroya fever. No vaccine is currently available.

Bartonella henselae Data suggest that exposure to cats is the most significant risk factor for contracting bartonellosis from *B. henselae* (Zangwill et al., 1993; Koehler et al., 1994). A very high incidence (89%) of prolonged bacteremia with this pathogen has been observed in cats belonging to CSD patients (Kordick et al., 1995b). In addition, a high incidence of this agent (9–41%) has been seen in control cats of all ages from the United States and Japan (Koehler et al., 1994; Kordick et al., 1995b; Maruyama et al., 1996). Transmission routes include cat scratches and bites and possibly by infected fleas (Zangwill et al., 1993; Koehler et al., 1994). Epidemiologic evidence suggests that fleas also might serve as a vector (Welch et al., 1992; Lucey et al., 1992). *Bartonella henselae* is currently the only *Bartonella* species known to be transmitted to humans by non-arthropod means. Control of the disease includes decreased exposure to cats during immunocompromised states, antibiotic therapy of infected cats and humans, vaccination of the cat reservoir and flea control. A vaccine is not yet available, but is being developed for use in cats.

Bartonella quintana Trench fever is transmitted to humans by exposure to infected human body lice (*Pediculus humanus*). Infected lice perennially shed *B. quintana* in their feces, and humans are subsequently exposed through openings in the skin (e.g., bite site or scratches). The insects can transmit the pathogen for long periods of time (Vinson and Fuller, 1961). Contact with the vector is increased by conditions of overcrowding and poor hygiene. However, lice have not been clearly implicated in the re-emergence of *B. quintana* in the inner city. Overt risk factors for "urban trench fever" include homelessness, non-Caucasian descent and alcoholism (Spach et al., 1995; Jackson and Spach, 1996). Although the arthropod vector of urban trench fever is still unclear, it probably is a blood-sucking insect such as a louse, mite or flea. Spread of trench fever has historically been controlled by de-lousing and hygienic measures. There are no vaccines currently available.

Bartonella elizabethae The epidemiology of *B. elizabethae* is a mystery. The endocarditis patient

from whom the species was isolated had no known exposure to small mammals, nor did he have predisposing factors (cardiac valvular abnormalities, immunosuppression, HIV infection, etc.) that could have contributed to infection (Daly et al., 1993).

Bartonella clarridgeiae Associated with cats, *B. clarridgeiae* may be transmitted to humans by cat bite or (Kordick et al., 1997) by other forms of cat trauma and ectoparasites such as fleas. The coincidental infection of house cats with *B. henselae* and *B. clarridgeiae* suggests the potential for cotransmission of these bacteria to humans (Gurfield et al., 1997).

Disease

Clinical Presentation

CAT SCRATCH DISEASE. This disease (CSD) typically manifests as granulomatous skin lesions (papules or pustules) that develop within one week following a scratch or bite from an infected cat (Fig. 10A). Skin lesions contain areas of necrosis bordered by histiocytes, lymphocytes and giant cells (Johnson and Helwig, 1969). Lymphadenitis is usually unilateral and characteristic, with the proximal draining lymph node displaying adenopathy at 2–3 weeks following infection. Like the skin papules, lymph node lesions are granulomatous microabscesses that contain infiltrated lymphocytes and giant cells, together with follicular hyperplasia (Carithers, 1985). In addition to skin and lymph node involvement, patients with CSD can present with mild fever, malaise and gastrointestinal distress. Complications involving the central nervous system, bone, lung, liver, spleen and eyes also have been reported (Carithers, 1985; Milam et al., 1990; McCrary, 1994; Doyle et al., 1994; Caniza et al., 1995). Within 8–12 weeks, CSD lymphadenopathy typically self-resolves.

Fig. 10A. The varied clinical manifestations of bartonellosis including: A) cat-scratch disease (CSD), B) bacillary angiomatosis (BA), C) bacillary peliosis (BP) of the liver (hepatis peliosis) and D) aortic valve from a homeless patient with *Bartonella quintana* endocarditis. Note the small vegetation on the valve surface and infiltration with mononuclear cells. The valvular stroma presents with an extensive fibrosis (hematoxylin-phloxine-saffron, original magnification 100×). (CSD photo from Sander, A, 1998; BA photo from Koehler et al., 1992; hepatis peliosis photo from Perkocha et al., 1990; and endocarditis photo courtesy of Hubert Lepidi and Pierre-Edouard Fournier; all with permission.)

The etiologic agent of CSD was the source of speculation for many years. The putative agent was isolated in 1988 from the lymph node of a patient with lymphadenopathy (English et al., 1988) and later named "*Afipia felis*" (Brenner et al., 1991). However, a further link between *A. felis* and CSD weakened when other CSD patients were not found to be seropositive for *A. felis*, and new isolates of the bacterium from other cases were not obtained (Regnery and Tappero, 1995). Later, antibodies to *B. henselae* were found in the sera of patients with CSD, providing a serologic link (Regnery et al., 1992b). Subsequently, isolation and detection of *B. henselae* in CSD patients as well as epidemiological links removed any doubt that *B. henselae* was a cause of CSD (Welch et al., 1992; Regnery et al., 1992a; Zangwill et al., 1993; Dolan et al., 1993; Perkins et al., 1992; Anderson et al., 1993; Bergmans et al., 1995; McGinnis-Hill et al., 1992). However, *B. henselae* does not appear to cause (based on the inability to detect *B. henselae* in clinical specimens or antibodies to *Bartonella* in patient sera) a small but significant percentage of CSD cases. Thus, the possibility exists for an additional etiologic agent of CSD.

The identity of a second etiologic agent (*B. clarridgeiae*) of CSD was recently proposed when high titers of specific anti-*B. clarridgeiae* antibodies were found in patients with CSD (Kordick et al., 1997; Margileth and Baehren, 1998). In addition, *B. clarridgeiae* has been isolated from cats residing with patients diagnosed with CSD (Clarridge et al., 1995; Kordick et al., 1997). More recently, specific antibodies to the flagellin protein of *B. clarridgeiae* were found in 3.9% of sera from patients diagnosed with CSD (Sander et al., 2000). Although it is clear *B. clarridgeiae* is found in cats, the detection or isolation of *B. clarridgeiae* in clinical specimens from patients with CSD is necessary to confirm the etiologic role of this agent and has not been reported as yet.

BACILLARY ANGIOMATOSIS. Also known as "BA," this illness results from infection with either *B. henselae* or *B. quintana* (Relman et al., 1990; Relman et al., 1992; Koehler et al., 1992; Welch et al., 1992). The syndrome was first observed in AIDS patients in the 1980s (Stoler

et al., 1983; Cockerell et al., 1987; Berger et al., 1989) and, although it usually affects immunodeficient individuals (Stoler et al., 1983; Koehler and Tappero, 1993), it has been reported in immunocompetent patients (Cockerell et al., 1990; Lucey et al., 1992; Tappero et al., 1993a). The course of disease can be subacute and insidious in immunodeficient patients, whereas it is sudden in immunocompetent individuals (Schwartzman, 1992). Like CSD, risk factors for BA include exposure to infected cats or cat fleas (Koehler et al., 1994). The disease is characterized by pseudoneoplastic cutaneous or subcutaneous vascular lesions (Fig. 10B), and unlike those of CSD, BA lesions lack granulomatous tissue. The papule or nodule-like lesions of BA contain extensive vascular channels bordered by cuboidal, protuberant endothelium and a multicellular inflammatory infiltrate with polymorphonuclear leukocytes that display leukocytoclastic characteristics (LeBoit et al., 1989; Cockerell et al., 1990). In addition, the lesions usually contain aggregates of bartonellae when stained by Warthin-Starry silver stain (LeBoit et al., 1988; Angritt et al., 1988). Cutaneous lesions of BA are similar to verruga peruana and superficially resemble vascular neoplasms such as Kaposi's sarcoma (LeBoit et al., 1988; Webster et al., 1992) or pyogenic granulomas (Koehler and Tappero, 1993). The lesions can last for several months (Koehler et al., 1992). Subcutaneous or visceral BA can involve a host of organ systems including the brain, bone, lymph nodes and eyes (Koehler et al., 1992; Spach et al., 1992; Koehler and Tappero, 1993; Tappero et al., 1993b; Kemper et al., 1990; Waldvogel et al., 1994; Slater et al., 1994; Golnik et al., 1994; Tappero et al., 1993b).

BACILLARY PELIOSIS. *Bartonella henselae* also is the agent of bacillary peliosis (BP; Marullo et al., 1992; Slater et al., 1992; Welch et al., 1992; Tappero et al., 1993b). The BP lesions are characterized by cystic blood filled cavities (Perkocha et al., 1990; Garcia-Tsao et al., 1992; Fig. 10C). Gastrointestinal distress, fever and chills may accompany peliosis, and the syndrome may occur alone or in combination with BA or bacteremic syndrome. The disease can involve single or multiple organs such as the liver, spleen and lymph nodes, and the lesions contain bartonellae when stained by Warthin-Starry silver stain (Perkocha et al., 1990). In the liver, BP can produce hepatomegaly, and patients typically show elevated serum levels of liver enzymes (e.g., γ-glutamyl transferase and alkaline phosphatase; Perkocha et al., 1990). Death following peliosis-induced liver failure also has been reported (Perkocha et al., 1990).

OROYA FEVER. Also referred to as "Carrion's disease" or "verruga peruana," this disease is endemic to South America (Alexander, 1995), particularly in Peru, Colombia and Ecuador (Kreier and Ristic, 1981), and has afflicted travelers visiting this region (Matteelli et al., 1994). The course of disease is very unusual and transpires sequentially in two disparate stages. The primary (hematic) phase is characterized by an acute bacteremia that occurs within four weeks of being bitten by a contaminated phlebotamine sandfly. From the inoculation site, *B. bacilliformis* efficiently colonizes the entire circulatory system. Nearly every erythrocyte becomes parasitized and approximately 80% are lysed (Hurtado et al., 1938), presumably by splenic culling (Reynafarje and Ramos, 1961). Case fatalities can reach 40–88% without antibiotic therapy (Weinman, 1965; Gray et al., 1990). The acute phase can be accompanied by anorexia, headache and coma in fatal cases (Roberts, 1995). Secondary infectious diseases such as salmonellosis, shigellosis, or recurrence of toxoplasmosis or tuberculosis are not uncommon during the hematic phase and can complicate patient prognosis (Urteaga and Payne, 1955; Cuadra, 1956; Gray et al., 1990). Patients present with secondary (tissue) phase symptoms, approximately four weeks following resolution of the primary phase. Tissue involvement results from bacterial invasion of the endothelial cells lining the capillary beds and generates bacteria-filled vacuoles (termed "rocha lima inclusions") and localized cellular proliferation leading to the formation of nodule or papule lesions termed "verruga peruana" (Arias-Stella et al., 1986). Verruga eruptions are usually cutaneous but may involve mucous membranes and viscera (Ricketts, 1949). Cutaneous lesions are found on the skin of the head and extremities and can persist for several weeks to months. Though the secondary phase is rarely fatal, verrugas can bleed and scar the patient (Weinman, 1965). Anemia is no longer present during the tissue stage (Ricketts, 1949), but viable bacteria can be isolated from the blood, marrow and hemangioma tissue of patients with verruga peruana.

TRENCH FEVER. A louse-borne disease caused by *B. quintana*, it is distributed throughout the world. The illness was first reported during World War I and was responsible for several epidemics among troops (McNee and Renshaw, 1916). Only influenza caused a greater morbidity and loss of man-hours during World War I (Strong, 1918). After a brief period of quiescence, trench fever reappeared during World War II (Kostrzewski, 1950) and has occurred sporadically thereafter. Currently, infection with *B. quintana*, the so-called "urban trench fever," is re-emerging in homeless, inner-city populations of the United States (Jackson and Spach, 1996). Cases of urban trench fever also have been reported in France (Raoult et al., 1996). Trench fever occurs approximately nine days following inoculation by the bite of an infected louse (Byam, 1919). Although symptoms of trench fever vary significantly between patients, the disease usually presents with mild to moderately severe fever, chills, malaise, myalgia and bone pain that is especially prominent in the tibia (hence "shinbone fever"; Varela et al., 1969). Occasionally, patients develop splenomegaly and a maculopapular rash resembling the rose spots of typhoid fever (Strong, 1918). The illness usually lasts about one week, but febrile episodes may be recurrent and the bacteremia protracted. Recent data also have implicated *B. quintana* as an emerging etiologic agent of bacillary angiomatosis and endocarditis.

ENDOCARDITIS. Although many microorganisms can cause endocarditis, data suggest that blood culture-negative cases often involve *Bartonella* species (Raoult et al., 1996; Fig. 10D). Endocarditis has been linked to infection with *B. henselae* (Hadfield et al., 1993; Drancourt et al., 1996; Raoult et al., 1996), *B. quintana* (Spach et al., 1993; Drancourt et al., 1995; Jalava et al., 1995; Raoult et al., 1996) and *B. elizabethae* (Daly et al., 1993). Endocarditis caused by bartonellae has been reported for both immunocompetent and immunosuppressed individuals.

BACTEREMIC SYNDROME AND FEVER OF UNKNOWN ORIGIN. Cases of relapsing

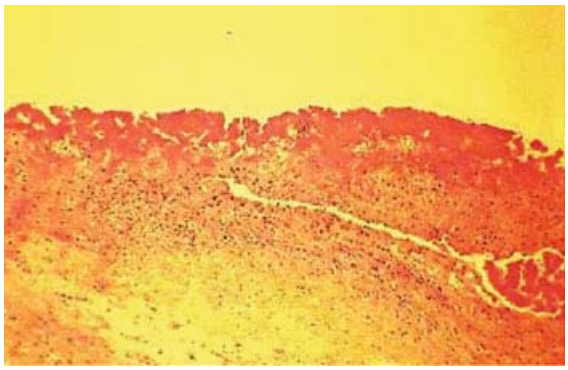

Fig. 10D. The varied clinical manifestations of bartonellosis including: A) cat-scratch disease (CSD), B) bacillary angiomatosis (BA), C) bacillary peliosis (BP) of the liver (hepatis peliosis) and D) aortic valve from a homeless patient with *Bartonella quintana* endocarditis. Note the small vegetation on the valve surface and infiltration with mononuclear cells. The valvular stroma presents with an extensive fibrosis (hematoxylin-phloxine-saffron, original magnification 100×). (CSD photo from Sander, A, 1998; BA photo from Koehler et al., 1992; hepatis peliosis photo from Perkocha et al., 1990; and endocarditis photo courtesy of Hubert Lepidi and Pierre-Edouard Fournier; all with permission.)

fever with persistent bacteremia have been reported in patients infected with *B. henselae* (Slater et al., 1990; Welch et al., 1992; Welch et al., 1993; Regnery et al., 1992a; Lucey et al., 1992) and *B. quintana* (Koehler et al., 1992; Maurin et al., 1994). The possibility that *B. henselae* is a relatively common cause of fever of unknown origin (FUO) in pediatric patients was suggested by a study that found 7 of 146 patients diagnosed with FUO had high antibody titers to *Bartonella* (Jacobs and Schutze, 1998). In a separate study 34% of patients with prolonged fever or FUO were found to have anti-*Bartonella* antibodies (Tsukahara et al., 2000). These later two studies suggest that *Bartonella* spp. may be a relatively common cause of FUO in immuncompetent individuals.

Diagnosis

Because *Bartonella* spp. are difficult to culture from clinical isolates, indirect identification of the pathogen is usually based upon individual patient history and symptomology (see "Clinical Presentation"). If culture of the agent is possible, identification of the bacterium can be made using the techniques described in "Identification" above.

CAT-SCRATCH DISEASE. Patients are generally immunocompetent children or young adults. There is a history of cat bite or scratch resulting in a papule or pustule-like lesion. Diagnostic characteristics include a positive CSD-skin test (more recently been replaced by serologic testing), an unexplainable lymphadenopathy, and characteristic lesion histopathology (granuloma and abscess formation and bacilli present when sectioned and stained by Warthin-Starry silver stain). Diagnosis is based on tests for seroconversion (Regnery et al., 1992a; Zangwill et al., 1993; Patnaik et al., 1992) and a more sensitive ELISA system (Barka et al., 1993). A titer of >64 by immunofluorescence assay is considered positive for *B. henselae* by the United States Centers for Disease Control and Prevention (CDC; Regnery et al., 1992b). When available, PCR on lymph node aspirates or biopsies is often successful (Anderson et al., 1994b).

BACILLARY ANGIOMATOSIS. Patients usually are immunocompromised. Cutaneous and/or subcutaneous nongranulomatous vascular lesions affect a variety of organs. Bacilli in sections of affected tissue can be visualized using Warthin-Starry silver stain. Diagnostic testing includes an anti-*B. henselae* IgG indirect fluorescent antibody assay (Regnery et al., 1992a; Zangwill et al., 1993; Patnaik et al., 1992) and an ELISA system (Barka et al., 1993).

BACILLARY PELIOSIS. Patients usually are immunocompromised. Diagnosis based on symptoms is difficult and may require biopsy. Cystic blood-filled liver lesions that are similar to those of BA, together with bacilli in sections of affected tissue, are diagnostic. Hepatomegaly and elevated serum levels of liver enzymes are characteristic. Bacillary peliosis should be suspected if patient has BA or bacteremic syndrome. Detection reagents used for BA diagnosis also can be used for bacillary peliosis.

OROYA FEVER. Patients have a history of travel or residence in South America and may have history of sandfly bite. Diagnostic symptoms of the primary stage include a dramatically low erythrocyte count (~500,000/mm^3; Hurtado et al., 1938; Reynafarje and Ramos, 1961; Kreier and Ristic, 1981) and numerous infected erythrocytes when blood smears are stained with eosin and thiazine (Knobloch et al., 1985). Secondary (tissue) phase presents with cutaneous angiomatous lesions (verruga peruana) that contain bacteria when sectioned and stained with Warthin-Starry silver stain.

TRENCH FEVER. Patients likely have a history of infestation with body lice (*Pediculus humanus*). Chronic alcohol abuse, homelessness and non-Caucasian descent are risk factors (Jackson and Spach, 1996). Diagnostic characteristics include pain in the bones (especially the tibia), fever and persistent bacteremia for several weeks to months following resolution of symptoms (Vinson et al., 1969). The presence of seroconversion to *B. quintana* can be tested; however, the antibody response usually is not specific to only *B. quintana* owing to crossreactivity within the genus (Regnery et al., 1992a).

ENDOCARDITIS. *Bartonella* infection should be considered in blood culture-negative cases of endocarditis. Patients usually have predisposing heart conditions or are at high risk for contracting infection with *B. henselae* or *B. quintana* (see *B. henselae* or *B. quintana* under "Epidemiology and Control"). Vegetative lesions are common in cases of *Bartonella endocarditis* (Daly et al., 1993; Raoult et al., 1996). The difficulty of culture from patient isolates and serological crossreactivity between *Chlamydia* spp., *Bartonella* spp. and *Coxiella burnetii* can complicate diagnosis (Drancourt et al., 1995; Knobloch et al., 1988b; La-Scola and Raoult, 1996). Seropositivity for *Bartonella* infection can be tested with the detection reagents described for diagnosis of BA. Molecular techniques involving PCR also should be used, particularly if species-level identification is desired (see "Identification").

BACTEREMIC SYNDROME. Patients are usually immunocompromised. Persistent bacteremia and recurring fevers, together with chronic fatigue and malaise, are diagnostic. Diagnosis can be made by blood cultures with subsequent identification protocols (see "Identification") or

by testing for seropositivity to *B. henselae* or *B. quintana* as described for BA.

Antimicrobial Therapy

A variety of antibiotics have been used successfully to treat bartonelloses. Antimicrobial therapy varies depending upon *Bartonella* species and in some cases is syndrome-dependent. CSD and trench fever generally are self-limiting illnesses that do not require therapy unless the infection is systemic. In contrast, BA can be life threatening and requires prompt antibiotic therapy. The immune state of the patient is also an important consideration for prescribing the type and duration of antimicrobial therapy for bartonellosis. For example, BA therapy for healthy patients is approximately three weeks, whereas immunocompromised patients may require several weeks to months, or possibly a lifetime, of therapy to resolve the infection (Adal et al., 1994). Relapse of bartonellosis is common even with antimicrobial therapy. Bartonellae are typically sensitive to most antibiotics in vitro (Maurin and Raoult, 1996), but are frequently resistant to them during human therapy. This observation may reflect the inability of the chemotherapeutic agent to access the pathogen located within host cells. Aminoglycosides are particularly bactericidal for bartonellae in vivo (Musso et al., 1995) and are recommended for therapy. Although optimal antibiotic regimens are still unclear, a list of antimicrobials that have successfully been used in treating various manifestations of bartonellosis is given in Table 4.

Immunity

The general course of bartonellosis begins with transient or persistent bacteremia that may involve erythrocyte parasitism, depending upon bacterial species. The pathogen subsequently infects the vascular bed within a variety of tissues, where vascular lesions are produced. Tissue involvement can be chronic, and presumably the pathogen is shed from the affected tissues into the bloodstream. Lymphadenopathy is a frequent complication in bartonellosis. The immune status of the host is a risk factor for infection. Typically, immunocompromised patients are at higher risk of opportunistic infection by bartonellosis than healthy individuals are. As a rule of thumb, trench fever, CSD, endocarditis and Oroya fever take place regardless of immune status of the patient, whereas BA, bacillary peliosis and bacteremic syndrome occur mainly in immuocompromised individuals. Bartonellosis symptoms are generally more pronounced in immunodeficient patients. In cases of BA, many patients display a marked CD4+ lymphocyte leukocytopenia, with counts of less than 100 (LeBoit et al., 1989; Koehler and Tappero, 1993). At best, the human immune response against *Bartonella* is poorly characterized, and for some species (*B. elizabethae* and *B. clarridgeiae*) it has never been studied. Because *Bartonella* spp. are found in a variety of body fluids and cells, involvement of both humoral and cellular arms of the immune system needs to be invoked for resolution of infection.

BARTONELLA BACILLIFORMIS. Lifelong humoral immunity supposedly results from an

Table 4. Antimicrobial agents used to treat bartonelloses.

Syndrome	Antimicrobial Agent(s)	Reference(s)
BA	Erythromycin or doxycycline	Bartlett, 1996
	Also chloramphenicol, sulfa-trimethoprim, aminoglycosides, azithromycin	Milde et al., 1995
	Ciprofloxacin	
	Clarithromicin	
Bacteremic syndrome	Erythromycin or doxycycline	Adal et al., 1994
BP	Erythromycin[a]	Perkocha et al., 1990
		Bartlett, 1996
CSD[b]	Ciprofloxacin, sulfa-trimethoprim or gentamicin	Bartlett, 1996
	Erythromycin or doxycycline	Smith, 1997
	Azithromycin	Bass, 1998
Endocarditis	Nafcillin + gentamicin	Daly et al., 1993
Oroya fever	β-Lactams, tetracycline + streptomycin, aminoglycosides, chloramphenicol if coninfected by enterics	Weinman, 1965
Pulmonary nodules	Doxycycline	Caniza et al., 1995
Retinal vasculitis and vitreitis	Ciprofloxacin	Soheilian et al., 1996
Trench fever[a]	Tetracycline or chloramphenicol	Moulder, 1974

Abbreviations: BA, bacillary angiomatosis; BP, bacillary peliosis; and CSD, cat-scratch disease.
[a]Alternatives as in BA.
[b]Usually self-limiting (does not require antibiotic therapy unless systemic).

active infection with *B. bacilliformis* (Ricketts, 1949; Weinman, 1965). Seropositivity (mainly IgM isotype) in endemic areas of Peru can reach 60% of the population, and many of these individuals are healthy (Knobloch et al., 1985). However, in spite of circulating antibody, many individuals who are asymptomatic or posteruptive for verruga peruana are often blood culture-positive for *B. bacilliformis* (Howe, 1943), and carrier rates can reach 15% in some areas of Peru (Herrer, 1953).

Immunosuppression is characteristic and probably results from the acute anemia and leukocytosis. Although a variety of proteins from *B. bacilliformis* are immunogenic (Knobloch, 1988a), the most prominent antigens include a GroEL homologue (BB65) (Knobloch and Schreiber, 1990), the flagellin protein (42 kDa), a phage coat protein (31.5 kDa) and an uncharacterized protein of 45 kDa (Minnick, 1994). The gene encoding a 43-kDa lipoprotein of *B. bacilliformis* reactive with human sera from bartonellosis cases was recently cloned, sequenced and expressed (Padmalayam et al., 2000b).

BARTONELLA QUINTANA. Although symptoms during *B. quintana* infections are highly variable, patients generally produce low-titer, complement-fixing antibody during the early phase of convalescence (Varela et al., 1969). However, in spite of antibodies, patients frequently display persistent and protracted bacteremia (Varela et al., 1969; Koehler et al., 1992; Maurin et al., 1994). In addition, *B. quintana* is markedly resistant to killing by complement fixed by classical or alternative pathways (Myers and Wisseman, 1978). Infection frequently is accompanied by leukocytosis (Vinson et al., 1969), possibly enhancing bacteremia.

BARTONELLA HENSELAE. Patients infected with *B. henselae* are generally seropositive when assayed by indirect fluorescence antibody tests (Regnery et al., 1992a). Antibodies apparently opsonize the pathogen and enhance production of oxygen radicals following phagocytosis, but do not enhance complement activation by the classical pathway. In fact, complement fixation mainly proceeds via the alternative pathway (Rodriguez-Barradas et al., 1995a). Persistent bacteremia with *B. henselae* is common in both humans and cats (Koehler et al., 1994), and respective antibody titers do not necessarily correlate with protection against the pathogen. A 17-kDa antigen has been shown to be highly reactive with human sera from patients with CSD (Anderson et al., 1995). The gene encoding this antigen is conserved among most *Bartonella* spp. but shows extensive amino acid sequence divergence (Sweger et al., 2000). A second protein of 83-kDa has been reported to react with human sera from patients with CSD (McGill et al., 1998). In addition to antibody reactivity, the cellular immune response in humans with CSD has been well recognized (Gerber et al., 1986). The aggravating cellular immune response to *B. henselae* both contributes to the pathogenesis of CSD and forms the basis of diagnostic skin test. This delayed-type hypersensitivity and T helper 1-type cytokine response has been recently reproduced in mouse models (Arvand et al., 1998; Karem et al., 1999).

CHAPTER 3.1.19

The Order Rickettsiales

XUE-JIE YU AND DAVID H. WALKER

Introduction

Rickettsiae are genetically related α-Proteobacteria with fascinating obligately intracellular lifestyles usually involving alternation between vertebrate and invertebrate hosts. These feats are accomplished with small, evolutionarily selected genomes. The agents classified as *Rickettsia*, *Orientia*, *Ehrlichia*, *Anaplasma*, *Wolbachia* and *Neorickettsia* cause diseases (such as epidemic louse-borne typhus fever, Rocky Mountain spotted fever, scrub typhus, human ehrlichioses, and bovine anaplasmosis) that have repeatedly altered the course of history (Zinsser, 1935), unexpectedly kill previously healthy tick-exposed persons, occur as highly prevalent endemic febrile illness, and are veterinary pathogens of major economic importance.

Although mostly known as pathogens transmitted by hematophagous ticks and insects, some of the Rickettsiales are insect endosymbionts (*Wolbachia*) that have evolved dramatic abilities to manipulate their host populations, and others (*Neorickettsia*) have a life cycle within a trematode that involves a series of aquatic hosts including snails, fish and insects.

The biology of the rickettsiae is difficult to define and investigate separately from the biology of their hosts. As a result of obligately intracellular growth and propagation difficulties in antibiotic-free cell culture or even in embryonated eggs, rickettsial physiology and metabolism are challenges to elucidate. Consequently, the study of these microorganisms and their diseases has been relatively neglected and there is the mistaken impression that they must be unimportant and uninteresting. Nothing could be further from the truth. The state of Rickettsiales knowledge presented in this chapter is to suggest to microbiologists opportunities for increasing scientific and medical understanding in this field.

On the basis of phylogenetic analysis of the 16S rRNA gene sequence (Fig. 1), the order Rickettsiales is a monophyletic group (Roux and Raoult, 1999) that currently includes the families Rickettsiaceae and Anaplasmataceae (Stothard and Fuerst, 1995; Dumler et al., 2001). All bacteria in the order Rickettsiales are Gram-negative α-Proteobacteria. The arrangement of the rRNA genes in Rickettsiales is unusual. While the 16S, 23S, and 5S rRNA genes are linked together in other bacteria, in rickettsial organisms, the 16S rRNA gene is separated from the 23S and 5S rRNA gene cluster, and the 23S rRNA gene is preceded by a gene that codes for methionyl-tRNA formyltransferase (Andersson et al., 1999; Massung et al., 2001). The genomic rearrangement of the rRNA genes preceded the divergence of the two families.

On the basis of phylogenetic analysis of 16S rRNA gene sequences, many species classified traditionally as Rickettsiales do not cluster with and have been removed from the Rickettsiaceae and Anaplasmataceae families. These include *Rickettsiella grylli*, *Coxiella burnetii*, *Wolbachia persica*, *Bartonella*, *Grahamella*, *Eperythrozoon ovis*, *Hemobartonella felis* and *H. muris* (Roux and Raoult, 1999).

The family Anaplasmataceae includes four genera, *Anaplasma*, *Ehrlichia*, *Neorickettsia* and *Wolbachia*. Members of the genera *Anaplasma*, *Ehrlichia*, and *Neorickettsia* in the family Anaplasmataceae are small obligately intracellular, Gram-negative, pleomorphic, coccoid to ellipsoidal organisms that reside in membrane-bound cytoplasmic vacuoles and form characteristic microcolonies resembling mulberries, termed morulae (Latin *morum* = mulberry; Fig. 2). Electron microscopy reveals two distinct morphological forms: a larger reticulate and a smaller dense-core cell. Both forms divide by binary fission, which is strong evidence that they are not stages in a developmental cycle (Popov et al., 1998; Popov et al., 2000). All known members of these genera are pathogenic for mammals, and some are pathogenic for human beings. Most members of the Anaplasmataceae target hematopoietic cells. *Anaplasma marginale* infects the erythrocytes of cattle and wild ruminants, and *A. bovis* infects the mononuclear cells of cattle. *Anaplasma phagocytophila* and

Fig. 1. The length of each pair of branches represents the distance between sequence pairs. The numbers on the branch indicate the bootstrap values.

A. platys infect mammalian neutrophils and canine platelets, respectively. All members of the genus *Ehrlichia* except *E. ruminantium* and *E. ewingii* infect monocytes. *Ehrlichia ruminantium* infects endothelium, and *E. ewingii* infects granulocytes.

Wolbachia pipientis and the genus *Anaplasma* form sister taxons by 16S rRNA gene and *groEL* gene sequence phylogeny (Wen et al., 1995; Yu et al., 2001). Thus, *W. pipientis* was reclassified into the family Anaplasmataceae (Dumler et al., 2001).

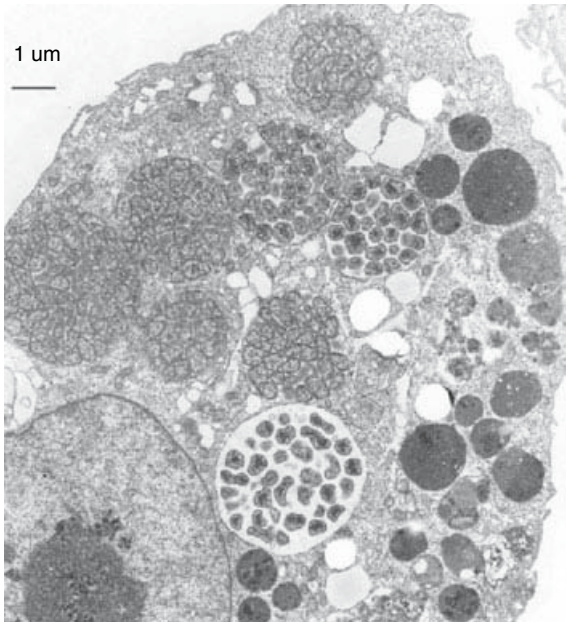

Fig. 2. Electron photomicrograph of a canine macrophage-like cell line (DH82) infected with *Ehrlichia canis* contains eight vacuoles (morulae) filled with ehrlichiae. Five morulae contain reticulate cell forms; three contain dense-core forms (particularly the morula in the lower center of the figure). See the Microbe Library website (http://www.microbelibrary.org/) for more electron micrographs of *Ehrlichia*.

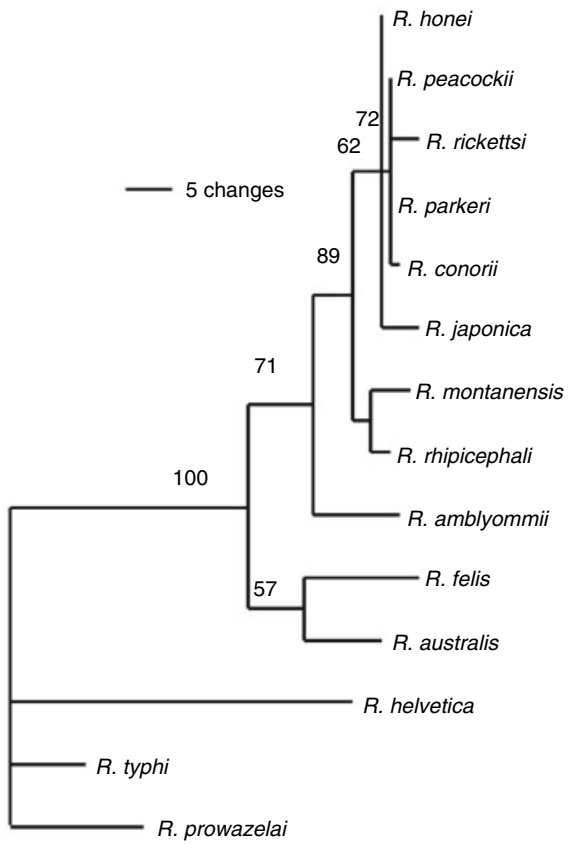

Fig. 3. Phylogenetic relationships of the organisms in the genus *Rickettsia* based on the DNA sequences of the 17-kDa protein genes (GenBank accession numbers for *R. honei*, A060704; *R. peacockii*, AF260571; *R. rickettsii*, RIRANTRR; *R. parkeri*, RPU17008; *R. conorii*, RIRANT17KA; *R. japonica*, RIR17KGCA; *R. montanensis*, RMU11017; *R. rhipicephali*, RPU11020; *R. amblyommii*, RAU11013; *R. felis* AF195118; *R. australis*, RIRTRAPRO; and *R. helvetica*, AF181036). The length of each pair of branches represents the distance between sequence pairs. The numbers on the branch indicate the bootstrap values.

Genus Rickettsia

Phylogeny

The evolution of the genus *Rickettsia* is demonstrated by phylogenetic trees developed from DNA sequence data that are based on the 16S rRNA, *groEL*, citrate synthase (*glt*), *rompA*, *rompB* and other genes (Roux and Raoult, 1995; Stothard and Fuerst, 1995; Roux et al., 1997; Fournier et al., 1998; Roux and Raoult, 2000; Fig. 3). The most ancestral species of the genus appear to be *R. bellii*, *R. canadensis*, and the AB male killing bacterium (Stothard et al., 1994). *Rickettsia* and mitochondria evolved from a common ancestor (Andersson et al., 1998). The phylogenetic tree may be overpopulated by species' names of spotted fever group rickettsiae, many of which are closely related and have been given separate names. The discovery of organisms very closely related to *R. bellii* in herbivorous pea aphids and associated with plant pathology (e.g., papaya bunchy top disease) suggests that knowledge and diversity of *Rickettsia* may have been determined more by medical investigations and medical entomology than by consideration of the complete picture (Chen et al., 1996; Davis et al., 1998).

Taxonomy

The family Rickettsiaceae consists of two genera: *Rickettsia* and *Orientia*. *Rickettsia* is further divided into two groups: the spotted fever group (SFG) and typhus group (TG), based on the difference in lipopolysaccharide (LPS) antigens. The TG rickettsiae include *R. prowazekii* and *R. typhi*. The SFG rickettsiae include *R. akari*, *R. australis*, *R. africae*, *R. conorii*, *R. honei*, *R. japonica*, *R. sibirica R. helvetica*, *R. slovaca*, *R. massiliae*, *R. rhipicephali*, *R. aeschlimannii*, *R. montanensis*, *R. parkeri*, and most likely *R. felis* (Roux and Raoult, 2000; Zhang et al., 2000; Bouyer et al., 2001). The numbers of named SFG rickettsiae have increased rapidly in recent years

owing to improved isolation approaches and molecular methods for identification; however, there is no consensus about the criteria used to define a species of SFG rickettsiae. Many designated species of SFG rickettsiae actually may be clones or strains of a single species, according to the standards used for classifying other bacteria. Other *Rickettsia* (such as *R. bellii*, *R. canadensis* and the AB male killing bacterium) do not fit into either the SFG or TG.

Habitat

Rickettsia are small (0.3–0.5 × 0.8–2.0 μm), Gram-negative, aerobic coccobacilli. They are obligately intracellular and reside free in the cytoplasm of the eukaryotic host cell where they divide by binary fission. SFG rickettsiae may also reside in the nucleus of the eukaryotic host cells. *Rickettsia* are dependent on arthropods (ticks, mites, fleas and lice) for their persistence in nature. For some, the arthropod host is both reservoir and vector. Transovarian transmission of the agent from the infected female to the next generation through the ova is the essential mechanism for many species (Burgdorfer, 1988).

Isolation

Isolation of rickettsiae from blood, buffy coat, or plasma historically employed inoculation of adult male guinea pigs or embryonated chicken eggs for *Rickettsia* and mice for *Orientia* (Walker, 1996a). More often at present Vero, L-929, HEL, and MRC5 cells in antibiotic-free media are inoculated with heparin-anticoagulated plasma or buffy coat ideally collected before antirickettsial treatment. Isolation of rickettsiae is enhanced by centrifugation of the inoculum onto monolayers in shell vials (LaScola and Raoult, 1996). Rickettsiae are detected by examining monolayers stained by Giemsa, Gimenez, or immunofluorescence methods, with 82% of positive samples identified after 48 hours incubation. Appropriate precautions should be taken for handling these P3 level pathogens.

Identification

Members of the genus *Rickettsia* have a typical Gram-negative bacterial cell wall that contains LPS, peptidoglycan, and outer membrane proteins. Isolated organisms can be identified as *Rickettsia* by the obligate intracellular parasitism, ultrastructural identification of cell wall morphology and of location free in the cytosol, reactivity with group-, species-, or strain-specific monoclonal or polyclonal antibodies, and restriction fragment length polymorphism of particular genes. Currently DNA sequence analysis of the genes of the 17-kDa lipoprotein, outer membrane proteins A and B, citrate synthase, and 16S rRNA is utilized most often to identify rickettsial isolates (Walker, 1996a).

Preservation

Stocks of *Rickettsia* are usually preserved frozen at –70 to –80°C or in the vapor phase of liquid nitrogen. They may also be preserved in a lyophilized state.

Physiology

Adherence to the Host Cell

Rickettsiae are inoculated into the dermis of the skin by a tick bite or through damaged skin from the feces of lice or fleas. Rickettsiae spread through the bloodstream and infect the endothelium. Adherence to the host cell is the first step of rickettsial pathogenesis. The adhesins must be outer membrane proteins. The outer membrane protein OmpA has been implicated as an adhesin of *R. rickettsii* because monoclonal antibodies to OmpA block *R. rickettsii* attachment (Li and Walker, 1998). The rickettsial adhesin must have evolved prior to the divergence of the SFG and TG rickettsiae because both groups are obligately intracellular. Lack of OmpA in TG rickettsiae indicates that there must be a more conserved or even more important adhesin in rickettsiae than OmpA for mammalian cells. There is evidence that both OmpA and OmpB are adhesins of *R. japonica* (Uchiyama, 1999). The receptor for *Rickettsia* has yet to be identified. Although the main target cells of *Rickettsia* in vivo are endothelial cells, rickettsiae can infect virtually every cell line in vitro. Thus, either the receptor for *Rickettsia* is ubiquitous among cells, or rickettsiae can bind to different receptors.

Invasion of the Host Cell

Upon attaching to the host cell membrane, rickettsiae are phagocytosed by the host cell. *Rickettsia* and *Orientia* are believed to induce host cell phagocytosis because they can enter cells that normally do not phagocytose particles (Walker, 1984a). Once phagocytosed by the host cell, rickettsiae and orientiae are observed to enter quickly the cytoplasm outside of the phagosome. Thus, they are said to escape the phagosome. Neither the molecules nor the mechanisms involved in rickettsial escape from the phagosome have been determined. Phospholipase A_2 (PLA_2) has been suggested to be involved in the lysis of the phagosomal membrane by *Rickettsia* (Winkler and Miller, 1982; Walker et al., 1984b; Winkler

and Daugherty, 1989; Silverman et al., 1992; Manor et al., 1994; Winkler et al., 1994; Ojcius et al., 1995); however, genome sequencing did not reveal a gene encoding a PLA_2. To search for the rickettsial PLA_2 gene by comparing rickettsial genes with PLA_2 genes of bees or snakes might not be warranted since the rickettsial PLA_2 involved in the lysis of host cell membrane may be very different. We have found a rickettsial protein (Accession no. RPXX03) with a calcium-independent PLA_2 motif (Yu et al., 2000c). The rickettsial protein is homologous to the exoenzyme (ExoU) of *Pseudomonas aeruginosa*. ExoU expression in *P. aeruginosa* is linked to acute cytotoxicity (Vallis et al., 1999). The enzymatic activity of the rickettsial protein has yet to be characterized.

Movement within and Release from the Host Cell Observations in cell culture systems suggest that the mechanisms of intracellular movement and destruction of the host cell differ among the spotted fever and typhus group rickettsiae (Silverman and Santucci, 1988; Silverman, 1997). TG rickettsiae are released from host cells by lysis of the cells. After infection with *R. prowazekii* or *R. typhi*, the rickettsiae continue to multiply until the cell is packed with organisms and then bursts. Cell death possibly results from apoptosis or membranolytic activity that previously has been hypothesized to be due to phospholipase A_2 (Winkler and Miller, 1982; Walker et al., 1984b; Winkler and Daugherty, 1989; Silverman et al., 1992; Manor et al., 1994; Winkler et al., 1994; Ojcius et al., 1995). Before lysis, TG rickettsia-infected host cells have a normal ultrastructural appearance.

SFG rickettsiae seldom accumulate in large numbers and do not burst the host cells. They escape from the cell by stimulating polymerization of host cell-derived F-actin tails (Fig. 4), which propel them through the cytoplasm and into tips of filopodia, from which they emerge (Schaechter et al., 1957; Teysseire et al., 1992; Heinzen et al., 1993; Heinzen et al., 1999). Infected cells exhibit signs of membrane damage associated with an influx of water, which is sequestered within cisternae of dilated, rough endoplasmic recticulum (Walker and Cain, 1980a). The means by which rickettsiae damage host cell membranes is uncertain, but there is experimental evidence to suggest a role for free radicals of oxygen, a phospholipase, or a protease (Walker et al., 1983b; Walker et al., 1984b; Walker et al., 2002; Silverman and Santucci, 1988; Silverman and Santucci, 1990; Eremeeva and Silverman, 1998; Eremeeva et al., 2001). The protein responsible for the actin-based movement in SFG rickettsiae has yet to be identified. The genome sequence of *R. conorii* did not reveal a rickettsial protein homologous to ActA or Ics, the proteins responsible for actin polymerization by *Listeria monocytogenes* and *Shigella flexneri*, respectively; however, a hypothetical protein of 520 residues (RC0909) exhibits an overall organization similar to that of ActA. Both proteins are highly charged at the N-terminus and have a central proline-rich region. RC0909 has a weak similarity to the Wiskott-Aldrich.

Syndrome protein (WASp) homology domain 2 regulates the formation of the actin filaments (Ogata et al., 2001).

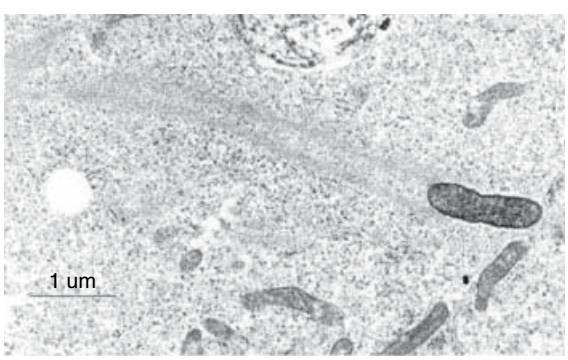

Fig. 4. Electron photomicrograph of an organism of *Rickettsia conorii* (right) with a long actin tail extending from its left pole to the left of the figure. Photomicrograph provided by Vesevolod Popov.

Reactivation of Rickettsia *Rickettsia rickettsii* loses its pathogenicity and virulence for guinea pigs in starved ticks (Spencer and Parker, 1923). Injection of triturated, starved, infected ticks into guinea pigs does not cause disease, but causes asymptomatic seroconversion; however, incubation of the tick vector at 37°C for 24–48 h or feeding the ticks on an animal for 10 h or longer before trituration results in clinically manifest disease in the inoculated guinea pigs. Spencer and Parker (1923) postulated that virulence of *R. rickettsii* in the tick vector is linked directly to the physiological state of the tick and defined this phenomenon as "reactivation." The mechanism of rickettsial reactivation is not understood; however, the reactivation may result from growth of rickettsiae or differential expression of rickettsial virulence factors at the elevated temperature or after stimulation by components of the blood meal. *Rickettsia rickettsii* increases 100-fold in the hemolymph of partially engorged ticks compared to unfed infected ticks (Wike and Burgdorfer, 1972). Differential expression of rickettsial proteins and ultrastructural changes has been confirmed by immunoblot and electron microscopy. Electron microscopy reveals

that reactivated *R. rickettsii* in ticks incubated at 37°C or in ticks fed on animals has a discrete microcapsular layer and a discrete electron-lucent slime layer outside the microcapsular layer. In starved ticks, the microcapsular layer and the slime layer of rickettsiae are inconspicuous or ragged (Hayes and Burgdorfer, 1982). Immunoblot analysis indicates that rickettsial proteins of 42, 43, 48, 75 and 100 kDa are induced in a tick cell line when shifted from 28 to 34°C (Policastro et al., 1997).

Genetics

The genomes of *R. prowazekii* and *R. conorii* have been completely sequenced (Andersson et al., 1998; Ogata et al., 2001). The *R. conorii* genome (1,268,755 bp) is slightly larger than that of *R. prowazekii* (1,111,523 bp). There are 804 common open reading frames (ORFs) between *R. conorii*, which has 1374 ORFs, and *R. prowazekii*, which has 834 ORFs; 552 ORFs were found only in *R. conorii* and 229 of them have a homologous noncoding remnant in *R. prowazekii*. The G+C content is 32.4 mol% for *R. conorii* and 29.0 mol% for *R. prowazekii*. The *R. conorii* genome contains more repetitive DNA than that of *R. prowazekii*. The higher G+C content of *R. conorii* is accounted for by the repetitive DNA, which is G+C rich (40%; Ogata et al., 2001).

Rickettsia genomes are very small, only about a quarter of the genome size of *Escherichia coli* strain K12 (4,639,221 bp, accession no. NC000913), a free-living Gram-negative bacterium. The small genomes of *Rickettsia* are the result of genome reduction, which shapes the relationship of intracellular bacteria and their hosts. Many genes involved in the biosynthesis and regulation of biosynthesis of amino acids and nucleosides were deleted inasmuch as host genes fulfill these functions. *Rickettsia* not only contain fewer genes but also contain more non-coding sequences (19% in *R. conorii* and 24% in *R. prowazekii*) than their free-living bacterial cousins contain (Andersson et al., 1998; Ogata et al., 2001). A large portion of the non-coding DNA in rickettsiae is hypothesized to be degraded remnants of unnecessary genes that have not yet been removed from the genome (Andersson et al., 1998).

Evolutionarily, rickettsiae were derived from a free-living bacterial ancestor. Once a free-living aerobic bacterium entered and established an intracellular parasitic relationship with the pro-eukaryote cell, many chemical substrates could be readily obtained from the host cells and used without further metabolic modification by the bacteria. The genes of the bacterium involved in metabolic pathways such as glycolysis, fermentation and biosynthesis of small molecules were functionally similar to their host cell's genes. These redundant genes then could mutate and become genes with new functions or pseudogenes. Pseudogenes eventually are deleted from the genome to increase the energy use efficiency of the bacterium. Owing to loss of genes essential to a free-living mode, the bacterium became further dependent on the host cell and eventually lost its ability to live outside the host cell.

All the enzyme genes for the tricarboxylic acid cycle are present in the rickettsial genome. *Rickettsia* retains genes for ATP synthesis complexes, despite the acquisition of an ATP/ADP translocator gene (Andersson et al., 1998). The ATP/ADP translocases are unique to *Rickettsia* and *Chlamydia* among bacteria and might have originated from plants (Wolf et al., 1999). This enzyme allows the importation of ATP from the host cell cytoplasm. The structural differences between the ATP/ADP translocases of mitochondria and those of *R. prowazekii* indicate their evolutionary origins are different, despite the evidence that mitochondria and rickettsiae evolved from a common ancestor (Andersson et al., 1998).

Genetic Manipulation of the Rickettsial Genome No resident plasmid or bacteriophage has been found in rickettsiae (Andersson et al., 1998; Ogata et al., 2001). Lack of genetic tools to manipulate the rickettsial genome has hampered our current understanding of the biology of rickettsiae. Recent advances in transforming rickettsiae may facilitate study of their molecular biology (Troyer et al., 1999; Rachek et al., 2000).

Autotransporter Proteins In Gram-negative bacteria, proteins are transported across the cytoplasmic or inner membrane and the outer membrane by several pathways including types I, II, III, IV and autotransporter secretion. Types I, II, and III secretion systems require the assistance of a variety of accessory proteins that function in combination with the general secretory pathway (Salmond and Reeves, 1993; Galan and Collmer, 1999). In contrast, autotransporters do not need accessory proteins for assistance in self-translocation. An autotransporter protein consists of three functional domains: the amino-terminal leader sequence, the secreted mature (α) protein and a carboxy-terminal (β) domain. The signal peptide inserts itself into the inner membrane and directs the export of the precursor molecule via the general secretion pathway into the periplasm. The signal peptidase cleaves the precursor, releasing the mature polypeptide into the periplasm. Once in the periplasm, the β-

domain of the protein is inserted into the outer membrane to form a β-barrel pore, and the passenger domain is translocated to the cell surface through the pore. The β-domain of autotransporters is conserved among even distantly related bacteria, whereas passenger domains are diverse, suggesting that autotransporters were either derived originally from a single gene or from recombination of genes for unrelated proteins with the β-domain gene (Henderson et al., 1998).

A striking feature of rickettsiae is that all the identified rickettsial outer membrane proteins belong to the autotransporter family. These proteins include OmpA, OmpB, and four ORFs encoding the hypothetical proteins Sca1 (accession no. PR018), Sca2 (RP081), Sca3 (RP451), and Sca5 (RP704; Andersson et al., 1998; Bouyer et al., 2001). Sca1 and Sca2 consist of only the β-domain without the passenger peptide. Thus, Sca1 and Sca2 may be involved in the transport of other rickettsial proteins. The precursor of OmpB is a 168-kDa protein that is post-translationally processed to the 135-kDa mature OmpB by cleavage of a 32-kDa β-peptide (Hackstadt et al., 1992). The amino acid sequences of the β-peptides of all five rickettsial autotransporters are highly homologous and also share homology with autotransporters from distantly related bacteria (Henderson et al., 1998). Most of the autotransporter proteins are adhesins or proteases of bacteria, indicating that OmpA, OmpB, Sca3 and Sca5 are possibly important rickettsial virulence factors.

OmpA, a 160–190-kDa protein, has been found in all tick-borne SFG but not TG rickettsiae. The flea-borne SFG rickettsia, *R. felis*, has an OmpA that is truncated by the presence of premature stop codons. Over 40% of the amino acid sequence of OmpA is devoted to a hydrophilic region of tandem repeat units (Anderson et al., 1990b). The repeat units are not identical and thus are divided into two types (I with 75 amino acids and II with 72 amino acids). The type II repeats are less conserved and further divided into two subtypes (IIa and IIb; Anderson et al., 1990b). The *rompA* sequences upstream and downstream of the repeat region are conserved among SFG rickettsial species. Although conserved among *R. rickettsii*, *R. conorii* and *R. akari*, the repeat sequences vary in number and order of repeat unit arrangement among SFG rickettsiae (Gilmore, 1993); however, the *R. australis* repeat unit differs greatly from other SFG rickettsial repeat units. *Rickettsia australis* has only one type of repeat unit with only 21% identity to the type I unit of *R. rickettsii* (Stenos and Walker, 2000). The antigenic diversity of SFG rickettsiae is determined in large part by the number, order, and type of repeat units. Recombinant OmpA stimulates immune protection in guinea pigs against rickettsial challenge (Sumner et al., 1995). OmpB, found in all rickettsiae, is the most abundant rickettsial surface (S-layer) protein (Ching et al., 1990) and contains species-, group- and genus-specific epitopes (Anacker et al., 1987). OmpB stimulates immune protection in mice and guinea pigs against challenge with *R. typhi* (Dasch et al., 1999).

Type IV Secretion System Genome sequencing revealed that *R. prowazekii* contains the genes *virB4*, *virB8*, *virB9*, *virB10*, *virB11* and *virD4* (Andersson et al., 1998), which are homologues of the type IV secretion systems founded in *Agrobacterium tumefaciens* (*virB* operon; Stachel and Nester, 1986; Kuldau et al., 1990), *Brucella abortus* (*virB*; Sieira et al., 2000), *E. coli* (*tra* genes; Winans and Walker, 1985; Pohlman et al., 1994), *Bordetella pertussis* (*ptl* genes; Weiss et al., 1993; Kotob et al., 1995), *Legionella pneumophila* (*dot-icm* genes and *lvh* genes; Brand et al., 1994; Segal and Shuman, 1997; Segal et al., 1999), *Helicobacter pylori* (*cag* genes; Covacci et al., 1999), *E. chaffeensis*, *A. phagocytophilum* (Ohashi et al., 2002), and *Wolbachia* (Brand et al., 1994; Masui et al., 2000; Sieira et al., 2000). The type IV secretion systems inject either bacterial DNA or proteins directly into the cytosol of eukaryotic host cells (Winans and Walker, 1985; Weiss et al., 1993; Christie, 1997; Covacci et al., 1999). In the facultative intracellular bacteria *L. pneumophila* and *B. abortus*, the type IV secretion systems are essential for the intracellular multiplication of the two organisms (Brand et al., 1994; Sieira et al., 2000). *Legionella pneumophila icm* mutant is deficient in its ability to cause lysis of the host cell. The dot/icm protein secretion apparatus of *L. pneumophila* secretes RalF, a protein required for recruiting ADP ribosylation factor (ARF) to the phagosome containing *L. pneumophila* and for vacuole biogenesis (Nagai et al., 2002). ARF is a highly conserved small GTP-binding protein that acts as a key regulator of vesicle traffic from the ER and Golgi apparatus. An *R. prowazekii* gene (G71694) similar to the *ralf* gene of *L. pneumophila* has been found by BLASTN search (Nagai et al., 2002). Because they are homologous to the eukaryotic ARF-specific guanine nucleotide exchange factors and not found in other bacteria, RalF and its rickettsial analogue might have been acquired from a eukaryotic gene by horizontal gene transfer (Nagai et al., 2002). On the basis of similarity with the RalF of *L. pneumophila*, the rickettsial protein encoded by gene G71694 may be the component that is transported by the rickettsial type IV secretion system; however, unlike *L. pneumophila*, *Rickettsia* do not live in vacuoles.

Thus, the function of rickettsial gene G71694 is still not clear. The role of the type IV secretion system in the pathogenesis of other bacterial infections suggests that the rickettsial *virB* genes may be associated with rickettsial intracellular survival.

Rickettsial Lipoprotein A 17-kDa protein has been identified in all *Rickettsia* species (Anderson, 1990a). The corresponding gene sequence is highly conserved among rickettsial species, indicating the importance of the protein to the survival of the rickettsiae. The protein, predicted to be a lipoprotein and known to be partly surface exposed, has been speculated to play a scaffolding and protective role in the rickettsiae (Anderson, 1990a).

Ecology

The importance of transovarial maintenance for the ecology of rickettsiae varies from essential (in the nonpathogenic *R. peacockii* where it is the only mechanism ensuring persistence in the environment) to necessary, but not sufficient (in the highly pathogenic *R. rickettsii*; McDade and Newhouse, 1986; Niebylski et al., 1996; Niebylski et al., 1997). The nonpathogenic organisms appear to coexist with their arthropod host, neither harming them nor possessing the virulence traits for horizontal transmission. In contrast, *R. rickettsii* under some circumstances harms its tick host resulting in its death or reduced production of offspring (Niebylski et al., 1999); however, the virulence mechanisms that harm the tick also permit horizontal transmission to small rodents and sufficient levels of rickettsemia to establish new lines of transmission to feeding ticks (Gage et al., 1990). In the United States, generally fewer than 5% of vector ticks are infected with rickettsiae, most of which are nonpathogenic *R. montanenisis* or *R. bellii* (Philip and Casper, 1981a; Philip et al., 1981b). Fewer than 1 in 1000 vector ticks carry virulent *R. rickettsii*, presumably a result of their deleterious interaction. Higher rates of rickettsial carriage by ticks are observed with less virulent pathogens. Application of specific diagnostic methods might reveal that some organisms previously of undetermined pathogenicity, such as *R. amblyommii*, *R. rhipicephali* and *R. helvetica*, are actually at least mildly pathogenic. This situation has occurred for *R. slovaca* and strain Thai tick-118 (now established as *R. honei*; Stenos et al., 1998).

Our view of *Rickettsia* ecology is highly anthropocentric and hematophagous arthropod- and medically oriented. Identification of strains closely related to *R. bellii* in herbivorous insects and even in association with a plant disease, papaya bunchy top disease, suggests that our knowledge of the diversity and evolutionary origin of *Rickettsia* might be dreadfully skewed (Chen et al., 1996; Davis et al., 1998).

Epidemiology

Twelve species of *Rickettsia* have been associated with human disease: *R. rickettsii* (Rocky Mountain spotted fever), *R. conorii* (boutonneuse fever, Mediterranean spotted fever, Kenyan tick typhus, Israeli spotted fever, Indian tick typhus, and Astrakhan spotted fever), *R. africae* (African tick-bite fever), *R. sibirica* (North Asian tick typhus), *R. japonica* (Japanese spotted fever), *R. australis* (Queensland tick typhus), *R. honei* (Flinders Island spotted fever), *R. akari* (rickettsialpox), *R. felis* (cat flea typhus), *R. slovaca* (tick-borne lymphadenopathy), *R. prowazekii* (epidemic louse-borne typhus, recrudescent typhus fever, and sylvatic typhus), and *R. typhi* (murine typhus). Each rickettsiosis has a particular geographic distribution determined by its natural history involving an arthropod host and in some cases a zoonotic vertebrate host (Table 1). Often during a particular season of the year, rickettsial diseases occur when humans encounter infected ticks, fleas, or mites that are seeking a blood meal. Louse-borne typhus fever occurs particularly in cold climates among impoverished persons who are infested with lice (Wolbach et al., 1922; Perine et al., 1992). Epidemics have been associated with war and natural disasters where there is crowding, prevalence of human body lice, and lack of opportunity to bathe and wash clothes (Patterson, 1993; Raoult et al., 1998).

Disease

General Considerations Rickettsioses vary in clinical severity according to the virulence of the *Rickettsia* and host factors, such as older age, male gender, and alcoholism, and other underlying diseases (McDade, 1990; Walker, 1990). The most virulent rickettsiae are *R. rickettsii* and *R. prowazekii*, which kill a significant portion of previously healthy infected persons, unless they are treated sufficiently early in the course of illness with an effective antirickettsial agent, usually doxycycline. *Rickettsia conorii* and *R. typhi* also possess the virulence to kill 1–2% of infected persons (Ruiz-Beltran et al., 1985; Raoult et al., 1986; Dumler et al., 1991). The other spotted fever rickettsioses can cause disseminated infection with multisystem involvement and illness of two weeks or more duration, but fatalities are rare and (for some entities) have never been reported.

Table 1. Geographic distribution, maintenance in nature, and human transmission.

Agent	Geographic distribution	Maintenance in nature	Human transmission
R. rickettsii	North, Central and South America	Transovarial maintenance in *Dermacentor*, *Rhipicephalus*, and *Amblyomma* ticks: less extensive horizontal transmission from tick to mammal to tick	Tick bite
R. conorii	Mediterranean basin, Africa, Asia	Transovarial maintenance in *Rhipicephalus* ticks	Tick bite
R. africae	Sub-Saharan Africa, Caribbean	Transovarial maintenance in *Amblyomma* ticks	Tick bite
R. sibirica	Russia, China, Mongolia, Pakistan, Kazakhstan, Kirgiziya, Tadzhikistan	Transovarial maintenance in *Dermacentor*, *Haemaphysalis*, and *Hyalomma* ticks; horizontal transmission from tick to mammal to tick	Tick bite
R. japonica	Japan, China	Presumably a transovarial tick host	Tick bite
R. australis	Eastern Australia	Transovarial transmission in *Ixodes* ticks	Tick bite
R. honei	Southern Australian islands, Thailand	Transovarial transmission in *Aponomma* ticks	Tick bite
R. akari	United States, Ukraine, Croatia, possibly worldwide	Transovarial transmission in *Liponyssoides sanguineus* mites; horizontal transmission from mite to mouse to mite	Mite bite
R. felis	North and South America and Europe	Transovarial transmission in *Ctenocephalides felis* fleas	Unknown
R. prowazekii	South and Central America, Africa, Asia, Mexico	Man to *Pediculus humanus corporis* louse to man	Louse feces scratched into skin
R. prowazekii	United States	Flying squirrel to louse and flea ectoparasites to flying squirrel	Presumably fleas of flying squirrels to man
R. prowazekii	Worldwide	Reactivation of latent human infection years after acute illness	None
R. typhi	Worldwide, predominantly tropical and subtropical	Rat to *Xenopsylla cheopis* flea to rat; opossum to cat flea C. *felis* to opossum	Flea feces scratched into skin; rubbed into conjunctiva or inhaled

All infections with organisms of the genus *Rickettsia* usually begin with introduction of rickettsiae into the skin, either through a tick bite or, in the case of contaminated flea or louse feces, through cutaneous abrasions. Rickettsiae enter dermal cells including endothelium and proliferate locally intracellularly with endothelial cell-to-cell spread for most SFG rickettsioses resulting in an eschar or tache noire, a zone of dermal and epidermal necrosis approximately 1 cm in diameter with a surrounding zone of erythema (Walker et al., 1988b). Eschars do not occur in epidemic and murine typhus and are rarely observed in Rocky Mountain spotted fever and Israeli spotted fever (Walker et al., 1981; Sarov et al., 1990). SFG rickettsioses often manifest regional lymphadenopathy in the drainage of the eschar, suggesting that rickettsiae may spread via lymphatic vessels from the tick bite inoculation site early in the infection. Rickettsiae spread throughout the body and infect mainly endothelial cells, establishing many foci of contiguous infected blood vessel-lining cells. Injury in these local sites causes vascular damage manifesting as rash, interstitial pneumonia, encephalitis, interstitial nephritis, and interstitial myocarditis, as well as lesions in the liver, gastrointestinal wall, pancreas, or indeed nearly any vascularized tissue of the body (Walker, 1988a; Walker, 1996b).

The most important pathophysiologic effect is increased vascular permeability with consequent edema, loss of blood volume, hypoalbuminemia, decreased osmotic pressure, and hypotension (Harrell and Aikawa, 1949). These effects can be life threatening in the lungs as non-cardiogenic pulmonary edema and adult respiratory distress syndrome (Donohue, 1978; Lankford and Glauser, 1980; Walker et al., 1980b). Hypovolemia and hypotension may result in prerenal azotemia or, if shock occurs, in acute tubular necrosis (Walker and Mattern, 1979). In the most severe cases of Rocky Mountain spotted fever, louse-borne typhus, boutonneuse fever, and murine typhus, central nervous system involvement is a critical life-threatening factor (Helmick

et al., 1984). The precise relative contributions of the altered blood-brain barrier, hypoperfusion, hypoxemia, cerebral edema, and other pathophysiologic effects have not been determined, but progressively severe illness involves confusion, delirium, stupor, ataxia, coma, focal neurologic signs, and seizures (Miller and Price, 1972a; Miller and Price, 1972b; Horney and Walker, 1988). Cerebrospinal fluid abnormalities may include pleocytosis and increased protein concentration. Hyponatremia occurs frequently with secretion of antidiuretic hormone as a manifestation of the appropriate response of the hypothalamus and posterior pituitary to hypovolemia (Kaplowitz and Robertson, 1983a). Despite interstitial inflammation in the myocardium, left ventricular function is maintained, and in a small proportion of cases, the principal pathophysiologic effect on the heart is arrhythmia, presumably owing to vascular lesions involving the cardiac conduction system (Schmaier et al., 2001).

Despite disseminated infection of the vascular endothelium, frequent occurrence of thrombocytopenia, and the stimulation of a procoagulant state, neither disseminated intravascular coagulation nor life-threatening hemorrhage occurs in rickettsial diseases except on rare occasions, as a remarkable manifestation of the homeostatic mechanisms of the coagulation system (Elghetany and Walker, 1999).

The mechanisms of immune clearance of disseminated intraendothelial rickettsiae have been determined for SFG and TG rickettsiae (Valbuena et al., 2002). Rickettsial infection stimulates an early innate immune response with activation of natural killer cells and production of gamma interferon (IFN-γ), which act in concert to dampen rickettsial growth. Adaptive immunity develops with clonal expansion of CD4 and CD8 T lymphocytes and antibody-producing B cells. Clearance of intraendothelial rickettsiae is achieved by rickettsicidal effects due to cytokine activation of the infected endothelial cells themselves. In mice, IFN-γ and tumor necrosis factor-α stimulate nitric oxide synthesis and nitric oxide-dependent rickettsial killing. In different human target cells activated by IFN-γ, tumor necrosis factor (TNF)-α, interleukin (IL)-Iβ, and RANTES (regulated on activation, normal T-cell expressed and secreted), rickettsicidal mechanisms include various combinations of nitric oxide, reactive oxygen species, and tryptophan degradation. Ultimate clearance of rickettsiae is mediated by major histocompatibility class (MHC) I-matched, cytotoxic CD8 T-lymphocyte activity that is largely perforin-dependent. The mechanisms by which the cytokine-secreting and cytotoxic cells are directed to the foci surrounding infected endothelium are important and undetermined. The production of particular chemokines in these foci suggests that the endothelium plays a key role. Remarkably, antibodies (including those directed at epitopes of OmpA and OmpB) also play a role in protective immunity.

Rocky Mountain Spotted Fever Rocky Mountain spotted fever is the most severe rickettsiosis. In the pre-antibiotic era, 20–25% of previously healthy, infected persons died of the illness (Parker, 1941). Today, even with particular antimicrobial agents that are highly effective, 3–5% of persons die owing mainly to late or missed diagnosis and delayed or ineffective antimicrobial treatment (Dalton et al., 1995). The onset of disease follows an infective bite by a week (range 2–14 days), beginning with fever, severe headache, and myalgia. When patients present to a physician during the first three days of illness, only 3% have the classic triad of fever, rash, and history of tick bite (Helmick et al., 1984). The reasons are that up to 40% of patients are unaware of a tick bite, which is painless and may go unnoticed or be forgotten, and that the rash does not usually appear until day 3–5 of illness. To further confound the difficulty of diagnosis, symptoms such as nausea, vomiting, diarrhea, abdominal pain, and cough may suggest other diagnoses including enterocolitis, acute surgical abdomen, or pneumonia (Table 2). The rash typically appears on the ankles and wrists as faint pink 1–5 mm macules that represent a focus of vascular infection and surrounding vasodilation that blanches on pressure. These lesions may progress to become maculopapular, owing to the leakage of edema fluid from the affected blood vessels, with the development of a hemorrhage (petechia) in the center of the lesions in approximately half of cases. The rash will spread to involve the entire extremities, trunk and, in about half of the patients, the palms and soles. Skin necrosis or gangrene occurs as a result of rickettsial damage to the microcirculation in only 4% of patients and in some cases necessitates amputation (Kaplowitz et al., 1981; Kirkland et al., 1993; Hove and Walker, 1995).

Just as the spread and growth of rickettsiae and damage to a greater portion of the vascular system occur in other organs, the involvement of the microcirculation of vital organs such as the lungs and brain causes life-threatening adult respiratory distress syndrome and encephalitis. In most fatal cases, death occurs 8–15 days after onset. If treatment is initiated during the first five days of symptoms, death is averted (Hattwick et al., 1978); however, in another clinical form, fulminant Rocky Mountain spotted fever, death

Table 2. Symptoms, signs, and laboratory data.

itself occurs within five days of onset (Parker, 1938). This course is so rapid that a rash appears only terminally, if at all. Glucose-6-phosphate dehydrogenase deficient males are particularly prone to fulminant Rocky Mountain spotted fever, apparently as a result of an effect of hemolysis, presumably on rickettsial growth or oxidative injury (Walker et al., 1983a).

Boutonneuse Fever and African Tick-Bite Fever Boutonneuse fever and its agent were first described in North Africa in 1910, and variants of *R. conorii* have been identified in South Africa, Kenya, Somalia, Israel, Morocco, Ethiopia, Russia, India and Pakistan (Conor and Bruch, 1910; Walker et al., 1995). In parts of Africa, tick-transmitted diseases caused by *R. conorii* and *R. africae* overlap geographically (Kelly et al., 1996; Table 1). Although their clinical manifestations also overlap, the differences were sufficient for a South African physician, Pijper, to suggest in 1936 that there were two different disease agents. Generally milder than boutonneuse fever, African tick bite fever has a lower incidence of rash, which is more often vesicular and sparse, a higher incidence of eschars that are frequently multiple, and more prominent regional lymphadenopathy (Raoult et al., 2001a). Each of these diseases has been diagnosed in the United States after patients return from vacation abroad, particularly from African safaris.

Rickettsialpox Recognized mainly in the urban United States as an agent maintained in a mite-mouse cycle with humans as an accidental host, *R. akari* may have a broader host range and geographic distribution (Kass et al., 1994). A papule appears at the site of mite feeding in the skin during the incubation period, and over 2–7 days,

it evolves into an eschar. Later fever, chills, malaise, headache, and myalgia develop, followed after 2–6 days by a macular rash that becomes maculopapular and then vesicular before crusting and healing. Fatalities have not been reported.

Cat Flea Typhus Despite the widespread geographic distribution and prevalence of *R. felis* in cat fleas, on very few occasions have clinical investigations of this potential diagnosis been undertaken.

Among eight reported cases of human infection with *R. felis* (five diagnosed by polymerase chain reaction [PCR] and three by differential antibody titers), all had fever and constitutional symptoms (Schriefer et al., 1994; Zavala-Velazquez et al., 2000; Raoult et al., 2001b). The majority manifested rash, headache, and central nervous system (CNS) involvement, and variable proportions suffered nausea, vomiting, diarrhea, abdominal pain, myalgia and conjunctivitis. The actual spectrum of illness of this infection requires further careful clinical studies.

Typhus Fever *Rickettsia prowazekii* infections occur in three situations: louse-transmitted epidemics, subsequent recrudescence of a long-standing latent infection, and zoonotic infection transmitted from flying squirrels by their ectoparasites (Sonenshine et al., 1978; McDade et al., 1980; Duma et al., 1981; Walker, 2001). Wolbach's study of typhus in Poland after World War I detailed a prodrome in 88%, followed by onset of fever, chills, headache, and myalgia. Macules of 2–6 mm usually appeared first on the trunk on day 5 and later spread to the extremities (Wolbach et al., 1922). Rales, conjunctival injection, and delirium were frequent manifestations.

Recrudescent typhus is a milder version of the same signs and symptoms (Brill, 1910; Zinsser and Castaneda, 1933). Flying squirrel-associated typhus too has been described as less severe; whether this is due to antimicrobial treatment or less virulent strains of rickettsiae is unclear.

Murine Typhus Flea-borne *R. typhi* infections cause extreme discomfort but are seldom fatal in previously healthy young persons (Silpapojakul et al., 1991a; Whiteford et al., 2001). The difficulty in detecting a rash in darkly pigmented skin was evident in a study finding only 20% of experimentally infected African-American volunteers had rashes, compared to 80% of Caucasian volunteers (Woodward, 1988). The infection can follow a mild course in children with as many as half suffering only fever at night, but necessitates intensive care unit support in 10% of hospitalized adult patients (Dumler et al., 1991; Silpapojakul et al., 1991a). Pneumonitis or meningoencephalitis can be the major manifestation in some patients (Silpapojakul et al., 1991b).

Diagnosis

The physician's suspicion, based on the patient's potential exposure to infected vectors and on clinical manifestations, is needed for early diagnosis of *Rickettsia* and *Orientia* infections, when effective and specific antimicrobial treatment (most antibiotics are ineffective) can be administered. Making an early diagnosis (i.e., within the first three days of infection) is difficult because key diagnostic features (history of tick bite, fever, and rash) at medical presentation are seen in only a small minority of patients, e.g., in 3% of patients with Rocky Mountain spotted fever (Helmick et al., 1984). For rickettsialpox, boutonneuse fever, African tick bite fever, North Asian tick typhus, Queensland tick typhus, Japanese spotted fever, Flinders Island spotted fever, and scrub typhus, careful inspection for and recognition of an eschar is a useful diagnostic clue. For scrub typhus, hearing loss and generalized lymphadenopathy are helpful when present (Watt and Walker, 2001).

In most clinical situations, both in developed and developing countries, local clinical microbiology laboratories offer little assistance for diagnosis during the acute stage of illness (Walker, 1989a). Methods that offer a timely laboratory diagnosis include immunohistochemical detection of SFG and TG rickettsiae and *Orientia* in biopsies of a rash or eschar, immunocytochemical detection of SFG rickettsiae in circulating endothelial cells captured on immunomagnetic beads coated with a monoclonal antibody against an endothelial cell surface antigen, and PCR detection of circulating organisms (Walker et al., 1980b; Walker et al., 1989b; Walker et al., 1997; Walker et al., 1999b; Kaplowitz et al., 1983b; Montenegro et al., 1983; Tzianabos et al., 1989; Furuya et al., 1991; Furuya et al., 1995; Sugita et al., 1993; Sexton et al., 1994; Williams et al., 1994; LaScola and Raoult, 1996; LaScola and Raoult, 1997; Zavala-Velazquez et al., 2000; Moron et al., 2001). These techniques are available only in a few research laboratories. Few patients have diagnostic antibody titers early in the course of illness, and few laboratories routinely perform the most sensitive and specific assays for antibodies to *Rickettsia* and *Orientia*.

Immunocytochemical examination of circulating endothelial cells has a sensitivity and specificity of 50 and 94%, respectively, in *R. conorii* infections. Immunohistochemical detection of

Rickettsia has been achieved in Rocky Mountain spotted fever, boutonneuse fever, African tick bite fever, rickettsialpox, murine typhus, and louse-borne typhus; *R. australis*, *R. sibirica* and *R. japonica* have been identified by immunohistochemistry in the tissues of experimentally infected animals, demonstrating further clinical feasibility. For Rocky Mountain spotted fever, the sensitivity and specificity of immunohistochemical diagnosis are 70 and 100%, respectively. PCR has been applied diagnostically to the detection of *R. conorii*, *R. africae*, *R. rickettsii*, *R. japonica*, *R. felis*, *R. slovaca*, *R. helvetica*, *R. typhi*, *R. prowazekii* and *O. tsutsugamushi*. For *Rickettsia*, the 17-kDa lipoprotein gene is the usual target, although DNA of the genes for citrate synthase, 16S rRNA, and OmpA have also been amplified diagnostically. The 56-kDa protein gene of *Orientia* is the usual target of PCR amplification for diagnosis of scrub typhus. For Rocky Mountain spotted fever, the diagnostic sensitivity of PCR has been disappointing, presumably owing to the presence of only a low concentration of these obligately intracellular organisms in the circulating blood. PCR amplification of DNA of *R. prowazekii* from lice removed from patients has been utilized effectively to diagnose typhus even in samples sent through the mail, providing an excellent opportunity to identify outbreaks before they progress to epidemic proportions (Roux and Raoult, 1999).

Currently used serologic assays for the diagnosis of rickettsioses include indirect immunofluorescence assay (IFA), indirect immunoperoxidase assay, latex agglutination, enzyme immunoassays based on antigens of whole organisms and recombinant antigens, line blot, Western immunoblot, and *Proteus vulgaris* OX-19 and OX-2 and *Proteus mirabilis* OX-K agglutination. IFA detects antibodies at a diagnostic titer of ≥64 usually in the second week of illness in patients with Rocky Mountain spotted fever. The diagnostic titer cut off may vary not only in individual laboratories but also in endemic areas for particular diseases. At an IFA cutoff titer for antibodies to *O. tsutsugamushi* of ≥400, the sensitivity was only 48% and the specificity was 96% in a scrub typhus endemic region (Brown et al., 1983). At a cutoff titer of ≥100, the sensitivity improves to 84% but the specificity is only 78%. IFA reagents are commercially available for SFG and TG rickettsiae and *Orientia*. Dot-enzyme immunoassay kits are available commercially for *R. rickettsii*, *R. conorii*, *R. typhi* and *O. tsutsugamushi*. The sensitivities and specificities appear to be satisfactory for murine typhus (88 and 91%, respectively, when compared with an IFA titer of ≥64), and this kit detects crossreactive antibodies in patients infected with *R. prowazekii* (Kelly et al., 1995); however, the specificities for diagnosing scrub typhus are only 77 and 66% when compared with IFA titers of ≥64 and ≥128, respectively (Weddle et al., 1995). Newer 56-kDa protein recombinant enzyme immunoassays are more encouraging, with sensitivities, specificities, and early detection of antibodies that appear superior to those of the well-established IFA (Kim et al., 1993; Ching et al., 2002). This assay is rapid, detects IgM and IgG separately, and is appropriate for point-of-care clinical use; however, in many situations the only laboratory method available is the Weil-Felix test. Although discredited owing to poor sensitivity and specificity, the Weil-Felix test is still useful in developing countries where the choice is between a *Proteus* agglutination assay and nothing at all for the detection of an epidemic of louse-borne typhus or for recognition of the increasing incidence of cases that might represent murine typhus, scrub typhus, or an SFG rickettsiosis. Indeed, antibodies detected by *Proteus* agglutination led to the identification of two newly emerging human pathogens, *R. japonica* and *R. honei*.

The precise etiologic agent of an SFG rickettsiosis is difficult to determine because immunodominant antigens (lipopolysaccharide, OmpA and OmpB) are shared among these organisms (Vishwanath, 1991). The situation for epitopes of lipopolysaccharides and Omp B shared between *R. typhi* and *R. prowazekii* is similar. The criterion of a four-fold or greater IFA titer distinguishes infections caused by *R. conorii* and *R. africae* in only 26% of cases and infections by *R. typhi* and *R. prowazekii* in only 34% of cases. The use of detection of species-specific antibodies against OmpA and OmpB by Western immunoblotting only identifies the agent of half of these cases. Cross-absorption of sera before IFA or Western immunoblotting is more effective but is too expensive and cumbersome for practical use. There is a serious need in clinics for more useful methods not only to diagnose life threatening, readily treatable diseases such as Rocky Mountain spotted fever but also for potential identification of bioterrorist-disseminated *R. prowazekii* and other rickettsiae.

Treatment

Doxycycline is the drug of choice for the treatment of infections caused by *Rickettsia* except in cases of pregnancy and tetracycline hypersensitivity (Raoult and Drancourt, 1991; Watt et al., 1996; Watt et al., 1999; Watt et al., 2002; Walker and Sexton 1999a). Recent studies have shown that doxycycline is superior to chloramphenicol for the treatment of Rocky Mountain spotted fever as it is associated with a lower

case fatality rate and a lower hospitalization rate (Holman et al., 2002). Because of the teratogenic risk of doxycycline, chloramphenicol has been used to treat pregnant patients with Rocky Mountain spotted fever in whom monitoring of serum chloramphenicol levels is recommended to avoid toxicity to the fetus. Several fluoroquinolones, josamycin, azithromycin, and clarithromycin, have been used successfully to treat boutonneuse fever but are not recommended for more pathogenic rickettsioses (Bella et al., 1990; Cascio et al., 2001). It should be emphasized that rickettsiae are highly resistant to most antibiotics. Most fatal cases of Rocky Mountain spotted fever have received substantial courses of antimicrobial treatment, including beta lactams, aminoglycosides, and erythromycin. Sulfonamide antimicrobials actually appear to exacerbate the severity of rickettsial infections.

Genus Orientia

Phylogeny

The genus *Orientia* consists of a single species *Orientia* (formerly *Rickettsia*) *tsutsugamushi* (Tamura et al., 1995). Its closest relatives are organisms in the genus *Rickettsia* (Fig. 1). Unlike members of the genus *Rickettsia*, *Orientia* does not have LPS and peptidoglycan in its cell wall (Tamura et al., 1995). *Orientia tsutsugamushi* has evolved in mites to form a distinct set of divergent clones in each geographic location of its vast geographic distribution (Dasch et al., 1996).

Habitat

Orientia tsutsugamushi is maintained by transovarial transmission in its various trombiculid mite hosts and requires no other host than the mite in its life cycle. *Orientia* resides free in the cytoplasm of its host cell. Although wild rats become infected and chiggers acquire rickettsiae when feeding on rats, the chiggers do not transmit the acquired organisms to the next generation (Traub and Wisseman, 1974).

Isolation

Orientia tsutsugamushi is isolated by inoculation of mice, cell culture, or embryonated chicken eggs.

Identification

Orientia tsutsugamushi may be identified by PCR amplification of the DNA of a species-specific gene, DNA sequencing of genes available in GenBank (ncbi.nim.nih.gov4/genbank), and reactivity with species-specific antibodies.

Preservation

Stocks of *O. tsutsugamushi* are usually preserved frozen at –70 to –80°C or in the vapor phase of liquid nitrogen. They may also be preserved in a lyophilized state.

Physiology

Orientia are obligately intracellular bacteria that reside free of the cytosol of the host cell. They possess an unusual Gram-negative cell wall that lacks lipopolysaccharide and peptidoglycan. They enter the host cell by attachment and induced phagocytosis. The adhesin has not been identified, but host cell surface heparan sulfate glucosaminoglycan plays a role as a receptor (Ihn et al., 2000). To escape the phagosome, *Orientia* has to be metabolically active (Rikihisa and Ito, 1982). Movement of *Orientia* occurs within the cytoplasm to the perinuclear microtubule organizing center, where it replicates, and is mediated by microtubules through rickettsial interaction with dynein, the minus end-directed microtubule-associated motor protein, rather than via F-actin tails (Kim et al., 2002b). *Orientia* is released from infected cells by budding. In mouse peritoneal mesothelial cells, *O. tsutsugamushi* multiplies in the cytoplasm, moves to the cell periphery and, surrounded by a host cell membrane, separates from the cell surface. *Orientia* enveloped by the host membrane enters other mesothelial cells, apparently by a phagocytic mechanism. Organisms escape from the phagocytic vacuole as the vacuole membrane and host cell membrane coat are disintegrated (Ewing et al., 1978). Scanning electron microscopy and ruthenium red staining clearly show that the budding rickettsiae are surrounded with a host cell membrane (Tsuruhara et al., 1982). Cells heavily infected with *Orientia* undergo apoptotic cell death in association with decreased content of focal adhesion kinase and paxillin, decreased actin stress fiber polymerization, and decreased expression of anti-apoptotic bcl-2 (Kee et al., 2002).

Genetics: Variable Immunodominant Antigens

Although *Orientia* consists of a single species, it contains many antigenic variants. Antigenic variability among geographic isolates of *Orientia* is determined by a type-specific protein (TSA), a 56-kDa immunodominant surface protein. The

TSAs of six *Orientia* antigenic variants range from 55,308 to 56,745-daltons with 521–532 amino acids. TSA has alternating hydrophobic and hydrophilic regions, which is a feature of transmembrane proteins. Comparison of the TSAs of *Orientia* variants revealed four variable domains with spans of 16–40 amino acids. The variable domains are located in the hydrophilic regions of the molecule and show different amino acid sequences among the strains (Ohashi et al., 1992). The antigenic variability of *Orientia* poses problems for vaccine design. Immunization with *Orientia* confers relatively strong protection lasting only 1–3 years against challenge by the homologous strain, whereas protection is very weak and short-lived against heterologous strains (Seong et al., 2001a).

Epidemiology

Scrub typhus cases occur when larval mites (chiggers) encounter humans as a source of a tissue fluid meal taken from the skin. Each mite host species has its own geographic distribution and seasonal activity pattern that determines the occurrence of scrub typhus (Audy, 1968). Often the geographic location of infected chiggers is highly focal. Of the 18,000 cases of scrub typhus that occurred among Allied troops in the Pacific and Asian theaters of operations during World War II, some were intensely focal, affecting persons in one location but not others very nearby (Audy, 1968).

Disease

Orientia tsutsugamushi is inoculated into the skin during feeding by the larva (chiggers) of trombiculid mites. A small, painless papule forms, enlarges, and undergoes central necrosis and crusting to form an eschar with associated regional lymphadenopathy during the incubation period, which averages 10 days (Brown, 1988). Bacteremia precedes onset of symptoms by 1–3 days. Onset is characterized by abrupt fever, headache, and often myalgia. About one third of patients will also experience hearing loss (Watt and Walker, 2001). Rash is observed at the end of the first week in half of primary infections, being recognized in a smaller proportion of those reinfected and with dark skin. A recent investigation of the 22.7% of scrub typhus patients with gastrointestinal symptoms showed severity of lesions assessed by gastric endoscopy was associated with cutaneous manifestations (Kim et al., 2000). The most serious organ involvement, pulmonary or neurological, may manifest clinically as cough, tachypnea, radiographic pulmonary infiltrates progressing to dyspnea and, in the most severe cases, as adult respiratory distress syndrome or CNS-related confusion and apathy, with seizures and coma occurring only rarely (Kim et al., 2002a; Tsay and Chang, 2002). These manifestations and peripheral vascular collapse lead to an age-dependent risk of death that was 10–30% in the pre-antibiotic era.

T-lymphocytes are critically important in immunity to *Orientia*, and antibodies to particular strain-specific epitopes of the major 56-kDa protein also play a role in inhibiting establishment of infection (Shirai et al., 1976; Jerrells and Geng, 1994; Seong et al., 2001b). Immune cytokines (including IFN-γ and TNF-α) play an anti-*Orientia* role in model systems and, along with cytotoxic T-lymphocytes, are likely to be important effectors of immunity to *Orientia* (Rollwagen et al., 1986; Hanson, 1991; Geng and Jerrells, 1994). *Orientia* infection of a murine macrophage cell line stimulated NF-κB-dependent expression of mRNA of macrophage inflammatory proteins 1 α/β and 2 and macrophage chemoattractant proteins, providing clues to the mechanism of development of perivascular lymphohistiocytic infiltrates in the multiple foci of vascular endothelial infection, presumably as a manifestation of the host defenses (Cho et al., 2001; Moron et al., 2001).

Treatment

Doxycycline is the drug of choice for the treatment of infections caused by *Orientia* except in pregnant and tetracycline-hypersensitive patients and in patients in northern Thailand where some strains of *O. tsutsugamushi* are resistant to tetracyclines and chloramphenicol (Walker and Sexton, 1999a). In northern Thailand where the case fatality rate of scrub typhus is 15% and doxycycline-resistant *O. tsutsugamushi* is prevalent, rifampicin has been shown to be more effective than doxycycline for mild scrub typhus infections (Watt et al., 2002). Azithromycin has been shown effective in vitro against doxycycline-susceptible strains of *Orientia* (Strickman et al., 1995). Azithromycin has been used successfully to treat two pregnant patients with scrub typhus, and three Japanese patients were treated effectively with clarithromycin (Miura et al., 2002).

Genus Anaplasma

Phylogeny

The evolution of the genus *Anaplasma* is demonstrated by phylogenetic trees developed from

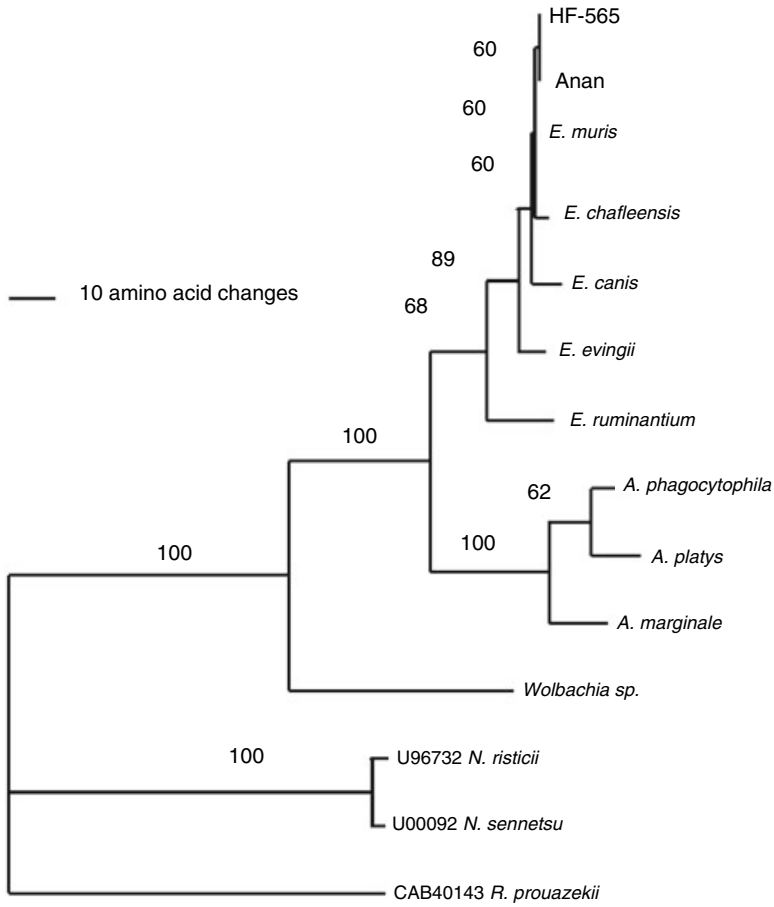

Fig. 5. Phylogenetic relationships of the organisms in the *Anaplasmataceae* family based on the amino acid sequences of the GroEL (GenBank accession numbers for strain HF-565, AB03271; strain Anan, AB032711; *E. muris*, AF210459; *E. chaffeensis*, L10917; *E. canis*, ECU96731; *E. ewingii*, AF195273; *E. ruminantium*, CRU13638; *A. phagocytophila*, U96729; *A. platys*, AY008300; *A. marginale*, AF165812; *Wolbachia* sp., AB002286; *N. risticii*, U96732; *N. sennetsu*, U88092; and *R. prowazekii*, CAB40143.) The length of each pair of branches represents the distance between sequence pairs. The numbers on the branch indicate the bootstrap values.

DNA sequence data based on the 16S rRNA gene, *groEL*, and other genes (Fig. 5).

Taxonomy

The genus *Anaplasma* includes *A. marginale*, *A. ovis*, *A. bovis*, *A. phagocytophilum* and *A. platys* (Dumler et al., 2001). The latter three species were formerly classified in the genus *Ehrlichia*. *Ehrlichia equi*, *E. phagocytophila*, and the human granulocytic ehrlichiosis agent have been consolidated to a single species, namely *A. phagocytophilum*.

Habitat

Anaplasma are obligately intracellular bacteria, residing in cytoplasmic vacuoles of their tick host's cells or in the vertebrate host's erythrocytes (*A. marginale*), neutrophils (*A. phagocytophilum*), platelets (*A. platys*), or monocytes/macrophages (*A. bovis*). Leukocytotropic *Anaplasma* have evolved mechanisms to avoid intracellular host defenses, including the effects of reactive oxygen species and fusion of lysosomes with their modified endosomal vacuole.

Isolation

Anaplasma have been isolated from their hosts in antibiotic-free cell cultures employing continuous lines of tick cells, such as IDE8 or leukocytes, e.g., HL-60 cells (Goodman et al., 1996; Munderloh et al., 1996).

Identification

Anaplasma have been identified historically by their host (mammals and ticks) and target cells on a morphologic basis. Contemporary criteria

for identification usually rely upon DNA sequence data (e.g., 16S rRNA, *groEL*, and *msp2* sequences).

Preservation

Anaplasma are fragile, obligately intracellular organisms that are best preserved as a stabilate of infected cells. *Anaplasma* stabilate is often frozen in a solution containing dimethylsulfoxide, so that thawing results in a portion of the infected cells being viable and containing infectious organisms.

Physiology

Anaplasma enter the skin through a tick bite. The adhesin of *A. marginale* is Msp-1, which is a heterodimer composed of two structurally unrelated polypeptides: Msp-1a and Msp-1b. Msp-1b adheres only to bovine erythrocytes and not to tick cells (de la Fuente et al., 2001). Thus, Msp-1a and Msp-1b are differential adhesins for vertebrate and invertebrate hosts. P-selectin on the neutrophil has been demonstrated as the receptor for *Anaplasma phagocytophilum* (Herron et al., 2000). The host cell receptors for other organisms of *Anaplasma* have yet to be identified. Upon attachment to the host cell, the organisms of Anaplasmataceae are phagocytosed by the host cell. *Anaplasma* induce their own entry into the host cell, e.g., *A. marginale* can invade nonprofessional phagocytic cells in cell culture, and the target cell of *A. marginale* is the erythrocyte. Inhibition of lysosomal fusion by *Anaplasma* may be critical for intracellular survival and replication of these organisms since *A. phagocytophilum* inhibits phagosome-lysosome fusion (Wells and Rikihisa, 1988; Barnewall et al., 1997; Mott et al., 1999). The *A. phagocytophilum* inclusion is neither an early nor a late endosome, and it does not fuse with lysosomes or Golgi-derived vesicles (Barnewall et al., 1997; Mott et al., 1999).

Genetics

Outer Membrane Protein Multigene Family and Persistent Infection with Anaplasma

Most of our knowledge of the molecular microbiology of *Anaplasma* comes from the study of *A. marginale*. The genome of *Anaplasma* is 1.2 Mb with a G+C content of 56 mol% (Alleman et al., 1993). Despite its small genome, *Anaplasma* contains a large amount of repetitive DNA sequences that encode outer membrane proteins. These repetitive genes are considered to be multigene families. Two multigene families (*msp-2* and *msp-3*) encode outer membrane proteins in *A. marginale* (Alleman et al., 1997; Palmer et al., 1994). The *msp-2* multigene family has been identified in all species of *Anaplasma* species except *A. platys*, which has yet to be investigated (Palmer et al., 1994; Palmer et al., 1998; Alleman et al., 1997; Ijdo et al., 1998; Murphy et al., 1998b). In *A. phagocytophilum* the *msp-2* genes have also been referred to as *p44* genes (Ijdo et al., 1998). The *msp-3* gene family has also been found in *A. ovis*. The actual total numbers of *msp-2* and *msp-3* genes have yet to be determined. The *msp-2* and *msp-3* genes have common features. All genes of the *msp-2* and *msp-3* families have a central hypervariable region flanked by 5′ and 3′ highly conserved sequences. Genes of the *msp-2* and *msp-3* gene families share conserved sequences, indicating a common evolutionary origin.

The multigene families of *Anaplasma* are involved in antigenic variation (Brayton et al., 2001). The evasion mechanism of persistent *A. marginale* infection is antigenic variation of surface proteins. Although *Anaplasma* contain multiple copies of the *msp-2* genes, only one *msp-2* gene is expressed in an individual *A. marginale* organism. The remaining *msp-2* genes are pseudogenes. The expressed *msp-2* gene is linked to a polycistronic expression site, which contains a promoter and three additional genes upstream of the *msp-2* gene (Barbet et al., 2000). The entire expression site is transcribed as a single polycistronic mRNA unit. Recombination between the *msp-2* gene in the expression site and a pseudogene of the *msp-2* family results in a new phenotypic Msp-2 and causes antigenic switching to a new serotype. Thus, segmental gene conversion of the expression site to link hypervariable *msp-2* sequences to the promoter and polycistron causes antigenic variation (Barbet et al., 2000). Although the *msp-2* and *msp-3* genes have different sequences, they are flanked by conserved sequences. Thus, recombination between the *msp-2* gene and *msp-3* gene through the conserved flanking sequences also causes gene switching and results in antigenic variation. Gene recombination occurs not only between the expression site and pseudogenes but also between *msp-2* pseudogenes. Gene recombination between *msp-2* genes and between *msp-2* and *msp-3* genes results in unlimited antigenic variation of *Anaplasma*.

One report indicates that Msp-2 antigens are predominantly expressed in human but not tick cells (Jauron et al., 2001). Thus, Msp-2 may be involved in regulatory changes that mediate survival of *A. phagocytophilum* by immune evasion after tick transmission. Msp-1a is encoded by a single gene, *msp-1α*, and Msp-1b is encoded by two genes, *msp-1β1* and *msp-1β2*

(Barbet et al., 1987; Viseshakul et al., 2000). Msp-1a is variable in molecular mass among geographic isolates because of a variable number of tandem 28 or 29 amino acid repeats (Allred et al., 1990).

Potential Glycoproteins of Anaplasma The 130- and 100-kDa proteins (p130 and p100) of *A. phagocytophilum* contain repeat units, and the repeats' motifs have limited homology with the *E. chaffeensis* 120-kDa glycoprotein repeats (Storey et al., 1998). Of particular interest regarding the p130, p100 and gp120 is that they all have larger molecular sizes than predicted on the basis of amino acid sequences. The aberrant size of these proteins is most likely caused by the glycosylation of the amino acids.

Ecology

The life cycle of *Anaplasma* includes two hosts: a tick and a vertebrate host. The organisms multiply in the tick midgut and salivary glands. Ticks transmit these bacteria in the course of feeding on mammals. The bacteria are transmitted in ticks from stage to stage (transstadially) when the tick molts or are passed from infected to noninfected ticks via vertebrate hosts that develop ehrlichemia. All species of *Anaplasma* cause persistent infection in their natural mammalian hosts. Thus, mammalian hosts serve as a reservoir.

Anaplasma marginale can also be transmitted mechanically by blood-contaminated instruments and biting flies as well as biologically by tick bite (Kocan et al., 1992; Kocan et al., 2000b). *Anaplasma marginale* has been experimentally transmitted by *Boophilus decoloratus*, *Rhipicephalus evertsi evertsi*, *R. simus*, *Hyalomma marginatum rufipes* (De Waal, 2000), *B. microplus* (Ribeiro and Lima, 1996), *Dermacentor andersoni* Stiles, *D. variabilis* Say (Stiller et al., 1989), and *B. annulatus* (Samish et al., 1993). *Rhipicephalus simus* experimentally transmits both *A. marginale* and *A. centrale* (Potgieter and van Rensburg, 1982; Potgieter and van Rensburg, 1987). Intrastadial transmission of *A. marginale* by male ticks is believed to be an important mechanism of transmission of anaplasmosis because the male tick seeks mates by feeding on multiple hosts (Kocan et al., 2000b). Tick infection rates are unaffected by bovine antibodies ingested during tick feeding on *A. marginale*-immune cattle (Kocan et al., 1996). *Anaplasma* is not maintained through transovarial transmission in the tick (Stich et al., 1989). Instead of inefficient maintenance mainly in the arthropod vectors, efficient maintenance of *Anaplasma* is achieved in mammalian hosts, whose prolonged infection facilitates spread to new vectors. Thus, *Anaplasma* has evolved a mechanism of persistent infection in their natural animal hosts. Cattle infected with *Anaplasma marginale* are carriers and maintain a low level of rickettsemia, which cannot be detected microscopically (Zaugg et al., 1986). Despite a strong immune response, animals surviving *A. marginale* infection become persistently infected with cyclic rickettsemia, with each rickettsemic cycle occurring every 6–8 weeks (French et al., 1998).

Ixodes ticks are the vectors of *A. phagocytophilum*. In the northeastern United States, the vector of *A. phagocytophilum* is *Ixodes scapularis* Say (Schauber et al., 1998), whereas on the Pacific coast of the United States, it is *I. pacificus* (Barlough et al., 1997). *Ixodes ricinus* and *I. persulcatus* are the vectors of *A. phagocytophilum* in Europe and Asia, respectively (Schouls et al., 1999; Cao et al., 2000).

Anaplasma phagocytophilum causes persistent infection in sheep (Kocan et al., 1986) and in *Peromyscus leucopus* (Telford et al., 1996). Human beings are an accidental host of *A. phagocytophilum* and play no role in the natural cycles of these organisms; however, human cases of persistent infection with *A. phagocytophilum* have been reported (Dumler and Bakken, 1996; Horowitz et al., 1998a). Other important mammalian hosts of *A. phagocytophilum* include white-tailed deer, roe deer, red deer, and wood rats.

Epidemiology

Bovine anaplasmosis is a worldwide tick-transmitted disease with substantial prevalence in the tropics and subtropics, and significant occurrences have affected beef production in the United States.

The first recognized case of human *A. phagocytophilum* infection occurred in 1990 (Bakken et al., 1994). By 1997, more than 449 human cases had been diagnosed in the United States, and human cases had been diagnosed in Europe (Lotric-Furlan et al., 1998; McQuiston et al., 1999). Most cases have occurred in areas endemic for Lyme borreliosis, which shares the same tick vectors in the northeastern and upper midwestern states, California, and Europe. Infections occur in suburban as well as rural areas. The incidence in New York and Connecticut is 3–16 cases per 100,000 population, and active surveillance in Connecticut and northwestern Wisconsin revealed an incidence greater than 50 cases per 100,000 population (Bakken et al., 1996; McQuiston et al., 1999). Tick bites or exposures are recalled in 75–85% of cases. Men and older patients (median age 40–60 years) are disproportionately affected. Most cases occur during sum-

mer with peak occurrence in June and July transmitted by nymphal ticks and a smaller peak in November coinciding with the emergence of adult ticks.

Disease

ANAPLASMOSIS IN CATTLE AND RUMINANTS *Anaplasma marginale* and *A. centrale* cause bovine anaplasmosis in cattle and wild ruminants. *Anaplasma marginale* identified by Theiler in South Africa in 1909 was first described as the "marginal points" in bovine erythrocytes with "marginale" (referring to the peripheral location of the organism in the host erythrocyte). Later, Theiler identified the less virulent *A. centrale* that was named after its central location within erythrocytes (Kumar et al., 1982). *Anaplasma marginale* infects only erythrocytes in cattle. The major clinical sign is anemia without hemoglobinemia and hemoglobinuria. Anemia is caused by extravascular destruction of *A. marginale*-infected erythrocytes by phagocytosis. Cattle that survive acute infection become persistently infected carriers with cyclic low-level rickettsemia.

ANAPLASMOSIS IN HUMANS Human granulocytotropic ehrlichiosis (HGE), in actuality human anaplasmosis, results from infection of neutrophils with *A. phagocytophilum*. The disease varies from a self-limited undifferentiated febrile illness to severe multisystem disease, and seroprevalence studies suggest the significant occurrence of subclinical infections (Aguero-Rosenfeld et al., 1996; Horowitz et al., 1998a; Horowitz et al., 1998b; Bjoersdorff et al., 1999; Bakken and Dumler, 2000). Presenting with chills and fever frequently accompanied by headache, myalgia, and mylaise, fewer than half of cases develop nausea, vomiting, diarrhea, abdominal pain, cough and confusion. Rash occurs only rarely. Most patients have thrombocytopenia with or without leukopenia and mild-to-moderate increases in serum concentrations of hepatic transaminases. The case fatality rate is 0.5–1% with a sepsis-like picture, adult respiratory distress syndrome, and opportunistic fungal and viral infections occurring in some patients as life threatening events. Host factors including older age and underlying diseases play a role in severity of illness. Although persistent infection and recrudescence are very unlikely, some patients suffer fevers, fatigue, sweats, body pain, and the feeling of poor health long after the acute illness, apparently as a post-infectious syndrome as they present no evidence of persistent infection (Ramsey et al., 2002).

ANAPLASMA PLATYS INFECTION OF DOGS Canine *A. platys* infection is associated with cyclic thrombocytopenia.

Control and Prevention of Anaplasmoses and Cowdriosis

Anaplasmosis and heartwater (cowdriosis) of cattle cause economic losses by affecting meat and dairy production; therefore, much attention and effort have been paid to controlling these two diseases in animals. Anaplasmosis and ehrlichioses in animals could be controlled and prevented by arthropod control, chemoprophylaxis, immunization with vaccines, and maintenance of *Anaplasma*-free herds (Kocan et al., 2000b). Ticks can be controlled by application of acaricides; however, repeated application of acaricides could result in environmental pollution and development of acaricide-resistant tick populations. Tetracyclines are used extensively in the United States for anaplasmosis control. Chemotherapy can prevent clinical anaplasmosis but does not prevent cattle from becoming persistently infected with *A. marginale*. Outbreaks of anaplasmosis or heartwater disease can occur when carrier cattle are imported. Thus, in areas where anaplasmosis or heartwater disease is not endemic, the diseases have been effectively controlled by avoiding importation of infected animals (Kocan et al., 2000b).

Vaccine for Anaplasmosis

Vaccines have been developed for prevention of deaths of animals caused by anaplasmosis and heartwater, although they do not prevent infection. Vaccine studies for these diseases in animals will lead to the development of vaccines for use against ehrlichioses in humans. Both live and killed vaccines for anaplasmosis have been used in the United States. The antigens for vaccines previously were prepared from *Anaplasma*-infected bovine blood before *A. marginale* could be cultivated in cell culture. Live vaccines employ *A. centrale*, a low virulence strain, or attenuated *A. marginale*. After vaccination with live *A. centrale* or attenuated *A. marginale*, cattle develop mild-to-inapparent infections and become persistent carriers, which protects them against clinical anaplasmosis upon challenge exposure with *A. marginale* (De Waal, 2000; Kocan et al., 2000b). The fact that live vaccines containing *A. centrale* and the attenuated *A. marginale* do not provide effective cross-protection in widely separated geographic areas limits their broad use (Kuttler et al., 1984; Brizuela et al., 1998).

Anaplasma marginale outer membrane proteins have been evaluated as a vaccine (Palmer et al., 1986a). Current research for a vaccine is focused on development of a recombinant Msp vaccine of *A. marginale*. Cattle immunized with recombinant Msp-1 are partially protected against *A. marginale* challenge, and monoclonal antibodies to Msp-1 neutralize *A. marginale* in vitro (Palmer et al., 1986a). The neutralization-sensitive epitope is conserved among different geographic isolates and is located on a 28- or 29-amino acid tandem repeat of the Msp-1a (Allred et al., 1990). The number of tandem repeats varies between isolates of *A. marginale*. Peripheral blood mononuclear cells obtained from calves immunized with purified outer membranes of *A. marginale* proliferate in response to antigenic stimulation with Msp-1, Msp-2 or Msp-3 (Brown et al., 1998).

Genus Ehrlichia

Phylogeny

Ehrlichia diverged from a common ancestor of *Anaplasma* with which they share many biologic similarities (Figs. 1 and 5).

Taxonomy

The genus *Ehrlichia* includes *E.* (formerly *Cowdria*) *ruminantium*, *E. canis*, *E. chaffeensis*, *E. ewingii* and *E. muris* (Dumler et al., 2001).

Habitat

Ehrlichia are obligately intracellular bacteria that reside in a cytoplasmic vacuole in their tick host's midgut or salivary gland cells or in the vertebrate host's monocyte/macrophages (*E. chaffeensis*, *E. muris* and *E. canis*), neutrophils (*E. ewingii*), or endothelium (*E. ruminantium*).

Ehrlichia have evolved mechanisms to avoid the intracellular host defenses such as blocking the Jak1, Jak2, and Stat 1 transduction pathways by which IFN-γ limits availability of iron to ehrlichiae and downregulates NF-κ B activation of reactive oxygen species-mediated killing (Barnewall and Rikihisa, 1994; Barnewall et al., 1999).

Isolation

Some *Ehrlichia* have been isolated from their hosts in antibiotic-free cell culture employing continuous lines of monocytes/macrophages, e.g., DH82 cells. Others including *E. ewingii* have been passaged only in their animal hosts.

Identification

Ehrlichia are identified by determining the DNA sequence of particular genes such as 16S rRNA, *groEL*, *p28* and *gp120*.

Preservation

Ehrlichia are fragile, obligately intracellular bacteria that are best preserved within frozen living cells that can be thawed in a viable state.

Physiology: Adherence to the Host Cell

Ehrlichia enter the skin through a tick bite. The most common adhesin and receptor interaction is lectin-carbohydrate recognition (Ofek et al., 2002). Many bacterial adhesins are lectins, a class of sugar-binding proteins that link the bacteria to carbohydrate moieties of glycoproteins or glycolipids on the mammalian host cells. In some cases, bacterial surface polysaccharide or lipopolysaccharides bind to cognate lectins on the host cell surface (Ofek et al., 2002). *Ehrlichia* does not have detectable LPS. Of particular interest as a potential adhesin is the ehrlichial surface gp120 of *E. chaffeensis* and gp140 of *E. canis*. The evidence supporting gp120 as an adhesin is that recombinant *E. coli* expressing gp120 attaches to and then enters HeLa cells (Popov et al., 2000), which are nonphagocytic cells. The host cell receptors for *Ehrlichia* have yet to be identified. Upon attachment to the host cell, the organisms of *Ehrlichia* are phagocytosed by the host cell. Inhibition of lysosomal fusion by *Ehrlichia* may be critical for intracellular survival and replication of these organisms (Wells and Rikihisa, 1988; Barnewall et al., 1997; Mott et al., 1999). *Ehrlichia chaffeensis* lives in an early endosomal compartment, which fuses with transferrin-rich endosomes (Wells and Rikihisa, 1988; Barnewall et al., 1997; Mott et al., 1999).

Genetics

P28 Outer Membrane Proteins and Persistent Infection by Ehrlichia The 28-kDa protein is an outer membrane protein of *E. chaffeensis* (Yu et al., 1993). Twenty-two genes homologous to the *p28* gene have been found in a single locus of both *E. chaffeensis* and *E. canis* (Yu et al., 2000b; Ohashi et al., 2001). The *p28* multigene family has been found in all members of genus *Ehrlichia*, including *E. chaffeensis*, *E. canis*, *E. muris*, *E. ewingii* and *E. ruminantium* (Sulsona et al., 1999; Yu et al., 1999; Yu et al., 2000b; Gusa et al., 2001; Ohashi et al., 2001). The *p28* genes are homologous to the *msp-2* genes on the basis of both nucleotide and amino acid sequences;

however, *p28* genes are structurally very different from *msp-2* genes. Members of *p28* gene family are more diverse than those of the *msp-2* gene family. The *p28* gene can be classified into four groups. Genes close to each other physically have higher homology than genes physically more distant (Yu et al., 2000b). No highly conserved nucleotide sequences could be found when all *p28* genes were aligned, indicating no selective pressure to keep the genes from mutating. The homology of *p28* genes ranges from 19 to 80%. There are three to four hypervariable regions among the *p28* genes in a single group. Unlike the *msp-2* genes, all *p28* genes are complete genes, i.e., no genes are truncated at their ends (Yu et al., 2000b). With a proper promoter, all the *p28* genes should be expressed. Moreover, most *p28* genes are actively transcribed in cell culture (Long et al., 2002). A monoclonal antibody recognizing the recombinant p28 protein of *E. chaffeensis* reacts with a group of 25- to 30-kDa proteins by Western blot, indicating that the multiple proteins are expressed by the *p28* gene family (Yu et al., 1993). Analysis of the clinical isolates from different geographic locations reveals an absence of gene recombination among the *p28* genes (Long et al., 2002). Thus, recombination of the *p28* genes is not important for antigenic variation of *E. chaffeensis*; however, antigenic variation of the p28 protein may be the result of differential expression of *p28* genes.

Glycoproteins of Ehrlichia A 120-kDa glycoprotein (gp120) of *E. chaffeensis* is an immunodominant outer membrane protein (Yu et al., 1997; McBride et al., 2000). The protein is differentially expressed on the dense-core cell, but not on the reticular cell of *E. chaffeensis* (Popov et al., 2000b). The *E. chaffeensis* gp120 contains nearly identical tandem repeats with 80 amino acids each (Yu et al., 1997). The number of repeats varies among *E. chaffeensis* isolates from two to five with corresponding differences in the molecular size of this surface glycoprotein (Chen et al., 1997; Yu et al., 1997; Sims et al., 2000; Standaert et al., 2000). A 140-kDa glycoprotein (gp140), the *E. canis* analog of gp120, contains 14 tandem repeats of 36 amino acids each (Yu et al., 2000c). The *E. canis* gp140 and the *E. chaffeensis* gp120 are O-linked glycoproteins (McBride et al., 2000). The carbohydrate content of the glycoproteins comprises approximately 50% of their molecular mass.

Ecology

The life cycle of *Ehrlichia* includes two hosts: a tick and a vertebrate host. The organisms multiply in the tick midgut and salivary glands (Groves et al., 1975). Ticks transmit these bacteria in the course of feeding on mammals. The bacteria are transmitted in ticks from stage to stage (transstadially) when the tick molts or are passed from infected to noninfected ticks via vertebrate hosts that develop ehrlichemia. All species of *Ehrlichia* cause persistent infection in their natural mammalian hosts. Thus, mammalian hosts serve as a reservoir.

Ehrlichia ruminantium causes persistent infection in sheep, cattle, African buffalo and other wild African ruminants (Andrew and Norval, 1989). *Ehrlichia chaffeensis* has been documented to cause persistent infection in dogs (Breitschwerdt et al., 1998) and deer (Dawson et al., 1994a). Chronic canine ehrlichiosis is the most notorious persistent ehrlichial infection (Harrus et al., 1998). Owing to the homology between the *msp-2* genes of *Anaplasma* and the multiple copies of the ehrlichial *p28* multigene family, *p28* is postulated to be involved in the antigenic variation of *E. chaffeensis* that allows it to evade the host immune system (Reddy et al., 1998).

Ehrlichia ruminantium is transmitted by *Amblyomma* ticks. *Amblyomma variegatum* is the most important vector of *E. ruminantium* in Africa, and *A. hebraeum* is probably the only natural vector in most parts of southern Africa. Other *Amblyomma* ticks that have been proven as field vectors of heartwater include *A. lepidum* in the Sudan, *A. astrion* on the islands of Sao Tome and Principe, and *A. pomposum* in Angola. Other species, including five African species (*A. cohaerens*, *A. gemma*, *A. tholloni*, *A. sparsum* and *A. marmoreum*; Walker and Olwage, 1987), have been proven to be capable of transmitting heartwater in the laboratory, but have not been implicated in field outbreaks of the disease. *Amblyomma marmoreum* and *A. sparsum* have been imported into Florida and are of great concern because both species may play an important role in the establishment and maintenance of *E. ruminantium* (Burridge et al., 2000). In contrast, American *Amblyomma* species (*A. maculatum*, *A. americanum* and *A. cajennense*) are not competent for transmitting *E. ruminantium* (Mahan et al., 2000). The mammalian hosts of *E. ruminantium* include cattle, sheep, goats, and a variety of nondomesticated animals (Deem, 1998).

The proven vector for *E. chaffeensis* is the lone star tick, *A. americanum* (Anderson et al., 1993; Wolf et al., 2000), but *Dermacentor variabilis* and *Ixodes pacificus* have also been found infected in nature (Kramer et al., 1999). Human monocytotropic ehrlichiosis (HME) has been reported in the south-central and southeastern states and California. The mammalian hosts of *E. chaffeensis* are deer and wild and domesticated canines

(Dawson et al., 1994a; Dawson et al., 1994b; Dawson et al., 1996; Lockhart et al., 1997; Breitschwerdt et al., 1998; Murphy et al., 1998a; Kocan et al., 2000a). *Anaplasma platys* DNA has been amplified from *R. sanguineus* (Inokuma et al., 2000). *Ehrlichia ewingii* is transmitted by *A. americanum* (Anziani et al., 1990; Wolf et al., 2000). The vector for *E. canis* is the brown dog tick, *R. sanguineus* (Groves et al., 1975; Smith et al., 1976). Wild and domestic canids are the natural reservoir of *E. canis*.

Epidemiology

The striking concept that is becoming clear is that human monocytotropic ehrlichiosis (HME) is a very common disease rather than a rare entity (Olano et al., 1999). The geographic distribution of HME corresponds to that of the lone star tick (*A. americanum*). Following the report of the first case of HME in 1987, more than 700 cases were recorded at the United States Centers for Disease Control and Prevention (CDC) by 1997. Passive reporting of cases suggests that even in the states with the greatest number of cases, the incidence is low (e.g., 0.5 cases per 100,000 population in Arkansas). In contast, prospective outpatient clinic-based surveillance reveals a rate of 10–100 cases per 100,000 population in an endemic area of southeastern Missouri and southwestern Illinois, which is in an area where the *E. chaffeensis* zoonotic cycle involving white-tailed deer and lone star ticks is likely very similar to that in much of the rural southern states. Cases occur between April and September with 68% in May, June and July.

Ehrlichiosis ewingii is also transmitted by the lone star tick and has been diagnosed in Missouri, Oklahoma and Tennessee, although its distribution is likely throughout the range of the vector. A high proportion (70%) of patients have clear evidence of immunocompromise. Canine infections, of course, have the same geographic occurrence.

Canine monocytotropic ehrlichiosis is widespread around the world where the brown dog tick, *Rhipicephalus sanguineus*, occurs.

Ehrlichia ruminantium is widely distributed in sub-Saharan Africa and the West Indies where African *Amblyomma* ticks occur naturally or have been introduced.

Disease

Human Monocytotropic Ehrlichiosis The most severe human ehrlichiosis yet identified is human monocytotropic ehrlichiosis (HME). Between 40 and 63% of patients require hospitalization for an illness that has a median of 23 days of duration (Fishbein et al., 1994; Everett et al., 1994; Olano et al., 1999; Standaert et al., 2000). Despite the dramatic efficacy of doxycycline treatment, the case fatality rate is 2.5–3% (McQuiston et al., 1999). More than 80% of patients report tick exposure. Generally 7–10 days after tick bite inoculation of *Ehrlichia chaffeensis*, the patient presents with fever, malaise and headache often accompanied by myalgia. The clinical manifestations worsen progressively with anorexia (66%), nausea (48%), vomiting (37%), rash (36%), abdominal pain (26%), diarrhea (25%), lymphadenopathy (25%) and confusion (20%). Life threatening effects of severe HME are respiratory failure owing to interstitial pneumonia and adult respiratory distress syndrome, meningoencephalitis, hypotension, acute renal failure, coagulopathy and hemorrhage. Patients with HME usually develop leukopenia, thrombocytopenia, and elevated levels of serum hepatic transaminases. Conditions of immunocompromise such as acquired immunodeficiency syndrome pose a risk for overwhelming infection, with *E. chaffeensis* leading to death in a high proportion of patients (Paddock et al., 2001). The higher age-specific incidence for older patients suggests the importance of host factors in the disease. It should be noted, however, that children can also become infected and even develop severe illness (Schutze and Jacobs, 1997). It is becoming clear that this is a very common disease rather than a rare entity (Olano et al., 1999).

Canine Monocytic Ehrlichiosis The course of canine infection with *E. canis* is generally described as comprising three sequential stages: acute illness, subclinical phase, and chronic illness often leading to death. The acute illness varies in severity, with some dogs experiencing life-threatening illness but most animals suffering only mild-to-moderate fever, anorexia, and diminished activity (Reardon and Pierce, 1981a). Laboratory evaluation reveals thrombocytopenia and leukopenia that continue through the subclinical phase when the animal appears healthy. The duration of the subclinical phase is variable, lasting from months to years even. It is generally believed that particular breeds of dog, e.g., German shepherds, are more susceptible to a severe course and fatal outcome. Although genetic analysis of *p28* and *gp140* genes indicates that a single clone of *E. canis* is widely distributed in the United States, the possibility that some strains possess virulence factors that others lack cannot be excluded. The mechanism of thrombocytopenia during the acute and subclinical stages includes both splenic sequestration and anti-platelet antibodies (Harrus et al., 1999). The terminal phase of chronic canine mono-

cytotropic ehrlichiosis involves bone marrow hypoplasia (Reardon and Pierce, 1981b). Some animals die because of hemorrhage, e.g., massive epistaxis; others die with opportunistic infections.

Heartwater Disease Heartwater (cowdriosis), caused by *E. ruminantium*, is an acute and often fatal infectious disease of cattle, sheep, goats and certain wildlife species and is associated with endothelial infection in the brain and with pericardial effusion. Heartwater can cause mortality rates of up to 90% in susceptible domestic ruminant species. Its distribution in sub-Saharan Africa, the islands of the South Atlantic and Indian Oceans and the Caribbean Sea is associated with the presence of the tick vectors of the genus *Amblyomma*. The risk of spread of heartwater from the Caribbean is of concern to livestock production on the North and South American mainland, where totally susceptible domestic and wild animal populations exist (Mahan et al., 2000).

Prevention of Ehrlichioses

Human monocytotropic ehrlichiosis can be avoided only by preventing tick bite or removal of tick vectors prior to transmission. Canine monocytic ehrlichiosis has been controlled by acaricide elimination of ticks and use of tetracycline prophylaxis in the outbreak setting. There are no vaccines for canine or human ehrlichioses; however, substantial effort has been devoted to the prevention of heartwater and the development of a vaccine against *E. ruminantium*.

To prevent heartwater disease in southern Africa, animals are usually intentionally infected with *E. ruminantium* and then treated with antibiotics. The method suffers several disadvantages including deaths of the infected animals and difficulty in standardization of the vaccine (Mahan et al., 1999). Chemically inactivated or lysed *E. ruminantium* derived from bovine endothelial cell culture protects goats, sheep and cattle against homologous and heterologous challenge. Cattle immunized with inactivated vaccine develop a mild disease after challenge. In immunized animals, *E. ruminantium* is presumably controlled by cellular immunity mediated by IFN-γ and TNF-α. CD_4^+. T-cell lines from cattle vaccinated with the inactivated vaccine secrete IFN-γ when stimulated with *E. ruminantium* antigens. CD_4^+ and γ δ T cells expressing high levels of TNF-α, IFN-γ, and IL-2 receptor α chain were detected in cattle vaccinated with the live vaccine. IFN-γ has been shown to inhibit *E. ruminantium* growth in vitro, and its administration in mice can prevent death by an ordinarily lethal challenge. Both live and inactivated vaccines induce T-cell responses to outer membrane proteins of *E. ruminantium* including Map-1 (the homolog of the p28 protein family) and Map-2, suggesting that Map-1 and Map-2 play roles in stimulating immunity to control *E. ruminantium*. DBA/2 mice immunized with a *map-1* DNA vaccine are partially protected against lethal challenge. Splenocytes from the immunized mice produce IFN-γ and IL-2 when stimulated with *E. ruminantium* lysates or recombinant Map-1 antigen.

Genus Wolbachia

Taxonomy

Wolbachia pipientis is included in the Anaplasmataceae family (Dumler et al., 2001).

Habitat

Wolbachia strains are dimorphic with small, irregular, rodlike (0.5–1.3 μm in length) and coccoid (0.25–0.5 μm in diameter) forms. *Wolbachia pipientis* grows in the cytoplasm of its host cell in a membrane-bound vacuole of host origin. *Wolbachia* are endosymbionts of arthropods and nematodes. *Wolbachia* are estimated to infect 16% of insect species. *Wolbachia* are obligately intracellular, and they are maternally inherited. *Wolbachia pipientis* has been observed mainly in the cytoplasm of cells in the reproductive organs of the mosquito. Occasionally, *W. pipientis* has also been found in Malpighian tubules, muscle and nervous tissue (Stouthamer et al., 1999).

Ecology

To ensure a steady stream of progeny, *Wolbachia* have evolved strategies to boost their own reproductive success by increasing that of infected female hosts. *Wolbachia* manipulate arthropod reproduction by cytoplasmic incompatibility (CI), parathenogesis, and feminization. In most insect species, *W. pipientis* induces CI that results in embryonic death. CI occurs when a *Wolbachia*-infected male insect mates with a female insect that is either uninfected or infected with a different *Wolbachia* strain. In a CI cross, the sperm can successfully enter the eggs, but paternal chromosomes are unable to properly decondense and fuse with maternal chromosomes before entering the first mitotic division (Lassy and Karr, 1996). Thus, the maternal chromosomes enter mitosis before the paternal chromosomes, and the paternal chromosomes are eliminated, which renders the developing embryo haploid (Lassy and Karr, 1996; Callaini

et al., 1997). These embryos eventually die in diploid species and some haplodiploid mite species, whereas they develop into normal (haploid) males in other haplodiploid species such as wasps (Stouthamer et al., 1999). The effect of CI on the population of insects is that *Wolbachia*-infected females have a higher fitness than uninfected females.

Parthenogenesis occurs when infected females produce all-female offspring without fertilization by a male (Stouthamer et al., 1999). Parthenogenesis occurs only in haplodiploid hymenopteran species through a modification of the first mitotic division. Hymenoptera exhibits arrhenotoky, in which males arise from haploid eggs and females arise from diploid eggs. In infected eggs, the first mitotic division is aborted in the anaphase, leading to a diploid nucleus in an unfertilized egg (Stouthamer et al., 1999).

Feminization of *Wolbachia* occurs in aquatic insects such as an isopod, which diverts infected genetic males of the isopod into a phenotypic female (intersexed; Stouthamer et al., 1999). Feminization in the woodlouse *Armadillidium vulgare* is caused by suppression of the formation of the androgenic gland, which produces androgenic hormone that induces male differentiation. Without androgenic hormone, individuals normally develop into females.

Other effects of *Wolbachia* on insects are male-killing and modification of fecundity and fertility (Stouthamer et al., 1999), which enhances the spread of *Wolbachia* in the insect populations. The effects of *Wolbachia* on insects may result in speciation of insects owing to mating incompatibility of related species.

Wolbachia and Helminthic Diseases

Although *Wolbachia* does not cause infection in mammals, a recent discovery indicated that the host inflammatory response in the cornea was due to the lipopolysaccharide of *Wolbachia* in a filarial nematode (Saint et al., 2002). Although *Wolbachia* are parasites in most invertebrates, they may live mutualistically with nematodes because *Onchocerca ochengi*, a filarial nematode in cattle, die when their bacteria are destroyed. In other species, the females simply become sterile (Zimmer, 2001). The fact that elimination of *Wolbachia* is lethal or harmful to the parasite provides a new approach to treat some parasitic infections. For example, the antibiotic doxycycline has been used effectively to treat river blindness (Hoerauf et al., 2000). Embryogenesis of filarial nematodes is completely dependent on the presence of *Wolbachia*; thus antibiotics can be used effectively to sterilize the adult female worm (Hoerauf et al., 2000).

Applications

Wolbachia may be used as a genetic tool to transform pests and manipulate the vectors of the diseases. For example, if a gene encoding resistance to *Plasmodium* is transformed in the *Wolbachia* genome and these *Wolbachia* are established in a malaria vector, the mosquito might not become infected with *Plasmodium*. The recent discovery that *Wolbachia* contains bacteriophages (Masui et al., 2001) may provide a key genetic tool to transform *Wolbachia*.

Genus Neorickettsia

Taxonomy

The genus *Neorickettsia* includes *N. risticii*, *N. sennetsu* and *N. helminthoeca*.

Habitat

Neorickettsia organisms are obligately intracellular bacteria that reside within a cytoplasmic vacuole in the vertebrate host. They normally reside in a trematode parasite.

Genetics

Heterogeneity of the surface antigens has been observed between strain 90-12 of *N. risticii*, which was isolated from a vaccinated horse suffering from clinical Potomac horse fever, and strain 25-D, which was originally isolated in 1984 (Vemulapalli et al., 1995). Strain 90-12 is more virulent for mice and horses than strain 25-D. Mice immunized with strain 25-D are only partially protected against challenge with strain 90-12, whereas mice immunized with strain 90-12 are completely protected against challenge with strain 25-D. Sera from the strain 25-D-infected horses neutralize the homologous strain but do not neutralize strain 90-12; however, sera from strain 90-12-infected horses neutralize both strains. Although most antigens are similar between the two strains, there is a significant difference between them in the 85- and 50-kDa antigens. The 85-kDa antigen is specific to strain 90-12, and the 50-kDa antigen is present only in strain 25-D; however, the 85-kDa protein crossreacts with a 50-kDa antigen (Vemulapalli et al., 1995). Different type tandem repeats are present in both the 85- and 50-kDa protein genes, and eight identical repeat motifs are found in both genes; however, the numbers and positions of the repeats differ between the genes. The difference in sizes of the 85- and 50-kDa proteins is caused by the variable sequences. The crossreactivity of the

recombinant proteins confirmed the presence of conserved epitopes between these two antigens. Mice immunized with the recombinant 85-kDa protein are protected against homologous and heterologous strains, whereas mice immunized with the 50-kDa protein are protected against only the homologous strain (Vemulapalli et al., 1995).

Ecology

Neorickettsia risticii is maintained in nature in a complex aquatic ecosystem. Aquatic insects are likely to play an important role in the epidemiology of Potomac horse fever (PHF). A broad intermediate host range has been found for the trematodes that are the reservoir host for *N. risticii. Neorickettsia risticii* has recently been detected in trematode stages found in snail secretions and in metacercariae found in immature and adult aquatic insects including caddisflies (Trichoptera), mayflies (Ephemeroptera), damselflies (Odonata and Zygoptera), dragonflies (Odonata and Anisoptera), and stoneflies (Plecoptera; Chae et al., 2000). Transmission of *N. risticii* to horses can occur through accidental ingestion of insects such as caddisflies containing *Neorickettsia*-infected metacercariae (Madigan et al., 2000). The trematode infection rate varies between 40 and 93.3% in large snails (shell size >15 mm) and between 0 and 13.3% in small snails (<15 mm). A study in California indicates that the highest trematode infection rate for large and small snails is observed in September, and the lowest infection rate for large snails is recorded in June and October (Chae et al., 2000).

Physiology

Neorickettsia possibly enter the bloodstream through the wall of the gastrointestinal tract after ingestion. After entering the body, these organisms attach to the target cell surface through an adhesin and a receptor. The evidence that organisms in the family Anaplasmataceae attach to the host cell through an adhesin of the organism and a host cell receptor came from the study of *N. risticii* (Messick and Rikihisa, 1993; Messick and Rikihisa, 1994). Proteinase- or paraformaldehyde-treated *N. risticii* lost the ability to bind to P388D1 cells, indicating that the ehrlichial ligand and host cell receptor are likely surface proteins. The binding to, internalization of, or proliferation of *N. risticii* in P388D1 cells is not affected by cytochalasin D, a microfilament-disrupting agent. Monodansylcadaverine, a transglutaminase inhibitor, does not affect the attachment of ehrlichiae to host cells, but suppresses internalization and proliferation of *N. risticii*. Thus, *N. risticii* is internalized by the P388D1 cells through receptor-mediated endocytosis (sensitive to monodansylcadaverine) and not through phagocytosis (sensitive to cytochalasin; Messick and Rikihisa, 1993; Messick and Rikihisa, 1994). *Neorickettsia risticii* has a different fate when it enters the host cell through an Fc-receptor. *Neorickettsia risticii*-specific IgG antibody-opsonized *N. risticii* is killed by P388D1 cells when it enters the cell through an interaction with Fc-receptor (Messick and Rikihisa, 1993; Messick and Rikihisa, 1994). *Neorickettsia risticii* inhibits phagolysomal fusion by a process that appears to require neorickettsial protein synthesis (Wells and Rikihisa, 1988).

Disease

Potomac Horse Fever Equine neorickettsial colitis was first recognized in Maryland. The disease has been documented in Pennsylvania, New Jersey, New York, Ohio, Idaho, Connecticut (Palmer et al., 1986b), California, South America (Uruguay and southern Brazil; Dutra et al., 2001), and Europe. The disease is seasonal, manifesting as sporadic colitis in unstressed horses. The incidence rate is generally low. Horses on pasture, as well as those stabled, can be affected. Clinical signs vary from fever and depression to severe diarrhea and laminitis. Occasionally, horses develop profound ileus and severe colic (Palmer et al., 1986b). The consistent clinical and hematologic features of horses experimentally infected with *N. risticii* include fever, depression, anorexia and leukopenia. Diarrhea develops in 73% of the horses. Rickettsemia (i.e., the *N. risticii* titer in the blood) reaches a maximum at the peak of fever. Mortality is 9%. There are no significant differences in clinical and hematologic features between horses that survive and those that die of *N. risticii* infection (Dutta et al., 1988).

Sennetsu Neorickettsiosis In 1953 in Japan, *N. sennetsu* was isolated from the blood, bone marrow, and lymph node of a patient with signs, symptoms, and laboratory data suggestive of infectious mononucleosis (Tachibana, 1986). The typical clinical manifestations are chills, fever of two weeks duration, headache, myalgia, and enlarged preauricular and posterior cervical lymph nodes (Misao and Kobayashi, 1955). Hepatosplenomegaly occurs in fewer than half of the patients. After early leukopenia, absolute lymphocytosis develops with 10% or more atypical lymphocytes.

CHAPTER 3.1.20

The Genus *Coxiella*

ROBERT A. HEINZEN AND JAMES E. SAMUEL

Introduction

Coxiella burnetii is a bacterial obligate intracellular parasite and the causative agent of human Q fever. The Australian physician Edward Derrick used the term "query (Q) fever" in 1935 to describe an outbreak of febrile illness of unknown etiology among abattoir workers in Queensland, Australia (Derrick, 1937). Although Derrick was successful in transmitting a febrile disease to guinea pigs using patient blood or urine, he was unsuccessful in visualizing or isolating the causative agent. Consequently, he sent infected guinea pig liver to Burnet and Freeman, who reproduced symptoms of the disease in various laboratory animals. Impression smears of spleen harvested from infected mice revealed large, intracellular vacuoles containing small rod-shaped organisms that resembled typical rickettsiae; consequently, the organism was named *Rickettsia burnetii* (Burnet and Freeman, 1937). Coincident with the Australian studies, a tick transmission study of Rocky Mountain spotted fever was being conducted in Hamilton, Montana, by Davis and Cox (Davis and Cox, 1938). They established a febrile illness in guinea pigs that did not mimic spotted fever in presentation. The causative agent, referred to as the "Nine Mile agent," was filterable and failed to grow on axenic media. A laboratory worker on the project became infected with the Nine Mile agent and developed symptoms of Q fever as described by Derrick and Burnet. This led to a collaboration between the two groups and a series of experiments that demonstrated that the Nine Mile and Australian Q-fever agents (*R. burnetii*) were the same microorganism. *Rickettsia burnetii* subsequently was reclassified as *Coxiella burnetii* in recognition of the efforts of Cox and Burnet in identifying the new bacterial pathogen (Philip, 1948).

Phylogeny

Because of an obligate intracellular nature, similar staining characteristics, and carriage by ticks, *C. burnetii* was historically classified within the α-1 subgroup of the *Proteobacteria* in the Rickettsiales order, the Rickettsiaceae family, and the *Rickettsia* tribe, which included the genus *Rickettsia* and formerly the genus *Rochalimaea* (*Rochalimaea* has now been reclassified as the genus *Bartonella*). A revised classification of *C. burnetii* will be described in the 2nd edition of *Bergey's Manual of Systematic Bacteriology*, where the organism will be taxonomically placed in the domain Bacteria, phylum *Proteobacteria* phy. nov., class "Gammaproteobacteria," order "Legionellales," family "Coxiellaceae." The other resident of the "Coxiellaceae" family is *Rickettsiella grylii*, an intracellular parasite of crickets (Roux et al., 1997), and the remaining genus within the order "Legionellales" is *Legionella*. Indeed, *C. burnetii* displays both phenotypic and genetic similarities to *L. pneumophila* (Drancourt and Raoult, 1994), including intracellular growth within a membrane-bound vacuole and marked sequence similarities for a variety of genes including *mip* (macrophage infectivity potentiator), a protein associated with increased survival within macrophages (Cianciotto et al., 1995; Mo et al., 1995), and components of a type IV secretory apparatus (Segal and Shuman, 1999). *Coxiella burnetii* is also distinguished from *Rickettsia* on a phenotypic level by displaying pronounced extracellular stability and resistance to chemical and physical disruption, by acid activation of metabolism, by an impressively diverse animal host range, and by an aerosol route of infection (Baca and Paretsky, 1983).

Isolates of *C. burnetii* derived from a variety of geographic areas and various hosts exhibit a considerable degree of phylogenetic homogeneity when examined by 16S rRNA gene sequencing and DNA-DNA hybridization, supporting the designation of a single species with the genus (Stein et al., 1993; Vodkin et al., 1986b). Interestingly, when *C. burnetii* total genomic DNA is examined by restriction fragment length polymorphism (RFLP) analysis, considerable heterogeneity in banding patterns is observed (Heinzen et al., 1990; Hendrix et al., 1991; Mal-

lavia, 1991). This apparent paradox may reflect, in part, the presence of repetitive DNA elements in the *C. burnetii* chromosome (Heinzen et al., 1991; Hoover et al., 1992). The RFLP analysis of genomic DNA resulted in the subdivision of *C. burnetii* isolates into six genomic groups (I to VI; Heinzen et al., 1990; Hendrix et al., 1991; Mallavia, 1991). Evidence suggests that *C. burnetii* isolates carry a single linear chromosome ranging from approximately 1,500 to 2,400 kilobases (kb; Willems et al., 1996; Willems et al., 1998). Most *C. burnetii* strains harbor 1 of 4 autonomously replicating plasmids, termed "QpH1," "QpRS," "QpDV" and "QpDG" (Mallavia, 1991). These plasmids range from 36–42 kb in size and share a common 30-kb "core" region along with unique regions (Mallavia, 1991; Samuel et al., 1985). In some isolates, plasmid sequences are integrated into the chromosome (Mallavia, 1991; Savinelli and Mallavia, 1990; Willems et al., 1997). There is an association of plasmid types with specific genomic groups. For example, QpHI is associated with genomic groups I, II and III, whereas QpRS is associated with genomic group IV (Mallavia, 1991). Common and unique plasmid sequences have been used with the polymerase chain reaction (PCR) to detect *C. burnetii* in clinical samples and as an epidemiologic tool (Willems et al., 1993). The absolute conservation of chromosomally integrated or autonomously replicating plasmid sequences among all C. burnetii isolates examined to date suggests that these sequences play a critical role in *C. burnetii* biology.

Habitat

Coxiella burnetii has a broad host range that includes arthropods (primarily ticks), fish, birds and a variety of mammals (Baca and Paretsky, 1983). The far-ranging zoonotic relationships and geographic distribution of *C. burnetii* are described in an extensive review by Babudieri (1959). The organism has a worldwide distribution with the exception of Antarctic regions and New Zealand (Babudieri, 1959; Hilbink et al., 1993). In both wild and domestic animals, *C. burnetii* does not appear to cause overt disease with the exception of sheep and goats where it can cause abortions (Palmer and Key, 1983). Infection of cattle also has been associated with reproductive problems, including infertility and low birth weight (Ho et al., 1995). All infected mammals shed organisms in feces, urine, milk, and birth products (Babudieri, 1959). During natural acute infection of animals, *C. burnetii* can be isolated from the lung, spleen, liver and blood (Maurin and Raoult, 1999). Chronic infection of females also targets the uterus and the mammary glands (Babudieri, 1959). Of particular significance is the tropism of *C. burnetii* for placental tissue, where the parasite load can reach concentrations $\geq 10^9$ organisms per gram (Babudieri, 1959). Unlike rickettsial agents, *C. burnetii* is remarkably resistant to desiccation and ultraviolet radiation and therefore can persist in contaminated soils for extended periods (Babudieri, 1959). Inhalation of contaminated aerosols is the primary route of human infection with *C. burnetii* (Maurin and Raoult, 1999), and an extremely low intraperitoneal infectious dose of 2–4 organisms has been demonstrated in the guinea pig model of Q fever (Moos and Hackstadt, 1987). Thus, *C. burnetii* represents an occupational hazard, particularly for individuals involved in animal husbandry operations where large numbers of organisms can be shed into the environment during parturition. In arthropods, *C. burnetii* replicates in the midgut or stomach (Babudieri, 1959). Regardless of the host and cell type, *C. burnetii* is an obligate intracellular bacterium that replicates in a membrane-bound vacuole having characteristics of a phagolysosome (Heinzen et al., 1996c).

Isolation

A handful of culture methods are available for isolation of *C. burnetii* from clinical samples or reservoir hosts. Isolation generally requires biosafety level 3 (BSL-3) laboratory practices as *C. burnetii* is notoriously infectious and one of the most common causes of laboratory-acquired infections (Harrison et al., 1990). As an obligate intracellular bacterium, *C. burnetii* requires a viable eukaryotic host cell for propagation, which can be in the form of laboratory animals (primarily guinea pigs and mice), embryonated hen eggs, or tissue culture cells (Maurin and Raoult, 1999). The use of animals for isolating *C. burnetii* is troublesome owing to the additional requirement of a BSL-3 animal care facility. *Coxiella burnetii* is shed in feces and urine of infected animals; consequently, infectious aerosols are generated that represent an occupational hazard for laboratory workers. Guinea pigs develop an illness comparable to that in humans and are particularly useful for obtaining isolates from contaminated samples. Typically, guinea pigs are injected intraperitoneally with a clinical sample and sacrificed about a week later. During acute infection, necrotic foci can be observed in the spleen, liver, bone marrow and other organs. Spleen homogenates are most commonly used for recovery of *C. burnetii* (Heggers et al., 1975).

Cell culture has supplanted animal and embryonated eggs as the method of choice for isolating

C. burnetii. A variety of primary and continuous cell lines support growth of the organism (Baca and Paretsky, 1983). Raoult and coworkers (Raoult et al., 1990b) have developed an especially efficient method of isolating *C. burnetii* from clinical samples. The technique employs infection of human embryonic lung (HEL) fibroblasts grown on a 12-mm round cover slip in a 3.7-ml shell vial. The HEL monolayers are inoculated with 1 ml of clinical sample and vials are centrifuged at 700 × *g* for 1 h at room temperature to promote adherence and internalization of *C. burnetii*. The *C. burnetii* in the coverslip preparations of infected cells are observed by immmunofluorescence or Gimenez staining (Gimenez, 1964) after 5–7 days of incubation. This procedure has been successfully used to isolate *C. burnetii* from a number of clinical specimens and has markedly increased the number of strains available for study (Maurin and Raoult, 1999; Raoult et al., 1990b).

Identification

Several methods are employed to visualize and identify *C. burnetii* within infected tissues and cell cultures. Conventional stains used to visualize *C. burnetii* include Giemsa, Macchiavello, and Gimenez stains, which color organisms purple, red, and bright red, respectively (Baca and Paretsky, 1983). Despite a prototypic Gram-negative cell envelope, the organism stains variably with the Gram stain (Baca and Paretsky, 1983). Infected cells display small (0.3 to 1.0 μm), highly pleomorphic coccobacilli within membrane-bound vacuoles. These vacuoles can grow to encompass nearly all of the cell cytoplasm with minimal cytopathic effect. The pleomorphism of *C. burnetii* results from the production of distinct morphological forms that are part of an incompletely defined biphasic developmental cycle (Heinzen et al., 1999).

Because of the notorious efficiency of aerosol transmission of *C. burnetii*, isolation and cultivation of the organism present an occupational risk to clinical laboratory workers and generally require BSL-3 level containment. Lengthy culture periods are often required and the recovery success rate is variable. Nonetheless, the procedure is conducted by trained personnel in select laboratories, often in combination with immunofluorescence to aid in unequivocal identification of *C. burnetii* as the infectious agent (Muhlemann et al., 1995; Musso and Raoult, 1995; Raoult et al., 1990b). Direct and indirect immunofluorescence using either monoclonal or polyclonal antibodies directed against *C. burnetii* antigens is effective in detecting the organism directly within tissue samples, particularly infected cardiac valves (Baumgartner et al., 1988; Brouqui et al., 1994; Raoult et al., 1994). A capture-enzyme linked immunoassay using a genus-specific monoclonal antibody directed against *C. burnetii* lipopolysaccharide (LPS) detects as few as 2,500 *C. burnetii* particles within clinical samples (Thiele et al., 1992).

Amplification of genus-specific DNA sequences using PCR has rapidly supplanted the use of radiolabeled probes as the nucleic acid method of choice for identifying *C. burnetii* strains in clinical samples and cell culture (Mallavia et al., 1990; Stein and Raoult, 1992; Willems et al., 1993; Willems et al., 1994). Chromosomal genes employed as targets include those encoding 16S rRNA (*rrs*), citrate synthase (*gltA*), and iron-containing superoxide dismutase (*sodB*). Another target of PCR amplification is a unique chromosomal repetitive transposon-like sequence with a copy number of about 19 (Willems et al., 1994). This strategy provides a sensitive and specific detection method that has been used to diagnose *C. burnetii* infections in humans (Maurin and Raoult, 1999; Willems et al., 1994). Unique and conserved *C. burnetii* plasmid DNA sequences also have been successfully employed to identify and strain type various isolates (Willems et al., 1993).

Structure

Coxiella burnetii displays a prototypic Gram-negative cell wall structure when observed by transmission electron microscopy (TEM; McCaul and Williams, 1981a). However, the agent does not stain with the Gram stain consistently and organisms are typically visualized using the Gimenez staining method (Gimenez, 1964). *Coxiella burnetii* is a small (0.3 to 1.0 μm), highly pleomorphic coccobacillus. The pleomorphic nature of the organism is due to the generation of morphologically distinct cell forms that arise as part of a biphasic developmental cycle (Heinzen, 1997a; McCaul, 1991a; McCaul and Williams, 1981a).

The cell wall peptidoglycan is biochemically similar to that of other Gram-negative bacteria. Although the glycan portion is sensitive to digestion by lysozyme, treatment does not result in dissociation of the sacculus structure (Amano and Williams, 1984b). This enhanced rigidity has been attributed to the presence of peptidoglycan-associated, protease-resistant, cell wall proteins (Amano and Williams, 1984b).

Coxiella burnetii undergoes a lipopolysaccharide (LPS) phase variation that is similar to that observed in the Enterobacteriaciae. Transition from a smooth (full-length O-side chains) phase I to a rough (truncated O-side chains) phase II LPS structure occurs upon repeated passage of

the organism in an immunoincompetent host such as embryonated eggs or tissue culture cells. Plaque-purified phase II organisms are avirulent for guinea pigs (a fever animal model of *C. burnetii* infection), whereas phase I *C. burnetii* causes disease and is always associated with naturally infected mammals and ticks (Hackstadt, 1990). A strain displaying a semi-rough-type LPS has intermediate virulence for guinea pigs (as evidenced by fever production) but lacks persistence in the spleen (Moos and Hackstadt, 1987). The genetic lesion(s) accounting for phase variation has not been precisely determined, but likely involves the loss of chromosomal regions carrying LPS biosynthesis genes (O'Rourke et al., 1985; Vodkin and Williams, 1986a).

Phase I and phase II *C. burnetii* are indistinguishable by TEM, and their intracellular growth characteristics are similar. However, the LPS of phase variants is biochemically and antigenically distinct (Amano and Williams, 1984a; Schramek and Mayer, 1982). The aldose sugar component of phase I LPS is chemically more complex, having at least nine different sugars as compared to two in phase II LPS (Schramek and Mayer, 1982). Two phase I sugars, L-virenose and dihydro-hydroxystreptose, are branched sugars that have not been previously described in LPS (Schramek et al., 1985). It has been suggested that these exotic sugars may afford *C. burnetii* protection from lysosomal digestion (Schramek et al., 1985). The central core regions of *C. burnetii* LPS contain a heptose-like moiety and a 2-keto-3-deoxyoctonate (KDO)-like component that is different from enteric KDO (Amano and Williams, 1984a; Hackstadt et al., 1985). *Coxiella burnetii* lipid A contains a complex and heterogeneous mixture of branched fatty acids (Wollenweber et al., 1985). The unusual biochemical makeup of *C. burnetii* LPS probably accounts for the 100- to 1,000-fold less toxicity in a mouse lethality assay when compared to LPS of *Escherichia coli* or *Salmonella typhimurium* (Amano et al., 1987).

Surface iodination experiments reveal a complex assortment of *C. burnetii* surface proteins with predominant labeling of proteins in the 12–14, 27–30, and 60 kDa range (Hackstadt, 1985; Hackstadt, 1988; Williams et al., 1984b; Williams and Stewart, 1984a). Although full-length LPS of phase I organisms is known to sterically block iodination of certain surface proteins (Hackstadt, 1988), the overall protein profile of phase variants appears identical, and phase-specific proteins have not been identified (Hackstadt, 1988; Williams et al., 1984b; Williams and Stewart, 1984a). The cloning of genes encoding four *C. burnetii* surface proteins has allowed a more detailed examination of their potential functions. Macrophage infectivity potentiator (Mip) is a peptidylprolyl isomerase (PPIase) localized to the cytoplasm, periplasmic space and outer surface of *C. burnetii* (Mo et al., 1995; Mo et al., 1998). Although the function of Mip in *C. burnetii* has yet to be defined, *L. pneumophila mip* mutants are attenuated in their ability to infect and survive in macrophages (Cianciotto and Fields, 1992). A second periplasmic and outer-surface-localized enzyme, Com-1, is a homologue of the disulfide bond-forming enzymes DsbA and DsbC (Hendrix et al., 1993). These enzymes are required for folding of virulence determinants in *Shigella flexnerii* and *E. coli* (Watarai et al., 1995). An immunogenic lipoprotein designated P2 (Williams et al., 1990) and a plasmid-encoded surface protein termed "E'" also have been described (Minnick et al., 1991).

Coxiella burnetii has an impressive ability (greatly surpassing that of bacterial vegetative cells) to survive in the extracellular environment and to resist physical and chemical disruption (Babudieri, 1959; Scott and Williams, 1990). Viable organisms can be recovered after heat treatment at 63°C for 30 min, exposure to a 10% salt solution for 180 days at room temperature, or sonication in distilled water for 30 min (Babudieri, 1959; Heinzen, 1997a). The remarkable resistance of *C. burnetii* is attributed to a small, resistant cell form that is part of a biphasic developmental cycle (Heinzen, 1997a; McCaul and Williams, 1981a). Two morphologically distinct cell types, termed "large-cell-variants" (LCVs) and "small-cell-variants" (SCVs), are part of this cycle. They can be isolated with relative purity by exploiting differences in their buoyant densities (Heinzen et al., 1996b; Wiebe et al., 1972). Preparations highly enriched for SCV also can be obtained by procedures that exploit the sensitivity of LCV to physical disruption (Heinzen, 1997a; McCaul et al., 1981b).

The LCV can reach a length exceeding 1.0 μm and is similar to a typical Gram-negative bacterium in possessing a clearly distinguishable outer membrane, periplasmic space, and cytoplasmic membrane (Heinzen, 1997a; McCaul et al., 1981b). The LCV is more pleomorphic than the SCV, with a thinner cell wall and a dispersed nucleoid (Heinzen, 1997a; McCaul et al., 1981b). Both LCV and SCV divide by binary fission (Heinzen, 1997a). The SCV is typically between 0.2 and 0.5 μm in size, rod-shaped, and very compact. The visible periplasmic space is replaced with an electron-dense region bounded by the cytoplasmic and outer membranes. The most distinctive ultrastructural characteristic of the SCV is the electron-dense, condensed chromatin (Heinzen, 1997a; McCaul et al., 1981b). A subpopulation of the SCV, called the "small, dense cell," has been described that displays extreme tolerance to breakage by high pressure

(20,000 lb/in^2), a procedure that destroys typical SCVs (McCaul et al., 1991b).

An electron-dense, membrane-bound, polar body termed a "spore-like particle" (SLP; Schaal et al., 1987) has been visualized by TEM within LCV (Heinzen, 1997a; McCaul et al., 1981b). Evidence obtained by McCaul and Williams (1981a) resulted in a model for *C. burnetii* development that includes both vegetative morphological differentiation of SCV to LCV and sporogenic differentiation of SLP within the LCV. In the postulated developmental cycle, it was proposed that SLPs are released from degenerating LCV to act as the infectious precursor of SCV. The SLPs are approximately 130–170 nm in diameter and are bounded by a limiting membrane. The particle is occasionally observed in cells morphologically classified as LCV and usually occurs in a polar location. From the center outward, the SLP is believed to be comprised of a dense core, a system of membranes, peptidoglycan and an outer membrane (McCaul, 1991a). One report indicates that SLPs contain DNA (McCaul and Williams, 1990). Whether the SLP is a developmental progenitor of the SCV remains to be proven. The biochemical spore marker, dipicolinic acid, is not detected in *C. burnetii* and traditional spore stains have little affinity for the SLP (McCaul, 1991a). Moreover, the SLP has not been purified to homogeneity and tested for infectivity.

Although the SLP has not been purified and biochemically characterized, analysis of purified SCV and LCV cell lysates and immunogold TEM of infected cells clearly demonstrate that SCV and LCV have a different protein composition (Heinzen, 1997a; Heinzen et al., 1996b; Heinzen et al., 1996c; Heinzen et al., 1999; McCaul et al., 1991b; Seshadri et al., 1999). Two SCV-specific DNA-binding proteins designated "Hq1" and "ScvA" have been identified and their encoding genes cloned (Heinzen and Hackstadt, 1996a; Heinzen et al., 1996b). Both proteins are very basic with high isoelectric points. The ScvA protein is only 30 amino acids in length and has no homologues in the protein database. The Hq1 protein is 117 amino acids in length and exhibits 34% and 26% identity with eukaryotic histone H1 and the histone-like protein Hc1 of *Chlamydia trachomatis*, respectively. Hc1 is thought to play a role in condensing chlamydial chromatin during reticulate-to-elementary body differentiation (Hackstadt et al., 1991). Immunogold TEM demonstrates an abundance of ScvA in association with the condensed chromatin of the SCV (Heinzen et al., 1996b), and both ScvA and Hq1 bind DNA in vitro (Heinzen and Hackstadt, 1996a; Heinzen et al., 1996b). These observations led to speculation that ScvA and Hq1 are integral components of the compact SCV nucleoid structure (Heinzen and Hackstadt, 1996a; Heinzen et al., 1996b). Binding of SCV genomic DNA by one or both of these proteins could serve a protective role by stabilizing the chromosome or inducing topological changes that alter gene expression. Several proteins also are differentially synthesized by the LCV. Immunoblotting with specific antibodies demonstrates that the translation elongation factor EF-tu is only detectable in lysates of LCV, whereas EF-ts is present at a fourfold higher concentration in LCV than in SCV (Seshadri et al., 1999). This observation led to the hypothesis that SCVs are functional equivalents of stationary phase growth forms, whereas LCVs represent log phase cell forms (Heinzen et al., 1999). This hypothesis seems unlikely with the recent discovery that synthesis of the stationary phase stress response sigma factor RpoS is dramatically upregulated in the large cell variant (R. Seshadri and J. E. Samuel, submitted). Expression of a major outer-membrane protein termed "P1" with porin activity is also upregulated in the LCV when compared to the SCV (McCaul, 1991a; McCaul et al., 1991b; Seshadri et al., 1999; S. Varghees and J. E. Samuel, submitted).

Cultivation

A milestone event in the study of *C. burnetii* and other rickettsiae occurred in 1941 with the successful propagation of these organisms in embryonated hen's eggs by Cox (1941). This method of propagation is still used and can yield up to 0.2 gram (wet weight) of purified *Coxiella* from one dozen yolk sacs (Baca and Paretsky, 1983). A drawback of this procedure is that it generates a significant amount of contaminated waste that must be carefully decontaminated. The protocol involves inoculation of the yolk sac of 5–7-day-old embryos with continued incubation for 10–12 days. The organism replicates to high densities in the yolk sac membrane.

Both continuous and primary tissue culture cell lines have been used to propagate *C. burnetii*. These include primary chick and mouse embryo fibroblasts and continuous cell lines like Vero (African green monkey kidney epithelial), L-929 (murine fibroblast), and J774.1 and P388D1 (both murine macrophage-like cells; Baca and Paretsky, 1983). Organisms are typically harvested when large vacuoles filled with *C. burnetii* are observed throughout the monolayer. Cells are scraped from culture flasks, and *Coxiella* are released by mechanical disruption or by gentle sonification (Baca and Paretsky, 1983).

Purification of *C. burnetii* from yolk sacs or tissue culture cells is a laborious and time-consuming procedure that involves a series of

differential centrifugation steps followed by density gradient centrifugation through sucrose or Renografin (Samuel et al., 1983; Weiss et al., 1975). The hydrophobic, truncated LPS of phase II *C. burnetii* results in tenacious adherence of organisms to host material, which consequently results in lower yields than that obtained for phase I organisms (Baca and Paretsky, 1983; Heinzen et al., 1999). Guinea pigs are the preferred laboratory animal for amplification and purification of *C. burnetii* isolates, although they are not as widely used since the development of cell culture methods. Necrotic foci are observed in the liver, spleen, and heart, and organisms are typically harvested from enlarged infected spleens 1–2 weeks following infection (Heggers et al., 1975).

Physiology

Our current understanding of the unique biology of *C. burnetii* is limited because of restrictions imposed by its obligate intracellular nature, the lack of workable genetic systems, and the relative paucity of laboratories engaged in research on the organism, which requires BSL-3 containment. However, some advances have been made in characterizing the physiologic requirements and capabilities of *C. burnetii*. The organism undergoes luxurious growth in the phagolysosome of host cells with an estimated doubling time of 8–12 hours (Baca and Paretsky, 1983). Replication occurs despite the presence of toxic factors that are normally considered bactericidal such as acid hydrolases and defensins. Minimal cytopathic effects are noted on infected host cells. *Coxiella burnetii* has evolved a unique adaptation to the phagolysosome, as the organism is an acidophile that has an absolute requirement for the moderately acidic pH (~4.5–5) found in the vacuole to activate its metabolism (Hackstadt and Williams, 1981a). An acidic environment is thought to provide a proton motive force that sufficiently energizes the cytoplasmic membrane and transporters of metabolites such as glutamate and proline (Hackstadt and Williams, 1983b; Hendrix and Mallavia, 1984). In vivo, *C. burnetii* replication can be inhibited by treatment of host cells with lysosomotropic amines (Hackstadt and Williams, 1981a) or bafilomycin A1 (Heinzen et al., 1996c), agents that result in alkalinization of the phagolysosome. Like more extreme acidophiles, *C. burnetii* maintains an intracellular pH near neutrality under optimal conditions (Hackstadt, 1983a). When host-cell free *C. burnetii* organisms are incubated at ~pH 4.7 without a metabolizable substrate such as glutamate, the intracellular pH is 5.88, whereas in the presence of glutamate, the intracellular pH rises to 6.7 (Hackstadt, 1983a). Thus, intracellular pH homeostasis of *C. burnetii* is at least, in part, an energy-requiring process. Moreover, intracellular ATP pools are unstable at pH 4.5 in the absence of glutamate, though they are stable at pH 7 with or without glutamate. These unique metabolic properties of *C. burnetii* represent a "biological strategy" (Hackstadt and Williams, 1981a) for maintaining extracellular stability while promoting intraphagolysosomal metabolism and replication.

A metabolic lesion(s) that would account for *C. burnetii*'s obligate parasitism has not been identified. The Embden-Meyerhof-Parnas (McDonald and Mallavia, 1971), oxidative pentose phosphate (McDonald and Mallavia, 1970), gluconeogenesis (McDonald and Mallavia, 1971), TCA cycle (Hackstadt and Williams, 1981b), nucleotide synthesis (Christian and Paretsky, 1977), and protein synthesis and catabolic (Zuerner and Thompson, 1983) pathways are all functional in *C. burnetii*. The mechanism of nutrient acquisition by the organism is undefined but likely involves trafficking and fusion of nutrient-laden autophagic and/or heterophagic vesicles with the parasite-containing phagolysosome where metabolites are hydrolyzed to provide precursors for *C. burnetii* metabolism (Heinzen and Hackstadt, 1997b; Heinzen et al., 1996c). Breakdown of extra- and intracellular high molecular weight compounds by lysosomal enzymes is known to generate high concentrations of monosaccharides, nucleosides, amino acids, fatty acids, sulfates, and phosphates in vesicles of the lysosomal pathway (Barrett, 1984). A vesicle-mediated nutrient delivery system is supported by the observation that low molecular weight fluorescent molecules do not passively diffuse into the *C. burnetii*-containing phagolysosome when microinjected into the cytosol of infected cells (Heinzen and Hackstadt, 1997b). *Coxiella burnetii* has a growth requirement for iron (Howe and Mallavia, 1999). Replication of the organism in J774.1 murine macrophage-like cells upregulates transferrin receptor synthesis with a coincident increase in the intracellular iron concentration. Moreover, growth is inhibited when the intracellular iron chelator desferrioxamine is added to the culture medium.

The physiologic relevance of LCV and SCV developmental forms is undefined. The results of a few studies suggest that LCVs are more metabolically and replicatively active than SCVs (Howe and Mallavia, 1999; McCaul, 1991a; McCaul et al., 1981b). Thus, they may play a more important role than SCVs in amplification and spread of *C. burnetii* within the infected host. A proposal was made that SCVs are simply the equivalent of stationary phase growth forms,

whereas LCVs represent log-phase cell forms (Heinzen et al., 1999). This idea is contradicted by a recent observation that the stationary phase stress response sigma factor RpoS is dramatically upregulated in the LCV (R. Seshadri and J. E. Samuel, submitted). The hardiness of the SCV is well documented (Heinzen et al., 1999). Thus, this cell form may survive the degradative enzymes and peptides of the phagolysosome for extended periods, and it is likely the cell form that is responsible for long-term extracellular survival and natural aerosol transmission of the agent. Because *C. burnetii* organisms do not actively lyse host cells and are transmitted by desiccated infected tissues, a sustained supply of resistant cell forms is critical to their survival. In the laboratory, both LCV and SCV are infectious for in vitro and in vivo models (Heinzen, 1997a; Wiebe et al., 1972), and infection by either cell form eventually results in phagolysosomes harboring a mixture of cell types (Wiebe et al., 1972). The observation that LCVs are infectious in vitro may have little relevance to natural transmission and infection because the fragile LCVs likely do not persist extracellularly in an infectious form for extended periods.

The environmental conditions that drive *C. burnetii* development are unknown, but two obvious candidates are pH and nutrient availability. Fluctuations in phagolysosomal pH may directly trigger pH-sensitive signal transduction systems in the outer membrane of *C. burnetii*, leading to up- or downregulation of developmental genes. *Coxiella burnetii* encodes at least one adaptive sensory kinase, but the environmental stimuli to which it responds are unknown (Mo and Mallavia, 1994). The metabolic status of the host may also drive development. Although not yet tested, the parasitic burden imposed by bacterial growth late in the infectious cycle probably inflicts nutritional stress on the host. Heavily infected host cells that are degenerating may reduce trafficking of nutrient-laden vesicles to the *C. burnetii*-containing vacuole (Heinzen et al., 1996c). This, in turn, may drive development of *C. burnetii* to a population dominated by SCVs, the cell types most likely to survive extracellularly.

Genetics

The genome size of *C. burnetii* isolates ranges from 1,600 to 2,400 kb (Willems et al., 1996; Willems et al., 1998), with a G+C content of 43 mol% (Tyeryar et al., 1973). Evidence suggests that there is one linear chromosome (Willems et al., 1998). Approximately 2% of the coding capacity of *C. burnetii* is carried on a moderately sized plasmid that is maintained at 1 to 3 copies per cell (Samuel et al., 1983). There are four described plasmid types (QpH1, QpRS, QpDG, and QpDV), ranging from 32.6 to 51 kb, associated with specific genomic groups that share a common 30-kb "core" region along with unique regions (Mallavia, 1991). Some isolates do not harbor an autonomously replicating plasmid, but instead have approximately 18 kb of plasmid-like sequences integrated into the chromosome (Savinelli and Mallavia, 1990; Willems et al., 1997). Interestingly, these isolates have all been obtained from Q fever endocarditis patients. The absolute maintenance of autonomously replicating or chromosomally integrated plasmid sequences in all *C. burnetii* isolates examined to date suggests a critical role for this DNA in some aspect of Coxiella biology and/or virulence. Unfortunately, the complete nucleotide sequence of QpH1 (36 kb) did not provide meaningful insight into the biological role of this molecule (Thiele et al., 1994b).

A repetitive DNA element (IS*1111*) resembling an insertion sequence is present at 19 copies in the *C. burnetii* Nine-Mile strain chromosome and comprises 1–2% of the coding capacity (Hoover et al., 1992). Nucleotide sequencing of three copies of this sequence reveals an approximate size of 1,400 bp with small inverted repeats flanking a single open-reading frame predicted to code for a protein with transposase-like properties (Hoover et al., 1992). If IS*1111* can be demonstrated to function as a mobile genetic element, it is intriguing to speculate that it may have utility as a genetic tool in *C. burnetii*.

Despite numerous technical obstacles, genetic transformation of *C. burnetii* has now been accomplished. This advance was aided by cloning a 5.8-kb *C. burnetii Eco*RI chromosomal fragment that autonomously replicates in *E. coli* (Chen et al., 1990; Suhan et al., 1994). Sequence analysis of this region also predicts that it functions as a *C. burnetii* chromosomal origin of replication (Chen et al., 1990; Suhan et al., 1994). A shuttle vector called "pSKO(+)1000" was constructed containing the *C. burnetii* replicon, a ColE1 replicon, and a *bla* gene coding for β-lactamase (Suhan et al., 1996). Electroporation of *C. burnetii* with pSKO(+)1000 and subsequent selection with ampicillin yielded transformants that carried both integrated and autonomously replicating forms of pSKO(+)1000, although the latter form was found to be unstable (Suhan et al., 1996). Using a similar approach, green fluorescent protein has now been expressed in *C. burnetii* (Lukacova et al., 1999). Employing this technology, gene inactivation via allelic exchange and genetic complementation should soon be possible in *C. burnetii*.

Epidemiology

Q fever is a zoonotic disease, and *C. burnetii* is maintained in extensive reservoirs in mammal, bird and tick species (Babudieri, 1959). The organism has a worldwide distribution excluding Antarctic regions and New Zealand (Babudieri, 1959; Hilbink et al., 1993). Wild rodents appear to be a significant wild reservoir (Webster et al., 1995), but domestic animals are most frequently associated with outbreaks of human disease (Marrie, 1990). Sheep, goats and cattle are often chronically infected with *C. burnetii* with no significant disease except for occasional late-term abortions (Palmer and Key, 1983). Abortion results from massive infection of trophoblast cells of the placenta (Babudieri, 1959). Infection of cattle has also been associated with reproductive problems including infertility and low birth weight (Ho et al., 1995). Dairy cows appear to harbor chronic infection at a higher rate than sheep and may be the most significant source of human infection in some areas (Enright et al., 1957). Household pets, especially cats during parturition, have been directly associated with several urban outbreaks (Marrie et al., 1988). Ticks appear to be the only significant arthropod host of *C. burnetii* and acquire the organism by feeding on a bacteremic animal. However, the role of ticks in the natural cycle of *C. burnetii* remains to be defined (Maurin and Raoult, 1999).

The primary mode of transmission of *C. burnetii* to humans is by direct inhalation of contaminated aerosols originating from infected placenta or amniotic fluid or contaminated wool (Maurin and Raoult, 1999; Tigertt et al., 1961). Heavily infected sheep placental tissue, for example, contains up to 10^9 bacteria per gram, and all infected mammals shed organisms in feces, urine, milk, and birth products (Babudieri, 1959). Adding to the insidious nature of *C. burnetii* is its remarkable resistance to desiccation and ultraviolet radiation, allowing survival in contaminated soils and fomites for extended periods, and an aerosol infectious dose of approximately 10 organisms (Babudieri, 1959; Tigertt et al., 1961; Wedum et al., 1972). Thus, *C. burnetii* represents an occupational hazard for individuals involved in animal husbandry operations such as abattoirs and dairy herd operations, where large numbers of organisms can be shed into the environment during parturition (Derrick, 1937). Although Q fever is endemic within some dairy herds in the United States, ingestion of contaminated milk and milk products is currently not a major source of infection (Enright et al., 1957). This is largely due to the modification of pasteurization protocols in the mid-1950s to ensure thermal inactivation of *C. burnetii* (Baca and Paretsky, 1983; Enright et al., 1957). In situations where pasteurization is not employed, and where goats substitute for cows as a source of dairy products, transmission via ingestion can cause significant disease (Benson et al., 1963; Fishbein and Raoult, 1992).

Rare person-to-person transmission of Q fever has been documented. These cases typically occur in association with medical procedures that expose uninfected individuals to contaminated aerosols originating from infected individuals, such as during an abortion of an infected fetus (Raoult and Stein, 1993) or an autopsy of an infected cadaver (Marmion and Stoker, 1950). Some have proposed that Q fever can be sexually transmitted (Kruszewska et al., 1996; Kruszewska and Tylewska-Wierzbanowska, 1993; Kruszewska and Tylewska-Wierzbanowska, 1997). Experimentally infected male mice have been shown to sexually transmit the disease to female mice (Kruszewska and Tylewska-Wierzbanowska, 1993), and *C. burnetii* has been isolated from bull semen (Kruszewska and Tylewska-Wierzbanowska, 1997). Circumstantial evidence also exists for sexual transmission of Q fever among humans (Kruszewska et al., 1996). Only two suspected instances of natural transmission of Q fever via tick bite have been reported (Beaman and Hung, 1989; Janbon et al., 1989). Thus, unlike other rickettsial diseases, tick transmission of Q fever appears to be of minor significance.

Q fever is a common laboratory acquired infection (Pike, 1979). Infections typically occur in research laboratories where *C. burnetii* is being propagated and purified. Q fever outbreaks have also occurred in facilities that conduct experimental research on sheep, a significant animal reservoir of *C. burnetii* (Hall et al., 1982; Meiklejohn et al., 1981).

Pathogenicity

The disease manifestations of Q fever in humans can be separated into acute and chronic illnesses. Following aerosol ingestion and an incubation period of 1–3 weeks, acute disease commonly presents as flu-like illness with hallmark cyclic fever, preorbital headache and myalgia (Maurin and Raoult, 1999). The initial target is the alveolar macrophage, although the organism can subsequently disseminate to replicate within a variety of tissues. Clinically the illness falls within the group of fever syndromes of unknown origin and is not commonly recognized and diagnosed (Fournier et al., 1998). Lung involvement also can lead to atypical pneumonia, which is normally clinically mild (Maurin and Raoult, 1999). Late in the incubation period, a transient bacteremia occurs in most patients, leading to

hematogenous spread to other organs. The liver is the most common site of disseminated infection, where disease normally manifests as a granulomatous hepatitis (Maurin and Raoult, 1999). In many geographic regions, a high percentage of the population (10–20%) has serological evidence of previous infection (Fournier et al., 1998), indicating that disease manifestations of Q fever are often subclinical or mild (Fournier et al., 1998). Indeed, outbreak surveillance reports indicate that approximately 60% of seroconverting individuals can be asymptomatic (Dupuis et al., 1987). Approximately 2% of patients experiencing acute disease will require hospitalization (Maurin and Raoult, 1999).

Clinical manifestations of Q fever lasting longer than 6 months have been classified as chronic disease (Fournier et al., 1998). It is estimated that chronic disease will develop in about 5% of patients that experience acute disease (Fournier et al., 1998). The heart is the most common site of chronic infection, accounting for 60–70% of chronic infections, and endocarditis is the most common clinical manifestation (Maurin and Raoult, 1999). The liver, arteries, and bones also can be involved (Fournier et al., 1998). Clinically, endocarditis presents as a subacute, blood-culture negative, cardiac insufficiency (Raoult et al., 1990a). Over 90% of patients who develop Q fever endocarditis have evidence of previous cardiac valve defects (Maurin and Raoult, 1999). The other predisposed population is the immunocompromised, which lack a vigorous T cell response (Fournier et al., 1998).

The long-term risk of developing vascular disease after infection with *C. burnetii* recently was described in a report by Lovey and co-workers (Lovey et al., 1999). They evaluated a Swiss cohort of 2,044 people exposed to a large outbreak of Q fever in 1983. They established that the 12-year mortality rate was significantly higher for those that were acutely infected in 1983. Moreover, the 12-year risk of developing arteriovascular disease, such as cerebrovascular accident or cardiac ischemia, was significantly higher among those who had been acutely infected than among those who had not been infected (7% versus 4%). Interestingly, an increased risk of development of endocarditis was not documented. These data suggest that acute infection with *C. burnetii* may lead to long-term vascular inflammation and may point to a latent *C. burnetii* infection comparable to that noted for *Chlamydia pneumonia* and other infectious agents.

Serological procedures are the methods of choice in specific diagnosis of acute and chronic Q fever, although culture and molecular techniques are conducted in specialized settings (Fournier et al., 1998). The early standard serologic assay used in diagnosis was the complement fixation test (Peter et al., 1987). This assay detects both phase I and II antigens (i.e., purified organisms of both phases) and is quite specific but less sensitive than alternative assays. Immunofluorescence (IFA), in a microimmunofluorescence format, is currently the preferred method with high specificity and sensitivity. A four-fold rise in IFA titer between acute and convalescent sera is considered diagnostic of Q fever (Maurin and Raoult, 1999). If a single serum sample is used, then IgG and IgM phase II titers of ≥200 and ≥50, respectively, are considered 100% predictive for acute fever, whereas an IgG phase I titer of ≥1,600 is considered 100% predictive of chronic Q fever (Maurin and Raoult, 1999). Immunofluorescence has also proven valuable in diagnosis of Q fever endocarditis by detecting the organism directly within infected cardiac valves (Baumgartner et al., 1988; Brouqui et al., 1994; Raoult et al., 1994). ELISA, immunoblotting and microagglutination assays also have been used for serosurvey and diagnostic evaluation of infection (Maurin and Raoult, 1999). Molecular methods employing PCR amplification of *C. burnetii*-specific DNA sequences from clinical samples and infected cell culture have shown utility in clinical diagnosis. An especially specific and sensitive method of detection uses a chromosomal repetitive transposon-like sequence as a PCR target. This procedure has been used in the diagnosis of Q fever in humans (Maurin and Raoult, 1999; Willems et al., 1994).

Acute Q fever is normally a self-limiting infection that usually spontaneously resolves within two weeks. Intervention with antimicrobial agents effectively minimizes clinical symptoms (Maurin and Raoult, 1999). Several tetracyclines (especially doxycycline) are the preferred antibiotic therapy for acute Q fever (Maurin and Raoult, 1999). Lincomycin, erythromycin, co-trimoxazole, and especially fluoroquinolones also are efficacious (Maurin and Raoult, 1999). Chronic infections are more refractory to antibiotic therapy. Q fever endocarditis, the most common chronic manifestation of *Coxiella* infection, has a mortality rate exceeding 50% (Maurin and Raoult, 1999). Although a good initial clinical response can result from prolonged therapy with tetracyclines, cessation of therapy frequently results in disease relapse and death (Maurin and Raoult, 1999). Combination therapy with doxycycline and a fluoroquinolone (perfloxacin or ofloxacin) shows promise in reducing mortality, but relapse rates remain high (Levy et al., 1991). Treatment with a combination of doxycycline and chloroquine, a drug that raises the pH of the phagolysosome (the intracellular niche of *C. burnetii*),

significantly reduces the relapse rate when compared to a combined doxycycline-ofloxacine regime (Maurin et al., 1992a; Raoult et al., 1999). Alkalinization of the phagolysosome is thought to increase the bactericidal activity of doxycycline (Maurin et al., 1992a). Although an efficacious formalin-inactivated whole cell vaccine against Q fever exists (Q-Vax), it is recommended only for individuals where Q fever is considered an occupational hazard. It is not licensed for use in the United States. In Australia, where Q fever is a particular problem, Q-Vax is used but requires skin testing for prior exposure before vaccination (Marmion et al., 1984; Marmion et al., 1990). Vaccinees that have had previous exposure to *C. burnetii* can develop a serious immune reaction at the site of inoculation.

Immunity

Infection of humans with *C. burnetii* induces robust humoral and cell-mediated immune responses (Maurin and Raoult, 1999). The combined response in acute disease patients usually abrogates clinical symptoms, resulting in a self-limiting illness, and typically confers long-lived protection against repeated infection. Occasionally, infection remains subclinical and persistent, and patients develop chronic disease. Chronic infection in the form of endocarditis usually involves suppression of components of an effective cell-mediated immune response and/or previous valvular damage (Maurin and Raoult, 1999).

Antibody develops against *C. burnetii* antigens during the second week of infection and proceeds with typical immunoglobulin class switching from IgM to IgG, developing increasing avidity for antigen (Guigno et al., 1992). Antibody that reacts with antigens isolated from phase II organisms develops first, followed several weeks later with antibody reacting with antigens from phase I organisms. The role of antibody in control of *C. burnetii* replication is not fully understood, but at least two functions have been reported. Specific antibody facilitates opsonized uptake by monocytes/macrophages. Immune-specific serum also lyses infected macrophages by an antibody-dependent cell-cytotoxicity mechanism (Koster et al., 1984). In addition, normal serum kills phase II bacteria but not phase I bacteria by the alternative complement pathway (Vishwanath and Hackstadt, 1988).

A vigorous cell-mediated immune response is necessary for effective clearance of *C. burnetii* infection. Athymic mice are attenuated in the ability to clear *C. burnetii* from spleen and blood when compared with euthymic litter mates (Kishimoto et al., 1978). *Coxiella burnetii* infection and antigens are potent stimulators of a delayed-type hypersensitivity response and macrophage activation (Waag, 1990). Chronic disease patients have a marked suppression of T cell proliferation in response to antigen-specific stimulation (Koster et al., 1985a; Koster et al., 1985b). A variety of immunosuppressive disease states, including HIV infection, cancer, lymphoma, chronic renal failure and pregnancy, have been associated with a predisposition for the development of chronic Q fever (Raoult et al., 1992; Raoult and Stein, 1993).

Although cytokines contribute significantly to the control of *C. burnetii* replication, they can also exacerbate chronic disease manifestations. Activated macrophages and monocytes effectively kill intracellular *C. burnetii* (Kishimoto et al., 1977). A key role for interferon-γ (IFN-γ) in stimulating host cells to inhibit *C. burnetii* replication was first demonstrated in infected mouse L929 cells and subsequently confirmed in various phagocytic cells (Turco et al., 1984). Recent studies have focused upon the interplay between several cytokine signals and the ability to effectively control *C. burnetii* replication. One model postulates that IFN-γ induces TNF-α expression by infected peripheral blood mononuclear cells (PBMC) causing the infected cells to die via an apoptotic pathway (Dellacasagrande et al., 1999). This would be a novel pathway for control of intracellular replication inasmuch as monocytes are normally resistant to induction of apoptotic death by TNF-α (Wallach et al., 1999). Infection of a mouse macrophage-like cell line (P388D1) with phase I *C. burnetii* induces TNF-α and IL-1 expression whereas infection with phase II *C. burnetii* only induces TNF-α (Tujulin et al., 1999). Chronic disease patients express elevated levels of TNF-α and IL-1β compared to uninfected control individuals. The PBMC from chronic patients produce dramatically elevated levels of IL-10 and TGF-β, which probably contributes to the previously reported immune suppression observed in chronic disease (Capo et al., 1996). Monocytes from these patients are unable to control *C. burnetii* replication compared with those obtained from healthy individuals (Dellacasagrande et al., 2000).

The relative importance of reactive nitrogen and oxygen intermediates (RNI and ROI) in the killing of *C. burnetii* is in question. Monocytes taken from chronic granulomatous disease patients, who are deficient in ROI-mediated killing, effectively clear *C. burnetii* if stimulated with IFN-γ (Dellacasagrande et al., 1999). Moreover, various in vitro studies have demonstrated the lack of measurable superoxide anion (O_2^-) production by human neutrophils following phago-

cytosis of Coxiella (Akporiaye et al., 1990; Baca et al., 1993a; Ferencik et al., 1984; Li et al., 1996). It appears that ingestion of *C. burnetii* fails to stimulate O_2^- release as opposed to parasite directed detoxification of the molecule (Baca et al., 1993a; Baca et al., 1993b; Li et al., 1996). Evidence suggests that *C. burnetii* synthesizes a tyrosine phosphatase that inhibits the oxidative burst and accompanying O_2^- release into the lumen of the phagolysosomal vacuole (Baca et al., 1993b; Li et al., 1996). The enzyme is thought to dephosphorylate and inactivate a critical signal transduction protein necessary for O_2^- production (Li et al., 1996). The role of RNI in control of *C. burnetii* growth is similarly unresolved. A study indicated that IFN-γ treated THP-1 human monocyte-like cells infected with *C. burnetii* do not produce nitric oxide (Dellacasagrande et al., 1999). A caveat of this study is the known difficulty in activating human monocytes in culture (Nathan, 1997). Conversely, IFN-γ inhibits growth of *C. burnetii* in mouse fibroblast L-929 cells. IFN-γ is a known inducer of inducible nitric oxide synthase in this cell line (Turco et al., 1984). It is reasonable to suspect that the reported growth inhibition may be due to subsequent RNI production.

Virulence Determinants and Host-Parasite Interactions

The identification of *C. burnetii* virulence determinants has been hampered by an inability to generate and test defined mutants. However, suitable animal models of acute human Q fever are available, with the guinea pig being the most relevant (Heggers et al., 1975). Guinea pigs challenged intraperitoneally with as few as 10 virulent organisms develop fever within 5 days. Bacteria can be isolated from a variety of tissues, including the spleen, for several months post-infection. Interestingly, a comparison of the relative virulence of isolates from acute and chronic infections found that as few as 10 IFU (inclusion forming units) of acute isolate induce a strong fever response, whereas 10^6 IFU of chronic isolate did not cause detectable fever in guinea pigs, although infection could be confirmed by isolation of these organisms from spleens (Moos and Hackstadt, 1987). In general, most mouse strains remain asymptomatic following infection, although *C. burnetii* can be found in granulomatous lesions in various organs (Scott et al., 1987). A mouse lethality model of human Q fever has been developed in A/J mice. These mice are particularly sensitive to infection by *C. burnetii* because of deficient INF-γ priming of a protective T cell response (Scott et al., 1987). Attempts to model human Q fever endocarditis have employed infection of both rabbits and mice (Atzpodien et al., 1994; Hackstadt, 1990; La Scola et al., 1998). Chronic endocarditis does not spontaneously develop in either experimental animal but requires the artificial induction of lesions on heart valves (rabbits; Hackstadt, 1990; La Scola et al., 1998) or immunosuppression (mice; Atzpodien et al., 1994). Interestingly, in both experimental animals vegetative cardiac lesions containing *C. burnetii* developed after infection with prototypic human acute disease isolates, indicating, at least in these animal models, that acute disease isolates may be capable of causing chronic infection (Hackstadt, 1990; La Scola et al., 1998).

Previous studies showing that acute and chronic disease isolates differed both genetically and biochemically led to the hypothesis that acute isolates were distinct in virulence potential from chronic isolates (Hackstadt, 1986; Hendrix et al., 1991; Mallavia, 1991; Samuel et al., 1985). This hypothesis lost epidemiologic support when isolates from chronic disease patients were identified with genetic markers of acute isolates (Thiele and Willems, 1994a). Nonetheless, the potential to cause acute or chronic disease may be determined by specific factors encoded by different isolates in combination with host factors such as immune status. The potential for dramatic phenotypic differences among these isolates was underscored by a report that the genome size between different isolates may vary by nearly one megabase (Willems et al., 1996).

To date, the only defined virulence determinant of *C. burnetii* is LPS. The organism undergoes a phase (LPS) variation that is similar to that observed in the Enterobacteriaciae. Transition from smooth (full-length O-side chains) phase I to rough (truncated O-side chains) phase II LPS occurs upon repeated passage of the organism in an immunoincompetent host such as embryonated eggs or tissue culture. Phase II organisms are avirulent for guinea pigs, whereas phase I *C. burnetii* causes disease and is always associated with naturally infected mammals and ticks (Hackstadt, 1990). A strain displaying a semi-rough-type LPS has intermediate virulence for guinea pigs (Moos and Hackstadt, 1987). Phase I to phase II transition is likely due to accumulation of point mutations in LPS biosynthesis genes or the loss of chromosomal regions that carry these genes (O'Rourke et al., 1985; Vodkin and Williams, 1986a). *Coxiella burnetii* LPS is weakly pyrogenic when compared to other Gram-negative LPSs (Hackstadt, 1990). Full-length LPS contributes to the virulence of phase I by inhibiting deposition of C3b complement component and subsequent complement-mediated killing by the alternative pathway (Vishwanath and Hackstadt, 1988).

Internalization into host cells occurs by microfilament-dependent, parasite-directed endocytosis (Baca et al., 1993a; Meconi et al., 1998). *Coxiella burnetii* plays a passive role in internalization, as inactivated organisms are internalized at a rate equal to that observed for viable bacteria (Baca et al., 1993a). Upon adherence of virulent phase I *C. burnetii* to THP-1 human monocytic cells, a dramatic reorganization of the actin cytoskeleton occurs, resulting in production of pronounced membrane protrusions (Meconi et al., 1998). Similar cellular effects are not observed upon adherence of avirulent phase II organisms (Meconi et al., 1998). Interestingly, this dramatic cytoskeletal response does not correlate with an increased rate of internalization of phase I over phase II organisms, as the latter are more efficiently internalized (Capo et al., 1999). This may reflect differential engagement of host cell receptors by phase variants. The THP-1 receptor for virulent phase I organisms consists of a complex of leukocyte response integrin $\alpha_v\beta_3$ and integrin-associated protein whereas avirulent phase II organisms additionally engage the CR3 receptor (Capo et al., 1999). The cytoskeletal rearrangements and resultant membrane projections associated with phase I adherence may restrict engagement of the CR3 coreceptor and lower the efficiency of internalization (Meconi et al., 1998). Full-length LPS of phase I also may sterically mask the critical *C. burnetii* CR3 ligand (Hackstadt, 1988). The *C. burnetii* ligand(s) mediating internalization are still unknown.

Studies strongly support the idea that once internalized, *C. burnetii* resides in a vacuole with characteristics of a secondary lysosome. The early parasite-containing phagosome proceeds through the endocytic pathway eventually acidifying to a pH of approximately 4.8 (Akporiaye et al., 1983b; Maurin et al., 1992b). *Coxiella burnetii* requires a moderately acidic pH (~5) to activate its metabolism and thus has evolved to exploit the only intracellular niche that provides this acidic environment (Hackstadt and Williams, 1981a). The *C. burnetii*-containing vacuole fuses with lysosomes as demonstrated by the colocalization of the lysosomal enzymes 5′-nucleotidase (Burton et al., 1971), acid phosphatase (Akporiaye et al., 1983b; Burton et al., 1978; Heinzen et al., 1996c), cathepsin D (Heinzen et al., 1996c), vacuolar type H+ ATPase (Heinzen et al., 1996c), and two predominant lysosomal glycoproteins (LAMP-1 and LAMP-2; Heinzen et al., 1996c). The organism undergoes luxurious growth within this vacuole despite the presence of factors normally considered bacteriocidal (Reiner, 1994). Maturation of the nascent *C. burnetii*-containing phagosome to a mature phagolysosome appears to be delayed (Howe and Mallavia, 2000). At one hour postinfection, the percentage of vacuoles containing viable *C. burnetii* that colocalize with lysosomal markers is roughly one-half that observed for vacuoles harboring inactivated *C. burnetii* (Howe and Mallavia, 2000). It is hypothesized that delayed maturation allows morphological differentiation of the environmentally stable SCV developmental form to the more metabolically active LCV developmental form (Howe and Mallavia, 2000). Supporting this idea is the observation that the SCV-specific DNA-binding protein ScvA is more efficiently degraded when purified *C. burnetii* organisms are metabolically activated at pH 5.5 than at pH 4.5 (the approximate pH of a mature phagolysosome; Howe and Mallavia, 2000). Degradation of ScvA is thought to be a prerequisite for SCV-to-LCV transition (Heinzen et al., 1996b); thus, delayed phagolysosomal maturation would provide optimal pH conditions for ScvA degradation and subsequent SCV-to-LCV morphological differentiation. These data also imply that a product of *C. burnetii* metabolism is responsible for delayed lysosomal fusion.

Strategies for combating the toxic constituents of the phagolysosome are likely important virulence determinants of *C. burnetii*. The biochemically unusual cell envelope of the organism may confer intrinsic resistance to the lysosomal environment (Amano and Williams, 1984a; Amano et al., 1984c; Schramek et al., 1985; Wollenweber et al., 1985). The SCV developmental form is particularly resistant to chemical and physical disruption and consequently may be able to survive the degradative conditions of the phagolysosome for extended periods (Heinzen, 1997a). The SCV also undergoes binary fission and can differentiate into the more metabolically and perhaps divisionally active LCV. This process may occur at a significant rate only when phagolysosomal conditions are more amenable for growth of the LCV (Heinzen, 1997a).

An innate host defense mechanism important in controlling replication of intracellular bacterial pathogens is the sequestration of iron (Britigan et al., 2000). *Coxiella burnetii* appears to resist this host defense by stimulating an increase in transferrin receptor biosynthesis. Inoculation of a J774.1 murine macrophage-like cell line with viable *C. burnetii* corresponds to an upregulation of transferrin receptor synthesis and a concomitant increase in total cellular iron (Howe and Mallavia, 1999). In vivo, *C. burnetti*-induced upregulation may compensate for IFN-γ-induced downregulation of transferrin receptor synthesis (Taetle and Honeysett, 1988). The mechanisms by which *C. burnetii* acquires iron from the host are undefined, but a ferric uptake regulatory protein (Fur) and a periplasmically localized protein

that is transcriptionally regulated by Fur have been identified (J. E. Samuel, unpublished).

Coxiella burnetii likely secretes molecules into the phagolysosomal vacuole that modify the environment. This behavior has been observed for a number of intracellular parasites that reside in membrane-bound vacuoles (Hackstadt, 1998; Small et al., 1994). In vitro studies have demonstrated that *C. burnetii* translocates a variety of proteins during metabolic acid activation in defined medium (Redd and Thompson, 1995). A few *Coxiella* enzymes that are localized to the outer membrane and/or secreted have been hypothesized to play roles in intracellular survival based upon their recognized activities in facultative intracellular bacteria. Macrophage infectivity potentiator (Mip) is a peptidylprolyl isomerase (PPIase) localized to the cytoplasm, periplasmic space, and outer surface of *C. burnetii* and *L. pneumophila* (Cianciotto et al., 1995; Mo et al., 1995; Seshu et al., 1997). Mutants of *L. pneumophila* that do not express Mip are attenuated in their ability to infect and survive in macrophages. A second periplasmic and outer surface-localized enzyme, Com-1, is a homologue of the disulfide bond forming enzymes DsbA and DsbC (Hendrix et al., 1993). These enzymes are required for folding of virulence determinants in *S. flexneri* and *E. coli* (Watarai et al., 1995). The *C. burnetii* com-1 gene complements an *E. coli dsbA* deletion mutant and purified recombinant Com-1 is enzymatically active (Hendrix et al., submitted). *Coxiella burnetii* synthesizes cytoplasmically localized catalase and iron-containing superoxide dismutase (Akporiaye and Baca, 1983a; Heinzen et al., 1992). These proteins presumably play important roles in detoxifying superoxide anion and hydrogen peroxide generated by *C. burnetii* oxidative respiration (Baca et al., 1994). Secreted forms of these enzymes, known virulence factors of other intracellular parasites (Amemura-Maekawa et al., 1999; Bandyopadhyay and Steinman, 1998; St. John and Steinman, 1996), have not been described for *C. burnetii*. However, a protein tyrosine acid phosphatase that blocks superoxide anion production by fMetLeuPhe-stimulated human neutrophils has been partially purified from *C. burnetii* (Baca et al., 1993b; Li et al., 1996). A specific inhibitor of the acid phosphatase dramatically reduces the percentage of L929 cells persistently infected with *C. burnetii* (Baca et al., 1993b). Neutrophils treated with *C. burnetii* acid phosphatase increase tyrosine phosphorylation of a ~44-kDa host protein (Li et al., 1996). Although the identity of this host protein is unknown, it may be involved in regulating the oxidative burst of neutrophils. Indeed, ingestion of *C. burnetii* by macrophage-like cell lines results in a greatly diminished respiratory burst with little production of superoxide anion (Akporiaye et al., 1990; Baca et al., 1993a; Ferencik et al., 1984; Li et al., 1996). Several facultative intracellular bacteria have been shown to block the oxidative burst by expressing an acid phosphatase enzyme, including *Legionella micdadei* (Saha et al., 1985) and *Yersinia pseudotuberculosis* (Bliska and Black, 1995).

Applications

A low infectious dose, extracellular stability, and an aerosol route of infection make *C. burnetii* a potential bioterrorism agent (Mobley, 1995). In response to a growing concern of such an insidious use, the Centers for Disease Control has recently designated *C. burnetii* as a "select agent," placing restrictions on transport.

CHAPTER 3.1.21

The Genus *Wolbachia*

MARKUS RIEGLER AND SCOTT L. O'NEILL

Introduction

Numerous invertebrate species form long lasting symbioses with bacteria (Buchner, 1949; Buchner, 1965). One of the most common of these bacterial symbionts is *Wolbachia pipientis*, which has been estimated to infect anywhere from 15–75% of all insect species (Werren et al., 1995a; West et al., 1998; Jeyaprakash and Hoy, 2000; Werren and Windsor, 2000) as well as many species of arachnids, terrestrial crustaceans and filarial nematodes (O'Neill et al., 1997a; Bandi et al., 1998). In most arthropod associations, *Wolbachia* act as reproductive parasites manipulating the reproduction of their hosts to enhance their own vertical transmission. There appears to be little direct fitness cost to the infected host besides the costs arising from the reproductive manipulations. However instances have been reported where *Wolbachia* can be either deleterious (Min and Benzer, 1997; Bouchon et al., 1998) or beneficial (Girin and Boultreau, 1995; Stolk and Stouthamer, 1995; Wade and Chang, 1995; Vavre et al., 1999b; Dedeine et al., 2001) to their hosts.

Wolbachia were first described as intracellular *Rickettsia*-like organisms (RLOs), infecting the gonad cells of the mosquito, *Culex pipiens* (Hertig and Wolbach, 1924), and were later named "*Wolbachia pipientis*" (Hertig, 1936). It was not until the work of Yen and Barr (Yen and Barr, 1971; Yen and Barr, 1973) that *Wolbachia* were implicated in causing crossing incompatibilities between different mosquito populations (Laven, 1951; Ghelelovitch, 1952). When polymerase chain reaction (PCR) diagnostics for *Wolbachia* became available, it became clear that this agent was both extremely widespread and also responsible for a range of different reproductive phenotypes in the different hosts it infected (O'Neill et al., 1992; Rousset et al., 1992; Stouthamer et al., 1993). The most common of these are cytoplasmic incompatibility, inducing parthenogenesis, overriding host sex-determination, and male-killing (O'Neill et al., 1997a). As of the time of this writing, more than 450 different *Wolbachia* strains with unique gene sequences, different phenotypes, and infecting different hosts have been deposited in GenBank and the *Wolbachia* host database (http://www.wolbachia.sols. uq.edu.au).

Phylogeny

Wolbachia pipientis (Hertig, 1936) is the only species of the genus *Wolbachia*, family Anaplasmataceae, order Rickettsiales, class α-proteobacteria (Dumler et al., 2001). Two other species, *Wolbachia persica* (Suitor and Weiss, 1961) and *Wolbachia melophagi* (Nöller, 1917; Philip, 1956), originally in the same genus have since been removed (Dumler et al., 2001). *Wolbachia*'s closest relatives in the Anaplasmataceae are the genera *Anaplasma*, *Ehrlichia* and *Neorickettsia* (Fig. 1). They are all obligate intracellular bacteria that reside in vacuoles of eukaryotic cells (Dumler et al., 2001).

On the basis of the phylogeny of the 16S *rRNA* gene, the genus *Wolbachia* as currently defined is monophyletic (O'Neill et al., 1992; Bandi et al., 1998; Lo et al., 2002). *Wolbachia* have been divided into six supergroups A–F on the basis of 16S *rRNA* and *ftsZ* gene sequences; A, B, E and F are associated with arthropods (Vandekerckhove et al., 1999; Lo et al., 2002), and C and D are associated with filarial nematodes (Bandi et al., 1998; Lo et al., 2002). The phylogenetic relationship between these supergroups is currently not well resolved (Lo et al., 2002; Fig. 2).

The validity of the A and B supergroups that infect insects has been confirmed by phylogenetic analysis of the heat shock operon *groE* (Masui et al., 1997), of the spacer 2 region between the 23S and the 5S *rRNA* coding genes (Van Meer et al., 1999) and of the surface protein gene *wsp* (Zhou et al., 1998; Fig. 3). There is evidence that homologous recombination between different *Wolbachia* strains occurs (Jiggins et al., 2001; Werren and Bartos, 2001) and thereby has the potential to confound the interpretation of phylogenetic data based on the sequences of single genes. The lack of congruency between phylogenetic trees of *Wolbachia*

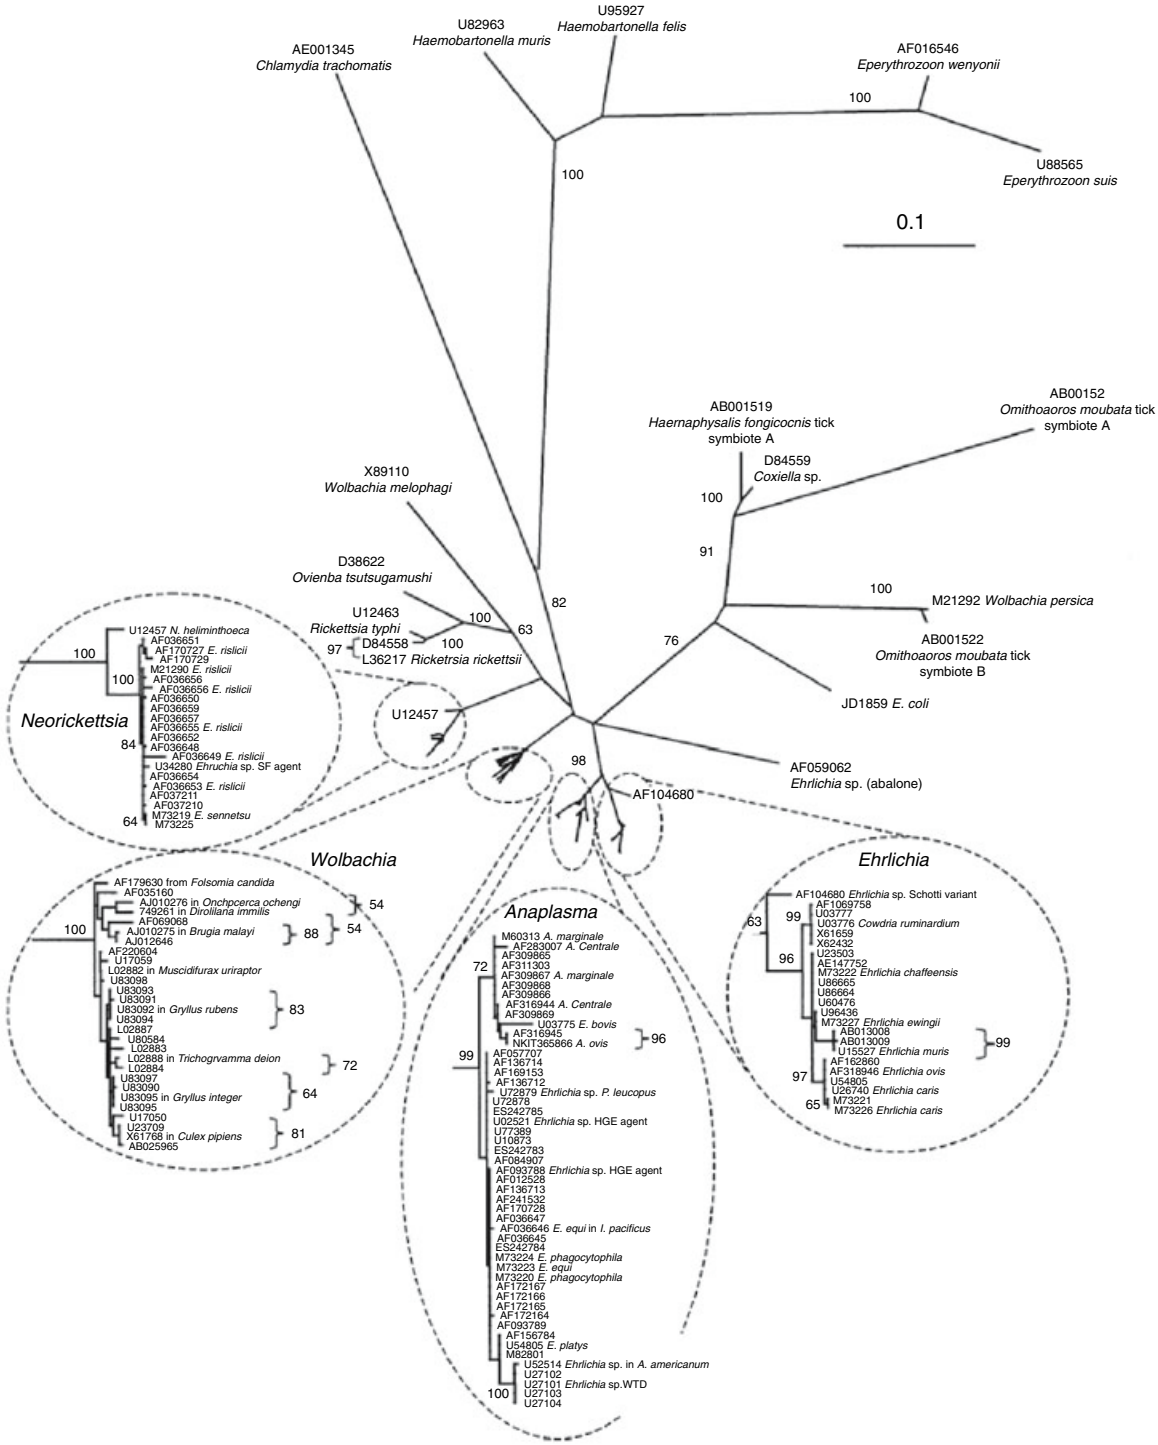

Fig. 1. Phylogenetic tree inferred from the small subunit (16S) rRNA gene sequences of *Ehrlichia*, *Anaplasma*, *Neorickettsia* and *Wolbachia* species, including 455 sites after removal of sites containing a gap in any sequence. The sequence from *Chlamydia trachomatis* (accession no AE001345 [www.ncbi.nlm.nih.gov/entrez/query.fcgi?db=nucleotide=search=AE001345]) was used as an outgroup. Numbers above internal nodes indicate the percentage of 1000 bootstrap replicates that supported the branch. All bootstrap values are included for clades that were consistently observed using the phylogenetic methods applied (maximum parsimony, minimum evolution, maximum likelihood and majority-rule bootstrap analysis of neighbor-joining trees). The maximum-likelihood tree is shown. Bars, estimated number of substitutions per site; the scales for the figure and insets are the same. From Dumler et al. (2001).

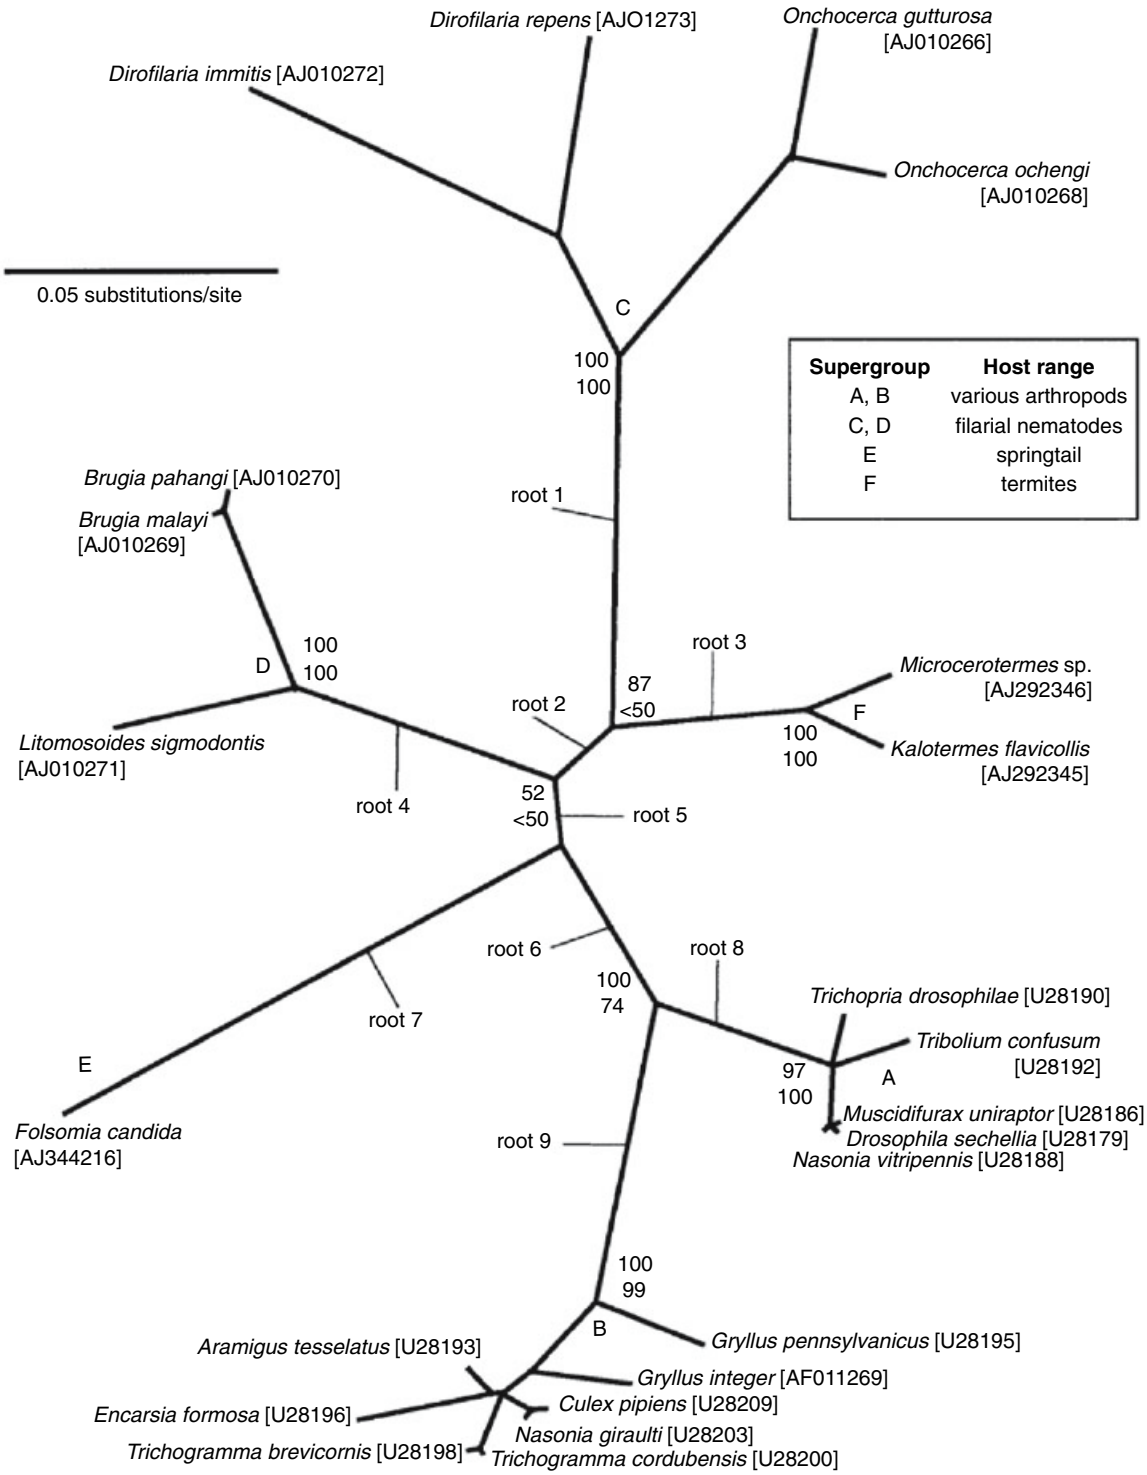

Fig. 2. Unrooted phylogenetic tree of *Wolbachia* endosymbionts of arthropods and filarial nematodes based on *ftsZ*, estimated using Bayesian inference of phylogeny. Posterior probabilities supporting nodes of interest are shown above bootstrap values from a maximum parsimony analysis. Names represent host species. Roots 1-9 indicate positions where the *ftsZ* gene of the outgroup *Anaplasma marginale* was constrained during likelihood estimations to examine the most appropriate root placement. Accession numbers are shown adjacent to each taxon. Each supergroup is labelled with one of the letters A-F. From Lo et al. (2002).

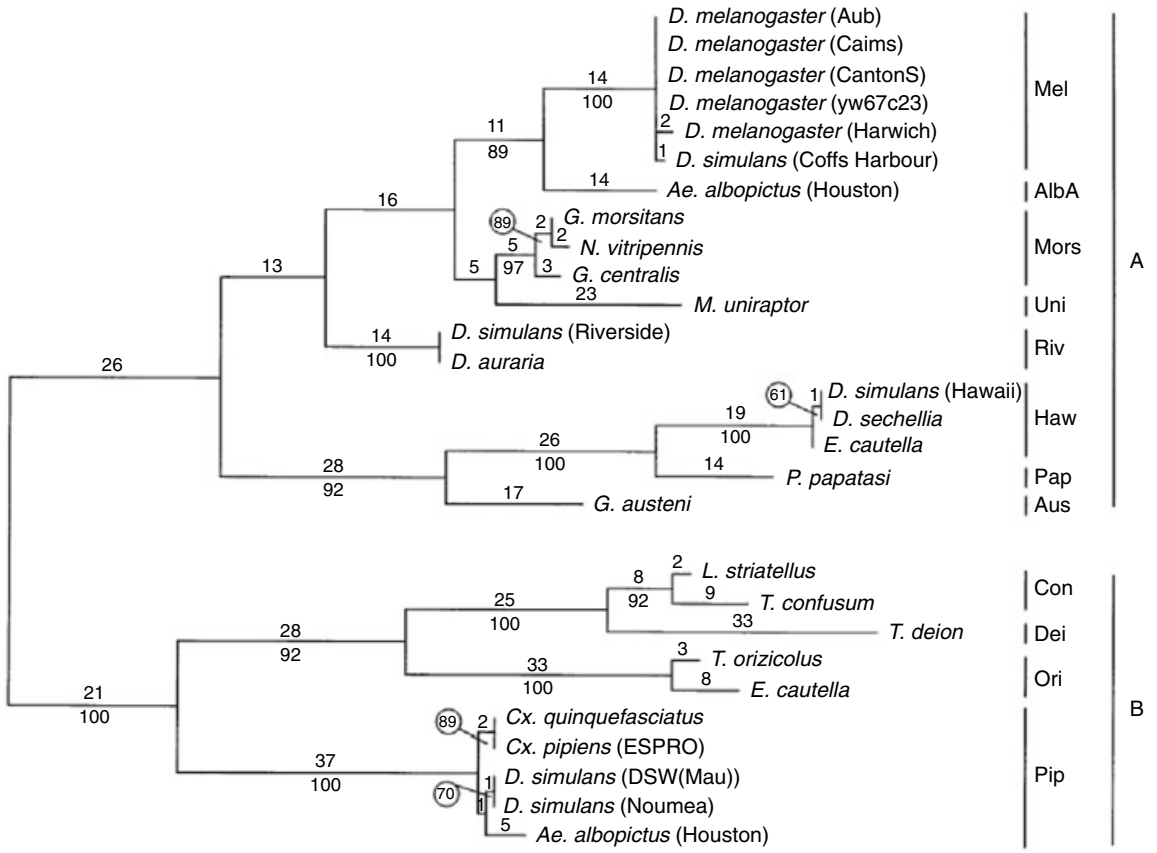

Fig. 3. One of four most parsimonious trees generated from a branch-and-bound search of aligned *wsp* sequences (tree length = 472; CI = 0.64). Tree shown is midpoint rooted. Branch lengths, as determined from the Phylogenetic Analysis using Parsimony (PAUP) table of linkages, are labelled above branches and bootstrap values (500 replicates) are labelled below branches. Bootstrap values less than 50 are not shown. Taxa are labelled as the host from which the *Wolbachia* strain was isolated. From Zhou et al. (1998).

strains and their hosts indicates that horizontal transfer of *Wolbachia* to new host species has occurred on multiple occasions during evolutionary history (O'Neill et al., 1992; Werren et al., 1995b; Vavre et al., 1999a).

Taxonomy

The species name *Wolbachia pipientis* (Hertig, 1936) was originally assigned to the infection in a particular host, the common house mosquito *Culex pipiens*. The name has since been extended to highly similar bacteria in arthropods and filarial nematodes. In most associations, the literature only refers to the genus name "*Wolbachia*." With the rapid discovery of numerous *Wolbachia* strains, a uniform nomenclature system became necessary. The current system was based on an abbreviation style *w*Host (Rousset and de Stordeur, 1994), as proposed in Zhou et al. (1998). This system is now widely accepted and has been further specified by Charlat et al. (2002a). Separate names should be assigned to strains differing in any of the following three traits: *Wolbachia* gene sequences, phenotypic effects on hosts, or the host species infected. Strain names should then consist of a *w* followed by two or three letters to refer to the *Wolbachia* strain and a subscript referring to the host species (e.g., $w\mathrm{No}_{D.sim}$ for the *Wolbachia* infection of *Drosophila simulans* originally identified from Noumea or $w\mathrm{Cer1}_{R.cer}$ for one of the *Wolbachia* infections of *R. cerasi*). Most *Wolbachia* strains of the A and B supergroup have now been assigned strain names on the basis of the sequence of the surface protein gene *wsp* (Zhou et al., 1998). It should be noted that while strain designation in itself makes no assumptions about relatedness and as such can be based upon any consistent genetic or ecological feature, rigorous phylogenetic analysis might require the use of multiple gene sequences to account for potential recombination between strains. The discovery in recent years of a large number of diverse *Wolbachia* strains suggests that the taxonomy of the

Wolbachia pipientis group as a whole will soon need to be re-examined with the possibility that the current species might end up being split into a number of new species, potentially based on supergroup assignments.

Habitat

Wolbachia are obligate intracellular bacteria of invertebrates, with the majority of the currently described hosts living in terrestrial habitats. *Wolbachia* have an impressive host range. Infections have been detected in all major orders of insects, arachnids (such as spiders and mites), terrestrial crustacean species, and filarial nematodes. This extreme diversity of hosts makes *Wolbachia* one of the most ubiquitous intracellular symbionts yet described. Within the host cell, *Wolbachia* is always seen within a vacuole, presumably of host origin (Fig. 4). The nature of this compartment and the extent it is modified by *Wolbachia* have yet to be determined. *Wolbachia* are inherited vertically by transovarial transmission through the cytoplasm of host eggs. As a result *Wolbachia* always infects the female germline of its host. *Wolbachia* is usually lost from the cytoplasm of sperm cells during spermatogenesis (Clark et al., 2002; Veneti et al., 2003) and as such is only maternally inherited. In addition to the germline, a range of other somatic tissues is known to be infected. The extent and diversity of somatic tissues infected vary with host and *Wolbachia* strain (Dobson et al., 1999).

Isolation

Wolbachia's entire life cycle is dependent on the cytoplasmic environment of the host. The bacteria cannot yet be cultivated on cell-free media and can only be maintained in individual hosts or cell lines (O'Neill et al., 1997b; Dobson et al., 2002; Noda et al., 2002). *Wolbachia* infections have been established in a variety of insect cell lines including those originating from *Aedes albopictus* (O'Neill et al., 1997b; Dobson et al., 2002; Noda et al., 2002), *Drosophila melanogaster*, *Spodoptera frugiperda* (Dobson et al., 2002), and *Heliothis zea* (Noda et al., 2002). *Wolbachia* can also be maintained in a mammalian cell line originating from mouse connective tissue (Noda et al., 2002). *Wolbachia* strains can be artificially transferred between host species by embryonic microinjections (Nigro, 1991; Boyle et al., 1993; Braig et al., 1994) or inoculation with crushed tissues from pupae (Williams et al., 1993), ovaries, and fat- and nervous tissues (Bouchon et al., 1998). Transinfection experiments have enabled the comparison of different *Wolbachia*-host interactions and provided a means to determine what aspects of the association are regulated by either host or symbiont (Clancy and Hoffmann, 1997; Poinsot et al., 1998; McGraw et al., 2001; Riegler et al., 2004). Transinfection experiments have also been used to segregate multiple infections from a single host (Charlat et al., 2002b; Riegler et al., 2004) or establish multiple infections within a single host (Rousset et al., 1999).

Identification

Wolbachia are coccoid or bacilliform in morphology, 0.8–1.5 μm long (Hertig, 1936). These Gram-negative bacteria have two cell membranes and are enclosed within a vacuole (Fig. 4). Several techniques have been utilized to visualize *Wolbachia* within host tissue. *Wolbachia* can be readily stained by Giemsa (Hertig, 1936) or general DNA-binding fluorochromes such as DAPI (4′,6-diamino-2-phenylindole dihydrochloride; O'Neill and Karr, 1990; Bressac and Rousset, 1993). Monoclonal and polyclonal antibodies have been developed for the outer membrane proteins of several species of the order Rickettsiales (Ohashi et al., 1998) and specifically also for *Wolbachia* (Kose and Karr, 1995; Dobson et al., 1999; Masui et al., 2001). *Wolbachia* have also been successfully detected using in situ hybridization techniques with *Wolbachia* specific DNA probes (Heddi et al., 1999). Several polymorphic genes of *Wolbachia* have been isolated and characterized for a wide range of strains. *Wolbachia* specific PCR primers have been designed and are commonly used to identify *Wolbachia* infections in total host genomic DNA extracts (Table 1). The best primers to detect a wide range of different *Wolbachia* strains are those in the 16S primer-set, which can be used for strains from all supergroups described so far (O'Neill et al., 1992; Bandi et al., 1998; Vandekerckhove et al.,

[a]Primers are for the 16S *rRNA* gene, the cell cycle gene *ftsZ* and the outer surface protein gene *wsp*, used for the detection of the six different *Wolbachia* supergroups A–F.

1999). However the polymorphism in the 16S gene is low, which makes the detection of multiple infections in individuals and the characterization of single strains difficult. For the latter, primers designed to amplify the cell cycle gene *ftsZ* (Holden et al., 1993; Werren et al., 1995b; Bandi et al., 1998; Lo et al., 2002) and the outer surface protein gene *wsp* (Braig et al., 1998; Zhou et al., 1998) are more suitable.

Preservation

Because of their intracellular biology, *Wolbachia* cannot easily be preserved and are best maintained in cultures of their hosts. Some of *Wolbachia*'s hosts undergo diapause phases to survive extreme conditions. Under such circumstances *Wolbachia* are usually retained in most associations. However loss of infections during diapause has been observed in a few cases (Perrot-Minnot et al., 1996). *Wolbachia* can also be kept in cell lines (O'Neill et al., 1997b; Dobson et al., 1999; Noda et al., 2002), where they can be stored at –80°C (O'Neill et al., 1997b). Treatment with antibiotics, particularly with tetracycline or rifampicin, in combination with high temperature is commonly used for removing *Wolbachia* infections (Dobson and Rattanadechakul, 2001a; Fenollar et al., 2003b; Volkmann et al., 2003). Rearing insects under nutritional stress has been reported to reduce the efficiency of maternal transmission (Sinkins et al., 1995; Clancy and Hoffmann, 1998).

Genomics

Wolbachia strains have small streamlined genomes comprised of a single circular chromosome. No plasmids are known to occur in *Wolbachia*. The genome size among the members of different *Wolbachia* supergroups varies considerably. Strains of the nematode-associated C and D supergroup have a chromosome size of 0.9–1.1 Mb, whereas members of the insect-associated A supergroup have chromosome sizes of 1.3–1.6 Mb (Sun et al., 2001) and 1.8 for B supergroup (Fenollar et al., 2003a). The reduced size in nematode *Wolbachia* correlates with their observed obligate mutualism and concordant evolution with their hosts (Bandi et al., 1998; Casiraghi et al., 2001).

The genome of the *Wolbachia* strain *w*Mel$_{D.\,mel}$ that naturally infects *Drosophila melanogaster* has recently been sequenced (Wu et al., 2004). This has revealed a striking number of repetitive elements within the *Wolbachia* genome. Over 14% of the chromosome is comprized of repeat sequences, many of them transposable elements. This high level of repetitive DNA is unique for a streamlined intracellular genome. Associated with this high level of repetitive DNA is the common occurrence of translocations and inversions between *Wolbachia* strains (Sun et al., 2003; Wu et al., 2004). Initial data indicate that the presence of repetitive DNA on the *Wolbachia* chromosome is an extremely sensitive marker for discriminating between different *Wolbachia* strains (M. Riegler, personal communication). The genome sequence of *Wolbachia* has also revealed a striking number of genes encoding ankyrin repeat domains. These domains, which mediate protein-protein interactions, are found in over 23 predicted genes of unknown function within the *w*Mel$_{D.mel}$ genome. It is currently hypothesized that they may play a major role in the interaction of *Wolbachia* with its various eukaryotic hosts (Wu et al., 2004).

Ecology

The majority of *Wolbachia* infections in arthropods are physiologically benign. Two strains have been reported as virulent so far, the *popcorn* infection in *D. melanogaster*, *w*MelPop$_I$ (Min and Benzer, 1997), and *w*Vul in *Porcellio dilatus* (Bouchon et al., 1998). Some *Wolbachia* associations have evolved obligate mutualisms with their hosts, as is seen in C and D supergroup infections of filarial nematodes (Bandi et al., 2001). In some insect associations, *Wolbachia* have positive effects on fertility (Girin and Boultreau, 1995; Vavre et al., 1999b) and sperm competition (Wade and Chang, 1995) and are essential for oogenesis (Dedeine et al., 2001). *Wolbachia* can also counteract the deleterious effects of certain mutations in *D. melanogaster* by rescuing oogenesis defects (Starr and Cline, 2002). In most associations, *Wolbachia* manipulate host reproduction, thereby favoring their own dispersal into host populations, a characteristic that leads to the most general definition of *Wolbachia* as reproductive parasites. These reproductive manipulations include cytoplasmic incompatibility, thelytokous parthenogenesis, male-killing and feminization (O'Neill et al., 1997a; Stouthamer et al., 1999).

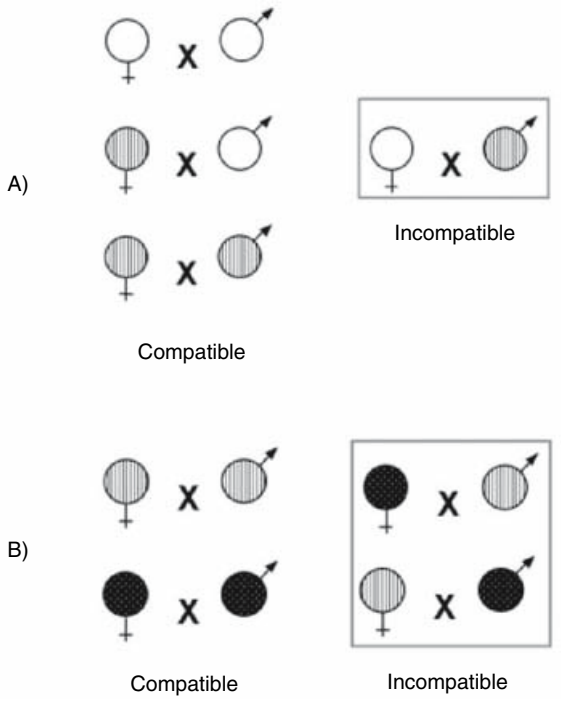

Fig. 5. Schematic illustration of cytoplasmic incompatibility. A) Unidirectional incompatibility is expressed when *Wolbachia* infected males (shaded) mate with uninfected females. These matings produce few viable offspring. All other crosses are compatible. B) Bidirectional incompatibility occurs when insects carrying different *Wolbachia* strains mate. In this case only crosses between individuals infected by the same *Wolbachia* strain are compatible.

Cytoplasmic Incompatibility

Cytoplasmic incompatibility (CI) is the most commonly described phenotype associated with *Wolbachia* infection and has been observed in many insect, mite and crustacean species (Hoffmann and Turelli, 1997). CI arises when infected males mate with females that are either uninfected or infected with a different strain of *Wolbachia* (Fig. 5). The result is a failure of the male pronucleus to successfully complete karyogamy during fertilization of the female eggs. This leads to embryonic lethality in diploid species (O'Neill and Karr, 1990) and either to production of males (Breeuwer and Werren, 1993) or embryonic lethality in haplodiploids (Vavre et al., 2000). Crosses between infected females and uninfected males or between individuals infected with the same strain of *Wolbachia* are fully compatible. The molecular basis of CI is not yet known. Cytological analyses suggest that *Wolbachia* influences proteins involved in host cell cycle regulation (Tram and Sullivan, 2002). *Wolbachia* delay the entry of male pronuclei into the first mitotic divisions either by a direct inhibition of the enzymatic machinery that drives cells into mitosis or indirectly through activation of cell cycle checkpoints (Tram et al., 2003).

A two-component model has been suggested to explain CI (Werren, 1997; Poinsot et al., 2003). *Wolbachia* modify the sperm of infected males during spermatogenesis (modification, or "mod function"), leading to embryonic death unless a related *Wolbachia* is present in the egg and restores viability (rescue, or "resc function"). *Wolbachia* strains can be classified according to their mod and resc capability. For example, a mod+ resc+ strain can induce CI as well as rescue the modification of the same strain, whereas a mod– resc+ strain is incapable of modifying sperm but can rescue sperm modified by closely related *Wolbachia* strains. The mod/resc model also explains other CI relationships such as bidirectional incompatibility between individuals infected with a different *Wolbachia* variant (Fig. 5) or unidirectional incompatibility between individuals infected with a variable number of different *Wolbachia* strains. In the latter case, multiple infections express unidirectional CI when males carry an additional CI inducing strain that is not present in the infected females (Merot et al., 1995; Rousset and Solignac, 1995; Perrot-Minnot et al., 1996; Dobson et al., 2001b; Riegler and Stauffer, 2002).

Thelytokous Parthenogenesis

Hymenoptera and some species of other insect orders possess a haplo-diploid sex determination system (Normark, 2003). Haploid embryos generally develop into males and diploid embryos develop into females. Females can control the laying of unfertilized and fertilized eggs, which then develop into males and females, respectively. Thus sexual haplodiploids are able to produce male offspring parthenogenetically and female offspring sexually (i.e., reproduce by arrhenotoky). Some *Wolbachia* strains are known to interfere with this system during the stage of chromosome segregation and enable females to produce parthenogenic female offspring (i.e., reproduce by thelytoky). In *Wolbachia* infected eggs, two haploid nuclei fuse at the end of the first mitotic division or during interphase before the second division (Gottlieb et al., 2002). Embryos thus develop into homozygous diploid females (Stouthamer and Kazmer, 1994). Thelytokous parthenogenesis induced by *Wolbachia* has been discovered in a variety of parasitoid species (Stouthamer, 1997). Parthenogenesis in the collembolan *Folsomia* has also been assumed to be induced by a *Wolbachia* strain (Vandekerckhove et al., 1999).

Feminization

Wolbachia infections in some terrestrial crustaceans are known to cause feminization (Rigaud, 1997; Bouchon et al., 1998). A similar phenotype has also been detected in a butterfly species (Kageyama et al., 1998; Kageyama et al., 2002; Kageyama et al., 2003). Both groups, crustaceans and butterflies, have unique ZZ or WZ sex chromosome sets with males being the homogamous and females the heterogamous gender (Rigaud, 1997; Kageyama et al., 2002). Feminizing *Wolbachia* strains induce genetic males to develop into functional phenotypic females, thereby providing an opportunity for the symbiont to be maternally transmitted to the next generation. In the isopod *Armadillidium vulgare*, *Wolbachia* prevents the formation of the androgenic gland and also changes the reaction of the host to androgenic hormone activity (Rigaud, 1997).

Male Killing

Wolbachia strains are known that exclusively kill male embryos in some host species. These "male-killing *Wolbachia*" have been found in Coleoptera (Majerus et al., 2000), Lepidoptera (Jiggins et al., 1998) and Diptera (Hurst et al., 2000). In infected populations, male-killing bacteria cause a female biased sex ratio and are thereby theorized to allow a more beneficial resource allocation that increases the reproductive fitness of female hosts and the bacteria they transmit (Hurst et al., 1997). A stable infection equilibrium balanced by resistance factors of the hosts is necessary to prevent the eradication of the infected populations (Randerson et al., 2000).

The type and level of expression of the various *Wolbachia*-induced phenotypes are determined by a mixture of strain and host genotypes. The most intriguing observations so far are switches from one phenotype to another. A switch from CI to a male-killing phenotype was documented after the transfer of *Wolbachia* between two moth species (Sasaki et al., 2002). Another switch in phenotype originally reported as a change from feminizing in one butterfly host species to male-killing in another butterfly species (Fujii et al., 2001) has since been resolved as overlapping feminizing and male-killing phenotypes in the original host (Kageyama and Traut, 2004). It has also been shown that the strength of CI in *Drosophila melanogaster* is dependent on male age (Reynolds and Hoffmann, 2002) and host genotype (McGraw et al., 2001; Reynolds et al., 2003). In many transfer experiments the attenuation or exacerbation of phenotypic effects suggests a strong involvement of host factors (McGraw et al., 2002; Riegler et al., 2004).

The strategy of being a reproductive parasite is not restricted to *Wolbachia*. Other microorganisms are also known to induce biased reproductive phenotypes in arthropods and crustaceans. Feminizing microsporidia are known in amphipod crustaceans (Bulnheim and Vavra, 1968), and male killers are known from the γ-proteobacteria as well as *Spiroplasma* and Bacteroidetes in beetles (Hurst et al., 1997), flies (Williamson et al., 1999), and wasps (Werren et al., 1986). Recently, *Cardinium hertigii*, a member of the Bacteroidetes group, has been shown to cause feminization (Weeks et al., 2001), parthenogenesis (Zchori-Fein et al., 2001; Zchori-Fein et al., 2004) and CI (Hunter et al., 2003) in its arthropod hosts.

The variety of *Wolbachia*-induced reproductive manipulations suggests that these infections impact the population genetics of their hosts. Most apparent is an indirect impact on other cytoplasmic factors, such as the mitochondrial genome. *Wolbachia* infections that cause unidirectional CI and spread into uninfected populations over generations also favor the spread of the infected mitochondrial haplotype and can cause a replacement of original mitochondrial haplotypes (Turelli and Hoffmann, 1991; Ballard et al., 1996). A linkage of *Wolbachia* strains with mitochondrial haplotypes has been shown in the case of CI-inducing strains (Turelli et al.,

1992), as well as in *Wolbachia* associations with other phenotypes such as feminization (Grandjean et al., 1993) and male killing (Jiggins, 2003).

However, CI does not lead to a reduction of nuclear gene flow between populations as long as it is unidirectional (Caspari and Watson, 1959). A few exceptions are seen in island situations (Telschow et al., 2002a). Alternatively, bidirectional incompatibility if complete can inhibit genetic exchange between host populations. In this context the reproductive isolation promoted by *Wolbachia* infections has been seen as a factor promoting speciation in infected hosts (Werren, 1998; Bordenstein et al., 2001; Telschow et al., 2002b).

The strict vertical inheritance of *Wolbachia* has been questioned after the finding of dissimilarities between phylogenetic trees of *Wolbachia* strains and their hosts (O'Neill et al., 1992; Werren et al., 1995b; West et al., 1998; Vavre et al., 1999a). Although efficient horizontal transfer between infected and uninfected individuals of the same parasitoid species has been observed (Huigens et al., 2000) and horizontal transfer of the *Wolbachia* infection of a fly species to a parasitoid wasp described (Heath et al., 1999), it is likely that the limiting factor for efficient horizontal transfer between species is the establishment of the infections in the germline and in the populations of the new host species (Heath et al., 1999; Riegler et al., 2004).

Disease

Despite the fact that *Wolbachia* can reach quite high densities in infected hosts, they do not appear to induce an innate immune response from their hosts (Bourtzis et al., 2000). Moreover most infections do not appear to reduce physiological host fitness appreciably (Hoffmann et al., 1990; Hoffmann et al., 1994; Hoffmann et al., 1998; Giordano et al., 1995; Turelli and Hoffmann, 1995; Bourtzis et al., 1996; Clancy and Hoffmann, 1997; Poinsot and Merot, 1997). Few *Wolbachia* infections cause disease. The best documented is the *popcorn* infection *w*MelPop$_{D.mel}$, which presumably by overreplicating drastically reduces the lifespan of the host *Drosophila melanogaster* (Min and Benzer, 1997). This strain shows a similar virulence phenotype when transferred into the related host species *D. simulans* (McGraw et al., 2002), suggesting that the virulence determinants are encoded by the genome of this particular *Wolbachia* strain. Another virulent *Wolbachia* strain has been described from isopods. Massive symbiont proliferation, followed by necrosis of the nervous tissues, was observed after the artificial transfer of a *Wolbachia* strain naturally infecting *Armadillidium* to *Porcellio dilatatus* (Bouchon et al., 1998).

In recent years *Wolbachia* has been implicated in the inflammatory pathogenesis of human filariasis. It is hypothesized that bacterial toxins released from the *Wolbachia* that infect the filarial nematode induce an inflammatory response in the mammalian host (Taylor and Hoerauf, 1999a; Taylor, 2003). This response has been thought to be largely mediated by lipopolysaccharide (LPS) released from *Wolbachia*. Curiously the genome sequence of the *Drosophila* infecting strain *w*Mel$_{D.mel}$ shows that this *Wolbachia* strain, like many intracellular symbionts, does not contain an intact pathway for LPS biosynthesis (Wu et al., 2004), suggesting either that nematode *Wolbachia* have gained this capability or that some other mechanism may be responsible for the observed pathogenesis.

Applications

The potential applied use of *Wolbachia*-mediated incompatibilities to control insect pests and associated diseases was suggested even before it was understood that *Wolbachia* was the etiological agent responsible for cytoplasmic incompatibility (Laven, 1967; Yen and Barr, 1971). Since then, *Wolbachia* has been proposed as a method to directly suppress pest populations, to modify the ability of insects to transmit disease agents, to enhance the mass production of beneficial insects used for biological control, and in recent years, as a new target for the control of filariasis.

Host Population Suppression

The application of CI as a means to suppress pest insect populations has been considered since its discovery (Laven, 1967; Boller et al., 1976; Brower, 1980). Analogous to the Sterile Insect Technique (SIT; Krafsur, 1998), an inundating release of incompatible males in natural populations should decrease or inhibit successful fertilization of wild females and thereby suppress wild populations. Field experiments with the mosquito *Culex pipiens* have shown promising results (Laven, 1967). However, this technique has a few drawbacks such as immigration of fertilized females (Curtis et al., 1982) and the risk of releasing compatible females along with males. An isolated population, combined with a reliable sexing technique, which guarantees the release of only males is essential for the success of population suppression. A combination of CI and SIT, whereby insects could be irradiated at lower doses and then sterilized in a conventional SIT program, has been suggested. *Wolbachia*

would induce the crossing sterility and the irradiation would prevent the release of fertile infected females (Arunachalam and Curtis, 1985; Shahid and Curtis, 1987). The use of cytoplasmic incompatibility, or the Incompatible Insect Technique (IIT; Blümel and Russ, 1989), has been suggested for a range of pests of agricultural and medical importance (Laven, 1967; Boller et al., 1976; Brower, 1980).

Modulating Insect-Transmitted Disease

In addition to direct population suppression, *Wolbachia*-based strategies could be used to interfere with the ability of insect populations to transmit pathogens, either through modifying their population age structure or by spreading genes into populations that block transmission of pathogens. In the first instance it has been proposed that overreplicating virulent *Wolbachia* strains (Min and Benzer, 1997; McGraw et al., 2002) could be used to skew population age-structure towards younger individuals and in so doing reduce the ability of the insect population to transmit disease agents such as dengue virus (Sinkins and O'Neill, 2000; Brownstein et al., 2003; Rasgon et al., 2003).

Alternatively *Wolbachia* could be used to drive refractoriness genes located either in themselves or in other maternally inherited factors such as mitochondria, viruses or inherited nutritive symbionts through host populations by a hitch-hiking effect (Beard et al., 1993; Curtis and Sinkins, 1998; Turelli and Hoffmann, 1999; Sinkins and O'Neill, 2000). The drive of nuclear genes into host populations using *Wolbachia* is less feasible, as there is no linkage between infections and the host nuclear genome. However, transformation of organisms with constructs that contain the genes involved in the induction of *Wolbachia* phenotypes together with the desired genes has been suggested (Curtis and Sinkins, 1998; Turelli and Hoffmann, 1999; Sinkins and O'Neill, 2000).

Wolbachia as a Target for Filariasis Control

Recent work suggests that *Wolbachia* endosymbionts of filarial nematodes are a major source of the inflammatory response observed in humans suffering from lymphatic filariasis (Taylor et al., 2000) and onchocerciasis (Saint Andre et al., 2002). Antibiotic therapy trials have led to long-term reductions of *Wolbachia* and interruption of nematode embryogenesis (Hoerauf et al., 2002). Similar antibiotic therapy strategies are currently being tried for other filarial diseases and should open new ways of controlling human filarial infection and disease (Taylor and Hoerauf, 2001).

Wolbachia as a Fitness Enhancer in the Rearing of Beneficials

Associations have been reported where *Wolbachia* clearly have favorable effects on their hosts. *Wolbachia* is known to increase fitness parameters in hymenopteran parasitoids (Girin and Boultreau, 1995; Stolk and Stouthamer, 1995; Vavre et al., 1999b). Similarly, male-killing bacteria are seen in the context of a better resource allocation in lady bird beetles (Hurst et al., 1997). Both groups of insects are commercially used in biological control. Hence, *Wolbachia*'s potential of favoring the reproduction of their hosts could become an important trait for the rearing of beneficials. This aspect has been discussed in the comparison of sexually and parthenogenetically reproducing *Trichogramma* lines (Stouthamer, 1993; Silva et al., 2000; Tagami et al., 2001; Tagami et al., 2002). *Wolbachia* infected thelytokous lines seem to perform better than uninfected arrhenotokous counterparts (Silva et al., 2000).

Acknowledgments. We thank Jeremy Brownlie, Sylvain Charlat, Molly Hunter, Inaki Iturbe-Ormaetxe, Wolfgang Miller and Elizabeth McGraw for valuable comments and stimulating discussions on the subject, as well as reading through earlier versions of the manuscript. We also acknowledge Oxford University Press, the Royal Society, the Society of General Microbiology and the authors J. S. Dumler and N. Loo for granting us permission to reproduce figures 1–3 of published articles.

CHAPTER 3.1.22

Aerobic Phototrophic Proteobacteria

VLADIMIR V. YURKOV

Introduction

For decades anoxygenic photosynthesis in purple bacteria has been widely assumed to be an anaerobic metabolic process, active in light and anaerobic conditions (Imhoff, 1988; Imhoff and Truper, 1989; Prince, 1990). However, many obligately aerobic species of a new physiological group of bacteria that have a purple bacterial type of photosynthetic apparatus have been isolated relatively recently. Nowadays, these bacteria are found world-wide in different geographical areas and ecological niches. They have been described as inhabitants of freshwater and marine microbial mats or as free-floating populations in sea water, meromictic lakes, warm and hot water springs, acidophilic drainage waters, and deep ocean hydrothermal environments of so-called black smokers (Shimada, 1995; Yurkov and Beatty, 1998a). Most strains of the aerobic phototrophs isolated so far inhabit a wide variety of eutrophic aquatic environments and seem to comprise a significant part of the aerobic heterotrophic bacterial population. Recently two new species, *Craurococcus roseus* and *Paracraurococcus ruber*, have been isolated from soil (Saitoh et al., 1998). Although this increasingly large group of bacteria is very heterogeneous phylogenetically, morphologically and physiologically, these bacteria share a common novel characteristic, which is the inability to use bacteriochlorophyll for anaerobic photosynthetic growth and the presence of photochemical reactions in cells only under aerobic conditions (Yurkov and Beatty, 1998a).

Until knowledge sufficient to create a taxonomic name has accumulated, convention among scientists in this field is to call this group "the aerobic phototrophic bacteria" (Shimada, 1995; Yurkov and Beatty, 1998a). This chapter refers to these bacteria as "the aerobic phototrophic bacteria."

Taxonomy, Phylogeny and Origin

At present, aerobic phototrophic bacteria are taxonomically classified into seven freshwater (*Sandaracinobacter*, *Erythromonas*, *Erythromicrobium*, *Roseococcus*, *Porphyrobacter*, *Acidiphilium* and *Roseateles*), six marine (*Erythrobacter*, *Roseobacter*, *Citromicrobium*, *Rubrimonas*, *Roseovarius* and *Roseivivax*) and two soil (*Craurococcus* and *Paracraurococcus*) genera (Table 1). The discovery of obligately aerobic heterotrophs that synthesize bacteriochlorophyll *a* aroused immediate interest and stimulated research on their evolution and origin. The most intriguing fact discovered was the inability of the "typical" photosynthetic apparatus of these bacteria to support anaerobic photosynthetic growth. Two major questions arose simultaneously: 1) What is the evolutionary origin of the aerobic phototrophic bacteria in general? and 2) How did the photosynthetic apparatus evolve in these predominantly aerobic heterotrophic microorganisms? Recently created phylogenetic trees show that aerobic phototrophs do not present a homogeneous cluster but are distributed among photosynthetic and nonphotosynthetic species, indicating that some species are not closely related. This situation (similar to that described by the phylogeny of anaerobic phototrophic bacteria) is the basis for the proposal that non-photosynthetic proteobacteria had a photosynthetic ancestor and the photosynthesis genes were lost in some phylogenetic lineages during evolution (Woese, 1987). Available data cannot explain whether the poorly developed and low efficiency photosynthetic apparatus of the aerobic phototrophs is a relict inherited from a "true" photosynthetic ancestor and kept by these bacteria during evolution towards the aerobic respiratory mode of energy generation, or whether the photosynthetic apparatus is a relatively recent evolutionary acquisition, which reoccured in some aerobic heterotrophic species. Although the evolutionary significance of the inability to grow anaerobically photosynthetically despite the presence of a photosynthetic apparatus is unclear, further investigations of aerobic phototrophs will ultimately solve this puzzle and contribute to our understanding of the evolution of photosynthesis.

Today, two independent theories weigh the evolutionary origin of aerobic phototrophic bac-

Table 1. Major properties of the aerobic phototrophic species.

Species	Phylogeny (subclass)	Color	Carotenoid in vivo peaks (nm)	Bchl in vivo peaks (nm)	Cell shape and size (μm)	DNA G+C content (mol%)	Place of isolation
Freshwater:							
Sandaracinobacter sibiricus	α-4	yellow-orange	424, 450, 474	800, 867	Thin, long rods (0.3–0.5 × 1.5–2.5)	68.5	Russia, hot temperature spring bacterial mat
Erythromonas ursincola	α-4	Orange-brown	430, 458, 485	800, 867	Ovoid (0.8–1.0 × 1.3–2.6)	65.4	Russia, Southern Kurily, hot temperature spring caynobacterial mat
Erythromicrobium							
ramosum	α-4	red-orange	466, 478	798, 832, 868	Rods, branched (0.7–1.0 × 1.6–2.5)	64.2	Russia, warm water spring algo-bacterial mat
ezovicum	α-4	red-orange	466,478	798, 836, 868	Long bacilli (0.6–0.8 × 2.7–2.8)	62.5	
hydrolyticum	α-4	red-orange	466, 478	798, 838, 868	Rods, branched (0.7–1.1 × 1.8–2.5)	65.2	
Roseococcus thiosulfatophilus	α-1	pink-red	482, 510, 538	800, 858	Coccoid (0.9–1.3 × 1.3–1.6)	70.4	Russia, hot temperature spring, cyanobacterial mat
Porphyrobacter							
neustonensis	α-4	orange-red	464, 491	799, 869	Pleomorphic (0.4–0.8 × 1.1–2.0)	65–66	Australia, subtropical pond, water surface
tepidarius	α-4	orange	460, 494	800, 870	Ovoid (0.5–0.7 × 0.8–1.4)	65	Japan, brackish hot spring
Acidiphilium							
cryptum	α-1	Pink	n.a.	n.a.	Rods (0.3–1.2 × 0.6–4.2)	67.3	Acid mineral environment
rubrum	α-1	Pink-red	465, 492	792, 864	Rods (0.6 × 2.0)	63.2	Acid mine drainage
multivorum	α-1	Pale pink	525	n.a.	Rods (0.5–0.9 × 1.5–3.8)	66.2–66.3	
Roseateles depolimerans	β	pink	482, 515, 550	800, 870	Rods (0.5 × 2.0)	66.2–66.3	Japan, river water

(Continued)

Table 1. *Continued*

Species	Phylogeny (subclass)	Color	Carotenoid in vivo peaks (nm)	Bchl in vivo peaks (nm)	Cell shape and size (μm)	DNA G+C content (mol%)	Place of isolation
Seawater:							
Erythrobacter							
longus	α-4	Orange	470	800, 869	Rods (0.4–0.5 × 1.0–5.0)	60–64	Japan, high-tidal seaweeds
litoralis	α-4	Red-orange	437, 461, 488	800, 868	Rods (0.2–0.3 × 1.0–1.3)	67	The Netherlands, marine cyanobacterial mats
Roseobacter							
litoralis	α-3	Pink	510	806, 868	Ovoid rod (0.6–0.9 × 1.0–2.0)	59.6 ± 0.5	Japan, high tidal seaweeds
denitrificans	α-3	pink	510	806, 868	Ovoid rod (0.6–0.9 × 1.0–2.0)	56.3–58.1	
Citromicrobium bathyomarinum	α-4	Citron yellow	433, 457, 487	800, 867	Extremely pleomorphic	67.5	Juan de Fuca Ridge, Northeastern Pacific, deep ocean hydrothermal vent environment
Rubrimonas cliftonensis	α-3	pink	n.a.	806, 871	Rods (1.0–1.5 × 1.2–2.0)	74.0–74.8	Australia, West Coast, saline lake water
Roseovarius tolerans	α-3	Pink-red	Around 510	800, 878	Rods (0.7–1.0 × 1.1–2.2)	62.2–63.8	East Antarctica, heliothermal meromictic Ekho Lake
Roseivivax							
halodurans	α-3	Pink	n.a.	803, 873	Rods (0.5–1.0 × 1.0–5.0)	64.4	Australia, West Coast, charophytes of the saline lake
halotolerans	α-3	pink	n.a.	805, 871	Rods (0.5–1.0 × 1.0–5.0)	59.7	Australia, West Coast, epiphytes on the stromatolites
Soil:							
Craurococcus roseus	α-1	pink	n.a.	800, 872	Coccus (0.8 × 2.0)	70.5	Japan, soil
Paracraurococcus ruber	α-1	red	n.a.	802, 856	Coccus (0.8 × 1.5)	70.3–71.0	Japan, soil

Abbreviations: n.a., data not available; and Bchl, bacteriochlorophyll.

Adapted from Yurkov et al., 1994b; 1997; Yurkov and Gorlenko, 1992b; Fuerst et al., 1993; Hanada et al., 1997; Wakao et al., 1993; Wakao et al., 1994; Suyama et al., 1999; Shiba and Simidu, 1982; Shiba, 1991; Yurkov et al., 1999; Suzuki et al., 1999b; Labrenz et al., 1999; Suzuki et al., 1999a; and Saitoh et al., 1998.

teria. One idea is that branching of aerobic phototrophic bacteria from different species of anaerobic phototrophic bacterial ancestors can explain the observed 16S rRNA phylogenetic heterogeneity as well as differences in the photosynthetic apparatus. Thus, aerobic phototrophic bacteria could represent an intermediate phase of evolution from anaerobic purple bacteria to non-photosynthetic aerobes (Woese et al., 1984).

A second possibility is that lateral transfer of photosynthesis genes (Blankenship, 1992; Nagashima et al., 1993; Nagashima et al., 1997b) might have resulted in the acquisition of a photosynthesis gene cluster by nonphotosynthetic aerobes. However, the relatively recent acquisition of multigene-dependent photosynthetic complexes by lateral gene transfer to all aerobic phototrophic bacteria seems to be less likely.

The majority of aerobic phototrophic species is phylogenetically associated with members of the α-subclass of the class *Proteobacteria* (Table 1). *Roseococcus thiosulfatophilus*, *Craurococcus roseus* and *Paracraurococcus ruber* are members of subclass α-1 and are moderately related to *Rhodopila globiformis*, *Thiobacillus acidophilus* and members of the genus *Acidiphilium*. *Erythromicrobium*, *Erythrobacter*, *Sandaracinobacter*, *Erythromonas*, *Citromicrobium* and *Porphyrobacter* are very closely related genera and are clustered in the α-4 subclass, more distant from other aerobic phototrophs. The 16S rRNA sequence data placed *Roseobacter*, *Rubrimonas*, *Roseovarius* and *Roseivivax* in a branch separate from α-4 and α-1 representatives and in a relatively close phylogenetic relationship with purple nonsulfur *Rhodobacter sphaeroides* and *R. capsulatus* within α-3 subclass (Fuerst et al., 1993; Kawasaki et al., 1993; Stackebrandt et al., 1996; Yurkov et al., 1994c; Yurkov et al., 1997; Yurkov et al., 1999; Suzuki et al., 1999b; Labrenz et al., 1999; Suzuki et al., 1999a). A phylogenetic study performed on a psychrophylic (gas-vacuolate) bacterium isolated from polar sea ice, *Octadecabacter*, identified this organism as a close non-phototrophic relative of *Roseobacter* species (Gosink et al., 1997). Recently, the nonphotosynthetic *Sphingomonas* group was included in the α-4 subclass (Yabuuchi et al., 1990), such that the *Erythromicrobium-Erythrobacter-Porphyrobacter* cluster is most closely related to members of the genus *Sphingomonas* (Yurkov et al., 1994c).

Only one species, *Roseateles depolymerans*, has been recently described to belong to the β-subclass of the *Proteobacteria* (Suyama et al., 1999). Because this is a very unique example, the ability of this species to grow anaerobically photosynthetically under different nonstandard growth conditions should be carefully investigated.

Habitat

When the first marine obligately aerobic phototrophic strain Och101 was isolated from different sites of Tokyo Bay (seaweed, seawater, sand and bottom sediments) and later described as the first known species, *Erythrobacter longus* (Shiba and Simidu, 1982), in this group, it was thought that something very rare, unique and extraordinary had been discovered. However, an extensive search for these bacteria during recent years has shown that the obligately aerobic phototrophic bacteria are widely distributed around the world and represent a significant portion of the heterotrophic microbial population in various environments. Ecological niches of the aerobic phototrophs are very diverse; nevertheless, the availability of oxygen seems to be an obligatory requirement. The majority of species has been isolated from aquatic environments with significant amounts of soluble organic matter (Table 1). They are often found accompanying layers of cyanobacteria as well as purple nonsulfur and purple sulfur bacteria in cyanobacterial mats. The mats from which the isolates came were largely composed of the cyanobacteria *Oscillatoria*, *Synechococcus* and *Phormidium*, diatoms and the purple phototrophic bacteria *Thiocapsa roseopersicina*, *Rhodopseudomonas palustris*, *Rhodomicrobium vannielii* and *Rhodopseudomonas viridis* (Yurkov and Beatty, 1998a). Samples of these mats contained up to 106 cells of aerobic bacteria containing bacteriochlorophyll *a* per ml. Some species were isolated from cyanobacterial mats developed in springs with considerably hot temperatures. *Erythromonas ursincola* was isolated from an environment with a temperature of about 40°C and *Roseococcus thiosulfatophilus* from a site with a temperature of 54°C (Yurkov and Gorlenko, 1992a; Yurkov and Gorlenko, 1993a). However, in pure laboratory cultures all of these strains demonstrated typical mesophilic properties and grew optimally at 28–30°C (Yurkov and Gorlenko, 1992a; Yurkov and Gorlenko, 1993a; Yurkov et al., 1992a; Yurkov et al., 1992b). The reasons why and how these obligately aerobic species survive in thermal environments are unclear.

Two moderately thermophilic or thermotolerant representatives, *Porphyrobacter tepidarius* and *Citromicrobium bathyomarinum*, were discovered recently (Hanada et al., 1997; Yurkov et al., 1999). *Porphyrobacter tepidarius* was isolated from bacterial mats in the brackish Usami hot spring (Japan) where the temperature at the sampling site was 42.7°C, the pH was 5.8, and the bacterial mat consisted mainly of a dark green layer of thermophilic filamentous cyanobacteria. This new species grew at temperatures up to 50°C, and optimal growth occurred at 40 to 48°C

(Hanada et al., 1997; Table 2). Aerobic anoxygenic phototrophic strains containing bacteriochlorophyll *a* were discovered in hydrothermal "black smoker" plume waters of the Juan de Fuca Ridge in the Pacific Ocean (Yurkov and Beatty, 1998b). Water samples taken from about 2000 m beneath the ocean surface were found to contain aerobic bacteria producing bacteriochlorophyll *a* in numbers of 20–40 cells/ml, about 30% of the pigmented strains that formed colonies on the rich medium used. The representative strain JF-1 (*C. bathyomarinum*) revealed a broad tolerance to culture conditions such as salinity, temperature and pH. Thus, growth was obtained in a freshwater medium and a medium supplemented with 10% NaCl, at temperatures ranging from 5 to 42°C, and at pH values of 5.5 to 10.0 (Table 2). Therefore, *C. bathyomarinum* is a salt, pH and thermotolerant species (Yurkov et al., 1999). The fact that such a bacterium was found at this location suggests that the ecology and microbial population of the black smoker environment is even more diverse than has been imagined.

The greatest variety of species and the largest numbers of strains have been found in sea, lake and river waters (Table 1). In Tokyo Bay, the proportions of these bacteria among the species that formed colonies (on the medium employed) ranged from 0.9 to 1.1% in the seaweed samples and from 1.2 to 6.3% in the beach sand samples (Shiba et al., 1979). The presence of aerobic heterotrophic bacteriochlorophyll-α synthesizing strains in high proportions (10 to 30% of the total heterotrophic bacterial strains isolated) was described for marine environments on the west and east coasts of Australia (Shiba et al., 1991b) and at the Pacific Ocean inlet English Bay in Vancouver, Canada (V. V. Yurkov et al., unpublished observation).

Several strains of the pelagic bacterium, *Porphyrobacter neustonensis*, were purified from the surface of a freshwater subtropical pond in Australia (Fuerst et al., 1993), and acidophilic heterotrophic bacteria that synthesize bacteriochlorophyll *a* were isolated from an acidic mine drainage system (Wakao et al., 1993). Aerobic phototrophic bacteria were detected in high numbers relative to the numbers of other heterotrophic strains in the North Adriatic Sea, where they comprised 5 to 55% of the total cultured cells (P. Lebaron, personal communication).

Microbial populations in saline lakes and stratified meromictic saline lakes showed a high presence of the aerobic phototrophic bacteria. *Rubrimonas cliftonensis*, *Roseivivax halodurans* and *Roseivivax halotolerans* have been isolated from the charophytes and the epiphytes on the stromatolites of a saline lake located on the west coast of Australia (Suzuki et al., 1999a; Suzuki et al., 1999b). Eight closely related strains of *Roseovarius tolerans* were recovered from various depths of the hypersaline, heliothermal and meromictic Ekho Lake (East Antarctica) which originated from fjords about 5,000–6,000 years ago (Labrenz et al., 1999). Ekho Lake contains many different environments throughout its depths. A total of 135 prokaryotic and 52 eukaryotic morphotypes were discovered. This high morphological diversity prompted the isolation of some 250 bacterial cultures from different depths of Ekho Lake. Prokaryotic photosynthetic primary producers such as cyanobacteria were almost completely absent from the lake and the aerobic phototrophic *Roseovarius* is at present the only photosynthetic bacterial species described from this lake (Labrenz et al., 1999).

Another meromictic lake (Mahoney Lake), which has stratified salinity without outflow, near Penticton in the dry region of South Central British Columbia, was found to be highly enriched in aerobic phototrophic strains. Earlier microbiological investigations of Mahoney Lake were done on the anaerobic anoxygenic phototrophs and revealed an extremely dense population of the purple sulfur bacterium *Amoebobacter purpureus* (Overman et al., 1991). Recent study of the lake's aerobic phototrophic bacterial population has found that this fraction of the community is very rich, diverse and environmentally specific. A large number (more than 30) of taxonomically new strains of the obligately aerobic phototrophic bacteria has been isolated (N. Yurkova et al., unpublished observation).

Some aerobic phototrophic species also occur in highly acidic environments. All species of the *Acidiphilium* genus (Table 1) were reported from acid mine drainage, coal refuse and coal mine drainage. Acidophilic aerobic phototrophs which grow at pH 2.0–6.0 are often found accompanied by *Thiobacillus ferrooxidans* in such environments. *Acidiphilium* is a genuine acidophile that requires high acidity to grow (pH 3.0) (Wakao et al., 1994; Harrison, 1981; Wichlacz and Unz, 1986).

In general, not much research has been done to identify aerobic phototrophic bacteria from soil. A recent report on the isolation from soil of two new genera, *Craurococcus* and *Paracraurococcus*, which are aerobic and bacteriochlorophyll *a*-containing, has established the soil environment as a new econiche for these bacteria (Saitoh et al., 1998).

Isolation and Enrichment

Aerobic phototrophic bacteria are predominantly heterotrophs that require oxygen and

[a]Reduces NO_2 to N_2O.

some organic carbon sources. Therefore, no selective medium has been developed to isolate aerobic phototrophic bacteria, and many nonphototrophic microorganisms grow well on agar of rich organic media. A wide variety of media rich in organic components such as yeast extract, peptone, casamino acids, salts of tricarboxylic acids or sugars has been used to isolate pure cultures of different aerobic phototrophic species. Direct inoculation (with dilution) of water samples (for isolating free-floating strains) or homogenized mat/sand samples (for isolating strains found in cyanobacterial communities or on solid surfaces) on to agar plates of rich organic media can serve this purpose (Fuerst et al., 1993; Hanada et al., 1997; Shiba et al., 1979; Shiba et al., 1991b; Shiba and Simidu, 1982; Wakao et al., 1994; Yurkov and Beatty, 1998b; Yurkov and Gorlenko, 1990b; Yurkov et al., 1994b). As a rule, inoculated plates have been incubated in the dark at temperature and pH values similar to those found in the environment from which samples were collected. Pure isolates of pigmented colonies are easily obtainable from streaked agar plates. When a pure culture is obtained, a single colony is transferred into liquid medium and cultivated aerobically in the dark.

Solid agar media most commonly used to isolate the obligately aerobic phototrophic bacteria from natural sites are:

1. Medium PPES-II described for the isolation of *Erythrobacter*, *Roseobacter* and some other marine species (Taga, 1968) consists of: polypeptone, 2.0 g; soytone, 1.0 g; proteose peptone N3, 1.0 g; yeast extract, 1.0 g; ferric citrate, 0.1g; artificial seawater, 700 ml; distilled water, 300 ml; and agar, 2%.
2. PA medium used to isolate many freshwater strains from the hot temperature spring cyanobacterial mats (Yurkov and Gorlenko, 1990b; Yurkov, 1990a) consists of: yeast extract, 0.1g; sodium acetate, 0.5g; trace element solution (Drews, 1983), 1 ml; potato broth, 500 ml; distilled water, 500 ml; and agar, 2%.
3. RO medium used to isolate freshwater and marine species (Yurkov and Gorlenko, 1990b; Yurkov et al., 1994b; Yurkov and Beatty, 1998b) consists of (in grams per liter of distilled water): yeast extract, 1.0; Bacto peptone, 1.0; sodium acetate, 1.0; KCl, 0.3; $MgSO_4 \cdot 7H_2O$, 0.5; $CaCl_2 \cdot 2H_2O$, 0.05; NH_4Cl, 0.3; K_2HPO_4, 0.3; for marine species add NaCl, 20.0; and agar, 2%. This medium was supplemented with a mixture of vitamins ([per liter of medium] 20 μg of vitamin B_{12}, 200 μg of nicotinic acid, 80 μg of biotin, and 400 μg of thiamine) and 1 ml per liter of a trace element solution (Drews, 1983).
4. Recommended media to grow acidophilic species (Wakao et al., 1994): basal salts (BS) medium consists of: 0.2% $(NH_4)_2SO_4$; 0.01% KCl; 0.01% K_2HPO_4; 0.01% $MgSO_4 \cdot 7H_2O$; and 0.001% $Ca(NO_3)_2$. The culture media are adjusted to pH 3.0 with H_2SO_4. The BS medium (pH 3.0) is supplemented with 0.5% polypeptone, 0.5% glucose, 0.2% vitamin-free casamino acids plus 0.5% glucose, 0.2% trypticase soy or 0.2% trypticase soy plus 1.0% glucose. These media were designated as BS-P, BS-G, BS-CG, BS-T and BS-TG media, respectively (Wakao et al., 1994).
5. PY agar medium (Fuerst et al., 1993) described for the isolation of *Porphyrobacter neustonensis* (in grams per liter of distilled water) consists of: peptone, 10.0; yeast extract, 5.0; NaCl, 5.0; and agar, 1.5%.
6. PYGV medium was used to isolate *Roseovarius tolerans* from the Antarctic hypersaline lake, Ekho Lake (Labrenz et al., 1999). This medium consists (per liter) of: 0.25 g each of Bacto peptone, Bacto yeast extract and glucose, as well as 20 ml of Hutners's basal salt solution (Cohen-Bazire et al., 1957) and 10 ml of vitamin solution N6 (Staley, 1968). Medium is solidified with 1.8% agar.

Identification

Both morphological and physiological properties are very important for the identification of the aerobic phototrophic bacteria. Selection and differentiation cannot be primarily based on a choice of media or specific culture conditions owing to the heterotrophy and oxygen dependence of these bacteria. Many nonphototrophic heterotrophic microorganisms will outgrow the aerobic phototrophic species when rich organic media solidified with agar are used. However almost all species of the aerobic phototrophs growing in standard aerobic conditions are intensely pigmented by carotenoids. Therefore, the color of bacterial colonies has been used as an initial indication of aerobic phototrophic bacteria, but confirmation still required the demonstrated presence of absorption spectra characteristic of bacteriochlorophyll. Aerobic phototrophic strains are distinguished from other heterotrophic bacteria by the presence of bacteriochlorophyll *a*, as indicated by absorption peaks in the region of 800 to 880 nm in cell suspensions or by an absorption peak of about 770 nm in acetone-methanol extracts of cells (Fig. 1).

A common misconception that has occurred in several recent taxonomic descriptions should be mentioned. Although it is known that phototrophic capacity is still recognized as an important taxonomic marker in bacterial classification, some heterotrophic strains that lack

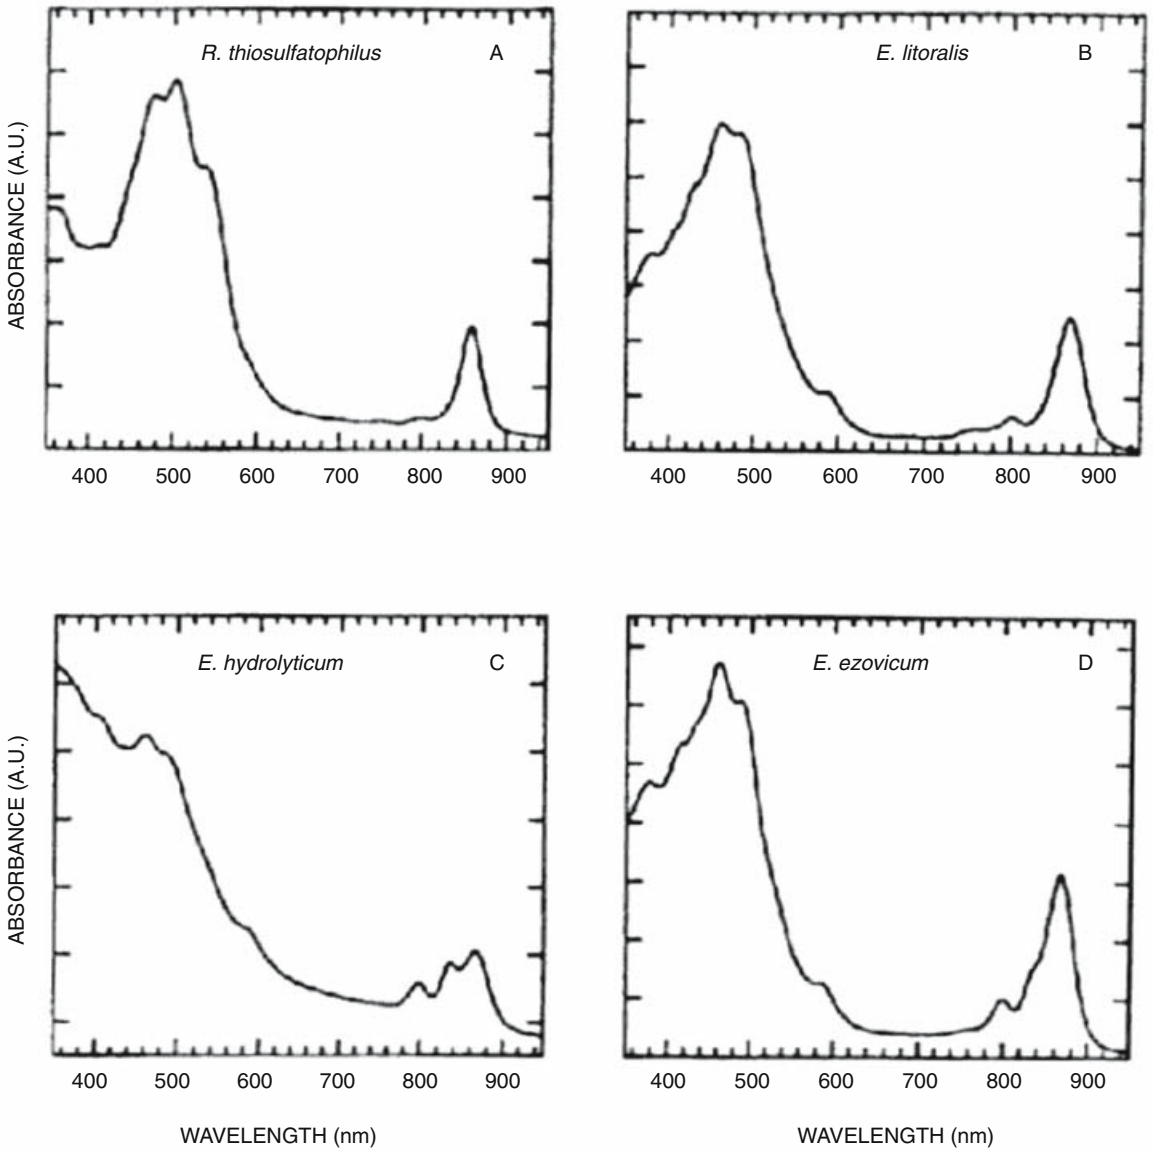

Fig. 1. Absorption spectra of crude membranes isolated from A) *R. thiosulfatophilus*, B) *E. litoralis*, C) *E. hydrolyticum* and D) *E. ezovicum*. Absorption peaks of the bacteriochlorophyll *a* are in the infrared region of 800–870 nm. Absorption peaks of the carotenoids are in the blue and green regions (420 to 550 nm). A.U., absorbance units.

photosynthetic apparatus have been identified as members of the aerobic phototrophic genus *Roseobacter*. Two *Roseobacter* species, *R. algicola* (Lafay et al., 1995) and *R. gallaeciensis* (Ruiz-Ponte et al., 1998), that do not produce bacteriochlorophyll *a* and photosynthetic complexes have been classified as members of the genus *Roseobacter*. *R. algicola* was recently reclassified as *Ruegeria algicola* (Uchino et al., 1998). Another example is the proposal to transfer the obligately aerobic phototrophic *Erythromonas ursincola* to the nonphototrophic genus *Sphingomonas* (Yabuuchi et al., 1999). In all cases the general requirement of bacterial taxonomy has not been followed: If a major phenotypic difference exists between two strains (in this particular case, the presence of photosynthetic apparatus and pigments), they should be in different genera. The only purpose of bacterial taxonomy is to identify and differentiate between microbial genera and species. This differentiation should be based on markers and techniques that are as simple and clear as possible and that can be easily followed by those who do not study taxonomy (microbial physiologists, biochemists or medical microbiologists). Photosynthetic pigments are readily detectable (even visually) in bacterial cells, and therefore photosynthesis is an excellent distinguishing marker.

The major feature that distinguishes the obligately aerobic phototrophic strains from the facultatively anaerobic purple nonsulfur phototrophic strains is the inability of the former to grow photosynthetically under anaerobic conditions. Because this inability to grow anaerobically in the light despite the presence of photosynthetic pigments is of taxonomic significance and importance, the photosynthetic growth should be investigated thoroughly. Different photosynthetic growth conditions such as medium composition, carbon (organic and inorganic) sources, presence and absence of reduced sulfur compounds and light intensities need to be tested.

All species of aerobic phototrophic bacteria synthesize large amounts of carotenoid pigments, which determine the color of the organism (Table 1) and give peaks (Fig. 1) in the blue and green regions (420 to 550 nm) of their absorption spectra (Fuerst et al., 1993; Shiba, 1991a; Shiba and Simidu, 1982; Yurkov and Gorlenko, 1990b; Yurkov and Gorlenko, 1992a; Yurkov and Gorlenko, 1993a; Yurkov et al., 1992c; Yurkov et al., 1994b; Yurkov et al., 1997; Yurkov and van Gemerden, 1993b). The carotenoid composition is species specific, often indicating a large number of different carotenoids of unusual chemical structure (Takaichi et al., 1988; Takaichi et al., 1990; Takaichi et al., 1991a; Takaichi et al., 1991b; Yurkov et al., 1993b).

About 20 different carotenoids have been found in the red-orange colored cells of *Erythromicrobium ramosum* (Yurkov and Beatty, 1998a); the ten predominant ones were purified and structurally characterized (Yurkov et al., 1993d; Table 3) as C_{40} carotenoids and classified into four types: 1) bicyclic carotenoids (β-carotene and hydroxyl derivatives such as zeaxanthin, adonixanthin, caloxanthin and nostoxanthin); 2) the monocyclic carotenoid bacteriorubixanthinal; 3) the acyclic spirilloxanthin; and 4) the polar carotenoid erythroxanthin sulfate. A carotenoid composition similar to that of *E. ramosum* was described in *E. longus* (Takaichi et al., 1991a; Takaichi et al., 1991b; Takaichi et al., 1988; Takaichi et al., 1990) and *E. litoralis* (Yurkov et al., 1994b), with the exception of adonixanthin and 2,3,2′,3′-tetra-hydroxy-β,β,carotene-4-one. Zeaxanthin is a major carotenoid in *Erythrobacter*, whereas in *Erythromicrobium*, zeaxanthin is a minor component and bacteriorubixanthinal, erythroxanthin sulfate and 2,3,2′,3′-tetra hydroxy-β,β, carotene-4-one are the major components (Yurkov et al., 1993d).

Bicyclic carotenoids such as β-carotene and its hydroxyl derivatives were found in *Erythrobacter* and *Erythromicrobium* species, and the color of *Erythromonas* and *Sandaracinobacter* indicates that these bacteria also contain carotene carotenoids, which are rarely present in purple phototrophic bacteria (small amounts of β-carotene were detected in *Rhodomicrobium vannieli*; Britton et al., 1975; Patel et al., 1983). The highly polar carotenoid sulfates have hitherto been found exclusively among the carotenoids of the aerobic phototrophic bacteria (Takaichi et al., 1991b; Yurkov et al., 1993d; Yurkov et al., 1994b) and were recently described as carotenoids having novel structures (Takaichi et al., 1991b).

The carotenoid composition of two other *Erythromicrobium* representatives, *E. ezovicum* and *E. hydrolyticum*, has not yet been analyzed in detail. Nevertheless, in vivo absorption spectra revealed carotenoid absorption peaks at 466 and 478 nm, as in *E. ramosum*, indicating a similar carotenoid composition in these species, which is also apparent in the color of liquid cultures (intensely red-orange) (Yurkov et al., 1997; Table 1).

The carotenoid composition of the pink-red colored *Roseococcus* species is not as rich as of *Erythrobacter* and *Erythromicrobium* species, but nevertheless it is unusual. *Roseococcus thiosulfatophilus* contains mainly two very polar red pigments, C_{30} carotene-dioate (4,4′-diapocarotene-4,4′-dioate) and the respective diglucosyl ester (di[β-D-glucopyranosyl]-4,4′-diapocarotene-4,4′-dioate). Together they contribute 95% of the total carotenoid content (Yurkov et al., 1993d). Such highly polar C_{30} carotenoid glyco-

Table 3. Carotenoids in *Erythromicrobium ramosum* (in order of polarity).

N	Carotenoid	Common name	Chemical formula
1	β,β-Carotene	*β-carotene*	$C_{40}H_{56}$

5	3,3′-Dihydroxy-β,β-carotene-4-one	*Adonixanthin*	$C_{40}H_{54}O_3$
6	2,3,3′-Trihydroxy-β,β-carotene	*Caloxanthin*	$C_{40}H_{56}O_3$
7	3,2′,3′-Trihydroxy-β,β-carotene-4-one (probable structure)	None	$C_{40}H_{54}O_4$
8	2,3,2′,3′-Tetrahydroxy-β,β-carotene	*Nostoxanthin*	$C_{40}H_{56}O_4$
9	2,3,2′,3′-Tetrahydroxy-β,β-carotene-4-one	None	$C_{40}H_{54}O_5$
10	3,2′,3′-Trihydroxy-β,β-carotene-4-one-3-sulfate	*Erythroxanthin-sulfate*	$C_{40}H_{54}O_7S$

sides have never before been observed in purple phototrophic bacteria, although the same carotenoid and its diglucosylated form had been postulated to exist in *Methylobacterium rhodinum* (formerly *Pseudomonas rhodos*; Kleinig et al., 1979).

The most abundant carotenoid detected in *Roseobacter* sp. is spheroidenone, which is the major carotenoid of anaerobic purple bacteria such as *Rhodobacter* species (Harashima and Nakada, 1983; Shiba, 1991a; Takaichi et al., 1991a).

The only carotenoid of *Acidiphilium rubrum* is spirilloxanthin, which is found in several purple phototrophic bacteria (Wakao et al., 1996).

Typically, cells of aerobic phototrophic bacteria contain small amounts of bacteriochlorophyll relative to the abundance of carotenoids (in contrast to anaerobic purple phototrophic bacteria). For example, the anaerobic phototrophic bacterium *Rhodobacter sphaeroides* may yield about 20 nmol of bacteriochlorophyll/mg dry weight of cells, whereas the bacteriochlorophyll content of obligately aerobic species was found to be: *Erythrobacter longus*, 2.0 nmol/mg dry weight of cells; *Sandaracinobacter sibiricus* and *Erythromicrobium hydrolyticum*, 1.0–4.0 nmol/mg of protein; *A. rubrum*, 0.7 nmol/mg dry weight of cells; *R. thiosulfatophilus*, 0.1–1.0 nmol/mg of protein. Therefore, the ratio of bacteriochlorophyll to carotenoid peaks in whole cells of aerobic phototrophic species is typically about 1 : 8 to 1 : 10 (Harashima et al., 1980; Shimada, 1995; Takemoto and Kao, 1977; Wakao et al., 1993; Yurkov, 1990a; Yurkov and Gorlenko, 1992a; Yurkov et al., 1992c; Yurkov et al., 1994b; Yurkov and van Gemerden, 1993c). With such a low number of photosynthetic units (reaction center + light harvesting system), the absence of an extensive intracytoplasmic system in obligately aerobic species is not surprising. An intracytoplasmic system was not detected in thin-section electron micrographs of *Erythrobacter*, *Erythromicrobium*, *Roseococcus*, *Porphyrobacter*, *Erythromonas* or *Citromicrobium* (Fuerst et al., 1993; Hanada et al., 1997; Yurkov and Beatty, 1998b; Yurkov and Gorlenko, 1992a; Yurkov and Gorlenko, 1993a; Yurkov et al., 1991b; Yurkov et al., 1994b; Yurkov et al., 1996; Yurkov et al., 1997; Yurkov et al., 1999). Occasionally, "chromatophore-like" vesicle structures have been observed in *Roseobacter denitrificans* (Harashima et al., 1982; Shimada, 1995). Thin-section electron micrographs of *S. sibiricus* (formerly *Erythrobacter sibiricum*) revealed rare vesicular or loop-like cytoplasmic invaginations (Yurkov et al., 1991b).

Natural Zn-containing bacteriochlorophyll *a* was discovered in the aerobic acidophilic bacterium *Acidiphilium rubrum* (Wakao et al., 1996). This Zn-containing bacteriochlorophyll (Bchl) *a* is esterified with phytol (Zn-Bchl a_p). Chemical analysis of *A. rubrum* cell extracts yielded a 13 : 2 : 1 molar ratio of Zn-Bchl : Mg-Bchl : bacteriopheophytin, and most of these pigments were determined to be photochemically active (Wakao et al., 1996). Bacteriochlorophyll *a* purified from *E. longus* and *R. denitrificans* was found to be Bchl a_p, which contains phytol as the esterifying alcohol, the most common bacteriochlorophyll *a* form found in purple phototrophic bacteria (Harashima et al., 1980; Harashima and Takamiya, 1989; Kondratieva et al., 1989; Kuntzler and Pfennig, 1973; Wakao et al., 1993). No bacteriochlorophyll *a* esterified to geranylgeraniol, as in the anaerobic phototrophic bacterium *Rhodospirillum rubrum* (Brockmann et al., 1973), has been detected in aerobic phototrophic species. However, the ester moiety of bacteriochlorophyll from most species of *Erythromicrobium*, *Erythrobacter*, *Roseococcus*, *Sandaracinobacter*, *Erythromonas* and other recently described genera has not yet been determined.

Important information can be further obtained from the size and consistency of the colonies on agar plates and microscopic examinations. Shape of the cells, cell width and length, motility and type of flagellation, mode of division, aggregates and capsule formation are important properties that can be obtained from both phase contrast light and electron microscopies. Cell ultrastructure should be observed in ultra thin sections under the electron microscope. The morphology and ultra structure of some representative species of the aerobic phototrophs are shown in Fig. 2 and 3.

DNA-DNA hybridization is used to distinguish between species that highly resemble each other (Yurkov et al., 1991a). Also G+C content of DNA has to be determined to describe a new species. Substrate utilization, vitamin requirement, antibiotic resistance and some other significant physiological properties are required for precise identification (Table 2). Recently a number of additional chemotaxonomic markers (such as quinones, soluble and membrane-bound cytochromes, fatty acids, polar lipids, light-harvesting and reaction center complexes) also have been employed. A summary of information available for species of the aerobic phototrophic bacteria currently described is presented in Tables 1, 2 and 4.

Modern achievements in phylogenetic research based on 16S rDNA sequence analysis used to complement modern approaches in bacterial taxonomy are considered valuable in the phylogenetic assessment of aerobic phototrophic species.

Preservation

It has been found that liquid (taken from late logarithmic growth phase) and agar surface cultures of most aerobic phototrophic species remain viable after storage at 4°C for at least two months (Yurkov and Beatty, 1998a). Long-term preservation is possible by storage in liquid nitrogen or freezing at –70°C. For this purpose, dense cell suspensions of liquid cultures (mid-logarithmic growth phase) are supplemented with glycerol (30%) as a cryoprotective agent. Lyophilization also can be used as a method of preservation.

Physiology

Photosynthetic Potential

Although the aerobic phototrophic bacteria and the anaerobic purple phototrophic bacteria have similar photosynthetic apparatus, electron transfer carriers (Garcia et al., 1994; Okamura et al., 1985; Okamura et al., 1986; Yurkov et al., 1994a; Yurkov et al., 1995; Table 4), reaction center and light-harvesting I polypeptides (Liebetanz et al., 1991), efficient photoinduced electron transfer is operative only under aerobic conditions in the aerobic phototrophic bacteria (Garcia et al., 1994; Okamura et al., 1985; Yurkov et al., 1995).

The photochemical activity of the aerobic bacterial photosynthetic apparatus has been analyzed independently in several laboratories using different species and techniques (Garcia et al., 1994; Hanada et al., 1997; Okamura et al., 1984; Okamura et al., 1985; Takamiya et al., 1988; Wakao et al., 1996; Yurkov et al., 1995). The results indicate that the photosynthetic apparatus of aerobic phototrophic bacteria, although it has some peculiarities, is functional in terms of a cyclic electron transfer system.

In species of the genera *Erythrobacter*, *Roseobacter*, *Roseococcus*, *Erythromicrobium*, *Erythromonas* and *Sandaracinobacter*, photoinduced cyclic electron transfer occurs only under relatively oxidized (aerobic) conditions (Garcia et al., 1994; Okamura et al., 1985; Yurkov et al., 1995). Under relatively reduced (anaerobic) conditions, no light-induced reaction center absorbance changes were observed. The lack of photochemistry under anaerobic conditions is consistent with the inability of these bacteria to grow by light-dependent photophosphorylation in the absence of oxygen (Okamura et al., 1986; Shiba, 1991a; Shiba and Harashima, 1986; Shiba

and Simidu, 1982; Yurkov and Gorlenko, 1990b; Yurkov and Gorlenko, 1992a; Yurkov and Gorlenko, 1993a; Yurkov et al., 1992c; Yurkov et al., 1994b; Yurkov et al., 1997). It was demonstrated that the photosynthetic electron transfer system of *R. denitrificans*, *E. litoralis*, *E. ramosum*, *E. ursincola*, *S. sibiricus* and *R. thiosulfatophilus* is inoperative in anaerobic cells, presumably because of the high mid-point potential (E_m) of the reaction center primary acceptor Q_A. The values of Q_A mid-point potential determined at pH 7.8 were +150, +80, +25 and +5 mV for *E. litoralis*, *E. ramosum*, *E. ursincola* and *S. sibiricus*, respectively. These are much higher values than determined for anaerobic phototrophic bacteria, such as *R. sphaeroides*, *R. rubrum*, *R. tenuis* and *R. viridis*, which yield negative Eh (ambient redox potential) values. The Em values of the primary electron acceptor measured above the pK (pH value above which the midpoint potential of an electron carrier is not affected by pH) for *E. litoralis*, *R. denitrificans*, *S. sibiricus* and *E. ursincola* are equal to –30, –44, –55 and –85 mV, respectively. These values are 65 to 120 mV more positive than those observed in anaerobic phototrophic bacteria (Yurkov and Beatty, 1998a). Therefore, it is likely that the Q_A of aerobic phototrophic bacteria is in the reduced state (i.e., dihydroquinol) under anaerobic conditions and acceptance of an electron from the special pair cannot occur unless an oxidant such as O_2 is provided to maintain Q_A in the quinone form, which is capable of acting as an electron acceptor.

Table 4. Comparative data[a] on the photosynthetic apparatus and electron carriers.

[a]Data presented for investigated species.

[b]Cultivated under dark-aerobic conditions.

Membranes of aerobic phototrophic bacteria are highly enriched in carotenoids. For example, the molar ratio of bacteriochlorophyll to carotenoid in membranes of *R. thiosulfatophilus* and *E. ramosum* is 1 : 4 and 1 : 7, respectively. However in purified photosynthetic pigment-protein complexes this ratio decreased to 1:1.4 in an enriched reaction center-light harvesting I (RC-LHI) core complex of *R. thiosulfatophilus*, to 1:(0.1–1) in the purified RC-LHI, and to 1:(0.3–1) in the purified LHII complex of *E. ramosum* (Yurkov et al., 1993d; Yurkov et al., 1994a). The RC-LHI core complex of *R. thiosulfatophilus* contained only the C_{30} carotenoid diglucosyl ester (di[β-D-glucopyranosyl]-4,4′-diapocarotene-4,4′-dioate).

Bacteriorubixanthinal is the major carotenoid in the pigment-protein complexes (LH and RC) of *E. ramosum*, along with small amounts of spirilloxanthin (RC-LHI) and zeaxanthin (LHII; Yurkov et al., 1993d).

The quantum yields of singlet energy transfer between carotenoids and bacteriochlorophyll (a light-harvesting function) calculated from comparison of absorption and fluorescence excitation spectra indicate that the majority of the carotenoids in the membrane of *E. ramosum* and *R. thiosulfatophilus* does not contribute to the light-harvesting function (Yurkov et al., 1994a). The function of such large amounts of carotenoids in these cells is unclear. Carotenoids could play a role in scavenging singlet oxygen or free radicals or both, a process observed for several carotenoids in organic solvents (Krinsky, 1979; Krinsky, 1989; Oliveros et al., 1992), or perhaps a role in screening cells from high intensities of blue light.

Cells of *E. longus* are also rich in such photosynthetically uncoupled carotenoids, as more than 70% of the total carotenoids present do not function as light-harvesting pigments (Noguchi et al., 1992).

The effect of light on pigment synthesis in both the aerobic phototrophic and the anaerobic phototrophic bacteria is roughly qualitatively similar, but there are quantitative differences. In common is the light stimulation of growth and inhibition of aerobic respiration, suggesting the operation of a photosynthetic electron transport system that shares components with a respiratory system in both groups (Harashima et al., 1987; Harashima et al., 1982). Differences are described below. In anaerobic phototrophic bacteria high light intensities repress the synthesis of bacteriochlorophyll, whereas moderate and low light intensities stimulate maximal bacteriochlorophyll synthesis (Bauer et al., 1993). In aerobic phototrophic bacteria the influence of light intensities as low as 20 $\mu E/m^2/s$ was found to be strongly inhibitory and abolished bacteriochlorophyll synthesis (Yurkov and van Gemerden, 1993c). Transient light stimulation of growth and complete inhibition of bacteriochlorophyll synthesis were demonstrated in batch culture experiments on *E. longus*, *R. denitrificans*, *E. hydrolyticum* and *S. sibiricus* (Harashima et al., 1982; Harashima et al., 1987; Liebetanz et al., 1991; Yurkov et al., 1993e; Yurkov and van Gemerden, 1993c). However, the clearest results were obtained using chemostat cultures of *E. hydrolyticum* (Yurkov and van Gemerden, 1993c).

The photosynthetic activity of aerobic phototrophic bacteria might seem to be negligible. However, under aerobic alternating light and dark conditions the photosynthetic electron transfer chain might contribute significantly to an increase of the proton gradient and thereby help to maintain an electrochemical potential in the cytoplasmic membranes. This increase could be used for ATP production or for transport of substrates. For example, it is thought that cells spend a large portion of their total energy budget for active transport (Madigan et al., 1997). Therefore, the use of light energy to enhance substrate transport could increase the efficiency of organic substrate consumption for biosynthesis. Such speculations are supported by results obtained with continuous cultures of *E. hydrolyticum* (Yurkov and van Gemerden, 1993c). Thus the simultaneous operation of photosynthesis with heterotrophic respiration may be of advantage in competition with heterotrophs that lack photopigments.

Oxygen Dependence and Heterotrophic Metabolism

Whereas (of the aerobic phototrophic bacteria) only *R. denitrificans* is capable of anaerobic denitrification, and can grow anaerobically with trimethylamine N-oxide (TMAO) as an electron acceptor (Arata et al., 1988; Shioi et al., 1988), the survival of most aerobic phototrophic bacteria seems to depend on the presence of O_2. For example, O_2 stimulates heterotrophic consumption of organic substrates, activates the growth rate and increases other metabolic activities (e.g. thiosulfate oxidation as an additional source of the energy that results in ATP generation in *E. hydrolyticum* and *R. thiosulfatophilus*; Yurkov et al., 1994b). This dependence on O_2 for growth, and thus the synthesis of bacteriochlorophyll and carotenoids, is contrary to the behavior of most species of anaerobic phototrophic bacteria. At present, only the purple nonsulfur species *R. centenum* and *R. sulfidophilum* are known to synthesize a functionally significant photosynthetic apparatus when O_2 concentration is high (Hansen and Veldkamp, 1973; Yildiz et al., 1991). In con-

trast, photophosphorylation and photosynthetic ATP synthesis in cells of *R. denitrificans* were reported to occur only under aerobic conditions. A decrease in O_2 concentration resulted in a decrease in ATP production, regardless of the presence of light (Okamura et al., 1986). Light-induced electron transport through cytochromes and the reaction center (RC) requires active aerobiosis in membrane preparations and intact cells of aerobic phototrophic bacteria (Garcia et al., 1994; Harashima and Takamiya, 1989; Yurkov et al., 1995). Moreover, it seems likely that due to the high mid-point potential of the RC primary acceptor Q_A, oxygen is necessary for aerobic phototrophic bacterial photosynthesis. Thus, these bacteria may have evolved to become aerobes that have retained photosynthesis as an accessory metabolic process that enhances growth under conditions of alternating exposure to light.

Most of the aerobic phototrophic bacteria can oxidize a great diversity of organic carbon sources to support chemotrophic growth (Table 2). Accordingly, media that contain a complex composition of organic sources of carbon such as yeast extract, peptone, casein hydrolysate, potato broth or soytone result in the highest growth yields (Fuerst et al., 1993; Hanada et al., 1997; Shiba, 1991a; Shiba and Harashima, 1986; Shiba and Simidu, 1982; Yurkov and Gorlenko, 1990b; Yurkov and Gorlenko, 1992a; Yurkov and Gorlenko, 1993a; Yurkov et al., 1992c). Most species can metabolize sugars, tricarboxylic acids, fatty acids and amino acids. Some species of *Erythromicrobium* use ethanol in low concentrations as the sole carbon source (Yurkov and Gorlenko, 1993a; Yurkov et al., 1994b). A lipolytic activity was established for many species on the basis of the ability to hydrolyze Tweens (Shiba, 1991a; Shiba and Simidu, 1982; Yurkov and Gorlenko, 1990b; Yurkov and Gorlenko, 1993a; Yurkov et al., 1994b), and some species hydrolyze gelatin or starch (Shiba and Simidu, 1982; Yurkov and Gorlenko, 1993a; Table 2).

The active growth of most aerobic phototrophic species in complex media containing high concentrations of organic compounds (Fuerst et al., 1993; Shiba, 1991a; Shiba and Simidu, 1982; Yurkov and Gorlenko, 1990b; Yurkov and Gorlenko, 1992a; Yurkov and Gorlenko, 1993b; Yurkov et al., 1992b; Yurkov and van Gemerden, 1993b) is in keeping with the high organic matter content of the eutrophic environments from which they were isolated (Fuerst et al., 1993; Shiba et al., 1979; Shiba et al., 1991b; Yurkov, 1990a; Yurkov et al., 1992b; Yurkov and van Gemerden, 1993b). The main exception is *Acidiphilium*, which grows best with relatively low concentration of nutrients (Wakao et al., 1993).

The aerobic phototrophic *Citromicrobium* isolated recently from the presumably oligotrophic environment of "black smoker" plume waters grows on an unusually low (for this physiological group) number of substrates. Glutamate, butyrate and yeast extract are the best carbon sources for *Citromicrobium*, and acetate and glucose support weak growth (Yurkov et al., 1999).

Like the purple nonsulfur bacteria, most species of the aerobic phototrophic bacteria have a highly versatile heterotrophic carbon metabolism. However, these two bacterial groups have different autotrophic growth and CO_2 fixation capabilities. None of the obligately aerobic species has yet been shown to grow autotrophically, and the key enzyme of Calvin cycle (ribulose-bisphosphate carboxylase; RubisCO) has not been found in any species (Shimada, 1995; Yurkov, 1990a; Yurkov and Gorlenko, 1992a; Yurkov and Gorlenko, 1993a; Yurkov et al., 1994b). Experiments on *S. sibiricus* using radiolabeled $^{14}CO_2$ indicated a low level of CO_2 fixation (0.4%) in both illuminated and dark conditions, consistent with heterotrophic CO_2 fixation (Brock et al., 1994; Gusev and Mineeva, 1985) attributed to the enzyme phosphoenolpyruvate (PEP) carboxylase (Yurkov, 1990a). Nonetheless, light stimulation of CO_2 uptake was detected for several species: *E. longus* (Yurkov, 1990a), *R. denitrificans* (Shiba and Harashima, 1986), *S. sibiricus* (Yurkov, 1990a) and *A. rubrum* (Kishimoto et al., 1995). This CO_2 fixation, too low to maintain autotrophic growth, could provide additional organic carbon intermediates for an otherwise essentially heterotrophic metabolism. This view is congruent with the observation that light-stimulated CO_2 uptake occurs in concert with light-activated consumption of acetate and stimulation of growth in chemostat cultures of *E. hydrolyticum* (Yurkov and van Gemerden, 1993c).

All aerobic phototrophic bacteria are able to utilize one or more of the sugars fructose, glucose or sucrose (Table 2). In some cases the ability or inability to use fructose is a specific characteristic of the species. For example, *R. thiosulfatophilus* grows on glucose as the sole carbon source, whereas fructose does not support growth (Yurkov and Gorlenko, 1992a; Yurkov et al., 1994b).

The catabolism of glucose by aerobic phototrophic bacteria was studied by analysis of enzyme activities for two species, *S. sibiricus*, strain RB16-17 (formerly *E. sibiricum*), and *E. longus*, strain OCh101 (Yurkov et al., 1992e). Both species possess glucose-6-phosphate dehydrogenase and 2-keto-3-deoxygluconate-aldolase. The high activity of these two enzymes indicates that glucose utilization is mainly via the Entner-Doudoroff pathway (Madigan et al.,

1997). Low activity of the key enzyme of the Embden-Meyerhof pathway, fructose-diphosphate aldolase, was detected and it was concluded that this enzyme functions in biosynthesis (Yurkov et al., 1992e). No 6-phosphogluconate dehydrogenase was detected in *S. sibiricus*, whereas *E. longus* cells contained trace amounts of 6-phosphogluconate dehydrogenase, suggesting that the pentose monophosphate pathway exists in *E. longus* (Yurkov et al., 1992e).

Aerobic phototrophic bacteria accumulate polysaccharides (e.g., glycogen), polyhydroxyalkoanates and/or polyphosphates (Fig. 4), depending on the growth conditions (Yurkov and Gorlenko, 1992a; Yurkov and Gorlenko, 1993a; Yurkov et al., 1991b; Yurkov et al., 1992b; Yurkov et al., 1994b). Cells of *S. sibiricus* accumulated heavily osmium-stained granules of presumably polyphosphates under nearly all experimental conditions studied: in the light and the dark, with high or low aeration, and growth with acetate, butyrate or sucrose as the sole organic carbon source (Yurkov et al., 1991b). The highest amount of polyphosphate was accumulated in a growth medium supplemented with sucrose. Under such conditions polyphosphate granules occupied about 30–40% of the total cell volume (Fig. 4).

Electron-transparent granules presumed to be polyhydroxyalkoanates (polyhydroxybutyrate, PHB) were found in several species of the genera *Roseococcus*, *Erythromicrobium* and *Sandaracinobacter* (Yurkov, 1990a; Yurkov and Gorlenko, 1992a; Yurkov and Gorlenko, 1993a; Yurkov et al., 1991b; Yurkov et al., 1992c), with *S. sibiricus*, strain RB16-17, as the greatest PHB accumulator. The PHB was formed when cells were grown in media unbalanced for nitrogen (urea as a nitrogen source), as well as during incubation in a medium lacking fixed nitrogen. Replacement of ammonia with nitrate as the source of nitrogen also resulted in pronounced formation of PHB granules. Under these conditions, large PHB granules occupied about 40–50% of the total cell volume, to the extreme of causing cell deformation (Fig. 4). Although storage compounds have been revealed in many aerobic phototrophic bacteria, little is known about the conditions that promote accumulation or consumption of these cytoplasmic inclusions.

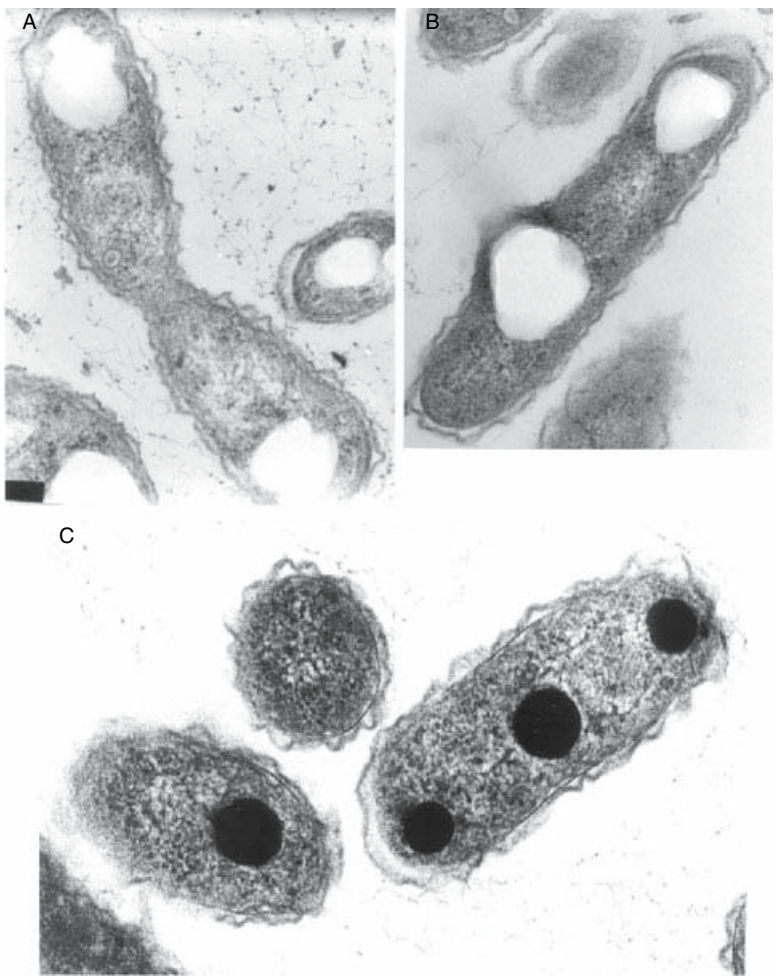

Fig. 4. Intracytoplasmic compounds of *S. sibiricus* revealed by electron microscopy of ultrathin sections. A) and B) Large electron-clear granules of presumed polyhydroxybutyrate (PHB) often occupied up to 40–50% of the total cell volume, deforming the cell shape. C) Electron-dense granules of presumed polyphosphate occupied up to 30–40% of the total cell volume.

Six species, *R. thiosulfatophilus*, *E. ramosum*, *E. hydrolyticum*, *E. ezovicum*, *E. ursincola* and *S. sibiricus* (formerly *E. sibiricum*), were analyzed for the use of sulfide or thiosulfate for growth with these compounds as the sole sulfur source in a defined medium containing acetate as the sole source of carbon. None of these species oxidized sulfide, whereas thiosulfate-oxidizing activity was detected for *E. hydrolyticum*, strain E4(1), and *R. thiosulfatophilus*, strain RB-7. Utilization of thiosulfate by both species was dependent on the presence of an organic carbon substrate and aeration. An increase in aeration increased the growth rate, which in turn provoked faster thiosulfate oxidation and the accumulation of the oxidized sulfur products, tetrathionate or sulfate, in the growth medium of *E. hydrolyticum* or *R. thiosulfatophilus*, respectively (Yurkov et al., 1994b).

Seven species of aerobic phototrophic bacteria (*E. litoralis*, *R. thiosulfatophilus*, *E. ramosum*, *S. sibiricus*, *E. ursincola*, *E. ezovicum* and *E. hydrolyticum*) were recently found to possess a high level of resistance (HLR) to tellurite and the ability to reduce TeO_3^{2-} to metallic tellurium (Yurkov et al., 1996; Table 5 and Fig. 5). The minimal inhibitory concentrations (MIC) of tellurite for aerobic phototrophic bacteria were found to be significantly higher than those determined for other representatives of the α-subclass of the *Proteobacteria*. The highest MIC of tellurite described for *R. capsulatus* and *R. sphaeroides* were 800 and 900 mg/ml, respectively (Moore and Kaplan, 1992; Moore and Kaplan, 1994), whereas MIC values of 2300, 2500 and 2700 mg/ml were found for the aerobic *E. ramosum*, *E. hydrolyticum* and *E. ursincola*, respectively (Yurkov et al., 1996). This reduction of tellurite to the relatively inert metallic tellurium, with accumulation of tellurium as intracellular deposits, seems to be one way bacteria detoxify tellurite (Lloyd-Jones et al., 1991; Moore and Kaplan, 1992; Taylor et al., 1988). However, HLR without metal accumulation was observed for *R. thiosulfatophilus* grown with L-glutamine, succinate, malate, tartrate or acetate and for *E. ezovicum* grown with acetate as the organic carbon source (Table 5). These results imply that tellurium accumulation is not essential to confer TeO_3^{2-} resistance and that another mechanism such as continuous tellurite efflux, complexing or methylation could specify this resistance.

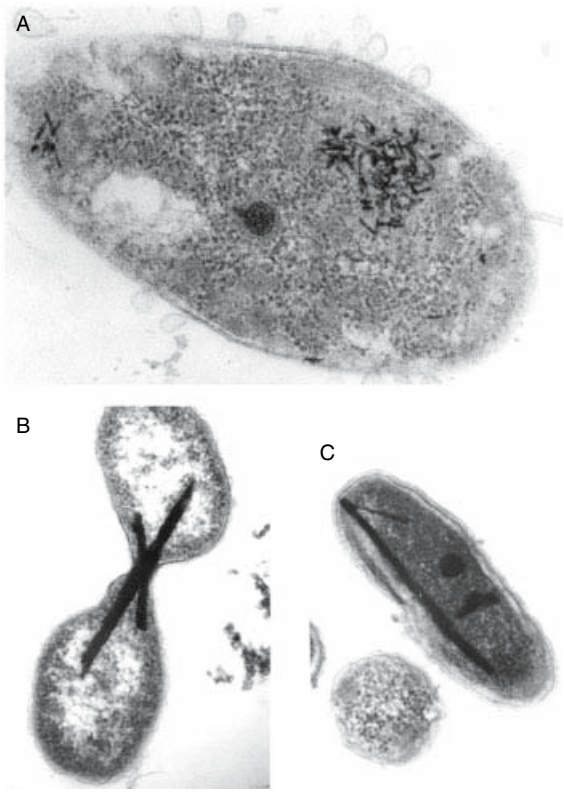

Fig. 5. Electron microscopy of ultrathin sections showing the intracellular deposits of tellurium as a product of tellurite reduction. A) *R. thiosulfatophilus*, relatively small Te crystals similar to Te deposits found in *E. coli* or *Rhodobacter* species. B) Two daughter cells of *E. ramosum* with tellurium crystals apparently interfering with cell division. C) *E. ursincola* accumulates long tellurium crystals.

Genetics

The study of the genetics of aerobic phototrophic bacteria is in its infancy, although the *puf* operon of *R. denitrificans* was cloned and sequenced and showed high sequence similarity (up to 70%) with *Rhodobacter* species (Liebetanz et al., 1991). Recently the *puf* operon of *R. denitrificans* was expressed in a *R. capsulatus puf puc* double-deletion mutant (Kortluke et al., 1997). The strongest expression of the *R. denitrificans puf* operon was observed under the control of the *R. capsulatus puf* promoter, in the presence of *R. capsulatus pufQ* and *pufX* genes, and in the absence of the *R. denitrificans pufC*. Reaction center charge separation and recombination between the primary donor P^+ and the primary acceptor Q_A- were observed in this strain, showing that the reaction center was correctly assembled. However, this strain did not grow photosynthetically under anaerobic conditions. The authors explained the absence of electron transport to Q_B under anaerobic conditions by the presence of M and L subunits from *R. denitrificans* and the H subunit from *R. capsulatus*, which did not interact so as to stabilize the Q_B site or allow electron transport from Q_A to Q_B (Kortluke et al., 1997). The uncertainties surrounding the photosynthetic metabolism of aerobic phototrophic bacteria will undoubtedly be

Table 5. Reduction of K_2TeO_3 by different species of aerobic photosynthetic bacteria: dependence on organic carbon source.

clarified by additional molecular biological investigations.

Recently DNA fragments (approximately 3.8 kb) containing *puf* operons and a part of *bchZ* gene obtained from *A. rubrum* and *A. angustum* and fragments (1.5 kb) containing *pufL* and *pufM* of *A. criptum*, *A. multivorum* and *A. organovorum* were amplified and sequenced (Nagashima et al., 1997a). The *puf* operons of *A. rubrum* and *A. angustum* contained *puf B*, *-A*, *-L*, *-M* and *-C* as seen in other purple bacteria with an unknown gene directly upstream of *pufB*. Comparing the deduced amino acid sequences of the *puf* genes of the *Acidiphilium* species with those of other purple bacteria showed that His L168, which is highly conserved in other bacteria, is replaced by a glutamic acid in *Acidiphilium* species. The three-dimensional structures of the reaction centers of *Blastochloris viridis* and *Rhodobacter sphaeroides* suggest that this residue is located close to a special pair of bacteriochlorophylls and may be involved in the stabilization and function of Zn-containing bacteriochlorophyll *a* found in *Acidiphilium* (Nagashima et al., 1997a).

Ecology

In spite of the broad geographical distribution of aerobic phototrophic bacteria in different ecological niches and their presence in high numbers, the ecology and ecological importance of this group of organisms (their role in microbial populations) have not been studied.

Applications

Until now the major application of the aerobic phototrophic bacteria has been as an experimental subject in many areas of microbiology. However, recent discovery of the extremely high resistance to heavy metal oxides and of the ability to reduce these toxic compounds and accumulate them intracellularly in elemental form suggests that these organisms have potential industrial and bioremediation uses.

The maximum size and total amount of tellurium crystals (intracellular product of tellurite reduction) in most of the aerobic phototrophic bacteria were much greater than those observed in *E. coli*, *Pseudomonas* or *Rhodobacter* species (Lloyd-Jones et al., 1994; Moore and Kaplan, 1992; Moore and Kaplan, 1994; Suzina et al., 1995; Taylor et al., 1988; Yurkov et al., 1996). In some cells of *E. ramosum* and *E. litoralis*, the metal crystals occupied 20–30% of the cell volume. The only exception was *R. thiosulfatophilus*, which accumulated small metallic deposits, similar to *E. coli* or *R. sphaeroides* (Yurkov et al., 1996; Fig. 5).

Tellurium (especially of valence IV) is very toxic not only for microbes but also for other organisms, including humans. Therefore, the microbial reduction of soluble Te(IV) to solid Te(0) could be an important mechanism for the removal of this poison from polluted sites. In this context, the development of microbiological methods for environmental remediation of locales contaminated with tellurium oxides could utilize aerobic phototrophic bacteria, which are able to transform very high concentrations of Te(IV) to Te(0). Species of the genera *Erythromicrobium*, *Erythrobacter* and *Erythromonas* were found to be resistant not only to tellurite but also to tellurate, selenite, selenate, arsenate and vanadate (V. V. Yurkov, unpublished observations). Such multi-metal resistance may increase the importance of these bacteria as prospective candidates for the bioremediation of industrial waste waters polluted by a combination of several different heavy metal ions.

Microbial activities are used in the concentration of metals from natural ores and mining tailings with metal levels too low for smelting. Bioleaching by *Thiobacillus ferrooxidans* and related thiobacilli, for example, results in the recovery of up to 70% of the copper in low-grade ores. About 10% of copper in the United States comes from leaching ore through the activity of bacteria such as *Thiobacillus* and *Leptospirillum* species (Prescott et al., 1993). Therefore, tellurium accumulation by aerobic phototrophic bacteria could be useful in tellurium extraction from ores or for recycling of tellurium oxides. Native tellurium is uncommon (an abundance in the lithosphere of 2 parts per billion [ppb]), usually occurring in conjunction with elemental sulfur. Tellurium is present in minerals as tellurides of lead, copper, silver, gold and antimony (Bagnall, 1975). The extraction of tellurium is difficult because of the low content in natural ores, and tellurium compounds are usually obtained as by-products of metal refining processes (Klevay, 1976). Aerobic phototrophic bacteria, which are easy to cultivate and which accumulate high amounts of Te in cells, could be used in microbiological metallurgy for tellurium concentration.

CHAPTER 3.1.23

The Genus *Seliberia*

JEAN M. SCHMIDT AND JAMES R. SWAFFORD

Bacteria of the genus *Seliberia* are recognized by the presence of radial clusters (starlike aggregates) of rod-shaped bacteria, a characteristic screwlike twisting of the rod surface, and the formation of oval or spherical reproductive cells by a budding process—usually at the apical end of rods in a radially arranged aggregate or at a tip of an individual rod (Aristovskaya and Parinkina, 1963; Aristovskaya, 1964). The rods are 0.5–0.7 μm wide and their length varies with the composition of the nutrient medium used (Aristovskaya, 1974). The oval "reproductive" cells, which are found in soil isolates cultivated on appropriate medium, may also occur in the center of the star-shaped aggregates, and these "reproductive" cells have been observed to germinate into rods. A preponderance of oval cells or spherical cells is referred to as the zoogleal stage. The spherical or oval cells of *Seliberia stellata*, a soil isolate, and several seliberia-like helically sculptured rods of aquatic origin are not observed when isolated strains of these bacteria are cultivated on dilute peptone or other routine laboratory maintenance media, rather than on soil extract medium; the rods then divide by transverse asymmetric binary fission. The small, rod-shaped daughter cells, released from the aggregate, are motile by a subpolar flagellum and later may attach to a substrate by means of a polar holdfast. These bacteria are Gram negative. Dichotomous branching is occasionally observed (Aristovskaya and Parinkina, 1963; J. R. Swafford, unpublished observations). The ability to accumulate ferric hydroxide is characteristic.

Habitats

The type species, *Seliberia stellata*, was isolated from soil, specifically from humus-illuvial podzol of the Karelian isthmus (Aristovskaya and Parinkina, 1963), where it was found to be widely distributed. A second species, *S. carboxydohydrogena*, was obtained from an aerotank of a sewage treatment plant (Zavarzin and Nozhevnikova, 1977); since this organism is a carboxydobacterium, capable of oxidizing carbon monoxide, and is also a hydrogen-oxidizing bacterium, it is discussed elsewhere (this Handbook, Chapter 15; see also Meyer, Lalucat, and Schlegel, 1980).

A number of freshwater strains of *Seliberia* (species so far undesignated), assigned to the genus because of their distinctive morphology, have been obtained from ponds, lakes, and streams which are very low in nutrient content rather than eutrophic (Schmidt and Swafford, 1979). Such bacteria have not been found in samples from eutrophic ponds or lakes in our studies—either in transmission electron microscopic surveys of the microbial populations, which would permit their recognition due to their peculiar morphologic characteristics, or in isolation experiments from eutrophic water samples under conditions which should have permitted growth of seliberia-like organisms. Under similar isolation conditions using inocula from oligotrophic water samples and enrichments prepared from them, these bacteria of aquatic origin were readily cultivated and detected. Seliberia-like bacteria have also been observed in stored samples of laboratory distilled water, which are very poor in organic nutrient sources. *Seliberia stellata* and the aquatic seliberia-like bacteria appear to be strict oligotrophs, inhabiting environments where nutritive substances are available only in low concentrations (Aristovskaya and Parinkina, 1963; Schmidt and Swafford, 1979).

Isolation

The isolates assigned to the genus *Seliberia* are oligotrophic and grow slowly on culture media that are very low in nutrients; the final growth yield is sparse. They seem to grow not at all on the somewhat richer nutrient media widely used for the growth of saprophytes, such as nutrient agar (Difco), which contains about 0.8% total nutrient concentration. Soil isolates are able to accumulate ferric hydroxide (Aristovskaya and Parinkina, 1963). These bacteria can be grown as chemotrophic heterotrophs (subcategorized as oligotrophs); with regard to the facultative chemoautotrophs categorized morphologically as *Seliberia carboxydohydrogena*, principles of isolation applicable to carboxide bacteria should be used.

This chapter was taken unchanged from the second edition.

Enrichment

For the oligotrophic soil and water *Seliberia* spp., specific heterotrophic enrichment procedures, which would give a large majority or preponderance of this particular sort of bacterium, are lacking. Many kinds of heterotrophic bacteria will grow or subsist in the very dilute nutrient concentrations that would encourage the development of these helically sculptured bacteria.

Particular enrichment methods for podzol-inhabiting seliberias were not outlined by Aristovskaya and Parinkina (1963), although they mention that these bacteria occurred, in characteristic star-shaped clusters, in great profusion in pedoscopes. Their development in pedoscope samplings of humus-rich soils represents a useful enrichment approach to the seliberias, which could be used as an aid to their isolation. Isolation techniques using pedoscopes have been described by Perfil'ev and Gabe (1969).

To enrich (nonspecifically) for seliberia-like bacteria of aquatic origin, we have successfully used water samples with an oligotrophic character. The water samples of from 250 to 800 ml have been incubated at 24–26°C in glass beakers covered with aluminum foil or plastic film to retard evaporation with (1) no addition of nutrients or (2) addition of very low concentrations of peptone broth (final concentrations of 0.001–0.005% peptone [Difco]) for extended periods of time—a few weeks to several months. Seliberia-like bacteria can usually be found floating at the air-water interface (in the surface pellicle, if heavy microbial growth has occurred). The presence of a dense pellicle may cause difficulties in subsequent isolation attempts, since seliberias are slow-growing organisms, and may occur in the extreme minority in such surface samples. Since seliberias attach firmly (and nonspecifically) to a variety of substrates (each other, other microbes, glass surfaces, for example), one could exploit this characteristic in isolation attempts by inserting glass slides or cover slips (preferably near the surface) into the enrichment.

Isolation of Seliberias from Soil

Organomineral complexes derived from soil humus are suitable for the isolation and cultivation of seliberias (Aristovskaya and Parinkina, 1961, 1963). The preparations of these media contain some somewhat qualitative steps. Brown humic or ulmic acids are extracted from soil (peat-podzolic soil horizon) with 0.1 N NaOH and precipitated from the alkaline extract with HCl. Fulvic acids, which predominate in podzolic zone soils, are separated by filtration and the ulmic acid precipitate is then redissolved in 0.1 N NaOH. The alkaline solution is adjusted to pH 3.5, and a qualitative precipitation with ferric chloride (a few drops of ferric chloride solution per several ml of ulmic acid solution) is performed. The resulting gel is then washed until the filtrate no longer gives a positive test for chloride. The ulmic acid gel is ground with a mortar to a homogeneous consistency. The pH is adjusted to 6.5–7.0. Dilution of the homogenized gel in water to a suitable nutrient concentration for the cultivation of oligotrophs is done qualitatively (1 : 100, 1 : 500, and 1 : 1,000 dilutions serve as a tentative range of nutrient levels in the hunt for oligotrophs such as the *Seliberia* spp.). For solid media, 1.5–2.0% agar is used.

Fulvic acids, which occur in the alkaline filtrate, can be precipitated by adjusting the pH to about 6.0. Filtration, washing, and trituration precede medium preparation, using a procedure similar to the final steps for the ulmic acid medium (Aristovskaya, 1958; Aristovskaya and Parinkina, 1961).

Soil samples known to contain seliberia-like bacteria from preliminary capillary pedoscope observations are streaked on the ulmic or fulvic acid agar media. Slow-growing colonies, particularly organisms whose colonies develop in 4–7 days and show an accumulation of ferric hydroxide, are of interest. However, ferric hydroxide accumulation is mainly characteristic of seliberias when they are growing in mixed cultures. Pure cultures deposit ferric hydroxide when grown on mineral-rich medium in the presence of about 1% CO_2 (Aristovskaya and Parinkina, 1963).

Isolation of Aquatic Seliberias

Surface material from oligotrophic water samples, some of which were enriched with low concentrations of peptone (0.001–0.005%) and incubated at 24–26°C for 2 weeks to several months, is streaked on the following media: (A) 0.2% peptone (Difco), 0.1% yeast extract, 1% Hunter's vitamin-free mineral base (Cohen-Bazire, Sistrom, and Stanier, 1957), 1.2 or 1.5% agar (Difco), and distilled water; (B) 0.02% peptone, 0.01% yeast extract, 0.1% glucose (filter-sterilized), 1% Hutner's base, 1.2 or 1.5% agar (Difco), and distilled water. Incubation should be at 25 or 30°C for 2 or 3 weeks. Colonies growing up rapidly (during the first few days of incubation) should be marked and subsequently ignored, since the seliberias grow slowly. The colonies that appear later are transferred with a fine inoculating needle or a toothpick onto patch plates of medium A. Use of a dissecting

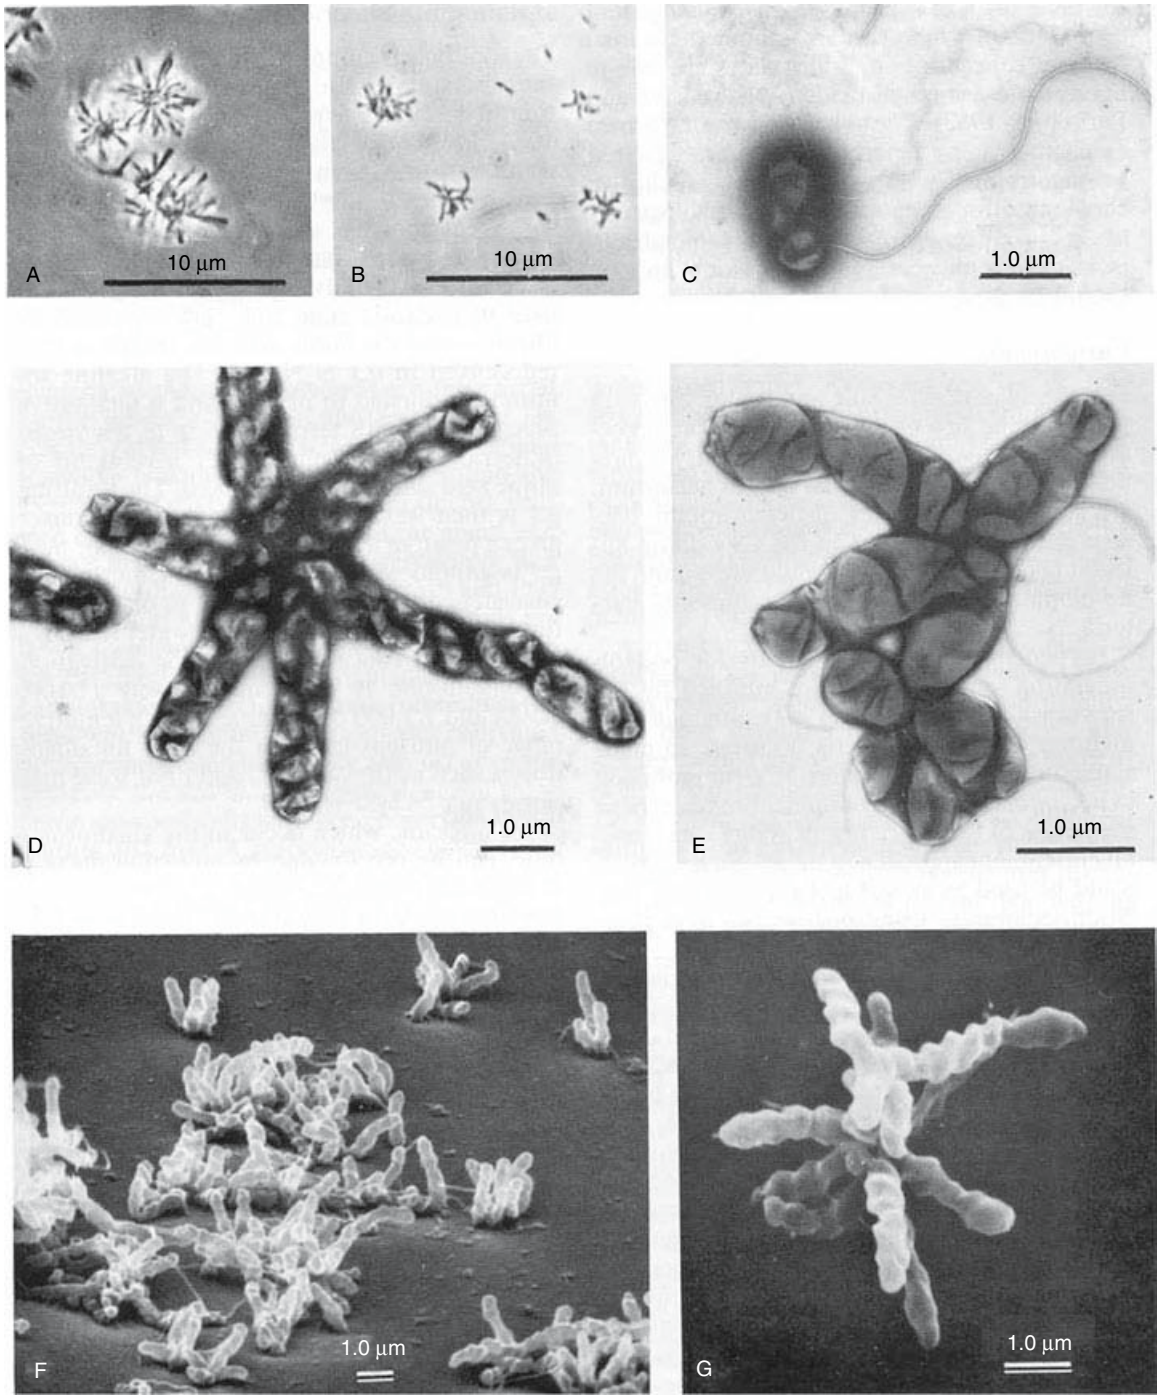

Fig. 1. The morphology of *Seliberia stellata*, a Russian soil strain, and seliberia-like aquatic isolates, as observed with light, transmission, and scanning microscopy. (A) *S. stellata* aggregates, phase-contrast microscopy. (B) An aquatic isolate of seliberia-like bacterium strain ICPB 4133 (Schmidt's strain OMF-1) showing rosettes; phase-contrast microscopy. (C) Negative-contrasted (0.5% Na tungstate) *S. stellata* cell, having two structurally different flagella, grown on peptone–yeast extract solid medium. (D) Star-shaped rosettes of *S. stellata*, showing surface sculpturing, negatively stained. (E) Aquatic isolate (ICPB 4134) with seliberia-like morphotype, grown on a carbon-supported, gold-coated electron microscope grid placed in peptone–yeast extract broth and then stained with 0.5% Na tungstate. Note furrowing of cell surface. (F and G) ICPB strain 4133, grown on glass cover slips, fixed with 2% glutaraldehyde, critical-point dried, and gold coated. Scanning electron microscopy clearly demonstrates attachment of cells at one pole to substrate and (in G) the helical morphology of the cells.

microscope facilitates the selection of appropriate colonies. Phase-contrast microscopy of the organisms from the patch plates (once again concentrating on those requiring several days to give visible growth) has been used to select rosette-forming, asymmetrically dividing, rod-shaped bacteria. From among these, seliberia-like rods, with their helical topography, can be distinguished from bacteriod and fusiform *Caulobacter* spp., *Agrobacterium* spp., and other aggregate-forming bacteria with transmission electron microscopy, using negative-contrast methods. The helical topography of the rods is better demonstrated by scanning electron microscopy (Fig. 1).

Identification

The presence of star-shaped aggregates (Fig. 1A, B) in preparations from seliberia colonies is not uniquely diagnostic of a *Seliberia* sp., since many other bacteria (certain species of *Agrobacterium*, *Pseudomonas*, *Caulobacter*, and *Asticcacaulis*, all rods) form aggregates or rosettes. Seliberias can usually be distinguished from caulobacters, since seliberias do not form stalks, and caulobacter prosthecae can usually be detected with phase-contrast photon microscopy. Apical daughter cells of seliberias are usually shorter than the parent rod (Fig. 1D). Transmission electron micrographs reveal a characteristic wrinkled (helical) surface of the seliberias (Fig. 1D, 1E). However, the tight helical surface of the rods is more apparent in scanning electron micrographs prepared by the critical-point drying technique (Fig. 1F, 1G). When *S. stellata* (one of Aristovskaya's strains, obtained from G. A. Zavarzin) is grown on agar-solidified peptone-yeast extract medium, two distinct kinds of flagella are present on the same cell: a subpolar sheathed flagellum and several thinner, undulating (apparently nonsheathed) lateral flagella (Fig. 1C). When grown in liquid medium, *S. stellata* produces only the sheathed type of flagellum. Nine independently obtained strains of the aquatic seliberia-like bacteria (19 isolates, total) have been examined, and all have a single subpolar sheathed flagellum in the motile stage of growth. Only one aquatic strain has been observed to produce the two distinctive kinds of flagella seen on *S. stellata*, under any cultural conditions so far examined. Very thin pili (40 Å in diameter) are present on both *S. stellata* and on the aquatic seliberia-like strains. One pole of the seliberia cell is adhesive, and a secretion of amorphous material, representing the holdfast, can sometimes be discerned in negative-contrast transmission electron micrographs at one pole of the cell or in the center of a star-shaped aggregate. In liquid medium, cells attached by a pole to a substrate (for example, to a glass cover slip) remain erect (Fig. 1F). Aristovskaya and Parinkina (1963) and Aristovskaya (1964) have described oval or spherical, budding, apical cells, found commonly in *S. stellata*, when grown on soil extract medium, and a zoogleal stage in its life cycle. Deposition of ferric hydroxide may occur particularly when *S. stellata* is cultivated in the presence of other soil organisms in mixed culture or in pure culture, under slightly increased carbon dioxide tension.

All isolates of seliberia-like aquatic bacteria and the one strain of *S. stellata* we have examined are Gram negative. They are somewhat sensitive to penicillin G (growth is inhibited by 1,000 units/ml but not by 10 units/ml), and they are lysed by exposure to lysozyme-ethylenediaminetetraacetate. Growth of the aquatic seliberia-like strains in dilute peptone-yeast extract medium is sparse, white in color, and very adherent to the agar medium; in liquid medium, most of the cells are in large granular aggregates or firmly attached to the glass surface of the culture vessel. Growth of *S. stellata* is relatively dispersed, giving uniform turbidity, although some cell aggregates are visible microscopically. All of the seliberia strains so far examined, including *S. stellata*, are obligately aerobic, although *S. stellata* can carry out denitrification anaerobically. The aquatic seliberia-like bacteria are weak denitrifiers. The possibility that *S. stellata* and the aquatic strains are facultative autotrophs (hydrogen oxidizers or carboxide bacteria) is being investigated.

CHAPTER 3.2.1

The Phototrophic Betaproteobacteria

JOHANNES F. IMHOFF

Introduction

The phototrophic purple β-Proteobacteria are purple nonsulfur bacteria able to perform anoxygenic photosynthesis with bacteriochlorophylls and carotenoids as photosynthetic pigments. Though genetic relationships and chemotaxonomic properties clearly distinguish these bacteria from the phototrophic α-Proteobacteria, both groups share a number of common physiological properties. Owing to their photosynthetic pigments, cell suspensions appear in various colors and have characteristic absorption spectra. Photosynthetic pigments are located in the cytoplasmic membrane and in internal membrane systems (small tubular invaginations of the cytoplasmic membrane) and are bacteriochlorophyll *a* and various types of carotenoids. In most species, the formation of pigments and of the internal membrane systems is repressed under oxic conditions but becomes derepressed at low oxygen tensions.

Phototrophic β-Proteobacteria have high metabolic flexibility. The preferred mode of growth is photoheterotrophically under anoxic conditions in the light. Most of the species also can grow photoautotrophically with molecular hydrogen as photosynthetic electron donor. Growth factors are generally required, most commonly biotin and thiamine, and growth of most species is enhanced by small amounts of yeast extract. Chemotrophic growth under microoxic to oxic conditions in the dark is common to these bacteria. Anaerobic dark growth by fermentation also occurs.

Phylogeny

According to 16S rDNA sequence comparisons, the phototrophic β-Proteobacteria of the genera *Rhodoferax*, *Rubrivivax* and *Rhodocyclus* are well separated phylogenetically from their counterparts of the α-Proteobacteria and belong to different phylogenetic lines within the β-Proteobacteria (Hiraishi, 1994). On this basis, they are highly related to strictly chemotrophic β-Proteobacteria. Such close relationships exist, e.g., between *Rhodoferax fermentans* and *Variovorax paradoxus* and between *Rubrivivax gelatinosus* and *Leptothrix discophora* (see Fig. 1).

The analysis of nucleotide sequences of DNA fragments coding for the L and M subunits of the photosynthetic reaction center showed that sequences of *Rhodoferax fermentans*, *Rubrivivax gelatinosus* and *Rhodocyclus tenuis* were positioned among those of α-Proteobacteria. This contrasts with their phylogenetic relations based on 16S rDNA sequences. The inconsistency was explained by possible horizontal transfer of the genes encoding the photosynthetic reaction center during evolution. Despite this disparity, sequences of the puf genes of *Rhodoferax fermentans* show 77% identity and are most similar to those of *Rubrivivax gelatinosus* (Nagashima et al., 1997).

Taxonomy

Prior to the recognition of their genetic relationship on the basis of 16S rDNA sequence comparison, the phototrophic purple nonsulfur bacteria belonging to the β-Proteobacteria have been included in the Rhodospirillaceae together with the phototrophic α-Proteobacteria (Pfennig and Trüper, 1974). In addition to their clear phylogenetic separation (Gibson et al., 1979; Fox et al., 1980; Hiraishi, 1994), a number of chemotaxonomic properties clearly distinguish the phototrophic β-Proteobacteria from the phototrophic α-Proteobacteria: They have ubiquinone and menaquinone (or rhodoquinone) derivatives with eight isoprenoid units in the side chain (Q-8, RQ-8 and MK-8); they have a "small type" cytochrome c_{551} as typically found in species of the Chromatiaceae and Ectothiorhodospiraceae, but not in phototrophic α-Proteobacteria (Ambler et al., 1979; Dickerson, 1980); and they have a characteristic phospholipid and fatty acid composition with the highest proportions of C-16 fatty acids (16:0 and 16:1) among all phototrophic purple bacteria and correspondingly very low ones of 18:1 (Hiraishi et

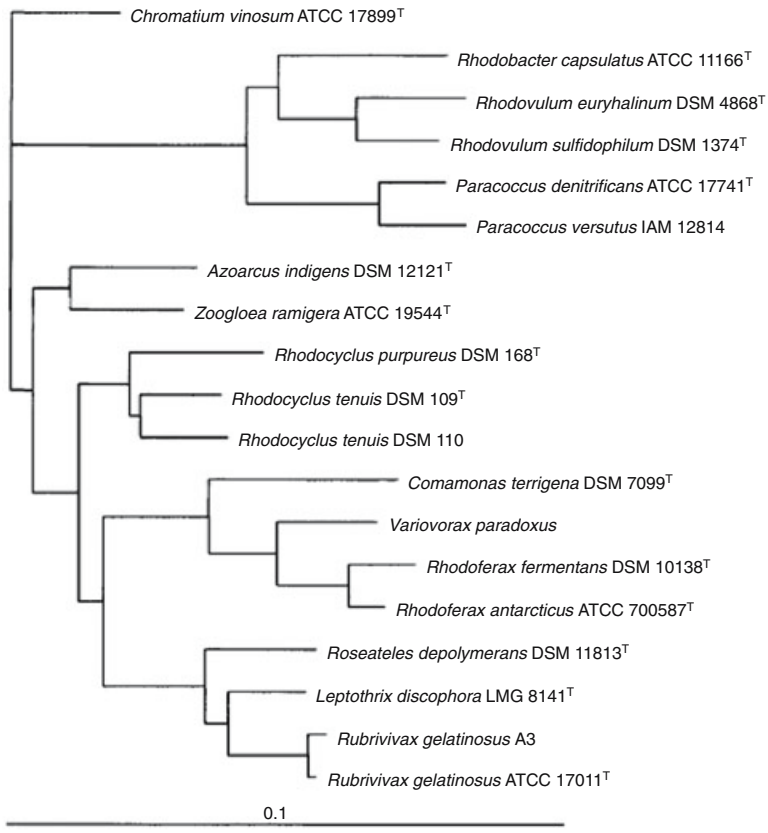

Fig. 1. Phylogenetic tree based on 16S rDNA sequences of phototrophic β-Proteobacteria and some chemotrophic relatives. The bar indicates 10% sequence divergence.

al., 1991; Imhoff, 1984a; Imhoff and Bias-Imhoff, 1995; Imhoff and Trüper, 1989). Their lipopolysaccharides characteristically contain significant amounts of phosphate and amide-linked 3-OH-capric acid (3-OH-C-10) in their lipid A moiety (Weckesser et al., 1995) or 3-OH-C-8:0, which is the major hydroxy fatty acid of *Rhodoferax fermentans* (Hiraishi et al., 1991).

As a consequence, *Rhodospirillum tenue* (Pfennig, 1969) was transferred to *Rhodocyclus tenuis* (Imhoff et al., 1984b). Also *Rhodopseudomonas gelatinosa* was transferred to this genus as *Rhodocyclus gelatinosus* (Imhoff et al., 1984b), but because of its phylogenetic distance to *Rhodocyclus purpureus*, it was assigned later to a new genus as *Rubrivivax gelatinosus* (Willems et al., 1991). Since then *Rhodoferax fermentans* has been described as a new genus and new species (Hiraishi and Kitamura, 1984b; Hiraishi et al., 1991) and *Rhodoferax antarcticus* as another new species of that genus (Madigan et al., 2000).

Rhodoferax fermentans was first known as the "*Rhodocyclus gelatinosus*-like (RGL)" group (Hiraishi and Hoshino, 1984a), because of great phenotypical similarity to *Rubrivivax gelatinosus* (at that time known as *Rhodocyclus gelatinosus*), in particular appearing to resemble *Rubrivivax gelatinosus* subgroup II (Weckesser et al., 1969). More detailed physiological, chemotaxonomic and genetic studies revealed major differences between the RGL group and *Rubrivivax gelatinosus*, and these observations led to the proposal to classify the RGL group as *Rhodoferax fermentans* (Hiraishi et al., 1991). The currently recognized species and genera together with some characteristic properties are listed in Table 1.

The Genus *Rhodocyclus*

At present this genus comprises two species, *Rhodocyclus purpureus* and *Rhodocyclus tenuis* (formerly *Rhodospirillum tenue*). While cells of *Rhodocyclus purpureus* are nonmotile and form a half- or full-circle, those of *Rhodocyclus tenuis* are slender, slightly curved and rapidly motile under optimal growth conditions. Significant differences between the two species also are reflected in their vitamin requirements and substrate utilization. Characteristic properties are summarized in Table 1.

A dichotomy has been observed in *Rhodocyclus tenuis* strains on the basis of the carotenoid composition (Schmidt, 1978), color of cell suspensions and absorption spectra (Biebl, 1973). Some strains assigned to *Rhodocyclus tenuis* have carotenoids of the rhodopinal series and others of the spirilloxanthin series. The type

Symbols: +, positive in most strains; –, negative in most strains: p-ABA, p-aminobenzoic acid.
Q-8, ubiquinone-8; RQ-8, rhodoquinone-8; MK-8, menaquinone-8 (Hiraishi and Hoshino, 1984; Imhoff, 1984).
[a]Some strains may require vitamin B_{12} (Siefert and Koppenhagen, 1982).
[b]Some strains may contain carotenoids of the spirilloxanthin series and lack rhodopinal (Schmidt, 1978)
[c]Some strains may also require pantothenate.
[d]Although detailed chemical evidence is lacking it appears likely that carotenoids of the spheroidene series are present, including spheroidene, OH-spheroidene and possibly spirilloxanthin.

strain (DSM 109^T) belongs to those strains that synthesize spirilloxanthin, whereas another group of strains (including strain DSM 110) does not form anhydrorhodovibrin and spirilloxanthin but accumulates major amounts of rhodopinal, rhodopinol and lycopenal (Schmidt, 1978). On the basis of 16S rDNA sequences, both of these strains (DSM 109^T and DSM 110) show a close relationship.

The Genus *Rubrivivax*

Rubrivivax gelatinosus has been reported to occur in two distinct morphological forms (Biebl and Drews, 1969). Form I cells are clearly curved, are 0.4–0.7 μm in diameter, and produce less slime during active growth. Form II cells are more or less straight rods, although they sometimes also are bent and produce more slime during active growth, causing sedimentation of the cells in a gelatinous layer. Form I cells utilize a greater variety of carbon sources and have a much shorter doubling time than do form II cells (Weckesser et al., 1969). Furthermore, the lipopolysaccharides of *Rubrivivax gelatinosus* show two different serotypes which do not crossreact with each other (Weckesser et al., 1975). The type strain of *Rubrivivax gelatinosus* was not included in these studies. Further studies are required to clarify the taxonomic status of the strains assigned to this species. Characteristic of *Rubrivivax gelatinosus* is the liquefaction of gelatin, which is catalyzed by an extracellular protease (Klemme and Pfleiderer, 1977). However, gelatin liquefaction is not unique to *Rubrivivax gelatinosus*; about half of the strains with this property have been identified as belonging to *Rhodobacter capsulatus*, whereas other strains with the morphology typical of *Rubrivivax gelatinosus* did not liquefy gelatin (Siefert et al., 1978). The taxonomic status of these strains needs to be clarified. Hydrolysis of gelatin is also catalyzed by *Rhodoferax fermentans* (Hiraishi et al., 1991). Characteristic properties of *Rubrivivax gelatinosus* are summarized in Table 1.

The Genus *Rhodoferax*

Two species of *Rhodoferax* are known. While *Rhodoferax fermentans* has been isolated from sewage and activated sludge (Hiraishi et al., 1991), *Rhodoferax antarcticus* is from an Antarctic microbial mat (Madigan et al., 2000). Both species are facultative photoheterotrophic bacteria that grow anaerobically in the light and aerobically in darkness at full atmospheric oxygen tension. Phototrophic liquid cultures become peach brown, whereas aerobic chemotrophic cultures are colorless or faintly pink. Absorption spectra of phototrophically grown cells or membrane preparations of *Rhodoferax fermentans* show major absorption maxima at around 800 and 850 nm, indicating that the cells contain the core light-harvesting complex (LH I) together with the photosynthetic reaction center and a peripheral light-harvesting complex (LH II). Long wavelength absorption maxima of bacteriochlorophyll in *Rhodoferax antarcticus* cells are at 800, 820 and 866 nm (Madigan et al., 2000), indicating the presence of different pigment/protein complexes. *Rhodoferax antarcticus* is well adapted to grow at low temperatures with an optimum at 12–20°C and the minimum close to 0°C, whereas all other known phototrophic β-Proteobacteria grow best at 25–30°C (Table 1).

Habitats and Ecology

The phototrophic β-Proteobacteria are freshwater bacteria common in stagnant waters exposed to the light that are enriched in organic compounds and nutrients. Sulfide-rich water bodies do not provide favorable conditions for these bacteria because of their inability to use sulfide as an electron donor for growth and their low tolerance to sulfide.

Rubrivivax gelatinosus is widely occurring in natural environments. Together with *Rhodocyclus tenuis*, it is found in the typical freshwater habitats of purple nonsulfur bacteria such as freshwater ponds, sewage ditches and activated sludge. *Rhodocyclus purpureus* appears to be a rare species; it has been isolated only once, from a swine waste lagoon in Ames, Iowa (United States), where it was the dominant phototrophic bacterium (Pfennig, 1978). Strains of *Rhodoferax fermentans* have been isolated from pond water, sewage and activated sludge (Hiraishi et al., 1991), similar habitats to those of *Rubrivivax gelatinosus*. As depicted in its name, *Rhodoferax antarcticus* was isolated from a microbial mat of an Antarctic habitat (Madigan et al., 2000). Accordingly, with an optimum temperature of 12–20°C and a range from 0–25°C, it appears to be better adapted to the lower range of environmental temperatures than are the other phototrophic purple bacteria.

Isolation

Selective Enrichment

Growth conditions employed for purple nonsulfur bacteria in general (Imhoff, 1988; Imhoff and Trüper, 1992) are also suitable for the enrichment of phototrophic β-Proteobacteria. Because

species of these bacteria cannot use sulfide or other reduced sulfur sources as electron donors for photosynthesis, but are strongly inhibited by low concentrations of them, addition of reduced sulfur compounds in enrichment media should be avoided.

The vitamin B_{12} requirement and its unusual carbon nutrition provide properties for selective enrichment and isolation of *Rhodocyclus purpureus*. From a suitable habitat, it should be possible to selectively enrich this species with benzoic acid as a carbon source and in the presence of vitamin B_{12}; anoxic conditions in the absence of reduced sulfur compounds, in particular hydrogen sulfide, should be established.

Suitable conditions for selective enrichment of *Rhodocyclus tenuis* are not available. This species will develop in suitable media for purple nonsulfur bacteria (Imhoff, 1988; Imhoff and Trüper, 1992) under exclusion of oxygen by sodium ascorbate and in the absence of hydrogen sulfide, vitamins and complex nutrients.

Utilization of citrate has proven to be useful for the selective enrichment of *Rubrivivax gelatinosus*, though this substrate also can be used by several other species.

Although it is not easy to perform selective enrichment of *Rhodoferax fermentans* from environmental samples, the addition of 0.5 mM EDTA to the enrichment medium may be effective for suppressing the overgrowth of possibly co-existing, fast-growing phototrophic species, such as *Rhodobacter capsulatus* and *Rhodobacter sphaeroides*. For enrichment, a basal mineral medium with one or more simple organic compounds (e.g., 0.1% acetate or 0.2% glucose) and a vitamin mixture or 0.01% yeast extract are suitable. Favorable incubation conditions are anaerobic in the light (incandescent illumination at 1,000–2,000 lux) at 28°C.

Although the upper temperature limit of *Rhodoferax antarcticus* prevents growth of this species at temperatures above 25°C, the application of low temperatures must not necessarily be of selective advantage because many bacteria with growth optima between 20–30°C are able to grow at 4°C. It should be noted that growth responses of most of the purple nonsulfur bacteria at temperatures below 15°C have not been determined.

Isolation Procedures

The methods employed for enrichment, isolation and maintenance of phototrophic α-Proteobacteria (Imhoff, 1988; Imhoff and Trüper, 1992) also are suitable for species of *Rubrivivax*, *Rhodocyclus* and *Rhodoferax*. Media and standard techniques for the isolation of anaerobic phototrophic bacteria in agar dilution series and on agar plates also can be applied for these bacteria (Biebl and Pfennig, 1981; Imhoff, 1988; Imhoff and Trüper, 1992).

A simple medium used for *Rhodoferax fermentans* (MYCA medium) contains 0.1% DL-malate, 0.3% yeast extract, 0.2% casamino acids and 0.05% $(NH_4)_2SO_4$ and has a pH of 6.6–6.8 (Hiraishi et al., 1991).

Identification

The phototrophic β-Proteobacteria have thin, slender cells of less than 1 µm diameter, single short tubes as internal photosynthetic membranes (if any at all), bacteriochlorophyll *a* as a reaction center and light-harvesting bacteriochlorophyll, a small type cytochrome c_{551} (Ambler et al., 1979), adenosine-5′-phosphosulfate (APS) as intermediate during assimilatory sulfate reduction (Imhoff, 1982), respiratory quinones with eight isoprenoid units (ubiquinone-8, menaquinone-8 and/or rhodoquinone-8; Imhoff, 1984a; Hiraishi et al., 1991), and characteristic molecular features of the lipid A moiety of the lipopolysaccharides, i.e., the amide linked 3-OH-10:0 fatty acid (not known for *Rhodoferax fermentans*, where 3-OH-8:0 is the major 3-OH-fatty acid) (Weckesser et al., 1979; Weckesser et al., 1995).

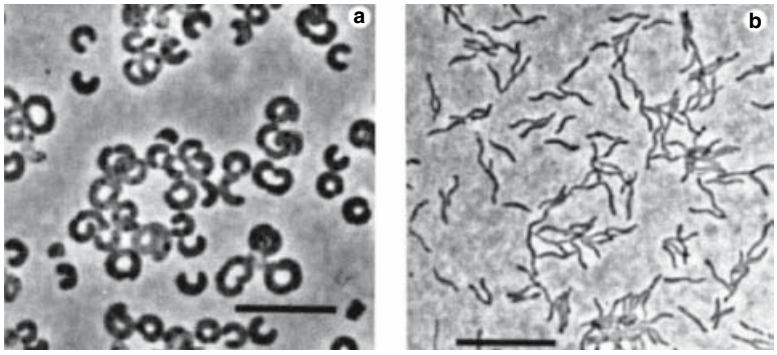

Fig. 2. The morphology of the two *Rhodocyclus* species; phase contrast microscopy. (a) *Rhodocyclus purpureus*; (b) *Rhodocyclus tenuis*. Bar = 10 µm.

Properties that enable the distinction and identification of the species of the genera *Rhodocyclus*, *Rhodoferax* and *Rubrivivax* are summarized in Table 1.

Preservation

For short-term preservation, late log-phase cultures may be kept in closed, air-tight screw-cap bottles at 6–10°C in a refrigerator or at room temperature for several months. Maintenance transfer of liquid cultures should occur at intervals of 2–6 months. For long-term storage, preservation in liquid nitrogen is recommended. Well-grown cultures are supplemented with 50% dimethyl sulfoxide to give a final concentration of 5%, thoroughly mixed, dispensed in plastic ampoules, sealed and frozen in liquid nitrogen.

Physiology

Most phototrophic β-Proteobacteria of the genera *Rhodocyclus*, *Rubrivivax* and *Rhodoferax* are mesophilic and neutrophilic fresh water bacteria with optimal growth temperatures of 25–30°C. *Rhodoferax antarcticus* has been isolated from Antarctic microbial mats and grows best at 12–20°C (Madigan et al., 2000). The species of *Rhodocyclus*, *Rhodoferax* and *Rubrivivax* are facultative anaerobic bacteria which preferably grow under anoxic conditions by anoxygenic photosynthesis. All species grow photoheterotrophically and most species are able to grow photoautotrophically with hydrogen as the photosynthetic electron donor. Under these conditions, the Calvin cycle is fully active. They all are able to grow aerobically to microaerobically in the dark by oxygen-dependent respiration. Under dark anaerobic conditions, most species slowly ferment their storage polysaccharides. Most pronounced fermenting capacities with external substrates were recorded for *Rubrivivax gelatinosus* (Gürgün et al., 1976) and *Rhodoferax fermentans* (Hiraishi et al., 1991).

They are true "nonsulfur" bacteria in being unable to use reduced sulfur compounds as photosynthetic electron donors and consequently cannot form elemental sulfur globules either in or outside their cells. All species are capable of assimilatory sulfate reduction, as far as tested via adenosine-5′-phosphosulfate (Imhoff, 1982).

Rhodocyclus

Cells grow well with simple organic compounds as electron donors and carbon sources and in complex media containing peptone, yeast extract or casamino acids. Photoautotrophic growth with hydrogen and photoheterotrophic growth with a variety of carbon compounds as electron donors are possible. Chemotrophic growth is possible by respiration under microoxic to oxic conditions in the dark and by fermentation.

Rhodocyclus purpureus assimilates only a few carbon compounds, but is capable of anaerobic degradation of aromatic compounds. Benzoate and cyclohexane carboxylate are both used, which may indicate the same pathway for anaerobic benzoate degradation is used by *Rhodocyclus purpureus* and *Rhodopseudomonas palustris* (Dutton and Evans, 1969; Pfennig, 1978; Gibson and Harwood, 1995). *Rhodocyclus tenuis* is more versatile with respect to carbon source utilization, although it is unable to break down aromatic compounds.

A requirement of vitamin B_{12} is not common among the purple nonsulfur bacteria (PNSB). Besides *Rhodocyclus purpureus*, only single strains of *Rhodocyclus tenuis* and *Rhodopseudomonas palustris* (Siefert and Koppenhagen, 1982) and a few more species have been reported to require vitamin B_{12}.

Rhodocyclus purpureus and *Rhodocyclus tenuis* also differ significantly in their nitrogen nutrition. Whereas the former species uses only ammonia and glutamine as nitrogen sources and is unable to fix dinitrogen (a property common to most species of the phototrophic α- and β-Proteobacteria), the latter species utilizes a greater number of amino acids as well as urea, dinitrogen, yeast extract, peptone and casamino acids (Masters and Madigan, 1983). Alanine dehydrogenase was absent from both species. Glutamate dehydrogenase (NADPH-dependent) is found in *Rhodocyclus purpureus* in high activities under all growth conditions, and the glutamine synthetase inhibitor methionine sulfoximine exerts no growth inhibition. This may be taken as an indication that the major route of nitrogen assimilation in *Rhodocyclus purpureus* is via glutamate dehydrogenase (unlike that in all other investigated PNSB). *Rhodocyclus tenuis* employs the glutamine synthetase/glutamate synthase (NADPH-dependent) pathway—as found in most phototrophic PNSB—for the assimilation of ammonia (Masters and Madigan, 1983; Drews and Imhoff, 1991).

Rubrivivax

Cells grow well with simple organic compounds as electron donors and carbon sources and in complex media containing peptone, yeast extract or casamino acids. Photoautotrophic growth occurs with hydrogen and photoheterotrophic growth with a variety of carbon compounds as electron donors. Chemotrophic growth is possi-

ble by respiration under microoxic to oxic conditions in the dark and by fermentation.

A characteristic property of *Rubrivivax gelatinosus*, shared only with a few other phototrophic purple bacteria, is the hydrolysis of gelatin owing to an extracellular protease (Klemme and Pfleiderer, 1977). *Rubrivivax gelatinosus* grows well with citrate as carbon source and thereby excretes large amounts of acetate into the medium, which serves as carbon source after citrate is exhausted (Schaab et al., 1972). Citrate lyase, the key enzyme for growth on citrate, has been characterized in this species (Giffhorn et al., 1972; Beuscher et al., 1974). However, because the other key enzyme, malate synthase, is lacking in acetate-grown cells, the glyoxylate cycle does not function and the serine-pathway has been proposed to be used for acetate assimilation in this species (Albers and Gottschalk, 1976). *Rubrivivax gelatinosus* also can be adapted to grow with CO as sole energy and carbon source under anoxic conditions in the dark (Uffen, 1976). Under these conditions, activities of enzymes of the serine pathway and ribulose bisphosphate carboxylase are enhanced (Uffen, 1983).

Rhodoferax

Growth is possible by photosynthesis, aerobic respiration, and fermentation. Photoheterotrophy with various organic compounds as carbon sources is the preferred mode of growth. Cells grow well with simple organic compounds as electron donors and carbon sources and in complex media containing peptone, yeast extract or casamino acids.

Fermentative growth of *Rhodoferax fermentans* in darkness occurs on pyruvate and sugars, among which fructose is the best substrate (Hiraishi and Kitamura, 1984b). *Rhodoferax fermentans* rapidly produces acid from glucose. The addition of bicarbonate enhances anaerobic growth in the dark significantly (Hiraishi, 1988a). The end products of fructose fermentation are acetate, formate, lactate, succinate and ethanol. Hypophosphite, a potent inhibitor of pyruvate-formate lyase, suppresses the production of formate completely and increases the amount of succinate excreted. These observations suggest that the bicarbonate-dependent fermentative growth may be linked to CO_2 fixation via part of the reductive tricarboxylic acid (TCA) cycle and the subsequent reduction of fumarate to succinate. The guanine diphosphate (GDP)-dependent phosphoenolpyruvate carboxykinase was suggested to function as a key enzyme for CO_2 fixation (Hiraishi, 1988b).

While several species of phototrophic purple nonsulfur bacteria exhibit anaerobic growth in darkness coupled with reduction of trimethylamine-*N*-oxide or dimethylsulfoxide as the terminal electron acceptor, *Rhodoferax fermentans* lacks these properties. Most strains of this species also are devoid of nitrate reductase activity, though one of the strains assigned to this species (strain DSM 10139) is highly active in nitrate reduction (Hougardy and Klemme, 1995).

Rhodoferax antarcticus, like *Rhodoferax fermentans*, can grow well with glucose and fructose, but is unable to ferment these substrates (Madigan et al., 2000).

Applications

The frequent occurrence of *Rhodocyclus*, *Rubrivivax* and *Rhodoferax* species in sewage treatment plants and lagoons (Siefert et al., 1978; Pfennig, 1978) points towards a function and possible application of these bacteria for the treatment of sewage. Sasaki et al. (1981) have developed a successful process for single-cell protein production from soybean wastes using *Rubrivivax gelatinosus*. Processes of single-cell protein production with *Rubrivivax gelatinosus* also have been developed using the agricultural byproduct wheat bran as carbon substrate (Shipman et al., 1975; Shipman et al., 1977).

CHAPTER 3.2.2

The *Neisseria*

DANIEL C. STEIN

Introduction

The genus *Neisseria* includes a group of closely related Gram-negative diplococci that are primarily commensal organisms of the mucous membranes of mammals (Knapp, 1988a). Several *Neisseria* spp. are opportunistic pathogens causing disease in immunocompromised hosts. Two species, *N. gonorrhoeae* (the gonococcus) and *N. meningitidis* (the meningococcus), are important human pathogens.

Phylogeny

Species Groups

While the 1994 edition of *Bergey's Manual of Determinative Bacteriology* lists 13 species within the genus, the systematics of *Neisseria* have been problematic, and strains have been frequently reclassified as new techniques have become available. DNA-DNA hybridization techniques, numerical taxonomy procedures (Barrett and Sneath, 1994) and sequence analysis of various genes (Smith et al., 1999) have divided the *Neisseria* into two subgroups: 1) the closely related pathogens *N. gonorrhoeae* and *N. meningitidis*, a related group of commensal *Neisseria* species that have been consolidated into the species *N. subflava* (Reyn, 1974) and *N. lactamica* (Hollis et al., 1969); and 2) a group of commensal organisms isolated from man and other animals (*N. cinerea*, *N. polysaccharea*, *N. canis*, *N. denitrificans*, *N. elongata*, *N. macacae*, *N. animalis*, *N. dentiae* and *N. weaveri* (Andersen et al., 1993; Bovre and Holten, 1970; Dent, 1982; Dewhirst et al., 1993; Sneath and Barrett, 1996). However, recent data have shown that while most *Neisseria* species can be separated into groups of related species, the relationship among and between species is distorted by interspecies recombination (Smith et al., 1999).

Relation to Phenotypic Characteristics

Phylogenetic analyses by rRNA similarities and DNA-DNA hybridizations have placed *N. meningitidis*, *N. gonorrhoeae*, *N. lactamica* and *N. cinerea* in a subgroup with particularly close interspecies relatedness (Guibourdenche et al., 1986; Kingsbury, 1967; Rossau et al., 1989). While these bacteria are closely related, they express very different pathogenicities. *Neisseria lactamica* and *N. cinerea* are typically nonpathogenic; *N. meningitidis* is an opportunistic pathogen and *N. gonorrhoeae* is an obligate pathogen. When *N. meningitidis* colonizes the nasopharynx, it does not cause disease. However, it may spread from there into the bloodstream, causing septicemia before crossing the blood-brain barrier to induce meningitis. *Neisseria gonorrhoeae* colonizes and invades the epithelium of the genitourinary tract, causing a localized inflammatory response.

Classification Errors and Problems

The species currently classified in the genus *Neisseria* are naturally competent for DNA uptake. As such, the genomes of these organisms are continually exposed to exogenous DNA. Using the pattern of nucleotide sequence variation among defined genes as a mechanism of classifying strains within the species has produced different genotypic relationships, depending on the gene used for the classification (Smith et al., 1999). These data indicate that the human commensal *Neisseria* spp. can be separated into discrete groups of related species but that the relationships both within and among these groups, including those reconstructed using 16S rRNA, can be distorted by interspecies recombination events. Proper speciation requires the analysis of multiple genes or the use of multiple classification methods.

Current Species

The genus *Neisseria* currently contains the following species: *N. gonorrhoeae*, *N. meningitidis*, *N. lactamica*, *N. cinerea*, *N. sicca*, *N. subflava*, *N. flavescens*, *N. mucosa*, *N. canis*, *N. denitrificans*, *N. elongata*, *N. polysaccharea*, *N. macacae*, *N. animalis*, *N. dentiae* and *N. weaveri*.

Habitat

In Humans

The *Neisseria* spp. colonize the mucosal surfaces of mammals. The nonpathogenic *Neisseria* spp. are part of the normal flora of the oro- and nasopharynx and are rarely isolated from other sites. Owing to taxonomic and methodologic problems, the prevalence of *Neisseria* spp. cannot be assessed accurately from the literature of early studies. However, when one examines the nature of the species identified, two types of Neisserial colonization were detected: heavy colonization with strains of the saccharolytic species (*N. perflava*, *N. sicca* and *N. mucosa*) and sparse colonization with many different species (Knapp, 1988a; Knapp and Hook, 1988b).

Only *N. gonorrhoeae* is considered to be always pathogenic. *Neisseria gonorrhoeae* causes the sexually transmitted disease gonorrhea. This disease is most frequently manifested as a localized infection of the columnar epithelial cells of mucosal surfaces, i.e., urethra, cervix, rectum, pharynx and eye; squamous epithelial cells are not susceptible to infection by gonococci. Pharyngeal and rectal infections are frequently asymptomatic. The organism is transmitted principally through sexual activities. Ocular infections with *N. gonorrhoeae* are seen most commonly in neonates, whose infections are acquired during passage through an infected birth canal.

Strains of *N. meningitidis* may colonize the oro-and nasopharynx. The organism may be asymptomatically carried by up to 25 percent of a population, where only a few of the infected individuals will go on to develop invasive disease (Hart and Rogers, 1993). The organism is transmitted principally by respiratory droplets from the nose and throat of an infected person. It can cause sudden serious illness and death in a previously healthy person, and as a consequence, meningococcal disease often causes considerable anxiety and even panic in the community. For many years, epidemics were believed to be more likely when the carriage rate rose above 20 percent, but now carriage rates at these levels and the beginning of epidemics do not appear to be associated (Apicella, 1995).

Neisseria lactamica frequently is isolated in children, but infrequently in adults. Correct identification of this species is important because it is able to grow on gonococcal selective media and may be misidentified as *N. gonorrhoeae* if inappropriate differential tests are performed to distinguish between these species. Strains of *N. cinerea* are more prevalent than previously recognized, probably because strains occur in small numbers in the oropharynx and are overgrown in cultures of specimens inoculated on nonselective media such as blood agar (Knapp, 1988a).

Most of the other commensal *Neisseria* spp. have been recognized as opportunistic pathogens. While the significance of the diseases caused by commensal organisms may be life threatening, the incidence of disease is quite low. Septic shock cases have been reported for *N. flavescens* (Quintero Otero et al., 1990). Strains of *N. mucosa* have been isolated from children with pneumonia and adults with endocarditis (Lechowski et al., 1995; Véron et al., 1959). Strains of *N. lactamica* have caused meningitis, septicemia or otis media (Denning and Gill, 1991; Orden and Amerigo, 1991). Strains of *N. cinerea* have been isolated from individuals suffering from proctitis, meningitis, septicemia, pneumonia and conjunctivitis (Dolter et al., 1998; Dossett et al., 1985; Kirchgesner et al., 1995). *Neisseria sicca* has been reported to cause meningitis, peritonitis, endocarditis, pneumonia, Bartholin's gland abscess and osteomyelitis (Gris et al., 1989; Lopez-Velez et al., 1994). *Neisseria subflava* has been associated with abscesses, meningitis, peritonitis and endocarditis (Berger and Muller, 1973; Denis et al., 1970; Scott, 1971; Vermeij et al., 1999).

In Animals

Neisseria also may colonize the mucosal membranes of animals. *Neisseria animalis* has been isolated from guinea pigs (Berger, 1960), *N. canis* from the throats of dogs (Berger, 1962), and *N. macacae* from the throats of rhesus monkeys (Vedros et al., 1983); *N. mucosa* has been isolated from dolphins (Vedros et al., 1973). Dent (1982) characterized 97 isolates of *Neisseria* spp. in dental plaque from 15 species of animals, including a variety of primates (five species), tenrecs, yaks, deer, kangaroos, llamas, black bears, panda bears, sheep, dairy cattle and domestic cats. Isolates were assigned to one of three clusters of organisms differentiated on the basis of acid production from maltose and polysaccharide production. Although nitrate reduction was determined, this characteristic was not used as a differential characteristic to define physiologic groups. While Dent (1982) did not attempt to identify isolates to the species level because the criteria for describing species overlapped, this study indicates that *Neisseria* spp. are inhabitants of a wide variety of animal species.

Isolation

Strains of *N. gonorrhoeae* and *N. meningitidis* may be detected, isolated and identified with similar procedures. Strains of both species are

fastidious and are susceptible to unfavorable environmental factors such as desiccation, heating or chilling, the action of autolytic enzymes, and acid and alkaline conditions. In addition, strains of both species require a CO_2-enriched atmosphere for primary isolation, although the supplemental CO_2 often is not required on subculture.

Neisseria gonorrhoeae

This nutritionally fastidious organism requires an enriched medium in a moist environment of 35–37°C with an atmosphere of 3–5% CO_2 for growth. Growth of *N. gonorrhoeae* from clinical specimens has been enhanced by the use of selective media that inhibit the simultaneous growth of other microorganisms (Thayer and Martin, 1966). Some gonococcal strains are susceptible to vancomycin and, consequently, may not grow on selective media (Windall et al., 1980). The gonococcus does not grow well in the presence of commensal organisms, and small numbers may be present in clinical material (Kraus et al., 1976). Optimum recovery of *N. gonorrhoeae* from endocervical specimens in women is achieved by direct inoculation of a selective gonococcal agar medium with direct incubation at 35°C in CO_2 (Knapp and Rice, 1995). However, the direct plating technique is not always practical, or even feasible, in some clinical facilities. To circumvent this need, specialized transport systems have been developed to allow for the transport of the test sample to an appropriately equipped clinical laboratory (Arbique et al., 2000).

The specimens selected for diagnosing gonorrhea depend on the gender, age and sexual preference of the patient. All specimens should be collected prior to the initiation of antimicrobial therapy. Urethral and cervical specimens routinely are collected from men and women, respectively. Isolation of the gonococcus from specimens obtained from the urethra and Skene's and Bartholin's glands of women also may be attempted. In addition, rectal and oropharyngeal specimens are collected from women and homosexual men; in 5–10% of women, the rectum may be the only site from which the gonococcus may be isolated.

While culture is routinely used for the laboratory diagnosis of gonorrhea in men, a presumptive diagnosis of gonorrhea may be made by performing a Gram stain of purulent materials and observing polymorphonuclear leukocytes and intracellular Gram-negative diplococci. Presumptive diagnosis based on culture results may be made by isolating colonies that contain Gram-negative, oxidase-positive diplococci on selective media inoculated with urethral, cervical or rectal specimens. Blood cultures and cultures of synovial aspirates or skin lesions should be attempted for patients with suspected disseminated gonococcal infection (DGI); blood should be inoculated directly into a blood culture medium.

Neisseria meningitidis

To isolate *N. meningitidis*, samples are taken from the nasopharynx, blood, cerebrospinal fluid and skin lesions and cultured on an enriched, selective medium such as modified Thayer-Martin medium (MTM) or Chocolate agar grown under increased carbon dioxide tension (Creitz et al., 1971). Medium to large, blue-gray, mucoid, convex colonies form in 48 h at 35–37°C.

Confirmation of the diagnosis of invasive meningococcal disease requires bacteriological isolation of *N. meningitidis* from a usually sterile site such as blood or cerebrospinal, synovial, pericardial or pleural fluid or from a petechial or purpuric lesion. A presumptive diagnosis is suggested by finding Gram-negative diplococci in cerebrospinal or synovial fluid or the aspirate from a petechial or purpuric lesion. Because *N. meningitidis* can be part of the normal flora of the nasopharynx and conjunctiva (Gold et al., 1978), isolation of this organism from a throat swab, nasopharyngeal aspirate, or conjunctival swab provides no information about the cause of the invasive disease.

Other *Neisseria* Species

Commensal *Neisseria* spp. have been isolated on blood agar medium (Berger and Wulf, 1961). Because blood agar is not selective, many *Neisseria* isolates may be overgrown by other bacteria that are normal flora in the sites from which the specimens are taken. A selective differential medium (LBVT.SNR) has been developed for the isolation of all *Neisseria* spp. that could grow on a simple nutrient medium. Through the incorporation of sucrose and an indicator in this medium, it is possible to differentiate colonial types of several strains of the same species present in a specimen (Knapp and Hook, 1988b). *Neisseria* spp. associated with animals have not been studied to the same extent as the human species. However, similar to studies of the human species, *Neisseria* spp. from animals have been isolated on blood agar (Berger, 1962).

Identification

Neisseria spp. are not very biochemically active. Most species are asaccharolytic or use relatively few carbohydrates and exhibit few other differ-

ential biochemical reactions. Not many tests are available that differentiate between species, particularly the species associated with animals. Many of the traditional differential biochemical reactions for human *Neisseria* spp. have been incorporated in rapid tests that allow one to determine if the isolate is a gonococcus, a meningococcus or another species. Serological (Menck, 1976) and nucleic acid probe tests have been developed to identify strains of *N. gonorrhoeae* (Black and Morse, 2000). Accurate identification is important because the misidentification of nongonococcal species as *N. gonorrhoeae* may have serious medicolegal implications.

Tests for the identification of *Neisseria* and related species include traditional biochemical tests that must be incubated for 24–48 h before results can be obtained (McDonald and Johnson, 1975) and rapid tests that permit the identification of *Neisseria* spp. after incubation for 2–4 h (Young et al., 1976). However, some isolates may not be identified correctly using rapid tests that lack the specific biochemical test critical for the accurate identification of an isolate. It is important to note, also, that many rapid tests may only be used to identify Gram-negative, oxidase-positive isolates that were isolated on gonococcal selective media. Other rapid tests may be used to identify isolates to the species level regardless of the medium on which they were isolated. Thus, the choice of a specific confirmation test will depend on the clinical or legal significance of an isolate and whether a "presumptive" or confirmed identification is required (Whittington et al., 1988).

Morphology and Colonial Characteristics

The *Neisseria* spp. are Gram-negative diplococci which typically grow in pairs or occasionally grow in tetrads or clusters (Fig. 1). With the exception of *N. elongata*, which are coccobacilli, the *Neisseria* spp. are readily distinguished by their characteristic kidney-bean shaped cells arranged with flattened adjacent sides. Individual cells range in size from 0.6–1.0 μm; strains of some species may form giant cells (Berger, 1963). Flagella and swimming motility are absent, but most species can be piliated and show "twitching motility" (Henrichsen, 1975).

Colony morphology varies among the different species and ranges from small, smooth, transparent, butyrous colonies to wrinkled, dry adherent colonies (Reyn, 1974). Gonococcal and meningococcal strains tend to be nonpigmented; pigmentation has little taxonomic value because pigment expression is highly dependent on growth conditions. Many species have the ability to variably express different surface components, and these changes can be recognized by changes in colony morphology. For example, gonococci grown on clear agar-based medium form colonies that exhibit diversity with respect to size, edge morphology and light refractivity. Figure 2 demonstrates some of the difference in colony morphology when pili are expressed (piliated, T1 or T2) or when pili are absent (non-piliated, T3

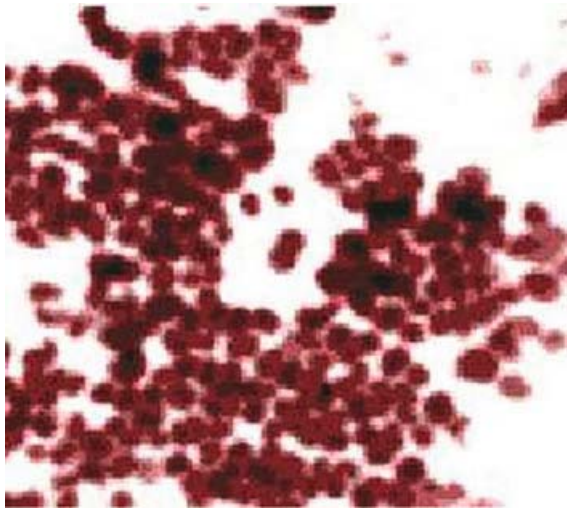

Fig. 1. Gram stain of *Neisseria gonorrhoeae* strain F62.

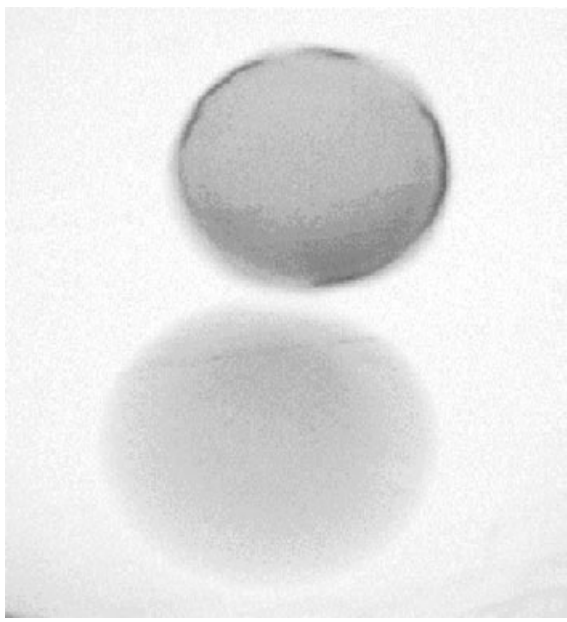

Fig. 2. Colony morphology variation due to the presence or absence of pili. The colonies were visualized under a dissecting microscope using light refracted with a sintered glass filter. The colony on the top represents a piliated colony, while the one on the bottom represents a non-piliated colony.

or T4 organisms). Variation in colony morphology also has been observed in other species and cannot be used as a differential character for the identification of *Neisseria* spp.

Strains of *N. meningitidis*, *N. lactamica*, *N. cinerea* and *N. polysaccharea* grow as translucent, nonpigmented colonies that closely resemble the gonococcus on isolation media (Morello et al., 1985). The colonies observed in young cultures (16–18 h) of most strains are smooth but may become sticky due to lysis of the cells with prolonged incubation. Strains of the *N. subflava*, *N. sicca* and *N. mucosa* are generally colistin-susceptible and do not grow on gonococcal isolation media. The colonies of most commensal strains are pigmented or opaque. The colonies of older cultures (>48 h) of *N. sicca* strains may be distinctly wrinkled.

Biochemical Characterization

Table 1 provides a list of traditional tests used to identify strains of *N. gonorrhoeae*.

Nucleic Acid Probes

The microbiological diagnosis of gonorrhea based on culture on selective medium produces about 80–95% sensitivity, with false-negative results attributed to poor specimen storage, transport problems, and inhibition of growth by the components of selective media (Hook and Handefield, 1990). As an alternative diagnostic test, DNA hybridization techniques have been developed and offer the promise of eliminating transport and specimen collection issues, which are believed to affect test sensitivity in the field setting.

Since 1992, two new nucleic acid-based tests for the diagnosis of gonococcal infection have been approved by the United States Food and Drug Administration (Gen-Probe Pace 2 and Abbott LCR). These nucleic acid hybridization tests are based on the ability of complementary nucleic acid strands to specifically align and associate to form stable double-stranded complexes with their target seqeunces. The GEN-PROBE PACE 2C System uses single-stranded DNA probes with chemiluminescent labels that are complementary to the ribosomal RNA of the target organisms. After the ribosomal RNA is released from the organisms, the labeled DNA probes combine with the ribosomal RNA of the target organisms to form stable DNA:RNA hybrids. The labeled DNA:RNA hybrids are separated from the nonhybridized probes and the amount of signal retained by the test sample is measured in a luminometer. The sensitivity for detecting *N. gonorrhoeae* infections with this system is ~96%, with a specificity of 99% (Iwen et al., 1995).

The ligase chain reaction (LCR) is an in vitro nucleic acid amplification technique that exponentially amplifies targeted DNA sequences. This assay amplifies target sequences within the *N. gonorrhoeae* opacity gene. The sensitivity for detecting *N. gonorrhoeae* infections using the LCR assays is also quite high, ~98% sensitivity, with a specificity of 99.7% (Ching et al., 1995).

Table 1. Differential characteristics of *Neisseria* spp.

Species	Acid from						Nitrate reduction	Polysaccharide from sucrose	DNAse	Colistin resistance
	G	Ma	Su	F	Mn	L				
N. gonorrhoeae	+	–	–	–	–	–	–[a]	–	–	R
N. meningitidis	+	+	–	–	–	–	–[a]	–	–	R
N. lactamica	+	+	–	–	–	+	+	–	–	R
N. cinerea	–	–	–	–	–	–	+	–	–	R
N. sicca	+	+	+	+	–	–	+	+	–	S
N. subflava	+	+	d	d	–	–	+	+/–	–	S

Symbols: +, present; and –, absent.

Abbreviations: G, glucose; Ma, maltose; Su, sucrose; F, fructose; Mn, mannitol; L, lactose; R, resistance; S, susceptibility; S/R, some strains are resistant and some are sensitive; and d, delayed reaction.

[a]Reduction can occur on low levels of nitrate; higher levels are toxic.

Preservation

Pathogenic species of *Neisseria* are notoriously difficult to maintain in a viable state for long storage periods (Cody, 1978). Storage at 4°C quickly leads to loss of viability. Freeze-drying is a convenient method for long-term storage of these organisms; however, many laboratories are not properly equipped to use this method. Long-term storage of Neisserial strains typically is achieved by suspending cells in trypticase soy broth supplemented with 15% glycerol, with subsequent freezing and storage of cells at –60°C or lower. *Neisseria gonorrhoeae* and *N. meningitidis* remain viable for up to 6 months when resuspended in a gelatin-based media, with storage at –20°C (Harbec and Turcotte, 1996).

Physiology

Metabolism

Oxygen Requirements *Neisseria gonorrhoeae* has been isolated from body sites where anaerobes can be isolated, suggesting that the gonococcus can grow under reduced oxygen tensions. *Neisseria gonorrhoeae* has been shown to grow anaerobically in the laboratory when provided with nitrite as a terminal electron acceptor for anaerobic respiration (Knapp and Clark, 1984a). Because nitrite is present in biological fluids, the ability to grow aerobically or anaerobically by anaerobic nitrite respiration may be one of the factors responsible for the diversity of body sites from which gonococci can be isolated. The gonococcus possesses a copper-containing nitrite reductase (AniA) in its outer membrane (Householder et al., 2000), whose expression is tightly regulated by oxygen (Hoehn and Clark, 1992b). The AniA is essential for growth and survival of gonococci in oxygen-depleted environments (Mellies et al., 1997). Gonococci cannot grow anaerobically by fermentation, and it is likely that the reduction of nitrite must be essential to the maintenance of the redox potential of the cell. Nitrite is reduced by all *Neisseria* spp. isolated from humans with the possible exception of some serogroups of *N. meningitidis* and some strains of *N. lactamica*, *N. cinerea* and *N. polysaccharea* (Morse and Knapp, 1987).

At least three gonococcal outer-membrane proteins (OMPs) are induced and at least five OMPs are repressed by anaerobic growth in gonococcal strain F62. In addition, AniA (formerly Pan1) is the major anaerobically induced OMP and its expression is restricted to anaerobically grown cells (Clark et al., 1987). The presence of antibodies in serum samples from patients with gonorrhea that react with one or more of the anaerobically induced proteins provides further evidence that gonococci are growing anaerobically in vivo (Clark et al., 1988).

Superoxide dismutase is thought to be ubiquitous in aerobes and a requirement for aerobic life (Fridovich, 1975). Gonococci are an apparent exception to this rule. Among aerotolerant cells, the gonococcus is unusual because despite its frequent isolation from purulent exudates containing polymorphonuclear leukocytes vigorously evolving O_2^- and H_2O_2, it contains no superoxide dismutase (SOD). The absence of SOD from *N. gonorrhoeae* strains has been demonstrated under a variety of oxygen-stress conditions. The high tolerance of *N. gonorrhoeae* for extracellular O_2^- and H_2O_2 appears to be due to very high constitutive levels of peroxidase and catalase activity combined with a cell envelope impervious to O_2^- (Archibald and Duong, 1986). Meningococci and the nonpathogenic *Neisseria* spp. differ from the gonococcus in that they possess SOD (Norrod and Morse, 1979).

Among the Neisseriae, *N. gonorrhoeae* is unusual in that the vast majority of strains produce large amounts of catalase (Archibald and Duong, 1986). Gonococci have catalase levels that are 50–5,000 times greater than those of *N. meningitidis* and the other *Neisseria* spp. (Norrod and Morse, 1979). The high catalase levels in gonococci may be partially responsible for its ability to survive aerobically in the absence of SOD. It has been hypothesized that the large amounts of catalase produced by *N. gonorrhoeae* effectively convert H_2O_2 into water and molecular oxygen, affording the organism direct protection against damage by H_2O_2 and indirect protection against damage by hydroxyl radicals formed from H_2O_2 produced by phagocytes (Hassett and Cohen, 1989). The ability to produce high levels of catalase also improves the survival of *N. gonorrhoeae* in the presence of H_2O_2-producing strains of *Lactobacillus acidophilus*, which suggests that catalase may contribute significantly to the ability of *N. gonorrhoeae* to colonize tissues of the female genital tract (Zheng et al., 1994).

Carbon Dioxide Requirement The gonococcus and the meningococcus both require an increased CO_2 tension for isolation from clinical specimens (Griffin and Racker, 1956; Tuttle and Scherp, 1952). *Neisseria gonorrhoeae* strains vary widely in their requirements for CO_2 and/or the HCO_3^- anion. Incubation in the presence of ambient CO_2 tends to maximize the growth response on solid medium of those strains that require it for growth. With a broth culture, $NaHCO_3$ (0.009 M) greatly reduces the lag phase and also increases the total growth (Talley and Baugh, 1975). The presence of ambient CO_2 is

particularly important if growth is to be obtained after the plating of small inocula. Medium containing 0.1% $NaHCO_3$, if incubated in a closed environment, appears to be equivalent to medium without bicarbonate incubated in ambient CO_2 in supporting the growth of some but not all strains of *N. gonorrhoeae* (Jones and Talley, 1977). The requirement for CO_2 is often lost on subculture (Platt, 1976).

The stimulatory effect of exogenous CO_2 or bicarbonate is linked to the initiation of growth and is most apparent during the lag phase. The amount of exogenous CO_2 required varies inversely with the size of the inoculum, suggesting that cellular metabolism can contribute to the CO_2 pool. Carbonic anhydrase is known to be involved in the assimilation of CO_2 by *Neisseria* spp. This enzyme has been cloned and characterized and is homologous to carbonic anhydrases from the animal kingdom (Chirica et al., 1997). Phosphoenolpyruvate (PEP) also can be carboxylated by the gonococcus (Cox and Baugh, 1977; Jyssum and Jyssum, 1962).

Carbohydrate Metabolism Much of our knowledge of intermediary metabolism in the Neisseriaceae has come from studies done in the 1970s and has been summarized in several reviews (Chen et al., 1989; Morse, 1976; Morse et al., 1977). From these studies it has been shown that *Neisseria* spp. do not catabolize many carbohydrates and some species (*N. cinerea*, *N. flavescens* and *N. elongata*) are asaccharolytic (Knapp et al., 1984c). Glucose is the only carbohydrate that can be used as an energy source by the gonococcus. The disaccharides maltose, lactose and sucrose are used by several *Neisseria* spp., and their utilization has been used as an aid in speciating isolates of *Neisseria* (White and Kellogg, 1965).

Amino Acid Metabolism The biosynthesis of amino acids by *Neisseria* spp. occurs by pathways similar to those in other microorganisms. The *Neisseria* spp. vary widely with respect to their amino acid requirements. In general, the nonpathogenic *Neisseria* spp. are able to grow in a defined medium containing one to five amino acids (McDonald and Johnson, 1975). The amino acid requirements of the pathogenic species are more complex. Amino acid requirements have been used to differentiate among isolates (auxotyping) for epidemiologic purposes (Carifo and Catlin, 1973). Auxotyping data have been useful in elucidating some of the pathways of amino acid biosynthesis in the gonococcus by demonstrating that the requirement for certain amino acids is associated with spontaneous mutations in genes encoding enzymes involved in the biosynthesis of amino acids (Lerner et al., 1980; Shinners and Catlin, 1978). While the arginine biosynthetic pathway is probably the best characterized of all of the amino acid biosynthetic pathways (Martin et al., 1990; Martin and Mulks, 1992; Picard and Dillon, 1989), most *Neisseria* biosynthetic pathways are genetically quite similar (Zhou and Spratt, 1992) and seem to share properties seen for most bacteria (Jyssum, 1992).

Most *Neisseria* spp. are able to grow with sulfate as a unique source of sulfur. However, while a few strains of *N. meningitidis* require cysteine, the need for cysteine (which can be satisfied by thiosulfate) is linked to the lack of sulfite-reducing-activity (Le Faou, 1984). The gonococcus exhibits an absolute requirement for cysteine (or cystine; Catlin, 1973).

Amino acids can be used as energy and carbon sources by many *Neisseria* spp. via their oxidation by the tricarboxylic acid (TCA) cycle (Hebeler and Morse, 1976a). Glutamate, proline, and to a lesser extent aspartate are the preferred amino acids (Holten, 1973; Holten, 1976; McDonald and Johnson, 1975). Glutamate dehydrogenase is a key enzyme in the catabolism of glutamate and proline, and all *Neisseria* spp. contain two species of glutamate dehydrogenase (Hebeler and Morse, 1976a; Holten, 1973).

Neisseria spp. posess aminopeptidases that are capable of hydrolyzing L-amino-acid-naphthylamide derivatives of various amino acids (D'Amato et al., 1978). Meningococcocci can be distinguished from gonococci by the presence of *N*-glutamyl aminopeptidase (Delmas et al., 1985). However, some of the nonpathogenic species (*N. mucosa*, *N. sicca*, *N. perflava*, *N. subflava* and *N. flava*) also produce *N*-glutamyl aminopeptidase (Hoke and Vedros, 1982; Riou et al., 1982).

Cellular Structures

Proteins These include the porins, opacity-associated proteins, the Opc protein, reduction-modifiable proteins, the H.8 protein, anaerobically induced proteins, other membrane proteins, iron-binding proteins, IgA protease and RTX homologs.

Porins The porins are the most abundant outer-membrane proteins on the Neisserial surface. Most *Neisseria* spp. express only one type, referred to as "Por"; the meningococcus is an exception, expressing two, PorA and PorB. The gonococcus is the only other *Neisseria* spp. known to have a *porA* gene, but this gene is not expressed owing to frameshift and promoter mutations (Feavers and Maiden, 1998). Although Por is antigenically diverse among strains, its expression is thought to be stable

within a given strain. Thus it exhibits allelic variability. These properties make the gonococcal porin an excellent marker for strain classification and epidemiologic studies. Immunological and biochemical data have determined that there are structural variants of the porin, allowing for their use in classification systems (the serovar typing system is based on reactivity to a panel of Por-specific monoclonal antibodies; Knapp et al., 1984b).

The nomenclature for Por has changed over the years. Initially, all meningococci were described as expressing either a class 2 or a class 3 outer-membrane protein (OMP), and most strains also express a class 1 OMP (P1 protein). The class 1 OMP has been named "PorA," and its gene has been designated "*porA*." Similarly, the class 2 and class 3 OMPs have been named "PorB" and their gene has been designated "*porB*." The amino acid sequences of PorA and PorB do not vary within an isolate, but sequence differences may be used to differentiate strains. The antigenic variety of meningococcal PorB and PorA proteins forms the basis of serotyping and serosubtyping, respectively (Abdillahi and Poolman, 1988; Frasch et al., 1985).

In the gonococcus, Por was originally described as Protein 1 (PI). It is now known that this protein is similar to the *porB* locus of the meningococcus. In the gonococcus, it has been shown to function as an anion-selective porin allowing the passage of small molecules through the outer membrane. The general structure of Por consists of nine internal conserved regions separated by eight surface-exposed regions that are highly variable in both amino acid sequence and length (Carbonetti et al., 1988). Constitutively expressed at high levels in all gonococci, Por is surface-exposed and elicits a strong immune reaction during infection (Ison, 1988).

Alleles of this locus in *N. gonorrhoeae* have been assigned to two homology groups based on close sequence and immunological relationships and are designated as either "PIA" or "PIB" (Carbonetti et al., 1988). These two homology groups differ in molecular weight, susceptibility to proteolysis, and antigenic reactivity. Alleles within each group are much more similar to each other than they are to members of the other group (i.e., PIA and PIB form distinct monophyletic groups which predate the splitting of species within the genus Neisseria), and individual *N. gonorrhoeae* strains express either a PIA or a PIB allele (Smith et al., 1995).

The meningococcal and gonococcal porins are candidates for inclusion in vaccines. They also can induce a T-cell dependent response toward normally T-cell independent antigens (e.g., polysaccharide) in both humans and mice (Donnelly et al., 1990). Many laboratories have characterized variants from many strains, resulting in the availability of DNA sequence for many genes. A three-dimensional structural homology model for *Neisseria* porins has been generated. The data indicate that the protein possesses a 16-strand β-barrel fold characteristic of porins (Derrick et al., 1999). The β-barrel structure is interspersed with more variable regions, forming the putative surface-exposed loops. This model has provided information on the spatial relationships of variable regions of peptide sequences in the PorA and PorB trimers and insights relevant to the use of these proteins in vaccines.

Gonococcal Por has been shown to translocate from the bacterial outer membrane into epithelial cell membranes at the site of contact between the bacteria and the cell membrane, suggesting that Por plays an active role in infection. Also, Por may impair neutrophil function by inhibiting phagocytosis, actin polymerization, the secretion of microbicidal enzymes, and opsonin receptor expression of stimulated neutrophils (Bjerknes et al., 1995; Haines et al., 1988; Haines et al., 1991). Gonococcal Por can inhibit phagosome maturation in human macrophages (Mosleh et al., 1998). Furthermore, translocation of porin to target cells leads to a Ca^{2+} influx, which promotes gonococcal invasion (Müller et al., 1999). The mechanism of Por immunopotentiating ability is unclear; however, in vitro studies have shown that purified Por can act as B-cell mitogens, inducing increased IgM secretion and B-cell proliferation (Wetzler et al., 1996). Mutagenesis of the *N. gonorrhoeae* porin reduces invasion in epithelial cells and enhances phagocyte responsiveness (Bauer et al., 1999).

The nucleotide sequence of Por from a number of *Neisseria* spp. has been examined. Alignment and analysis of all available Por sequences by use of the structurally conserved regions derived from the PorA and PorB structural models have allowed researchers to perform phylogenetic analysis. The phylogenetic relationships of the porin genes from most of the commensal and animal *Neisseria* spp. (*N. animalis*, *N. canis*, *N. cinerea*, *N. dentirificans*, *N. flavescens*, *N. flava* and *N. sicca*) indicate significant sequence variation, with many lineages emerging near the root. Phylogenetic analyses were consistent with an important role for horizontal genetic exchange in the emergence of different porin classes and confirmed the close evolutionary relationships of Por from *N. meningitidis*, *N. gonorrhoeae*, *N. lactamica* and *N. polysaccharea*. Only members of this group contained three conserved lysine residues, which form a potential guanosine triphosphate (GTP)-binding site implicated in pathogenesis. The model placed these residues on the inside of the pore, in close proximity, consistent with their role in regulating pore function

when inserted into host cells (Derrick et al., 1999).

Opacity-associated Proteins Colonies with markedly differing color and opacity characteristics were found when gonococci were propagated on translucent, solid medium. The optical properties were independent of piliation and appeared to be related to the degree of aggregation among the gonococci comprising the colonies. Dark, opaque colonies contained highly aggregated gonococci that were more susceptible to killing and to solubilization of their surface components than were organisms comprising light, transparent colony forms (Swanson, 1978a). Most, but not all, gonococcal Opa proteins are associated with pronounced colony opacity; there is no relationship between colony opacity and expression of Opa proteins in the meningococcus (Hagman and Danielsson, 1989). Gonococci from opaque colonies have cell-wall, outer-membrane proteins, which are lacking from organisms that form transparent colonies. These proteins exhibit heat modification of their apparent subunit molecular sizes, are easily extracted by deoxycholate, have apparent subunit molecular weights varying from 24–29 kDa, and are exposed on the surfaces of gonococci (Swanson, 1980). The opacity-associated proteins are more susceptible to hydrolysis by trypsin than is the major outer membrane protein (OMP), but gonococci possessing the opacity-associated protein(s) also show enhanced susceptibility of their major OMPs to the action of trypsin (Swanson, 1978b). In the older literature, these proteins were referred to as "Opacity proteins," "protein II," or "p.II" in the gonococcus and "Class 5 proteins" in the meningococcus. A standard nomenclature has been adopted and these proteins are now referred to as "opacity proteins" (Opa).

DNA sequence analysis of *opa* genes from a variety of Neisserial strains indicates that Opas have eight transmembrane β strands and four surface-exposed loops (Blake et al., 1981; Malorny et al., 1998). The two-dimensional structural model containing four surface-exposed loops was constructed based on rules derived from porin crystal structure and on conservation of sequence homology within transmembrane strands. In addition, a variety of epitopes recognized by monoclonal antibodies have been mapped to the surface loops (Malorny et al., 1998).

The Opa (opacity) proteins are a family of antigenic and phase-variable OMPs with a monomer molecular mass of approximately 28 kDa found in all *Neisseria* spp. (Stern and Meyer, 1987; Wolff and Stern, 1995). They play a critical role in the colonization, survival, transmission and pathology of Neisserial diseases. Multiple *opa* loci containing different *opa* alleles are scattered around the chromosomes of *N. gonorrhoeae* (11 to 12 *opa* loci; Bhat et al., 1991) and *N. meningitidis* (8 loci; Achtman et al., 1988; Aho et al., 1991).

The importance of Opa proteins in infection is demonstrated by the frequent Opa phase and antigenic variation observed during human infections (Hobbs et al., 1994; Jerse et al., 1994; Schmidt et al., 2000). Figure 3 shows variations in colony morphology due to changes in Opa expression. Intensive research on this area has allowed investigators to define the genetic basis for the variability seen in Opa expression. All *opa* genes sequenced to date contain a repeated pentameric sequence (CTCTT). Changes in the number of pentamers are responsible for the high-frequency phase variable expression seen for these genes (Stern et al., 1986). As a result, a given organism can reversibly express zero, one or multiple different Opa proteins (Blake and Gotschlich, 1984). In addition, among clonally related epidemic meningococcal isolates, there is greater variation of Opa protein expression than can be accounted for by the *opa* gene repertoire of any individual strain. Characterization of *opa* genes by DNA sequence analysis and Southern blot experiments of eight closely related isolates of serogroup A *N. meningitidis* (subgroup IV-1) from a recent meningitis epidemic in West Africa indicated that changes occurred in the *opa* genes of these bacteria as they spread through the human population over a relatively short period of time. The distribution of sequences present in hypervariable (HV) regions of the *opa* genes suggests that duplication of all or part of *opa* genes into other *opa* loci changed the repertoire

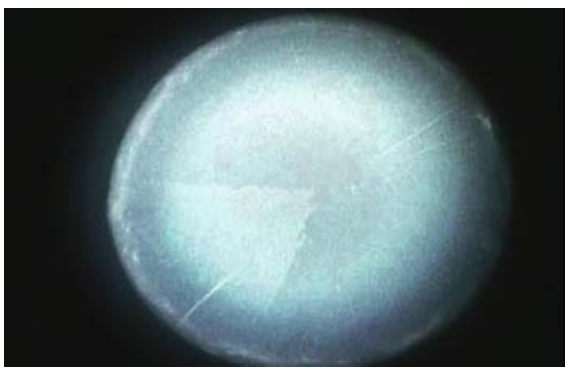

Fig. 3. Variation of Opa expression within a colony. Colonies expressing Opa give rise at high frequency to variants that no longer express Opa. These Opa minus variants appear transparent when the colony is visualized under a dissecting microscope with oblique light. In the colony shown here, the majority portion of the colony is expressing Opa.

of Opa proteins that could be expressed. Additional variability in this gene family appears to have been introduced by horizontal exchange of *opa* sequences from other meningococcal strains and from the gonococcus. These results indicate that processes of recombination and genetic exchange contributed to variability in major surface antigens of this clonal population of pathogenic bacteria (Hobbs et al., 1994).

The large array of Opa proteins provides the Neisserial cell with a diverse surface. Each Opa protein seems to bind to a specific receptor on a eukaryotic cell, with specific Opa proteins mediating adhesion and/or invasion of epithelial cells; different cell lines give different results for the same Opa, indicating that Opa expression is a determinant of cell tropism (Bessen and Gotschlich, 1986; Bos et al., 1997; Grant et al., 1999; Griffiss et al., 1999). The binding of Opa to various eukaryotic cells can initiate different signaling cascades, leading to entry of bacteria via distinct pathways. When Opa mediates binding to heparan sulfate proteoglycan (HSPG) receptors, invasion is mediated through a novel pathway that begins with the localized recruitment of HSPG receptors, F-actin, and tyrosine-phosphorylated proteins at the attachment sites (Grassme et al., 1996; Merz et al., 1996; Merz and So, 1997). This stimulates at least two lipid hydrolysis enzymes, the phosphatidylcholine-specific phospholipase C (PC-PLC) and an acidic sphingomyelinase (Smase; Grassme et al., 1997). This system does not utilize clathrin-coated pits or caveolae (Grassme et al., 1996).

A second uptake pathway directed through HSPG-binding Opa proteins occurs through bacterial binding to vitronectin (Duensing and van Putten, 1997). Infection experiments demonstrated that proteoglycan-deficient Chinese hamster ovary cells efficiently internalized dextran sulfate/vitronectin-coated gonococci, suggesting that soluble sulfated polysaccharides could substitute for cell surface glycosaminoglycans in the internalization process. These results suggest a novel mechanism of vitronectin binding in which sulfated polysaccharides act as molecular bridges, linking the glycosaminoglycan-binding sites of vitronectin and gonococcal Opa (Duensing and van Putten, 1998). Opa-vitronectin interactions promote adhesion and entry into cells, which are nonpermissive for invasion in the absence of vitronectin (van Putten et al., 1998).

A number of Opa proteins function as adhesins through binding to CD66 receptors present on human cells. These CD66 antigens, or carcinoembryonic antigen family members, constitute a family of glycoproteins belonging to the immunoglobulin superfamily. All Opa variants recognize this class of receptors in a differential manner (Bos et al., 1998). A HeLa cell line expressing human CGM1a antigen (HeLa-CGM1a) binds recombinant *Escherichia coli* expressing gonococcal Opa and subsequently engulfs the bacteria (Chen and Gotschlich, 1996a). Some of the carcinoembryonic antigen (CEA) gene family members bind some Opa proteins but not others (Popp et al., 1999). Because single residue changes within Opa, in the so-called "adhesiotopes," can change specificity for Opa binding (Virji et al., 1999), this indicates that (depending on the particular Opa protein expressed) different host cell responses occur, including binding, uptake and the activation of different signal transduction pathways.

Opc Protein The class V outer-membrane protein was cloned in studies of meningococcal antigens and renamed "Opc." The *opc* gene is present in many but not all meningococcal strains and is associated with virulence (Olyhoek et al., 1991; Seiler et al., 1996). Also present in the gonococcal (GC) genome are *opc* homologs of undefined function (Zhu et al., 1999). Expression of *opc* undergoes clonal variation via mutations in a poly-C tract within its promoter region. Spontaneous mutational variation in the number of cytidine residues changes expression levels or eliminates expression altogether (Sarkari et al., 1994). Expression of *opc* in *E. coli* confers a weak adhesive phenotype. Expression of Opc in nonencapsulated meningococci confers on the bacteria the ability to adhere to and invade endothelial cells independently of Opa and pili (Virji et al., 1992; Virji et al., 1995). Pre-exposure of Opc-expressing bacteria to serum increases the number of bacterial interactions at the apical surface, suggesting that Opc binds to serum factor(s) and this in turn increases adherence to tissue culture cells (Virji et al., 1994). The expression of Opc appears to enable bacteria to utilize the normal signal-transduction mechanism of host cells via ligands in sera that adhere to endothelial cell integrins. The Opc protein can bind vitronectin (perhaps indirectly) and it has been proposed that, as with Opa30, vitronectin forms a molecular bridge between the bacterium and integrin receptors on the cell surface (Virji et al., 1994).

Reduction-modifiable Proteins Gonococci and meningococci both contain a protein whose apparent molecular weight in sodium dodecyl-sulfate polyacrylamide gel electrophoresis (SDS-PAGE) increases upon treatment with a reducing agent such as β-mercaptoethanol (McDade and Johnston, 1980). In older literature, the gonococcal reduction-modifiable protein was termed "protein III," whereas the meningococcal one was designated "the class 4 protein." Under

the new nomenclature for the Neisseria, these proteins are now referred to as "Rmp."

Reduction-modifiable proteins (Rmps) are constitutively expressed and antigenically invariable (Lytton and Blake, 1986). Cross-linking studies with bifunctional reagents suggested that gonococcal Rmp is closely associated with the Por (Leith and Morse, 1980; Newhall et al., 1980). Structurally and immunologically conserved among gonococci (Judd, 1982), Rmp possesses surface-exposed domains (Swanson et al., 1982). The structural genes for Rmp have been cloned from both gonococci and meningococci, and there is 96% homology at the DNA level for these genes (Gotschlich and Seiff, 1987; Klugman et al., 1989). According to its predicted amino acid sequence, the molecular mass of Rmp should be about 24 kDa (Gotschlich et al., 1987). However, this protein contains two disulfide loops and migrates in SDS-PAGE gels at about 32 kDa under reducing conditions. No free C-terminal amino acids are released by carboxypeptidase digestion of Rmp, suggesting that the carboxy terminus is blocked or unavailable for cleavage (Blake et al., 1989). The amino acid sequence of Rmp is homologous to that of the C-terminal part of OmpA from *E. coli* and to that of OprF from *Pseudomonas aeruginosa* (Sugawara et al., 1996).

The function of the Rmp, both in the pathogenesis and in the physiology of the organism, remains unknown. The *rmp* gene is found exclusively in chromosomal DNA of pathogenic Neisseriae, indicating that this protein contributes to the virulence of *N. gonorrhoeae* and *N. meningitidis* (Wolff and Stern, 1995). In the meningococcus, this protein forms complexes with the lactoferrin receptor LbpA, the transferrin receptor TbpA and the siderophore receptor FrpB as well. This complexation apparently resulted in a stabilization of oligomeric forms of these iron-regulated proteins. In vitro experiments further revealed a reduced ability to acquire iron from human lactoferrin in a *rmp* mutant (Prinz and Tommassen, 2000). In the gonococcus, antibody to Rmp increases susceptibility to gonococcal infection (Plummer et al., 1993).

Rmp may have an important role in serum resistance; it is highly immunogenic. Because some murine monoclonal antibodies (MAbs) against Rmp block the serum bactericidal activity of other antibodies directed against gonococci and meningococci (Virji and Heckels, 1988), the blocking action is ascribed to anti-Rmp antibodies competing for binding with other antibody complexes on the gonococcal surface, resulting in the deposition of C5b-9 in a nonbactericidal form, preventing killing of the bacterium (Joiner et al., 1985). Human complement-fixing immunoglobulin G (IgG) antibodies to Rmp block the bactericidal activity of IgG directed to cell-surface antigens such as lipooligosaccharide (LOS; Rice, 1989). Anti-meningococcal bactericidal activity of normal human sera is inhibited by the presence of antibodies directed against Rmp. The ability of Rmp to induce blocking antibodies suggests that its presence in experimental vaccines, based on meningococcal outer membranes, may be antagonistic to the development of effective bactericidal immunity (Munkley et al., 1991). However, antibodies against Rmp have been purified from sera from vaccinees immunized with the Norwegian meningococcal group B outer-membrane vesicle vaccine. While the human sera and purified antibodies reacted strongly with Rmp in immunoblots, experiments with whole bacteria showed only weak reactions, indicating that the antibodies mainly reacted with parts of Rmp that were not surface-exposed. The purified human anti-Rmp antibodies were neither bactericidal nor opsonic against live meningococci. However, these antibodies were not vaccine induced, as they were present also before vaccination. The data indicate that vaccination with meningococcal outer-membrane vesicle vaccines containing the Rmp does not induce blocking antibodies (Rosenqvist et al., 1999).

H.8 Protein The pathogenic *Neisseria* possess an OMP designated "H.8," which possesses a conserved monoclonal antibody (MAb)-binding epitope. The H.8 DNA sequence predicted a 6.9-kD peptide comprising 14 tandemly repeated pentameric sequences. Also predicted was a lipoprotein leader consensus sequence, which probably specified acylation because the *E. coli*-expressed protein was tightly associated with lipid. Lipid appeared to contribute significantly to H.8 antigen's unusual electrophoretic mobility. When outer-membrane preparations from some *Neisseria* spp. are subjected to SDS-PAGE and Western blots are probed with an H.8-specific monoclonal antibody, a cone-shaped monoclonal antibody-binding band with an apparent molecular mass ranging from 18–30 kDa is observed. The protein responsible for this band, designated "the H.8 protein," does not stain with Coomassie blue but can be visualized by staining with silver. The apparent molecular mass of this protein varies in different strains but appears to be constant within a single gonococcal or meningococcal strain (Cannon et al., 1984).

A gonococcal mutant lacking the H.8 protein has been obtained by insertional inactivation of the gene, indicating that this protein is not essential for the growth and survival of gonococci in a complex medium (Woods et al., 1989). The association of the H.8 protein with the pathogenic *Neisseria* spp. has led to the speculation that it

may be important in pathogenesis or as a candidate vaccine. The lipid-modified azurin (Laz), one of two distinct surface proteins recognized by the H.8 monoclonal antibody, is present in all pathogenic Neisseria. The mature protein has two domains; one contains an H.8 epitope and the other has extensive homology to azurins, a class of bacterial copper-binding proteins. The cellular location of Laz and the serum immune response to Laz have been examined in patients with disseminated Neisserial infections and show that Laz is probably contained in the Neisserial outer membrane, although unlike most OMPs, it is Sarkosyl soluble. By probing recombinant bacteriophages encoding the H.8 and azurin domains of Laz, Trees and Spinola (1990) showed that (whereas the H.8 epitope is immunogenic in patients with disseminated Neisserial infections) the azurin domain of Laz plays little role in eliciting an antibody response in these patients.

Anaerobically Induced Proteins When the gonococcus is grown under anaerobic conditions with nitrite as a terminal electron acceptor, at least three gonococcal OMPs are induced and at least five OMPs are repressed by anaerobic growth in gonococcal strain F62. The major anaerobically induced OMP, AniA (formerly Pan1), is tightly regulated, and its expression is restricted to anaerobically grown cells (Clark et al., 1987). Western blot analyses with sera from patients with gonococcal disease indicated that infected individuals responded to AniA, suggesting that AniA is expressed in the host and that the gonococcus encounters an anaerobic environment during infection (Clark et al., 1988). An antigenically related anaerobically induced OMP was detected in all strains of gonococci tested and in a number of commensal *Neisseria* strains but was poorly expressed in *N. meningitidis* strains (Hoehn and Clark, 1990).

Northern blot analysis demonstrated the lack of *aniA* message in aerobically grown cells. Primer extension data from anaerobically grown cells suggested the presence of two RNA transcripts differing in length by only 9 bps representing two overlapping promoters, one with homology to *E. coli* σ70 promoters and the second sharing homology with *E. coli* gearbox promoters (Hoehn and Clark, 1992a). (Gearbox promoters were named for their characteristic of producing a gene product at a rate inversely proportional to the growth rate of the cell.) These promoters are induced during the stationary phase in *E. coli* (Vicente et al., 1991). Also, AniA shares significant identity with copper-containing nitrite reductases (Mellies et al., 1997). Additional structural studies have shown that AniA is a lipoprotein (Hoehn and Clark, 1992b). Immunological data suggest that *N. lactamica* and *N. cinerea* possess homologs to AniA, whereas *N. sicca*, *N. flava* and *N. mucosa* did not. The other commensals tested, *N. subflava* and *N. perflava*, exhibited only a minor reaction (Hoehn and Clark, 1990).

Iron-binding Proteins Iron is an essential component and serves as a cofactor of the membrane-bound electron transport chain and of certain soluble enzymes of most bacteria. Free iron is rare in the human body, generally being complexed by a number of high-affinity binding proteins, including transferrin (Tf) in plasma and lactoferrin in secretions and macrophages (Bullen et al., 1978). Because the free iron concentration in the human host is extremely low, the *Neisseria* spp. must have mechanisms for obtaining iron from its host. The sources of iron on human mucosal surfaces that are available to the gonococcus are not well understood; however, the observation that gonococcal strains deficient in the ability to utilize iron from mucosal surfaces are avirulent (Cornelissen et al., 1998) indicates that there is sufficient utilizable iron on the mucosal surface to support infection. Gonococci and meningococci express many novel proteins when grown in vitro under conditions of iron restriction (Dyer et al., 1988; Mietzner et al., 1984; Norqvist et al., 1978). These proteins are synthesized also in vivo inasmuch as antibodies to these proteins can be detected in serum specimens from patients with meningococcal and gonococcal disease (Black et al., 1986; Fohn et al., 1987).

Many microorganisms synthesize low-molecular-weight, high-affinity, iron-binding compounds called "siderophores," which overcome the insolubility of iron and effectively compete with the host iron-binding proteins transferrin and lactoferrin. While the pathogenic *Neisseria* do not produce siderophores (West and Sparling, 1985), in the milieu of the mucosal surface, neighboring microbes do. Neisserial strains scavenge siderophores made by other bacteria, including the *E. coli* hydroxamate siderophore aerobactin (Beucher and Sparling, 1995; West and Sparling, 1987). Neisserial species also transport the *E. coli* phenolate siderophore ferric enterobactin. The process of iron utilization via a siderophore intermediate requires specific binding of the ferric siderophore to a surface-exposed receptor. Both the meningococcus and gonococcus possess genes that share homology with siderophore receptors. Because exogenous siderophores support the growth of these organisms, it indicates that the gonococcus and meningococcus possess pathways for the uptake of iron-siderophore complexes released by neighboring bacteria (West and Sparling, 1985).

Energy is provided to these TonB-dependent receptors in the form of the proton motive force through the function of an energy-transducing complex of proteins, TonB, ExbB and ExbD (Klebba et al., 1993).

The gonococcus can bind and utilize iron from human transferrin (Blanton et al., 1990; Lee and Schryvers, 1988). Gonococci also can use iron bound to the dihydroxamate siderophores aerobactin, arthrobactin and schizokinen (West and Sparling, 1987; Yancy and Finkelstein, 1981), but they are unable to use the iron bound to the trihydroxamate siderophores desferrioximine B mesylate (Desferal), ferrichrome, ferrichrome A, ferrichrysin, ferricrocin, ferrirubin, and coprogen and the phenolate siderophores enterochelin and vibriochelin (Yancy and Finkelstein, 1981). The gonococcus and meningococcus also utilize iron bound to human lactoferrin, hemoglobin and heme (Mickelsen et al., 1982). The majority of nonpathogenic *Neisseria* spp. cannot use either transferrin or lactoferrin as an iron source (Mickelsen et al., 1982; Mickelsen and Sparling, 1981).

Transferrin Binding In the transferrin-iron internalization system, two proteins (TbpA and TbpB) are essential for the utilization of host-derived iron sources. Mutants defective in the synthesis of either TbpA or TbpB, but not defective in both proteins, can bind transferrin, suggesting that both proteins are surface exposed and function in transferrin binding (Pintor et al., 1998). Because TbpA is similar to other TonB-dependent receptors, it is thought that it forms the pore through which transferrin-bound iron enters the periplasm (Cornelissen et al., 1992). The genes encoding these proteins have been cloned and sequenced from a number of strains.

The TbpA protein is likely to form a TonB-regulated transmembrane β-barrel, through which iron can enter the periplasm. When integrated into the outer membrane, TbpA may form a β-barrel composed of 22 transmembrane strands and probably has a periplasmic globular domain equivalent. Sequence diversity among gonococcal TbpAs is largely confined to four small regions that are postulated to be surface exposed in the gonococcus (Cornelissen et al., 2000). Mutagenesis studies have identified discrete domains within TbpA that are necessary for ligand binding and iron uptake (Boulton et al., 2000). Because expression of the Tf receptor is required to initiate infection in a human challenge model of gonococcal infection (Cornelissen et al., 1998), identification of domains of TbpA that are necessary for the optimal function of this receptor could lead to therapies or prevention strategies aimed at abrogating its function.While gonococcal TbpBs are more diverse than gonococcal TbpAs (Cornelissen et al., 1997), they do not share the great diversity found among meningococcal TbpBs (Rokbi et al., 1993). Meningococcal TbpBs fall into two distinct classes based on molecular mass and sequence characteristics. The low-molecular-weight family, consisting of approximately 26% of tested strains, expresses a TbpB protein of 68 kDa, whereas the high-molecular-weight family expresses a TbpB of 85 kDa (Rokbi et al., 1993). The TbpB protein increases the efficiency of iron uptake from transferrin by virtue of its specificity for the ferrated ligand (Anderson et al., 1994). Also, TbpB is lipidated and exposed on the outer leaflet of the outer membrane (Anderson et al., 1994). Although both Tbps specifically and independently bind human transferrin, TbpB selectively binds the ferrated form of this protein, whereas TbpA binds both ferrated and apo transferrin (Boulton et al., 1998). The study of meningococcal and gonococcal mutants expressing either TbpA or TbpB has shown that both proteins are required for the optimal uptake of human transferrin iron (Cornelissen and Sparling, 1996; Legrain et al., 1993). The conservation of two structurally distinct proteins, both capable of independently binding human transferrin, implies that they play different but related roles. The requirement for both Tbps further suggests that these proteins may interact, forming the functional human transferrin receptor. The meningococcal human transferrin receptor is composed of a TbpA dimer in association with a single molecule of TbpB. This complex binds 1–2 molecules of human transferrin, with TbpB preferentially binding the diferric form of this protein. The TbpA and TbpB proteins bind to distinct separate sites on the human transferrin molecule (Boulton et al., 1998).

Lactoferrin Binding Lactoferrin is the major source of iron on mucosal surfaces. All meningococcal strains possess an iron-regulated cell surface receptor that is specific for human lactoferrin-bound iron as the sole source of iron; many gonococcal strains lack this receptor and cannot grow when iron is complexed with lactoferrin (Mickelsen et al., 1982). Iron uptake from lactoferrin is energy dependent (McKenna et al., 1988). The meningococcal lactoferrin receptor is composed of the integral outer-membrane protein LbpA and the peripheral lipoprotein LbpB. The *lbpA* gene encodes an outer-membrane, lactoferrin-binding protein with homology to the transferrin-binding protein, TbpA. The lactoferrin receptor consists of a macromolecular complex of LbpA and LbpB, where LbpA is present in this complex as a dimer (Prinz et al., 1999). Like TbpA/TbpB, this uptake system is TonB dependent.

The DNA sequence of *lbpA* is highly conserved in the gonococcus and the meningococcus and encodes for a 103-kDa protein. A topology model for LbpA suggests that the protein traverses the outer membrane 26 times in a β-sheet conformation, exposing 13 loops to the bacterial surface (Pettersson et al., 1998). The striking 94% identity between gonococcal and meningococcal genes suggests that the two proteins have the same function. This conservation also suggests that LbpA does not undergo much antigenic variation in vivo, perhaps indicating that it is masked or not highly surface exposed. Primer extension and reverse transcription-polmerase chain reaction (PCR) analysis indicate that *lbpB* and *lbpA* are cotranscribed on a polycistronic iron-repressible mRNA (Lewis et al., 1998). These genes contain a relatively well-conserved ferric uptake regulator (Fur) box upstream of their coding sequence, further supporting the notion that their expression is iron regulated.

The complete nucleotide sequence of *lbpB* has been determined and the gene encodes a 77.5-kDa protein, probably a lipoprotein, with significant homology to the TbpB of *N. meningitidis*. A unique feature of LbpB is the presence of two stretches of negatively charged residues, which are postulated to be involved in lactoferrin binding. Isogenic mutants lacking either LbpA or LbpB exhibit a reduced ability to bind lactoferrin, with *lbpA* mutants being unable to use lactoferrin as a sole source of iron (Pettersson et al., 1998). The genes encoding LbpB have been analyzed from several gonococcal and meningococcal strains and are generally 70–80% identical at the amino acid level, with most of the variability found in two stretches with a high content of negatively charged amino acids. The high degree of variability is disadvantageous for vaccine development, but may be useful for epidemiological studies (Pettersson et al., 1999).

Heme and Hemoglobin Binding Heme compounds are an important source of iron for the pathogenic Neisseriae (Archibald and DeVoe, 1980). They are able to obtain iron from hemoglobin (Hb), haptoglobin-hemoglobin (Hp-Hb) and apo-haptoglobin (apo-Hp; Dyer et al., 1987). Two distinct surface receptors are involved in heme-iron acquisition, HmbR (Stojiljkovic et al., 1996) and HpuA/HpuB (Lewis et al., 1997). The expression of *hmbR* and *hpuAB* undergoes phase variation, with expression controlled by frameshifting involving a polyguanine tract located within the *hmbR* and hpuA loci (Lewis et al., 1999).

The gene for HpuB has been cloned from the meningococcus and the predicted amino acid sequence indicates that HpuB is an outer-membrane receptor belonging to the TonB family of high-affinity transport proteins. Adjacent to and cotranscribed with hpuB is a second open-reading frame (Orf), predicted to encode a 34.8-kDa lipoprotein, HpuA. The 3.5-kb polycistronic *hpuAB* mRNA is transcriptionally repressed by iron, with the transcriptional start site appropriately positioned around consensus promoter and Fur-box sequences. The structure of this operon suggests that HpuA-HpuB is a two-component receptor analogous to the bipartite transferrin receptor TbpB-TbpA (Lewis et al., 1997).

The HmbR receptor is an iron-regulated, 89.5-kDa protein that binds Hb, extracts the heme from it, and transports the heme into the periplasm (Stojiljkovic et al., 1995; Stojiljkovic et al., 1996). An *hmbR* mutant of *N. meningitidis* is attenuated in an infant rat infection model, confirming the importance of Hb acquisition in meningococcal virulence (Stojiljkovic et al., 1995). The HpuAB bipartite receptor is most likely the main Hb receptor of gonococci, inasmuch as the *hmbR* gene contains a premature stop codon in all gonococcal strains tested (Chen et al., 1996b). The lack of *hmbR* and the high prevalence of hpuB in commensals suggest more recent acquisition of *hmbR* by meningococci (Richardson and Stojiljkovic, 1999).

The HemO protein is essential for heme, hemoglobin (Hb), and haptoglobin-Hb utilization. The *hemO* gene is located upstream of the *hmbR* and encodes a protein that is homologous to enzymes that degrade heme. This gene is ubiquitous in commensal and pathogenic Neisseriae. Also, HemO genetic knockout strains of *N. gonorrhoeae* and *N. meningitidis* are unable to use any heme source, whereas the assimilation of transferrin-iron and iron-citrate complexes is unaffected. Furthermore, *hemO* mutants can transport heme into the cell because both heme and Hb were shown to complement an *N. meningitidis* hemA *hemO* double mutant. The expression of the HmbR receptor is reduced significantly by the inactivation of the *hemO*, suggesting that *hemO* and *hmbR* are transcriptionally linked. Comparison of the polypeptide patterns of the wild-type and the *hemO* mutants indicates a general role of HemO in the regulation of gene expression in Neisseriae (Zhu et al., 2000).

The gonococcus and meningococcus can use iron (Fe) from a variety of sources. Insertional mutation of the gonococcal *tonB* homologue results in the failure of gonococci to grow with transferrin, lactoferrin or human hemoglobin as a sole iron source. The *tonB* mutation does not prevent the utilization of Fe from citrate or hemin. This indicates that the pathways for utilization of Fe bound to transferrin, lactoferrin or human hemoglobin are dependent on the TonB

system (Biswas et al., 1997). An alternative TonB-independent system also exists for the utilization of iron from hemoglobin, transferrin or lactoferrin. This system functions with the TonB-dependent receptors HmbR in *N. meningitidis* and HpuB in *N. gonorrhoeae* for growth with hemoglobin (Desai et al., 2000).

A 76-kDa iron-regulated OMP common among Neisserial species, FetA, has homology to the TonB-dependent class of OMPs of Gram-negative bacteria. It is expressed by most Neisserial strains and is a potential vaccine candidate for both gonococcal and meningococcal disease prevention. In addition, FetA functions as an enterobactin receptor. A linked gene, *fetB*, is predicted to encode a protein with sequence similarity to periplasmic binding proteins necessary for transporting siderophores through the periplasmic space of Gram-negative bacteria. Insertional inactivation of *fetB* abolishes ferric enterobactin utilization without causing a loss of ferric enterobactin binding. These data show that FetA binds ferric enterobactin and that FetA/FetB may be part of a system responsible for transporting enterobactin into the cell (Carson et al., 1999).

IgA Protease The pathogenic *Neisseria* secrete immunoglobulin A1 (IgA1) protease, an enzyme that cleaves the hinge of human IgA1 (hIgA1; Plaut et al., 1975). All gonococcal isolates produce one of two similar types of the enzyme (type 1 or 2), which cleave different bonds (Pro-Ser and Pro-Thr, respectively) in the 18-amino-acid hinge region of hIgA1. Production of gonococcal IgA1 protease involves self-directed secretion and autocatalytic processing of a larger precursor protein encoded by the *iga* gene (Klauser et al., 1993). Both proteases are secreted into the culture medium throughout exponential growth. Interestingly, this protein only seems to be found in pathogenic species (Wolff and Stern, 1995).

Numerous functions have been ascribed to it, but its role in pathogenesis remains enigmatic. Alternative roles in gonococcal pathogenesis, other than cleavage of IgA1 at mucosal surfaces, have been proposed for IgA1 protease as it can cleave synaptobrevin II in vitro and, when introduced into the cytosol of bovine chromaffin cells, blocks exocytosis (Binscheck et al., 1995). The type 2 IgA1 protease cleaves LAMP1 (lysosome/late endosome-associated membrane protein; Lin et al., 1997), a major integral membrane glycoprotein of lysosomes. The protease has been proposed to promote bacterial colonization through cleavage of hIgA1 found on the mucosal surfaces. Proteolysis accelerates the LAMP1 degradation rate and results in multiple alterations in the lysosomes of infected cells (Ayala et al., 1998). An *iga* mutant is defective in intracellular growth, compared to the wild-type (WT) parent strain, and this phenotype is likely to be due to the inability of the mutant to cleave LAMP1 and alter lysosomes. In in vitro invasion studies, *iga* mutants are defective in their ability to traverse T84 monolayers (Hopper et al., 2000). A recent human challenge study showed that an *iga* (IgA1 protease gene) mutant is not impaired in its ability to initiate an infection in the human male urethra (Johannsen et al., 1999). These findings suggest that IgA1 protease and other *iga* gene products may contribute to Neisserial pathogenesis at intracellular stages of the infection process. However, a gonococcal *iga* mutant is not impaired in its ability to invade human fallopian tube organ cultures (Cooper et al., 1984).

The IgA1 protease is able to induce proinflammatory cytokines such as tumor necrosis factor (TNF)-α, interleukin, (IL)-1b, IL-6 and IL-8 from peripheral blood mononuclear cells. The capacity of IgA1 protease to elicit such cytokine responses in monocytes is enhanced in the presence of T lymphocytes. Also, IgA1 protease does not induce the regulatory cytokine IL 10. The immunomodulatory effects caused by IgA1 protease require a native form of the enzyme, but the proteolytic activity is not required for the cytokine induction (Lorenzen et al., 1999). The importance of IgA1 protease expression in natural infections is further supported by the observation that invasive isolates of *N. meningitidis* possess protease activity compared to colonizing strains (Vitovski et al., 1999). However, when IgA1 in cervical mucus is examined by Western blotting, no evidence of cleavage fragments characteristic of IgA1 protease activity is seen in gonococcus-infected or control patients. These results suggest that cleavage of IgA1 by gonococcal IgA1 protease within the lumen of the female lower genital tract is unlikely to be a significant factor in the pathogenesis of infections by *N. gonorrhoeae* (Hedges et al., 1998). Taken in total, all of these results suggest that the importance of this protease is in functions other than IgA1 cleavage.

RTX homologs Two iron-regulated proteins (FrpA and FrpC) have been shown to be related to the RTX family of toxins (Thompson and Sparling, 1993a; Thompson et al., 1993b; Thompson et al., 1993c). These genes are predominantly found in some meningococcal isolates. While no hemolytic or leukotoxic activity has been detected for these proteins, their presence in meningococcal strains strongly suggests that they contribute to some aspect of meningococcal pathogenesis.

Other Membrane Proteins. Martin et al. (1997) have reported the identification in the

outer membrane of *N. meningitidis* of a low-molecular-weight protein, Neisserial surface protein A (NspA), that was antigenically conserved and accessible at the surface of intact bacterial cells of all *N. meningitidis* isolates tested. Neisserial surface protein A-specific MAbs were shown to be bactericidal in vitro against several meningococcal isolates. Intraperitoneal injection of these bactericidal MAbs passively protected mice against a lethal meningococcal challenge. They also demonstrated that the injection of recombinant NspA (rNspA) protein produced by *E. coli* protected mice against experimental meningococcal infection. A homolog of this protein also is found in the gonococcus, suggesting that the NspA protein is highly conserved among pathogenic *Neisseria* strains (Plante et al., 1999).

The genes encoding a homologous 85-kDa OMP of *N. gonorrhoeae* and *N. meningitidis* have been cloned and sequenced. The gonococcal gene encodes a 792-amino-acid protein having a typical signal peptide and a carboxyl-terminal phenylalanine characteristic of OMPs. Southern analysis demonstrated that *omp85* is present as a single copy in *N. gonorrhoeae* and *N. meningitidis* (Manning et al., 1998).

A 44-kDa protein has been shown to be structurally invariant among 14 strains of *N. gonorrhoeae*. This OMP fractionated with other Sarkosyl-insoluble OMPs and is susceptible to cleavage in situ by cathepsin. It also covalently binds radiolabelled benzylpenicillin in vitro. Thus, the data suggest that the 44-kDa peptidoglycan-binding OMP and PBP3 are the same OMP (Judd et al., 1991).

Several other Neisserial OMPs have been described. Some of these proteins appear to be both highly conserved and surface exposed. The outer-membrane protein-macromolecular complex (OMP-MC) is a major protein component of the outer membrane, accounting for about 10% of its protein mass (Hansen and Wilde, 1984; Newhall et al., 1980). The OMP-MC has a molecular mass of 800 kDa and is composed of 10–12 identical subunits of 76 kDa. The *omc* gene, which encodes the OMP-MC, has been cloned and sequenced (Tsai et al., 1989). Antibodies against OMP-MC are produced during a natural infection, and anti-OMP-MC antibodies are bactericidal for both homologous and heterologous gonococcal strains in a complement-dependent assay system (Corbett et al., 1988). The function of this protein has yet to be elucidated.

Pathogenic and nonpathogenic *Neisseria* spp. appear to have a common, surface-exposed 70-kDa antigen (Martin et al., 1986). There is some evidence suggesting that anti-70-kDa antigen antibodies have a role in natural immunity to gonorrhea (Aoun et al., 1988a). Nonpathogenic *Neisseria* spp. possess the 70-kDa antigen structure, but elicited less frequently an antibody response in children (Aoun et al., 1988b).

Yang et al. (1995) identified an open-reading frame (Orf) coding for a protein with a predicted size of 19.2 kDa with a typical lipoprotein signal sequence of 21 amino acids. Antisera raised against this protein reacted with meningococcal membrane fractions on a Western blot but did not elicit complement-dependent bactericidal activity. The DNA sequences of the gene from several strains of *N. gonorrhoeae* and *N. meningitidis* were compared and found to be almost identical, except that the coding sequences from all of the gonococcal strains were terminated prematurely as a result of a frameshift mutation.

Lipooligosaccharide Neisserial lipooligosaccharide (LOS) has been examined by chemical, biological and immunological techniques, as well as through visualization after SDS-PAGE (Apicella et al., 1981; Connelly and Allen, 1983; Frasch et al., 1976; Guymon et al., 1982; Jennings et al., 1980; McDonald and Adams, 1971). Gonococcal LOS mediates most of the toxic damage in the fallopian tube model (Gregg et al., 1981), is a key target on the cell surface for bactericidal antibody (Ward et al., 1978), and regulates complement activation on the surface of the organism (Joiner et al., 1985). It also is implicated in the attachment of gonococci to host cells by piliated and nonpiliated organisms (Watt et al., 1978), in the presence or absence of opacity (Opa) proteins (Porat et al., 1995; van Putten, 1993).

Lipooligosaccharides are heterogeneous glycolipids without repeating oligosaccharides (Griffiss et al., 1987) that show wide antigenic diversity among different strains (Apicella et al., 1981; Mandrell et al., 1986). In studies using molecular sieve chromatography, fluorescent-activated cell sorting, and SDS-PAGE analysis, it has been shown that within a strain, LOS components differ in their relative concentrations and in the antigens they express (Apicella et al., 1987; Schneider et al., 1985; Schneider et al., 1988). Antigenic differences between strains are the result of substitutions of various glycose units, alterations in the types of linkages that connect the sugars, or additional decorations of the sugar backbone. *Neisseria* LOSs structurally resemble human glycosphingolipids (Griffiss et al., 1988).

Each gonococcal strain has the genetic potential to make a series of structurally related molecules (Gibson et al., 1989). The oligosaccharides (OSs) of LOS are multiantennary and can branch at two basal heptose residues and at an internal galactose residue (Gibson et al., 1989;

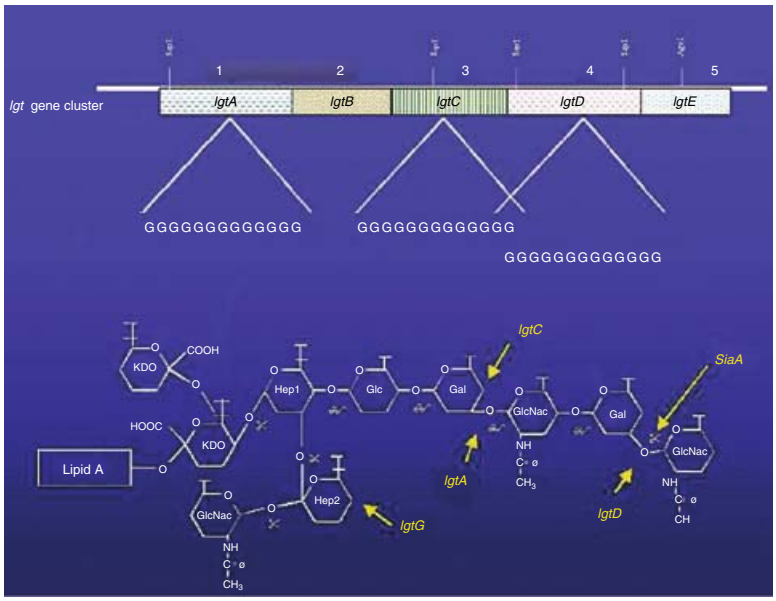

Fig. 4. Schematic depiction of genes and structures of gonococcal LOS. The top part of the figure is a depiction of a gene cluster that is responsible for the synthesis of the major carbohydrate portion of gonococcal LOS (See Gotschlich, 1994). The poly G region indicates the presence of strings of guanines that are responsible for the variable expression of the protein. The bottom part of the figure is a schematic representing the chemical structure of gonococcal LOS. The gene designations indicate those genes whose expression is regulated by changes in the polyguanine tract. When the gene contains enough guanines so that the reading frame for the entire gene is out of frame, the LOS molecule's structure would terminate at this point.

Schneider et al., 1984; see Fig. 4). Besides lipid A and ketodeoxyoctonate (KDO), this molecule contains heptose, glucose, galactose, *N*-acetylglucosamine and *N*-acetylgalactosamine. A culture of gonococcal cells consists of different variants or clonotypes, each of which makes one or more LOS and each of which can interconvert at high frequency (10^{-3}/cell/generation; Apicella et al., 1987; Gibson et al., 1989; Schneider et al., 1984; see Fig. 5 for an example of LOS variation within a colony). The LOS repertoire of the population as a whole represents a summation of the proportional contributions of each clonotype.

In addition to possessing the ability to produce multiple LOS components with different antigenic determinants (Fig. 6), the gonococcus can modify its LOS by "borrowing" host factors and adding them to the OS. Gonococci examined directly from urethral exudates are resistant to the killing action of normal human serum (NHS), but become susceptible upon culture (Apicella et al., 1990; Parsons et al., 1990; Ward et al., 1970). This resistance is due to the fact that the gonococcus sialylates its LOS, adding *N*-acetylneuraminic acid (*NANA*) from cytidine monophosphate-*N*-acetylneuraminic acid to its LOS. The *NANA* can be added to the LOS structure containing the lacto-*N*-neotetrose LOS structure (Mandrell et al., 1990), or the LOS that mimics the human P^k globosyl LOS (Griffiss et al., 2000). Sialylation of Neisserial LOS can contribute to pathogenicity in several ways, including the reduction of phagocytosis by human neutrophils (Kim et al., 1992; Rest and Frangipane, 1992; Wetzler et al., 1992), the binding of IgM and IgA (Vogel et al., 1997), and the oxidative burst in neutrophils (Rest and Frangipane, 1992). In addition, LOS mediates an increased binding of Factor H (a critical downregulator of complement activation; Ram et al., 1998a; Ram

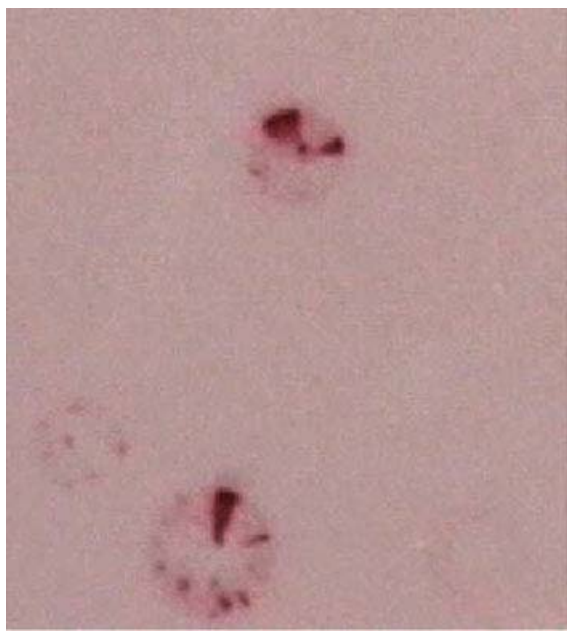

Fig. 5. Demonstration of high-frequency LOS antigenic variation. Colonies of *N. gonorrhoeae* strain F62 were transferred onto Nitrocellulose and analyzed for their ability to bind an LOS specific MAb, 2-1-L8. While the bulk of the colonies transferred were incapable of reacting with the MAb, occasional colonies arose that contained sectors of reactive cells. These sectors are visualized in red.

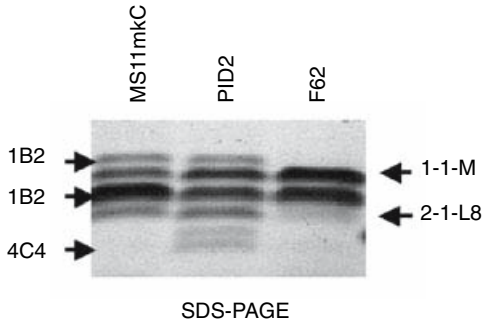

Fig. 6. Complexity of LOS expression. *Neisseria* strains are capable of simultaneously expressing multiple LOS components that each possess unique antigenic properties. The figure represents typical SDS-PAGE profiles that are seen for gonococcal strains. Reactivities with various MAbs have been used as markers for the presence of specific components. The MAb used and its component bound are identified with the arrows.

et al., 1998b). Sialylation also interferes with adherence of bacterial cells to neutrophils in the absence of complement and antibody (Rest and Frangipane, 1992).

The mechanisms by which serum-sensitive gonococci resist the killing action of normal human serum are not fully understood. While gonococci initially recovered from urethral exudates are resistant to the killing actions of nonimmune sera because their LOSs are sialylated (Parsons et al., 1992; Ward et al., 1970), some gonococci are serum resistant even though they lack the LOS form that can be sialylated (Schneider et al., 1985). While the interaction of antibody and complement on the bacterial cell surface may result in the killing of the organism (Rice and Kasper, 1977), some antibodies may block killing by combining with antigens that are identical or adjacent to sites that recognize bactericidal antibody (Joiner et al., 1985). Apicella et al. (1986) demonstrated that the bactericidal activity of lytic IgG antibody can be blocked by IgA antibodies directed against the same LOS or a molecule in close proximity. The identification of loci important for serum resistance has been compounded by the use of strains with different OMP profiles (Cannon et al., 1981; Shafer et al., 1982), different assays for serum resistance (Cannon et al., 1981; Hildebrandt et al., 1978), and the study of LOS targets whose expression is variably expressed. Genetic studies indicate that multiple genes influence the degree of gonococcal resistance to normal human serum (Cannon et al., 1981; Shafer et al., 1982). Our understanding of the role of innate immunity in preventing gonococcal infection is hampered by the lack of information on the structure of the relevant antigens.

The allocation of genetic information and metabolic energy to the task of rapidly changing its surface glycan structures implies that LOS is important to the organisms' survival. *Neisseria gonorrhoeae* is strictly adapted to the molecular environment of the mucous membranes of man. In vivo, LOS phase shifts occur (Apicella et al., 1990) and persistence and induction of symptomatic urethral gonorrhea require that the infecting strain shift to clonotypes that make higher molecular weight OS that share surface epitopes with human polymorphonuclear leukocytes. Also, LOS provides a library of potential surface structures that can be rapidly shifted and that are necessary for the organism's adaptation to the molecular environments of different epithelial surfaces.

A variety of MAbs has been produced that have been used to distinguish between the various LOS components (Kim et al., 1988; Schneider et al., 1985). The MAb 2-1-L8 finds its epitope on an internal α-chain lactose (Lac) residue attached to Hep1 of the basal oligosaccharide (Schneider et al., 1984) forming a highly conserved 3.6-kDa LOS (Kim et al., 1988; see Fig. 4 for structures). Additions of a *N*-acetyl lactosamine (LacNac) residue to the third carbon of the terminal chain lactose can give rise to a component with an apparent molecular mass of 4.5 kDa, capable of binding MAb 1B2 (Kim et al., 1988; Schneider et al., 1985). Further extensions or modifications of this chain are also possible, adding Gal-NAc (binds MAb 1-1M), adding an additional lactosamine (binds 1B2; John et al., 1999) or adding host-derived cytosine monophosphate (CMP)-*NANA*. The α-chain lactose can alternately be extended by adding a galactose to the fourth carbon, producing a structure that reacts with MAb L1-17-1. Although MAb 3G9 and 2C7 reactivity has been used as a marker for elongation of the β-chain, these MAbs are capable of binding to several structurally distinct LOS clonotypes.

The data from many laboratories indicate that removal or addition of a single sugar from the structures shown in Fig. 4 may result in the exposure of new immunogenic epitopes. Specific MAbs may recognize each of these epitopes. However, the presence of LOS structures with the same apparent molecular weight that fail to bind a structure-specific MAb indicates that there are other heretofore unknown structures or structural modifications. Likewise, the ability of LOSs with different migration distances on SDS-PAGE to bind the same MAb indicates that predicting the structure of an LOS molecule based on its MAb binding can be misleading.

The structure of a sufficient number of LOS molecules has been determined (Gibson et al., 1989; John et al., 1991; Yamasaki et al., 1991a; Yamasaki et al., 1991b; Yamasaki et al., 1994) to form a coherent yet incomplete picture as to how the organism assembles its LOS. *Neisseria* spp. synthesize LOS by sequentially adding monosaccharides onto a basal unit. However, the composition of this basal unit and its role in the biosynthetic process are unknown. Although there appears to be some similarity between LOS biosynthesis and LPS biosynthesis, enough differences have been detected to suggest that our reliance on knowledge of LPS biosynthesis in the enterics, although serving as a useful starting point for studies on LOS biosynthesis, has hampered the development of appropriate models for LOS biosynthesis. The multiantennary nature of LOS molecules permits increased molecular diversity, as oligosaccharide chains can be extended from more than one antenna, i.e., to either or both heptose residues and to either internal (Lac) or terminal (LacNac) galactose (Gal) residues. It is this same biosynthetic flexibility that provides diversity among mammalian cell surface glycolipids. This ability to vary both composition and configuration in LOS is also another sharp reminder of the differences between LOS and LPS.

Most work on the genetic basis of Neisserial LOS biosynthesis has been performed on isogenic sets of gonococcal strains: FA19 and its LOS defective counterparts FA5100 and JWS1; 1291 and its LOS defective counterparts 1291a-1291e and F62. The LOS-defective mutants were originally selected as spontaneous pyocin-resistant mutants and have been described previously (Dudas and Apicella, 1988; Shafer et al., 1982). Strains resistant to the killing action of pyocin have alterations in their LOS (Connelly and Allen, 1983; Dudas and Apicella, 1988; Morse and Apicella, 1982). In fact, SDS-PAGE analysis of FA19 reveals several distinct LOS components ranging in apparent molecular weight from 3.6–5.0 kDa. Strain FA5100 produces a single small molecular weight component consisting of a single heptose linked to two KDO molecules (Gibson et al., 1993): JWS1 produces a single LOS that lacks heptose (D. C. Stein, unpublished observations). The structure of the LOS isolated from 1291 and its LOS-defective variants has also been determined (John et al., 1991). The 1291 mutants differ from each other in the sequential loss of individual sugars on the α-OS chain. The structure of LOS isolated from strain 15253 also has been determined and the data indicate that this strain elongates the β-chain (Erwin et al., 1996; Yamasaki et al., 1994). The structure of LOS isolated from strain MS11mkC possesses an *N*-acetyl-lactosamine repeat added onto the α-chain lacto-*N*-neotetraose structure (John et al., 1999). Comparing the structure of LOS from F62 (Yamasaki et al., 1991b) to that seen in 1291 provides further evidence for additional structural variations. While both strains possess the same basic sugar backbone in their OS, they differ in the composition of their γ-chain (in F62, this is composed of an *N*-acetylglucosamine, whereas in 1291, it is composed of 1, 4 diacylglucosamine).

Glycolipid biosynthesis is extremely complex (Robbins et al., 1967). For its biosynthesis, it requires genes encoding for glycosyl transferases, other lipid biosynthetic enzymes, the synthesis of biosynthetic precursors, and housekeeping molecules involved in transport or extracytoplasmic assembly. By comparing the structures of various pyocin mutants, it is possible to infer the types of mutations that could produce the altered LOS phenotype, but it is not possible to infer the exact function of individual genes.

Most of the genes involved in LOS biosynthesis in the gonococcus have been cloned. The gene *lsi-1* encodes a homologue to the *E. coli* gene, *rfaF*, and can complement the LOS defect in FA5100 and restore it to FA19-like LOS expression and reactivity with LOS-specific MAbs (Petricoin and Stein, 1989; Sandlin et al., 1994). The LOS antigenic variation can be regulated by *lgtA*. This gene encodes a glycosyltransferase involved in the addition of *N*-acetylglucosamine-β(1–3) to galactose (Burch et al., 1997). This gene is the first gene in a cluster of genes needed to synthesize the α-oligosaccharide chain (that chain that is the one that is known to be sialylated, as shown in Fig. 4). This cluster also has been cloned and characterized by several research groups in both the gonococcus and the meningococcus (Gotschlich, 1994a; Jennings et al., 1995; Wakarchuk et al., 1996). Several additional genes involved in LOS biosynthesis also have been identified. By altering the anomeric configuration of heptose, subsequent sugar additions were blocked or, when added, failed to form native conformations (Drazek et al., 1995). This indicates that there is a real need to identify the nature of the genetic defect to understand how the phenotype arose. An additional gene, *lgtG*, is needed for β-chain extension. This gene contains a polycytosine tract. When this gene contains cytosines that would produce a full-length protein, strains extend the β-chain and acquire the ability to bind the MAb 3G9 (Banerjee et al., 1998).

The regulation of LOS antigenic variation operates by a mechanism that is different from that described for Opa and pilin. The activity of the protein expressed by *lgtA* is modulated at the DNA level, depending on the number of gua-

nines found in the middle of its coding sequence. Changes in the number of guanine residues change the reading frame, resulting in the production of a functional protein (makes an LOS that reacts with MAb 1B2) or a nonfunctional protein resulting in the production of a truncated LOS (reacts with MAb 2-1-L8). This same gene also is involved in determining if a strain surface expresses multiple LOS components (Burch et al., 1997). While gonococci expressing the lacto-*N*-neotetraose (binds MAb 1B2) moiety can invade human genitourinary epithelial cell lines Hec1b or PC3 (J. M. Griffiss, presented at the 10th International Pathogenic *Neisseria* conference) or ME180 cells (Song et al., 2000), it is not known if this molecule is required for invasion of all epithelial cells, nor if other LOS components also can mediate this process. It is believed that this type of invasion is mediated by LOS binding to the asialoglycoprotein receptor (Apicella et al., 1996; Harvey et al., 1997; Porat et al., 1995). These data indicate the importance of the lacto-*N*-neotetraose structure in gonococcal pathogenesis. However, because attachment and invasion can occur in the absence of this LOS clonotype (Song et al., 2000; van Putten et al., 1995), it further demonstrates the complexity of what is essential for gonococcal pathogenesis.

Although structural studies on gonococcal LOS have been extremely useful in helping understand the genetic pathways utilized for their synthesis, the focus of these studies on a few strains that express highly similar LOS structures has led to the incorrect conclusion that only a small number of LOS structures are present in the gonococcus. Furthermore, studying the role of this molecule in pathogenesis by utilizing strains that can vary the expression of this molecule, without determining if variation of the molecule occurred during the study, has led to incorrect conclusions for the role of this molecule in pathogenesis.

Meningococcal LOS is a critical virulence factor in *N. meningitidis* infections and is involved in many aspects of pathogenesis, including the colonization of the human nasopharynx, survival after bloodstream invasion, and the inflammation associated with the morbidity and mortality of meningococcemia and meningitis. The meningococcus also can express a diverse range of LOS structures. This diversity has been divided into 12 immunotypes, each recognized by a distinct MAb (Scholten et al., 1994). The genetic loci responsible for LOS synthesis in the meningococcus are highly similar to those identified in the gonococcus (Jennings et al., 1999). However, the genetic organization of the *lgt* gene cluster appears to be more variable, with deletions of genes needed to add the terminal Gal*N*ac onto the lacto-*N*-neotetraose precursor commonly occurring. These data indicate that LOS variability in the meningococcus has fewer options owing to the loss of genetic material.

However, the type of LOS structure expressed by the meningococcus is a key factor in meningococcal-host cell interactions. Strains expressing Opc and a sialyated LOS are noninvasive relative to bacteria expressing a nonsialyated LOS (Virji et al., 1995). Studies in the mouse model of meningococcal infection indicate that the L8 immunotype (the α-chain consisting of a lactose) predominates in the nasopharynx, though the L3, 7 and 9 immunotypes are found most commonly in the blood of infected mice (Mackinnon et al., 1993). These studies strongly support the role of terminal LOS structures and their phase variation in pathogenesis of meningococcal disease.

Recent research has shown that meningococcal LOS possesses both quantitative and qualitative differences in immunotype expression. The LOSs are more heterogeneous than what would be predicted using current LOS serotyping (Griffiss et al., 2000). Meningococcal strains, like gonococcal strains, use different kinases and glycosyl transferases to substitute LOS in a variety of ways. The structure of the surface-expressed molecule can vary owing to changes in growth conditions and changes in levels of expression of glycosyl transferases. When a strain has the ability to express multiple LOSs, one may predominate. However, the role that these less well-expressed LOSs play in pathogenesis cannot be understated. Whether these organisms express LOS in vivo and whether certain LOS molecules that are poorly expressed in vitro are necessary for pathogenesis remain to be determined.

Most studies on LOS biosynthesis in the Neisseriaceae have focused on pathogenic strains. However, several commensal *Neisseria* spp. make LOS that share epitopes with the gonococcus and the meningococcus (Kim et al., 1989). However, studies of LOS expressed by a variety of commensal *Neisseria* spp. indicate that considerable heterogeneity exists with respect to size of the molecules made and their chemical composition (Johnson et al., 1976; Sandlin and Stein, 1991). The SDS-PAGE analysis of LOS expressed by several commensal species indicates that some are capable of expressing LPS. This clearly demonstrates another biosynthetic potential found within the genus.

Recently, Virji and coworkers demonstrated the presence of the phosphorylcholine in the LOS of several species of commensal Neisseriae and this property could be used to differentiate commensal from the pathogenic strains. Furthermore, the expression of this epitope is encoded by genes that could undergo antigen variation. They further postulated that the incorporation of

this epitope in LOS has the potential to confer the property of immune avoidance and thus of persistence on mucosa (Serino and Virji, 2000).

Pili Neisseria spp. elaborate type IV pili. Pili are filamentous cell surface structures composed of pilin monomers and a small number of accessory proteins. They mediate the initial attachment of the gonococcus to host mucosal epithelial cells (Swanson, 1973) and are essential in the establishment of infection. Gonococcal pilus phase variation is characterized by a rapid on/off switch in which piliated cells give rise to nonpiliated variants and vice versa. In strain MS11, two regions of the gonococcal chromosome act as pili expression loci (*pilE1* and *pilE2*), whereas several other chromosomal regions contain silent (nonexpressing) pilin sequences (Hagblom et al., 1985).

Pilin is encoded by *pilE* (Meyer et al., 1982). Pilin variation depends on a family of variant genes that undergo homologous, intragenic recombination. When the structural gene is located on the chromosome where it will be expressed, the pilin gene is said to be in the *pilE* site. Additional copies of the gene are located in silent sites (*pilS*). Strain MS11 contains a total of 17 silent copies, which are to varying degrees truncated at their 5′ end. These silent loci can be grouped in seven distinct *pilS* loci (Haas et al., 1992).

Antigenic variation of the gonococcal pilus results from the nonreciprocal transfer of partial pilin sequence information from *pilS* into *pilE* (Haas and Meyer, 1986; Hagblom et al., 1985). The resultant, altered *pilE* gene sequence may encode either an immunologically distinct pilin monomer, which can be assembled into functional pili (antigenic variation), or a pilin monomer which is not produced or is inefficiently assembled. This will result in a switch from a piliated (P^+) to a nonpiliated (P^-) colony phenotype (Hagblom et al., 1985).

PCR-based screening has detected homology to a conserved *N*-terminal region of *pilE* in most *Neisseria* spp. examined, including all human commensal isolates. (The three species failing to display homology were isolated from nonhuman sources.) The predicted protein sequences from these species display features typical of all type IV pilins, possessing the two highly conserved regions, SV2 and CYS2. However, a comparative analysis of *pilE* loci from pathogenic and nonpathogenic species reveals two distinct structural groups: one composed of the pilin genes from *N. lactamica*, *N. cinerea*, and the class II pili-producing subset of *N. meningitidis* isolates; the other of gonococcal and meningococcal class I pilin-encoding genes. Because both class I and class II pilin-producing meningococci can act as pathogens, structural relationships among Neisserial pilin genes do not obviously reflect either species membership or ability to cause human disease (Aho et al., 2000).

Pili participate in a surprising number of functions, including bacterial aggregation (Swanson et al., 1971), adhesion to host cells (Nassif et al., 1993; Swanson, 1973), twitching motility (Brossay et al., 1994; Swanson, 1978a), pilus retraction (Merz et al., 2000), dispersal from aggregates and loss of pili (Pujol et al., 1999). These molecules also interact with host cells in a variety of ways, inducing host responses such as cytosolic Ca^{2+} fluxes (Kallstrom et al., 1998), cortical plaque formation (Merz et al., 1999), and cytotoxicity (Dunn et al., 1995; McGee et al., 1981).

The pilus fiber is composed primarily of pilin, an 18-22-kDa polypeptide. Pilin is synthesized as a precursor protein that is processed by the PilD prepilin peptidase/transmethylase (Freitag et al., 1995). This results in a mature pilin subunit with an α-methylated phenylalanine residue at its N terminus (*N*-met-Phe). Neisserial pilins are further posttranslationally modified by *O*-glycosylation and phosphorylation at sites mapping to the exposed surface of the fiber (Forest et al., 1999; Jennings et al., 1998).

The structure of mature GC pilin has been solved to 2.6 Å resolution (Parge et al., 1995). Fiber diffraction, cryoelectron microscopy, antigenic mapping, and molecular modeling indicate that pilin subunits polymerize into a right-handed helical cylinder with fivefold symmetry about the helix axis (Forest et al., 1996; Parge et al., 1995). The pilin tails form a helical coiled-coil bundle; the pilin heads face outward with the globular domain, forming a 30-residue surface-exposed loop. This loop is the hypervariable region of pilin that exhibits the greatest primary sequence and antigenic diversity (Seifert, 1996).

Neisserial pilins undergo primary sequence variation in nature, as well as in the laboratory (Seifert et al., 1994). Variation occurs through a variety of genetic mechanisms at extraordinary rates of 10^{-4} per cell division and is especially prevalent in regions that map to the fiber surface (Seifert, 1996). Small alterations in the primary structures of Neisserial pilins cause changes in immunoreactivity, posttranslational modification, and adhesive function. While mutations that abolish *O*-glycosylation of the meningococcal pilus or phosphorylation of the gonococcal pilus cause only minor effects on adhesion to host cells and other pilus-related functions, other point mutations cause dramatic changes in host cell binding and tropism (Jonsson et al., 1994; Marceau et al., 1998; Nassif et al., 1993; Virji et al., 1991).

Pilus assembly is hypothesized to occur within the cytoplasmic membrane or periplasm (Fuss-

enegger et al., 1997). Multiple gene products are implicated in pilus assembly. Transposon insertion mutants indicate that the *pilF* and *pilD* gene products are required for gonoccocal pilus biogenesis. Mutants lacking the *pilD* gene product, a pre-pilin peptidase, are unable to process the pre-pilin subunit into pilin and were nonpiliated. The *pilF* mutants processed pilin but did not assemble the mature subunit. Both classes of mutants released S-pilin, a soluble, truncated form of the pilin subunit previously correlated with defects in pilus assembly (Freitag et al., 1995), and are present in the bacterial cytoplasm or associated with the bacterial inner membrane.

The formation of surface expressed pili requires the expression of many proteins: 1) a prepilin peptidase that cleaves a short leader peptide from the subunits; 2) a set of integral membrane proteins located in the inner cytoplasmic membrane that may serve as a platform for fimbrial assembly; 3) a hydrophilic nucleotide-binding protein located in the cytoplasm or associated with the cytoplasmic face of the inner membrane that may energize secretion by ATP hydrolysis; and 4) an OM component that forms a channel allowing the translocation of assembled pili through the OM. Pili biogenesis entails three genetically dissociable steps: 1) fiber formation; 2) fiber stabilization; and 3) surface localization of the intact organelle.

In the gonococcus, translocation of pili occurs by the general secretion apparatus where the pre-PilE precursor is processed during secretion into the periplasmic compartment. These molecules are retained in the inner membrane by their hydrophobic *N*-terminal segments, with their hydrophilic C-terminal domains oriented towards the periplasm (Fussenegger et al., 1997). The PilD signal peptidase removes the leader sequence from the cytoplasmic side of the prepilin to generate mature PilE, which can then undergo assembly as subunits associated with their hydrophobic stems. Although their functions are not well understood, PilF, PilG and PilT are among the factors required for this assembly. It has been suggested based on studies of its homologues that PilF may function as an ATPase or kinase (Freitag et al., 1995). The PilG molecule has been proposed to play a role in the optimal localization or stabilization of PilD and PilF (Tønjum and Koomey, 1997). The assembled pili are thought to be translocated across the OM by a gated pore formed by a multimeric form of PilQ (Drake and Koomey, 1995). The PilP molecule appears to function in stabilizing the expression of PilQ as a multimer (Drake et al., 1997). Gonococcal PilT mutants constructed in vitro no longer display twitching motility. In addition, they have lost the ability to undergo natural transformation, despite the expression of structurally and morphologically normal pilus (Wolfgang et al., 1998). The PilC adhesin appears to facilitate passage of the growing organelle through this pore, although the molecular basis for the role of PilC in this process is not well understood (Rudel et al., 1995a; Rudel et al., 1995b).

PilA and PilB are proposed to be members of the two-component family of prokaryotic proteins that transduce environmental signals to cytoplasmic regulators via phosphorylation. The amino-terminal portion of PilA was predicted to contain a DNA-binding motif, and it has been demonstrated that PilA binds DNA in a sequence-specific manner (Arvidson and So, 1995; Taha and Giorgini, 1995). The predicted protein sequence for PilA has significant homology to two GTPases of the mammalian signal recognition particle (SRP), SRP54 and Srα (Taha et al., 1991).

The PilC protein provides gonococcal pili with adhesive properties. The protein is produced in small quantities and is encoded by two variant genes in *N. gonorrhoeae* MS11 (Jonsson et al., 1991). The expression of PilC is controlled by short variable G stretches affecting the translational reading frame and the expression of each *pilC* gene and thus pilus-mediated adherence to epithelial cells (Rudel et al., 1992). The PilC protein has been located at the tip of type 4 pili (Rudel et al., 1995b) as well as on the surface of the gonococcus (Rahman et al., 1997). Surface-bound PilC is involved in DNA uptake (Rudel et al., 1995a) and probably also in pilus transport. Purified PilC, isolated from either gonococci or meningocooci, binds to epithelial cells in vitro (Rudel et al., 1995b; Ryll et al., 1997). Pili mediate adhesion to several human cell types including epithelial cells, endothelial cells and sperm cells (Gomez et al., 1979; Swanson, 1973).

Gonococci and meningococci engage in twitching motility. The *pilT* mutants have more pili than the wild-type strain, adhere avidly (125–200% of wild-type levels) to epithelial cells, and do not twitch (Wolfgang et al., 1998). Furthermore, *pilT* mutants are defective for the DNA uptake step of genetic transformation (Biswas et al., 1989; Wolfgang et al., 1998). The PilT molecule also is involved in pilus retraction. Gonococcal pilus fibers that lack *pilC* do not support epithelial cell adherence, strongly corroborating earlier observations that meningococcal PilC is essential for epithelial adherence.

Peptidoglycan The peptidoglycan composition of the *Neisseria* is typical of other Gram-negative bacteria. The peptidoglycan is composed of muramic acid, glucosamine, alanine, diaminopimelic acid and glutamic acid in an approximate molar ratio of 1 : 1 : 2 : 1 : 1, respectively

(Hebeler and Young, 1976b). The percentage of peptide crosslinking is approximately 41%, which is relatively high for a Gram-negative bacterium (Rosenthal et al., 1980). Gonococcal peptidoglycan is extensively *O*-acetylated, making it more resistant to lysozyme and other human peptidoglycan hydrolases (Blundell et al., 1980; Rosenthal et al., 1983), and this resistance to hydrolases might enable gonococci to persist in vivo or potentiate the biological effects of peptidoglycan in vivo.

Gonococci do not survive long after the cessation of growth. This decrease in viability is often accompanied by cellular lysis (autolysis) that occurs following the depletion of glucose in the medium (Morse and Bartenstein, 1974). Several peptidoglycan-degrading enzymes have been described in the gonococcus by direct biochemical analysis or deduced by the analysis of released peptidoglycan fragments. D-Alanine carboxypeptidase (or endopeptidase; Chapman and Perkins, 1983; Davis and Salton, 1975), *N*-acetylmuramyl-L-alanine amidase (Hebeler and Young, 1976c), transglycosylase (Rosenthal, 1979; Sinha and Rosenthal, 1980), exo-*N*-acetyl-glucosaminidase (Chapman and Perkins, 1983), and endo-*N*-acetylglucosaminidase (Chapman and Perkins, 1983; Gubish et al., 1982) activities have been described in gonococci. It is likely that some of these enzymes normally have a biosynthetic role in cell growth, but that under non-growth conditions (i.e., no cell wall biosynthesis), enzyme activity results in peptidoglycan hydrolysis. Only AtlA, a peptidoglycan transglycosylase that acts as an autolysin in the stationary phase, has been characterized at the molecular level (Dillard and Seifert, 1997).

Other Enzymes And Polysaccharides A variety of *Neisseria* spp. have been shown to synthesize amylosucrase, a glucosyltransferase that synthesizes an insoluble α-glucan from sucrose. The catalytic properties of the highly purified amylosucrase from *N. polysaccharea* have been characterized. This enzyme has been shown to catalyze polymer synthesis, as well as sucrose hydrolysis. Maltose and maltotriose synthesis occur by successive transfer of the glucose moiety of sucrose onto the released glucose. This enzyme also is able to mediate the synthesis of glucosyl transfer onto fructose (Potocki de Montalk et al., 2000). A similar enzyme has been isolated from *N. perflava* (Tao et al., 1988).

An esterase catalyzing the hydrolysis of acetyl ester moieties in cellulose acetate has been purified from *N. sicca* strain SB, a strain that can assimilate cellulose acetate as the sole carbon and energy source. The enzyme is strongly inhibited by phenylmethylsulfonyl fluoride and diisopropyl fluorophosphate, which indicates that the enzyme is a serine esterase (Moriyoshi et al., 1999).

For a discussion of capsules expressed by *N. meningitidis*, please see section below.

Genetics

DNA Content

The genomic DNA sequence of several Neisserial strains has been determined for gonococcal strains FA1090 (http://www.genome.ou.edu/gono.html), for *N. meningitidis* serogroup B strain MC58, and for *N. meningitidis* serogroup A strain Z2491 and *N. meningitidis* serogroup C strain FAM18. Each of these genomes is approximately 2.2 megabases.

Plasmids in *Neisseria* spp. have attracted considerable attention because of their potential role in virulence and association with antibiotic resistance. Many *Neisseria* spp. contain cryptic plasmids, i.e., plasmids with no measurable phenotype. The best-studied plasmid is the gonococcal cryptic plasmid. Almost all gonococcal strains harbor this plasmid (Dillon and Pauze, 1981). The DNA sequence for this plasmid has been determined (Korch et al., 1985b). While early studies suggested that cryptic plasmid sequences could be found in the chromosome of gonococcal strains, subsequent experimentation has shown that this homology is due to the presence of repetitive sequences that can be detected by hybridization under low stringency conditions (Sarandopoulos and Davies, 1993b).

Three promoters have been identified in the cryptic plasmid coding sequence that can direct transcription in *E. coli*. These promoters do not seem to function at a detectable level when the gonococcus is grown in vitro under normal growth conditions. The derived amino acid sequence of a 1.2-kb segment of the plasmid shows a high degree of sequence similarity to the Mob proteins encoded by the colicinogenic plasmids ColA, ColE1 and ColK. An additional Orf has been shown to have significant homology to *cppB* gene, whose product is expressed when the gonococcus is grown under the appropriate growth conditions (Sarandopoulos and Davies, 1993a). Variant cryptic plasmids have been identified that harbored insertion within the *cppB* gene and these insertions would interrupt the expression of this gene. The presence of the insertion suggests a mechanism of modulating the expression of the *cppB*, suggesting an unknown role for this gene in virulence (Roy et al., 1988).

Other *Neisseria* spp. occasionally carry cryptic plasmids. Some strains of *N. meningitidis*, *N. lactamica*, *N. mucosa* and *N. cinerea* carry plas-

mids of various sizes that hybridize with probes made from the gonococcal cryptic plasmid (Ison et al., 1986). Some *Neisseria* spp. also carry cryptic plasmids that do not hybridize to the gonococcal cryptic plasmid probes (Verschueren et al., 1982).

Plasmids encoding β-lactamase have been identified in the gonococcus and meningococcus (Bäckman et al., 1993; Roberts, 1989). These nonconjugative plasmids range in size from 4.1–7.3 Kb in size and share considerable homology with one another (Dillon and Yeung, 1989). These plasmids may have evolved by insertion of the Tn*A* sequence (perhaps introduced from enteric bacteria) into a phenotypically cryptic plasmid of *Haemophilus parainfluenzae*, with subsequent introduction into gonococcal strains (Brunton et al., 1983). Sequence analysis of plasmids of differing molecular weight suggests that these plasmids are all derived from a common progenitor plasmid (Pagotto et al., 2000).

Two types of conjugative plasmids have been described in the *Neisseria* spp. A 24.5-MDa plasmid carries no detectable markers for antibiotic resistance. However, it efficiently mobilizes itself and β-lactamase plasmids between strains of gonococci, meningococci and other commensal *Neisseria* (Roberts and Knapp, 1988b). A 25.2-MDa conjugative plasmid that encodes tetracycline resistance has been identified in gonococci and meningococci. This plasmid was formed by the transposition of the TetM determinant onto the 24.5-MDa conjugative plasmid. Like the β-lactamase plasmids, this plasmid seems to have arisen on several independent occasions (Xia et al., 1995) The 25.2-MDa plasmid will mobilize β-lactamase plasmids and has an extended host range (Roberts and Knapp, 1988a; Roberts and Knapp, 1988b). A variety of Neisserial strains possessing elevated levels of resistance to erythromycin have been identified. Genetic analysis of these strains indicates that they have acquired one or more known rRNA methylase genes, including *ermB*, *ermC* and/or *ermF* (Roberts et al., 1999b). Many of these isolates also are multiresistant and carry a complete copy of the conjugative transposon.

A group of plasmids that are genetically related to the enteric plasmid RSF1010 have been described in *N. meningitidis*, *N. mucosa*, *N. subflava* and *N. sicca* (Facinelli and Varaldo, 1987; Pintado et al., 1985; Rotger et al., 1986). Some of these plasmids specify resistance to sulfonamide alone, whereas others specify resistance to sulfonamide, streptomycin and penicillin.

Genetic Mechanisms

TRANSFORMATION Catlin (1961), who showed that nearly all *Neisseria* spp. were transformable, originally described transformation in the Neisseria. While all gonococcal strains are naturally competent for DNA uptake, successful transformations occur at a much higher frequency when the organism is piliated (Sparling, 1966). Phenotypic expression of competence requires only a utilizable energy source (glucose) and cations, preferentially Mg^{2+} or Ca^{2+}. Piliated gonococci are competent in genetic transformation in all stages of growth in minimal and enriched media, but nonpiliated cells are almost totally incompetent (Biswas et al., 1977).

Experimental data indicate that DNA enters cells in native, double-stranded form (Biswas and Sparling, 1981). More recent experiments suggest that single-stranded DNA intermediates may be part of the transformation process (Chaussee and Hill, 1998). It is known that single-stranded DNA can transform the gonococcus (Stein, 1991). The DNA is taken up into a DNAse resistant state very quickly (Dougherty et al., 1979). In addition, DNA fragments containing the sequence GCCGTCTGAA are preferentially taken up from the environment (Goodman and Scocca, 1988). These sequences are located throughout the genome. They appear to be located more commonly at the end of coding sequences. These sequences are not absolutely required for transformation, as uptake-sequence independent transformation does occur, albeit at a dramatically lower frequency (Boyle-Vavra and Seifert, 1996).

The transformation process can be divided into three distinct steps: 1) sequence-specific uptake of transforming DNA into a DNase-resistant state; 2) transfer of DNA to the cytosol; and 3) processing and recombination of the incoming with the resident DNA. Mutants defective in each of these steps have been identified (Biswas et al., 1989). The process of DNA uptake in gonococci requires the expression of at least three distinct components: pili, PilT and ComP (Wolfgang et al., 1999). Piliated *pilT* and *comP* mutants are deficient in sequence-specific DNA uptake into the cell, the earliest demonstrable step in Neisserial competence (Wolfgang et al., 1998). The ComA, ComL and Tpc factors are not essential for DNA uptake and rather act in a subsequent step. Mutants in *comA* grow normally and are DNA-uptake proficient but blocked in the translocation of DNA into the cytoplasm (Facius and Meyer, 1993). The *comL* gene encodes a peptidoglycan-linked lipoprotein, which is required for efficient transformation; most mutations in *comL* appear to be lethal (Fussenegger et al., 1996a). The *tpc* mutants produce a distinctive rough-colony morphology and bacterial growth in clusters of four (tetrapacs; Fussenegger et al., 1996b). Tetrapacs can be resolved by cocultivation with wild-type gono-

cocci, indicating that Tpc is a diffusible protein. Interestingly, Tpc is absolutely required for the natural transformation competence of piliated gonococci. Each of these mutants lacks the characteristic nucleolytic processing observed with the incoming DNA in both wild-type and non-transformable RecA-deficient gonococci, indicating that they are blocked in the processing and/or the delivery of DNA to the cytoplasm (Facius et al., 1996). Transformation of gonococci with plasmid DNA is markedly more efficient when the transformation recipient contains homologous plasmid DNA (Graves et al., 1982). When the recipient strains lack a homologus sequence, the majority of the transformants identified contain deletions (Sox et al., 1979).

Conjugation A conjugation system was initially discovered in β-lactamase-producing gonococci because they could mobilize small non-self-transmissible R plasmids into other gonococci, *Neisseria* spp. and *E. coli*. This conjugation system is mediated by a self-transmissible plasmid of about 24.2 MDa. This plasmid is found in about 8% of gonococcal strains (Norlander et al., 1979; Sox et al., 1978). A 25.2-MDa tetracycline-resistance plasmid also has been found in gonococci. This plasmid appears to be unrelated to the 24.2-MDa conjugative plasmid (Gascoyne et al., 1990). Restriction endonuclease analysis mapping has shown that there are at least two different conjugative tetracycline-resistance plasmids found in the gonococcus (Gascoyne et al., 1991). Conjugal transfer between various Neisserial and other species occurs, but the rates of transfer can vary significantly. Two highly tetracycline-resistant, β-lactamase-producing *N. gonorrhoeae* strains have been used as donors for conjugation with *N. meningitidis* and commensal *Neisseria* spp. Transfer rates for the 4.4- and 3.2-MDa βlactamase plasmids varied, with frequencies between 10^{-1} and 10^{-9} (Roberts and Knapp, 1988a). These data indicate that once an antibiotic-resistance plasmid finds its way into a Neisserial strain, it is only a matter of time before it will oblate the usefulness of that antibiotic.

Bacteriophage Although many investigators have attempted to isolate bacteriophage capable of infecting various *Neisseria* spp., only a few successes have been reported in the literature (Cary and Hunter, 1967; Phelps, 1967). Phage isolates capable of forming plaques on *N. perflava* were similar in terms of host range, latent period, burst size, antigenic properties, morphology and nucleic acid content. Because neutralization studies with antisera demonstrated that the isolates exhibited a very high degree of serological relatedness, this suggests that the isolates represented a single strain of bacteriophage. This phage exhibited a high degree of host specificity, attacking only one of the several strains of *N. perflava* tested and none of the other species tested (Steinberg et al., 1976). Genomic sequence analysis of FA1090 indicates that this strain possesses many genes that are homologous to phage-encoded genes. However, no evidence indicates that these genes are part of a functional bacteriophage.

Restriction and Modification Systems

Restriction enzymes and their associated methylases have been identified in a wide variety of prokaryotes (Roberts and Macelis, 1993). The presence of modified DNA in the *Neisseria* spp. was first studied by analyzing the ability of various DNA samples to resist cleavage with commercially available restriction endonucleases (Norlander et al., 1981; Prere and Fayet, 1985). These studies suggested that the gonococcus possesses three different DNA methyltransferases (Mtases). Korch and coworkers extended these observations by analyzing DNA sequencing gel profiles generated using chemical sequencing methods. They determined that several palindromic sequences contained methylcytosine and postulated the existence of eight different Mtases (Korch et al., 1985a; Korch et al., 1985b). The molecular basis for each of these enzymes was demonstrated by their cloning (Gunn et al., 1992; Gunn and Stein, 1997; Stein et al., 1992; Sullivan and Saunders, 1988) and biochemical characterization (Clanton et al., 1978; Piekarowicz, 1994; Piekarowicz and Stein, 1995; Piekarowicz et al., 1988a; Piekarowicz et al., 1988b; Piekarowicz et al., 1988c; Piekarowicz et al., 1988d). The data presented in Table 2 summarize what is known about gonococcal R/M systems.

While almost all gonococcal strains examined have been shown to express the Mtases at levels sufficient to give complete modification of the endogenous DNA, the expression of the corresponding endonuclease is highly variable (Gunn and Stein, 1993; Piekarowicz et al., 1988a; Piekarowicz et al., 1988b; Piekarowicz et al., 1988d). Genomic analysis indicates that some of these gene pairs have overlapping coding sequences (Gunn and Stein, 1997; Stein et al., 1995; Stein et al., 1998; Sullivan and Saunders, 1988), suggesting a possible transcriptional regulation mechanism.

The biological implications of expressing multiple R/M systems have been examined. Using strains that differed in their ability to express the S.*Ngo*II R/M system, Stein and coworkers showed the endogenous expression of restriction enzymes is able to efficiently restrict the entry of DNA into the gonococcus via transformation, but not conjugation (Stein et al., 1988). This

Table 2. Mtases present in *N. gonorrhoeae*.

Abbreviations:

[a]Indicates the specificity name given to various gonococcal enzymes, based on their recognition sequence, regardless as to what strain they were isolated from.

[b]Indicates the recognition sequence of the Mtase.

[c]Indicates the method by which the enzyme was detected: 1) purification by column chromatography; 2) protection assays based on the ability of chromosomal DNA to resist cleavage by the named isoschizomer; 3) indicates that the gene has been cloned; and 4) indicates that the presence of the corresponding ENase restricts transforming DNA.

[d]Indicates the ENase used in protection assays.

[e]Indicates that the ENase has been detected, either by column chromatography or via a biological assay.

[f]ND = none detected.

[g]Although this clone encodes an enzyme with the same recognition sequence as *S.Ngo*II, the DNA encoding this sequence shares no detectable homology.

[h]This clone methylates the first cytosine in the recognition sequence at the N4 position. It imparts resistance to cleavage by *Hae*III, but not by *Ngo*PII.

[i]The clone encoding this enzyme has significant homology with the *Eco*K system of *E. coli.*

restriction activity could be prevented with appropriate methylation of the incoming DNA (Butler and Gotschlich, 1991). This host-mediated restriction also could be overcome if the large amounts of transforming DNA are employed, thereby overwhelming the restriction system (Gunn and Stein, 1996).

The presence of multiple restriction systems is not limited to the gonococcus. All *Neisseria* spp. that have been examined have been found to be capable of producing multiple R/M systems (Ritchot and Roy, 1990). Genomic sequence analysis suggests that meningococcal strains possess multiple gene pairs, with each sequenced strain possessing about 16 putative R/M systems (Parkhill et al., 2000; Sullivan et al., 1987). According to the Restriction Enzyme Database (REBASE), which is a collection of information about restriction Enases, Mtases, and the microorganisms from which they have been isolated, thus far eight R-M systems have been solely identified in meningococci (Bart et al., 2000; Bucci et al., 1999; Claus et al., 2000; Roberts and Macelis, 1999a; Sparling and Bhatti, 1984). However, the recognition sites of only a few of the meningococcal R-M systems are known, and only a small number have been cloned and/or defined by their restriction activities in cellular lysates (Claus et al., 2000).

The commensal *Neisseria* spp. also appear to have a wealth of diverse R/M systems (Labbe et al., 1990; Lau et al., 1994; Morgan et al., 1996; Qiang and Schildkraut, 1986; Silber et al., 1988). It has been suggested that because the *Neisseria* spp. are naturally competent for DNA uptake, members of this genus have accumulated these genes from other bacteria over time (Stein et al., 1998). The presence or absence of specific R/M systems in various strains has proven to be useful in studying clonal lineages of epidemic strains (Claus et al., 2000).

DNA Repair

Studies on DNA repair in the gonococcus are limited. The gonococcus is deficient in several DNA repair functions, including photoreactivation (Campbell and Yasbin, 1979) and error-prone repair (Campbell and Yasbin, 1984b). Interestingly, the defect in error-prone repair

may actually reflect the absence of an SOS-like system (an inducible DNA repair system), which is needed to trigger the repair process (Black et al., 1998). Gonococci can repair UV-induced damage using two distinct systems: *uvr*-mediated excision repair (Black et al., 1995; Black et al., 1997; Campbell and Yasbin, 1984a) and RecFOR recombinational repair (Mehr and Seifert, 1998). A broader picture of the DNA repair capacity of the gonococcus has emerged with the availability of the complete genome sequence of *N. gonorrhoeae* strain FA1090. Sequence analysis verifies that the gonococcus lacks the genes associated with error-prone repair and photoreactivation. However, it does possess the genes that encode the necessary proteins for recombinational repair, mismatch repair, very short patch repair, excision repair and oxidative damage repair.

Epidemiology

Strain Typing

NEISSERIA GONORRHOEAE Different serological methods have been used to classify and distinguish between various strains of the gonococcus. The most widely employed method for differentiating between various gonococcal strains is based on a combination of auxotyping and serological characterization. Auxotyping is based on the observations of Catlin and coworkers (Carifo and Catlin, 1973), who determined that most gonococcal strains have defects in various biosynthetic pathways, which prevent the organism from growing on chemically defined media in the absence of specific amino acids. Hence a proline auxotroph will only grow on chemically defined media supplemented with proline.

Knapp and coworkers developed a serological method for differentiating antigenic variants of *N. gonorrhoeae* (Knapp et al., 1984a). This is a Por-based serovar classification system, where serovars are defined by their reactivity with Por-specific MAbs. In combination with auxotyping, serological characterization has proved useful for elucidating the epidemiology of *N. gonorrhoeae* (Van Looveren et al., 1999).

Isoenzyme typing, based on multilocus enzyme electrophoresis, has been applied for the epidemiological studies of gonococcal disease (Selander et al., 1986). Genetic relatedness of gonococcal isolates also has been assessed by using DNA-based typing techniques, including restriction endonuclease analysis using frequently or rarely cutting enzymes (Poh et al., 1992) and random and repetitive-motif-based amplification of polymorphic DNA fragments (Poh et al., 1996). The discriminatory abilities of pulsed-field gel electrophoresis (PFGE) and random and repetitive-motif-based amplification of polymorphic DNA have been shown to be superior to that of traditional auxotype/serovar typing.

The use of various primer sets has been used to develop PCR-based methodologies. For example, O'Rourke et al. (1995) developed a PCR-RFLP method using the *opa* gene as the target for amplification. The 11 *opa* genes are amplified with a single pair of primers and digested with frequently cutting restriction enzymes, and the radioactively labelled fragments are separated on polyacrylamide gels to index the strains to particular *opa* types. This *opa* typing is highly discriminatory and is able to establish the close identity of isolates collected from sexual contacts and of differentiated isolates from a worldwide collection made over the last 30 years.

Although auxotype/serotype classification and DNA amplification/fingerprinting can be used in the epidemiologic characterization of strains, DNA amplification/fingerprinting offers a better discriminatory index than auxotyping or serotyping. It is especially useful for differentiating serologically identical strains and nontypable strains. A combination of serotyping and DNA amplification fingerprinting seems to be the best way to differentiate gonococcal strains in epidemiologic studies, bringing together the simplest techniques and the best discriminatory power among isolates (Camarena et al., 1995).

NEISSERIA MENINGITIDIS This species is classified into serogroups based on the immunological reactivity of the capsular polysaccharide (see Table 3 for the structure of the capsules). Although 12 serogroups have been identified, the three serogroups (A, B and C) account for over 90% of meningococcal disease. The serogroup specificity of *N. meningitidis* is determined by the structure of the expressed capsular polysaccharide. The serogroup A capsule is composed of repeating units of (α1-6)-linked *N*-acetyl-D-mannosamine-1-phosphate (O'Rourke et al., 1995). This structure is chemically distinct from those of the capsules of the other major disease-associated meningococcal serogroups, B, C, Y and W-135, which are composed of or contain sialic acid (Liu et al., 1971).

Many investigators have employed molecular typing methods and shown that meningococcal disease is associated with a variety of different epidemiological patterns. The choice of a typing method is dependent upon the epidemiological questions to be answered and on the population genetics of the organism under investigation. With highly clonal populations comprising independent non-recombining lineages, such as serogroup A meningococci, ribotyping, multilocus

enzyme electrophoresis (MLEE), pulsed-field gel electrophoresis (PFGE), multilocus sequence typing (MLST), and PCR with arbitrary primers (RAPD) or with other gene-based primers provide a constant measure of the relationship between strains. A more restricted portfolio of molecular methods—PFGE, MLEE and MLST—is appropriate for the investigation of the less clonal serogroup B and C meningococci from localized outbreaks (Yakubu et al., 1999).

Most epidemiological investigations of meningococcal disease utilize classification schemes based on differences among meningococcal cell envelope molecules. Like the gonococcus, variations in PorB form the basis for meningococcal serotyping. *Neisseria meningitidis* serogroups B and C were originally subdivided into serotypes by the use of two different classification systems based upon type-specific bactericidal antibodies and immunoprecipitation in agar gels, respectively. The serotype specificities were later found to be associated with different MOMPs and with the lipopolysaccharide. The four or five MOMPs were physiochemically characterized. A new serotyping nomenclature and scheme based on these four or five proteins and the LPS is now used.

Disease Incidence

GONORRHEA The number of reported cases of gonorrhea increased steadily from 1964 to 1977, fluctuated through the early 1980s, increased until 1987, and since 1987 has decreased annually. The incidence of gonorrhea is highest in high-density urban areas among persons under 24 years of age who have multiple sex partners and engage in unprotected sexual intercourse. In 1997, there were 324,901 cases of gonorrhea reported in the United States. The overall rate of gonorrhea has declined 74% since 1975; however, the rate of infection in 1997 was still 122.5 cases per 100,000 persons. The overall gonorrhea rate is much higher in large cities (229.1 per 100,000 people in cities with populations over 200,000). Owing to underreporting, the actual number of cases in the United States is estimated to be about 800,000 cases annually. The annual cost of gonorrhea and its complications is estimated at close to $1.1 billion per year.

MENINGITIS *Neisseria meningitidis* is the leading cause of bacterial meningitis in children and a major cause of septicemia. The majority of cases of invasive meningococcal disease have been caused by *N. meningitidis* serogroup B (46%) and serogroup C strains (45%; Advisory Committee on Immunization Practices, 2000). Disease is most common in children younger than four years, with an attack rate of about eight cases/100,000 individuals. The case fatality rates range from 10–20%, even with rapid and appropriate care. The mortality rate is higher for fulminant meningococcemia than for meningococcal meningitis.

In North America, disease is most common in the late winter and early spring. Blacks have a higher rate of infection than Caucasians (1.5 versus 1.1 in 100,000), and males account for 55% of the cases. People at increased risk for disease include close contacts of index cases, travellers to countries recognized to have hyperendemic or epidemic rates, and persons with functional or anatomic asplenia, properdin deficiency or a terminal complement deficiency (C5 through C8) (Figueroa and Densen, 1991).

Antecedent viral infection, household crowding, chronic underlying illness, and both active and passive smoking also are associated with increased risk for meningococcal disease. During outbreaks, bar or nightclub patronage and alcohol use also have been associated with higher risk for disease. In the United States, persons of low socioeconomic status have been consistently at higher risk for meningococcal disease. However, race and low socioeconomic status are likely risk markers, rather than risk factors, for this disease (Advisory Committee on Immunization Practices, 2000).

Meningococcal meningitis occurs globally. The disease is endemic in temperate climates, causing a steady number of sporadic cases or small clusters with a seasonal increase in winter and spring. A different pattern, with epidemics flaring for two to three consecutive years, has been observed in countries in sub-Saharan Africa. This area has experienced epidemic cycles every 8–12 years in the past, and the intervals between major epidemics have become shorter and more irregular since the beginning of the 1980s. The largest epidemics of meningococcal meningitis are experienced by sub-Saharan African countries within the "meningitis belt" which extends from Ethiopia in the east to Senegal in the west. Epidemics occur in the dry season in this area. While the highest disease rates are found in young children, during epidemics older children, teenagers and young adults also are affected.

Disease

Gonorrhea

Gonorrhea is one of the most common bacterial venereal diseases. Gonorrhea is considered epidemic in the United States. Complicating the high incidence of disease is the increasing appearance of multiple antibiotic resistance. The disease is generally spread via sexual activity; however, gonococcal eye infections can occur in infants infected during the process of passing through the birth canal.

Disease in men occurs after an incubation period of from 2–14 days. Onset of disease is usually marked by mild discomfort in the urethra, followed a few hours later by dysuria and a purulent yellowish green urethral discharge. In women, symptoms usually begin within 7–21 days after infection. A significant portion of infected women is asymptomatic. However, onset is sometimes severe, with dysuria and vaginal discharge. The cervix and deeper reproductive organs are the sites most frequently infected, followed by the urethra, rectum, Skene's ducts and Bartholin's glands. Salpingitis is a common complication.

In women and homosexual men, rectal gonorrhea is common. Women are usually asymptomatic, but perianal discomfort and a rectal discharge may occur. Severe rectal infection is more common in homosexual men. Patients may note a coating of mucopus on stools and report pain on defecation or rectal intercourse. Gonococcal pharyngitis from orogenital contact is usually asymptomatic, but some patients complain of a sore throat and discomfort on swallowing; the pharynx and tonsillar area may be red, exudative and occasionally edematous.

Diagnosis Even though newer nonculture-based molecular methods such as gene amplification and other techniques such as nucleic acid probes are becoming more widely used in diagnostic laboratories, culture is still the most commonly used method of identifying individuals infected with gonorrhea. A Gram-stained smear of urethral discharge allows rapid identification of the gonococcus in >90% of men. However, the cervical Gram stain is only about 60% sensitive in women. This is probably due to the fact that the concentration of *N. gonorrhoeae* in the endocervix can be as low as 10^2 CFU/ml (Perry, 1997). Culture requires that exudates from the urethra, cervix, rectum and other infected sites be inoculated onto a suitable medium (e.g., modified Thayer-Martin medium) and incubated at 35–36°C for 48 h in an atmosphere containing 3–10% CO_2 (Knapp and Rice, 1995).

Nonculture methods, such as enzyme immunoassays and methods based on current molecular biology techniques (i.e., DNA probes, ligase chain reaction, etc.), have been recently incorporated into many clinical laboratories. The advantages to nonculture methods include rapid turnaround time, batching of tests, and the ability to detect nonviable *N. gonorrhoeae*. The enzyme immunoassay methods produce variable results with specimens isolated from women (Donders et al., 1996). The DNA probe assay appears to be much more effective in identifying organisms, with reported sensitivity ranging from 96.3–100% and a specificity of greater than 99% (Iwen et al., 1995; Stary et al., 1993; Stary et al., 1997). While these techniques are more sensitive and more specific and allow testing of urine and vaginal swab specimens, there is still a need for rapid, less expensive, accurate diagnostic tests for gonococci.

Complications In men, postgonococcal urethritis, a common sequela, actually results from infection with other organisms (e.g., *Chlamydia trachomatis*). These two agents are acquired simultaneously but chlamydia has a longer incubation period and does not respond to penicillins and cephalosporins. Epididymitis is

uncommon and usually unilateral. Infection ascends from the posterior urethra along the vas deferens to the lower pole of the epididymis, which becomes painful, warm, tender and swollen. A secondary hydrocele may follow. Abscesses of Tyson's and Littré's glands; periurethral abscesses; infection of Cowper's glands, the prostate, and the seminal vesicles; and urethral stricture are less common.

In women, salpingitis (pelvic inflammatory disease) is the most important clinical problem. This syndrome has two important consequences: 1) sterility and ectopic pregnancy resulting from scarring of the fallopian tubes; and 2) susceptibility to chronic infections due to alterations of fluid flow in the damaged area. Disseminated gonococcal infection (DGI) with bacteremia is more common among women than men.

Gonococcal arthritis, a more focal form of DGI, may be preceded by symptomatic bacteremia. The onset typically is acute, with fever, severe pain and limitation of movement in one or a few joints, unlike DGI, which involves multiple joints. Joints are swollen and tender, and the overlying skin is warm and red. Synovial fluid is usually purulent (WBCs >25,000/μl) and contains gonococci demonstrable on Gram stain and culture. Patients with DGI rarely have positive blood and synovial fluid cultures simultaneously. After aspiration, treatment is started immediately to limit destruction of the articular surfaces of the joint. Pericarditis, endocarditis, meningitis and perihepatitis occur rarely. Ocular infections occur most frequently in newborns but are prevented by prophylaxis.

Prevention At this time, there is no vaccine to prevent gonorrhea. Several prototype gonococcal vaccines have shown limited or no protection against reinfection with *N. gonorrhoeae* despite the generation of serum antibody responses against the vaccine antigens (Boslego et al., 1991). Although candidate vaccines consisting of pilus protein and Protein I (PI) have been evaluated (Tramont, 1989), the results from vaccine trials parallel observations regarding natural gonococcal infections, where local and systemic antibodies have been detected by immunofluorescence in secretions and serum from infected patients, yet there is a high rate of recidivism of gonococcal infections among patients attending sexually transmitted disease (STD) clinics (Tapchaisri and Sirisinha, 1976). The development of a vaccine also is hampered by the lack of an animal model in which to test candidate vaccines. The estradiol-treated mouse model may serve as a useful tool for the evaluation of potential gonococcal vaccine candidates (Plante et al., 2000). There is still hope for the development of effective vaccines because serovar-specific immunity among sex workers has been reported (Plummer et al., 1989).

Meningitis

Two clinically overlapping syndromes—meningitis and bloodstream infection (meningococcemia)—are caused by infection with *N. meningitidis* (meningococcal disease). Meningitis is an infection of the membranes (meninges) and cerebrospinal fluid (CSF) surrounding the brain and spinal cord and is a major cause of death and disability worldwide. The etiology of bacterial meningitis varies by age group and region of the world. Approximately one million cases of bacterial meningitis occur each year, with as many as 200,000 fatalities associated with this infection. Up to 54% of survivors are left with disability due to bacterial meningitis, including deafness, mental retardation and neurological sequelae.

Transmission of the causative agent is by direct contact, including respiratory droplets from nose and throat of infected persons. Most infections are subclinical and many infected people become symptomless carriers. Approximately 20% of the population is colonized with *N. meningitidis* at any given time.

Meningococcal meningitis is characterized by the sudden onset of an intense headache, fever, nausea, vomiting, photophobia and stiff neck. Neurological signs include lethargy, delirium, coma and/or convulsions. Even when the disease is diagnosed early and adequate therapy instituted, the case fatality rate is 5–10% and may exceed 50% in the absence of treatment. A less common but more severe (often fatal) form of meningococcal disease is meningococcal septicemia, which is characterized by rapid circulatory collapse and a hemorrhagic rash.

Diagnosis The proper collection of clinical specimens is important in the isolation of *N. meningitidis*. Clinical specimens should be obtained before antimicrobial therapy is begun to avoid loss of viability of the etiological agent. Treatment of the patient, however, should not be delayed while awaiting collection of specimens. Presumptive diagnosis can be made by observation of Gram-negative diplococci in CSF. However, CSF and blood should be processed in a bacteriology laboratory as soon as possible to allow for comfirmatory culture. Blood and/or CSF are collected and plated on an enriched agar (trypticase soy agar plus IsoVitaleX), with incubation of the agar plates in a 5% CO_2 at 36°C.

Complications The majority of people who contract bacterial meningitis and meningococcal

septicemia survives and make a full recovery; however, some are left with aftereffects or serious disabilities. Physical disabilities and aftereffects include hearing impairments/deafness/tinnitus (can be temporary), loss of sight/changes in eyesight, brain damage, residual headaches, stiffness in joints, loss of balance, clumsiness or lack of coordination, fits/epilepsy, tissue damage (due to acute septicemia, skin grafts may be needed), amputation of digits or limbs (due to acute septicemia) and arthritis.

Prevention Vaccination has proven effective in reducing the incidence of meningococcal disease. The currently available vaccines protect against some serogroups. A single dose of the vaccine may decrease the risk of disease caused by *N. meningitidis* serogroups A, C, Y and W-135. However, vaccination will not totally eliminate risk of the disease because the vaccines do not protect against serogroup B and because, although they are highly effective, they do not confer 100% protection.

Chemoprophylaxis is used for people in close contact with patients in the endemic situation. High risk individuals who should seek chemoprophylaxis include: household contacts, especially young children; child-care or nursery school contacts during previous 7 days; those directly exposed to index patient's secretions through kissing or sharing toothbrushes or eating utensils; those involved in mouth-to-mouth resuscitation or unprotected contact during endotracheal intubation during 7 days before onset of illness; and individuals who frequently sleep or eat in same dwelling as index patient. However, chemoprophylaxis is not an effective means of interrupting transmission during an epidemic. Potential antimicrobials for chemoprophylaxis are rifampicin, mynocycline, spiramycin, ciprofloxacin and ceftriaxone.

Antibiotic Treatment

Gonorrhea The emergence of drug-resistant gonococci has limited the usefulness of many antibiotics for the treatment of uncomplicated gonorrhea. In addition, coexisting chlamydial infections are sufficiently common to require simultaneous presumptive treatment. The United States Centers for Disease Control and Prevention (CDC) recommends that broad-spectrum cephalosporins and fluoroquinolones be used to treat uncomplicated gonorrhea. The CDC currently recommends regimens of fluoroquinolones (single-dose, oral therapy with ciprofloxacin and ofloxacin) for the primary treatment of uncomplicated gonorrhea. In patients known to harbor penicillin-sensitive gonococci, amoxicillin with probenecid may be used.

Meningococcal Disease The use of antibiotics has resulted in a significant decrease in mortality rates among patients with invasive disease. Meningococcal infections are usually treated with penicillin, ampicillin or a combination of penicillin and chloramphenicol.

Antibiotic Resistance

Gonococcal resistance to antimicrobial agents is an increasing problem in the treatment of gonorrhea. A high prevalence of plasmid-mediated high-level or chromosomally mediated low-level resistance to penicillin or tetracycline has been recognized in Southeast Asia and in African countries (Chalkley et al., 1997). The emergence of gonococcal isolates with reduced susceptibility to fluoroquinolones also has become a significant concern (Ison et al., 1998). Antimicrobial resistance in *N. gonorrhoeae* is defined as organisms having a minimum inhibitory concentration (MIC) greater than ≥2.0 mg/liter for penicillin, ≥2.0 mg/liter for tetracycline, ≥128.0 mg/liter for spectinomycin, ≥1.0 mg/liter for ciprofloxacin and ≥2.0 mg/liter for ofloxacin.

Antimicrobial resistance to a variety of antibiotics has been recently reported for *N. meningitidis*. For example, strains expressing a chloramphenicol acetyl transferase possess an MIC for chloramphenicol of ≥64 mg/liter (Galimand et al., 1998). Isolates of *N. meningitidis* with increased levels of resistance to penicillin have been reported, with resistance generally being due to the development of altered forms of the penicillin-binding protein PBP-2 (Mendelman et al., 1988). The MIC for penicillin has increased about 20-fold, with MICs of 1 μg/ml being common. The production of a β-lactamase as a mechanism of penicillin resistance in meningococci is occasionally seen (Dillon and Yeung, 1989). Although the prevalence of resistance in meningococci is still low, continued surveillance is necessary to monitor trends in their susceptibilities to antimicrobial drugs and to advise clinicians on appropriate empirical therapy and chemoprophylaxis.

CHAPTER 3.2.3

The Genus *Bordetella*

ALISON WEISS

Introduction

Description of Genus *Bordetella*

The genus *Bordetella* encompasses a group of Gram-negative, small coccobacilli. They are obligate aerobes and fail to ferment carbohydrates such as glucose. Most members have adapted to live in close association with higher organisms, either as overt primary pathogens or in commensal associations that occasionally result in opportunistic diseases.

Current systematic analysis of 16S rDNA sequences has established *Achromobacter* (Gerlach et al., 2001), not *Alcaligenes* as previously reported, as the bacterial species most closely related to the *Bordetella* (see Fig. 1). *Achromobacter* are free-living organisms that are widespread in soil and water but are also commonly isolated from the hospital environment. They only rarely cause disease, and then in compromised individuals, and appear to lack the constellation of virulence factors associated with *Bordetella*. Interestingly, a missing link uniting the environmental *Achromobacter* and the pathogenic *Bordetella* has been identified recently. A novel microbe, strain Se-1111R (Gerlach et al., 2001), was isolated from river sediment and, unlike the *Bordetella*, is able to grow as a facultative anaerobe under nitrate and selenate-reducing conditions. Comparative analysis of the 16S ribosomal, *rpoB*, *ompA* sequences and other biochemical and genetic factors clearly places this organism in the genus *Bordetella*, and a new species has been proposed, *Bordetella petrii* (Gerlach et al., 2001). Further characterization of this environmental isolate will likely provide important clues to the genetic changes that have occurred, which allow *Bordetella* to evolve from a free-living environmental microorganism to a sometimes pathogenic microorganism within a mammalian host.

Species Within the Genus *Bordetella*

The three main species of *Bordetella*, *B. pertussis*, *B. parapertussis* and *B. bronchiseptica*, are respiratory pathogens of mammals and have an important economic impact on both human health and agriculture. Historically, the classification into species was based on host range and severity of clinical disease. However, it is now apparent that by true genetic criteria, they actually comprise a single group of highly related subspecies. *Bordetella pertussis* and *B. parapertussis* appear to be more host-adapted and differentiated and are less representative of the group as a whole than are *B. bronchiseptica* strains. As a result, the designation "*B. bronchiseptica* cluster" has been adopted to more accurately refer to this group of highly related organisms and will be used in this chapter. Distinguishing *B. pertussis*, *B. parapertussis* and *B. bronchiseptica* is useful for clinical purposes and these species designations will likely remain as a part of medical microbiology. *Bordetella pertussis* would be more accurately designated as *B. bronchiseptica* subspecies *pertussis*, for example; however, the terms "*B. pertussis*" and "*B. parapertussis*" will be used to refer to these important human pathogens in this chapter.

Other distinct species of *Bordetella* have been identified. A few characteristics can be used to distinguish between the different species (Table 1). These include the ability to grow on MacConkey agar, motility, the ability to produce a positive oxidase reaction using Kovács' reagent or Gaby-Hadley reagent, urease activity, and production of a brown pigment. *Bordetella avium* is most distantly related to the *B. bronchiseptica* cluster, with a G+C content of only 62%, compared to 66–68% for the *B. bronchiseptica* cluster (Fig. 2). It is a respiratory pathogen of birds, and disease in turkeys is of major economic importance to the poultry industry (Temple et al., 1998). *Bordetella trematum* is a causative agent of ear and wound infections in humans (Vandamme et al., 1996). *Bordetella hinzii* colonizes the respiratory tracts of poultry (Vandamme et al., 1995) and on occasion has caused disease in humans, with one report of a fatal septicemia (Kattar et al., 2000). *Bordetella holmesii* also causes septicemia in humans (Weyant et al., 1995). Comparison of 16S rDNA

Table 1. Properties that distinguish between members of the genus *Bordetella*.

Species	Hosts and diseases	Mol% G+C	Growth on MacConkey	Motility	*Oxidase*[a] *by* K	*Oxidase*[a] *by* G-H	Urease	Pigment
B. bronchiseptica cluster		66–68						
B. pertussis	Human, whooping cough		–	–	+	+	–	–
B. parapertussis	Human, mild whooping cough		+	–	–	?	+	+
B. bronchiseptica	Mammals, respiratory disease Dogs, kennel cough Pigs, atrophic rhinitis		+	+	+	+	+	–
B. holmesii	Human, septicemia, respiratory disease	61.5–62.3	+	–	–	?	–	+
B. hinzii	Birds, respiratory tract infections, human opportunist	65–67	+	+	+	+	+	–
B. avium	Birds, respiratory tract, turkey coryza	62	+	+	+	–	–	–
B. trematum	Humans, wounds, ear infections	64–65	+	+	–	–	–	–

[a]Different oxidase assays can give different results (Vandamme et al., 1996). K assays were performed using Kovács' reagent. G-H assays were performed using Gaby-Hadley reagent.

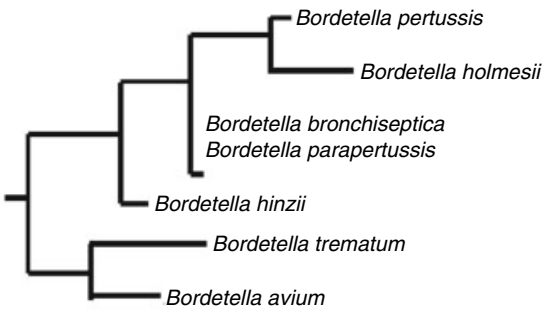

Fig. 2. Phylogenetic relationship of the *Bordetella* based on 16S rDNA sequences. Adapted from Gerlach et al. (2001).

sequences (Gerlach et al., 2001) aligns this species closely with *B. pertussis* (Fig. 2); however, comparison of the 62% G+C content of *B. holmesii* with 67% for *B. pertussis* argues against such a close genetic relationship.

Characterization of the *Bordetella bronchiseptica* Cluster

All members of the *B. bronchiseptica* cluster have been implicated in respiratory disease in mammals. The genomes of a *B. pertussis*, *B. parapertussis* and *B. bronchiseptica* isolate are currently being sequenced (see The *Bordetella pertussis* Genome Project, http://www.sanger.ac.uk/Projects/B_pertussis/ and http://www.medmicro.mds.qmw.ac.uk/bp/). The genomes of *B. bronchiseptica* and *B. parapertussis* are similar in size, approximately 4,400 kilobase pairs (kbp). Interestingly, *B. pertussis* has a smaller genome of approximately 4,000 kbp. It has been hypothesized that in the process of adapting to the human host as its sole pathogenic niche, *B. pertussis* lost genes needed for survival as a free-living organism in the environment. This concept is supported by the fastidious growth requirements of *B. pertussis* and its inability to grow at ambient temperatures much less than 37°C.

Bordetella pertussis is an obligate human pathogen, which causes whooping cough or pertussis. It comprises a distinct and very closely related group of organisms, suggesting recent evolution. The first clinical description of pertussis was recorded in 1640 in France. The unique presentation of whooping cough (the failure of Hippocrates, who accurately described diphtheria and tetanus, to describe pertussis) supports the view that the disease is of recent origin (Cone, 1970). *Bordetella parapertussis* strains also comprise a highly related group of organisms and cause a disease in humans similar to a mild case of whooping cough. Recently, the *B. parapertussis* designation has been applied, inappropriately, to a population of strains that cause

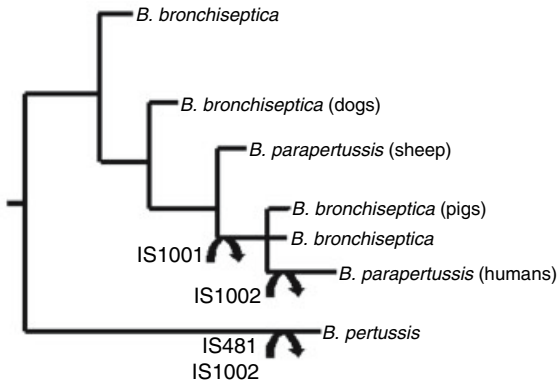

Fig. 3. Genetic relationships between members of the *Bordetella bronchiseptica* cluster based on the presence of genetic elements and multiple enzyme electrophoresis typing. Data from van der Zee et al. (1997) and adapted from Gerlach et al. (2001).

respiratory infections in sheep. These strains have been shown to be more closely related to other *B. bronchiseptica* (van der Zee et al., 1997; Gerlach et al., 2001) than to human *B. parapertussis* isolates (Fig. 3), and this designation should no longer be used for these isolates. *Bordetella parapertussis* will be used only to describe the human cluster in this chapter.

Bordetella parapertussis isolates and human *B. pertussis* appear to have evolved along different evolutionary pathways but interestingly share a unique insertion element, IS1002 (van der Zee et al., 1997), that is present in multiple copies in their chromosomes, which suggests it was shared by horizontal transmission. In addition, *B. pertussis* possesses a unique insertion sequence, IS481. *Bordetella parapertussis* also has a second insertion sequence, IS1001, which is also present in some of the pathogenic *B. bronchiseptica* (van der Zee et al., 1997).

Bordetella bronchiseptica isolates comprise a more diverse group of isolates that vary widely in host range as well as virulence. Members of this group can infect many mammalian species, and the result can vary from persistent colonization without symptoms to serious, debilitating disease. Highly related subgroups have been identified. The strains within a subgroup often have a single preferred host (for example, pigs or dogs) and are more virulent than the broad host-range strains.

Evolution of the *Bordetella* Species

Recent studies suggest that the genus *Bordetella* evolved by a paradigm quite distinct from that put forward by the pathogenicity island theory to explain acquisition of virulence in the enteric species, including *Escherichia*, *Shigella* and *Salmonella* (Ochman et al., 2000). In the pathogenicity island theory, horizontal transmission of blocks of genes (pathogenicity islands) from other species directs evolution into new pathogenic niches. Pathogenicity islands often possess a G+C content quite different from that of the rest of the genome, suggesting they originated from a foreign source, and they are often flanked by tRNA genes, which suggests they were introduced into the chromosome via homologous recombination into these highly conserved, repetitive sites. In contrast to *Escherichia coli*, the genome sequence of *B. pertussis* revealed that the G+C content and codon preferences are uniform for all genes, including those involved in basic bacterial metabolism as well as virulence factors. These observations suggest that the acquisition of virulence traits by *Bordetella* is not recent and the virulence genes evolved in the context of the rest of the genome.

When the genomes of the *B. bronchiseptica* cluster are compared, virulence and adaptation to different hosts appear to involve a selective silencing of genes. The most dramatic example is expression of the pertussis toxin operon. Almost all members of the *Bordetella bronchiseptica* cluster possess the genes for pertussis toxin synthesis and secretion; however, only *B. pertussis* produces pertussis toxin. The inability of *B. bronchiseptica* and *B. parapertussis* to express pertussis toxin appears to be due to the lack of a functional promoter, not to defects in the structural genes. Thus the introduction of a functional promoter allows for expression and secretion of toxin in these strains (Hausman et al., 1996).

A reciprocal relationship is observed with regard to motility and expression of the flagellar genes. *Bordetella bronchiseptica* isolates express flagellar genes and are motile. In contrast, *B. pertussis* isolates possess the genes for flagella, but do not produce flagella (Akerley and Miller, 1993; Leigh et al., 1993) and are not motile. Other examples of selective silencing of genes have been reported for the *Bordetella bronchiseptica* cluster. The interested reader is directed to an excellent review of the evolution of the *Bordetella* (Gerlach et al., 2001).

Significance

Human Diseases

Bordetella pertussis is the causative agent of human whooping cough. While largely controlled by vaccination in industrialized nations, whooping cough remains a major cause of mortality worldwide, resulting in approximately 400,000 deaths a year. Most of the victims are

children. In industrial nations, the disease is rarely fatal, except in infants. *Bordetella pertussis* is spread by coughing and has no environmental reservoir other than infected humans. It has become apparent that milder subclinical disease, which is not recognized as "whooping cough," is rather common in teenagers and adults who were vaccinated as children. This milder form of disease is characterized primarily by a persistent cough that can last four weeks or more (Cherry, 1999b; Jackson et al., 2000). These individuals are thought to serve as the reservoir that allows *B. pertussis* to maintain itself in the human population. All infected individuals are capable of transmitting the organisms, and in a nonimmune individual this can result in a textbook case of whooping cough as described below.

All of the other *Bordetella* species, with the exception of *B. avium*, have been isolated from humans. *Bordetella parapertussis* isolates are primary pathogens and cause a milder form of whooping cough. The other *Bordetella* species cause opportunistic infections and appear to lack the ability to infect a healthy human host.

Agricultural Diseases

Kennel cough in dogs and atrophic rhinitis in pigs (the result of nasal passage deformation due to inappropriate cartilage and bone growth) are the diseases with the biggest economic impact caused by the *B. bronchiseptica* group. *Bordetella avium* is a respiratory pathogen of birds. Turkey coryza is of major economic importance to the poultry industry.

It can be argued that the strains with the greatest agricultural impact are not primary pathogens, but rather are opportunists. While fatal disease is often observed on farms, experimentally induced infections are often asymptomatic and self-limiting. These opportunists take advantage of the crowded, stressful and unhealthy conditions that result from modern large-scale farming conditions. For example, the concentration of ammonia in the air on pig farms can exceed what is allowable for even short-term human exposure. The resulting damage to the respiratory tract enables *B. bronchiseptica* to evade the immune defenses present in the healthy host. In addition, there is evidence for strain-specific susceptibility to disease in agricultural animals, which are extremely inbred. The development of effective vaccines is a goal of both human and agricultural research. Cross protection among different members of the *B. bronchiseptica* cluster has not been demonstrated. For example, the pertussis vaccine can prevent infection by *B. pertussis* but not by *B. parapertussis* (Khelef et al., 1993).

Habitats and Isolation

Pertussis or Whooping Cough (*B. pertussis*)

Whooping cough can be separated into three relatively distinct phases: catarrhal, paroxysmal and convalescent. Disease initiates with the catarrhal phase. The bacteria establish a localized infection in the respiratory tract, resulting in local tissue damage, and produce symptoms similar to the common cold (cough, fever and runny nose). After about a week, the disease progresses to the more serious paroxysmal phase. Patients develop the characteristic cough, where prolonged expulsive coughing ends with a "whoop," in a frantic effort to inhale. Vomiting of thick mucus often follows. Interestingly, following a paroxysm the patient can appear to be quite healthy for several hours until some event triggers another paroxysm. This phase of the disease can be very persistent, and the Chinese call whooping cough the "Cough of One Hundred Days." After prolonged illness, patients enter the convalescent stage and their symptoms gradually improve. Mortality is very rare in children over the age of one with access to good health care, but it can be fatal in infants.

In addition to the characteristic cough, the presence of an elevated white cell count, or lymphocytosis, is an important diagnostic aid. Lymphocytosis is due to the effects of pertussis toxin. Antibiotic treatment is beneficial to the patient only if initiated before whooping has begun. This is consistent with the concept that the early symptoms of the disease result from bacterial damage to the respiratory tract and the later symptoms are due to toxins released by the bacteria. Antibiotics can eradicate the microorganisms but cannot reverse the effects of toxins, which can cause damage far from the site of bacterial growth. Since diagnosis is often delayed until the paroxysmal coughing develops, it is often too late for antibiotics to be helpful.

Isolation and Cultivation of *B. pertussis* and Other Fastidious *Bordetella*

Bordetella pertussis isolates have been isolated only from the human respiratory tract. They are slow growing and will double only once every 4 hours under optimal conditions. It can be difficult to obtain logarithmic growth, suggesting that under such conditions only a subset of the bacteria are replicating, even if the density of the culture is increasing. *Bordetella pertussis* isolates are sensitive to fatty acids, and Dacron swabs, rather than cotton, are used to transfer the bacteria. Bordet-Gengou agar is the most commonly used growth medium for laboratory cultivation. The base medium contains potato infusion, sodium chlo-

ride and glycerol and may be supplemented with casein or peptone digests. After autoclaving, 15% sterile defibrinated blood (usually sheep blood) is added to the cooled agar before plates are poured.

An advantage to using Bordet-Gengou agar is that it allows for visualization of hemolysis, or lysis of the blood cells, which is mediated by the adenylate cyclase toxin, a protein that is only expressed when the bacteria are in the virulent state. All members of the *B. bronchiseptica* cluster undergo a phase variation from a virulent phase, where genes involved in promoting survival in the mammalian host are expressed, to an avirulent state where virulence genes are not expressed. The transition from a virulent to an avirulent state is controlled by a two-component regulatory system encoded in the *bvg* (*Bordetella* virulence genes) locus, which will be described in more detail in the section, Phase Variation and Bvg Control. Spontaneous mutants in the bvg locus can arise at a high frequency when the bacteria are grown in vitro, and it is important to monitor production of hemolysis to ensure the culture has not mutated.

Many clinical laboratories use Regan-Lowe charcoal agar to cultivate *B. pertussis* from an appropriate clinical sample (Tilley et al., 2000). The antibiotic cephalexin can be added at 40 µg/ml to inhibit the growth of other respiratory flora. *Bordetella pertussis* possesses a chromosomally encoded β-lactamase that confers resistance to penicillin and cephalosporin antibiotics. Regan-Lowe medium has a longer shelf life than Bordet-Gengou has (Hill et al., 2000), which is important since pertussis is often sporadic, and it is expensive to maintain a constant supply of medium that is only suitable for cultivation of *B. pertussis*. *Bordetella pertussis* colonies can be identified on either Bordet-Gengou or Regan-Lowe as tiny gray colonies that can take up to 7 days to develop. The colonies have a "mercury droplet" or a pearl-like appearance under a dissecting scope. They are oxidase positive and will not grow on chocolate agar. Agglutination with *B. pertussis* antiserum confirms the diagnosis.

The extra antigens present in complex media are not desirable for vaccine production, and it is preferable to use a defined medium that does not contain animal products such as blood. Stainer-Scholte broth is a simple defined medium that is commonly used in vaccine production (Table 2).

It has been reported that after several days of growth in vitro, *B. pertussis* can induce their own modulation to the Bvg-minus, avirulent state (Bogdan et al., 2001) by a process associated with production of sulfate ions from compounds present in the growth medium. Variability of cultures with respect to the Bvg phenotype could result in considerable variation in experimental results, and investigators wishing to examine the role of bacterial virulence factors need to ensure that the culture being examined is in the Bvg-positive virulent state.

Table 2. Stainer-Scholte Broth

Part 1. Stainer-Scholte salts solution	
Tris hydrochloride	6.36 g
Tris base	1.18 g
Glutamate (monosodium salt)	10.72 g
Proline	0.24 g
NaCl	2.5 g
KH_2PO_4	0.5 g
KCl	0.2 g
$MgCl_2$ (or 0.5 ml of 1 M solution)	0.1 g
$CaCl_2$ (0.135 ml of 1 M solution)	0.02 g
Dissolve in 1 liter of deionized water and sterilize by autoclaving.	
Part 2. Supplements (100 X stock solution)	
L-Cystine	0.4 g
Dissolve in few ml of concentrated HCl, adjust to 100 ml with deionized water. Add	
$FeSO_4 \cdot 7H_2O$	0.1 g
Ascorbic acid	0.1 g
Niacin	0.04 g
Glutathione (reduced)	1.0 g
Filter sterilize, add 10 ml per liter of sterile salts solution (store refrigerated).	

Clinical Diagnosis of Pertussis Widespread use of the pertussis vaccine has greatly reduced (but not eliminated) pertussis in developed nations. Pertussis vaccines appear to confer a sustained level of protection through school age, but it is now apparent that mild disease is common in teenagers and adults (Cherry, 1999a). These individuals likely serve as the source of infection to infants, and infection during infancy is frequently fatal. The disease appears to be on the rise and even today, the source of infection cannot be determined for about a third of all cases in infants. Public health efforts to control the disease could be improved if better diagnostic tests were available.

Diagnosis of pertussis is a challenge, and several methods are commonly used (Hallander, 1999; de Melker et al., 2000; Tilley et al., 2000). Culture from nasopharyngeal swabs or aspirates is the gold standard for diagnosis of disease. Swabs should be immediately transferred to a transport medium of 1% casamino acids in phosphate buffered saline (PBS) and plated within 24 hours if possible. It is difficult to grow these fastidious microorganisms, and not all clinical laboratories can successfully culture *B. pertussis*. Furthermore, sensitivity diminishes with the

duration of illness, leading to the problem that it is difficult to isolate the organisms when pertussis is most likely to be considered in a differential diagnosis. Polymerase chain reaction (PCR)-based tests are available for pertussis, and PCR can be more sensitive than culture, especially in the later stages of disease (Heininger et al., 2000). However PCR suffers from the usual specificity problems, and not all laboratories can reliably perform these tests.

There are also a number of commercially available enzyme-linked immunosorbent assays (ELISAs). Some assays compare initial titers with convalescent titers, looking for an increased response to *Bordetella* antigens. While useful for epidemiological studies, such assays are less useful for diagnostic purposes. Single-point serologic tests are being developed that look for a response above a threshold value thought to be negative based on population studies (de Melker et al., 2000). However, it has become apparent that there may be problems with the existing ELISAs, especially the single-point serologic tests, and the utility of these may be compromised in the future. They all measure titers to antigens present in the acellular vaccines (pertussis toxin, filamentous hemagglutinin (FHA), pertactin, or fimbriae), making it difficult to diagnose pertussis in vaccinated individuals who may already possess high titers to these antigens. Thus, development of new assays that measure responses to antigens not present in the pertussis vaccine is needed.

Treatment of Pertussis The symptoms of clinical pertussis are the result of two different microbial processes. Local damage of the respiratory tract is due to the presence of the bacteria in a normally sterile site of the body. In addition, systemic manifestations are due to the elaboration of toxins, in particular pertussis toxin. Many symptoms of the disease have been replicated in experimental animals treated with purified pertussis toxin in the absence of the microorganisms. These symptoms include lymphocytosis, hyperinsulinemia, hypoglycemia, and sensitivity to treatments that alter metabolic balance, such a serotonin, endotoxin and cold. Antibiotic treatment will eradicate the microorganisms, but has no effect on toxin-mediated symptoms. Therefore, antibiotic treatment is most beneficial to the individual if it is given early in the infection, before significant levels of pertussis toxin have been produced. Antibiotic treatment can prevent transmission and is particularly useful in an epidemic where heightened awareness of the disease improves the chances of early diagnosis. The possible benefits of passive therapy with anti-pertussis immunoglobulin are being evaluated (Granstrom et al., 1991; Bruss and Siber, 1999a; Bruss et al., 1999b).

Bordetella pertussis produces a β-lactamase and is innately resistant to ampicillin and related antibiotics, and these are not useful for treating pertussis. Erythromycin and related antibiotics are used most frequently to treat whooping cough when an early diagnosis is made, and erythromycin is used for prophylaxis of contacts. A few erythromycin-resistant isolates have been recovered from patients that failed to respond to erythromycin treatment, but for the most part it is assumed that *B. pertussis* isolates are universally susceptible to erythromycin. Standardized procedures for antibiotic-resistance testing have been developed (Hill et al., 2000), but routine antibiotic susceptibility testing is not performed.

Secondary infections by other microorganisms can occur and should be treated with antibiotics. Secondary pneumonia was a major cause of mortality from whooping cough in the preantibiotic era and remains a serious complication in individuals without access to good health care.

Isolation and Cultivation of Other *Bordetella*

As discussed above, with the exception of *B. pertussis*, all species of *Bordetella* can be readily cultivated under normal laboratory conditions without the need for special media and are even able to grow on selective medium, such as MacConkey agar (see Table 1). Many grow well at 25°C and 37°C.

Ecophysiology

Infection by members of the *B. bronchiseptica* cluster is characterized by local infection of the trachea. In some instances, especially following infection by *B. pertussis*, systemic symptoms due to toxin production are also observed. The bacteria elaborate numerous virulence factors that allow them to cause disease, which can be broken down into three general categories: adhesins, factors that enable the bacteria to evade the immune defenses, and toxins, as outlined in Table 3. Several putative virulence factors have been proposed based on DNA homology to virulence factors in other bacterial species (Antoine et al., 2000) and are also listed in Table 3. The actual role of these factors awaits experimental evaluation. The pathogenesis of *B. pertussis* is understood in the most detail and will be discussed first. The other species will be discussed primarily with respect to their differences from *B. pertussis*.

Table 3. Virulence factors of *Bordetella bronchiseptica* cluster.

	Known virulence factors			
	Species			
Factor (size)	Expression	Function	Cellular location	In acellular vaccine?
FHA (200kDa)	All	Adhesin	Surface and secreted	Yes
Fimbriae (polymerized)	All	Adhesin	OM	Some
Pertactin (69kDa)	All	Adhesin	OM	Some

Abbreviations: FHA, filamentous hemagglutinin; OM, outer membrane; BrkA, "*Bordetella* resistance to killing" protein; TCF, tracheal colonization factor; Vag, Vir-activated gene; and Vrg, Vir-repressed gene.
[a]From Antoine et al. (2000).

Phase Variation and Bvg Control

A hallmark of the *Bordetella* is the use of a two-component global regulatory system, encoded by the bvg (*Bordetella* virulence genes) locus, which regulates expression of the virulence factors. The BvgS protein is an integral inner-membrane protein. The periplasmic N-terminal domain senses environmental conditions, such as temperature and ion concentrations, and transmits this information to the cytoplasmic C-terminal domain (Martinez de Tejada et al., 1996). The cytoplasmic C-terminal domain interacts with a transcriptional activator, the BvgA protein, via a phosphorelay system (Uhl and Miller, 1994). In its activated (phosphorylated) form, BvgA binds to the promoters of target genes and activates transcription (Boucher and Stibitz, 1995; Boucher et al., 1997; Boucher et al., 2001).

The reversible switch from the ON (Bvg^+, Vir^+, or virulent state) to the OFF (Bvg^-, Vir^-, or avirulent state) is called "modulation." Temperature is an important switch for *B. bronchiseptica*, which only expresses virulence factors when grown at temperatures around 37°C, the body temperature of its mammalian hosts. Temperature is less of a regulatory factor for *B. pertussis*, which is never thought to persist outside of a human host and grows very poorly at temperatures much less than 37°C. The presence of high concentrations (10–40 mM) of SO_4 ions also causes modulation. Where in the human body *B. pertussis* could encounter such high concentrations of SO_4 ion and why this should serve as a signaling mechanism has been somewhat of a mystery. Recent studies suggest that *B. pertussis* can produce sulfate from sulfur-containing compounds in the growth medium (Bogdan et al., 2001). High concentrations of nicotinic acid and some analogues (Melton and Weiss, 1993) also can promote modulation. Whether the bacteria also produce this signaling compound or acquire it from some other source remains to be determined. Accumulation of sulfate and other compounds could serve as a density-sensing mechanism similar to or in conjunction with quorum-sensing mecha-

nisms (de Kievit and Iglewski, 2000) utilized by other bacteria.

In *B. pertussis*, the Bvg-activated genes include toxins (pertussis toxin, adenylate cyclase toxin and dermonecrotic toxin), adhesins (FHA, pertactin and BrkA), or colonization factors, such as tracheal colonization factor, and BrkA (which protects the bacterium from killing by complement). Interestingly, the product of one of the Bvg-activated genes is BvgR (Merkel et al., 1998a), which acts as a repressor for expression of a class of genes called "the Vir-repressed genes" (or Vrgs). In *B. bronchiseptica*, Vir-repressed genes are important for allowing the bacteria to survive in the environment outside of the mammalian hosts in a nonpathogenic state. Expression of flagella and the motile phenotype are only observed in the avirulent (Bvg–) state (Akerley and Miller, 1993), enabling the bacteria to cope in an aqueous environment. In addition, *B. bronchiseptica* are able to survive in a nutrient-poor environment in the avirulent state, but not the virulent (Bvg^+) state (Cotter and Miller, 1994).

The role of the Vir-repressed genes in *B. pertussis* is unclear. *Bordetella pertussis* isolates are nonmotile and have never been recovered from a source other than a human host and are unlikely to exist outside of the laboratory environment. Mutants in the Bvg-locus are incapable of surviving in mammalian models of disease (Weiss and Goodwin, 1989). In one study, expression of Bvg-induced virulent phase genes was reported to be necessary and sufficient for virulence in *B. pertussis* (Martinez de Tejada et al., 1998), but in another study, mutants lacking BvgR expression had a modest reduction in virulence (Merkel et al., 1998b). Interestingly, Bvg^- minus mutants have been recovered from human cases late in the infection (Kasuga, 1954), suggesting they occur in vivo.

Recently, a new class of Bvg-regulated genes (intermediate-phase genes) has been identified (Cotter and Miller, 1997). Some of these genes are only expressed in a very narrow range of conditions that bridge the fully induced Bvg-activated state and the fully OFF Bvg-repressed state (Stockbauer et al., 2001). Special adhesins that are not expressed in the fully ON Bvg virulent phase have been demonstrated in *B. bronchiseptica* (Register and Ackermann, 1997; Brockmeier, 1999; Stockbauer et al., 2001). These adhesins could enable *B. bronchiseptica* to adhere to the respiratory tract when the bacteria are transitioning from an environmental reservoir where they express the avirulent Bvg^- phenotype and before they have had time to express the virulent phase Bvg^+ adhesins like FHA.

Furthermore, recent studies suggest that the amount of BvgA protein influences the level of expression of the Bvg-activated genes (Kinnear et al., 2001), and some promoters require many copies of BvgA to be bound before expression will be activated. It has been demonstrated that the structural gene for FHA, *fhaB*, is an early gene, coming on within minutes of a switch from the Bvg^- to the Bvg^+ state. The genes in the pertussis toxin operon are late genes, requiring hours to be expressed when the bacteria are switched from the Bvg^- to the Bvg^+ state. Finally, pertactin has been shown to be an intermediate gene (Kinnear et al., 1999). In an elegant study, promoter swap mutants were constructed such that the late-gene pertussis toxin promoter drove FHA expression and the early-gene FHA promoter drove pertussis toxin expression (Kinnear et al., 2001). All of the promoter swap mutants had a modest reduction in virulence, supporting a role for qualitative differences in regulation in addition to the ON/OFF switch.

Together these studies suggest that the Bvg regulon functions in two ways. First, it can act as a switch to sense the conditions and alternate expression of two sets of genes. Each set of genes is designed to permit maximal adaptation to a single ecological niche. Thus, this ON/OFF switch prevents simultaneous expression of both sets of genes, which would be counterproductive. One set of genes is designed to promote colonization of a mammalian host, and the other is designed to promote survival as a free-living environmental microorganism. While it is clear that *B. bronchiseptica* can occupy these two ecological niches, little evidence suggests that *B. pertussis* can survive anywhere but in a human host, and the need for an ON/OFF switch is unclear.

Secondly, in addition to acting as an ON/OFF switch, the Bvg regulon can also act as a rheostat and can fine tune gene expression to promote optimal levels, even when committed to the pathogenic state, as demonstrated by the differential gene expression in response to quantitative difference in BvgA levels. The fine-tuning function performed by the Bvg regulon is likely to be important in *B. pertussis*.

Bvg regulation appears to be a general adaptation in the genus *Bordetella*. The presence of a Bvg-like regulon has been demonstrated in the distantly related *B. avium* (Gentry-Weeks et al., 1991). Temperature has been identified as an environmental signal that controls motility in *B. avium* (Temple et al., 1998), and avirulent mutants in *B. avium* (as in *B. bronchiseptica*) arise at a very high frequency, suggesting a global regulatory switch occurs in these pathogens as well. The presence of an analogous system in the most distantly related of the *Bordetella* species suggests a system like Bvg is likely to be present in other *Bordetella*.

New evidence from the pertussis genome project suggests that the Bvg regulon is only part

of a very large regulatory network in *B. pertussis*. Homologies with 15 complete two-component regulatory systems have been identified, as well as 7 sensors and 5 regulators and 15 σ factors (Locht et al., 2001). Clearly, we have only begun to understand this very complex process.

Virulence Factors of *B. pertussis*

As a successful pathogen, *B. pertussis* has evolved complex mechanisms to maintain itself in the human respiratory tract, even in the presence of a vigorous immune response. A one-to-one correspondence between a human mucosal immune defense and a specific counter defense elaborated by the bacteria is now being identified, and we have only begun to appreciate the subtleties in this complex relationship between host and bacterial pathogen.

ADHESINS Like other *Bordetella*, *B. pertussis* preferentially attaches to the ciliated cells of the trachea. Filamentous hemagglutinin (FHA; Locht et al., 1993), pertactin (Leininger et al., 1991), fimbriae (van den Berg et al., 1999b), and BrkA (Fernandez and Weiss, 1994) have been directly shown to promote attachment to mammalian cells. In addition, tracheal colonization factor (Finn and Stevens, 1995) and Vag8 (Vir-activated gene 8; Finn and Amsbaugh, 1998) may play a role in this process. As a result of the redundancy of adhesins, with the exception of BrkA (Weiss and Goodwin, 1989), mutants deficient in production of a single adhesin are often as virulent as the wildtype strain in animal models of disease (Weiss and Goodwin, 1989; Goodwin and Weiss, 1990; Khelef et al., 1994), and only mutants lacking more than one adhesin are reduced in virulence.

Filamentous Hemagglutinin A large protein of about 220 kDa, FHA is synthesized from a 367-kDa precursor. The N-terminus is modified and most of the C-terminus is cleaved from the mature peptide (Jacob-Dubuisson et al., 1996). Molecules of FHA are found both attached to the bacterial surface and secreted in the culture medium. Mediating attachment by several mechanisms (Locht et al., 1993), FHA uses an RGD (arginine, glycine, and aspartic acid) integrin receptor motif to bind to mammalian cells, and it also binds to carbohydrate and heparin sulfate groups on lipids and proteins.

Autotransporter Protein Family (Pertactin, BrkA, Tracheal Colonization Factor and Vag8) *Bordetella pertussis* possesses several outer membrane proteins in the autotransporter family, several of which have been shown to promote adherence. Pertactin has been shown to mediate attachment via an RGD tripeptide (Leininger et al., 1991). It is processed (Charles et al., 1989) from a large precursor to a form with an apparent molecular mass of 69 kDa and a 30-kDa form. The larger N-terminal portion acts as the adhesin. The 30-kDa C-terminal fragment acts as an autotransporter that promotes translocation of the N-terminal portion to the outer membrane.

The crystal structure of the N-terminal portion of pertactin has been determined, and it has a unique β-helical structure (Emsley et al., 1996; Fig. 4). The structure of the autotransporter has not been determined.

BrkA is 29% identical to pertactin and it is processed in a similar manner. The N- and C-terminal portions of BrkA are 73 and 30 kDa, respectively. The role of the 30-kDa fragment as an autotransporter domain with a role in translocation is supported by studies that demonstrate it can form pores in the outer membrane (Shannon and Fernandez, 1999). Like pertactin, BrkA has two RGD sequences. BrkA mediates adherence to cells (Fernandez and Weiss, 1994). BrkA, but not pertactin, can protect the bacteria from the bactericidal activity of complement, and this additional activity is thought to be its major contribution to virulence (Fernandez and Weiss, 1994). This will be discussed in more detail in the section, "BrkA and Complement Resistance."

Other autotransporter proteins have been characterized. Tracheal colonization factor (TCF) has been shown to promote bacterial

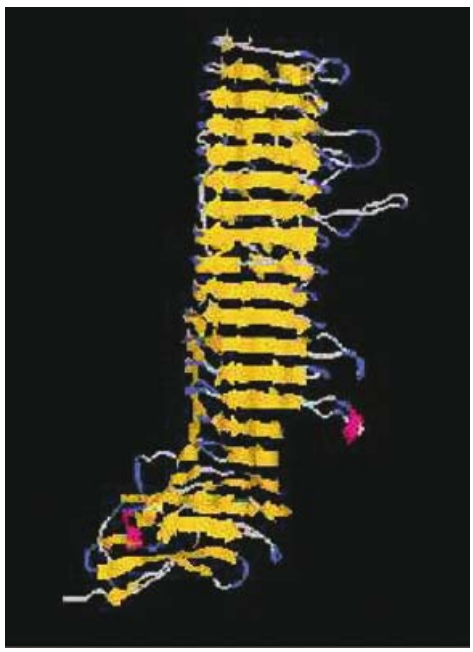

Fig. 4. Cartoon diagram of the crystal structure of pertactin showing the parallel (yellow) β-strands forming one of the three faces in the unique β-helix structure (Emsley et al., 1996).

growth in the trachea (Finn and Stevens, 1995), and Vag8 has no known function (Finn and Amsbaugh, 1998). Both of these proteins possess RGD motifs and could be adhesins. In addition to these confirmed proteins, at least 10 other genes containing autotransporter motifs have been identified in the genome sequence of *B. pertussis* (Locht et al., 2001).

Fimbriae *Bordetella pertussis* also produces several antigenically distinct fimbriae (or pili) that promote adherence (Geuijen et al., 1998; van den Berg et al., 1999b). The minor fimbrial protein, FimD, acts as the adhesin (Hazenbos et al., 1995). The major fimbrial proteins, which form the bulk of the pilus structure and determine the fimbrial serotype, include the serotype 2 and 3 fimbrial proteins. Fimbriae can undergo phase variation, and a single bacterium can express one fimbrial type, two fimbrial types, or no fimbriae (Willems et al., 1990).

Other Roles for Adhesins

Adhesins as Toxins The act of binding to a cell and engaging certain cell receptors can activate signaling pathways that, in the end, result in toxicity. Clear examples of the lethal potential of molecules that mediate toxicity through binding activities are the superantigens, for example, toxic shock syndrome toxin (TSST) of *Staphylococcus aureus*. These toxins bind to the T cell receptor and major histocompatibility complex (MHC) class II molecules (Swaminathan et al., 1992), inducing T cell proliferation and overexpression of cytokines, which can lead to shock and even death. It has recently become apparent that virulence factors of *Bordetella*, which were once considered to only act as adhesins, can also promote toxicity.

Toxic activities have been described for FHA. For example, FHA can be toxic to macrophages by inducing apoptosis (Abramson et al., 2001). In addition, FHA can suppress IL-12 expression by macrophages, resulting in a suppression of Th1-helper T cell-mediated immune responses (McGuirk and Mills, 2000b). Th1-mediated immunity can result in faster clearance of the bacteria (Mills et al., 1993; Redhead et al., 1993; Ryan et al., 1998). Preventing development of a more effective immune response would confer an obvious advantage to the bacteria. It should not be surprising if future studies demonstrate that the other purported adhesins of *B. pertussis* possess additional activities with toxic potential, and there may be a need to inactivate adhesins included in pertussis vaccines.

BrkA and Complement Resistance Complement is present in serum, but it is not generally appreciated that complement is also extruded from the blood to the mucosal surfaces (Persson et al., 1991; Brandtzaeg, 1995) and can play a role in defending against bacteria present on mucosal surfaces. For example, like *B. pertussis*, *Vibrio cholerae* is a mucosal pathogen that produces a potent protein toxin, cholera toxin. Immunity to cholera toxin does not correlate well with the immune response to cholera toxin; instead it correlates with the vibriocidal assay, which measures the ability of serum to kill *V. cholerae* by antibody-mediated complement fixation (Glass et al., 1985; Losonsky et al., 1996). Until recently, the role of bactericidal activity in immunity to *B. pertussis* has been largely overlooked.

The "*Bordetella* resistance to killing" (BrkA) protein can confer resistance to killing by complement (Fernandez and Weiss, 1994). Past reports have suggested that *B. pertussis* is sensitive to killing by complement (Friedman et al., 1992). Explanations for the discrepancies could be due to differences in conditions used to culture the bacteria. *Bordetella pertussis* has been shown to automodulate expression of the Bvg-regulated genes during growth in vitro (Bogdan et al., 2001). The BrkA protein is only expressed in the virulent state, and downregulation of the bvg-locus would in turn downregulate BrkA, resulting in a complement-sensitive phenotype. In addition, growth phase has been shown to influence susceptibility to complement, and stationary phase bacteria are much more resistant to complement (Barnes and Weiss, 2002). It is important for investigators who wish to examine the role of bacterial virulence factors to ensure that the cultures they are using are in the Bvg-positive, virulent state.

Complement has several antibacterial activities. The proteolytic products of complement activation (C4a, C3a and C5a) can upregulate the immune response. Also, C3b deposited on the bacterial surface is a powerful opsonin and can promote phagocytosis by neutrophils and macrophages. Finally, the terminal complement components (C5–C9) form the membrane attack complex. Insertion of the membrane attack complex into the membranes of Gram-negative bacteria leads to bacterial lysis and death (Taylor, 1992; Moffitt and Frank, 1994). *Bordetella pertussis* has several defenses against complement. The surface of *B. pertussis* does not appear to activate the alternative pathway of complement (Fernandez and Weiss, 1994). Antibodies bound to *B. pertussis* can activate the classical pathway, but the BrkA protein protects against the bactericidal activity of complement and antibody (Fernandez and Weiss, 1994). Specifically, BrkA inhibits activation of the complement cascade after the initial step of C1 binding to the bacterial surface (Barnes and Weiss, 2001). In addition to

preventing formation of the membrane attack complex, inhibition of the complement cascade at this initial step prevents activation of other antibacterial activities of complement, including generation of signaling molecules (C4a, C3a and C5a) and deposition of the opsonin C3 on the bacterial surface.

Vaccination with acellular pertussis vaccines does not appear to induce bactericidal activity (Weiss et al., 1999) and may even antagonize an existing bactericidal response (Weingart et al., 2000b). However, some individuals have been shown to mount an immune response that overcomes this bacterial defense (Weiss et al., 1999). Bactericidal antibodies to lipopolysaccharide (LPS) appear to be important in overcoming the BrkA-mediated resistance to complement killing (Weiss et al., 1999).

Toxins of *B. pertussis*

In whooping cough, the bacteria remain localized to the ciliated cells of the respiratory tract for the duration of the infection, causing considerable local damage through the action of tracheal cytotoxin. However, whooping cough also has aspects of a toxin-mediated disease (Pittman, 1979; Pittman, 1984), and *B. pertussis* produces several protein toxins. Two toxins of *B. pertussis*, adenylate cyclase toxin and pertussis toxin, have been shown to be essential for virulence in experimental models of disease. Interestingly, the two toxins act at different times in the disease (Goodwin and Weiss, 1990). Adenylate cyclase toxin appears to be needed immediately upon infection of the host, since adenylate cyclase toxin mutants fail to establish infection and are rapidly cleared from the lungs. Adenylate cyclase toxin has been shown to target the innate immune defenses, especially neutrophils. In contrast, pertussis toxin appears to exert its effects later in infection, since mutants lacking pertussis toxin survive and multiply in the lungs of infected mice for about 10 days, but are then rapidly eliminated by the immune defenses. These results suggest pertussis toxin is needed to disrupt the acquired immune responses. The role of a third toxin in whooping cough, the dermonecrotic toxin, is unclear, but it has been shown to play a role in disease caused by other *Bordetella*.

Tracheal Cytotoxin

The first immune defenses to challenge *B. pertussis* are the mucociliary defenses. The mucociliary escalator is essential for keeping the lungs and lower respiratory tract sterile. Mucus in the respiratory tract traps bacteria, and the beating action of cilia moves the mucus and bacterial particles to the back of the throat where the mucus is swallowed and sterilized by stomach acid. Following attachment by *B. pertussis*, ciliated cells stop beating and eventually die. This process is in part mediated by a factor called "tracheal cytotoxin," which is derived from the bacterial peptidoglycan. Tracheal cytotoxin, in conjunction with LPS, promotes production of interleukin 1-alpha and nitric oxide (Flak et al., 2000), leading to death of the ciliated cells and negating mucociliary clearance.

Pertussis Toxin

Pertussis toxin is a member of the AB_5 toxin family, which also includes cholera toxin and Shiga toxin. With five different protein subunits (termed "S1–S5"), it is the most complex bacterial toxin known. The enzymatic or A subunit, S1, catalyzes ADP-ribosylation of G proteins in the target mammalian cell and blocks signaling through these G proteins. Transfection of mammalian cells with only the S1 gene suggests that the S1 subunit alone is sufficient to confer toxicity (Castro et al., 2001). The B, or binding subunit (composed of subunits S2–S5), is needed to ensure delivery of S1 to the cytoplasm of the target mammalian cells by inducing receptor-mediated endocytosis and retrograde transport through the Golgi (el Baya et al., 1997; el Baya et al., 1999).

Pertussis toxin is essential for bacterial virulence (Weiss et al., 1984; Goodwin and Weiss, 1990). Pertussis toxin interferes with the mechanisms used by host cells to remain in communication with the rest of the body. Introduction of pertussis toxin in experimental animals can also cause the pancreas to secrete too much insulin. Pertussis toxin can also cause weight loss, elevated IgE production, and increased sensitivity to histamine, serotonin and cold. While pertussis toxin alters the behavior of many human and animal cells, its ability to inhibit activation and recruitment of the cells of the immune system (neutrophils, macrophages, monocytes, natural killer (NK) cells, and lymphocytes) in response to infection best explains its role in human whooping cough. Pertussis toxin-induced lymphocytosis is second only to coughing in defining pertussis.

Assembly and secretion of pertussis toxin is a complex process. Each pertussis toxin subunit is synthesized with a signal peptide and is secreted to the periplasm by a Sec-mediated process, where the subunits fold and are assembled into the holotoxin. Finally, nine pertussis toxin liberation (Ptl) proteins, PtlA–H, are required for secretion of the holotoxin past the outer membrane (Craig-Mylius and Weiss, 1999; Craig-Mylius et al., 2000; Weiss et al., 1993). The Ptl-secretion system is a member of the type IV secretion system (Burns, 1999). Interestingly, most of the type IV systems are involved in bacterial conjugation. Each of the nine Ptl proteins

is highly homologous to proteins in bacterial conjugation systems, and the closest matches are to the VirB system of *Agrobacterium* (Weiss et al., 1993). The 11 VirB proteins mediate the transfer of protein-coated DNA from the cytoplasm of the bacteria into the cytoplasm of plant cells. In spite of the strong structural similarities, the job performed by these two systems is very different. The conjugation systems mediate the transfer of DNA past as many as four bacterial membranes, whereas the Ptl complex only moves an AB_5 toxin past the outer membrane. However, in conjugation the DNA is transferred as a protein-coated complex, and this complex may bear some structural resemblance to the protein complex of assembled pertussis toxin.

Pertussis Toxin B Subunit Activities The B subunit of pertussis toxin is the most complex of all AB_5 toxins. For most toxins, the B subunit is formed from five identical proteins. However, for pertussis toxin, four different protein subunits associate to form the B pentamer. There is a single copy of S2, S3, and S5, and two copies of S4.

Dissociation studies performed by sequential treatments with increasing concentrations of urea have separated the B-subunit into different functional units (Tamura et al., 1982). Subunits S1 and S5 have the lowest affinity for the pertussis toxin complex and dissociate first. Addition of more concentrated urea releases two heterodimers. One copy of S4 remains associated with S2, and the second copy of S4 remains associated with S3 (Tamura et al., 1982). The heterodimers are able to bind to mammalian cells and the receptors appear to be present on S2 and S3, but not S4. The S2 and S3 heterodimers have different substrate specificities for glycoproteins and glycolipids on mammalian cells (Witvliet et al., 1989). Additional urea dissociates the heterodimers, but binding activity is lost, suggesting S4 is needed to stabilize the conformation of the binding sites.

The B subunit has been shown to contribute to the disease process in the absence of A-subunit (ADP-ribosylation) activity. The B-subunit possesses T-cell mitogenic activity in the absence of A-subunit enzymatic activity (Gray et al., 1989). In a recent study the purified dimer S3-S4 was shown to have mitogenic activity, as well as a new activity. Purified S3-S4 dimer was shown to cause a reversal in the ratio of CD_4^+/CD_8^+ in T-cells cultured from lymph nodes (Latif et al., 2001). This activity could have important implications in the generation of autoimmune disease, as well as therapeutic potential.

Several different experimental approaches have been used to identify the sites on pertussis toxin that mediate binding to host cells. These include mutational analysis, using synthetic peptides to directly block toxin activity, using synthetic peptides to elicit neutralizing antibodies (Loosmore et al., 1990; Loosmore et al., 1993), and solving the crystal structure of pertussis toxin (Stein et al., 1994a; Stein et al., 1994b). Together these studies suggest that at least three distinct regions on pertussis toxin are responsible for binding to host cells. Two amino acids (tyrosine 102 and tyrosine 103) present on both S2 and S3 bind sialic acid (Fig. 5, shown in red). Since sialic acid is common on mammalian cells, this serves as a universal receptor for pertussis toxin, a notion supported by the nearly universal susceptibility of cells to pertussis toxin. Mutations in the sialic acid-binding domain of S3 reduce toxicity to Chinese hamster ovary (CHO) cells by 10-fold, but did not alter lymphocytosis-promoting activity in mice (Loosmore et al., 1990; Loosmore et al., 1993). A second domain of S3 was shown to be important for the development of lymphocytosis. Lymphocytosis, or elevated white cell counts, occurs when pertussis toxin blocks the ability of lymphocytes to migrate from the blood to the lymphatics. Tyrosine 82 (Fig. 5, shown in orange) present on S3 appears to be required for optimal CHO cell toxicity, as well as lymphocytosis-promoting activity, since mutants in this region are deficient in both toxicity assays.

In vaccine production, methods must be developed that will inactivate toxins, but still preserve enough structure to elicit a good immune response. Ideally, inactivation of pertussis toxin should be done in a way that preserves important functional domains, such as the binding regions. Several different methods are currently used to

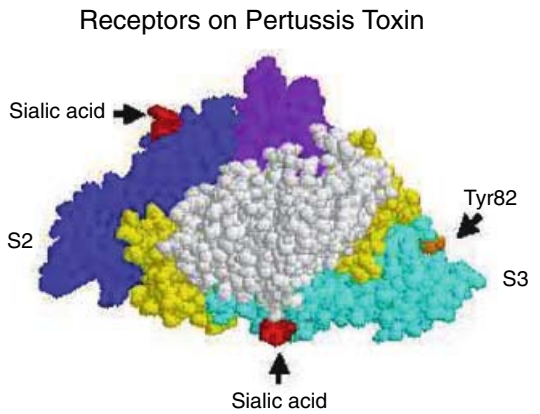

Fig. 5. Amino acids of pertussis toxin necessary for recognition of host cell receptors. A space-filling representation of the crystal structure of pertussis toxin is shown looking down from the top. Subunit S1 is white, S2 is blue, S3 is cyan, S4s are yellow and S5 is purple. Sialic acid residues (from the host) are shown in red. Tyrosine 82 is shown in orange.

inactivate (or make a toxoid from) pertussis toxin. Tetranitromethane (used in the Massachusetts Public Health Labs vaccine) modifies tyrosine residues. Hydrogen peroxide (used in the Amvax vaccine) oxidizes methionine, cysteine (cystine), tryptophan and tyrosine residues. Both of these methods alter tyrosines, the amino acids that are important for toxin binding. These methods are highly likely to completely inactivate the toxin, but are unlikely to elicit antibodies that neutralize the toxin by binding to the receptor binding sites. Formalin (used in the SmithKline, Connaught and other vaccines) covalently modifies primary amines and lysine residues. Interestingly, the S1 subunit of pertussis toxin lacks lysine residues, and formalin treatment primarily affects the B-subunit. However, formalin treatment should not affect the receptor-binding sites. The Chiron vaccine uses genetically inactivated pertussis toxin. In this vaccine, only two critical amino acids in the enzymatic S1 domain of pertussis toxin are altered, and the B subunits remain intact. This vaccine should elicit the broadest antibody response. In human trials, the genetically inactivated pertussis toxin was shown to be the most immunogenic when comparable doses of antigen were compared (Keitel and Edwards, 1999).

The ability of pertussis toxin to bind nearly every type of mammalian cell (el Baya et al., 1999) raises an interesting question. Pertussis toxin is produced by *B. pertussis* in the respiratory tract, but in disease, pertussis toxin is known to affect cells far from the site of infection. How does the toxin reach the distal cell targets when it is capable of being bound and internalized by all of the cells in between? It has been shown that some types of mammalian cells bind pertussis toxin more readily and are more susceptible to the toxin (el Baya et al., 1999). It is also interesting that pertussis toxin can bind to a soluble serum protein, haptoglobin (Witvliet et al., 1989; Latif et al., 2001). This question has not been directly examined, but it is possible that pertussis toxin circulates in the bloodstream loosely bound to haptoglobin and is only able to intoxicate cells that have a higher affinity for pertussis toxin than that of haptoglobin.

Adenylate Cyclase Toxin The adenylate cyclase toxin is a 177 kDa, single chain toxin (for a recent review, see Ladant and Ullmann, 1999). In contrast to pertussis toxin, which is secreted, adenylate cyclase toxin appears to remain on the bacterial surface and only affects the cells that come in contact with the bacteria.

As its name suggests, the adenylate cyclase toxin is an enzyme that can catalyze the conversion of ATP to cyclic AMP (cAMP). Interestingly, the toxin requires the eukaryotic calcium-binding regulatory protein, calmodulin, for maximal activity. Calmodulin regulates the endogenous mammalian adenylate cyclase, and it has been suggested that the bacteria might have originally acquired the gene for the toxin from a eukaryotic source.

The adenylate cyclase toxin can also elevate intracellular cAMP levels in target cells (Gray et al., 1998), an activity referred to as "adenylate cyclase toxin activity" because following exposure to the toxin, cytoplasmic cAMP levels can far exceed what can be achieved by normal cellular mechanisms. While this may not affect the viability of the cell, it can lead to dire consequences for the host. In the case of neutrophils, elevated cAMP inhibits their ability to phagocytose and kill microorganisms (Confer and Eaton, 1982).

A pore-forming activity of the toxin allows the catalytic domain to traverse the cytoplasmic membrane of eukaryotic cells. The toxin is synthesized as an inactive precursor, and posttranslational addition of a fatty acid group (palmitoylation) is needed for the toxin to interact with the mammalian target cells and promote pore formation (Hackett et al., 1995). Unmodified toxin retains enzymatic activity and produces cAMP if supplied with ATP, but it cannot form pores and cannot elevate cAMP inside mammalian cells, and hence it lacks toxin activity (Ehrmann et al., 1992). Pore-forming ability confers a second toxic activity; the adenylate cyclase toxin can cause hemolysis, or lysis of red blood cells. Toxin molecules lacking the palmitoyl modification are unable to mediate hemolysis. This activity is independent of enzymatic activity, since mutants unable to generate cAMP can still cause hemolysis (Gray et al., 1998).

Adenylate cyclase toxin has been shown to be essential for bacterial virulence (Weiss et al., 1984; Goodwin and Weiss, 1990). Several cells of the immune system, including neutrophils and monocytes, are programmed to shut down in response to high cyclic AMP levels, and toxin-treated cells are inhibited for chemotaxis, phagocytosis, superoxide generation, and microbial killing (Confer and Eaton, 1982). Adenylate cyclase toxin also induces macrophages to undergo apoptosis, or programmed cell death (Khelef and Guiso, 1995).

Dermonecrotic Toxin All members of the *B. bronchiseptica* cluster as well as the distantly related *B. avium* group produce dermonecrotic toxin (DNT). The conservation of this toxin would apparently attest to its importance in disease; however, this has not been the case, and its role in disease remains enigmatic. Purified DNT can be lethal to animals when injected; however, DNT is primarily localized to the cytoplasm of

the bacteria (Cowell et al., 1979), and less toxin is delivered when intact bacteria are injected into experimental animals than when sonicated bacteria are injected. To date, no secretion mechanism has been identified that would allow for efficient delivery of the toxin to cells. Also, DNT has been shown to be a virulence factor in some experimental infections, and these will be discussed. However, *B. pertussis* mutants lacking expression of DNT appear to be as virulent as wildtype bacteria when delivered intranasally to infant mice (Weiss and Goodwin, 1989), and a role for the toxin in simple respiratory infection by *B. bronchiseptica* has not been established.

DNT has been shown to play a role in turbinate atrophy in swine atrophic rhinitis. Atrophic rhinitis only affects piglets, not adults, because disease is not due to tissue damage, but rather failure of the turbinates to develop properly in the growing piglet. In particular, DNT has been shown to impair proper development of osteoblasts in culture, resulting in failure of proper bone development (Horiguchi et al., 1991; Horiguchi et al., 1995).

Mutants of *B. avium* lacking expression of the dermonecrotic toxin were avirulent in a turkey model of disease (Temple et al., 1998), but the nature of the genetic lesion in these mutants was less well characterized than in the *B. pertussis* mutants.

The N-terminus of DNT protein has been determined (Kashimoto et al., 1999). The actual start codon for the DNT gene appears to be a GTG, 39 base pairs upstream from a previously predicted ATG start, resulting in a 160-kDa protein (Kashimoto et al., 1999). The N-terminus of DNT mediates binding and internalization into the target cell, and the C-terminus possesses the catalytic activity. DNT has been shown to deaminate glutamine 63 on the mammalian protein, Rho, a GTPase that regulates actin cytoskeletal rearrangements. Deamination by DNT results in decreased GTPase activity, leaving Rho in a constitutively active state (Kashimoto et al., 1999; Schmidt et al., 1999). The connection between molecular activity of DNT leading to activation of Rho and dermonecrotic lesions is not entirely clear, but cytoskeletal rearrangements and shape changes could lead to breaking of tight junctions in the endothelium, resulting in vascular leakage and the blue-black bruise-like lesions seen in experimental models. Other roles for the toxin in disease remain to be determined.

Lipopolysaccharide

Lipopolysaccharide (LPS) serves as an important bacterial defense against toxic compounds; however, it is also a major target for the immune system. The members of the *Bordetella bronchiseptica* cluster produce structurally and antigenically different forms of LPS, and these differences are likely to play an important role in host-range specificity and resistance or susceptibility to the innate immune defenses.

The structure of the LPS of *B. pertussis* has been determined (Caroff et al., 2000), and the genetic basis for the different LPS structures among the members of the *B. bronchiseptica* cluster has been elucidated (Allen and Maskell, 1996; Allen et al., 1998). When LPS from *B. pertussis* is separated on acrylamide gels and subjected to silver staining, two low molecular weight bands are typically observed. The slower-migrating band has been designated "band A" and the faster-migrating band has been designated "band B" (Peppler, 1984). Monoclonal antibodies that distinguish between the two forms have been developed. Band B has been shown to consist of lipid A, linked to one molecule of 2-keto-3-deoxy-D-manno-octulosonic acid (KDO) and a branched oligosaccharide containing heptose, glucose, glucuronic acid, glucosamine, and galactosaminuronic acid (Lebbar et al., 1994; see Fig. 6, double-lined box). Band A contains an additional three sugars, *N*-acetylglucosamine (Glc*N*Ac), a mannuronic acid residue (Man2*N*Ac3*N*AcA), and a fucosyl residue (Fuc2*N*Ac4*N*Me; see Fig. 6, triple-lined box).

Bordetella bronchiseptica produces LPS with the identical band A and B structure, but in addition, it synthesizes an O-antigen structure consisting of polymerized 2,3-dideoxy-di-*N*-acetyl-galactosaminuronic acid (2,3-di-*N*AcGalA; Preston et al., 1999; see Fig. 6, large box). However, some isolates of *B. bronchiseptica* express different antigenic forms of LPS (Gueirard et al., 1998b). The genes for O-antigen synthesis have been deleted from the *B. pertussis* chromosome, and they lack this modification (Preston et al., 1999). *Bordetella parapertussis* synthesizes O-antigen, but the core LPS does not react with the antibodies that recognize band A or band B, and the structures corresponding to band A and band B in *B. parapertussis* have been termed A′ and B′ (Harvill et al., 2000). Twelve genes, *wlbA-L* in the *wlb* gene cluster, have been shown to be required to complete the synthesis of band A, starting from the band B precursor, and the different structure in *B. parapertussis* is due to a difference in the activity of one of the enzymes needed to synthesize this structure (Allen et al., 1998).

The different forms of LPS confer different properties. *Bordetella bronchiseptica* isolates expressing full length LPS are more resistant to the action of antimicrobial peptides than are mutants expressing only truncated B-band LPS (Banemann et al., 1998), and they are also more

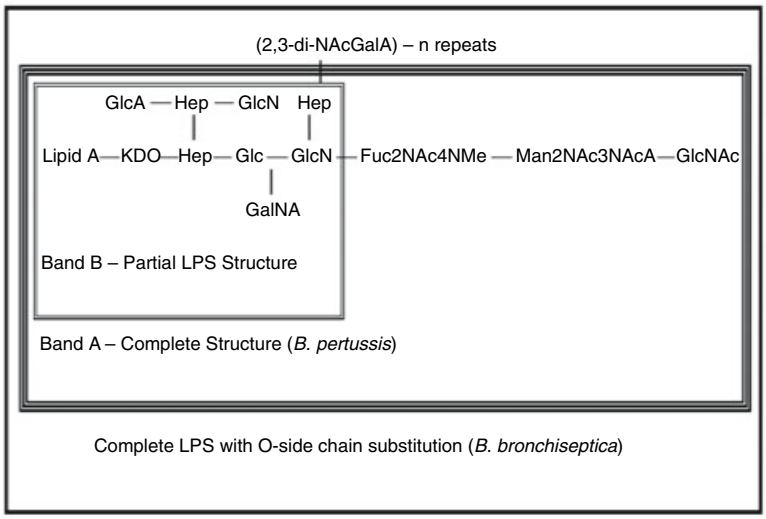

Fig. 6. Structure of lipopolysaccharide (LPS) from *B. pertussis* and *B. bronchiseptica*.

resistant to the action of antimicrobial peptides than *B. pertussis* is (Banemann et al., 1998), a phenotype that could be due to the expression of the O-side chain, although this has not been tested directly. The virulence of mutants of *B. bronchiseptica*, *B. parapertussis* and *B. pertussis* deleted for the *wlb* locus, expressing only band B LPS, was studied (Harvill et al., 2000). Compared to the wildtype strain, the LPS mutants of all three species were defective in the ability to colonize mice in experimental infections and were more susceptible to the bactericidal activity of serum complement from rabbits (Harvill et al., 2000). However, the virulence of each strain was the same in wildtype and C5-complement deficient mice, suggesting complement does not play a role in clearing the infection. Mice have been shown to express inhibitors of complement (Appelmelk et al., 1992), and this may have been a factor in these studies. Interestingly, wildtype LPS was shown to protect against the innate immune defenses for *B. pertussis* and *B. parapertussis*, but LPS appeared to have a role in protecting *B. bronchiseptica* from the acquired immune response (Harvill et al., 2000).

Molecular Basis of Whooping Cough

Innate Immune Defenses in the Respiratory Tract

Immune defenses can be classified as innate (constitutive) or acquired. Acquired defenses (with T cells and B cells as the primary effector cells) mediate the immune responses to microbial agents that the host has encountered previously. Acquired defenses are immunologically specific for each pathogen and are qualitatively improved by repeated exposure to the agent. In contrast, the innate defenses represent initial lines of defense that do not depend upon prior exposure to a microbe. These defenses provide protection against pathogens in the first few minutes of infection (versus 3–5 days for adaptive immune responses) and act to localize the infection and promote adaptive immunity.

Phagocytosis and killing by neutrophils is one of the most important parts of the innate immune defenses. A role for neutrophils in immunity to pertussis has been demonstrated in mouse models of disease. A significant neutrophil infiltration was observed in the lungs of naïve mice and mice immunized with the whole cell pertussis vaccine following aerosol challenge (McGuirk and Mills, 2000a). Neutrophil recruitment was associated with efficient clearance of the bacteria. Adenylate cyclase toxin was shown to be essential for *B. bronchiseptica* to counter neutrophils (Harvill et al., 1999b). Wildtype organisms, but not adenylate cyclase toxin mutants, caused a lethal infection in T- and B-cell-deficient mice. However, both wildtype and adenylate cyclase toxin mutants were lethal in neutropenic mice, suggesting that neutrophils play a critical role in resolving the infection and adenylate cyclase toxin can block clearance by neutrophils.

A similar role for adenylate cyclase toxin could not be demonstrated for *B. pertussis* because even wildtype *B. pertussis* lacks the ability to cause a lethal disease in adult mice (Harvill et al., 1999a), and until recently, the contribution of neutrophils to immunity in human disease had not received much consideration. Early reports suggested that *B. pertussis* was capable of surviving following phagocytosis by neutrophils (Steed

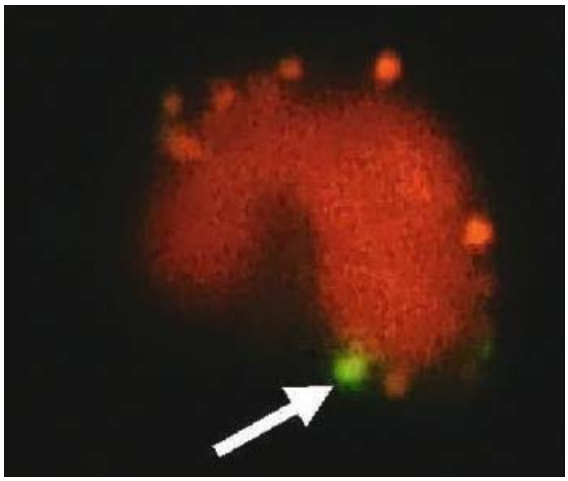

Fig. 7. Method to distinguish extracellular adherent from phagocytosed, intracellular *B. pertussis*. Bacteria expressing the green fluorescent protein (GFP) were incubated with human neutrophils for 1 hour, followed by staining with ethidium bromide. Extracellular bacteria accumulate the stain and appear orange by fluorescence microscopy; however, intracellular bacteria resist staining and remain green (see arrow). Micrograph courtesy of Christine Weingart. From Weingart et al. (1999).

et al., 1991; Torre et al., 1994), but recent quantitative studies report that 98% of the intracellular bacteria are killed by neutrophils (Lenz et al., 2000), suggesting this could be a powerful clearance mechanism (Fig. 7). However, two virulence factors (FHA and adenylate cyclase toxin) alter phagocytosis of *B. pertussis*. Bacteria expressing FHA, but not FHA mutants, attach efficiently to neutrophils but remain extracellular (Weingart and Weiss, 2000a), suggesting that FHA mediates attachment of *B. pertussis* to a site on neutrophils that fails to provoke phagocytosis. Adenylate cyclase toxin inhibits phagocytosis, since mutants lacking adenylate cyclase toxin were efficiently phagocytosed, but only when the bacteria were opsonized with human immune serum (Weingart et al., 1999; Weingart and Weiss, 2000a; Weingart et al., 2000c). Addition of neutralizing antibodies to adenylate cyclase toxin promoted phagocytosis of wildtype *B. pertussis* (Weingart et al., 2000c). Adenylate cyclase toxin is not included in any of the acellular pertussis vaccines and addition of an inactivated form of adenylate cyclase toxin might promote clearance by neutrophils.

Recently, more attention has been directed toward understanding the molecular nature of the innate immune defenses. It has become clear that the innate immune system has evolved receptors (pattern recognition receptors) to detect pattern recognition molecules, or highly conserved microbial structures. Examples of these pattern recognition molecules include peptidoglycan, carbohydrates such as glycans and mannans, bacterial DNA (specifically the CpG motif), teichoic acids (produced by Gram-positive bacteria) and LPS. It is thought that there are up to 100 different pattern recognition receptors. This contrasts sharply with the 10^{18} possible immunoglobulin and T-cell receptors that can be generated by gene rearrangement and somatic mutation. In addition, engagement of the pattern recognition receptors triggers immediate effector responses, and proliferation is not required. The pattern recognition receptors can be secreted or expressed on cell surfaces (primarily macrophages, dendritic cells and B cells).

Secreted pattern recognition receptors target microorganisms for phagocytosis or complement activation. Complement protein C1q, a member of the collectin family, has been shown to activate the alternative pathway of complement in the absence of antibody for some Gram-negative bacteria, but this does not occur with *B. pertussis* (Barnes and Weiss, 2001). As pathogens of the respiratory tract, the *Bordetella* must resist the action of other collectins, surfactant protein A (SP-A) and surfactant protein D (SP-D; Ofek et al., 2001). SP-A has a high affinity for LPS (McCormack, 1998) and can promote phagocytosis and upregulate the immune response. Different types of LPS differ in their ability to interact with SP-A (Song and Phelps, 2000), and it would seem reasonable that respiratory pathogens such as the *Bordetella* would evolve to have minimal susceptibility to this immune defense.

Other receptors of LPS have been described, for example, the soluble LPS-binding protein (LBP). Cells of the myeloid-lineage have a surface bound receptor, CD_{14}, which detects LPS via interaction with LPB. A glycosylphosphatidylinositol anchors CD_{14} to the membrane (Beutler, 2000). Since it lacks a cytoplasmic domain, it cannot signal by itself. Intracellular signaling by LBP and CD_{14} is mediated through interactions with TLR4 (toll-like receptor 4; Lien et al., 2000), and binding of LPS through these molecules initiates a cytokine cascade that in humans can lead to lethal shock following septicemia. Mice lacking TLR4 expression are resistant to endotoxic shock (Beutler, 2000). It will be interesting to determine how efficiently the LPS of *B. pertussis* activates this pathway. In addition, a synergistic interaction of tracheal cytotoxin and LPS has been described (Flak et al., 2000), and it is likely that this occurs through another pathway mediated by pattern recognition receptors.

Other molecules on the mucosal surface such as lactoferrin and transferrin act by limiting the availability for the essential nutrient, iron. Members of the *B. bronchiseptica* cluster are able to

synthesize an iron-scavenging siderophore (Brickman and Armstrong, 1999). Interestingly, mutants of *B. pertussis* deficient in siderophore synthesis were as virulent as the wildtype strain in a mouse model of disease (Pradel et al., 1998), whereas mutants of *B. bronchiseptica* lacking siderophore synthesis were shown to colonize animals, but lacked full virulence in a piglet model of atrophic rhinitis (Register et al., 2001). It is not clear if these differences are due to the mammalian host, the bacterial strain, or both.

The antimicrobial peptides produced on mucosal surfaces are also important in conferring protection from infection. In general, they are small (3–5 kDa) cationic peptides that bind to the microbial surfaces and have a detergent-like action on the membrane. Different antimicrobial peptides have different specificities, and the composition of the LPS plays a major role in conferring susceptibility or resistance to these peptides (Banemann et al., 1998). *Bordetella pertussis* has been shown to resist the action of some antimicrobial peptides via BrkA (Fernandez and Weiss, 1996).

There is considerable species variation in the number of different defensins produced and their tissue distribution. For example, the antimicrobial defensins are abundant in human neutrophil granules, as well as neutrophil granules from rabbits, guinea pigs, rats and hamsters. Interestingly, neutrophils of mice and pigs lack this class of antimicrobial peptide, but do express antimicrobial peptides of the cathelicidin family (Ganz, 1999; Ganz, 2001). This is unfortunate, since mice are the most commonly used species for experimental infections, and it is likely that susceptibility or resistance to defensins plays an important role in determining host specificity for the *Bordetella*.

In addition to these molecular defenses, other factors can play a role in limiting host specificity for *B. pertussis*. The respiratory tract is cooler than the core body temperature and *B. pertussis* prefers to grow at 35°C. Many mammalian species have a higher body temperature than humans, which could influence susceptibility. Anatomical differences could also be important. For example, *B. pertussis* attaches to the cilia of both mice and humans, but just considering relative size of the two species, there is over 1,000-fold difference in the amount of ciliated tissue. Lung infection is common in experimentally infected mice, but less common in humans, and it may be more difficult to access the lungs of humans. Since the innate defenses are often more variable between different species than the acquired immune response is, it is likely that resistance or susceptibility to the innate immune defenses plays an important role in determining host specificity of the *Bordetella*.

Transcriptional Responses to *B. pertussis*

In pioneering studies, microarray analysis was used to examine changes in the transcription program of a respiratory epithelial cell line following incubation with *B. pertussis* (Belcher et al., 2000). The data is {available electronically} [{at relman.stanford.edu}]. Sixty-five genes were downregulated following infection, including several transcription factors and cell adhesion molecules. Thirty-three genes were upregulated, and eight of these encoded proinflammatory cytokines, including neutrophil and monocyte chemoattractants. *Bordetella pertussis* isolates were shown to upregulate expression of mucin by the epithelial cells and to adhere to the mucin that was produced by the cells. Expression of both pro-apoptotic and anti-apoptotic genes was observed. The NF-κB pathway appeared to be activated, but there was no evidence of apoptosis. However, these experiments were performed in transformed cell lines, which may resist apoptosis. Pertussis toxin was shown to downregulate expression of several proteases and fibroblast activation protein. Such responses could alter the composition of the respiratory secretions and may be responsible for the thick mucus observed in pertussis patients.

Overall, it appears that the epithelial cells can detect the infection and send out cytokine signals to mobilize the inflammatory immune defenses, including recruitment of neutrophils. Presumably the bacteria rely on adenylate cyclase toxin and other bacterial defenses to prevent clearance by phagocytes. However, the bacteria, in part via the action of pertussis toxin, alter the transcriptional program to change the fluid composition of the airways in a way that would prevent mucociliary clearance. Future studies promise to yield even more secrets about this complex host-parasite interaction.

Acquired Immunity to Pertussis and the Pertussis Vaccine

The pertussis vaccine was first introduced in the 1940s and standardized in the 1950s. Use of the pertussis vaccine has reduced the incidence of the disease in the United States from 150,000 cases per year in 1925 to about 6,000 in 1998 (Anonymous, 1999). Worldwide, pertussis causes an estimated 400,000 deaths per year, most of which are believed to be vaccine preventable. Part of the problem is that multiple doses of pertussis vaccine are needed to confer protective immunity. A five-dose schedule at 2, 4, 6 and 18 months of age and a booster at school entry are used in the United States. Access to medical care in developing nations can be erratic at best, and immunizing every child after birth using this schedule requires constant access to medical care

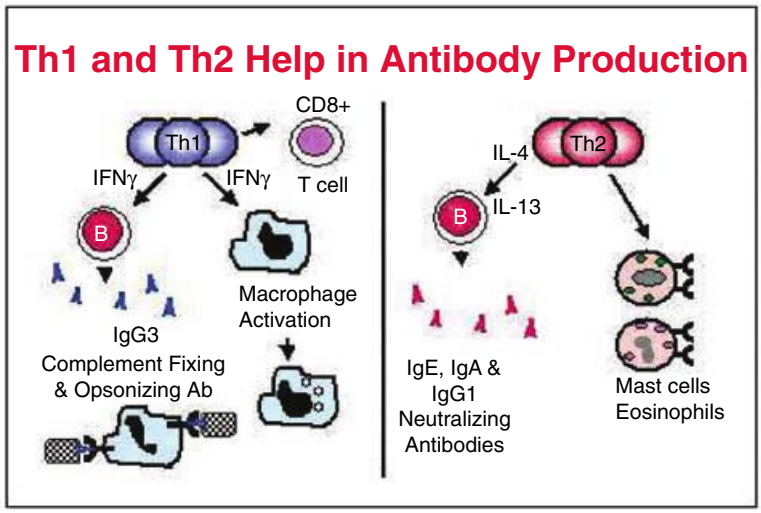

Fig. 8. Th1 and Th2 helper T cells promote antibody production. Th1 cells help promote production of IgG3, the class of antibody that works best with cells, such as macrophages (and neutrophils), that are upregulated by Th1 help. Th2 cells help promote high levels of antibody expression of many classes, including IgE, the class of antibody that works best with the cells that are upregulated by Th2 help, such as mast cells and eosinophils.

and may be more of a challenge than obtaining vaccine.

The whole-cell pertussis vaccine is made of killed *B. pertussis* organisms. Use of this vaccine is associated with adverse effects that are more common after age 6, and the whole-cell pertussis vaccine is not given after this age. The whole-cell vaccine is very inexpensive to manufacture and remains in use in countries where cost is an issue.

The newer acellular vaccines are made with purified protein and appear to have fewer side effects than the whole-cell vaccines. Several formulations have been approved for use. All contain inactivated pertussis toxin, and most are supplemented with varying combinations of the bacterial adhesins: FHA, fimbriae (one or two antigenic types), and pertactin. It is clear that immunization does not yield lifelong immunity, which may account for more frequent occurrence of pertussis in teenagers and adults. Licensing of booster doses for adults using the safer acellular vaccines is being considered.

Recent studies have shed a great deal of light on the benefits and limitations of the current pertussis vaccines. Two studies (Cherry et al., 1998; Storsaeter et al., 1998) designed to establish a serologic correlate of protection have shown that the level of the antibody response to pertactin (Prn), fimbriae (Fim) and pertussis toxin (PT) correlate with protection, but antibodies to FHA do not correlate with protection. A detailed study by Storsaeter et al. (1998) showed that following household exposure to whooping cough, greater than 80% of the unvaccinated individuals coughed for 21 days or more, but so did 24% of the individuals receiving the most efficacious acellular vaccine. In addition, about a third of these vaccinated individuals showed evidence of harboring the microorganisms and coughed for at least a day. Vaccinated individuals with mild disease are a potential source of transmission to those too young to vaccinate, and it would be desirable to develop a vaccine that is more effective at preventing colonization by *B. pertussis*.

The actual mechanisms by which the pertussis vaccines confer immunity have not been clearly elucidated. While there are limitations in using animal studies to study a human disease, experiments by Mills and colleagues using a mouse model for pertussis suggest that the immune system may successfully protect against disease using two different pathways, one involving a Th2 pathway and the other involving the Th1 pathway (Mills et al., 1998b).

The acellular pertussis vaccine induces primarily a Th2 response in mice and protection is correlated with antibody production. Antibodies to pertussis toxin presumably neutralize its toxic activities and antibodies to the adhesins (FHA, pertactin and fimbriae) block attachment and reduce, but do not totally prevent, colonization of the airways (Mills et al., 1998b). Mast cells and eosinophils, the effector cells of the Th2 pathway, do not appear to play a role in immunity to pertussis.

In contrast, the whole-cell vaccine and natural disease induce primarily a Th1 response. Production of the Th1 cytokines upregulates innate defenses (Mills et al., 1998a), recruits neutrophils to the site of infection, and mobilizes other defenses. Neutrophils and the other defenses mediate rapid clearance of the bacteria. In contrast to the Th2 pathway, a clear role for antibody to any specific antigen has not been determined for the Th1 pathway in mice (Mills et al., 1993; Mahon et al., 2000), but opsonizing antibodies may augment phagocytic clearance. The Th1 pathway appears to generate a more effective

immune response than the Th2 antibody-mediated immune response. There is some evidence to suggest that these results in mice correlate well with what is observed in human disease, but human disease presents a more complicated picture.

A difficulty in determining what constitutes a protective immune response in humans may be due to the long period for disease symptoms to develop following infection with *B. pertussis*. Following exposure, individuals may be asymptomatic for a week and have very mild symptoms for another two weeks before experiencing severe symptoms. A secondary immune response to the vaccine antigens will certainly be generated during the first week when no symptoms are apparent, and in the following weeks a primary immune response will be generated against other bacterial antigens not included in the vaccine. It is likely that in some cases, vaccine-induced immunity may be sufficient to protect from disease, but in other cases the immune response to the non-vaccine antigens may be needed to clear the infection. If so, it will be difficult to predict whether an individual will be susceptible or immune to pertussis following vaccination, considering the protective immune response may not have been generated yet.

The hypothesis that vaccine-induced immunity works to slow the growth of the bacteria, and that an immune response to antigens not included in the vaccine may be needed for clearing the infection, agrees well with what is known about the role of the vaccine antigens in the pathogenesis of the disease. The acellular vaccine should generate antibodies to block adherence and neutralize pertussis toxin. Antibodies to the adhesins reduce, but do not appear to eliminate, bacterial attachment to mammalian cells in culture (van den Berg et al., 1999a). Pertussis toxin exerts its effects late (after 15 days) in experimental models of pertussis infection (Goodwin and Weiss, 1990) and seems primarily to target development of the acquired immune response. To date, the vaccine has not been shown to elicit bactericidal immune responses that could eliminate the bacteria (Weiss et al., 1999; Weingart et al., 2000b; Weingart et al., 2000c). Two antigens, adenylate cyclase toxin and BrkA, have been shown to be important in protecting *B. pertussis* from bactericidal immune defenses of opsonophagocytosis and complement killing and should be considered for inclusion in future vaccine formulations.

Possible Development of Vaccine Resistant Strains

There has been concern that the use of only a limited number of antigens in the pertussis vaccines may allow the bacteria to develop antigenic variants that can escape vaccine control. Recently, polymorphisms have been observed in two vaccine antigens (pertussis toxin and pertactin) in clinical isolates of *B. pertussis* collected over several decades (Mooi et al., 1998). The polymorphisms in pertussis toxin involved up to three amino acid substitutions in the S1 subunit, and the polymorphisms for pertactin consisted of amino acid substitutions and changes in the number of GGxxP repeats. These are relatively minor changes in two very large proteins, but they did occur in regions known to be antigenic. Furthermore, it was noted that clinical isolates from 1950 to 1960 had the same antigenic types as in the pertussis vaccine, but more recent isolates expressed antigenic types different from those in the pertussis vaccine. During this same period, the incidence of pertussis was on the rise, and the disturbing hypothesis that *B. pertussis* undergoes antigenic variation to escape vaccine protection was put forward to explain these observations. It should be noted that for the most part, the strains used to develop the pertussis vaccines were isolated in the 1950s, and it should not be too surprising that isolates from this time more closely resemble the vaccine isolates than contemporary isolates.

A similar analysis was performed on isolates from Finland (Mooi et al., 1999), and a shift away from vaccine types was observed in this country as well. In contrast to the situation in the Netherlands, the pertussis vaccine program was successful in controlling the disease in Finland.

B. pertussis strains from the United States collected from 1935 to 1999 have been characterized for polymorphisms in pertussis toxin and pertactin (Cassiday et al., 2000) and by pulsed-field gel electrophoresis (PFGE; Bisgard et al., 2001). The PFGE profiles suggest that *B. pertussis* forms a relatively homogeneous bacterial population, but differences in subtypes and polymorphisms in pertussis toxin and pertactin were observed. Interestingly, decreasing genetic diversity was noted since vaccination was initiated in the United States. Variation in isolates from an epidemic in the Cincinnati area in 1993 suggests that this epidemic was not due to a single clone (which would be consistent with vaccine escape), but was more likely the result of a true increase in the disease rate, possibly due to the presence of more susceptible hosts (Bisgard et al., 2001).

Several studies have attempted to test directly the ability of antigenic variants to escape vaccine protection. In one study, a pertussis toxin variant with 42 amino acid differences was neutralized as effectively as the form of pertussis toxin used in the immunization, suggesting that neutralizing antibodies can tolerate many amino acid changes (Hausman and Burns, 2000). In another study,

mice immunized with a tri-component vaccine (pertussis toxin, FHA and pertactin) similar to human acellular vaccine formulations conferred good protection to strains expressing the same antigenic type used in the vaccine and to strains expressing different antigenic types than the vaccine (Boursaux-Eude et al., 1999).

Overall, these results are more consistent with the hypothesis that *B. pertussis* naturally undergoes population shifts. Polymorphisms in pertactin and pertussis toxin (as well as other genomic changes) have been seen over time for isolates from different countries on different continents regardless of vaccine usage or efficacy, suggesting that vaccine escape is not the primary driving force for these changes. Furthermore, the amino acid changes are so minor they do not appear to alter the ability to mount an effective immune response.

Virulence Factors of the *B. bronchiseptica* Cluster

Type III Secretion System

A type III secretion system has been identified in *B. bronchiseptica* (Yuk et al., 1998). Expression is regulated by the Bvg locus and occurs in the virulent phase. While the genes are present in all members of the *B. bronchiseptica* cluster, transcription has not been detected in most isolates of *B. pertussis* and *B. parapertussis*. Mutants of BscN, the protein believed to energize the secretion process, produced fewer extracellular polypeptides and displayed decreased cytotoxicity for macrophage and epithelial cell lines. Incubation with wildtype *B. bronchiseptica*, but not the BscN mutant, resulted in reduced tyrosine phosphorylation of mammalian cell proteins, an activity similar to that mediated by the YopH phosphatase of Yersinia. The BscN mutants were unable to maintain long-term colonization of the trachea of rats, but nasal colonization was unaffected (Yuk et al., 1998). Wildtype bacteria expressing the type III secretion system, but not mutants, were shown to induce apoptosis by a mechanism that seems to involve inappropriate localization of NF-κB (Yuk et al., 2000). Higher anti-Bordetella titers were observed in animals infected with the mutants in type III secretion system, suggesting it acts to inhibit an acquired immune response (Yuk et al., 2000).

FHA and Fimbriae While mutants in FHA or fimbriae did not display a strong phenotype in experimental infections of *B. pertussis*, *B. bronchiseptica* mutants lacking production of these adhesins were shown to have a more pronounced defect in virulence. In a rat model of disease, FHA is required for efficient colonization of the trachea, but is not required for nasal colonization (Cotter et al., 1998b). The efficient attachment mediated by FHA has been proposed to be important for overcoming mucociliary clearance mechanisms, since FHA was not needed for colonization of the trachea in anesthetized animals where the mucociliary defenses are compromised. Also, FHA was shown to play a role in persistence in the trachea (Cotter et al., 1998b). Fimbriae have also been shown to enhance tracheal colonization in rats and to be essential for persistence at this site (Mattoo et al., 2000).

Bordetella bronchiseptica expresses multiple fimbrial types, and certain types may play a role in host species specificity. A monoclonal antibody to the *B. pertussis* serotype 2 fimbriae was shown to bind to some, but not all, fimbriae expressed by intact bacteria (Burns et al., 1993). *Bordetella bronchiseptica* isolates from different species were characterized and reactivity with the monoclonal antibody was found to correlate with host species (Burns et al., 1993), suggesting that colonization of a specific host species may be enhanced by expression of a certain fimbrial serotype.

Role for the Intracellular State in *Bordetella* Infection Members of the *B. bronchiseptica* cluster have been shown to survive in mammalian cells following phagocytosis (Ewanowich et al., 1989). These studies were among the first to examine the intracellular fate of a bacterial species, which up to that point had been considered to be an exclusively extracellular pathogen. It is now clear that *Bordetella* are not particularly unique in this regard. *Escherichia coli*, *Staphylococcus aureus* (Guzman et al., 1994), and many other bacterial species have been shown to be capable of transient survival inside mammalian cells, and the existence of an intracellular niche for *Bordetella* will be critically examined.

A clinical study published in 1991 found *B. pertussis* associated with alveolar macrophages isolated from children with acquired immunodeficiency syndrome (AIDS) and pertussis, but the authors noted that their methodology could not distinguish intracellular from extracellular bacteria, and they failed to recover viable organisms from the patients, suggesting that intracellular bacteria might not be viable (Bromberg et al., 1991). Several in vitro studies published about this time suggested *B. pertussis* was capable of long-term survival, and perhaps replication, in professional phagocytes, including polymorphonuclear cells (neutrophils) and macrophages (Steed et al., 1991; Friedman et al., 1992; Torre et al., 1994), a surprising result con-

sidering the potent killing mechanisms available to these cells.

Technical issues plagued some of these early reports. Complement was used to kill the extracellular bacteria (Friedman et al., 1992), but *B. pertussis* expressing the BrkA protein resists the action of complement (Fernandez and Weiss, 1994). Inefficient killing by complement could have led to survival of extracellular bacteria, which were assumed to be intracellular. In other studies the bacteria were labeled with fluorescein isothiocyanate (FITC) to allow visualization by fluorescence microscopy (Steed et al., 1991). An amine-reactive probe, FITC covalently binds to the α-amino-groups at the N-terminus or the ε-amino groups of lysines on proteins that are exposed on the bacterial surface. The FITC-labeling was shown to inactivate the adenylate cyclase toxin, which has a lysine in the active site (Weingart et al., 1999). Adenylate cyclase toxin has long been known to be an important bacterial counter-defense, particularly for neutrophils (Confer and Eaton, 1982). As might be expected, neutrophils were shown capable of efficient phagocytosis of FITC-labeled bacteria (Weingart et al., 1999). In contrast, *B. pertussis* labeled cytoplasmically with green fluorescent protein (GFP) was found to efficiently adhere to neutrophils, but to resist phagocytosis (Weingart et al., 1999; Weingart and Weiss, 2000a; Weingart et al., 2000b; Weingart et al., 2000c). Of the few bacteria that were internalized, only about 1% of the bacteria remained viable (Lenz et al., 2000). These data suggest that the primary strategy of *B. pertussis* is to remain extracellular and resist phagocytosis through the action of adenylate cyclase toxin. Bacteria that are successfully phagocytosed are killed.

More recent reports suggest there is a clear difference in the kinetics of intracellular survival between *B. bronchiseptica* and *B. pertussis* strains. While neither species appears capable of replicating intracellularly, *B. bronchiseptica* remains viable for days within mammalian cells and *B. pertussis* has only transient intracellular survival (Friedman et al., 1992; Masure, 1992; Masure, 1993; Guzman et al., 1994; Schipper et al., 1994; Banemann and Gross, 1997; Chhatwal et al., 1997). In one study, fewer than 100 of the more than 100,000 *B. pertussis* internalized by macrophages survived for 24 hours, a rate not too different from that of the avirulent *E. coli*, DH5α (Banemann and Gross, 1997). Furthermore, other studies even suggest that the continued presence of viable *B. pertussis* induces apoptosis and kills mammalian cells (Khelef and Guiso, 1995; Gueirard et al., 1998a), making it unlikely that *B. pertussis* could persist as an intracellular pathogen. These results suggest that a role for intracellular survival is not likely to be important in the pathogenesis of *B. pertussis*. However, *B. bronchiseptica* are capable of long-term intracellular survival, but the role this may play in pathogenesis of the disease remains to be determined.

Conclusions

The genus *Bordetella* comprises a group of Gram-negative bacteria that are well adapted as respiratory pathogens of mammals and birds. They remain a significant threat to human health and agricultural activities. Controlling the diseases caused by the *Bordetella* has proven to be challenging, and there is a need to improve the human pertussis vaccine and to develop effective vaccines or other preventative measures for some of the agricultural diseases. While there is much to learn, the availability of the genome sequence for three members of the *Bordetella bronchiseptica* cluster should aid in this process.

CHAPTER 3.2.4

Achromobacter, *Alcaligenes* and Related Genera

HANS-JÜRGEN BUSSE AND ANDREAS STOLZ

The genus *Alcaligenes* is the type genus of the family *Alcaligenaceae* (De Ley et al., 1986), which is affiliated with the "*Betaproteobacteria*." Other genera within this family, although not all formally described as members of the family, are *Achromobacter*, *Bordetella*, *Kerstersia*, *Pigmentiphaga* and most likely also *Oligella*, *Taylorella* and *Pelistega*. Phylogenetically, they form a homogeneous cluster separate from other taxa within the "*Betaproteobacteria*." Within *Alcaligenaceae*, the species of the genera *Oligella*, *Taylorella* and *Pelistega*, which were reported to have a relatively low G+C-content (36.5–47.5 mol%) of the genomic DNA (Sugimoto et al., 1983; Rossau et al., 1987; Vandamme et al., 1998; Jang et al., 2001), form a separate subbranch.

Like other members of the "*Betaproteobacteria*," species of the genera *Alcaligenes*, *Achromobacter* and *Pigmentiphaga* contain the quinone system ubiquinone Q-8 (Fletcher et al., 1987; Oyaizu-Masuchi and Komagata, 1988; Busse et al., 1992; Lipski et al., 1992; Yokota, et al., 1992; Ahrens et al., 1997; Blümel et al., 2001; Schroll et al., 2001) and a polyamine pattern that contains the predominant compound putrescine and the diagnostic polyamine, 2-hydroxyputrescine (Busse and Auling, 1988; Busse et al., 1992; Hamana and Takeuchi, 1998). Generally, fatty acids of members of these taxa are exclusively straight-chained, completely saturated or monounsaturated. Hydroxylated fatty acids and cyclopropane acids are present as well (Foss et al., 1998; Blümel et al., 2001; Coenye et al., 2003a; Coenye et al., 2003b; Table 1). Identification at the genus level can be easily obtained by comparison of 16S rRNA gene sequences. Unfortunately, no other features are known which are characteristic for a single genus within the family. So far, polar lipid profiles are the most promising tool for a reliable identification at the genus level. As indicated from the data available, the genera *Alcaligenes*, *Achromobacter* and *Pigmentiphaga* may be distinguished on the basis of their different polar lipid profiles but unfortunately, only profiles of *Al. faecalis* (Yabuuchi et al., 1995), *Ac. xylosoxidans* and *P. kullae* have been reported. Owing to this limited information, it is not clear whether the differentiating features in the polar lipid profiles are characteristics for only these species or for the corresponding genus. Thus, analyses of additional representatives of each genus are needed to clarify the specificity of the different polar lipid profiles. More information on the family *Alcaligenaceae* and affiliated genera is summarized by Busse and Auling (2004).

Genus *Alcaligenes*

The genus *Alcaligenes* was described by Castellani and Chalmer (1919). After numerous reclassifications, it now encompasses two species whose names have been validly published: the type species of the genus *Alcaligenes faecalis* with the two subspecies *Alcaligenes faecalis* subsp. *faecalis* and *Alcaligenes faecalis* subsp. *parafaecalis* (Schroll et al., 2001) and *Alcaligenes defragrans* (Foss et al., 1998). The third species [*Alcaligenes*] *latus* (Palleroni and Palleroni, 1978) cannot be considered a member of the genus *Alcaligenes* because phylogenetic studies have demonstrated that [*Al.*] *latus* is most closely related to *Rubrivivax gelatinosus* and *Leptothrix discophora* (Willems et al., 1991), which are not affiliated to the family *Alcaligenaceae*. Thus, this species is not dealt with in the context of this chapter.

Members of the genus are Gram-negative, strictly aerobic rods or coccobacilli that are motile by means of 1–9 peritrichous flagella. They possess oxidase and catalase. They grow well on complex media such as nutrient agar. The fatty acid profiles are predominated by $C_{16:0}$, $C_{16:1\omega7c}$, $C_{17:0cyclo}$, $C_{18:1\ \omega\ 7c}$ and/or 3-OH $C_{14:0}$ (Foss et al., 1998; Schroll, et al., 2001; Coenye et al., 2003a; Table 1). *Alcaligenes faecalis* has been reported to possess among its polar lipids an ornithine lipid (Yabuuchi et al., 1995). This characteristic differentiates it from representatives of *Achromobacter* and *Pigmentiphaga*. However, it still has to be examined whether this feature is characteristic for the species or the entire genus.

Table 1. Relative fatty acid compositions, polar lipid contents, and G+C contents of species of the genera *Alcaligenes*, *Achromobacter*, *Pigmentiphaga* and *Kerstersia*.

[a]Coenye et al. (2003a).

[b]Foss et al. (1998). Cells were grown under denitrifying conditions with acetate as the sole source for carbon and energy.

[c]Coenye et al. (2003b).

[d]Blümel et al. (2001).

[e]Given as summed-in-feature 2 or 3 ($C_{16:1\ ISO\ I}$ and/or 3-OH $C_{14:0}$).

[f]Given as summed-in-feature 3 ($C_{16:1\ \omega7c}$ and/or 2-OH $C_{15:0\ ISO}$).

[g]Given as $C_{18:1\ \omega7c}$ or $C_{18:1\ \omega9t}$.

[h]Given as summed-in-feature 7 ($C_{18:1\ \omega7c}$, $C_{18:1\ \omega9t}$, and/or $C_{18:1\ \omega12t}$).

[i]Compounds in parentheses were reported to be present in moderate or minor amounts (Yabuuchi et al., 1974; 1995; Blümel et al., 2001).

Strains of *Al. faecalis* have been isolated from soil, water, feces, urine, blood, sputum, wounds, pleural fluid, nematodes and insects (Kersters and De Ley, 1984). The mol% G+C of genomic DNA in *Al. faecalis* subsp. *faecalis* and *Al. faecalis* subsp. *parafaecalis* is 55–59 (De Ley et al., 1970; Pichinoty et al., 1978; Schroll et al., 2001). Carbohydrates are not used as sole source of carbon and energy. The type strain of *Al. faecalis* subsp. *parafaecalis* and two strains of *Al. faecalis* subsp. *faecalis* (including the type strain) display almost identical Biolog GN patterns but differ in reaction for L-serine, L-ornithine and L-histidine (Schroll et al., 2001). Other distinguishing phenotypic traits between the two subspecies are nitrite reduction, gelatin liquefaction, assimilation of L-tryptophan and gentisate, growth at 42°C or in the presence of 7% NaCl, the low content of the diagnostic diamine 2-hydroxyputrescine, and the significantly higher content of $C_{16:1}$ in *Al. faecalis* subsp. *parafaecalis* (Schroll et al, 2001). However, the reliability of these distinguishing traits will have to be confirmed by examination of more strains of both subspecies.

Strains of *Al. defragrans* have been isolated under denitrifying conditions after enrichment from activated sludge samples and a ditch sample from a forest, with one of the monoterpenes ((+)-menthene, α-pinene, 2-carene, or α-phellandrene) as the sole source of carbon and energy (Harder and Probian, 1995). Strains in 2-ml portions of activated sewage sludge from a local wastewater treatment plant were enriched in 0.5 liter bottles that contained 400 ml of enrichment medium, 4 ml of degassed anoxic 2,2,4,4,6,8,8-heptamethylnonane (HMN), and 200 µl of liquid or 200 mg of solid substrate (monoterpenes) and in a N_2-CO_2 (90 : 10, vol/vol) atmosphere at 28°C in the dark (Harder and Probian, 1995). Numerous monoterpenes can serve as sources for carbon and energy. However, *Al. defragrans* also grows on simple complex media such as nutrient agar (Deutsche Sammlung von Mikroorganismen und Zellkulturen, 2001). The genomic DNA of the type strain of *A. defragrans* has a G+C-content of 66.9 mol%. The fatty acid profiles of strains of *A. defragrans* are strongly dependent on the growth conditions. When cells are grown on monoterpenes, the fatty acids $C_{17:0cylo}$ and $C_{16:0}$ and high amounts of $C_{19:0cyclo}$ are predominant. In contrast, when grown in the presence of acetate as sole source of carbon and energy, the contents of $C_{17:0cyclo}$ and $C_{19:0cyclo}$ decrease and the contents of $C_{16:1}$ and $C_{18:1}$ increase significantly.

Nutrient Agar

Peptone	5.0 g
Meat extract	3.0 g
Agar	15.0 g
Distilled water	1000 ml

Adjust pH to 7.0

Anoxic Medium for Enrichment of *Alcaligenes defragrans* (Harder and Probian, 1995)

NaCl	1.0 g
$MgCl_2 \cdot 7H_2O$	0.1 g
$CaCl_2$	0.04 g
KCl	0.5 g
NH_4Cl	0.125 g
Na_2SO_4	0.2 g
KH_2PO_4	0.4 g
K_2HPO_4	1.2 g
$NaNO_3$	0.85 g
Distilled water	1000 ml

After autoclaving and cooling the medium under an N_2/CO_2 atmosphere (90/10; vol/vol), add from sterile stock solutions 2 ml of nonchelated trace element mixture, 2 ml of a selenite-tungstate solution, 1 ml of riboflavin solution (25 mg/liter in 25 mM sodium phosphate buffer pH. 3.2), 1 ml of thiamine · HCl solution (100 mg/liter in 25 mM sodium phosphate buffer, pH 3.7), 1 ml of cyanocobalamin solution (vitamin B_{12}; 50 mg/liter), 1 ml of vitamin solution, and 20 ml of a 1 M $NaHCO_3$ solution and adjust the pH to 7.0.

Nonchelated Trace Element Solution (Widdel et al., 1983)

Distilled water	987 ml
100mM HCl	12.5 ml of a 25 % HCl
7.5 mM $FeSO_4 \cdot 7H_2O$	2100 mg
0.5 mM H_3BO_3	30 mg
0.5 mM $MnCl_2 \cdot 4H_2O$	100 mg
0.8 mM $CoCl_2 \cdot 6H_2O$	190 mg
0.1 mM $NiCl_2 \cdot 6H_2O$	24 mg
0.01 mM $CuCl_2 \cdot 2H_2O$	2 mg
0.5 mM $ZnSO_4 \cdot 7H_2O$	144 mg
0.15 mM $Na_2MoO_4 \cdot 2H_2O$	36 mg

Autoclave the trace element mixture in bottles tightly closed with rubber-fitted screw caps or fixed stoppers; leave a head space of approx. 1/3 of the volume (air for common use; N_2 for strictly anoxic procedures).

Selenite–tungstate Solution (from Gram-Negative Mesophilic Sulfate-Reducing Bacteria in the second edition; Widdel and Bak, 1992)

Distilled water	1000 ml
10 mM · NaOH	0.4 g
0.02 mM · $Na_2SeO \cdot 5H_2O$	6.0 mg
0.02 mM · $NaWO_4 \cdot 2H_2O$	8.0 mg

Autoclave the solution as described for the trace element solution.

Vitamin Solution (Aeckersberg et al., 1991)

D(+)-Biotin	15.0 mg
Folic acid	40.0 mg
Pyridoxamine dihydrochloride	150.0 mg
Nicotinic acid	100.0 mg
Ca-D-pantothenate	100.0 mg
4-Aminobenzoic acid	40.0 mg
D,L-a-Lipoic acid	15.0 mg
Sodium phosphate buffer (20 mM; pH 7.2)	1 liter

Filter sterilize.

Genus *Achromobacter*

The type species of the genus *Achromobacter* is *Achromobacter xylosoxidans* (Yabuuchi and Ohyama, 1971; Yabuuchi and Yano, 1981; Yabuuchi et al., 1998). Other species are *Achromobacter denitrificans*, *Achromobacter piechaudii*, *Achromobacter ruhlandii*, *Achromobacter insolitus* and *Achromobacter spanius* (Packer and Vishniac, 1955; Rüger and Tan, 1983; Kiredjian et al., 1986; Yabuuchi et al., 1998; Coenye et al., 2003b). The taxonomic status of *Ac. denitrificans* is still controversial. Originally described as *Alcaligenes denitrificans* (Leifson and Hugh, 1954; Rüger and Tan, 1983), it was combined with *Achromobacter xylosoxidans* in a single species with two subspecies, *Al. denitrificans* subsp. *denitrificans* and *Al. denitrificans* subsp. *xylosoxidans* (Kersters and De Ley, 1984). Owing to taxonomic priority, Kiredjian et al. (1986) proposed the new combination *Al. xylosoxidans* subsp. *denitrificans* and *Al. xylosoxidans* subsp. *xylosoxidans*. On the basis of polyphasic evidence that these two taxa are sufficiently different to classify them as separate species, Vandamme et al. (1996) proposed the two species *Al. denitrificans* and *Al. xylosoxidans*. Yabuuchi et al. (1998) recombined the two species, despite their phenotypic and genotypic heterogeneity, into the single species *Achromobacter xylosoxidans* with the two subspecies *xylosoxidans* and *denitrificans*. However, Coenye et al. (2003b) revived the species *Achromobacter denitrificans* because they could substantiate earlier results that *Achromobacter xylosoxidans* and *Achromobacter denitrificans* can be easily differentiated by results from DNA-DNA hybridizations, whole cell protein patterns, fatty acid profiles, and other phenotypic traits. Since this taxonomic conclusion conforms to present standards, we here refer to the latter taxonomic rearrangements.

The species of the genus *Achromobacter* are Gram-negative, strictly aerobic rods that are motile by means of 1–20 peritrichous flagella. They are positive for catalase and oxidase and grow well on nutrient broth agar. Predominant fatty acids are $C_{16:0}$, $C_{17:0\ cyclo}$, 3-OH $C_{14:0}$, and $C_{16:1\omega7c}$ (Coenye et al., 2003b; Table 1). Strains of *Ac. xylosoxidans* have been isolated from human clinical specimens (blood, spinal fluid, pleural fluid, peritoneal fluid, pus, urine, stools, and swabs of eyes, ears and pharynxes), distilled water, and chlorhexidine solutions in hospitals (Yabuuchi and Yano, 1981). *Achromobacter xylosoxidans* is also capable of persistent infection of the respiratory tract of persons with cystic fibrosis (Dunne and Maisch, 1995; Burns et al., 1998; Peltroche-Llacsahuanga et al., 1998) and can cause meningitis (Ramos et al., 1995; Pan et al., 1996) and bacteremia (Ramos et al., 1996). Because *Ac. xylosoxidans* is frequently confused with species within the *Burkholderia cepacia* complex (Blecker-Shelly et al., 2000; McMenamin et al., 2000), which is associated with significantly increased rates of morbidity and mortality in cystic fibrosis, a polymerase chain reaction (PCR) assay based on 16S rRNA gene sequences has been developed to enable more accurate identification of *A. xylosoxidans* (Liu et al., 2002). Owing to its pathogenic potential, *Ac. xylosoxidans* is classified as a safety level 2 organism. *Achromobacter ruhlandii* has been isolated from soil (Packer and Vishniac, 1955). Strains of *Ac. piechaudii* were isolated from pharyngeal swabs, a nose wound, blood, human ear discharge, and soil (Kiredjian et al., 1986). Strains of *Ac. insolitus* were recovered from wounds, urine and a laboratory sink, and strains of *Ac. spanius* were recovered from human blood (Coenye et al., 2003b). However, the pathogenic potential of these three species remains to be determined.

The species can be distinguished from each other on the basis of several physiological characteristics (Yabuuchi et al., 1998; Coenye et al., 2003b; Table 2), but *Ac. xylosoxidans* and *Ac. ruhlandii* differ in only few physiological traits (Yamasato et al., 1982; Yabuuchi et al., 1998; Table 2). *Achromobacter xylosoxidans* can be also distinguished from the other species of the genus (no data available for *Ac. ruhlandii*) by 2-OH $C_{14:0}$ in its fatty acid profile. Within the family *Alcaligenaceae*, this feature was only reported for species of *Bordetella* (Vandamme et al., 1995; Vandamme et al., 1996), *P. kullae* (Blümel et al., 2001) and representatives of *Kerstersia* (Coenye et al., 2003a).

Since the taxonomic status of the majority of *Alcaligenes* and *Achromobacter* strains examined for pathogenicity; potential for denitrification; degradation of natural, aromatic and xenobiotic compounds; heavy metal resistance; occurence in the environment; and biotechnologically useful enzymes is not clear, we are applying the nomenclature used in the original literature in the following text.

Alcaligenes and *Achromobacter* Strains as Human Pathogens

There are several reports about the isolation of *Alcaligenes* and *Achromobacter* strains from clinical material. Most of these strains were identified as *Alcaligenes denitrificans* subsp. *xylosoxidans* (Pickett et al., 1991). This taxon has been recognized as an opportunistic human pathogen capable of causing a variety of infections including bacteremia, pneumonia, wound and urinary tract infections, peritonitis and meningitis (Decre et al., 1992; Duggan et al., 1996;

Table 2. Selected physiological characteristics useful for differentiation between species of the genera *Alcaligenes*, *Achromobacter*, *Pigmentiphaga* and *Kerstersia*.

Knippschild and Ansorg, 1998; Liu et al., 2002). The organism has also been repeatedly isolated from the sputum of cystic fibrosis patients (Burns et al., 1998; Tan et al., 2002). Furthermore, *Achromobacter*/*Alcaligenes* strains (shown to survive in soaps, antiseptic solutions, respirators, tap water, and dialysis fluids) have been connected to several outbreaks of nosocomial infections (Lehours et al., 2002). Many clinical isolates are multiple resistant to major antibiotics (Decre et al., 1992; Decre et al., 1995). Although in the literature most opportunistic pathogen identification was by classical techniques and therefore some cases may be erronous, there are several contemporary examples of *Achromobacter xylosoxidans* strains isolated from nosocomial infections and cystic fibrosis patients identified by modern DNA-technology (Krzewinski et al., 2001; Ferroni et al., 2002; Lehours et al., 2002; Liu et al., 2002).

Denitrification by *Achromobacter*/*Alcaligenes* Strains

The most extensively studied trait of bacteria belonging to the genera *Alcaligenes* and *Achromobacter* is their ability to dissimilatorily denitrify under anaerobic conditions. This metabolic pathway, by which nitrogen oxide compounds are reduced to dinitrogen gas, has also been described in various other bacterial species such as *Pseudomonas stutzeri*, *Paracoccus denitrificans*, *Rhodobacter capsulatus*, *Thiobacillus denitrificans*, and *Thiosphera pantotropha* (Ferretti et al., 1999; Kukimoto et al., 2000). *Alcaligenes* bacteria are worldwide suggested to be the second most prevalent group (after pseudomonads) of denitrifiers (Gamble et al., 1977). The dissimilatory reduction of nitrate is initiated by nitrate reductase, and the nitrite produced in this reaction is reduced by nitrite reductases to NO, which is the first specific reaction in denitrification. These reactions involve the transfer of a single reduction equivalent to the substrate. Two different types of nitrite reductases are found in bacteria; members of the first group contain cd_1 heme, while members of the second group contain copper ions in their catalytic center. The latter enzymes obtain the required reducing equivalents from a group of blue periplasmatic copper containing reductases called "pseudoazurins." Nitric oxide (NO) is further reduced by NO reductase to nitrous oxide (N_2O) and finally converted by a N_2O reductase to N_2. The denitrification processes have been intensively studied in three putative members of the *Alcaligenaceae*. These organisms are *Alcaligenes xylosoxidans* NCIMB 11015, "*Achromobacter cycloclastes*" (ATCC 21921; IAM 1013), and *Alcaligenes faecalis* S-6. *Alcaligenes xylosoxidans* NCIMB 11015 was originally isolated and described by Iwasaki as "*Pseudomonas denitrificans*" (Inoue et al., 1998) and was used for an early intensive study of the heterotrophic denitrification process (Iwasaki and Mori, 1955; Iwasaki, 1960; Iwasaki et al., 1963).

"*Achromobacter cycloclastes*" (ATCC 21921; IAM 1013) was described first by Iwasaki and Matsubara (1972) as a denitrifying organism, but unfortunately no reference to the enrichment conditions or the reason to describe the organism as "*A. cycloclastes*" was given.

Alcaligenes faecalis S-6 was originally isolated by Kakutani et al. (1981a) using an enrichment with a nutrient broth (NB)-acetate medium with nitrate under a nitrogen atmosphere. The organism was characterized as Gram-negative, peritrichously flagellated, oxidase- and catalase positive. It showed no growth on glucose and had a G+C DNA content of 58 mol% (Kakutani et al., 1981a).

The dissimilatory nitrite reductases from *Alcaligenes xylosoxidans* NCIMB 11015, "*Achromobacter cycloclastes*" and *Alcaligenes faecalis* S-6 have been described as trimeric periplasmatic green or blue enzymes which contain two atoms of copper per enzyme subunit. The copper centers in the nitrite reductases are type 1 centers (giving rise to the green or blue color) and type 2 centers (not significantly contributing to the visible spectrum).

The nitrite reductase from *Alcaligenes xylosoxidans* NCIMB 11015 (formerly *Pseudomonas denitrificans*) was the first nitrite reductase studied in greater detail by Iwasaki and colleagues (Suzuki and Iwasaki, 1962; Iwasaki et al., 1963; Masuko et al., 1984) and later by Abraham et al. (1993). This enzyme was described as "blue" nitrite reductase. The reaction mechanism was analyzed in detail by steady state kinetics and electron spin resonance (EPR) spectroscopy (Abraham et al., 1997). The structure of the enzyme was determined by X-ray scattering in solution (Grossmann et al., 1993) and by analysis of protein crystals (Dodd et al., 1998). The corresponding gene was cloned and the deduced amino acid sequence shown to have about 48–77% sequence identity to previously cloned nitrite reductases (Prudêncio et al., 1999; Suzuki et al., 1999). The function of different amino acids in the nitrite reductase reaction has recently been analyzed by site-specific mutagenesis (Ellis et al., 2002; Prudêncio et al., 2002).

The nitrite reductase from *Alcaligenes faecalis* S-6 was purified and characterized as "green" nitroreductase by Kakutani et al. (1981c). The corresponding gene was cloned, and the enzyme was found to be translated with an amino-terminal signal sequence which was removed upon transport into the periplasm (Nishiyama

et al., 1993). The enzyme was crystallized in the reduced and oxidized form in the absence or presence of nitrite and the corresponding structures were determined (Kukimoto et al., 1994; Murphy et al., 1995; Murphy et al., 1997). Furthermore, this enzyme has been modified by site specific mutagenesis to analyze nitrite binding and catalysis and also the interaction between the nitrite reductase and the natural electron donor pseudoazurin (Kukimoto et al., 1996; Boulanger et al., 2000; Boulanger and Murphy, 2001).

The "green" nitrite reductase from "*A. cycloclastes*" was initially purified for comparison with the archetypal nitrite reductase from *A. xylosoxidans* NCIMB 11015 (then *P. denitrificans*) by Iwasaki et al. (Iwasaki et al., 1972; Iwasaki et al., 1975). The binding of the copper ions to the protein and to nitrogen monoxide was analyzed by resonance Raman spectroscopy and electron paramagnetic resonance spectroscopy (Dooley et al., 1988; Suzuki et al., 1989). The enzyme from "*A. cycloclastes*" was the first nitrite reductase for which a three-dimensional structure was determined (Godden et al., 1991; Adman et al., 1995). The encoding gene was cloned and a sequence homology to the isofunctional enzyme from *S. faecalis* S-6 of 81% has been described (Chen et al., 1996).

In general, it can be stated that the encoding genes for all the above described intensively studied nitrite reductases are clearly homologous, and these reductases and their copper centers also clearly resemble each other. Although these well studied denitrifying *Alcaligenes* strains all synthesize copper-containing nitrite reductases, some presumed *Alcaligenes* strains have been described that possess heme-containing nitrite reductases (Coyne et al., 1989).

Under physiological conditions, the reduction of the dissimilatory nitrite reductases is catalyzed by small blue copper proteins which belong to the cupredoxin family and are identifiable as so-called "azurins" or "pseudoazurins" by a characteristic amino acid sequence and optical spectrum. Thus a rather unique electron transfer chain is present in these organisms that involves the direct interaction of two different blue (or green) copper-containing enzymes. Also these pseudoazurins have been studied in parallel in *A. xylosoxidans* NCIMB 11015, "*A. cycloclastes*" and *A. faecalis* S-6 A, and it was suggested that pseudoazurins would deliver the electron to green nitrite reductase and azurins to the blue enzyme.

Alcaligenes xylosoxidans NCIMB 11015 synthesizes two biochemically distinct azurins, both of which are able to donate electrons to the purified nitrite reductase (Dodd et al., 1995). The single pseudoazurin from *A. faecalis* S-6 has been analyzed in more detail. The protein was originally purified and crystallized by Kakutani et al. (1981b), who demonstrated that under aerobic conditions the reduced form of pseudoazurin reacted with molecular oxygen to produce H_2O_2, which inactivated the nitrite reductase from the organism. The sequence of the protein was determined directly by Hormel et al. (1986) and deduced from the sequence of the encoding gene by Yamamoto et al. (1987). The structure of the pseudoazurin was determined independently in two laboratories (Petratos et al., 1987; Petratos et al., 1995; Adman et al., 1989), and the interaction sites of the protein with the nitrite reductase were investigated by site-specific mutagenesis (Kukimoto et al., 1995).

The pseudoazurin from "*A. cycloclastes*" was purified and characterized by Liu et al. (1986) and electrochemically and optically analyzed (Kohzuma et al., 1995), and the crystal structures of the oxidized and reduced forms were determined (Inoue et al., 1999). Recently, the protein was also analyzed by paramagnetic proton nuclear magnetic resonance (^{1}H NMR; Sato and Denisson, 2002).

Compared to the nitrite reductases and pseudoazurins, the other enzymes involved in denitrification in the three strains discussed here have been much less studied. The nitric oxide reductase was purified from "*A. cycloclastes*" and shown to form a membrane-bound cytochrome *bc* complex (Jones and Hollocher, 1993). The genes encoding a cytochrome-*b* and -*c* type protein and some accompanying genes which presumably encode parts of the nitric oxide reductase complex were subsequently cloned from *A. faecalis* S-6. It was found that the organization of the genes clearly resembled that in other denitrifying bacteria which do not belong to the *Alcaligenaceae* (Kukimoto et al., 2000).

The N_2O reductases from "*A. cycloclastes*" and *A. xylosoxidans* NCIMB 11015 have been biochemically characterized and shown to be similar to N_2O reductases from other organisms. They are soluble dimeric enzymes which contain about four copper atoms per subunit (Ferretti et al., 1999).

In addition to the well-characterized strains *Alcaligenes xylosoxidans* NCIMB 11015, "*Achromobacter cycloclastes*," and *Alcaligenes faecalis* S-6, the denitrification process has also been studied with some other presumed members of the *Alcaligenaceae*, e.g., *A. faecalis* IAM 1015 (Matsubara and Iwasaki, 1971), *A. denitrificans* NCTC 8582 (Baker, 1988; Hoitink et al., 1990; Romero et al., 1993; Salgado et al., 1996), *A. xylosoxidans* GIFU 1051 (Inoue et al., 1998), and *Alcaligenes* sp. STC1 (Ozeki et al., 2001).

Members of the *Alcaligenaceae* also have been intensively studied because of their ability to

perform heterotrophic nitrification under aerobic conditions. Thus, an *Alcaligene*s strain, which oxidizes under aerobic conditions pyruvic oxime and hydroxylamine to nitrite, has been described as the most active heterotrophic nitrifier. This organism is able to carry out both heterotrophic nitrification and denitrification of nitrite (Castignetti and Gunner, 1980; Castignetti and Gunner, 1981; Castignetti and Hollocher, 1982). The ability to oxidize pyruvic oxime has also been described for *Alcaligenes faecalis* ATCC 8750 (Castignetti and Hollocher, 1984). A heterotrophic nitrification of ammonia has been described for *Alcaligenes faecalis* OKK17 (the strain was identified by biochemical tests and the API test system [bioMérieux, France]; Nishio et al., 1994) and *Alcaligenes faecalis* TUD (LMD 89.147) was shown to produce high amounts of N_2O during denitrification as well as heterotrophic ammonia oxidation (Otte et al., 1996; Otte et al., 1999). An aerobic heterotrophic denitrification process, which produced N_2 and N_2O from ammonia and nitrite, was confirmed for *Alcaligenes faecalis* TUD by gas chromatography and ^{15}N mass spectrometry (Robertson et al., 1995).

Aerobic Degradation of Natural Compounds by Presumed *Alcaligenes* Strains

Bacteria belonging to the genera *Alcaligenes*/*Achromobacter* have often been reported to degrade isoprene derivatives under aerobic and also anaerobic conditions (see below). Thus, an enrichment with isoprene resulted in the isolation of strain JE 75, which was identified as *Alcaligenes denitrificans* subsp. *xylosoxidans* by the Deutsche Sammlung von Mikroorganismen und Zellkulturen (DSMZ; German Collection of Microorganisms and Cell Cultures). This strain has been studied because of its ability to effectively cometabolize trichloroethene (TCE) in the presence of isoprene under aerobic conditions (Ewers et al., 1990). The aerobic degradation of α-pinene has been related to the presence of an *Achromobacter xylosoxidans* strain (identified using the BIOLOG test system; Kleinheinz et al., 1999) and the degradation of resin acids (tricyclic, diterpenoid carboxylic acids found in the bark of pine trees) has been associated with *Alcaligenes* sp. D11-13 (Morgan et al., 1996). Another *Alcaligenes* strain (*A. faecalis* MTCC3134) was shown to degrade lantadene (a group of pentacyclic triterpenoidins found in the leaves of a hepatotoxic plant; Singh et al., 1999).

Several *Alcaligenes xylosoxidans* strains (Cm1, Cm3, Cm4, and Ep3), identified by 16S rDNA sequencing, have been isolated from the rhizosphere of the garden peas and Indian mustard because they contain the enzyme 1-aminocyclopropane-1-carboxylate (ACC) deaminase, which hydrolyzes the direct precursor of ethylene in plants. Bacterial strains with this ability are supposed to stimulate plant growth and are considered as plant growth promoting rhizobacteria. During this study it was observed that *A. xylosoxidans* strains with the screened phenotype were especially prevalent in loamy sod-podzolic gleyic arable soil (Belimov et al., 2001).

From *Alcaligenes faecalis* IFO 14479, an aromatic amine dehydrogenase (one of the two known bacterial enzymes that contain a tryptophan tryptophylquinone as prosthetic group) has been studied in some detail. The enzyme catalyzes the oxidative deamination of aromatic amines including tyramine and dopamine to the corresponding aldehydes (Iwaki et al., 1983; Nozaki, 1987; Govindaraj et al., 1994; Hyun and Davidson, 1995b). Surprisingly, it was observed in this context that an azurin (see Denitrification by Achromobacter/Alcaligenes strains) acted as physiological electron acceptor during the oxidative deamination of aromatic amines (Edwards et al., 1995; Hyun and Davidson, 1995a). Recently, the genes encoding the two subunits of the aromatic amine dehydrogenase from *Alcaligenes faecalis* were cloned and sequenced and it was shown by growth experiments and DNA-hybridization that a very similar activity is presumably present also in *A. xylosoxidans* ATCC 15175 (Chistoserdov, 2001).

Poly(3-hydroxybutyrate) (PHB) depolymerases have been described from two *Alcaligenes faecalis* strains. *Alcaligenes faecalis* T_1 was isolated from the activated sludge of a sewage treatment plant and only tentatively designated as *A. faecalis* (Tanio et al., 1982). The extracellular PHB depolymerase from *A. faecalis* T_1 hydrolyzed not only hydrophobic PHB but also the water-soluble trimer and larger oligomers of D-(–)3-hydroxybutyrate regardless of their solubility in water (Shirakura et al., 1983; Shirakura et al., 1986; Fukui et al., 1988). The gene encoding the PHB depolymerase was cloned and functionally expressed in *E. coli* (Saito et al., 1989) and it was subsequently demonstrated that the PHB depolymerase from *A. faecalis* T_1 clearly resembled the isofunctional enzyme from *Pseudomonas* (now *Paucimonas*) *lemoignei* (Shinohe et al., 1996). More recently, a structure-function relationship was established for the PHB depolymerase using different kinds of mutants (Nojiri and Saito, 1997).

Alcaligenes faecalis AE122 (identified by the National Collections of Industrial and Marine Bacteria Ltd, United Kingdom [NCIB]) was isolated from a coastal seawater sample by its ability to use PHB as sole source of carbon and

energy. The extracellular PHB depolymerase was purified and it was found that the enzyme activity was enhanced in the presence of seawater (Kita et al., 1995; Kita et al., 1997).

As indicated above, *Alcaligenes* strains have also been found in marine environments and some interesting enzymatic activities have been described from marine *Alcaligenes* strains. A well characterized marine strain is *Alcaligenes faecalis* M3A (identified by the Vitek [bioMérieux, Inc., Durham, NC] system, MIDI [Microbial ID, Inc., Newark, DE, USA] fatty acid analysis, and 16S rDNA sequencing), which was isolated from a salt marsh sediment. From this organism, a dimethylsulfide (DMS)-producing enzyme was studied. Quantitatively the most important biogenic sulfur compound emitted from oceans and salt marshes, DMS is biologically formed from the osmolyte of marine algae dimethylsulfoniopropionate (DMSP) by the action of a lyase, which converts DMSP to DMS and acrylate. The enzyme responsible for this reaction, a DMSP lyase, has first been isolated and characterized from the above-mentioned *Alcaligenes* strain (de Souza and Yoch, 1995; Ansede et al., 1999).

Isolated from a marine sediment, a putative *Alcaligenes* strain XY-234 (identified by a few biochemical tests and the G+C content of the DNA) was shown to excrete a β-1,3-xylanase at a high level into the culture medium. Because of its potential usefulness for the hydrolysis of the cell walls of seaweeds, the enzyme was purified and characterized and the corresponding gene cloned (Araki et al., 1998; Okazaki et al., 2002).

Degradation of Aromatic Compounds

Several enrichments from different groups with biphenyl as sole source of carbon and energy resulted in the isolation of *Achromobacter* or *Alcaligenes* species (which were in most cases identified according to classical taxonomic procedures; e.g., Ahmed and Focht, 1973; Furukawa and Matsumura, 1976; Furukawa et al., 1978). More recently, another strain of *Alcaligenes xylosoxidans xylosoxidans* (which was identified by the Czech Collection of Microorganisms) was isolated by enrichment with biphenyl from contaminated soil and used for the conversion of different polychlorinated biphenyls in soil microcosms (Haluska et al., 1995).

From these strains, *Achromobacter xylosoxidans* KF701 and *Alcaligenes* sp. KF711 were studied in greater detail, but unfortunately almost no information was given about the reasons to affiliate these strains to the relevant genera. They degrade biphenyl via the "standard pathway" which involves the extradiol ring-fission of 2,3-dihydroxybiphenyl and the intermediate formation of benzoate. This intermediate is subsequently converted to catechol which is subject to another extradiol ring-fission reaction. Hybridization studies with a gene probe containing the *bphABC* genes from a *Pseudomonas* strain demonstrated that the *bph* genes of strains KF701 and KF711 were clearly homologous to the genes from the pseudomonad (Furukawa et al., 1989). The genes encoding the catechol 2,3-dioxygenases from both organisms were later cloned and partly characterized. A sequence alignment demonstrated that the deduced sequence of the enzyme from *A. xylosoxidans* KF 701 highly resembled (up to 96% sequence identity) the catechol 2,3-dioxygenases from different pseudomonads (Chang et al., 1992; Moon et al., 1997). From *A. xylosoxidans* KF701 also the gene encoding a 2-hydroxymuconic acid semialdehyde dehydrogenase (*bphG*), which is part of the meta-cleavage pathway for catechol, was cloned and sequenced. Also with this enzyme a high degree of sequence identity (94%) was found with the isofunctional enzyme from *Pseudomonas putida* mt-2 (Kang et al., 1998).

Achromobacter xylosoxidans T7, which was isolated from soil after an enrichment with a mixture of toluidines (methylanilines), offers another example of a member of the *Alcaligenaceae* with a meta-cleavage pathway. The DSMZ identified this strain (DSM 11852) by biochemical tests and 16S rDNA sequencing. The organism was able to degrade all three isomers of toluidine and it was suggested that the substrates were degraded via an initial oxidative deamination to the corresponding methylcatechols followed by a classical meta-cleavage pathway (Hinteregger and Streichsbier, 2001).

Alcaligenes faecalis CCT 7145 was isolated from an Amazonian soil sample after an enrichment with phenol. The classification of the organism was done by the Biolog system (Hayward, CA, USA), fatty acid analysis using the MIDI system, and 16S rDNA sequencing, which demonstrated 97% sequence identity with *A. faecalis* ATCC 8750 (Bastos et al., 2000).

There is some evidence available that suggests that *Alcaligenes* strains are also able to degrade polycyclic aromatic hydrocarbons (PAK). Thus, Kiyohara et al. (1982) identified the phenanthrene degrading organism *Alcaligenes faecalis* AFK2 by a rather intensive classical taxonomic methodology which also involved the determination of the G+C-content (68.4–68.8 mol%) of the organism. (This high G+C content contradicts the affiliation of this strain with *A. faecalis* on the species level.) Later, a fluoranthene degrading organism was identified according to the API test system as *Alcaligenes denitrificans* (Weissenfels et al., 1990). Other naphthalene,

2,6-dimethylnaphthalene, or phenanthrene degrading *Alcaligenes* strains have been reported (Miyachi et al., 1993; Møller and Ingvorson, 1993; Guerin and Boyd, 1995) and there are some indications by 16S rDNA sequence analyses that uncharacterized *Alcaligenes* strains may become the dominant microorganisms in soils contaminated with C5+ (a complex mixture of aromatic hydrocarbons; Greene et al., 2000).

Anaerobic Degradation of Natural Compounds by Denitrifying *Alcaligenes*/*Achromobacter* Strains

As indicated above, *Al. defragans* has been obtained from anaerobic ennrichments with monoterpenes such as (+)-menthene or α-pinene as sole carbon source and nitrate as electron acceptor. α-Pinene and other monoterpenes are intermediately converted by *A. defragans* 54Pin to geranic acid (Heyen and Harder, 2000). The strain can grow under denitrifying conditions with natural essential oils (such as lemon, pine needle, parsley seed, or camphor oil) and its ability to grow under anaerobic conditions with terpenoid compounds might be environmentally important for the anaerobic turnover of these important plant derived volatile compounds (Harder et al., 2000).

Other references describe the anaerobic degradation of aliphatic sulfonic acids or aromatic compounds by *Alcaligenes* strains. Thus from an enrichment under strictly anoxic conditions starting with material from the anaerobic digestors of communal sewage works with taurine (2-aminoethanesulfonate) as electron donor and nitrate as electron acceptor, strain NKNTAU (DSM 11046) was isolated, which, according to 16S rDNA sequencing, was *Alcaligenes defragrans*. The strain could also grow aerobically with taurine (Denger et al., 1997; Ruff et al., 2003). Another putative *Alcaligenes* strain (LuBRes1) was obtained after an enrichment under anaerobic conditions with resorcinol and nitrate.The strain was classified by classical biochemical methods and the G+C content of the DNA (Gorny et al., 1992).

Aerobic Degradation of Xenobiotic Compounds by *Achromobacter* and *Alcaligenes* Strains

Enrichments with various aliphatic or aromatic compounds which carry rare substituents (such as chloro-, fluoro-, nitro-, or sulfo-groups) repeatedly resulted in the isolation of bacteria belonging to the genera *Achromobacter* or *Alcaligenes*. Unfortunately, the taxonomic affiliation of many of these strains is questionable because only very limited taxonomical data have been presented. Nevertheless, there is good evidence that indeed some bacterial strains with rare degradative abilities are *Achromobacter* or *Alcaligenes*.

Some of the presumed *Alcaligenes*/*Achromobacter* strains that degrade sulfonated compounds have been taxonomically studied in greater detail. The most intensively studied example is *Alcaligenes* sp. strain O-1 (isolated from a sewage treatment plant by an enrichment with orthanilic acid as sole source of carbon and energy), which degrades orthanilic acid (2-aminobenzenesulfonic acid; Thurnheer et al., 1986). Good evidence (i.e., ubiquinone [Q-8] is the main ubiquinone and 2-hydroxyputrescine and putrescine are the dominant polyamines) shows that this organism indeed belongs to the "*Betaproteobacteria*." Antibodies raised against the isolate crossreacted specifically with cells of *A. xylosoxidans*, and also the G+C content of the DNA (66.1 mol%) and DNA reassociation measurements suggested an affiliation of this organism to the genus *Alcaligenes* (Jahnke et al., 1990). However, on the basis of recent reclassifications (Yabuuchi et al., 1998), strain O-1 now can be considered to represent a novel species of the genus *Achromobacter*. *Alcaligenes* sp. strain O-1 degrades orthanilic acid by a rather unique pathway which involves an initial oxidative deamination of orthanilic acid to 3-sulfocatechol, an oxidative attack on 3-sulfocatechol by a "3-sulfocatechol dioxygenase" activity which results in ring-fission and desulfonation, and finally the formation of the ring-fission product 2-hydroxymuconic acid. The oxygenases of this pathway have been purified and characterized. They belong to the major groups of ring-hydroxylating or ring-cleaving dioxygenases that have been found in several other Proteobacteria (Thurnheer et al., 1990; Junker et al., 1994a; Junker et al., 1994b; Mampel et al., 1999). The genes encoding this degradative pathway are encoded (at least partly) on a 117-MDa plasmid in this strain (Jahnke et al., 1990; Jahnke et al., 1993).

The degradation of alkanesulfonates by *Achromobacter*/*Alcaligenes* strains has been reported. Thus, the taurine (2-aminoethanesulfonate)-degrading strain studied by Kondo and coworkers has been deposited as *A. xylosoxidans* NCIMB 10751 (Erdlenbruch et al., 2001). This strain degrades taurine via sulfoacetaldehyde to acetate plus sulfite (Kondo et al., 1971; Kondo et al., 1973; Kondo and Ishimoto, 1972; Kondo and Ishimoto, 1975). More recently, an ethanesulfonate degrading organism (strain AE4) was isolated from activated sludge (Erdlenbruch et al., 2001) and identified by some biochemical tests and 16S rDNA sequencing to

be related to *A. xylosoxidans* (98% sequence identity). For strain AE4, an initial oxidative desulfonation of ethanesulfonate by a monooxygenase to acetaldehyde was suggested (Erdlenbruch et al., 2001).

The evidence that certain *Alcaligenes*/*Achromobacter* strains can degrade aliphatic and aromatic chlorinated compounds is also good. Thus, Heinaru and coworkers demonstrated by 16S rDNA similarity analyses that the 2,4-dichlorophenoxyacetic acid (2,4-D)-degrading organism EST4002 (previously isolated in their laboratory) had the highest identity (about 99%) with *A. xylosoxidans denitrificans*. This strain harbors a 78-kb plasmid, which contains a set of genes that resemble the genes of the chlorocatechol pathway from the well studied plasmid pJP4 (originally isolated from *Ralstonia eutropha* JMP134; Vedler et al., 2000).

A presumed strain of *Alcaligenes denitrificans* (NTB-1) was obtained from sewage sludge after an enrichment with 4-chlorobenzoate as sole source of carbon and energy. The substrate was converted by a hydrolytic mechanism to 4-hydroxybenzoate. The strain also grew with 4-bromo- and 4-iodobenzoate. Furthermore, 2,4-dichlorobenzoate was degraded, involving presumably an initial reductive conversion to 4-chlorobenzoate (van den Tweel et al., 1986; van den Tweel et al., 1987). The aerobic degradation of 2,4- and 2,5-dichlorobenzoate was also shown for two other bacterial strains (BRI 3010 + BRI 6011), which were tentatively identified by some standard taxonomic tests and the commercial API and Biolog test systems as *Alcaligenes denitrificans* (Miguez et al., 1990).

Another *Alcaligenes* species (strain L6) has been obtained from a freshwater sediment after an enrichment with 3-chlorobenzoate under a 2% O_2 atmosphere. The almost complete 16S rRNA gene showed the highest degree of sequence identity (94%) with the gene of *Alcaligenes xylosoxidans* subsp. *denitrificans*. This organism differed from most known aerobic 3-chlorobenzoate degraders because it did not metabolize 3-chlorobenzoate via the well-known chlorocatechol pathway and it was suggested that the strain used either the protocatechuate or the gentisate pathway for the degradation of 3-chlorobenzoate (Krooneman et al., 1996).

The metabolism of all three fluorobenzoate isomers was demonstrated for another tentative *Alcaligenes* strain (RHO22). This strain performed with 4-fluorobenzoate a hydrolytic dehalogenation reaction (Oltmanns et al., 1989) similar to the conversion of 4-chlorobenzoate to 4-hydroxybenzoate by *Alcaligenes denitrificans* NTB-1 (see above).

There are also some reports of degradation of aliphatic chlorinated compounds by *Alcaligenes*/*Achromobacter* strains. For example, strains ABIV and RS9 can degrade the herbicide Dalapon (2,2-dichloropropionate) and other short-chain chlorinated alkanoates. These organisms were identified by morphological, biochemical, and serological tests as *Alcaligenes*/*Achromobacter xylosoxidans* (*denitrificans*). The haloalkanoate halidohydrolase genes of both strains were found to be encoded on conjugative 60 kb-plasmids, which could be functionally transferred to a strain of *Pseudomonas fluorescens* (Brokamp and Schmidt, 1991; Brokamp et al., 1997b; Schwarze et al., 1997). The sequence of the D,L-haloalkanoate acid halidohydrolase of strain ABIV was found to be rather unique among previously known halidohydrolases (Brokamp et al., 1997a).

Alcaligenes strain CC1 (ATCC 49033) was isolated from sewage sludge after an enrichment with *trans*-3-chlorocrotonic acid and shown to degrade several α-chlorinated aliphatic acids (e.g., 2-chlorobutyrate, 2-chloropropionate, and chloroacetate) as well as β-chlorinated four-carbon aliphatic acids (3-chlorobutyrate, *cis*- and *trans*-3-chlorocrotonate) as sole source of carbon and energy. Direct attack of the 2-halo acid by a 2-haloacid dehalogenase and the necessity for intermediate formation of the corresponding CoA esters of the substrates to dehalogenate the β-chlorinated four-carbon compounds were suggested (Kohler-Staub and Kohler, 1989).

The similarities observed in the degradative plasmids of the 2-chloroalkanoate-degrading *Achromobacter xylosoxidans denitrificans* strains and the 2,4-D degrading *Achromobacter* species EST4002 with isofunctional plasmids from *Pseudomonas* or *Ralstonia* strains (Brokamp et al., 1997b; Brokamp et al., 1997a; Vedler et al., 2000) suggest that *Alcaligenes*/*Achromobacter* strains are able to take up broad host-range degradative plasmids and also functionally express the relevant enzymatic activities. This was also suggested by a report of McGowan et al. (1998), who within a collection of 2,4-D degrading organisms identified (by 16S rDNA sequencing) strain TFD9 to be highly related to *Alcaligenes xylosoxidans*. The sequence of the gene encoding TfdA (the first enzyme in the 2,4-D degradative pathway) was almost identical with that of *tfdA* from plasmid pJP4.

The metabolism of several types of non-natural nitrogen-containing compounds by true or presumed strains of *Achromobacter* and *Alcaligenes* has also been reported. Two strains (JS867 and JS871) with the ability to aerobically degrade 2,4-dinitrotoluene were found presumably to belong to the genus *Alcaligenes* using the Biolog test system and 16S rDNA sequencing (Nishino et al., 2000). According to 16S rDNA ribotyping, strain JS867 is most closely related to

Alcaligenes xylosoxidans (Smets and Mueller, 2001). The metabolism of 2,4-dinitrotoluene by strain JS867 was also studied under oxygen-limited conditions, and its conversion under oxygen-limited conditions was suggested to be by an oxygenolytic denitration pathway (Smets and Mueller, 2001).

Also N-containing heterocycles are degraded by presumed *Alcaligenes* strains. Thus an indole degrading bacterium has been tentatively identified as *Alcaligenes* spec. strain In3 (Claus and Kutzner, 1983). In addition, isoquinoline, or quinaldic acid (quinoline 2-carboxylic acid), kynurenic acid (4-hydroxyquinoline 2-carboxylic acid), and xanthine were utilized by *Alcaligenes faecalis* Pa and *Alcaligenes* sp. F-2, respectively, which were identified by standard tests according to *Bergey's Manual of Systematic Bacteriology* and *The Prokaryotes* (Röger et al., 1990; Bubeck et al., 1996). Also, a report suggests the presence of an atrazine dechlorinating activity in *Alcaligenes* sp. SG1 (Seffernick et al., 2000).

A bacterium that utilized the insecticide carbofurane (2,3-dihydro-2,2-dimethyl-7-benzofuranyl methylcarbamate) as nitrogen source was identified by different commercial test systems as *Achromobacter* sp. WM111 (Karns et al., 1986). The enzyme that hydrolyzed the carbamate linkage of various *N*-methylcarbamate insecticides was later purified (Karns and Tomasek, 1991) and shown to be encoded by a gene on a rather large plasmid (Tomasek and Karns, 1989).

An enrichment with the synthetic chelating agent iminodisuccinate (IDS) resulted in the enrichment of *Achromobacter xylosoxidans* subsp. *xylosoxidans* B3 (identified by standard methods and 16S rDNA sequencing), which was able to use IDS as sole source of carbon and energy (Reinecke et al., 2000).

An *N*,*N*-dimethylformamide degrading strain (KUFA-1) was identified by basic classical taxonomic studies as *Alcaligenes* sp. The genes encoding the two subunits of the formamidase have been cloned and sequenced and shown to be only distantly related to other amidases (Hasegawa et al., 1997; Hasegawa et al., 1999).

Another presumed *Achromobacter* strain, which degrades hydrazine and methylhydrazine (main components of hydrazine rocket fuels), has been described. This strain can degrade hydrazine to N_2 in the presence of a second nitrogen source (Ou, 1987; Ou, 1988). Recently, methylhydrazine-containing organic components present in waste waters from the Kennedy Space Center in Florida were found to be degraded by the addition of some defined bacterial strains, including *Achromobacter* strain M-30-Y (ATCC 21910; Nwankwoala et al., 1999).

Heavy-Metal and Arsenite-Resistant *Achromobacter*/*Alcaligenes* Strains

Although the best characterized bacterial strain which demonstrates several heavy metal resistance mechanisms (*Alcaligenes* strain CH34) has recently been transferred to the genus *Ralstonia* as *R. metallidurans* (Goris et al., 2001), "true" members of the *Alcaligenes*/*Achromobacter* group contain some heavy metal resistant strains. Thus, *Ac. xylosoxidans* 31A isolated in the presence of nickel ions was shown to possess a rather high degree of nickel resistance. The strain carries two megaplasmids (pTOM8 and pTOM9) that confer nickel resistance. The respective plasmids could be functionally transferred to *Ralstonia eutropha* by conjugation (Schmidt and Schlegel, 1989; Schmidt et al., 1991). Two distinct nickel resistance loci were found on plasmid pTOM9. One of these loci is homologous to other well characterized cation efflux pumps (e.g., in *R. metallidurans* CH34) and a second one (which confers a lower degree of nickel resistance) belongs to the major facilitator superfamily (Schmidt and Schlegel, 1994; Grass et al., 2001). A rather high degree of nickel tolerance has also been found in *Alcaligenes denitrificans* 4a-2 (DSM 5537; Kaur et al., 1990), and another cadmium-resistant isolate from soil has been identified by 16S rDNA sequencing as *Alcaligenes* sp. strain CT14. This strain also expressed a cation/proton antiporter highly homologous to the one from *R. metallidurans* CH34 (Kunito et al., 1996).

From *Al. faecalis* NCIB 8687, an arsenite oxidase has been characterized that oxidizes toxic arsenite (AsO_2^{-1}) to the less toxic arsenate (AsO_4^{-3}). The enzyme contains molybdenum bound to the molybdenum cofactor and it was suggested that azurin would serve as electron acceptor during the arsenite oxidase reaction (Anderson et al., 1992). The structure of this enzyme has been resolved, and in contrast to all other previously known molybdoenzymes, it contains a Rieske type (2Fe-2S) center (Ellis et al., 2001).

Detection of Presumed *Alcaligenes*/*Achromobacter* Strains in Various Environments

Alcaligenes/*Achromobacter* strains can be isolated from various soils, aquatic freshwater and marine environments, and also various living organisms. Recently, molecular ecology techniques have revealed that *Alcaligenes* strains may be rather frequent in various environments and found in some unexpected habitats. Thus amplified ribosomal DNA restriction analysis (ARDRA) and fatty acid analysis results showed

that in the summer about 6% of the culturable bacteria in sediments of a forested pristine stream in Tennessee are *Alcaligenes* strains (Halda-Alija and Johnston, 1999). Strains of *Alcaligenes xylosoxidans* (H151, HR5, and HR6) and *Alcaligenes faecalis* (HR4) (identified by Biolog and 16S rDNA sequencing) have also been identified in the feces of the microarthropods (collembolans [springtails]) as putative acceptors of conjugative plasmids (Hoffmann et al., 1998). The 16S rDNA sequencing of cultured microorganisms from a deep (224-m) subsurface environment revealed that *Alcaligenes* strains also seem to be quantitatively important members of this environment (Boivin-Jahns et al., 1995).

Potential Uses of *Alcaligenes*/*Achromobacter* Strains or Enzymes in Biotechnological Processes

Enzymes from *Achromobacter*/*Alcaligenes* strains have been used for the production of several industrially relevant chemicals. From the number of reports, most attention has been paid to the ability of various *Alcaligenes*/*Achromobacter* strains to produce D-aminoacylases. D-Aminoacylases (*N*-acyl-D-amino acid amidohydrolases) are zinc-containing enzymes that catalyze the hydrolysis of *N*-acyl-D-amino acids to the corresponding D-amino acids (used as intermediates in the preparation of pesticides, bioactive peptides, and antibiotics). The enzymes from the *Achromobacter*/*Alcaligenes* strains were shown to possess higher specific activities with several *N*-acyl-D-amino acids than the isofunctional enzymes from other bacterial strains possessed. The most intensively studied strain in this respect is *Al. xylosoxidans* A-6 which produces three *N*-acyl-D-amino acid amidohydrolases with strictly different substrate specificities. A D-aminoacylase specific for N-acyl derivatives of neutral amino acids and two D-aminoacylases specific for acidic *N*-acetyl-D-amino acids (such as *N*-acetyl-D-glutamate or *N*-acetyl-D-aspartate), in contrast to previously described D-aminoacylases, were found to be present in this organism (Sakai et al., 1990; Sakai et al., 1991a; Sakai et al., 1991b; Moriguchi et al., 1993a; Moriguchi et al., 1993b). The genes encoding D-aminoacylase, *N*-acyl-D-glutamate deacylase and *N*-acyl-D-aspartate amidohydrolase were cloned and sequenced, and the deduced amino acid sequences of the three enzymes were found to share more than 40% sequence identity with each other (Wakayama et al., 1995a; Wakayama et al., 1995b; Wakayama et al., 1995c). More recently, the amino acids involved in the binding of the catalytically important zinc ions by the D-aminoacylase have been identified by site-specific mutagenesis techniques (Wakayama et al., 2000).

D-Aminoacylases have also been characterized to some extent from *Alcaligenes faecalis* strains DA1 and DA181. These strains were identified by classical biochemical tests and the determination of the G+C content of the DNA (57.8 mol% and 65.1 mol%, respectively; Tsai et al., 1988; Tsai et al., 1992; Yang et al., 1991; Yang et al., 1992). For the D-aminoacylase from *Al. faecalis* DA-1, not only the deacetylation of *N*-acetylmethionine, but also the reverse reaction has been described (Chen et al., 1994). The gene encoding the enzyme from *Al. faecalis* DA1 was recently cloned and analyzed by mutational studies (Hsu et al., 2002). Other D-aminoacylases have also been described from *Al. denitrificans* MI-4 (Sakai et al., 1991a; Sakai et al., 1991b) and from some uncharacterized strains of *Al. denitrificans* and *Al. faecalis* (Tripathi et al., 2000).

The ability of *Alcaligenes*/*Achromobacter* strains to synthesize industrially relevant *N*-acylase activities has also been reported for *Achromobacter xylosoxidans* NCIMB 40407, which exhibited the ability to selectively hydrolyze glutaric acid from glutaryl-3-deacetoxy-7-aminocephalosporanic acid (Franzosi et al., 1995).

Alcaligenes/*Achromobacter* strains or their enzymes used to synthesize amino acids have also been reported. Thus, a novel 5-oxoprolinase, which converts pyroglutamate (an unwanted tasteless side product formed during the brewing of soy sauce) to the flavor compound glutamate, has been described from a putative *Al. faecalis* strain N-38A. (Unfortunately this strain was only preliminarily taxonomically characterized.) The gene encoding the 5-oxoprolinase was recently cloned, sequenced and heterologously expressed (Murao et al., 1995; Nishimura et al., 1999; Nishimura et al., 2000).

Other potentially useful organisms with the ability to convert amino acid derivatives include *Al. xylosoxidans* strain IFO 12669, which has a low-specificity D-threonine aldolase that can produce a key intermediate in the synthesis of a drug used to treat parkinsonism (Liu et al., 2000), and "*Achromobacter cycloclastes*" ATCC 21921 (see Denitrification by Achromobacter/Alcaligenes strains), which can be used to transform γ-butyrobetaine to L-carnitine (Naidu et al., 2001).

Some nitrilases of industrial relevance have been described from *Alcaligenes* strains. *Alcaligenes faecalis* ATCC 8750^T synthesizes a nitrilase that highly enantioselectively forms *R*-mandelic acid from racemic mandelonitrile (Yamamoto et al., 1991). Another strain of *Al. faecalis* (LU 1650) has been mentioned in a more recent patent (German patent application DE 198 48 129 A1) that described the enantioselective

hydrolysis of substituted (*R*,*S*-)mandelonitrile(s) to substituted *R*-mandelic acid(s). *Alcaligenes faecalis* JM3 (isolated because of its ability to hydrolyze indole-3-acetonitrile) has been shown to preferentially hydrolyze arylacetonitriles. The strain was identified by classical physiological tests and its G+C content (57–59 mol%) as *Al. faecalis*. The activity and specificity of nitrilase as well as the corresponding gene were subsequently characterized (Mauger et al., 1990; Nagasawa et al., 1990; Kobayashi et al., 1993).

The utilization of a nitrilase from another *Alcaligens faecalis* strain for the industrial production of some heterocyclic carboxylic acids has been described in some patents by Lonza AG (Switzerland; Liese et al., 2000).

A cell-wall degrading activity from "*Achromobacter lyticus*" M497-1 (ATCC 21456, IFO 12725) was originally described because of its ability to lyse cells of *Micrococcus* (now *Deinococcus*) *radiodurans* and *Staphylococcus aureus* in the presence of detergents. This activity was related to enzymes that degrade peptide-moieties of cell wall peptidoglycans (Nakamura et al., 1973; Horinouchi et al., 1977). This commercially available bacteriolytic agent known as "Achromopeptidase" has a broader bacteriolytic spectrum and higher bacteriolytic activity than lysozyme and has bacteriolytic activities towards several lysozyme-resistant pathogenic strains of *Staphylococcus*, *Streptococcus* and *Clostridium*. The Achromopeptidase activity is due to at least two proteases: the so-called "α-lytic protease" is a mammalian type serine protease, which hydrolyzes peptides at the carboxyl side of small hydrophobic amino acids such as alanine and valine. The enzyme cleaves the *N*-acetylmuramoyl-L-alanine amide bond and also D-Ala-Gly and Gly-Gly bonds in the peptidoglycan of *Staphylocoocus aureus* (Li et al., 1997). The so-called "β-lytic protease" is a zinc-containing metal protease that has been described as the most active part of the Achromopeptidase. This enzyme preferentially hydrolyzes the D-Ala-Gly/Ala and the Gly-Gly bonds at the linkage between the peptide subunit and the interpeptide chain and within the interpeptide bridge (Li et al., 1998). More recently, another bacteriolytic activity with *N*-acetylmuramoyl-L-alanine amidase activity was purified from the Achromopeptidase preparation (Li et al., 2000).

A third protease (= protease 1) was purified from "*Achromobacter lyticus*" M497-1 and its ability to specifically cleave proteins at lysine residues was studied (Masaki et al., 1978; Masaki et al., 1981a; Masaki et al., 1981b). This enzyme will cleave proteins specifically for the production of peptides during the sequencing of proteins. The sequence of the enzyme was determined, the encoding gene cloned, and several amino acids exchanged by site-specific mutagenesis to identify the amino acids responsible for the lysine specificity and the broad pH optimum of the enzyme in the alkaline region (Tsunasawa et al., 1989; Ohara et al., 1989; Norioka et al., 1994; Shiraki et al., 2002a; Shiraki et al., 2002b).

Alcaligenes sp. DS-S-7G (identified by classical physiological tests) was shown to preferentially assimilate *R*-3-chloro-1,2-propanediol (monochlorhydrin). The strain was able to convert racemic 3-chloro-1,2-propanediol to almost enantiomerically pure *S*-3-chloro-1,2-propanediol (Suzuki et al., 1992). An electron acceptor-dependent halohydrin dehydrodehalogenase was identified as the responsible enzyme for the resolution of the racemate. Later, it was demonstrated that the strain was also able to enantioselectively convert nonchlorinated diols (e.g., 1,2-butanediol or 1,2-hexanediol; Suzuki et al., 1994b; Suzuki et al., 1994a).

Very recently, a novel subspecies of *Al. faecalis* has been described (*Al. faecalis* subsp. *parafaecalis*) which produces PHB from the by-products of the acetone-butanol fermentation of *Clostridium beijerinckii*. The potential usefulness of this organism for the production of higher-value PHB from the waste of the acetone-butanol fermentation has been suggested (Schroll et al., 2001).

Some *Alcaligenes*/*Achromobacter* strains also seem to excrete some products that interact with other organisms. Thus from Kalimantan (Indonesia), a strain producing three antibiotics (Kalimantacin A, B and C) was identified by a thorough classical taxonomic analysis (including the determination of the G+C content of the DNA) as *Alcaligenes* sp. Yl-02632S (FERM-12694; Kamigiri et al., 1996; Tokunaga et al., 1996). *Alcaligenes* strain MFA1 was isolated from carnation (*Dianthus caryophillus* L.) roots and suppresses a vascular wilt of carnation caused by the fungal pathogen *Fusarium oxysporium* f. sp. *dianthi*. The bacterium inhibits the colonization of the plant roots by the fungus but also inhibits microconidial and chlamydospore germination of the fungal pathogen. The germination inhibition is presumably mediated by a siderophore produced by *Alcaligenes* sp. MFA1. The results of fatty acid analysis using gas chromatography (GC) suggested that the strain might be closely related to *Alcaligenes xylosoxidans* subsp. *denitrificans* (Yuen and Schroth, 1986; Martinetti and Loper, 1992). The proposed production of a siderophore by the vascular wilt-suppressing *Alcaligenes* strain MFA1 is in accordance with the description of a dihydroxamate siderophore (Alcaligin) from *Alcaligenes xylosoxidans* subsp. *xylosoxidans* KN 3-1, which was identified using the API test system and the

tests suggested by *Bergey's Manual* (Nishio et al., 1988; Nishio and Ishida, 1990).

Alcaligenes/*Achromobacter* strains are also reported to produce antibiotic resistance factors. Thus, a bacterial isolate resistant to the antibiotic Albicidin, which is produced by a phytopathogenic *Xanthomonas* strain and inhibits DNA replication in plastids and bacteria, was identified by a series of biochemical tests and the determination of the G+C content (69.5–70 mol%) as *Al. denitrificans subsp. denitrificans* (Basnayake and Birch, 1995). Furthermore, a penicillin acylase from *Alcaligenes faecalis* has been studied because of its high potential for enzymatic modification of β-lactam antibiotics and was found to have a very high affinity for natural and semisynthetic substrates (Vedas et al., 1997; Verhaert et al., 1997; Alkema et al., 1999).

Genus *Kerstersia*

The genus *Kerstersia* with the single established species *Kerstersia gyiorum* has been described as an *Alcaligenes faecalis*-like organism isolated from human clinical samples (Coenye et al., 2003a). Members of the genus are Gram-negative coccoid cells, which occur singly, in pairs, or in short chains. Cells grow on complex media such as nutrient broth. They possess catalase, but no oxidase, urease, arginine dihydrolase, lysine decarboxylase, ornithine decarboxylase, gelatinase, amylase, DNase, or β-galactosidase. Cells grow at temperatures between 28°C and 42°C. The fatty acid profile contains predominantly $C_{16:0}$, $C_{17:0\ cyclo}$, 3-OH $C_{14:0}$ and $C_{18:1\ \omega\ 7c}$ (Table 1). *Kerstersia gyiorum* shares with *Pigmentiphaga kullae* combined presence of 2-OH $C_{14:0}$, relatively high amounts of $C_{18:1\ \omega\ 7c}$, and trace amounts of 2-OH $C_{12:0}$. *Kerstersia gyiorum* can be distinguished from other species of the family also on the basis of a set of physiological characteristics. Although reported to be isolated from different wounds, no pathogenic potential has been reported for *K. gyiorum*.

Genus *Pigmentiphaga*

So far the description of the genus *Pigmentiphaga* and the species *Pigmentiphaga kullae* is based on a single strain (Blümel et al., 2001). Cells are Gram-negative, motile and rod-shaped. They grow on complex media such as Luria-Bertani medium and at temperatures between 30°C and 42°C but not at 4°C. They are positive for catalase and oxidase. The type strain uses numerous organic acids as sole source of carbon and energy, but sugars are not utilized. The polyamine pattern consists of the predominant diamines putrescine and 2-hydroxyputrescine and a quinone system ubiquinone Q-8, which are "*Betaproteobacteria*"-specific characteristics. The polar lipid profile consists of the phosphate-containing lipids, phosphatidyl ethanolamine (predominant) and phosphatidyl glycerol and diphosphatidyl glycerol (minor compounds). The fatty acid profile of *Pigmentiphaga kullae* (Table 1) contains the majority of characteristics of the family *Alcaligenaceae* except for the presence of 2-OH $C_{12:0}$ and relatively high amounts of $C_{19:0cyclo\omega 8c}$. Recently, close association of a 2,6-naphthalenedisulfonic acid degrading strain with *Pigmentiphaga kullae* has been reported which was based on 16S rRNA gene sequence comparison and phenotypic characterization (Uchihashi et al., 2002).

Pigmentiphaga kullae^T K24 has been isolated during a continuous adaptation experiment with the model azo dye 1-(4′-carboxyphenylazo)-4-naphthol (carboxy-Orange I) as sole source of carbon and energy. It is one of the very few microorganisms described that are able to grow with azo dyes. The strain was originally described as *Pseudomonas* sp. K24 (Kulla, 1981; Kulla et al., 1984) and recently described as a new genus within the *Alcaligenaceae* (Blümel et al., 2001). The aerobic azoreductase from this organism has been purified and characterized (Zimmermann et al., 1984), and recently the sequence of the gene encoding the azoreductase has been determined and shown to be unrelated to previously described aerobic azoreductases (Blümel and Stolz, 2003). Some other recent work suggested that *Pigmentiphaga* strains were also obtained after enrichment with naphthalene-2,6-disulfonate (Uchihashi et al., 2002; Uchihashi et al., 2003).

Genus *Taylorella*

The genus *Taylorella* (Sugimoto et al., 1983) encompasses two species, *Taylorella equigenitalis*, which originally was described as *Haemophilus equigenitalis* (Taylor et al., 1978), and *Taylorella asinigenitalis* (Jang et al., 2001). Cells of the two species are Gram-negative, nonmotile, short rods. Growth occurs under microaerobic conditions in an atmosphere with 5–10% CO_2 at 37°C. They are catalase and oxidase positive and do not produce acid from carbohydrates. Compared to other members of the family, the G+C-content of the genomic DNA is relatively low (36.5–37.8 mol%). Fatty acid profiles consist of predominant acids summed-in-feature (SIF) 7, $C_{16:0}$, $C_{18:0}$ and SIF 3 (Table 3). *Taylorella equigenitalis* (an inhabitant on the external genitalia of stallions) is usually transmitted venereally to

Table 3. Relative fatty acid compositions and G+C contents of species of *Taylorella*, *Pelistega* and *Oligella*.

mares. *Taylorella equigenitalis* is the causative agent of contagious equine metritis (CEM), a venereal disease in horses causing vaginal discharge, infertility, or early abortion (Wada et al., 1983). This disease has been detected in many countries all over the world in various breeds of horses (Taylor et al., 1978; Kagawa et al., 2001). Diagnosis of CEM is not possible on the basis of clinical signs because of similarity of the disease to other bacterial infections of the reproductive tract (Powell, 1981). To detect *T. equigenitalis* in clinical samples several PCR assays have been developed (Bleumink-Pluym et al., 1994; Anzai et al., 1999; Arata et al., 2001; Kagawa et al., 2001; Premanandh et al., 2003). *Taylorella equigenitalis* is sensitive to penicillin G, ampicillin, carbenicillin, cephaloridine, erythromycin, tetracycline, kanamycin, gentamicin, chloramphenicol, and polymyxin B and resistant to clindamycin, lincomycin, trimethoprim and sulfamethoxazole (Sugimoto et al., 1983). Strains of *T. asinigenitalis* have been isolated from the urethral fossae of donkeys, but they were not associated with the development of signs of disease in mares (Jang et al., 2001).

Genus *Pelistega*

Phylogenetically, the only representative of the genus *Pelistega*, *Pelistega europaea*, is the nearest relative of the genus *Taylorella* (Vandamme et al., 1998). Cells are Gram-negative and nonmotile with variable shape. They grow under microaerobic conditions on conventional media such as nutrient broth at 37°C and 42°C but not at 24°C and grow aerobically but not anaerobically. Cells are positive for catalase and oxidase. Acid is not produced from carbohydrates. The low G+C content (42–43 mol%) is in agreement with their close relatedness to the genus *Taylorella*.

In the fatty acid profile, SIF 7, 4, and 3 and $C_{16:0}$ and $C_{14:0}$ predominate. Strains of *P. europaea* have been isolated from samples of lungs, air sac

exudate, trachea mucosa, liver, spleen, and swabs taken from the palatine cleft or trachea of living acutely diseased pigeons. On the basis of clinical observations, *P. europaea* is considered to be pathogenic and involved in pathogenesis of respiratory diseases in pigeons.

Genus *Oligella*

Described by Rossau et al. (1987), the genus *Oligella* encompasses the species *Oligella urethralis* (formerly *Moraxella urethralis*) and *Oligella ureolytica* (formerly CDC group IVc2). Cells are Gram-negative, aerobic, small rods or coccobacilli. Incubation in the presence of 5% CO_2 enhances growth. They are oxidase and usually catalase positive. They grow on nutrient agar, but growth is enhanced by addition of serum, blood, or yeast autolysate. Few organic acids and amino acids are oxidized or used as sole source of carbon. The G+C content of the genomic DNA of the two species is in the range 46–47.5 mol%. *Oligella urethralis* contains a quinone system with the predominant compound Q-8 (Moss et al., 1988) and a polyamine pattern with the predominant polyamines putrescine and 2-hydroxyputrescine (H.-J. Busse, unpublished results). The fatty acid profiles consist of the major acids $C_{18:1\omega\ 7c}$ and $C_{16:0}$ and the hydroxylated acids 3-OH $C_{14:0}$ and 3-OH$C_{16:0}$ are detected (Jantzen et al., 1987; Rossau et al., 1987; Moss et al., 1988; Table 3).

Oligella urethralis has been isolated from human urine, genitourinary tract, and ear. *Oligella ureolytica* has been isolated from human urine. Both species have been reported to cause urosepsis (Rockhill and Lutwick, 1978; Pugliese et al., 1993).

CHAPTER 3.2.5

The Genus *Spirillum*

NOEL R. KRIEG

Introduction

The genus *Spirillum* contains only a single species—*Spirillum volutans* (Krieg, 1984b). Prior to 1973, however, the genus *Spirillum* included other aerobic/microaerophilic, chemoheterotrophic spirilla as indicated in the 8th edition of *Bergey's Manual of Determinative Bacteriology* (Krieg, 1974). Hylemon et al. (1973b) divided the genus into the three genera *Spirillum*, *Aquaspirillum*, and *Oceanospirillum* on the basis of their DNA base composition and certain physiological characteristics. The genus *Spirillum* was reserved for large, microaerophilic, freshwater spirilla having a DNA base composition of 38 mol% G+C (thermal denaturation method) or 36 mol% G+C (buoyant density method).

Within the Proteobacteria, *S. volutans* is a member of the beta division, based on oligonucleotide cataloguing of 16S rRNA (Woese et al., 1982; Woese et al., 1984; Woese, 1987). Its nearest neighbor is *Thiobacillus thioparus*, according to the *Bergey's Manual* revision of the Ribosomal Database Tree. Other fresh-water spirilla (i.e., *Aquaspirillum* species) are not closely related to *S. volutans*, although very few species have been analyzed. They have been placed in subgroups 1 and 2 of the beta subdivision and in the alpha subdivision of the Proteobacteria (Woese et al., 1984; Woese, 1987).

Other organisms provisionally named "*Spirillum*" are not included in the genus. These include "*Spirillum minus*," *Spirillum pulli*," and "*Spirillum pleomorphum*." These names have no official standing in nomenclature, and the taxonomic placement of these organisms is uncertain. They may be related to aquaspirilla or to campylobacters (Krieg, 1984a). "*S. minus*" is a causative agent of rat-bite fever in humans; "*S. pulli*" causes a diphtheroid stomatitis in chickens. Neither has been grown on artificial media. "*S. pleomorphum*" is a psychrophile isolated from Antarctic soil.

A large spirillum called "*Aquaspirillum voronezhense*" was described by Grabovich et al. (1987), which has a number of features similar to those of *S. volutans*. These include helical cells 1.5–2.1 to 3.0 μm wide, bipolar flagellar fascicles with up to 50 flagella in each fascicle, poly-beta-hydroxybutyrate granules, and inability to use carbohydrates. However, the organisms differ by being aerobic, catalase-positive, and urease-positive and by having a mol% G+C of the DNA of 58.5–60.0.

Habitat

S. volutans is widely distributed in many stagnant freshwater environments. Only two strains have been isolated in pure culture, one from hay infusions prepared with water from a pond in Virginia (Wells and Krieg, 1965) and the other from the cooling water of a sugar refinery in England (Rittenberg and Rittenberg, 1962). In hay infusions, the organisms are most abundant after several days. The spirilla accumulate in the microaerobic region just beneath the surface scum of aerobic bacteria.

Isolation

Selective Enrichment

Mixed cultures of the organism occurring in hay infusions or other sources can be enriched by inoculating Pringsheim's soil medium (Rittenberg and Rittenberg, 1962). One wheat or barley grain is placed in a large test tube and covered with 3–4 cm of garden soil. The tube is then filled almost to the top with tap water and is sterilized by autoclaving for 30 min. After inoculation, *S. volutans* multiplies to approximately 1–2 $\times$ 10^6 cells/ml with incubation at room temperature, while the total bacterial population reaches approximately 1 $\times$ 10^9 cells/ml (Rittenberg and Rittenberg, 1962).

Isolation Procedure

Isolation is difficult, even with enrichment, because *S. volutans* is greatly outnumbered by

other organisms and because no selective media are available. To date, the only successful method for isolation is a mechanical method first described by Giesberger (1936) and used successfully with *S. volutans* by Rittenberg and Rittenberg (1962). This method is also useful for isolating other freshwater and marine spirilla (Giesberger, 1936; Jannasch, 1965). In this procedure, the center of a short section of sterile cotton-plugged 5-mm glass tubing is softened in a flame and pinched with square-ended forceps until almost closed. The flattened portion is reheated and drawn out rapidly to form a long, thin-walled capillary tube, 15–30 cm long and 0.1–0.3 mm in diameter, with oval cross-section. The ends of the capillary are sealed in a flame and the tubes are stored in a dust-free environment. Before use, the capillary is broken near the tip with sterile forceps and 10–20 cm of sterile medium are drawn into it, followed by 2–4 cm of enrichment culture, with no air space between the two liquids. Leaving a small air space at the tip of the capillary, the tip is sealed in a flame. The tube is mounted horizontally on the stage of a microscope so that it can be examined along its length at a magnification of about 100×. Because of the rapid motility of *S. volutans*, the organism will frequently be able to reach the distal portions of the capillary before other motile bacteria. In many instances an aerotactic band of *S. volutans* may form and travel down the length of the tube; however, one should look for spirilla travelling ahead of this band, because the band itself may be contaminated by other highly motile bacteria. As soon as some spirilla have migrated far enough along the capillary to have outdistanced the contaminants, the capillary is broken behind the spirilla and sealed in a flame. The outside of the sealed capillary is sterilized in strong hypochlorite solution, followed by sterile thiosulfate solution. The tip is then broken again and the contents expelled into a dialysis sac containing sterile Pringsheim's medium (soil plus supernatant). The dialysis sac is suspended in a beaker of similar medium that has been inoculated with some of the original mixed culture. The main function of the mixed culture outside the dialysis sac appears to be that of decreasing the level of dissolved oxygen or possibly of destroying toxic forms of oxygen in the medium, thereby allowing the microaerophilic *S. volutans* organisms to grow in pure culture inside the sac. The dialysis sac system is incubated at room temperature until *S. volutans* has multiplied within the sac. Purity of the culture within the sac should be verified microscopically. When a pure culture has been obtained, it should be transferred to a fresh dialysis sac system every few days because some of the organisms growing in the mixed culture outside the sac may cause the sac to disintegrate through cellulolytic activity. Eventually, transfers should be made to tubes of a suitable medium such as semisolid modified peptone-succinate-salts (MPSS) or casein hydrolysate-succinate-salts (CHSS) medium.

Because *S. volutans* grows readily in semisolid MPSS and CHSS media, it is possible that the need for the intermediate dialysis sac cultures in the above procedure could be avoided by expelling the cells from the capillary tube directly into the semisolid medium.

Media for *Spirillum volutans*

MPSS Broth for *S. volutans* (Caraway and Krieg, 1972)

Succinic acid (free acid)	1.0 g
$MgSO_4 \cdot 7H_2O$	1.0 g
Bacto Peptone (Difco)	5.0 g
$(NH_4)_2SO_4$	1.0 g
$FeCl_3 \cdot 6H_2O$ (0.2% aqueous solution)	1.0 ml
$MnSO_4 \cdot H_2O$ (0.2% aqueous solution)	1.0 ml

The first four ingredients are dissolved in 1 liter of distilled water and the pH is adjusted to 7.0 with 2 N KOH. The $FeCl_3$ and $MnSO_4$ solutions are added and the medium is sterilized by autoclaving. The medium is stored in the dark to avoid photochemical production of hydrogen peroxide.

Semisolid MPSS medium is prepared by adding 0.15% agar to the liquid medium. MPSS agar is prepared by adding 1.5% agar to the liquid medium.

CHSS Broth for *S. volutans* (Padgett and Krieg, 1986)

Succinic acid (free acid)	1.0 g
$MgSO_4 \cdot 7H_2O$	1.0 g
Acid-hydrolyzed casein, "vitamin-free, salt-free" (ICN Nutritional Biochemicals, Cleveland, OH)	2.5 g
$(NH_4)_2SO_4$	1.0 g
NaCl	0.1 g
KH_2PO_4	0.14 g
$FeCl_3 \cdot 6H_2O$ (0.2% aqueous solution)	1.0 ml
$MnSO_4 \cdot H_2O$ (0.2% aqueous solution)	1.0 ml
Potassium metabisulfite	0.05 g

The first eight ingredients are dissolved in 1 liter of distilled water and the pH is adjusted to 7.0 with 2 N KOH. The potassium metabisulfite is added and the pH readjusted to 7.0. The medium is sterilized by autoclaving and stored in the dark.

Semisolid CHSS medium is prepared by adding 0.15% agar to the medium after addition of the potassium metabisulfite, boiling to dissolve the agar, and then autoclaving. CHSS agar is prepared by adding 1.5% agar to the liquid medium.

Goatcher et al. (1984) reported that Bactocasitone (Difco) could substitute for the indi-

cated casein hydrolysate and that $MnSO_4$ could be omitted under these conditions. Bowdre and Krieg (1974) did not include NaCl in their original formulation of CHSS broth. However, Padgett et al. (1982) found that the casein hydrolysate used by Bowdre and Krieg was not completely salt-free. When salt-free batches of casein hydrolysate were used, a low level of NaCl was required for growth. Levels of NaCl greater than 0.02% inhibited growth. Bowdre and Krieg (1974) did not include KH_2PO_4 in their original formulation of CHSS broth. However, its addition to the medium has since been found to increase the growth response of *S. volutans* (Friedman, 1987).

Colony Count Medium (CCM) (Alban and Krieg, 1996)

Succinic acid (free acid)	1.0 g
$MgSO_4 \cdot 7H_2O$	1.0 g
Acid-hydrolyzed casein, "vitamin-free, salt-free" (ICN Nutritional Biochemicals, Cleveland, OH)	2.6 g
$(NH_4)_2SO_4$	1.0 g
NaCl	0.04 g
KH_2PO_4	0.12 g
Sodium pyruvate	0.3 g
$FeCl_3 \cdot 6H_2O$ (0.2% aqueous solution)	1.0 ml
$MnSO_4 \cdot H_2O$ (0.2% aqueous solution)	1.0 ml
Potassium metabisulfite	0.05 g

The first nine ingredients are dissolved in 1 liter of distilled water and the pH is adjusted to 7.3 with 2 N KOH. The pH is adjusted to 7.3 with KOH and the potassium metabisulfite is added. The pH is readjusted to 7.3. The medium is sterilized by autoclaving and stored in the dark. The pH of the cooled medium should be 6.8.

For semisolid medium and for colony counts, 0.7 g of agar is added after addition of the potassium metabisulfite, and the medium is boiled to dissolve the agar prior to autoclaving.

Identification

S. volutans can be differentiated from other chemoheterotrophic, aerobic or microaerophilic, motile, curved or helical or vibrioid bacteria by the characteristics indicated in Table 1. Of particular importance are the large cell size, the exceptionally large bipolar fascicles of flagella (which can be seen readily by phase contrast microscopy), and the failure of the organism to grow aerobically on any ordinary solid medium. Verification of identification is best obtained by comparing an isolate with the type strain, ATCC strain 19554.

S. volutans cells have the form of a left-handed, or counterclockwise, helix (Swan, 1985). The cells have 1–5 turns, a wavelength of 16–28 μm, a helix diameter of 5–8 μm, and a helix length of 14–60 μm. Numerous refractile intracellular granules of poly-β-hydroxybutyrate are present. The bipolar flagellar fascicles consist of many individual nonsheathed flagella of long wavelength (Fig. 1). Flagellar hooks and basal structures have been described by Swan (1985). *S. volutans* swims in straight lines, and during swimming, the fore fascicle is bent toward the aft end of the cell and describes a wide bell; the aft fascicle extends behind the cell and describes a wide goblet. A cell often reverses its direction of swimming, and when this happens both flagellar fascicles reorient their configuration simultaneously, so that what was previously the fore fascicle now becomes the aft fascicle and vice versa. Cells that are flagellated at only one pole can reverse their swimming direction, indicating that either a fore or aft fascicle alone can propel the cells (Swan, 1982). Ramia and Swan (1994) have used high-speed cinemicrography to record the swimming of unipolarly flagellated cells. The geometry of these cells was numerically modeled with curved isoparametric boundary elements (from the measured geometrical parameters), and an existing boundary element method (BEM) program was applied to predict the mean swimming linear and angular speeds. A helical cell shape is not required for motility, as straight-cell variants of *S. volutans* are able to swim at nearly the same speed as wild-type helical cells (Padgett et al., 1983). The aerotactic behavior of *S. volutans* has been described by Caraway and Krieg (1974).

Electron microscopy of ultrathin sections of *S. volutans* reveals an intracellular "polar membrane," which is attached to the cytoplasmic membrane (Coulton and Murray, 1978). This structure has been observed mainly in helical bacteria, such as *Aquaspirillum*, *Campylobacter*, *Rhodospirillum*, *Selenomonas*, and *Vibrio*, but it has also been detected in nonhelical bacteria such as *Methanococcus* and *Chromatium*. The polar membrane of *Campylobacter jejuni* consists of an assemblage of ATPase molecules (Brock and Murray, 1988).

Round cells, called coccoid bodies, such as occur commonly in old cultures of other helical or curved bacteria, such as *Aquaspirillum itersonii* and *Campylobacter jejuni*, do not occur in cultures of *S. volutans*.

Cultivation

Optimal growth occurs between 30 and 36°C and at pH values of 7.0–8.2 (Moore, 1984). Although the organism is a microaerophile, cultures in semisolid media can be incubated in an air atmosphere due to stratification of the medium. Growth begins as a thin disk some distance

Table 1. Differential characteristics of the genus *Spirillum* and of other motile, aerobic or microaerophilic, Gram-negative, helical or curved bacteria.

	Cell shape	Cell diameter (μm)	Requires host for growth	Oxygen requirement	Usual arrangement of flagella	Catalase	Requires sea water or >1% NaCl	Inhibited by 35% NaCl	Carbohydrates catabolized	Nitrogenase activity (microaerobic conditions)	G+C content (mol%)	Habitat
Spirillum volutans	Helical	1.4–1.7	–	Micr	Large tufts, BP	–	–	+	–	–	36–38	Stagnant freshwater
Aquaspirillum	Helical[b]	0.2–1.4	–	Aer	Tufts, BP[e]	+[d]	–	+	–[e]	–[f]	49–66	Stagnant freshwater
"Aquaspirillum voronezhense"[g]	Helical	1.5–3.0	–	Aer	Large tufts, BP	+	–	+	–	–	58–60	Sewage treatment air tank
Arcobacter	Vibrioid	0.2–0.9	–	Aer[h]	1, SP	+[i]	D	D	–	D	27–30	Humans and other animals; roots of salt marsh grasses
Asospirillum	Vibrioid[j]	0.9–1.5	–	Aer	1, SP[k]	+	–	D	+	+	68–70	Soil and plant roots
Bdellovibrio	Vibrioid	0.2–0.5	+[l]	Aer	1, SP	D	D	D	–	–	33–52	Freshwater and marine
Campylobacter	Vibrioid[m]	0.2–0.9	–	Micr	1, SP or BP[n]	D	–	D	–	–	30–38	Humans and other animals
Helicobacter	Vibrioid[o]	0.5–1.0	–	Micr	Various types; some have sheathed flagella	+	–	+	–	–	35–44	Stomachs or intestines of humans and other animals
Herbaspirillum	Vibrioid[p]	0.6–0.7	–	Aer	1–3, SP or BP	+	–	+	+	+	66–67	Stagnant freshwater
Magnetospinillum	Helical	0.2–0.7	–	Micr	1, BP	D	–	+	–	D	64–71	Stagnant freshwater
Marinomonas communis	Curved	0.7–1.5	–	Aer	1, SP	+	+	–	+	–	45–48	Marine
Oceanospinillum	Helical[q]	0.3–1.4	–	Aer	Tufts, BP[r]	D	+	–	–[s]	–	42–51	Coastal marine waters

Pseudoalteromonas undina	Curved	0.7–1.5	–	Aer	1, SP	+	+	–	+	–	43–44	Marine
"Spirillumminus"	Helical	0.2	+		1 or more BP							Humans and rodents[l]
"Spirillumpulli"	Helical	1.0	+		1, SP or BP							Chickens[u]
"*Spinillum pleomorphum*"	Helical or curved	0.7–1.0	–	Aer	1, SP	+	–	–	+[t]	ND	603	Antarctic soil
Vampirovibrio	Vibrioid	0.3	+[w]		1, SP						50	Freshwater
Wolinella succinogenes	Helical	0.5–1.0	–	Micr	1, SP	–	–	ND	ND	–	47	Bovine rumen

[a]Symbols: +, all species positive except where noted; –, all species negative except where noted; D, differs among species; BP, both poles; SP, single pole; Aer, aerobic; Micr, microaerophilic; ND, no data.
[b]*A. delicatum* is mainly vibrioid.
[c]*A. delicatum* has mainly a single flagellum at one pole; *A. polymorphum* has mainly a single flagellum at each pole.
[d]*A. putridiconchylium* is catalase-negative or very weakly positive.
[e]*A. gracile*, *A. itersonii*, and *A. peregrinum* can catabolize only a very restricted variety of sugars.
[f]*A. peregrinum* and some strains of *A. itersonii* have nitrogenase activity.
[g]Described by Grabovich et al., 1987, Microbiologiya 56:666–672.
[h]May be microaerophilic on primary isolation. Although *A. nitrofigilis* is a microaerophilic nitrogen fixer, it can grow aerobically in complex media such as Brucella agar.
[i]*A butzleri* is weakly catalase positive.
[j]Some cells in *Azospirillum* cultures are straight rods.
[k]Some *Azospirillum* species form numerous lateral flagella in addition to the polar flagellum when cultured on solid media.
[l]All wild-type strains of *Bdellovibrio* upon initial isolation are dependent on intraperiplasmic growth in susceptible bacterial prey. Mutants capable of axenic growth ("prey-independent" strains) have been derived from the predacious strains, and some strains are facultative, i.e., capable of growth in the presence and absence of prey cells.
[m]Chains of *Campylobacter* cells may have a helical appearance. *C. rectus*, *C. showae*, and *C. gracilis* are straight rods.
[n]*C. showae* has a tuft of flagella at one pole.
[o]*H. trogontum* and *H. bilis* are fusiform straight rods. *H. bizzozeronii* and *H. felis* cells are long helices. *H. cholecystus* cells are coccoid to short curved rods.
[p]Some cells in cultures of *Herbaspirillum* are helical.
[q]*O. kriegii* and *O. jannaschii* are straight rods.
[r]*O. pusillum* has mainly a single flagellum at each pole. *O. kriegii* and *O. jannaschii* have a single flagellum at one pole.
[s]Causes one form of rat-bite fever in humans.
[u]Causes a diphtheroid stomatitis in chickens.
[t]Produces acid fiomxylose but not from other sugars that have been tested; it is also distinguished by failing to grow at temperatures above 20°C.
[w]Predacious on eukaryotic algae.

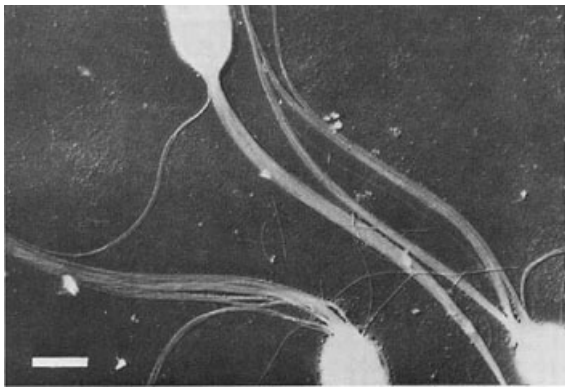

Fig. 1. Polar flagellar fascicles of *S. volutans* ATCC 19554 n by electron microscopy. Bar = 1 μm. (From Hylemon et al., 1973a.)

below the surface at a point where the respiratory rate of the cells matches the rate of diffusion of oxygen to the cells. As the cell numbers increase, the disk becomes denser and migrates toward the surface. After 48 h dense growth occurs just beneath the surface.

Cultures grown in MPSS broth (no agar added) or on solid media for colony development should be incubated under an atmosphere of 6% O_2 and 94% N_2. A convenient way to do this is to use a polycarbonate jar such as those that are used routinely for cultivation of anaerobes, provided that it has a vent to allow evacuation. After placing the inoculated media in the jar and sealing it, the jar is evacuated to 0.286 of the normal atmospheric pressure. Nitrogen gas is then added until the atmospheric pressure is restored.

Padgett et al. (1982) reported that cells inoculated into MPSS broth can grow under aerobic conditions if the medium is supplemented with either bovine superoxide dismutase (SOD) (4 units/ml), catalase (0.8 units/ml), potassium metabisulfite (0.02%), or norepinephrine (0.002%).

Cultures in CHSS broth (no agar added) can grow aerobically (Bowdre and Krieg, 1974). Five-ml volumes contained in 20 × 125-mm loosely screw-capped tubes are inoculated with several drops of culture and incubated at 30°C in a slanted position. Growth occurs near the surface of the medium in 24 h. Transfers must be made daily, with several drops of each previous culture serving as inoculum for the next tube. Cultures usually die within 48 h, possibly due to the high pH (>8.0) that develops as the result of oxidation of the succinate. Bowdre et al. (1976) used a chemically defined liquid medium containing norepinephrine, which, like CHSS broth, supports growth of *S. volutans* under aerobic conditions. Growth of *S. volutans* on the surface of solid media (MPSS or CHSS broth solidified with 1.5% agar) is difficult but can be achieved by methods described by Padgett et al. (1982). The agar media must be supplemented with potassium metabisulfite (0.002%), catalase (230 units/ml), or SOD (30 units/ml). If catalase or SOD is used, it is added aseptically to the molten medium at 45°C just before dispensing into Petri dishes, whereas potassium metabisulfite is added prior to autoclaving. The medium is dispensed into Petri dishes (20 ml per dish) under dim illumination or red photographic safelight (red light does not cause photochemical generation of toxic forms of oxygen in the medium). The plates are allowed to dry in the dark at room temperature for 24 h. In dim illumination, 0.1-ml portions of appropriate dilutions of a broth culture of S. volutans are spread onto the agar surface with a glass rod. The plates are incubated for 5 days at 30°C in the dark in a sealed vessel containing 6–12% O_2 (the balance being N_2). It is essential that the vessel be lined with moistened filter paper to maintain a high humidity. Even with these precautions, only 22–72% of the cells inoculated onto the plates develop into colonies.

A method for obtaining reproducible colony counts was reported by Alban and Krieg (1996). The method uses a semisolid version of colony counting medium (CCM) as an overlay for a thicker layer of sterile medium. The medium contains pyruvate, which destroys hydrogen peroxide. Cells to be used for colony counts are grown in 5.0 ml of CCM broth contained in slanted 20 × 120-mm loosely screw-capped tubes incubated aerobically for 24 h at 30°C. Sterile semisolid medium (CCM plus 0.7% agar) is dispensed into Petri dishes (15 ml per dish) and allowed to gel for 30 min. A 0.1-ml volume of an appropriate dilution of the inoculum is added to 10 ml of semisolid CCM at 45°C and is poured onto the plates as an overlay. After this has gelled, the plates are incubated at 30°C in an atmosphere of 6% O_2 and 94% N_2 for 3–4 days.

Preservation

Preservation of *S. volutans* can be accomplished by the following procedure (Pauley and Krieg, 1974): Cells from a turbid 24-hour-old broth culture are centrifuged at 3,500 × g and washed once in nutrient broth. The cells are then suspended by gentle agitation in a small amount of nutrient broth containing 10% dimethyl sulfoxide (DMSO). The resulting dense suspension is allowed to incubate for 30 min at room temperature and then 0.4-ml volumes are dispensed into plastic or glass vials suitable for liquid nitrogen preservation. The vials are sealed, frozen in a mixture of dry ice and alcohol, and then stored by submersion in liquid nitrogen. For recovery of

the organisms, the vials are thawed in water at 30°C and transferred to semisolid MPSS or CHSS medium.

Physiology

S. volutans has a strictly respiratory type of metabolism with oxygen as the terminal electron acceptor. It is microaerophilic in ordinary liquid media, such as nutrient broth (in which it grows poorly) and MPSS broth, and on solid media, such as CHSS agar supplemented with bisulfite. Also, it can grow aerobically in special liquid media such as CHSS broth or the chemically defined medium of Bowdre et al. (1976). Growth is inhibited by very low concentrations of H_2O_2 (0.29 μM or greater), and the organism is rapidly killed by concentrations of 10 μM or greater (Alban and Krieg, 1988). The microaerophilic nature of the organism has been attributed to the high susceptibility of the organism to toxic forms of oxygen which occur spontaneously in MPSS or CHSS broth under aerobic conditions, particularly when the media are illuminated (Padgett et al., 1982). Destruction of toxic forms of oxygen by media supplements such as SOD, catalase, potassium metabisulfite, or norepinephrine allows the organism to grow aerobically in broth (Padgett et al., 1982). However, even with these supplements, *S. volutans* can form colonies on MPSS, CHSS, or CCM agar only under microaerobic conditions (12% O_2 or less). It will not grow even under microaerobic conditions unless the media supplements are present. Padgett and Krieg (1986) described two variant strains of *S. volutans* which, unlike the wild type, could grow in an air atmosphere (i.e., 21% O_2) on CHSS agar containing potassium metabisulfite. Cell extracts of those aerotolerant variants exhibited greater *o*-dianisidine peroxidase activity than did the wild type, and this enzyme may be important for aerotolerance. The catalase-negative microaerophile *Spirillum volutans* is killed rapidly by levels of H_2O_2 greater than 10 μM. Alban and Krieg (1998) described a mutant isolated by single-step mutagenesis with diethyl sulfate that was able to survive and grow after exposure to 40 μM H_2O_2 and was effective in eliminating H_2O_2 added to the medium. Nevertheless, the mutant was no more tolerant to O_2 than the wild type. The only apparent phenotypic difference between the wild type and the mutant was that the mutant had high NADH peroxidase activity (0.072 IU per mg protein) whereas the wild type had no detectable activity (<0.0002 IU per mg protein). Alban et al. (1998) found that the mutant constitutively expresses a 21.5 kDa protein that is undetectable and noninducible in the wild type cells. Part of the gene that encodes the protein was cloned and the deduced 158 amino acid polypeptide showed high relatedness to rubrerythrin and nigerythrin—proteins previously described only in certain anaerobic members of the Bacteria and Archaea.

S. volutans is relatively inert biochemically in most routine characterization tests but is oxidase- and phosphatase-positive and produces H_2S from cysteine (Hylemon et al., 1973a). It is negative for the enzymes catalase, DNase, RNase, urease, and arylsulfatase; gelatin liquefaction; hydrolysis of casein, starch, and esculin; indole production; reduction of nitrate and selenite; anaerobic growth with nitrate; and growth in the presence of 1% bile or 1% glycine. Carbohydrates are not catabolized. Carbon and energy sources include the salts of various organic acids. Succinate, fumarate, malate, oxaloacetate, and pyruvate are oxidized readily, whereas citrate, aconitate, isocitrate, and α-ketoglutarate are oxidized weakly (Caraway and Krieg, 1974). Vitamins are not required for growth (Bowdre et al., 1976). In CHSS medium very low levels of NaCl are required, but growth is inhibited by levels greater than 0.02% (Padgett et al., 1982). Oxygen uptake by cells suspended in a chemically-defined motility medium is inhibited by 50 mM phosphate (pH 6.8) but not by 10 mM phosphate (Caraway and Krieg, 1974). Crude cell extracts possess an iron-containing superoxide dismutase and very low levels of peroxidase (Padgett and Krieg, 1986).

The response of *S. volutans* ATCC 19554 to 44 antibiotics and other chemotherapeutic agents was determined by Friedman (1987). The organism was inhibited by each of the agents tested except clindamycin, cloxacillin, lincomycin, and oxacillin. It is interesting that, although *S. volutans* respires with oxygen, its growth is completely inhibited by as little as 0.05 μg/ml of metronidazole, a compound that is selectively toxic toward anaerobes. As indicated by Padgett and Krieg (1986), this provides circumstantial evidence for the occurrence of ferredoxins or flavodoxins in *S. volutans*, because metronidazole reduction is preferentially linked to these electron carriers.

Applications

Growth in low concentrations of Zn^{2+}, Ni^{2+}, Cu^{2+}, Hg^{2+}, Pb^{2+}, and various other toxic substances results in formation of cells that have either an aft flagellar fascicle at each pole or a fore fascicle at each pole, with consequent inhibition of motility (Krieg et al., 1967; Caraway and Krieg, 1972). This is the basis of a simple method for biological detection of toxicants in the effluents from industrial plants (Bowdre and Krieg, 1974). The

method essentially involves combining a sample of the material to be tested with cells of *S. volutans*; samples are removed periodically for microscopic examination to determine whether motility has been affected. The method has since been modified and evaluated by several investigators (Dutka et al., 1983; Goatcher et al., 1984; Moore, 1984; Cortes et al., 1996; Ghosh et al., 1996; Lacava and Ortolono, 1997) and has been found to be a useful screening procedure. Although this method cannot identify the pollutants present in an industrial effluent, it can detect the presence of toxic substances before the effluent is discharged into a receiving stream or river. Chemical and physical methods can then be used to identify the particular substances responsible. The method also has been used to detect the presence of toxic chemicals that may affect the normal operation of sewage treatment plants (McElroy, 1983).

CHAPTER 3.2.6

The Genus *Aquaspirillum*

BRUNO POT, MONIQUE GILLIS AND JOZEF DE LEY

Helical bacteria have been found in nature under very diverse circumstances. For over 300 years people have admired these graceful forms of life under the microscope. Van Leeuwenhoek (1670) mentioned helical shapes when he described the first bacteria (animalcules). In contrast to their easy detection, spirilla have been very difficult to isolate and to maintain in pure culture. Müller (1773, 1786) described eight species of the genus *Vibrio*, three of which were spirilliforms. According to Williams (1959), the present type species of the genus *Aquaspirillum*, *Aquaspirillum serpens*, can be recognized in Müller's original description of "*Vibrio serpens*," but as noted by Terasaki (1980) and Krieg and Hylemon (1976), it is very unlikely that identification by modern standards can be made from the descriptions and drawings made by Müller.

The genus *Spirillum* was created by Ehrenberg (1832), with *Spirillum volutans* as the type species. Migula (1894, 1895, 1900) described many species within the genus *Spirillum*, mostly, however, based on mixed cultures. The genus *Spirillum* was reviewed thoroughly by Williams and Rittenberg (1957). They retained 19 species, mainly on the basis of morphology and a few nutritional and physiological characteristics. By cross-agglutination tests of cells of all 29 *Spirillum* strains, using antisera specific for *Spirillum* thermolabile antigens, McElroy and Krieg (1971) found 17 serogroups. Their subdivision was the basis of the classification of the genus *Spirillum* presented in the eighth edition of *Bergey's Manual of Determinative Bacteriology* (Krieg, 1974). However, Hylemon et al. 1973 proposed that the genus *Spirillum* be split into the genera *Aquaspirillum*, *Oceanospirillum*, and *Spirillum* on the basis of DNA base composition and a limited number of physiological characteristics. Large obligately microaerophilic spirilla with large bipolar tufts of flagella and having a DNA base composition of 38 mol% GC constituted the redefined genus *Spirillum* (Hylemon et al., 1973), for which only one species, the type species of the original genus *Spirillum* (*Spirillum volutans* [Ehrenberg, 1832]), was described (see The Genus *Spirillum* in Volume 5). All marine spirilla requiring seawater for growth and having a GC content of 42 to 48 mol% were included in the new genus *Oceanospirillum*, containing five species (see The Genus *Oceanospirillum* in the second edition). *Oceanospirillum* was later extended with eight new species (Terasaki, 1973; Bowditch et al., 1984). The genus *Aquaspirillum*, with 13 species, was created for all aerobic freshwater spirilla having a low salt tolerance and a GC content of 50 to 65 mol%. Later the genus was also extended by addition of five new species (Aragno and Schlegel, 1978; Kumar et al., 1974; Maratea and Blakemore, 1981; Strength et al., 1976; Terasaki, 1973, 1979). As mentioned by Krieg (1981), this was an improvement over the previous classification, but it was still not entirely satisfactory. Indeed, on the basis of phenotypic characteristics, there seems to exist a continuum between the spirilla and a variety of other oxidative, Gram-negative bacteria, resulting in rather vague generic definitions. A vast polyphasic approach including genotypic studies was obviously needed to obtain a better insight in the relationship between these species. As a result *Oceanospirillum* has been redefined (Pot et al., 1989); it is described elsewhere (see The Genus *Oceanospirillum* in the second edition).

Results of DNA-rRNA hybridization studies (Pot et al., 1989) and 16S oligonucleotide cataloging (Woese et al., 1982, 1984b) incited us to explore further the inter- and intraspecific relationships within the genus *Aquaspirillum*. A very heterogeneous group of bacteria, spread over rRNA superfamilies III and IV, was found, indicating that *Aquaspirillum* can no longer be considered as one genus. The original genus name should be restricted to the species *Aquaspirillum serpens*, *A. bengal*, and *A. fasciculus*. As no definite proposals have been made yet to rename the other, misnamed, *Aquaspirillum* species, we will indicate their current (misnamed) status by square brackets.

All *Aquaspirillum* species described in *Bergey's Manual of Systematic Bacteriology* (Krieg, 1984) share the following characteristics: they are all rigid helical cells, except for *[A.] delicatum* which is vibrioid and *A. fasciculus* which is a straight rod. All species so far examined by electron microscopy have a polar membrane underlying the cytoplasmic membrane. They generally have bipolar tufts of flagella, but one single flagellum at each pole may be present (as in *[A.] polymorphum* and *A. magnetotacticum*, the latter being the only named *Aquaspirillum* species which was not included in our taxonomic investigations; for detailed information see Blakemore et al., 1989). In addition, *[A.] delicatum* possesses one or two flagella at one pole only. Intracellular poly-β-hydroxybutyrate is formed (except in *[A.] gracile* and *[A.] psychrophilum*) or is presumably formed (*A. magnetotacticum*). Coccoid bodies which predominate in old cultures (three to four weeks) may be formed (*[A.] peregrinum* subsp. *peregrinum, [A.] polymorphum*, *[A.] itersonii* and *A. fasciculus*). Aquaspirilla are typically aerobic, although some species grow in microaerophilic conditions (*[A.] peregrinum* and *A. fasciculus*), under which these species may exhibit nitrogenase activity (Strength et al., 1976). They have a respiratory type of metabolism with oxygen as terminal electron acceptor although some species can also grow anaerobically using nitrate. They are chemoorganotrophic; however, one species (*[A.] autotrophicum*) is facultatively autotrophic, as it can oxidize hydrogen. Only a few species can catabolize a limited number of carbohydrates; amino acids or organic acids usually serve as the major carbon source. Since the original description, the range of GC content of the genus has been

This chapter was taken unchanged from the second edition.

extended to vary between 49 and 66 mol%. An overview of differentiating phenotypic features is listed in Table 1.

Habitats

Freshwater spirilla are widely distributed in stagnant waters, and *Aquaspirillum* species have been isolated from various freshwater sources, including distilled water (Leifson, 1962), ditch and canal water (Giesberger, 1936), and sewage (Myers, 1940). *[A.] autotrophicum* was isolated from a eutrophic lake in Switzerland (Aragno and Schlegel, 1978). Some aquaspirilla have been isolated from putrid infusions of freshwater mussels, but according to Terasaki (1980) and Krieg (1976) it is more likely that these bacteria derived from the adherent mud rather than from the mussels. Giesberger (1936) also reported the isolation of a spirillum from horse or pig manure after it had been in contact with the stable floor ("*Spirillum pleomorphum*," presently regarded as a spirillum possibly belonging to the genus *Aquaspirillum*; Krieg, 1984). Presumably the bacteria were derived from the (wet) floor rather than from the (anaerobic) manure, as soil is a source of spirilla (Inoue, 1976; Inoue and Komagata, 1976).

In 1973, Scully and Dondero used the most-probable-number method to estimate the number of spirillum-like bacteria in samples of different origins. In nonmarine samples, spirilla numbers ranged from approximately 4% of the total bacterial population in algal samples to less than 0.01% in samples of cultivated field soil and drainage or forest soil. Generally the population density varied between 0.1 and 0.6% for pond mud, pond water, stream water, and cow manure.

Our new insights into the taxonomic relationships with and within the aquaspirilla (see "Identification and Taxonomy," The Genus *Aquaspirillum* in Volume 5) make it probable that the variety of habitats from which spirillum-like organisms will be isolated in the future will enlarge considerably. Indeed, B. Pot et al. (unpublished observations) found *[A.] autotrophicum* to be related at the intrageneric level with unnamed, slightly helical bacteria isolated from wounds and blood and with a group of generically misnamed [*Pseudomonas*] species pathogenic for sugarcane plants. *[A.] aquaticum* was found to have a DNA-DNA homology of at least 55% with a second group of unnamed, slightly helical bacteria of clinical origin (isolated from wounds, sputum, etc.), indicating a relationship at the species level. Although both [*Aquaspirillum*] species have to be renamed (see below), it indicates that clinical material can also be a source for the isolation of spirilla. Table 2 gives details on the isolation of all *Aquaspirillum* species presently included in the genus.

Isolation

Although spirilla have a very typical morphology, are widespread in nature, and were already described in the very early days of microbiology, they remained for a long time one of the least characterized groups of bacteria, due to 1) the lack of medical importance; 2) the difficult isolation of the organisms; and 3) the difficulties encountered for preservation (Hylemon et al., 1973). These obstacles have partly been removed since the publication of several techniques for enrichment, isolation, and pure culture preservation.

Enrichment is a necessary step in the isolation of spirilla since they are relatively slow-growing and never occur in predominant numbers.

Enrichment, Isolation and Maintenance of the Aquaspirilla

Since freshwater spirilla are rarely the predominant bacteria in any particular natural source (Scully and Dondero, 1973), for successful isolation several enrichment and isolation techniques (almost as many as there are species in the genus *Aquaspirillum*) had to be developed. A historical overview is given below.

GIESBERGER (1936) Giesberger (1936) used the following technique for the enrichment of freshwater spirilla from polluted water (Table 2):

> To a 300-ml Erlenmeyer flask, containing 200 ml of the water sample, was added:
>
> | | |
> |---|---|
> | Calcium malate or lactate | 2.0 g |
> | NH_4Cl | 0.1 g |
> | K_2HPO_4 | 0.05 g |
> | $MgSO_4 \cdot 7H_2O$ | 0.05 g |
>
> The pH was brought nearly to neutrality, but within 24 h the reaction became acidic and the pH had to be readjusted to 7.3. Spirilla began to develop from the third day, usually reaching a maximum after a week. Incubation at 40°C rather than 30°C resulted in good growth in 24 h. Giesberger also replaced the chemicals by a hay infusion (a handful of hay per liter of the water sample). Such infusions incubated at 30°C also gave good growth of spirilla after one week. The enriched cultures were streaked on peptone agar plates on which the excess moisture was removed by placing a filter paper soaked in glycerol in the cover. Although this helped to prevent contaminating bacteria from spreading too quickly over the plates, the colonies of the slow-growing spirilla were often rapidly overgrown by contaminants or were inhibited. For some spirilla, the addition of 0.5 to 1.0% sodium pyruvate to the peptone agar plates improved the isolation and culturing; for others Giesberger (1936) had to start by picking up the very small colonies with the aid of a microscope and a micromanipulator, after which they were blown out onto fresh peptone agar plates.

[a]This taxon was found to be in rRNA superfamily III (see The Proteobacteria: Ribosomal RNA Cistron Similarities and Bacterial Taxonomy in the second edition).
[b]The taxonomic status of this species was not investigated by DNA-rRNA hybridizations. For taxonomic status see Blakemore et al. (1989).
[c]This taxon was found to be in rRNA superfamily IV (see The Proteobacteria: Ribosomal RNA Cistron Similarities and Bacterial Taxonomy in the second edition).
[d]The taxonomic status of this species was not investigated by DNA-rRNA hybridizations. For taxonomic status see Krieg (1984).
[e]By phase-contrast microscopy of 24- to 48-h-old broth cultures.
[f]*A. fasciculus* is a straight rod; the helix length refers to the length of the rod.
[g]*[A.] delicatum* is vibrioid rather than helical, thus wavelength can not be determined; the helix diameter refers to the width of the vibrio, and length of helix refers to the length of the vibrio.
[h]For *[A.] gracile*, acid from glucose, galactose and arabinose (aerobically). For *[A.] itersonii*, acid from glycerol (aerobically), fructose (aerobically and anaerobically) and glucose (anaerobically only). For *[A.] peregrinum*, acid from fructose (aerobically and anaerobically). Peptone concentrations must be kept low (0.2% or less) in order to detect change in pH indicator. Although *[A.] itersonii* and *[A.] peregrinum* acidify sugar media anaerobically, turbid growth does not occur and the organism should be considered to have mainly a respiratory rather than fermentative type of metabolism.
[i]See "Procedures for Testing Special Characters" in Krieg (1984).
[j]*[A.] gracile* requires biotin and *[A.] aquaticum* requires niacin.
[k]Positive at 37°C but not at 41°C.
Misnamed *Aquaspirillum* species are indicated between straight brackets.
Symbols: +, positive for all strains; –, negative for all strains; ND, not determined; H, helical (one or more complete turns or twists); V, vibrioid (less than one complete turn or twist); SR, straight rod; C, clockwise or right-handed helix (indicated by the pattern //// when focusing on the bottom of the cells); HA, helix absent; CC, counterclockwise or left-handed helix (indicated by the pattern \\\\ when focusing on the bottom of the cells); BT, bipolar tufts; U(1–2), 1 or 2 flagella at only one pole; BS, single flagellum at each pole; W, weak reaction; d, differs among strains.
Based on Krieg (1984) and Blakemore et al. (1989).

Table 2. List of type strains for all species presently included in the genus *Aquaspirillum*.

Name of organism according to Krieg (1984)[a]	Strain number of the type strain	Synonymous strain number	Source and place of isolation	References
[A.] anulus	NCIB 9012	LMG 5404	Freshwater pond, USA.	Williams and Rittenberg, 1957; Hylemon et al., 1973
[A.] aquaticum	ATCC 11330	LMG 2370	Small lake, USA.	Hylemon et al., 1973; Kropinski, 1975
[A.] autotrophicum	ATCC 29984	LMG 4326	Eutrophic lake Le Loclat, St. Blaise, Switzerland.	Aragno and Schlegel, 1978
[A.] bengal	ATCC 27641	LMG 6234	Freshwater pond, West Bengal.	Kumar et al., 1974; Boivin et al., 1985
[A.] delicatum	NCIB 9419	LMG 4327	Stored distilled water.	Leifson, 1962; Hylemon et al., 1973
[A.] dispar	ATCC 27510	LMG 4329	Fresh water, USA.	Hylemon et al., 1973
[A.] fasciculus	ATCC 27740	LMG 6233	Pond water hay infusion, USA.	Strength and Krieg, 1971; Strength et al., 1976
[A.] giesbergeri	ATCC 11334	LMG 4332	Freshwater pond, USA.	Williams and Rittenberg, 1957; Hylemon et al., 1973
[A.] gracile	ATCC 19624		Surface waters, USA.	Canale-Parola et al., 1966; Hylemon et al., 1973
[A.] itersonii subsp. *itersonii*	ATCC 12639	LMG 4337	Freshwater pond.	Giesberger, 1936; Hylemon et al., 1973
[A.] itersonii subsp. *nipponicum*	ATCC 33333	LMG 6237	Freshwater shellfish, Japan.	Terasaki, 1973; Terasaki, 1979
A. magnetotacticum[b]	MS-1		Fresh water from Cedar Swamp, Woods Hole, Mass.	Blakemore et al., 1979; Maratea and Blakemore, 1981
[A.] metamorphum	NCIB 9509	LMG 4338	Putrid infusion of freshwater mussel (*Corbicula japonica* Prime).	Terasaki, 1961b; Hylemon et al., 1973
[A.] peregrinum subsp. *peregrinum*	NCIB 9435	LMG 4340	Primary oxidation pond.	Pretorius, 1963; Hylemon et al., 1973
[A.] peregrinum subsp. *integrum*	IFO 13617	LMG 5407	Putrid infusion of freshwater mussel.	Terasaki, 1973; Terasaki, 1979
[A.] polymorphum	ATCC 11332	LMG 4392	Freshwater pond, USA.	Williams and Rittenberg, 1957; Hylemon et al., 1973
[A.] psychrophilum	IFO 13611	LMG 5408	Antarctic moss.	*Terasaki, 1973; Terasaki, 1979*
[A.] putridiconchylium	ATCC 15279	LMG 4342	Putrid infusion of freshwater mussel (*Semisulcospira bensoni* Philippi).	Terasaki, 1961a; Hylemon et al., 1973
[A.] serpens	ATCC 12638		Pond water.	Giesberger, 1936; Hylemon et al., 1973
[A.] sinuosum	ATCC 9786	LMG 4347	Freshwater pond, USA.	Williams and Rittenberg, 1957; Hylemon et al., 1973

[a]Generically misnamed *Aquaspirillum* species are indicated by brackets.
[b]The taxonomic status of this species was not investigated by DNA-rRNA hybridizations.

WILLIAMS AND RITTENBERG (1957) Williams and Rittenberg (1957) used the following techniques for the isolation of spirilla from stagnant water samples from small ponds (Table 2).

> The water was collected in wide-mouthed jars along with an amount of algae from the same source. After 10 to 14 days incubation at room temperature, the spirilla were collected near the surface of the infusion.
>
> A 100-ml water sample could also be supplemented with 1 g of peptone or yeast autolysate rather than algae. After three days incubation at room temperature the spirilla appeared, reaching a maximum development at seven days. Further enrichment could be achieved by a successive nutrient depletion. Therefore, part of the initial enrichment culture was diluted with an equal volume of the source water and autoclaved; the unsterilized part of the enrichment culture was then used for inoculation of this sterilized portion. After proper incubation, this procedure could be repeated one to three times until the spirilla were predominant.

Both Giesberger (1936) and Williams and Rittenberg (1957) added 1% of calcium malate or lactate to the water samples. NH_4Cl or other external sources of nitrogen were not used because other bacteria then overgrew the spirilla. Subsequent transfers (three to four times) of grown enrichment cultures into sterile source water samples containing malate or lactate also resulted in cultures predominated by spirilla.

> Isolation was achieved by diluting the enriched cultures 1:100 to 1:100,000 with sterile tap water. The dilution bottles were shaken and allowed to stand for 20 min, during which the spirilla accumulated near the surface. A loopful of the surface water was then streaked onto nutrient agar plates supplemented with 0.3% yeast autolysate or onto solidified Giesberger's medium containing 1% malate or lactate. The plates were incubated for 24 h at 30°C and were examined microscopically for characteristic colonies: umbonate (larger spirilla) or pulvinate (smaller spirilla) with a distinctive granular and ground-glass appearance and a typical wavy, interlaced texture with fimbriated edges. After another 24 h of incubation, the presence of spirilla was confirmed by the preparation of wet mounts. The colonies were then streaked until uniform in appearance and until microscopic examination indicated a uniform population.

Williams and Rittenberg (1957) established three principles important for successful enrichment and isolation of spirilla: 1) spirilla tend to grow well in diluted media while in concentrated media they are rapidly overgrown by other bacteria; 2) they grow relatively well in media with low levels of nitrogen, although infusions can give good results as well; and 3) the salts of organic acids (e.g. calcium malate or lactate) tend to selectively improve the growth of spirilla. These principles have been used by many other investigators for the successful isolation of spirilla.

TERASAKI (1961a, 1970) Terasaki isolated a spirillum (Table 2) from a putrified freshwater snail, *Semisulcospira bensoni* (Philippi), and cultivated it for about two years in vitro by the following methods:

> Broken putrid shellfish together with a teaspoon of mud were incubated at 27 to 28°C in a Petri dish filled with a 0.1% sodium chloride solution. Regular microscopic observation revealed large numbers of various spiral organisms, moving around together with other micro-organisms. The isolation medium contained:
>
> | | |
> |---|---|
> | Peptone | 5 g |
> | Yeast extract | 3 g |
> | NaCl | 1 g |
> | Water | 800 ml |
> | Shell fish extract | 200 ml |
>
> pH adjusted to 7.0 to 7.2 before sterilization.
>
> The shellfish extract was prepared by boiling 250 g broken shellfish in 500 ml of water for 20 min. The extract was filtered before use.
>
> Isolation was achieved by successively streaking on five isolation medium plates with a loop dipped into a small drop of the enrichment culture. The plates were incubated at 20°C for several days. Colonies were then transferred to tubes containing liquid isolation medium. Pure cultures were subcultured on isolation medium, in nutrient broth, or on nutrient agar containing beef extract (0.5%) and peptone (0.3%). For the preparation of nutrient agar either 0.7% agar or 12% gelatin was added; the pH was brought to 7.0 to 7.2.

TERASAKI (1961b, 1970) Terasaki used roughly the same method (Terasaki, 1961b) for the isolation of *[A.] metamorphum* (Table 2) from the freshwater shellfish *Corbicula japonica.* The shellfish extract was prepared; the pH of the culture medium was 8.0 to 8.2, and the incubation temperature was 30°C. According to Terasaki (1980) and Krieg (1976), the mud used during isolation is more likely to be the source of the spirilla, rather than the shellfish.

LEIFSON (1962) Leifson isolated a spirillum (*[A.] delicatum*) from a distilled water supply using the following medium, containing per l:

> | | |
> |---|---|
> | Casitone (Difco) | 3.0 g |
> | Yeast extract | 1.0 g |
> | K_2HPO_4 | 1.0 g |
> | Agar | 15 g |
>
> pH 7.1.
>
> The plates were dried overnight at 37°C and 0.1 ml of diluted water samples were spread over the plates. The plates were incubated at 20°C for three to five days.

PRETORIUS (1963) For enrichment, Pretorius used three different media:

> (a) An infusion of dried grass was prepared by boiling 1 g of small pieces of grass in 100 ml distilled water for 1 h, keeping the volume constant; the infusion was used as

such or as the filtrate; (b) a defined medium as described by Myers (1940) with calcium lactate as the carbon source and NH_4Cl as the nitrogen source; and (c) a basal medium containing per liter distilled water 1.0 g each of K_2HPO_4, $(NH_4)_2SO_4$, NaCl, $MgSO_4 7H_2O$, peptone, ethanol, glycerol, calcium lactate and cellulose powder and one drop of a 1% solution of $MnSO_4$ and $FeCl_3$. The medium was sterilized at 121°C for 15 min. Glucose, fructose, and cellobiose at 1.0% solutions were filter-sterilized and added to the heat-sterilized medium. After mixing with the inoculum, the pH was brought to 7.0. For the three media, the incubation temperature was 30°C. Isolation was achieved with the capillary tube method as described by Rittenberg and Rittenberg (1962).

Jannasch (1965) Jannasch mixed equal volumes of eutrophic water and double-strength Giesberger's medium to which he added portions of dead or fresh subsurface plants. When the organic content of the medium was high the proportion of spirilla was low. Jannasch further enriched the cultures by transferring a portion of the scum and underlying layer into a second flask, supplemented with lactate or malate, K_2HPO_4 and $MgSO_4$, without addition of organic material. In cases where spirilla reached 80 to 90% of the population, he isolated the spirilla by streaking undiluted enrichment cultures on a suitable medium containing 0.1% peptone, 0.01% yeast extract, 0.05% asparagine, and 1.8% agar; when population densities of spirilla were lower in the initial cultures, dilutions were streaked on the agar medium or small drops were placed on sterile cover slips (with the edges sealed with vaseline to prevent evaporation) which were inverted over a depression slide. The unicellular isolations made in this way could not be brought to multiply on agar plates, but were subcultured in a hanging drop culture containing enrichment medium supplemented with 0.005% ascorbic acid, before being transferred with a Pasteur pipette to agar plates.

Canale-Parola et al. (1966) The authors described a selective isolation procedure for a specific morphological and physiological type of spirillum from surface waters (*[A.] gracile*, Table 2).

The medium used for isolation from nature and for routine culturing (medium A) contains per l tap water:

Peptone	5 g
Yeast extract	0.5 g
Tween 80 (sorbitol monooleate polyoxyethylene)	20 mg
K_2HPO_4	0.1 g
Agar	10 g

pH 7.2.

The yeast extract could be replaced in medium B by:

Thiamine ·HCl	0.5 mg
Biotin	0.05 mg
$MgSO_4 \cdot 7H_2O$	0.1 g
$MnSO_4 \cdot H_2O$	0.05 g
Sodium succinate $\cdot 6H_2O$	1 g

The latter compound may be replaced in medium C by:

Lactic acid	1 g

The pH of media B and C was 7.3.

Enrichment was accomplished by taking advantage of the very small size of the cells. Sterile cellulose ester filter disks (0.45 µm average pore size) were placed on plates of medium A, B or C. Pond or stream water (0.05 ml) was deposited in the center of the filter disk and the plates were incubated at room temperature for 1.5 to 5 h after which the filter disk was removed. After three days or more of incubation, spreading, semitransparent areas of cells developed entirely within the agar medium where the filter disk had been located. In all cases this characteristic subsurface growth consisted of thin spirilla (0.25 to 0.30 µm in diameter). The organisms were isolated by streaking on medium A, B or C, respectively.

Cody (1968) In 1968 Cody reported on a selective agent for the isolation of freshwater spirilla. He found that 5-fluorouracil at concentrations of 300 µg/ml had little or no inhibitory action on the growth response of *A. serpens* and that pure culture isolates of spirilla could be obtained from natural sources on media containing this chemical substance. Scully and Dondero (1973), however, showed that the use of this agent is generally not as effective as the use of other enrichment procedures.

Strength and Krieg (1971) and Strength et al. (1976) In 1971, Strength and Krieg reported the isolation of an aquatic bacterium from a pond water hay infusion which they later assigned to the genus *Aquaspirillum* as *A. fasciculus* (Strength et al., 1976; Table 2). The two isolation procedures they described at that time (the decreased-oxygen method and the cellulose-powder method) have proven to be unreliable for the isolation of additional strains (Strength et al., 1976) and will therefore not be described here. A more reliable method was described as follows (Strength et al., 1976):

A pond-water hay infusion incubated at 30°C in shallow pans reached maximal numbers of spirilla in the surface scum at three days. Initial enrichment was performed in Pringsheim's soil medium (Rittenberg and Rittenberg, 1962) for four days. A loopful of the surface pellicle of the enrichment culture was suspended in 10 ml sterile water and shaken vigorously in order to disperse the cell flocs that were characteristically formed by this organism. Serial dilutions in sterile water were made from this suspension and each dilution used to seed plates of melted, cooled proline (PR) medium with the following composition (per l distilled water):

L-Proline	0.5 g
K_2HPO_4	0.45 g
$MgSO_4 \cdot 7H_2O$	0.25 g
$MnSO_4 \cdot H_2O$	1 mg

$FeCl_3 \cdot 6H_2O$	1 mg
Agar	7.5 g

pH adjusted to 7.0 with KOH.

After 36 h incubation at 30°C, numerous small (0.1 to 0.4 mm), white, irregularly shaped colonies could easily be detected with a dissecting microscope. The colonies were picked up with a sterile capillary tube and blown out into tubes of PR medium with 0.15% agar. It was better to crush the agar plugs from the capillary tubes after the transfer. Purity was checked by darkfield microscopy: the spirilla were characterized as rods with a diameter of 0.7 to 0.9 µm with bipolar fascicles of flagella responsible for the helical wave propagation.

KUMAR ET AL. (1974) From a freshwater pond in West Bengal, Kumar et al. (1974) isolated a large spirillum with the unique high optimal growth temperature of 41°C (*A. bengal*, Table 2). Later this species was found to be synonymous with *A. serpens* by slot blot hybridization experiments (Boivin et al., 1985) and by DNA-DNA hybridizations (Pot et al., unpublished observations). Enrichment and isolation were accomplished as follows:

In 250 ml Erlenmeyer flasks 10 ml of pond water was added to 90 ml of a sterile 0.5% peptone (Oxoid) solution. Within 24 to 72 h at 30°C the number of spirilla increased 100 to 400 times, but the enrichment was not selective, and incubation for longer periods resulted in a rapid decrease of the number of spirilla. Further enrichment of spirilla was achieved by low-speed centrifugation (1,000 × *g*, for 5 min) which caused the comparatively large spirilla to sediment more rapidly than other, smaller bacteria. The supernatant was carefully decanted and the sediment suspended in 2 ml of sterile tap water.

For isolation the capillary method (Rittenberg and Rittenberg, 1962) was ineffective; the diluting plating method, however, was successful.

From a series of decimal dilutions of the concentrated spirilla, 0.1 ml samples were spread on the surface of tomato-extract agar, containing per l pond water: Evans peptone (0.5%), tomato extract (40 ml, prepared by pressing pieces of fresh, ripe tomatoes through cheesecloth and filtering the juice through paper) and 2% agar. The pH was adjusted to 7.4 with KOH and the medium sterilized at 121°C for 15 min. The dilution plates were incubated at 40°C for 72 h and were then examined with a low-power microscope for colonies. The selected colonies were transferred to slants of the tomato-extract agar and purified by repeated dilution plating.

KROPINSKI (1975) The cultures isolated by Giesberger (1936) were lost but Williams and Rittenberg (1957) reisolated a spirillum which closely resembled *Spirillum serpens* (Giesberger, 1936) and deposited the strain in the American Type Culture Collection (ATCC 11330). Hylemon et al. (1973) renamed this strain *[A.] aquaticum* (Table 2). A chemically defined medium (AAM) containing nicotinic acid was described for this organism in 1975 by Kropinski.

The AAM medium contains per liter:

Na_2HPO_4	7 g
KH_2PO_4	3 g
$(NH_4)_2SO_4$	2 g
$MgSO_4 \cdot 7H_2O$	0.2 g
Sodium succinate$6H_2O$	5.6 g
Nicotinic acid	20 mg

pH 6.8.

INOUE AND KOMAGATA (1976) From antarctic soil, an obligate psychrophilic spirillum ("*Spirillum pleomorphum*") was isolated by Inoue (1976) and Inoue and Komagata (1976). The medium they used (PYG) contained per liter:

Peptone	10 g
Yeast extract	5 g
Glucose	3 g
Agar	15 g

pH 7.2.

Inoculated plates were incubated at 0°C for 14 to 24 days. Subsequent subcultures were incubated at the optimum temperature of 9°C.

ARAGNO AND SCHLEGEL (1978) Two strains of a facultatively autotrophic, hydrogen-oxidizing spirillum were isolated from a small eutrophic lake in Switzerland by Schweizer and Aragno (1975). Aragno and Schlegel (1978) classified the strains in the genus *Aquaspirillum* as *[A.] autotrophicum* (Table 2).

Isolation was achieved by filtering the water samples through membrane filters, which were then deposited on mineral agar and incubated under an atmosphere of 60% H_2, 30% air, and 10% CO_2 at 30°C. Pure cultures were obtained by repeated subculturing on mineral agar plates incubated under the same conditions. Purity of the cultures was determined by plating on different organic media and by microscopic observation.

BLAKEMORE ET AL. (1979, 1989) A bipolarly flagellated, microaerophilic, heterotrophic, magnetotactic spirillum containing intracellular chains of magnetite crystals was isolated by Blakemore et al. (1979) by applying a magnetic field to the sediments from a freshwater swamp. The organism was later assigned to the genus *Aquaspirillum* as *A. magnetotacticum* (Maratea and Blakemore, 1981; Table 2). Enrichment, isolation, and growth of strain MS-1 (Table 2) was achieved as follows:

Enriched cultures were obtained by the undisturbed incubation of loosely covered jars filled with water and mud from the sample origin (Table 2) to approximately two thirds of their volume, during one month or more at room temperature (22°C) in dim light. After that time a small amount of mud slurry, containing magnetotactic cells, was diluted 1:100 and dispensed into each of many small vials containing one sixth of their volume of the isolation medium. The vials were sealed and the atmosphere

replaced with an appropriate gas mixture (for routine purposes, the atmosphere was replaced by nitrogen and sufficient air added to provide 0.6 to 1.0% oxygen in the gas phase). After suitable incubation, survival of magnetotactic bacteria was determined from direct microscopic countings of motile, magnetotactic cells. From these cultures, large numbers of magnetotactic cells were separated from the sediment by the application of steady, non-uniform magnetic fields formed by permanent bar magnets. The cells were washed in filtered and sterilized bog water and injected through the stoppers of culture tubes containing prereduced, semisolid isolation medium containing per 90 ml distilled water:

Filtered swamp or bog water	10 ml
Vitamin elixir (Wolin et al., 1963)	1 ml
Mineral elixir (Wolin et al., 1963)	1 ml
Potassium phosphate buffer, pH 6.7	0.5 mM

Add to this mixture:

Vitamin B-12	5 µg
NH_4Cl	25 mg
Sodium acetate (anhydrous)	10 mg
Resazurin	0.2 mg
Ionagar no. 2 (Oxoid)	90 mg

The pH is adjusted to 6.7 with NaOH.

The medium was prereduced under nitrogen, using titanium citrate as reducing agent (Zehnder and Wuhrmann, 1976). The culture tubes were filled in an anaerobic hood and sealed. After inoculation the tubes were incubated at 22°C in the dark until growth became evident as diffuse, spreading, fluffy areas containing the magnetotactic spirilla. A well-isolated area of growth was homogenized, and cells were purified by serial dilution into tubes containing molten, prereduced isolation medium containing 0.85% Ionagar no. 2. Well-isolated colonies, which appeared in these tubes after one week at 30°C, were microscopically homogeneous. However, the cells were subcultured a second and a third time before the cultures were considered pure.

Maintenance of strain MS-1 (Blakemore et al., 1979)

Strain MS-1 was maintained at 30°C with weekly transfers in screw-capped culture tubes with a semisolid growth medium containing per 98 ml of distilled water:

Vitamin elixir (Wolin et al., 1963)	1 ml
Mineral elixir (Wolin et al., 1963)	1 ml
KH_2PO_4	5 mM
Ferric quinate solutions	2.5 ml
Resazurin	0.2 mg

Add to this mixture:

Succinic acid	0.1 g
Sodium acetate (anhydrous)	20 mg
$NaNO_3$	10 mg
Sodium thioglycolate	5 mg
Agar	130 mg

The agar was added after the pH was brought to 6.7 with NaOH. The ferric quinate solution was prepared by adding 2.7 g of $FeCl_3$ and 1.9 g of quinic acid to 1 liter of distilled water. The medium was boiled and 12 ml was added to each screw-capped tube containing approximately 0.1 ml of 5% Na thioglycolate in distilled water. Tubes of semisolid growth medium were autoclaved with caps tightened and allowed to stand overnight for the establishment of O_2 gradients. Inocula consisted of 0.2 ml (about 7×10^7 cells) per 12 ml of medium. Chemically defined growth medium was identical to the semisolid growth medium without agar. The vessels containing the medium were sealed before autoclaving, but after the atmosphere had been replaced by nitrogen and after sufficient air was provided to obtain 0.6 to 1.0% oxygen in the gas phase (Balch and Wolfe, 1976).

A homogeneous population of nonmagnetotactic variants was obtained from cultures of MS-1 grown in isolation medium made with distilled water rather than bog water. Cells grown in this medium, especially with twice as much as the usual amount of nitrate and succinate, grew nonmagnetotactically. To obtain a nonmagnetotactic pure culture from strain MS-1, cultures were transferred five successive times in this medium and were subsequently cloned three successive times as described above. Stocks of the nonmagnetotactic variant were maintained in defined growth medium without ferric quinate.

Terasaki (1980) Terasaki (1973) described five new species and two new subspecies of the genus *Spirillum* (Ehrenberg, 1832), on the basis of an extended morphological, physiological, and biochemical study that he performed. After he transferred these *Spirillum* species to their respective new genera in 1979 (i.e., for *Aquaspirillum*, the transfer to *[A.] psychrophilum*, *[A.] itersonii* subsp. *nipponicum* and *[A.]peregrinum* subsp. *integrum;* Table 2), Terasaki published in 1980 a more detailed description of the methods used for enrichment (boiled shellfish infusion method), selection (glass capillary method) and isolation (streak plate method) of aerobic, mesophilic freshwater and marine chemoheterotrophic spirilla from 20 mud and sand samples collected at various locations in Japan from 1970 to 1980. He concluded that 1) the boiled shellfish infusion method gave a definite increase of numbers of spirilla deriving from mud or sand samples; 2) the capillary method was useful for separating highly motile spirilla from non-motile bacteria, giving highly enriched crude cultures; 3) pure cultures can be isolated by simple streaking on agar plates; and 4) simple modifications could be devised for the isolation of microaerophilic, thermophilic, or psychrophilic spirilla.

Preservation of the Aquaspirilla

The spirilla mentioned in Table 2, except for *A. magnetotacticum*, have been maintained in our laboratory by weekly transfers on peptone succinate-salt medium (MPSS).

MPSS Medium (Krieg, 1984)

Per liter of distilled water add:

Succinic acid (free acid)	1.0 g
$MgSO_4 \cdot 7H_2O$	1.0 g
Bacto peptone (Difco)	5.0 g
$(NH_4)_2SO_4$	1.0 g

$FeCl_3 \cdot 6H_2O$ (0.2% aqueous solution) 1.0 ml
$MnSO_4 \cdot H_{20}$ (0.2% aqueous solution) 1.0 ml

pH is adjusted to 6.8 with KOH.

The medium is dispensed in 10 ml portions before sterilization (121°C for 20 min) into loosely screw-capped tubes. After cooling the tubes are closed and stored at 4°C until use. Inoculum consists of three to five drops from a MPSS culture, delivered from a Pasteur pipette. Inoculated, loosely capped tubes are incubated at 28°C (except for *[A.] psychrophilum* which is incubated at 17°C) until visible turbidity occurs (one to three days, depending on the strain). The tubes of grown culture are then closed and stored at 4°C for one week. Before the next transfer, tubes are brought to room temperature and the new MPSS tubes are inoculated. Purity is regularly checked by plating on MPSS agar.

Giesberger (1936) reported maintenance on ordinary peptone agar slants with three to four monthly transfers. However some strains required the addition of pyruvate and more frequent transfers were necessary for such strains. Terasaki (1972) maintained strains in nutrient agar stabs with monthly transfers. Hylemon et al. (1973) used a semisolid MPSS broth with peptone increased to 1% and containing 0.15% agar with weekly transfers.

Long-term preservation can be accomplished by centrifuging cells from a grown 10 ml MPSS broth culture, suspending them in 2 ml MPSS broth supplemented with 15% glycerol as cryoprotective agent in sterile tubes, and freezing them in liquid nitrogen or at –80°C in a deep freezer. Lyophilization is achieved by resuspending the centrifuged cells of two 10 ml MPSS broth cultures in 3 ml of sterile horse serum (70%) supplemented with glucose (7%) and nutrient broth (0.6%). The suspension is dispensed in 8 to 12 small sterile lyophilization tubes with proper labeling and freeze dried overnight. The lyophilization tubes are sealed by heat and stored at 4°C. Terasaki (1975) has reported the results of freeze-drying freshwater spirilla.

Identification and Taxonomy

The present description of the genera *Spirillum*, *Aquaspirillum*, and *Oceanospirillum* in *Bergey's Manual of Systematic Bacteriology* (Krieg, 1984) is mainly based on morphological, nutritional, and physiological data and on DNA base composition. However, the number of exceptions to the general description of the genera is large. Morphologically, cells are not all helical but can also be vibrioid (*[A.] delicatum*) or straight rods (*A. fasciculus*), and the flagellation can be one flagellum at one (*[A.] delicatum*) or both poles (*[A.] polymorphum* and *A. magnetotacticum*) instead of bipolar tufts. *A. magnetotacticum* is the only member that is obligately microaerophilic, and it is oxidase and catalase negative. Although some species have physiological characteristics which are very typical for the genus, they may show an aberrant morphology; also species with a typical spiral morphology may have physiological properties which do not agree with those described for the genus. Genetic evidence for close intrageneric relationships within *Aquaspirillum* was not available to Krieg (1984). On the contrary, the comparison of the 16S rRNA oligonucleotide catalogs (Woese et al., 1982) of three strains representing *A. serpens*, *[A.] itersonii*, and *[A.] gracile* and DNAr-RNA hybridizations (De Smedt et al., 1980) with *[A.] itersonii* and *[A.] polymorphum* revealed a large heterogeneity, indicating that a thorough genotypical reexamination of the genus was necessary in order to reveal the different subgroups probably present in this genus. This was performed by more DNAr-RNA hybridizations with almost all available strains of all *Aquaspirillum* species, except *A. magnetotacticum* (Pot et al., 1984. Genetic heterogeneity within *Aquaspirillum* and *Oceanospirillum*. Abstract C8 of the FEMS Symposium on "Evolution of Prokaryotes," Munich, FRG). Results of oligonucleotide cataloging of 16S rRNA of representative strains of *A. bengal*, *[A.] dispar* and *[A.] aquaticum* also became available (Woese et al., 1984b). For the species studied with both methods, the results were comparable (Pot et al., manuscript in preparation) and can be summarized as follows (see also The Proteobacteria: Ribosomal RNA Cistron Similarities and Bacterial Taxonomy in the second edition).

Aquaspirillum Species Belonging to rRNA Superfamily III

All *Aquaspirillum* species except three (*[A.] peregrinum*, *[A.] polymorphum*, and *[A.] itersonii*) belong in rRNA superfamily III, corresponding to the beta group of the Proteobacteria. Within this rRNA superfamily they belong to known rRNA branches (mostly representing a known genus) or they constitute separate rRNA branches or subbranches. This indicates that most of these *Aquaspirillum* species are generically misnamed.

Within rRNA superfamily III, only *A. serpens* and *A. bengal* have very similar rRNA cistrons, supporting the proposal of Boivin et al. (1985) to emend *A. serpens* to include *A. bengal* as a subjective synonym. They constitute a separate rRNA branch which also comprises *A. fasciculus* at a lower $T_{m(e)}$ level (see The Proteobacteria: Ribosomal RNA Cistron Similarities and Bacterial Taxonomy in the second edition). *A. fasciculus* is the only rod-shaped member of *Aquaspirillum*; it has been classified in this genus

because of its bipolar tufts of flagella and because it possesses some of the typical physiological features of the genus. Because this rRNA branch contains the type species of the genus, *Aquaspirillum* sensu stricto should be restricted solely to members of this rRNA branch. Despite the large difference in GC content (10 mol%), we propose to include also *A. fasciculus* in *Aquaspirillum* sensu stricto. The differentiating features can be found in Table 1.

Eight [*Aquaspirillum*] species (*[A.] anulus*, *[A.] aquaticum*, *[A.] delicatum*, *[A.] giesbergeri*, *[A.] gracile*, *[A.] metamorphum*, *[A.] psychrophilum* and *[A.] sinuosum*) belong in the acidovorans rRNA complex (Willems et al., 1987, 1989). Krieg and Hylemon (1976) have found a resemblance between *[A.] delicatum* and the genera *Comamonas* and *Pseudomonas*. *[A.] aquaticum* is closely related to a group of clinical isolates which also exhibit a characteristic corkscrewlike type of motility; they both belong in the genus *Comamonas* described in The Genus *Comamonas* in the second edition. Among the seven other species only *[A.] giesbergeri* and *[A.] sinuosum* are closely related. All other species occupy a separate position in the acidovorans rRNA complex. In the future, their taxonomic status will be further unravelled by a polyphasic approach.

[A.] dispar and *[A.] putridiconchylium* each constitute a separate rRNA branch in rRNA superfamily III equally far removed from the authentic *Aquaspirillum* rRNA branch and from the genera *Chromobacterium* and *Neisseria*. Woese et al. (1984b) found *[A.] dispar* to be somewhat more related to *A. serpens* than to the other members of the beta group.

[A.] autotrophicum is generically related to *Janthinobacterium*, to *[Pseudomonas] rubrisubalbicans* (a generically misnamed *Pseudomonas* species pathogenic for sugar cane), and to an unnamed group of clinical isolates from different origins, which also show a characteristic corkscrewlike type of motility (Goor et al., 1986).

[*Aquaspirillum*] Species Belonging to rRNA Superfamily IV

Three species are members of rRNA superfamily IV (Stackebrandt et al., 1988; alpha group of the *Proteobacteria*). *[A.] peregrinum* (both subspecies), *[A.] itersonii* subsp. *itersonii*, and *[A.] itersonii* subsp. *vulgatum* are highly related and constitute a separate rRNA subbranch in the *Azospirillum-Rhodospirillum* rRNA complex. This subbranch is comparable with, and equidistantly related to, the subbranches formed by *Azospirillum* and *Rhodospirillum*. This is in agreement with the cataloging data obtained by Woese et al. (1984a, 1984b). Within the alpha group, *[A.] itersonii* was also found to be approximately equally far removed from *Rhodospirillum rubrum* and from *Azospirillum brasilense*. As a consequence, these two [*Aquaspirillum*] species deserve a separate generic rank; the intrageneric relationships within this new genus have not yet been determined completely. *[A.] polymorphum* belongs also in the *Azospirillum-Rhodospirillum* rRNA complex and is equidistantly removed from the former three rRNA subbranches. Therefore this species probably represents another genus. All three [*Aquaspirillum*] species in rRNA superfamily IV share a high GC content and can be differentiated from the other *Aquaspirillum* species by a counterclockwise helix and by the hydrolysis of esculin. They are also characterized by a predominance of coccoid bodies in three to four week-old cultures. Among other aquaspirilla, this feature was only found in *A. fasciculus* and *A. magnetotacticum*. N_2-fixing capacity occurs in *[A.] peregrinum* and *[A.] itersonii*, not in *[A.] polymorphum*. *[A.] polymorphum* and *[A.] magnetotacticum* are the only aquaspirilla having a single polar flagellum at each pole. The genotypic position of *[A.] itersonii* subsp. *nipponicum* is not clear yet; the strain which we have included in our DNA-rRNA hybridizations does not belong in rRNA superfamily IV.

The genotypic heterogeneity within the aquaspirilla has not yet been used to make new nomenclatural propositions because all the data needed are not yet available. Therefore we propose to base identification on the results of Krieg (1984), Boivin et al. (1985) and Blakemore et al. (1989; Table 1). In this table the different species are grouped according to their genotypic relationships. *Spirillum volutans* is not included in this scheme, because according to its rRNA catalogs (Woese et al., 1984b), it belongs in the beta group where it constitutes a separate branch together with *Nitrosovibrio*, *Nitrosospira*, *Nitrosolobus*, *Nitrosococcus mobile*, and *Nitrosomonas europaea*. It is clearly different from the other aquaspirilla by its low GC content and its large cell dimension.

From these results it is obvious that future identification must rely heavily on the phenotypic reinvestigation of the present *Aquaspirillum* species in order to 1) describe the species in view of their new generical position; and 2) detect differentiating characteristics with their closest neighbors, needed for an appropriate identification key. This may drastically change some of the present definitions but should allow a more reliable identification. The present definition of the genus *Aquaspirillum* will also drastically change. The fact that a straight rod, capable of fixing nitrogen, is the only species

besides the type species that can be maintained in the genus *Aquaspirillum* (except for *A. magnetotacticum*, which was not investigated) raises more questions on the taxonomical value of the helical structure. Moreover, it is generally known that the ability to form spirals tends to disappear after prolonged transfer in culture media, indicating that the spiral form is not a very stable feature and hence not reliable for identification purposes. The fact that (rigid) spiral forms are distributed all over the Gram-negative bacteria (see also The Genus Oceanospirillum in the second edition.) makes it questionable if the spiral form is an ancestral form rather than a feature that can arise by mutation.

CHAPTER 3.2.7

Comamonas

ANNE WILLEMS AND PAUL DE VOS

Introduction

The genus *Comamonas* contains species of Gram-negative, aerobic, nonpigmented, rod-shaped bacteria, which are motile by means of at least one polar tuft of flagella and have a non-fermentative chemoorganotrophic metabolism. They are quite ubiquitous in the environment and have been isolated from soil, mud and water. *Comamonas* strains have also been isolated from denitrifying activated sludge as well as from various clinical samples and from the hospital environment, but they are not seen as pathogenic to healthy humans. The genus currently comprises four species, *Comamonas terrigena*, *Comamonas testosteroni*, *Comamonas denitrificans* and *Comamonas nitrativorans*.

Phylogeny

Phylogenetically, the genus *Comamonas* belongs to the Comamonadaceae lineage in the β-subclass of the Proteobacteria together with other genera including *Acidovorax*, *Brachymonas*, *Hydrogenophaga*, *Polaromonas*, *Rhodoferax*, *Variovorax*, *Xylophilus* and various species inappropriately assigned to the genus *Aquaspirillum*. This position was first elucidated by DNA:rRNA hybridizations (De Vos et al., 1985; Willems et al., 1991) and later by 16S rDNA sequence analysis (Wen et al., 1999). A dendrogram based on 16S rDNA sequences showing the positions of the four *Comamonas* species that presently comprise the genus is given in Fig. 1. Whereas all *Comamonas* species are grouped together, the former *Comamonas acidovorans* is further removed and consequently, and in view of additional differences, was transferred to a new genus, *Delftia*, as *Delftia acidovorans* (Wen et al., 1999). None of the other members of the Comamonadaceae appears especially closely related to *Comamonas*, with all genera having approximately 92–94% 16S rDNA similarity with *Comamonas*.

Taxonomy

Before its revival in 1985 (De Vos et al., 1985), the taxonomic position of the *Comamonas* strains had been obscure because of incomplete descriptions and lack of original cultures for comparison. The genus has had a rather turbulent nomenclatural history (Table 1).

The name *Comamonas* was proposed in 1962 to replace the name *Lophomonas* which appeared to be a later homonym of a protozoan taxon (Davis and Park, 1962). The genus *Lophomonas* had earlier been created for a group of Gram-negative rod-shaped bacteria which, like the peritrichous genus *Alcaligenes*, attack only few carbohydrates but bear two to four lophotrichous flagella. They are common in the human intestine as well as in water and mud (Galarneault and Leifson, 1956). The monotype strain was *Lophomonas alcaligenes*, and one of its strains was reported to mutate into a stable peritrichously flagellated organism, leading Galarneault and Leifson to decribe *Lophomonas alcaligenes* as identical to the peritrichously flagellated *Vibrio alcaligenes*. This last name had been proposed to replace *Bacillus faecalis alcaligenes* (Lehmann and Neumann, 1927), a species of Gram-negative rods that do not attack carbohydrates and were isolated from human feces (Petruschky, 1896).

When replacing the name *Lophomonas* with *Comamonas*, the former type species *Lophomonas alcaligenes* was considered inappropriate because of differences between the original descriptions of *Vibrio alcaligenes* (syn. *Lophomonas alcaligenes*) and those of the new genus *Comamonas* (Davis and Park, 1962). Therefore *Vibrio percolans*, isolated from the filtrate of a hay infusion, was designated as the new type species "*Comamonas percolans*." *Vibio cyclosites* and *Vibrio neocistes* were also assigned to *Comamonas* but their species allocation was not specified (Davis and Park, 1962).

Comamonas percolans was renamed "*Comamonas terrigena*" by Hugh (1962) because he

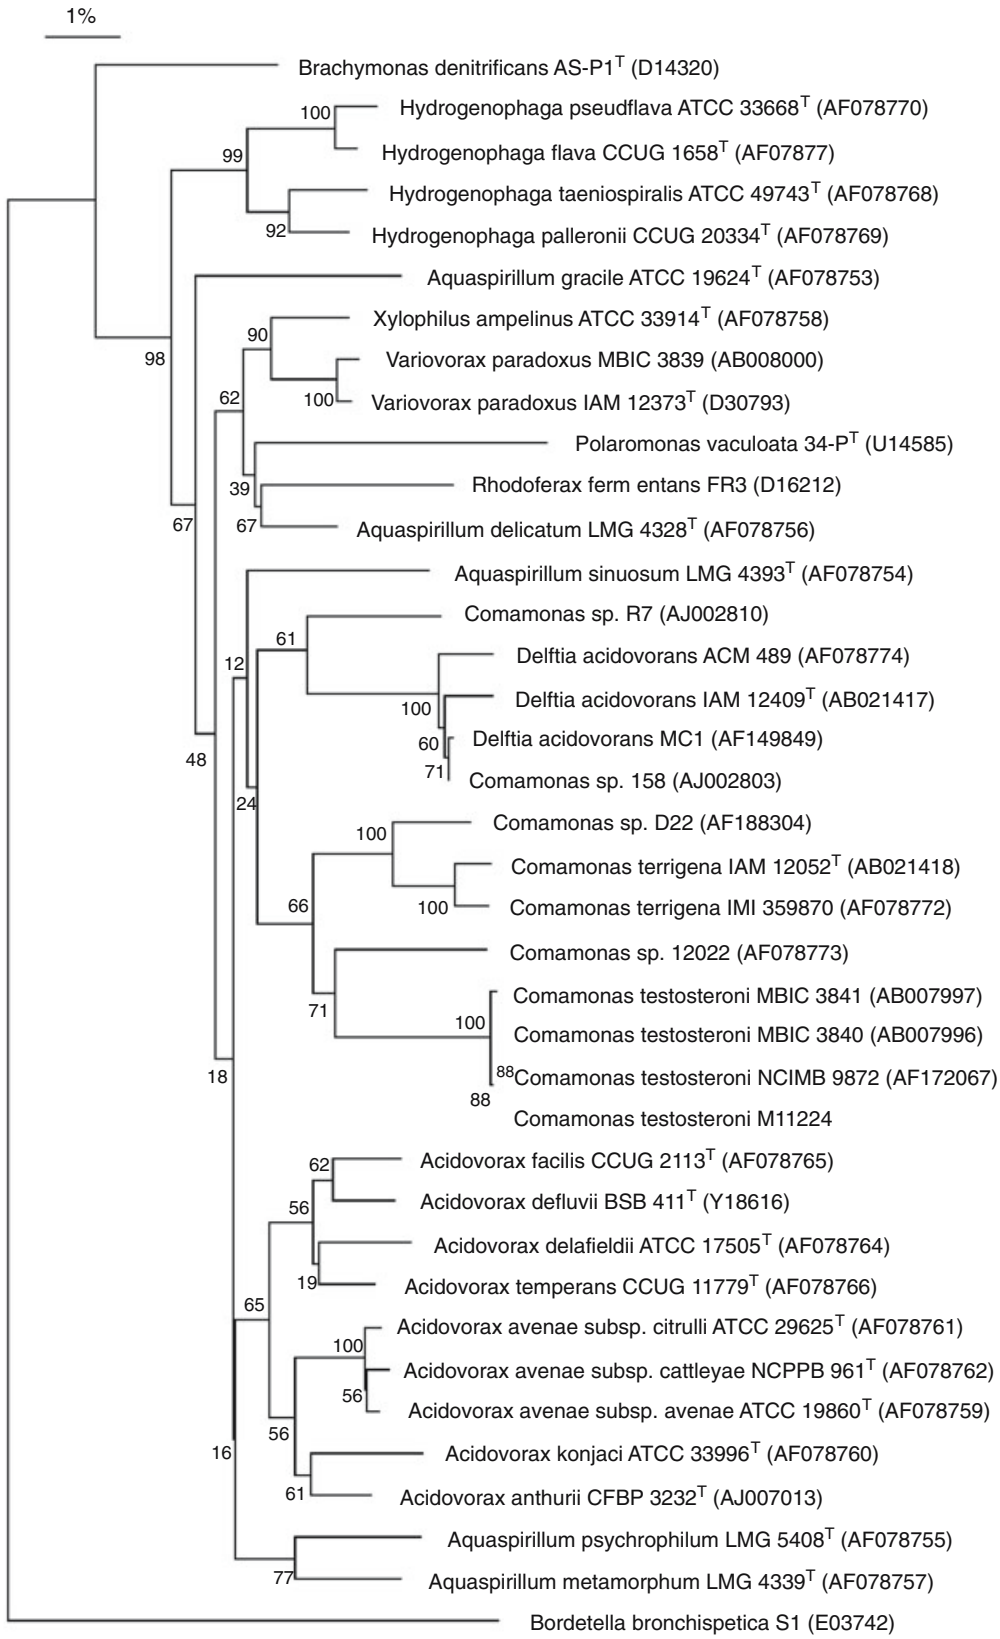

Fig. 1. Dendrogram showing the phylogenetic position of *Comamonas* in the family Comamonadaceae. The neighbor-joining tree was derived from a distance matrix of 16S rDNA sequences. European Molecular Biology Laboratory (EMBL) accession numbers are given at the branch tips and bootstrap values (% of 500 replications) are given at the branching points.

Table 1. The history of *Comamonas*.

Year	Author	Observation
1894	Gunther	*Vibrio terrigenus* is isolated from soil
1896	Petruschky	*Bacillus faecalis alcaligenes* is isolated from human stools
1923	Mudd and Warren	*Vibrio percolans* is isolated from the filtrate of a hay infusion
1926	Den Dooren de Jong	*Pseudomonas acidovorans* sp. nov. is isolated from soil
1927	Lehmann and Neumann	*Bacillus faecalis alcaligenes* is replaced by *Vibrio alcaligenes*
1928	Gray and Thornton	*Vibrio cyclosites* sp. nov. and *Vibrio neocistes* sp. nov.
1956	Galarneault and Leifson	*Lophomonas alcaligenes* gen. nov. is synonym of *Vibrio alcaligenes*
1962	Davis and Park	*Lophomonas* is renamed *Comamonas* gen. nov. with type species *Comamonas percolans*. *Vibrio alcaligenes*, *Vibrio cyclosites* and *Vibrio neocistes* are also assigned to *Comamonas*
1962	Hugh	*Comamonas percolans* is renamed *Comamonas terrigena*
1965	Hugh	*Comamonas terrigena* and *Pseudomonas testosteroni* united as *Pseudomonas terrigena*
1974	Nozhevnikova and Zavarzin	*Comamonas compransoris* sp. nov.
1980	Söder	*Comamonas compransoris* is renamed *Pseudomonas compransoris*
1980	Skerman et al.	*Comamonas* and *Lophomonas* not on the *Approved Lists of Bacterial Names*
1985	De Vos et al.	*Comamonas terrigena* is revived
1987	Tamaoka et al.	*Pseudomonas acidovorans* and *Pseudomonas testosteroni* are renamed *Comamonas acidovorans* and *Comamonas testosteroni*
1991	Willems et al.	*Aquaspirillum aquaticum* and clinical group E. Falsen (EF) 10 incorporated into *Comamonas terrigena*
1991	Willems et al.	Family Comamonadaceae is created
1993	Meyer et al.	*Comamonas comparansoris* transferred to *Zavarzinia compransoris* gen. nov.
1999	Wen et al.	*Comamonas acidovorans* transferred to *Delftia acidovorans* gen. nov.
2001	Gumaelius et al.	Description of new species: *Comamonas denitrificans*
2001	Etchebehere et al.	Description of new species: *Comamonas nitrativorans*

considered it to be a later subjective synonym of *Vibrio terrigenus*, an organism isolated from surface soil and motile by means of bipolar tufts of flagella (Gunther, 1894). While the original isolate was no longer available, Hugh (1962) showed that Gunther's description matched that of *Comamonas percolans*. Later, he reported that *Comamonas terrigena* ATCC 8461^T and *Pseudomonas testosteroni* ATCC 11996^T are highly similar and suggested that both species be united as *Pseudomonas terrigena* (Hugh, 1965).

The new species *Comamonas compransoris* was proposed for a facultatively lithotrophic CO- or H_2-oxidizing organism (Nozhevnikova and Zavarzin, 1974). In *Bergey's Manual of Systematic Bacteriology*, it was placed in *Pseudomonas* section V as "*Pseudomonas compransoris*" (Palleroni, 1984). It has since been shown to belong to the α subclass of the Proteobacteria and has been transferred to a new genus as *Zavarzinia compransoris* (Meyer et al., 1993).

Comamonas was not included in the *Approved Lists of Bacterial Names* (Skerman et al., 1980), nor in *Bergey's Manual of Systematic Bacteriology* (Krieg and Holt, 1984).

On the basis of DNA:rRNA hybridization, phenotypic, serological and protein electrophoresis data, the genus *Comamonas* was revived and *Vibrio cyclosites* and *Vibrio neocistes* were included in *Comamonas terrigena*, which was designated a monotype species (De Vos et al., 1985). Using DNA:rRNA hybridizations, it was shown that *Comamonas terrigena* is a member of rRNA superfamily III, now called "the βsubclass of the Proteobacteria," where it belongs to the *Pseudomonas acidovorans* rRNA branch together with *Pseudomonas testosteroni* and several other *Pseudomonas* species (De Vos et al., 1985). Later *Pseudomonas acidovorans* and *Pseudomonas testosteroni* were renamed "*Comamonas acidovorans*" and "*Comamonas testosteroni*," respectively, on the basis of phenotypic, chemotaxonomic and DNA homology data (Tamaoka et al., 1987).

In a polyphasic study of the genus *Comamonas*, five genotypic subgroups were found on the basis of DNA:rRNA and DNA:DNA hybridizations, immunotyping and protein gel electrophoresis. Three of these subgroups corresponded to the three species (*C. terrigena*, *C. testosteroni* and *C. acidovorans*, now *Delftia*), whereas the fourth subgroup contained *Aquaspirillum aquaticum*, a freshwater spirillum, and clinical isolates of E. Falsen (EF) group 10 and the fifth subgroup contained other EF group 10 strains and misnamed *Pseudomonas alcaligenes* and *Pseudomonas pseudoalcaligenes* subsp. *pseudoalcaligenes* strains. Phenotypic analysis, however, revealed three large phena, corresponding to the three named species, with the phenon of *Comamonas terrigena* also comprising the strains of the fourth and fifth genotypic subgroups. Therefore these

latter two subgroups were included in *Comamonas terrigena* together with the type strain of *Aquaspirillum aquaticum* (Willems et al., 1991).

Later, as conclusion from a 16S rDNA phylogenetic study of the family Comamonadaceae, *Comamonas acidovorans* was removed from *Comamonas* and transferred to a new genus as *Delftia acidovorans* (Wen et al., 1999).

Finally, denitrifying members of the genus have been isolated from activated sludge in South America and Europe and were nearly simultaneously described as *Comamonas nitrativorans* (Etchebehere et al., 2001) and *Comamonas denitrificans* (Gumaelius et al., 2001), respectively. The close phylogenetic relationship (more than 97% rDNA sequence similarity) of both species certainly supports the need for a more detailed taxonomic study including DNA relatedness. Furthermore, the phenotypic data as reported for the two species do not allow a clear phenotypic differentiation (see below).

Habitat

Comamonas commonly occurs in soil, mud and water, natural as well as polluted environments, various clinical samples, the hospital environment, and horse or rabbit blood (Willems et al., 1991). *Comamonas testosteroni* has also been reported in bulk tank milk (Jayarao and Wang, 1999), metal working fluids (Laitinen et al., 1999), and activated sludge (Boon et al., 2000). *Comamonas denitrificans* (Gumaelius et al., 2001) and *Comamonas nitrativorans* (Etchebehere et al., 2001) have so far only been reported once as a member of the microbial denitrifying component in activated sludge. Clinically isolated *Comamonas* strains are regarded as rare opportunistic pathogens (Gilardi, 1985).

Isolation

No specific selective isolation procedures yielding only *Comamonas* isolates have been described, but *Comamonas* strains can generally be isolated from water by plating on nutrient agar. The original *C. terrigena* type strain was isolated on a medium of hay infusion filtrate (Mudd and Warren, 1923). The capacity of *Comamonas* strains to degrade particular aromatic compounds, hydrocarbons and higher dicarboxylic acids can be exploited for selective enrichment by using these compounds as sole carbon source and nitrogen (in the case of nitrogen-containing aromatic compounds) source in a mineral medium. For some strains of *C. terrigena*, methionine and nicotinamide act as growth factors and should be added to mineral media (Tamaoka et al., 1987). Compounds used to isolate or enrich for *Comamonas* strains include phenol and *m*-cresol (Gray and Thornton, 1928), abietic and dehydroabietic acid (Morgan and Wyndham, 1996), and poly-3-hydroxybutyrate (Jendrossek et al., 1993). *Comamonas testosteroni* strains have been isolated using the following compounds: testosterone (Talalay et al., 1952), imidazolyl-propionate and imidazolyl-lactate (Coote and Hassal, 1973), *p*-cresol (Dagley and Patel, 1957), fumarate, bromosuccinate, anthranilate, kynurenate and poly-3-hydroxybutyrate (Stanier et al., 1966), naphthalene (García-Valdés et al., 1988), phenanthrene (Goyal and Zylstra, 1996), chloro- and methyl-phenol (Hollender et al., 1997), polychlorinated biphenyls (Joshi and Walia, 1995), nitrophenols and nitrobenzene (Zhao and Ward, 1999), and 3-chloroaniline (Boon et al., 2000). *Comamonas testosteroni* strains have also been isolated by selecting for cadmium resistance (Kanazawa and Mori, 1996).

Furthermore, *Comamonas* members were also isolated from the clinical environment (Gilardi, 1971; Gilardi, 1985; Ben-Tovim et al., 1974; De Vos et al., 1985; Willems et al., 1991). Sources include blood, pus, urine, pharyngeal mucosae, kidneys, feces, burst appendix, intravenous tubing, and urinary catheters. The isolation procedures from such clinical samples are those generally used for the isolation of Gram-negative glucose-nonfermenters. They include the use of a blood agar medium such as trypticase soy agar (TSA) plus defibrinated blood and a selective enteric medium such as MacConkey agar. The commonly used incubation regime for primary isolation media of 24 h at 35°C should be extended with 24 h at 30°C to permit growth of glucose-nonfermenters that grow slowly at 35°C and may be masked by other bacteria (Rubin et al., 1985).

Identification

Comamonas cells are straight to slightly curved rods, 0.5–2 by 1–6 μm. They are motile by means of polar or bipolar tufts of flagella. On nutrient agar, colonies of *C. terrigena* and *C. testosteroni* are round with a smooth to wavy margin, convex, smooth to granular, and nonpigmented. After three days at 28°C, colony diameters of 0.4–3 mm are attained. Colonies of *C. nitrativorans* are reported as cream-colored on TSA (Etchebehere et al., 2001), while those of *C. denitrificans* are described as yellow-white on nutrient agar by Gumaelius et al. (2001). Some *Comamonas* strains may produce a brown diffusible pigment.

Reliable and relatively fast identification at genus level is possible by determining the 16S

rDNA sequence of a strain thought to belong to *Comamonas*, since sequences from reference strains are available for comparison. An oligonucleotide probe targeting the 16S rRNA has been used to identify strains of *Comamonas*, then still including *Comamonas acidovorans* (Amann et al., 1996), but not the two newest species. Amplified 16S rDNA restriction analysis using two restriction enzymes permits differentiation of the different genospecies (Vaneechoutte et al., 1992). It will be necessary to include at least the type strains of all species in a DNA fingerprint study to verify the identification level of these techniques.

Identification is also possible using polyacrylamide gel electrophoresis of cellular proteins and immunofusion (De Vos et al., 1985; Willems et al., 1991), zymogram and fatty acid analyses (Tamaoka et al., 1987), and DNA:DNA hybridizations (Tamaoka et al., 1987; Willems et al., 1991).

Phenotypic identification on its own can be more complicated because many bacterial taxa share general phenotypic properties with *Comamonas*. The taxa to be compared with *Comamonas* will be determined largely by the isolation source (e.g., clinical or environmental) of the strains.

Comamonas strains from the clinical environment will have to be compared with other Gram-negative taxa, such as Enterobacteriaceae, some *Pseudomonas* species, and *Stenotrophomonas maltophilia*. Enterobacteriaceae are easily recognized by their fermentative carbohydrate metabolism and negative oxidase reaction, but differentiation from *Pseudomonas* species is more complex. The following characters were proposed as minimal requirements for the identification of clinically isolated *Comamonas* strains: motility by means of bipolar tufts of at least three flagella; no acid produced from glucose; acid produced from fructose and mannitol by *C. acidovorans*, but not by *C. testosteroni*; indophenoloxidase positive; no H_2S production in Kligler iron agar; and accumulation of poly-3-hydroxybutyrate (Gilardi, 1985). In this scheme, differentiation from *Pseudomonas alcaligenes* and *Pseudomonas pseudoalcaligenes* subsp. *pseudoalcaligenes*, species that are easily confused with *Comamonas* (Pickett and Greenwood, 1986), is based only on a different flagellation (less than three polar flagella in the *Pseudomonas* species). The following additional tests can be used: growth on L-arginine and diaminobutane (regarded as absent in *Comamonas*, present in both *Pseudomonas* species) and growth on adipate, pimelate, suberate, azelate, and sebacate (present in *Comamonas*, but absent in both *Pseudomonas* species). Some of these characters are present in at least one of the denitrifying *Comamonas* species (e.g., growth on L-arginine in *C. denitrificans*) or were not reported for them.

Comamonas strains from soil and water have to be differentiated from a larger variety of taxa. Table 2 presents features for the differentiation of *Comamonas* from most other Gram-negative taxa that may be isolated from soil and water. It

Table 2. Differentiating phenotypic features between *Comamonas* and other Gram-negative taxa occurring in soil and water.

Taxon	Not present in *Comamonas*	Present only in *Comamonas*
Vibrionaceae	Fermentative carbohydrate metabolism	
Enterobacteriaceae	Fermentative carbohydrate metabolism	Oxidase
Delftia	Growth on D-fructose and D-mannitol	
Hydrogenophaga and *Flavobacterium*	Insoluble yellow pigment	
Acidovorax	Polar monotrichous flagellation, growth on D-glucose	Bipolar tufts of flagella
Brachymonas	Nonmotile coccobacilli, denitrification	
Stenotrophomonas		Poly-3-hydroxybutyrate inclusions
Rhizobium and *Agrobacterium*	Exopolysaccharide production on carbohydrate-containing media, symbiotic nitrogen-fixation with legumes, or plant tumor induction	
Rhodospirillaceae	Facultatively photo- or chemi-autotrophic growth, photosynthetic pigments (brown-red to purple or green)	
Pseudomonas	Use of D-glucose as sole carbon source	
Alcaligenes	Peritrichous flagellation	
Aquaspirillum	Helical cell shape	
Acinetobacter		Oxidase
Sphaerotilus	Cells forming long chains, sheet formation	
Xanthobacter	Insoluble yellow pigment, microaerophilic, and nitrogen fixation	
Azospirillum	Microaerophilic, nitrogen fixation

can be added here that the presence of hydroxy putrescine is characteristic for the genera of the β-Proteobacteria. Table 3 gives features for the differentiation of *Comamonas* species.

Cultivation

Comamonas strains can be grown on nutrient agar and many other commonly used media such as tryptic soy agar and Columbia agar with or without blood. They are able to use many organic acids and amino acids, but few sugars (De Vos et al., 1985). They can degrade a variety of complex aromatic compounds, steroids and many man-made complex organic compounds. Optimal growth temperature is 30°C.

Preservation

Comamonas cultures can be maintained on nutrient agar slants at 4°C for up to 2 months. Lyophilization or storing in liquid nitrogen can be used for long-term preservation of strains on the condition that cryoprotectants are added. Generally, the use of standard procedures is recommended.

Physiology

Comamonas strains have an aerobic respiratory type of metabolism. Most strains of *C. terrigena* and *C. testosteroni* are capable of nitrate reduction, but cannot reduce nitrites (Willems et al., 1991), while all strains of *C. nitrativorans* and *C. denitrificans* can reduce nitrate all the way to N_2. Although *Comamonas* strains were identified in a study of denitrifying biofilms at a water treatment plant, they were thought not to be true members of the biofilm community, but to have washed in from previous stages (Lemmer et al., 1997). Other data, however, confirm the denitrification capacity of some members of the genus (Vanbrabant et al., 1993). In particular, it has been shown that *Comamonas* strain SGLY2 is capable of aerobic denitrification and nitrogen production without nitrite building up. This strain has been studied for use in mixed-culture aerated reactors (Patureau et al., 1997).

Comamonas strains are able to degrade a wide variety of aromatic compounds. *Comamonas* strain JS765 has a 1,2-dioxygenase able to break down nitrobenzene to nitrohydrodiol which spontaneously decomposes to catechol and nitrite. Catechol is then broken down via the meta-cleavage pathway, the genes of which have been sequenced (Parales et al., 1997; Genetics). This pathway has been studied in comparison with similar pathways in *Pseudomonas* strains (He and Spain, 1999). *Comamonas testosteroni* strains that degrade polycyclic aromatic compounds such as phenanthrene, naphthalene and anthracene have been described and the genes involved Genetics have been characterized (Goyal and Zylstra, 1996). The mechanism for phenol tolerance was studied in the phenol-degrading *C. tesosteroni* strains P15 and E23 (Yap et al., 1999).

The meta-cleavage pathway is used by *C. testosteroni* for the degradation of 4-chlorophenol and related compounds (Hollender et al., 1997). *Comamonas testosteroni* can degrade 4-toluene sulfonate, which is thought to be taken up by an inducible secondary proton symport system (Locher et al., 1993). The degradation of 4-toluene sulfonate and 4-toluene carboxylate involves oxygenation of the side chain to 4-sulfobenzoate and terephthalate, respectively, which are then oxidized to protocatechuate. Genes involved in these pathways have been sequenced and characterized (Junker et al., 1997b; Genetics). Terephthalate is broken down by a terephthalate dioxygenase system to (1R, 2S)-dihydroxy-3,5-cyclohexadiene-1,4-dicarboxylic acid which is further degraded to protocatechuate by (1R,2S)-dihydroxy-1,4-dicarboxy-3,5-cyclohexadiene dehydrogenase (Oppenberg et al., 1995). The dioxygenase system is a Rieske [2Fe-2S] protein with two subunits α and β which are thought to form an $\alpha_2\beta_2$ structure (Schlaefi et al., 1994). The sulfonate and sulfate ester degradation as a source of sulfur for growth of Gram-negative bacteria has recently been reviewed (Kertesz, 2000).

Comamonas testosteroni I2 was shown to degrade recalcitrant components such as aniline and chloroaniline (Boon et al., 2001). Both components are among the most widely produced industrial amines commonly used for the production of polyurethanes, rubber, azo dyes, drugs, pesticides, etc. The presence of these toxic amines in natural environments is strictly regulated by the environmental protection agencies of the European Union (EU) and the United States.

Testosterone can be used as sole carbon source by *C. testosteroni* and induces the expression of enzymes involved in catabolism of steroids and aromatic hydrocarbons and the repression of at least one amino acid degrading enzyme. It was suggested that steroids may play a regulatory role in the synthesis of catabolic enzymes during adaptive growth (Moebus et al., 1997). Several of the enzymes involved in the conversion and break down of steroids have been studied and their genes sequenced (Genetics). The structure and function of δ^5-3-ketosteroid isomerase and 3-oxo-δ^5-steroid isomerase, which catalyze the the conversion of δ^5- to δ^4-3-ketosteroids by intramolecular proton transfer, have been studied (Brothers et al., 1995; Zao et al., 1996, 1997). A bile acid 3-α-sulfate sulfohydrolase of *C. testosteroni* was purified and characterized (Tazuke et al., 1994).

Comamonas strains enriched from wastewater from an aerated stabilization basin of a bleached kraft pulp mill were reported to degrade terpenes such as abietane and pimarane-type resin acids (Morgan and Wyndham, 1996).

Some *Comamonas* strains are able to degrade poly-3-hydroxybutyrate using an extracellular poly-3-hydroxybutyrate depolymerase, which can also hydrolyze poly(3-hydroxybutyrate-co-3-hydroxyvalerate) and poly-3-hydroxyvalerate. The enzyme differs from other poly-3-hydroxybutyrate depolymerases in that it is insensitive to phenylmethylsulfonyl fluoride and hydrolyzes poly-3-hydroxybutyrate to 3-hydroxybutyrate monomers (Jendrossek et al., 1993). The encoding gene of a *Comamonas* sp. strain was cloned and partly sequenced, and the resulting partial protein was analyzed (Jendrossek et al., 1995). A very similar sequence was obtained for *C. testosteroni* strain YM1004 (Shinomiya et al., 1997). *Comamonas* sp. strain P37C, isolated from compost, was able to degrade a range of poly-3-hydroxyalkanoates (Quinteros et al., 1999).

The enzymes involved in the first steps of quinoline and 3-methyl quinoline degradation by *C. testosteroni* strain 63, quinoline 2-oxidoreductase and 2-oxo-1,2-dihydroquinoline 5,6-dioxygenase, have been characterized. Quinoline 2-oxidoreductase is a molybdo-iron flavoprotein and 2-oxo-1,2-dihydroquinoline 5,6-dioxygenase is a single component protein (Schach et al., 1995).

Comamonas testosteroni produces 5-aminolevulinic acid, a precursor to tetrapyrroles, from aminoacylated tRNA-Glu via a two-step pathway involving glutamyl-tRNA reductase and glutamine-1-semialdehyde-2,1-aminomutase (Hungerer et al., 1995).

The biosynthesis of aromatic amino acids via several pathways has been extensively studied among pseudomonad bacteria. In *C. testosteroni* prephenate dehydrogenase and arogenate dehydrogenase are reactive with either nicotinamide adenine dinucleotide (NAD) or nicotinamide adenine dinucleotide phosphate (NADP). No arogenate dehydratase activity is present; prephenate dehydratase is present and its activity is stimulated by L-tyrosine (Byng et al., 1983).

Genetics

The genes of *C. testosteroni* involved in the degradation of naphthalene and phenanthrene have been cloned and characterized. At least two different sets of phenanthrene degradation genes may be present among different *Comamonas testosteroni* strains. They are different from the naphthalene degradation genes (*nha*) of *Pseudomonas putida* (Goyal and Zylstra, 1996).

The gene *phtD* for 4,5-dihydroxyphthalate decarboxylase, an enzyme involved in phthalate metabolism in *C. testosteroni*, has been identified and sequenced. The deduced amino acid sequence shows similarity to the *pth5* genes of *P.*

putida, and the sequence upstream of *pthD* shows a high similarity to *pth1* in *P. putida*, where it is thought to be a positive regulator of the other *pth* genes. These findings suggest a common origin for the genes involved in the phthalate metabolism (Lee et al., 1994).

The *bphD* gene of *C. testosteroni* strain B-356, encoding for 2-hydroxy-6-oxo (phenyl/chlorophenyl) hexa-2,4-dienoic acid hydrolase, was sequenced, and the gene product has a mechanism of action similar to that of classical lipases and hydrolases (Ahmad et al., 1995). In the same strain, biphenyl/chlorobiphenyl dioxygenase, the enzyme system involved in the first step of the degradation of biphenyl or chlorobiphenyl compounds, was characterized. The genes for the three components of this enzyme system have been sequenced: *bphA* and *bphE* encode the two subunits of a terminal Fe-S oxygenase, *bphF* encodes a ferredoxin, and *bphG* encodes a ferredoxin reductase and is not located near the *bphAEF* genes (Sylvestre et al., 1996b). Many of these enzymes have been characterized (Hurtubise et al., 1995; Hurtubise et al., 1996) and some have been used to produce enzyme chimeras by combination with oxygenase components from other bacteria (Chebrou et al., 1999). Genes for subsequent degradation steps have also been characterized: *bphB* encodes 2,3-dihydro-2,3-dihydroxybiphenyl dehydrogenase (Sylvestre et al., 1996a) and *bphC* encodes 2,3-dihydroxybiphenyl-1,2-dioxygenase which catalyzes meta-1,2 fission of the aromatic ring (Bergeron et al., 1994). Finally, it has been demonstrated (Hein et al., 1998) that in this strain two meta-cleavage dioxygenases coexist with different degrees of sensitivity towards intermediates of the biphenyl catabolic pathway and suggesting a complex regulation system.

Genes involved in the degradation of catechol via the meta-cleavage pathway have been sequenced and amino acid sequences deduced for strain *Comamonas* sp. JS765: *cdoE* encodes catechol 2,3-dioxygenase, *cdoT* encodes a ferredoxin, and *cdoR* is a regulatory gene (Parales et al., 1997).

A gene cluster encoding for the degradation of 3-(3-hydroxyphenyl)-propionate from *C. testosteroni* strain TA441 was cloned and sequenced. It contains a regulatory gene, *mhpR*, and the following six genes for catabolic enzymes: *mhpA* for a flavin-type hydroxylase, *mhpB* for an extradiol dioxygenase, *mhpD* for 2-keto-4-pentenoate hydratase, *mhpF* for an acylating acetaldehyde dehydrogenase, *mhpE* for 4-hydroxy-2-ketovalerate aldolase, and *mhpC* for a meta-cleavage hydrolase (Arai et al., 1999b). The same research group (Arai et al., 2000) studied the arrangement and the regulation of the meta pathway in the breakdown of phenol.

The genes involved in the degradation of 4-toluene sulfonate and 4-toluene carboxylate of *C. testosteroni* have been extensively studied. The first step of oxygenation of the side chain to 4-sulfobenzoate and terephthalate, respectively, requires three enzymes: a 4-toluenesulfonate methyl-monooxygenase system consisting of a reductase B and oxygenase M encoded by the *tsaBM* genes, a 4-sulfobenzyl alcohol dehydrogenase encoded by *tsaC* and a 4-sulfobenzaldehyde encoded by *tsaD*. These genes are coexpressed under the regulation of the product of *tsaR*. Some of the enzymes involved have been purified and partially characterized. The tsaMB oxygenase system is a class IA mononuclear iron oxidase with tsaM having a Rieske [2Fe-2S] center, and tsaC is a short-chain zinc-dependent dehydrogenase (Junker et al., 1996). The conversion of 4-sulfobenzoate to protocatechuate is catalyzed by a 4-sulfobenzate-3,4-dioxygenase system consisting of a reductase C and an oxygenase A, again with a Rieske [2Fe-2S] center, encoded by the genes *psbAC* (Junker et al., 1996). The genes *tsaMBCD*, *tsaR*, and *psbAC* are located on conjugative plasmids in some *C. testosteroni* strains (Junker and Cook, 1997a). Terephthalate is also broken down to protocatechuate, but genes involved have not yet been characterized. Protocatechuate is broken down via a meta-cleavage pathway by enzymes thought to be encoded on the chromosome (Junker and Cook, 1997a).

The gene cluster encoding a phenol hydroxylase in the phenol-degrading *C. testosteroni* strain R5 (*phcKLMNOP*) and the regulatory gene *phcR* have been cloned and expressed in *Pseudomonas aeruginosa*, conferring the use of phenol as sole carbon source on this bacterium (Teramoto et al., 1999). A second gene cluster which can confer the ability to use phenol (*aphKLMNOPQB* and the corresponding regulatory genes *aphR* and *aphS*) was studied in *C. testosteroni* strain TA441 (Arai et al., 1999a).

In *C. testosteroni*, the genes for several enzymes involved in the breakdown of steroid compounds have been studied. The gene for a 3-α-hydroxysteroid dehydrogenase has been sequenced and expressed through cloning, and the enzyme was characterized (Abalain et al., 1995; Oppermann and Maser, 1996a). Because of its similarity to ribosomal proteins L10 and L7/12, it was suggested that this enzyme may be formed by fusion of two ribosomal proteins (Baker, 1996). The gene for 3-ketosteroid-δ^4-5-α-dehydrogenase was sequenced and located downstream of a gene for 3-ketosteroid-δ^1-dehydrogenase. Although both enzymes are functionally similar, their genes are probably not derived from a common ancestor (Florin et al., 1996). A 3β/17β hydroxysteroid dehydrogenase

was studied by mutagenic replacement within the active site to identify important residues (Oppermann et al., 1997). The steroid-inducible gene *stdC* of *C. testosteroni* was cloned and sequenced. It was homologous to open reading frames (ORFs) of unknown function in the polyhydroxyalkanoic acid cluster of several other bacteria and is transcribed as a monocistronic mRNA that is abundant in cells grown on steroid carbon sources (Cabrera et al., 1997). Recently, in a model for the regulation of the 3-α-hydroxysteroid hydrogenase/carbonyl reductase (Xiong et al., 2001), it was proposed that the hydrogenase is under the control of two repressor proteins of which the binding to the promotor and the messenger RNA is de-repressed by an inducer such as testosterone.

The gene for an aliphatic nitrilase from *C. testosteroni* was sequenced and overexpressed, and the enzyme was purified and its primary structure determined. A Cys^{163} residue is thought be essential in the active site (Levy-Schil et al., 1995).

Several plasmids have been isolated from or transferred to *Comamonas* strains, and they may contribute to the catabolic versatility of these organisms. *Comamonas testosteroni* strains T-2 and PSB-4 and the type strain were reported to contain plasmids pTSA and pT2T, plasmid pPSB, and no plasmids, respectively (Junker and Cook, 1997a). Plasmid pTSA (85 kb) is a conjugative plasmid of the IncP1 group and carries the genes *tsaMBCD*, *tsaR* and *psbAC*, involved in the degradation of 4-toluene sulfonate to protocatechuate, and two copies of insertion sequence IS*1071*. Plasmid *pPSB* (85 kb) also is a conjugative plasmid; it carries only the *psbAC* gene as well as two copies of IS*1071*. Conjugative experiments with the type strain have suggested that the psb genes are located in a composite transposon (Junker and Cook, 1997a).

Plasmid RP4::Tn*4371* with genes for biphenyl and 4-chlorobiphenyl degradation was transferred from *Enterobacter agglomerans* to indigenous soil bacteria, including *Comamonas* strains, where these catabolic enzymes were successfully expressed (De Rore et al., 1994). Plasmid PR4::Mu3A, carrying chromosomal DNA fragments encoding for the use of biphenyl as a sole carbon source, were transferred to *C. testosteroni* and the enzymes were effectively expressed (Springael et al., 1996). Plasmids pACK5 and pACT72, including a replicon of the cryptic *Acetobacter pasteurianus* plasmid pAC1, were transferred to and successfully expressed in *C. terrigena* (Grones and Turna, 1995). Plasmid pE43 from *Pseudomonas aeruginosa* and plasmid pPC3 from *Arthrobacter globiformis*, carrying genes for dehalogenation of chlorobenzoates, permitted *C. testosteroni* strain VP44 to grow on ortho- or para-biphenyls as sole carbon source (Hrywna et al., 1999).

Plasmid PNB2 (Boon et al., 2001) has been isolated from *Comamonas testosteroni* I2, an aniline- and chloroaniline-degrading strain. So far, the chloroaniline capacity could not be demonstrated on the plasmid by conjugative transformation with a *Ralstonia* strain, in contrast to the aniline capacity. Additional data suggest that oxidative deamination of chlorinated and non-chlorinated aromatics may be completed by a different set of genes (Boon et al., 2001).

Ecology

Comamonas strains have been recovered from sites heavily contaminated with complex organic compounds and heavy metals, and resistance to heavy metals such as cadmium and nickel has been reported (Stoppel and Schlegel, 1995; Kanazawa and Mori, 1996). A strain tentatively identified as *C. testosteroni* was among the strongest chromate-reducing bacteria found in the cooling water of an electricity plant and may therefore be implicated in the blockage of pipes through precipitation of chromium (III) oxide (Cooke et al., 1995). Most of the isolates from a polychlorinated biphenyl (PCB)-polluted site were *Comamonas testosteroni* strains capable of degrading biphenyl and a variety of polychlorinated biphenyls (Joshi and Walia, 1995).

Many *Comamonas* strains from various environments are capable of degrading poly-3-hydroxybutyrate (PHB; Mergaert and Swings, 1996), and the extracellular PHB depolymerase of one strain has been purified and characterized (Jendrossek et al., 1993).

The broad substrate specificity of its 3-α-hydroxysteroid dehydrogenases and its occurrence in the intestinal tract of vertebrates have led to suggestions that *C. testosteroni* and related bacterial strains may contribute to the bioactivation or inactivation of hormones, bile acids and xenobiotics (Oppermann and Maser, 1996a). *Comamonas testosteroni* possesses steroid-inducible hydroxysteroid dehydrogenases and carbonyl reductases which may provide protection against natural and synthetic toxic compounds in soil and the intestinal tract of mammals (Oppermann et al., 1996b).

Pathogenicity

Although many *Comamonas* strains have been isolated from clinical samples and from the hospital environment (Willems et al., 1991), they are regarded as very occasional opportunistic pathogens (Gilardi, 1985), and no evidence of

pathogenic effect on healthy people has been reported.

Applications

Because they can break down a wide variety of complex organic compounds (including carboxylic and dicarboxylic aliphatic or unsaturated carboxylic acids, aromatic compounds, and sterols), *Comamonas* strains contribute to bioremediation processes. *Comamonas testosteroni* has been used for the degradation of 4-toluenesulfonic acid in a continuously operated fixed-bed biofilm reactor (Khlebnikov and Peringer, 1996). Analysis of the bacterial communities in activated sludge revealed the presence of *Comamonas* strains (Kaempfer et al., 1996). *Comamonas terrigena* strain N3H, immobilized in an alginate gel, has been used for the degradation of the anion-active surfactant dihexyl-sulfosuccinate (Huska et al., 1996; Toth et al., 1996; Proksova et al., 1999). *Comamonas* strains JS46 and JS 47 have been studied in mixed and non-mixed culture immobilized cell reactors for the degradation of *m*- and *p*-nitrobenzoate (Goodall et al., 1998b). The experimental data were used for process modeling (Goodall and Peretti, 1998a).

A quinohemoprotein ethanol dehydrogenase, which catalyzes the NAD-independent oxidation of a broad range of alcohols to their aldehydes and on to the carboxylic acid, has been purified from ethanol-grown *C. testosteroni* cells. The enzyme was studied for use in the production of (S)-solketal (2,2-dimethyl-1,3-dioxolane-4-methanol) by enantioselective oxidation of racemic solketal (Geerlof et al., 1994; Machado et al., 1999). The active holoenzyme contains pyrroquinoline-quinone, calcium ions, and heme *c* (De Jong et al., 1995). The encoding gene (*qhedh*) was cloned, sequenced and expressed in *E. coli* (Stoorvogel et al., 1996). The enzyme has been applied in electrodes through immobilization in a redox polymer network (Stigter et al., 1997) and can be used for the enantioselective oxidation of secondary alcohols (Godde et al., 1999).

The capacity of *C. testosteroni* BS1310 (pBS1010) to degrade sulfoaromatic compounds resulted in the design of a Clark-type electrode to measure the *p*-toluene concentration (Makarenko et al., 1999).

The ability of *C. testosteroni* to selectively degrade L-lysine from racemized lysine crystals has been applied in the large-scale production of D-lysine (Takahashi et al., 1997).

Finally, a number of studies point to other potential applications of *Comamonas* strains. *Comamonas testosteroni* strain CMI 2848 had the highest activity for hydroxylating 3-cyanopyridine to 3-cyano-6-hydroxypyridine among 4600 isolates screened in a study contributing to the synthesis of new agricultural chemicals (Yasuda et al., 1995). Because hydroxylated *N*-hetero-aromatic compounds are difficult to produce, the characteristic of a quinoline-oxidoreductase of *C. testosteroni* 63 to mediate the hydroxylation of *N*-hetero-aromatic compounds such as pyridine to hydroxy-substituted pyrimidines may be of pharmaceutical importance (Fetzner, 1999).

CHAPTER 3.2.8

The Genera *Chromobacterium* and *Janthinobacterium*

MONIQUE GILLIS AND JOZEF DE LEY

Purple-pigmented bacteria have been described since the end of the 19th century; they were reported as discoloring a variety of natural materials and occasionally as the causative agent of septicemia in humans and animals. Bacteria producing purple and violet colonies due to the production of a nondiffusible pigment, violacein, were classified in a redefined genus *Chromobacterium* by Buchanan (1918). The structure of violacein, an indole derivative produced via the oxidation of tryptophan, is shown in Fig. 1. It can be easily identified (Johnson and Beer, 1971) spectrophotometrically from the following properties: 1) in ethanolic solution it has an absorption maximum at 579 nm and a minimum at 430 nm; 2) by adding 10% (v/v) H_2SO_4 the solution turns green with an absorption maximum at 700 nm; and 3) when NaOH is added to an ethanolic solution, the solution turns green and afterwards reddish brown. Recently, violacein has also been characterized by nuclear magnetic resonance spectroscopy and mass spectrometry (Riveros et al., 1988). The pigment is only abundantly produced when tryptophan is available in the culture medium.

Although violacein is produced by only a few groups of bacteria, its presence does not necessarily indicate a close relationship between these organisms. An extensive phenotypic study (Sneath, 1956, 1960, 1974) within *Chromobacterium*, as defined by Buchanan (1918), provided evidence of two groups within this genus: a fermentative and mesophilic one (growth at 37°C but not at 4°C) and a nonfermentative and psychrophilic one (growth at 4°C but not at 37°C), for which he proposed two species, *Chromobacterium violaceum* and [*Chromobacterium*] *lividum*, respectively. However, these two species have been reported as being not closely related (Moffet and Colwell, 1968; Sneath, 1974) and since the latter was misnamed, in this chapter its epithet and all other misnamed epithets shall be enclosed in square brackets.

Violacein is not a good taxonomic marker as shown by the fact that not only have nonpigmented *Chromobacterium violaceum* and [*Chromobacterium*] *lividum* strains been isolated, but also since marine, violacein-producing strains were isolated, which were assigned on phenotypic grounds to the genus *Alteromonas* (Gauthier, 1976, 1982). Later, Van Landschoot and De Ley (1983) confirmed that these marine strains were genuine *Alteromonas*.

The relationships between the violacein-producing bacteria classified in *Chromobacterium* (Sneath, 1974) could finally be elucidated by De Ley et al. (1978). DNA-rRNA hybridizations within and between the *violaceum* and the *lividum* taxons and with different other Gram-negative genera demonstrated clearly that these purple-pigmented bacteria represent two tight but separate groups within rRNA superfamily III (see also De Ley's introduction to the Proteobacteria in The Proteobacteria: Ribosomal RNA Cistron Similarities and Bacterial Taxonomy in the second edition) which are less related to each other than to other genera from this rRNA superfamily. In consequence, a new genus *Janthinobacterium* with one species *J. lividum* was created for the *lividum* taxon and the genus name *Chromobacterium* was restricted to the mesophilic, fermentative *violaceum* taxon (De Ley et al., 1978). *Chromobacterium* constitutes a separate rRNA branch on which all *violaceum* strains cluster with a $T_{m(e)}$ of 76.5 to 80°C. *Janthinobacterium* constitutes a separate rRNA subbranch which is closely related to the rRNA subbranch containing [*Pseudomonas*] *rubrisubalbicans* and a yet unnamed group of bacteria isolated from clinical material (see Fig. 6 in The Proteobacteria: Ribosomal RNA Cistron Similarities and Bacterial Taxonomy in the second edition). The *Janthinobacterium*-[*Pseudomonas*] *rubrisubalbicans* rRNA branch is more closely related to the solanacearum rRNA branch than to *Chromobacterium*, emphasizing the deep phylogenetic gap between *Chromobacterium* and *Janthinobacterium*. Cataloging results (Woese et al., 1984) confirm the separate position of both genera in the beta group (Stackebrandt et al., 1988). In this chapter, *Chromobacterium* and *Janthinobacterium* are treated together merely on historical grounds.

Moss et al. 1978 described a new group of violacein-containing, fermentative, psychrophilic, fresh water bacteria and assigned them to a new species *fluviatile* in the genus *Chromobacterium*. It differs from *C. violaceum* by a thin flat, spreading colony type, some other phenotypic features (see below) and % GC values of 50 to 52. Within *C. violaceum* the GC content varies from 65 to 68 mol%, indicating at once that these new organisms cannot be members of *Chromobacterium*. DNA-rRNA hybridizations (Moss and Bryant, 1982) demonstrated that [*Chromobacterium*]* *fluviatile* is not closely related to the *C. violaceum* rRNA cluster. With a $T_{m(e)}$ of 70 to 71°C vs. the *C. violaceum* rRNA probe, they occupy a separate position and are further removed from *C. violaceum* than the latter species is from the Neisseriaceae (Rossau et al., 1989). Comparison of their 16S rRNA sequences corroborates this conclusion (Dewhirst et al., 1989). Therefore, these organisms cannot belong in *Chromobacterium*; they have thus been misnamed and shall not be discussed here further. The differentiation of these three groups of violacein-producing organisms is given in Table 1.

This chapter was taken unchanged from the second edition.

*Since this manuscript was submitted, Logan (1989) proposed a monospecific genus *Iodobacter* to accomodate the [*Chromobacterium*] *fluviatile* group. Their phenotypic results on *Iodobacter* and the "atypical, *Janthinobacterium lividum* strains" are integrated in Table 1.

Chromobacterium

The following description of the genus is based on that of *Chromobacterium violaceum* by Sneath (1974, 1984). The genus *Chromobacterium* consists of Gram-negative, oxidase-positive, catalase-positive rods with rounded ends which are usually motile by both a single polar flagellum and by one to four lateral flagella. The two types of flagella differ in their wave types, staining capacity, and antigenic characteristics. Chromobacteria are facultative anaerobes and produce violet colonies on solid media; a violet ring is formed in liquid media at the surface with a fragile pellicle. Growth is best at 30 to 35°C; the minimum growth temperature is 10 to 15°C and the maximum is 40°C (20% of the strains can grow at 44°C). They are chemoorganotrophs using mainly carbohydrates fermentatively. Nitrate and usually nitrite are reduced, mostly with a variable gas production. They grow on ordinary media and are resistant to benzylpenicillin (10 µg/ml) and to vibriostatic agent 0/129 [2,4-diamino-6,7-diisopropylpteridine (30 µg/disc)]. The GC content of the DNA is 65 to 68 mol%. Other characteristics are as described by Sneath (1984) for *C. violaceum*. The type and sole species is *C. violaceum*. Between representative strains of this species, more than 83% DNA binding was found (De Ley et al., 1978).

C. violaceum is a saprophyte from soil and water and is normally considered as nonpathogenic for humans. Occasionally, however, it is an opportunistic pathogen of extreme virulence for humans and animals (see below).

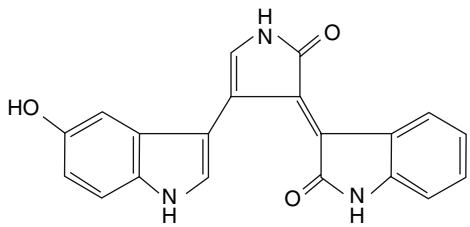

Fig. 1. Structure of violacein.

Habitats

C. violaceum is mainly found in soil and water (Sneath, 1956), where it usually constitutes only a minor component of the total microflora. It is found in temperate but more frequently in tropical and subtropical regions. It was suggested that it can be isolated more frequently from soil than from water (Corpe, 1951; Moss and Ryall, 1981). Its role in the rhizosphere of plants is not clear, although Hussain and Vančura (1970) isolated *C. violaceum* strains from rhizosphere soil of maize and demonstrated that the inoculation of maize

Table 1. Characteristics differentiating the groups of violacein-producing organisms.

[c]O, oxidized.
[d](+) weakly positive.
The phenotypic data are from Sneath (1984), Moss et al. (1978) and Logan (1989). The GC values are from De Ley et al. (1978) and from Moss et al. (1978) for *Iodobacter* [*Chromobacterium*] *fluviatilis*.

seeds with such *C. violaceum* strains significantly increased the yield of dry matter of the plant.

C. violaceum could not be recovered from food products (Koburger and May, 1982).

C. violaceum has been isolated from severe infections in humans and animals; water or soil contaminated with *C. violaceum* is mostly the causal agent. Although a *C. violaceum* infection in humans can result in mild diarrhea with a subsequent recovery (Sneath et al., 1953), it is mostly fatal for both humans and animals. A review of the earlier literature concerning chromobacteriosis was given by Sneath (1960). Later rare fatal cases of infection with *C. violaceum* were reported in different countries, i.e., the United States (Johnson et al., 1971), Vietnam (Ognibene and Thomas, 1970), Cuba (Machin Villafranca et al., 1986), Taiwan (Wu et al., 1986), Argentina (Kaufman et al., 1986), Nigeria (Onile et al., 1984), Brazil (Petrillo et al., 1984), and Australia (Wilkey and McDonald, 1983). The symptoms of the infection can vary considerably but lead mostly to septicemia, causing a rapid death. In the different case reports the symptoms were liver and lung abscesses (Sneath, 1960), meningitis (Shetty et al., 1987), adenitis (Sorensen et al., 1985), periorbital cellulitis (Simo et al., 1984; Feldman et al., 1984), toxemia, and multiple skin abscesses (Petrillo et al., 1984). Only exceptionally nonfatal chromobacterial sepsis has been reported as, i.e., a case of multiple liver abscesses (Suarez et al., 1986) or a systemic chromobacteriosis (Victorica et al., 1974). The disease can be cured by tetracyclines if treated at an early stage (Moss and Ryall, 1981). A recent comparison of the in vitro activity of 25 antimicrobial agents against clinical strains of *C. violaceum* showed that ciprofloxacin, norfloxacin, and perfloxacin are also highly active (Aldridge et al., 1988). For some eye infections, early recognition and aggressive treatment (with tetracycline, chloramphenicol, and cotrinoxazole) may result in a higher cure rate (Feldman et al., 1984).

Infections in animals were also described and studied intensively, i.e., in swine (Laws and Hall, 1964; Liu et al., 1988), Malayan gibbons, a Malayan sun bear (Groves et al., 1969), an Assam macaque (McClure and Chang, 1976), a dog (Gogolewski, 1983), and monkeys (Collins et al., 1985).

Virulence for mice and the pathology of infections appear to be similar for both nonpigmented and pigmented *C. violaceum* strains (Sivendra and Tan, 1977). Virulent *C. violaceum* strains produce an endotoxin which is more reactive than that from avirulent strains and it is suggested that the virulent strains are protected from phagocytic attack by elevated levels of superoxide dismutase and catalase (Miller et al., 1988). Experimental infections with *C. violaceum* or with its endotoxin were studied in mice and pigs (Zwang et al., 1987; Liu et al., 1988).

Enrichment and Isolation

The medium and conditions used to isolate and enumerate *C. violaceum* can strongly influence their recovery (Ryall and Moss, 1975; Koburger and May, 1982). Chromobacteria can grow easily on common laboratory media such as nutrient agar or GYCA (1% glucose, 0.5% yeast extract, 3% $CaCO_3$, and 2% agar in distilled water), and violacein is produced in the presence of oxygen. Sneath (1960) concluded that blood agar base was more suitable for the isolation of small numbers of *C. violaceum* from medical sources, because they can be inhibited by the presence of peroxide which can be present in nutrient agar.

For isolation from soil and water, the common media are not so suitable because chromobacteria represent only a minor part of the present microflora, so that large numbers of other bacteria can overgrow or prevent chromobacteria from growing well and producing violacein, which is an important feature in screening. Therefore, an enrichment procedure or a selective medium is recommended. In most cases, the selective media enrich for *Chromobacterium* as well as for *Janthinobacterium* and [*Chromobacterium*] *fluviatile*. The latter two taxa can be differentiated from *C. violaceum* afterwards by their phenotypic features (see Table 1).

Corpe (1951) described the following simple enrichment technique: "Five grams samples of soil were placed in sterile Petri dishes and soaked with sterile distilled water. Sterile polished or precooked rice grains were sprinkled over the surface of the soil and the plates incubated at 23–25°C for five days. At the end of the incubation period, the rice grains were partially covered with purple membranous growth indicating the presence of *Chromobacterium* sp."

Ryall and Moss (1975) used a selective medium based on quarter strength nutrient agar to count chromobacteria and janthinobacteria in water samples:

Composition of the Medium of Ryall and Moss (1975).

Beef extract (Oxoid)	0.25 g
Yeast extract	0.5 g
Peptone	1.25 g
NaCl	1.25 g
Agar	20 g
Distilled water	1 liter

To the molten agar medium (45°C), filter-sterilized solutions of colistin and sodium deoxycholate were added to give final concentrations of 15 µg/ml and 0.3 mg/ml, respectively. For counting chromobacteria and janthinobacteria in soil samples, cycloheximide was also added to

give a final concentration of 30 µg/ml to prevent overgrowth by fungi.

Composition of the Medium of Keeble and Cross (1977).

An improved selective medium (Keeble and Cross, 1977) is based on Bennett's agar:

Yeast extract (Difco)	1 g
Beef extract (Oxoid)	1 g
Bacto-casitone (Difco)	2 g
Glucose	10 g
Agar (Lab. M no. 2)	18 g
Distilled water	1 liter

To the molten agar medium were added filter-sterilized solutions of neomycin hydrochloride, cycloheximide, and nystatin to give a final concentration of 50 µg/ml of each. This medium is described as improving the pigmentation.

After comparing several media, Koburger and May (1982) reported that Bennett's agar was best for the isolation of both *C. violaceum* and *Janthinobacterium lividum* when incubated at 25°C but that at 35°C *Aeromonas* membrane agar gave the highest recoveries of *C. violaceum*. *Aeromonas* membrane agar (Rippey and Cabelli, 1979) is prepared as follows:

Tryptose	0.5 g
Trehalose	0.5 g
Yeast extract	0.2 g
NaCl	0.3 g
KCl	0.2 g
$MgSO_4 \cdot 7H_2O$	0.02 g
$FeCl_3 \cdot 6H_2O$	0.01 g
Bromothymol blue	0.004 g
Deionized water	100 ml

The ingredients are dissolved at room temperature, the pH is adjusted to 8.0 with 10 N NaOH, 1.5 g agar is added, and the mixture is autoclaved at 121°C for 15 min. After the addition of 1.0 ml ethanol, the mixture is cooled to 50°C, and 2 mg ampicillin and 10 mg desoxycholate are added. It is recommended that the poured plates be stored in the dark at 4°C and used within 6 weeks.

For inoculation, 0.1-ml samples are pipetted onto the surface and spread. They are allowed to dry for 30 min and incubated at 25 and 35°C for 7 and 5 days, respectively. All purple colonies developing on the plate were isolated and identified. Koburger and May (1982) suggested that the failure in other studies (Ryall and Moss, 1975; Keeble and Cross, 1977) to recover *C. violaceum* from soil and water and their own failure to isolate it from a limited number of food products can be related to the temperature sensitivity of these organisms. *C. violaceum* dies rapidly at 4°C.

Chromobacterium can also be isolated on a citrate-ammonium salts medium (Moss and Ryall, 1981) as described for *Janthinobacterium* further in this chapter.

Preservation of Strains The organisms can survive for several years in dilute peptone water (0.1% peptone) at room temperature. On GYCA or nutrient agar slants they can be kept for some months. Lyophilization and L-drying can be used to preserve them for longer periods. Freezing in nutrient broth containing 15% glycerol with storing at –80°C or in liquid N_2 is also recommended.

Identification

When definitely pigmented, *Chromobacterium* has only to be differentiated from other violacein-producing nonmarine strains belonging in the genus *Janthinobacterium* or to [*Chromobacterium*] *fluviatile*. The differentiating features are given in Table 1. *Chromobacterium* differs from *Alteromonas luteoviolacea* in its higher GC content and its ability to use citrate, glucose, fructose, and mannose (Gauthier, 1976, 1982).

Nonpigmented *C. violaceum* strains can be confused with members of *Vibrio* and *Aeromonas*. However, *C. violaceum* differs from *Aeromonas* in its flagellar morphology, its negative reaction for indole and for methyl red, and its production of HCN. Moreover, *C. violaceum* differs from *Vibrio* in its GC content and by a negative response to the lysine and ornithine decarboxylase tests but by a positive reaction in the arginine decarboxylase test. Unlike *C. violaceum*, most strains of the genera *Aeromonas* and *Vibrio* are able to use D-mannitol as a carbon source (Sneath, 1984; Sivendra and Tan, 1977). Singh et al. (1988) used a DNA dot blot technique and a DNA probe from their nonpigmented isolate to differentiate the latter strain from *Aeromonas* and to identify it as *C. violaceum*.

Members of *Chromobacterium* can easily be identified by hybridization with a ^{3}H-labelled 23S rRNA probe from *C. violaceum* NCTC 9757: only members of *C. violaceum* have $T_{m(e)}$ values between 76.5 and 80°C. [*Chromobacterium*] *fluviatile* strains have $T_{m(e)}$ values of 70 to 71°C. Members of *Janthinobacterium* have $T_{m(e)}$ values of 67 to 68°C and can further be identified by hybridization with a ^{3}H-labelled 23S rRNA probe of *J. lividum* NCTC 9796. All other taxa are below 72°C $T_{m(e)}$.

Special Features and Applications

In this part, we call attention to products or metabolic pathways that have been intensively studied in *C. violaceum* and their possible applications.

First of all, the biosynthesis of violacein (Riveros et al., 1988) and the different effects of this pigment have been studied. Violacein has antibiotic activity (DeMoss, 1967; Hoshino et al., 1987) and protects against predation by protozoa. In the older literature (Burbanck, 1942; Singh,

1942, 1945), *C. violaceum* and violacein itself are described as lethal to some ciliated protozoa. Amoebae and flagellates can also be killed by these bacteria (Singh, 1942). Later Groscop and Brent (1964) showed that violacein is toxic to soil amoebae while *C. violaceum* is toxic to *Vorticella microstoma* (Curds and Vandyke, 1966). Violacein has also a trypanocide effect (Riveros et al., 1988).

The production of violacein can be used as a microbiological assay for L-tryptophan (Sebek, 1965).

Apart from violacein, *C. violaceum* produces other antibiotics. Several were isolated and characterized in the last years: aerocyanidin, bearing an isonitrile group and being active against Gram-positive bacteria (Parker et al., 1988); aerocavin, exhibiting in vitro activity against both Gram-negative and Gram-positive bacteria (Singh et al., 1988); 3,6-dihydroxyindoxazene, inhibiting growth of Gram-negative bacteria (Hamada et al., 1983); and factor Y-T0678H (6-hydroxy-3-oxo-1,2-benzisoxazolin), exhibiting a selective activity against Gram-negative bacteria (Imai et al., 1983).

Other important compounds are produced by *C. violaceum*: arphamenines A and B, two specific inhibitors of aminopeptidase B that enhance immune responses (Umezawa et al., 1983).

The production and function of *C. violaceum* aminopeptidases involved in enkephalin hydrolysis was studied by Weiss et al. (1983).

Cooper et al. (1985) studied novel potentiators of β-lactam antibiotics and isolated two new compounds, SQ 28,504 and SQ 28,546, from a *C. violaceum* strain. These novel bacterial metabolites are glycopeptides which act synergistically with β-lactam antibiotics against Gram-negative bacteria.

Earlier β-lactamase, primarily active against cephalosporins, was shown in a *C. violaceum* strain (Farrar and O'Dell, 1976).

C. violaceum has also been used in studies on the production of HCN (Brysk et al., 1969; Niven et al., 1975), of unusual sugar compounds (Stevens et al., 1963), and of extracellular polysaccharides (Corpe, 1964). The tough membranous aspect of some *C. violaceum* colonies is the result of the latter polysaccharides (Corpe, 1964). Their role in the formation of soil aggregates has been suggested (Martin and Richards, 1963).

The Copper-containing phenylalanine monooxygenase (Benkovic et al., 1986; Pember et al., 1987a, 1987b; Fujisawa and Nakata, 1987) and the denitrification processes (Bazylinski et al., 1986) were intensively studied. It was shown that denitrification terminates with the production of N_2O and that NO_2^- reduction to N_2O is not coupled to growth but may serve as a detoxification mechanism.

A *C. violaceum* strain has been isolated that can grow on and use acetonitrile as sole carbon source (K. D. Chapatwale et al., 1988)

Another *C. violaceum* strain solubilized a considerable amount of pure gold after 40 days incubation in nutrient medium because the cyanide produced during growth and stationary phase formed the complex anion $[Au(CN)_2]^-$ with gold (Smith and Hunt, 1985).

Janthinobacterium

The basic description of this genus was given by Sneath in 1984. *Janthinobacterium* consists of Gram-negative rods with rounded ends, sometimes slightly curved. No resting stages are formed. They are usually motile by means of both a single polar flagellum and by one to four lateral flagella. They are strict aerobes. They produce violet colonies on solid media; in nutrient broth a violet ring is formed at the junction of the liquid surface and the container wall. They are resistant to benzylpenicillin (10 μg/ml) and to vibriostatic agent 0/129 (30 μg/disc). The most striking features are: 1) janthinobacteria are aerobic chemoorganotrophs with a strictly respiratory type of metabolism with oxygen as the terminal electron acceptor. 2) They have an optimum growth temperature of 25°C, a maximum growth temperature of 32°C and a minimum growth temperature of 2°C. 3) Only a few strains produce HCN. 4) They can grow rapidly on a medium containing citrate and ammonia as sole carbon and nitrogen source. 5) Nitrate and nitrite are reduced mostly with visible gas production. 6) The GC content is 61 to 67 mol%.

They are soil and water organisms (Moss et al., 1978; Koburger and May, 1982) common in temperate climates. They are sometimes the causative agent of food spoilage. The type and sole species is *J. lividum*. Within this species, percentages of DNA binding of at least 48% were encountered between representative strains (De Ley et al., 1978). The membrane-forming strains, formerly named *C. amethystinum* or *C. membranaceum* and sometimes referred to as "atypical *C. lividum* strains" (Moss and Ryall, 1981), and an unusual strain (ATCC 14487) which preferentially grows at 4°C all belong in *J. lividum* (De Ley et al., 1978; Sneath, 1984). The typical features in which *Janthinobacterium* differs from *Chromobacterium* can be found in Table 1.

Habitats

J. lividum strains have been isolated from water and soil from rivers, creeks, lakes, and springs (Ryall and Moss, 1975; Koburger and May, 1982; Williams and Albright, 1984; Quevedo-

Sarmiento et al., 1986; Gonzalez et al., 1987). They mostly comprise only a small percentage of the total microflora, e.g., a mean of 5% of the total aerobic heterotrophic bacterial population in natural spring water (Quevedo-Sarmiento et al., 1986); a mean of 915 *J. lividum* isolates in 1 g water or soil (Koburger and May, 1982); and less than 1 to 3% of the total population sampled in lake water (Williams and Albright, 1984). According to Moss et al. (1978) they constitute approximately 75% of the total amount of purple-pigmented bacteria isolated from water and soil samples in a lowland river (river Wey in the UK).

They are frequently isolated from a variety of foods, i.e., processed poultry (Cox, 1975); turbot (Mudarris and Austin, 1988); various vegetables (Koburger and May, 1982); and Japanese noodles (Naito et al., 1986a). In turbot gills (Mudarris and Austin, 1988), *J. lividum* represented approximately one-third of the aerobic heterotrophic bacteria (7×10^5/g wet weight of gill tissue). In vegetables, they are present in quantities varying from 130 to over 6000/g (Koburger and May, 1982). Isolates from slaughterhouse effluents (Etherington et al., 1976) were colorless, could grow on meat, and exhibited a high proteolytic activity (Dainty et al., 1978), which is exceptional for members of this genus (Sneath, 1984).

Bettelheim et al. (1968) isolated bacterial strains from germinating seeds of *Psychotria nairobiensis* (Rubiaceae) and *Ardisia crispa* (Myrsinaceae), which they identified then as *C. lividum*, thus now *J. lividum*. By an immunofluorescence technique, Bettelheim et al. (1968) detected these organisms in tissues of several leaf-nodulated Rubiaceae and Myrsinaceae, and presented the hypothesis that some *J. lividum* strains are bacterial endophytes. We shall not review the discussions and disagreements in the literature on this issue (Lersten and Horner, 1976; see also The Genera Chromobacterium and Janthinobacterium in Volume 5) because it was shown that Bettelheim's isolates are not genuine janthinobacteria (De Ley et al., 1978) since they belong in rRNA superfamily IV, where they are a member of the [*Flavobacterium*] *capsulatum* rRNA branch (The Proteobacteria: Ribosomal RNA Cistron Similarities and Bacterial Taxonomy in the second edition).

The role, if any, of *J. lividum* strains in the induction of sporangia in *Phytophthora cinnamomi* has been discussed (Zentmeyer, 1965; Broadbent et al., 1974).

Enrichment and Isolation

As mentioned before, *Janthinobacterium* can be enriched and isolated on the same media as given in detail for *Chromobacterium* above.

According to Moss and Ryall (1981), they grow rapidly and can be selected on a citrate ammonium salts agar medium:

Citric acid	2 g
NaCl	1 g
$MgSO_4 \cdot 7H_2O$	0.2 g
$NH_4H_2PO_4$	1 g
K_2HPO_4	1 g
Ionoagar nr. 2 (Oxoid)	15 g
Distilled water	1 liter

Koburger and May (1982) recovered *J. lividum* from a variety of food samples only on Bennett's agar (see above) at 25°C. On this medium they found higher counts in water and soil samples than on the medium of Ryall and Moss (1975) or on *Aeromonas* membrane agar (Rippey and Cabelli, 1979).

Maximal numbers of *J. lividum* were isolated at 25°C from turbot gills (Mudarris and Austin, 1988) on the following medium (%w/v or v/v):

$CaCl_2$	0.1
Yeast extract	0.1
Beef extraxt	0.5
Casein	0.6
Tryptone	0.2
Agar no. 1	1.5
Aged sea water	75
pH	7.2

Identification

Characteristics differentiating *J. lividum* from *C. violaceum* and *Iodobacter fluviatilis** have been given in Table 1. Differences with *Alteromonas luteoviolacea* have been reported above. Although colorless *J. lividum* strains could be confused with *Pseudomonas fragi* (Moss and Ryall, 1981), Dainty et al. (1978) were able to identify correctly their nonpigmented isolates as *J. lividum*.

Because *J. lividum* strains constitute a narrow rRNA cluster with $T_{m(e)}$ values between 77 and 79°C vs. ^{3}H labelled 23S rRNA from *J. lividum* NCTC 9796, they can easily be identified by hybridizing with this rRNA probe. [*Pseudomonas*] *rubrisubalbicans*, [*Aquaspirillum*] *autotrophicum*, and an as yet unnamed group of strains isolated from clinical material and described by E. Falsen (Culture Collection, University of Göteborg, Sweden) have $T_{m(e)}$ values of approximately 76°C and are the closest neighbors of *J. lividum* (see The Proteobacteria: Ribosomal RNA Cistron Similarities and Bacterial Taxonomy in the second edition). Phenotypically (M. Goor et al. 1986; see The Genus *Aquaspirillum* in Volume 5) it is possible to differentiate *J.*

*The latter species was originally named *Iodobacter fluviatile,* but since *Iodobacter* is masculine, it obviously has to be *Iodobacter fluviatilis.*

Table 2. Characteristics differentiating *Janthinobacterium* from [*Pseudomonas*] *rubrisubalbicans* and similar unnamed clinical isolates.

Character	*Janthinobacterium*	[*Pseudomonas*] *rubrisubalbicans* and unnamed clinical isolates[a]
Urease	–	+
Hydrolysis of esculin	+	–
Growth on D-fucose, 5-keto-gluconate, acetate, caprate, amylamine, and tryptamine	–	+
Growth on L-histidine	+	–

Isolates of Falsen (1989).

lividum from the group formed by [*Pseudomonas*] *rubrisubalbicans* and the unnamed clinical isolates (Table 2) and from [*Aquaspirillum*] *autotrophicum* (see Table 1 in The Genus *Aquaspirillum* in Volume 5).

Results from M. Goor et al. (1986).

Preservation of Strains *J. lividum* strains survive for several years at 4°C in 0.1% peptone or at –80°C in nutrient broth with 15% glycerol as a cryoprotectant. Lyophilization and storage at 4°C is also applied although the viability may be low (Sneath, 1984).

Special Features and Applications

For the different effects of violacein, we refer to the discussion under "*Chromobacterium*" above. The antimicrobial activity of violacein isolated from *J. lividum* has recently been described (Naito et al., 1986b). The location of the pigment was investigated by Lin and Kester (1988), and in broth cultures, both intracellular and extracellular pigment was found. Intracellular pigment is located in the cell membrane. Extracellular pigment is water soluble and shows a blue shift when compared to solvent-extracted pigment. It was suggested that extracellular pigment is possibly non-covalently bound to a small protein.

J. lividum produces 2,5-diketogluconate (Bernaerts and De Ley, 1971) via 2-ketogluconate.

Kwok et al. (1987) described a *J. lividum* strain as a bacterial antagonist inducing suppression of *Rhizoctonia* damping-off in container media amended with composted hardwood tree bark.

Strains from food produce sometimes extracellular metallo-proteinases (Etherington et al., 1976; Dainty et al., 1978) which could play a role in tenderizing meat.

A *J. lividum* strain was used to study the effects of the insecticide acephate on bacterial growth and nutrient uptake (Williams and Albright, 1984).

Acknowledgments. We are indebted to the National Fund for Scientific Research (Belgium) and the Fund for Medical Scientific Research (Belgium) for research and personnel grants.

CHAPTER 3.2.9

The Genera *Phyllobacterium* and *Ochrobactrum*

JEAN SWINGS, BART LAMBERT, KAREL KERSTERS AND BARRY HOLMES

The study of leaf nodulation in several tropical plant families dates back to the beginning of the 20th century. Various genera of bacteria, e.g., *Phyllobacterium*, were thought to be associated with leaf nodules (see below). *Phyllobacterium* was described by Knösel (1962) but the genus only found wide taxonomic recognition with the publication of *Bergey's Manual of Systematic Bacteriology* (Knösel, 1984). DNA-rRNA hybridizations revealed a close relationship between *Phyllobacterium* and bacteria from the Centers for Disease Control (CDC) group Vd within the "alpha" subclass (rRNA superfamily IV) of the proteobacteria together with those throughout of the genera *Brucella*, *Rhizobium*, *Mycoplana*, and *Agrobacterium* (De Ley et al., 1987; Stackebrandt et al., 1988). Holmes et al. 1988 proposed the name *Ochrobactrum anthropi* for CDC group Vd. They also demonstrated that *Phyllobacterium* showed closest phenotypic similarity to *Ochrobactrum anthropi*. In the present chapter, the genera *Phyllobacterium* and *Ochrobactrum* are treated together because of their close phylogenetic relatedness. Nevertheless, the ecological niches from which these bacteria have been isolated are quite different: *Phyllobacterium* strains occur in leaf nodules and in the rhizosphere, whereas *Ochrobactrum* strains have been isolated almost exclusively from human clinical material. In clinical microbiology, *Ochrobactrum*, more recently described as *Achromobacter* group Vd until formally named, was usually treated together with *Achromobacter xylosoxidans* (more recently known as *Alcaligenes xylosoxidans* subsp. *xylosoxidans*) (Gilardi, 1978; Rubin et al., 1985). It has now become apparent that *Ochrobactrum* and *Phyllobacterium* are not related phylogenetically to *Achromobacter xylosoxidans*, which belongs to the *Alcaligenaceae* in the "beta" subclass (rRNA superfamily III) of the proteobacteria (De Ley et al., 1986).

Habitats

The Occurrence of *Phyllobacterium* in Leaf Nodules

Plants of over 400 species of the families Rubiaceae and Myrsinaceae are reported to produce leaf nodules. Short-lived bacterial colonies become established intercellularly and die before full leaf expansion (Lersten and Horner, 1976). Bacterial leaf nodules were defined by Horner and Lersten (1972) as:

Internal cavities in the leaf lamina, open to the exterior by way of stomatal pores only in early stages of nodule development. The bacteria inhabiting such nodules are part of a population maintained by the host plant in the vegetative and floral buds and passed to the succeeding generations through the seeds.

This definition rules out all casual bacteria-plant associations.

Despite more than a century of research on leaf nodulation (for a review, see Lersten and Horner, 1976) it is not yet clear which bacteria are involved and how they participate in the nodulation process. In the past, the bacterial symbionts in the nodules were recognized as belonging to the genera *Chromobacterium*, *Xanthomonas*, *Klebsiella* and *Phyllobacterium* (Horner and Lersten, 1972). Knösel (1962) isolated and described *Phyllobacterium* and stated that it is able to induce characteristic nodules on leaves (Knösel, 1984), basing his conclusions on earlier investigations by Miehe (1911), von Faber (1912), and de Jongh (1938). However, it is not clear whether the bacteria previously studied by these workers are identical to those described by Knösel. There is no proof for the leaf nodulation capacity of *Phyllobacterium*.

The Occurrence of *Phyllobacterium* in the Rhizosphere

Pseudomonas fluorescens and *Phyllobacterium* were found to be the two most frequently occurring bacteria on root surfaces during a large-scale assessment of the rhizobacterial communities of young sugar beet plants (between the second and 10th leaf stage) (Lambert et al., 1990). These bacteria were found in 198 out of 1,100 plants investigated in Belgium and Spain at densities up to 2×10^8 per gram of root. This was the first record of the occurrence of *Phyllobacterium* in the rhizosphere. Extensive analyses of the microflora from the rhizoplane of other crop plants have not revealed the presence of *Phyllobacterium*.

This chapter was taken unchanged from the second edition.

Occurrence of *Ochrobactrum* (CDC group Vd) in Clinical Samples and the Environment

Ochrobactrum anthropi strains have been isolated predominantly from human blood, urogenital tracts, urine, respiratory tracts, ears, and wounds (Tatum et al., 1974; Holmes et al., 1988). Only a few strains were isolated from feces, spinal fluid, eye, hospital apparatus, or the environment (arsenical cattle-dipping fluid, soil, sewage, and from thin-layer Sephadex plates) (Holmes et al., 1988). The clinical significance of *O. anthropi* remains largely unknown; strains of this species are considered to be opportunistic pathogens. One strain has been reported in association with a pancreatic abscess (Appelbaum and Campbell, 1980) and another has been associated with a puncture wound leading to osteochondritis of a foot (Barson et al., 1987).

Isolation

Isolation of *Phyllobacterium* from the Sugar Beet Rhizosphere (Lambert et al., 1990)

> The entire root system of a plant is carefully washed to remove adhering soil, then vigorously shaken for 15 min using a flask shaker in a phosphate buffered saline solution containing 0.025% Tween 20. Serial dilutions of the resulting suspensions are plated on 10% trypticase soy broth plus 2% agar (TSBA). After incubation at 28°C for 2 days, *Phyllobacterium* colonies are beige-colored, large (±5 mm), and convex with an entire edge. They are very mucoid and glistening. Several subcultures are necessary in order to obtain pure isolates. *Phyllobacterium* readily grows on other nonselective media for aerobic, heterotrophic bacteria (nutrient agar, trypticase soy agar, Luria-Bertani agar, etc.).

Isolation of *Phyllobacterium* from Leaf Nodules (Knösel, 1984)

> Washed leaf pieces containing nodules are macerated by rubbing and placed in saline. After shaking, serial dilutions of the suspension are plated onto carrot juice agar containing yeast extract. After incubation at 28°C, a variety of pigmented and nonpigmented colonies develops. Typical colonies are transferred into liquid carrot juice medium which is then used to inoculate the tests used for identification. The cultures should be observed after 24 to 48 h to confirm the presence of star clusters.

Isolation of *Ochrobactrum anthropi* from Clinical Material

> Samples from human blood, urine and urogenital tract, sputum, wound, throat, stool, rectum, and other material are plated on blood agar or on MacConkey agar (Rubin et al., 1985; Holmes et al., 1988). Two colony types were recognized on blood agar at 35°C after 48 h: 1) an extremely mucoid type, 0.1 to 4 mm in diameter, opaque and gray-white, showing beta-hemolysis; and 2) a pinpoint type, opaque and semiglossy, gray or white, showing beta-hemolysis after prolonged incubation (Chester and Cooper, 1979). On MacConkey agar after continued incubation, colonies from 3 to 5 mm diameter were formed, opaque and pink to purple. Half the strains produced colonies with such notably gummy consistency that it was difficult to remove them from the agar surface (Chester and Cooper, 1979). On MacConkey agar, *Ochrobactrum* can be easily overlooked due to the small size of the colonies after overnight incubation (Chester and Cooper, 1979).

Preservation of Cultures

Well-grown cultures may be kept at 4°C for 2 to 3 months on nutrient agar slants in screw-capped bottles. Isolates can be stored freeze-dried or as a suspension in 25% glycerol at –70°C.

Identification

Phyllobacterium and *Ochrobactrum* are both Gram-negative, strictly aerobic bacteria with a respiratory type of metabolism. They show oxidase and catalase activity and both grow on nutrient agar. Indole is not produced. They oxidize glucose and xylose but not lactose (Clark et al., 1984; G. L. Gilardi, personal communication, Lambert et al., 1990). They do not produce extracellular enzymes for the hydrolysis of Tween 80, DNA, gelatin, starch, or casein (Gilardi, 1978). The API 20NE system will identify them as *Achromobacter* sp., which is still a "dumping ground" (Kersters and De Ley, 1984) for various aerobic peritrichously flagellated rods. Recent work on *Phyllobacterium* and *Ochrobactrum* has led to the differentiation scheme given in Table 1. An extensive description of *Phyllobacterium* and *Ochrobactrum* can be found in Lambert et al. (1990) and Holmes et al. (1988), respectively. A comment should be made on the flagellar arrangement of strains of both genera. *Phyllobacterium* and *Ochrobactrum* strains both show 1 to 3 polar, subpolar, or

Table 1. Features that differentiate *Phyllobacterium* and *Ochrobactrum* (CDC group Vd).

Property	*Phyllobacterium*[c]	*Ochrobactrum*[d]

Using API ZYM strips.
15 strains total. From Lambert et al. (1990).
56 strains total. From Holmes et al. (1988).

lateral flagella (Lambert et al., 1990). According to Holmes et al. 1988 and Gilardi (1978) *Ochrobactrum* strains are characterized by peritrichous flagella, but other workers have found only polar, subpolar, or lateral flagella but no definitely peritrichous flagella (Clark et al., 1984; Chester and Cooper, 1979).

An unambigous identification of *Phyllobacterium* or *Ochrobactrum* is possible by application of carbon assimilation tests (API 50CH, 50AO, or 50AA) or various conventional tests (Tatum et al., 1974; Rubin et al., 1985; Holmes et al., 1988; Lambert et al., 1990) or by protein electrophoretic fingerprinting. Variability in Gram reaction, the presence of curved cells with swollen-ends, and the formation of extremely small colonies after overnight incubation, which develop into mucoid colonies upon continued incubation, may lead to incorrect identification as *Corynebacterium* or *Klebsiella* (Chester and Cooper, 1979).

Knösel (1984) used the criterium of nitrate reduction to differentiate *Phyllobacterium myrsinacearum* (+) from *P. rubiacearum* (–). Lambert et al. (1990), however, found that *P. rubiacearum* LMG $1t1^T$ reduced nitrates. Using the API 2ONE system, they found that all *Phyllobacterium* strains showed a slight NO_3^- reduction. These observations cast serious doubt on the usefulness of this criterion for species differentiation within the genus *Phyllobacterium*. All *Ochrobactrum* strains are capable of nitrate reduction (Gilardi, 1978; Clark et al., 1984; Holmes et al., 1988).

Physiological Properties

Cellular fatty acids of *Ochrobactrum anthropi* (Dees and Moss, 1978) as well as antimicrobial susceptibilities have been determined (von Graevenitz, 1985; Gilardi, 1989). Growth of *Phyllobacterium* strains was inhibited by doxycycline, novobiocin, framycetin, and tetracycline (Lambert et al., 1990). The most intriguing question that remains unanswered is whether *Phyllobacterium* has a real symbiotic cyclical relationship with its hosts. Reinfection studies did not allow unambiguous conclusions to be made. It has also been suggested that leaf nodule bacteria produce plant growth hormones, particularly cytokinins, which are necessary for the normal functioning of the plant (Fletcher and Rhodes-Roberts, 1976; reference is not an exact matchRodrigues-Pereira et al., 1972). Other authors claimed that leaf nodule bacteria can fix nitrogen, but this was contested by Van Hove (1976) and Lersten and Horner (1976). The lack of ability to fix nitrogen is also indicated by the absence of the *nif* HDK-like genes (Lambert et al., 1990), which occur in all the classical nitrogen-fixing bacteria.

Phyllobacterium is able to interact with plant tissues, as demonstrated by the tumor induction by Ti-plasmid-carrying *Phyllobacterium* strains on *Kalanchoe* plants (Lambert et al., 1990). Tumor induction involves the attachment of bacterial cell wall sites to plant cell wall sites prior to the induction of T-DNA transfer. The chromosomal genes *chv*A, *chv*B, *exo*C, and *att* are the only ones found to be involved in attachment but could not be detected in *Phyllobacterium* strains, suggesting that other genes are present with similar functions. There are no data indicating that *Phyllobacterium* is pathogenic or deleterious to plants.

A striking feature, common to both *Phyllobacterium* and *Ochrobactrum*, is nutritional versatility, which makes their rapid growth and proliferation possible in rich environments such as the root surface and clinical sites.

A number of *Phyllobacterium* isolates showed antifungal and antibacterial activities (Lambert et al., 1990).

The oxidation of lactose to 3-ketolactose is a unique feature of many *Agrobacterium* strains (Kersters and De Ley, 1984) and is negative for all *Phyllobacterium* and *Ochrobactrum* strains.

Applications

No applications of the genera *Phyllobacterium* or *Ochrobactrum* are yet known. However, the fact that *Phyllobacterium* is a predominant bacterium on the root surface of sugar beet plants, its capacity to "communicate" with plant tissues, and its non-pathogenic status make this bacterium an interesting new candidate for use in plant growth promotion or biological control of soil-borne diseases. Indeed, some of the sugar beet isolates exert a broad-spectrum antifungal activity against major phytopathogenic fungi.

CHAPTER 3.2.10

The Genus *Derxia*

JAN HENDRIK BECKING

In the genus *Derxia* only a single species is recognized, *D. gummosa*. This species was originally described by Jensen et al. (1960) from an isolate obtained from Indian soil, but was later found to be widely distributed in soils of South America (Brazil), Southern Africa, Indonesia, and China, but not in temperate regions.

Although Roy and Sen (1962) described a second species of *Derxia* (*D. indica* sp. nov.) from a sample of partially retted jute plant (*Corchorus olitorius* L.) from Uttar Pradesh, India, they did not present cultural and physiological data showing that their isolate was sufficiently different from *Derxia gummosa* to warrant the designation of a new species.

The genus is named for H. G. Derx (1894–1953), a Dutch microbiologist.

Using rRNA cistron similarity as a criterion for genetic relatedness, De Smedt et al. (1980) found that *D. gummosa* is quite different from species of the genera *Azotobacter*, *Azomonas,* and *Beijerinckia*. From hybridization studies with DNAs from three *D. gummosa* strains using the ^{14}C-labeled rRNAs from a great variety of other organisms, it was quite obvious that the *Derxia* rRNA cistrons most closely resemble those of *Pseudomonas acidovorans*, *P. solanacearum*, *Chromobacterium violaceum*, *Janthinobacterium lividum*, and *Alcaligenes faecalis.* These taxa, together with a few others, constitute the third rRNA superfamily of De Ley (see The Proteobacteria: Ribosomal RNA Cistron Similarities and Bacterial Taxonomy in the second edition). Members of these taxa have in common that they consist of Gram-negative rods, usually 1.0–4.0 µm in length and 0.5–1.0 µm in diameter, do not possess resting stages, have a GC content of the DNA of 57–72 mol%, are chemoheterotrophic, exhibit respiratory (oxidative) metabolism, and occur in soil and water habitats. The third rRNA superfamily of De Ley (De Smedt et al., 1980) is identical with the beta subclass of the Proteobacteria, according to the phylogenetic taxon nomenclature of Stackebrandt et al. 1988.

Based on numerical analysis of a large number of attributes, Thompson and Skerman (1979) showed fusion of their five *Derxia* strains tested with "*Azotomonas*" ("*Azotomonas insolita*" Stapp, 1940, sometimes termed "*Pseudomonas insolita*" [Stapp] Brisou, 1961) at group 1296 in their dendrograms of hierarchical interrelations (see also Krieg and Holt, 1984). This indicates that *Derxia* is not related to the genera *Azotobacter* or *Azomonas* and thus confirms the conclusions of De Smedt et al. (1980).

Habitats

Derxia is primarily a soil organism occurring in tropical soils. There is no plausible explanation for why this organism is exclusively found in tropical environments and is apparently absent from temperate soils. It has not yet been recorded from aquatic habitats, although it is likely that it also occurs there. Such habitats in these regions have, however, not yet been thoroughly investigated using conditions selective for this organism.

Isolation

The original isolate was obtained from a West Bengal (Adisaptagram, India) soil of pH 6.5 by the sieved-soil plate method (see "General Enrichment Procedures" in The Family Azotobacteraceae in the second edition) using plates with a nitrogen-free, mineral mannitol (2%) agar, incubated at room temperature (about 25°C). Yellowish colonies appeared after 5 days around some of the soil particles; these colonies gradually increased in size and finally assumed a rust-brown color. Isolation and further purification were performed by repeated transfer and plating on the same nitrogen-free mannitol agar.

Campêlo and Döbereiner (1970) obtained this organism from Brazilian soils also with the sieved-soil plate method, utilizing a nitrogen-free, mineral starch (2%) medium. This medium was a modification of a medium used by Lipman (1903), supplemented with $NaHCO_3$ (0.1 or 0.01%).

Isolation Medium for *Derxia gummosa* (Campêlo and Döbereiner, 1970; Modified from Lipman, 1903)

Distilled water	1 liter
Starch	20.0 g
K_2HPO_4	0.05 g
KH_2PO_4	0.15 g
$MgSO_4 \cdot 7H_2O$	0.20 g
$CaCl_2$	0.02 g
$NaHCO_3$	0.1 g
$FeCl_3$ (10%, aqueous solution)	1 drop
$Na_2MoO_4 \cdot 2H_2O$	0.002 g
Bromothymol blue (0.5%, ethanol solution)	5 ml
Agar	20.0 g

In a survey of 100 samples of Brazilian soil from the states of São Paulo, Rio de Janeiro,

This chapter was taken unchanged from the second edition.

Pernambuco, and Para, Campelo and Döbereiner (1970) found that 36% of the soils tested were positive for this organism. Soil humidity seems to favor the presence of *Derxia*, since 77% of the flooded soils, 36% of the humid soils, and only 13% of the drier soils tested contained this organism. In a comparative study with agar plates seeded with soil or with root pieces of various plants (mostly Gramineae) of the same locality, *Derxia* appeared more frequently on the plates inoculated with roots (33%) compared to those inoculated with soil (26%). *D. gummosa* was found to be present in soils ranging in pH from 4.5 to 6.5, but was observed to be most frequent in soils of pH 5.1–5.5.

This species was isolated by the author from various soils of Indonesia, China, Brazil, tropical Africa, and South Africa with the sieved-soil plate method using nitrogen-free, mineral, glucose (1–2%) agar (J. H. Becking, unpublished observations).

Derxia strains are relatively acid tolerant and were therefore also isolated by the author from cultures designed to enrich for *Beijerinckia* strains using a liquid, acidic, nitrogen-free, glucose medium. This liquid medium has the following composition:

Enrichment Medium for *Derxia gummosa* (J. H. Becking, unpublished observations)

Distilled water	1 liter
Glucose	20.0 g
KH_2PO_4	1.0 g
$MgSO_4 \cdot 7H_2O$	0.5 g

Adjust to pH 5.0.

The medium is dispensed into petri dishes so as to form a thin layer 2–3 mm deep in order to maintain aerobic conditions. The liquid medium is inoculated with soil particles and incubation is at 25° or 30°C.

In the sieved-soil plate method mentioned for the isolation, soil particles are evenly distributed over the surface of nitrogen-free mineral agar containing mannitol (Jensen et al., 1960), glucose (J. H. Becking, unpublished observations), or starch (Campelo and Döbereiner, 1970). It should be noted that mannitol is not utilized by all *Derxia gummosa* strains. Of the six strains tested by Thompson and Skerman (1979), three did not use mannitol. Moreover, some strains, including the type strain, produced only very scant growth on starch. All strains did, however, utilize glucose as sole source of carbon.

Therefore for general practice of the sieved-soil plate method, the following glucose mineral agar medium is recommended:

Nitrogen-free, Mineral Glucose Agar for the Isolation of *Derxia gummosa* with the Sieved-Soil Plate Method (g/liter of distilled water):

Glucose	20.0
K_2HPO_4	0.8
KH_2PO_4	0.2
$MgSO_4 \cdot 7H_2O$	0.5
$FeCl_3 \cdot 6H_2O$	0.025 (or 0.05)
$Na_2MoO_4 \cdot 2H_2O$	0.005
$CaCl_2$	0.05
Agar	15.0

Adjust to pH 6.9.

On the agar plates seeded with the soil particles, yellowish colonies develop around the soil particles. These colonies eventually become larger and acquire a rust-brown color. Isolates should be further purified by repeated streaking on new agar plates. For agar plates obtained from liquid enrichment cultures, one should look for slimy, yellowish colonies with a rather plicated surface (see Fig. 5).

Cultivation

For routine maintenance, the following nitrogen-free, mineral glucose medium can be used (g/liter of distilled water):

Nitrogen-free, Mineral Glucose Agar Medium

Glucose	10.0 (or 20.0)
K_2HPO_4	0.5
$MgSO_4 \cdot 7H_2O$	0.25 (or 0.2)
NaCl	0.25
$FeSO_4 \cdot 7H_2O$	0.1
$CaCl_2$ or $CaCO_3$	0.1
$Na_2MoO_4 \cdot 2H_2O$	0.005
Agar	15.0

Adjust to pH 6.9.

Jensen et al. (1960) used a nitrogen-free, mineral mannitol agar of the following composition (g/liter of distilled water):

Nitrogen-free, Mineral Mannitol Agar Medium

Mannitol	10.0
K_2HPO_4	0.5
$MgSO_4 \cdot 7H_2O$	0.2
$CaCl_2$	0.1
$CaCO_3$	5.0
$Na_2WO_4 \cdot 2H_2O$	0.0005
$FeCl_3$ and $Na_2MoO_4 \cdot 2H_2O$	trace
Agar	15.0.

The medium recommended by Campelo and Döbereiner (1970) contained starch as carbon source (g/liter of distilled water):

Nitrogen-free, Mineral Starch Agar Medium

Starch	20.0 g
K_2HPO_4	0.05 g
KH_2PO_4	0.15 g
$MgSO_4 \cdot 7H_2O$	0.2 g
$CaCl_2$	0.02 g
$NaHCO_3$	0.1 g
$FeCl_3$ solution (10%, aqueous solution)	1 drop

$Na_2MoO_4 \cdot 2H_2O$	0.002 g
Bromthymol blue solution (0.5%, ethanol solution)	5.0 ml
Agar	20.0.

As already stated before, not all *Derxia gummosa* strains can utilize mannitol as sole source of carbon, while with starch as the carbon source, some strains only produce scant growth.

Preservation of Cultures

The maintenance procedures of *Derxia gummosa* are the same as those described for the genus *Beijerinckia* (see The Genus *Beijerinckia* in Volume 5).

Identification

Derxia can be distinguished from other genera of N_2-fixing bacteria by its very slimy (gummy) growth, both on agar plates and in liquid media, combined with the very pleomorphic appearance of the cells (Figs. 1 to 2, 3, 4) depending on age and type of medium. On agar media *Azotobacter* and *Azomonas* species never produce such slimy colonies as those of *Derxia* (Fig. 5). Confusion with *Beijerinckia* is unlikely, since *Beijerinckia* cells usually show very characteristic cells with only two polar lipoid bodies, whereas *Derxia* cells contain numerous lipoid bodies. Moreover, in contrast to *Beijerinckia* colonies, the colonies of *Derxia* acquire on aging a typical dark rust-brown or mahogany-brown color. In addition, in contrast to *Azotobacter*, *Azomonas* and *Beijerinckia*, *Derxia* cells are catalase negative.

In contrast to the spiral-shaped or vibrioid cells of *Azospirillum* (see The Genera Azospir-

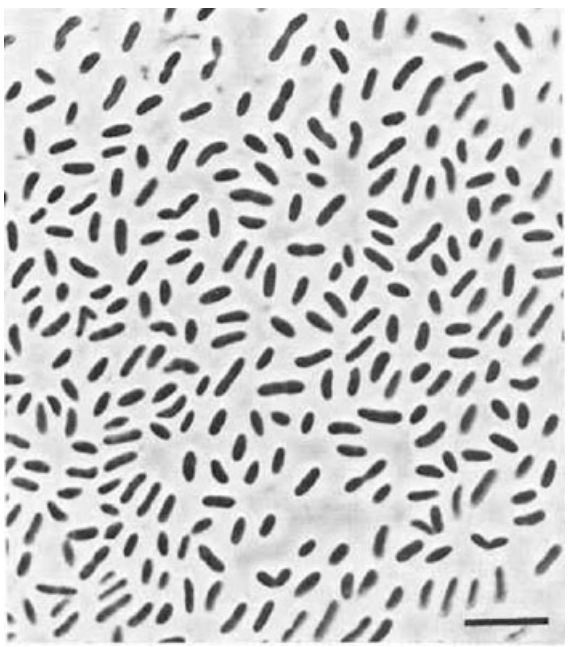

Fig. 1. Seven-day-old cells of *Derxia gummosa* on nitrogen-free agar containing 2% glucose. Phase contrast microscopy. Bar = 10 µm.

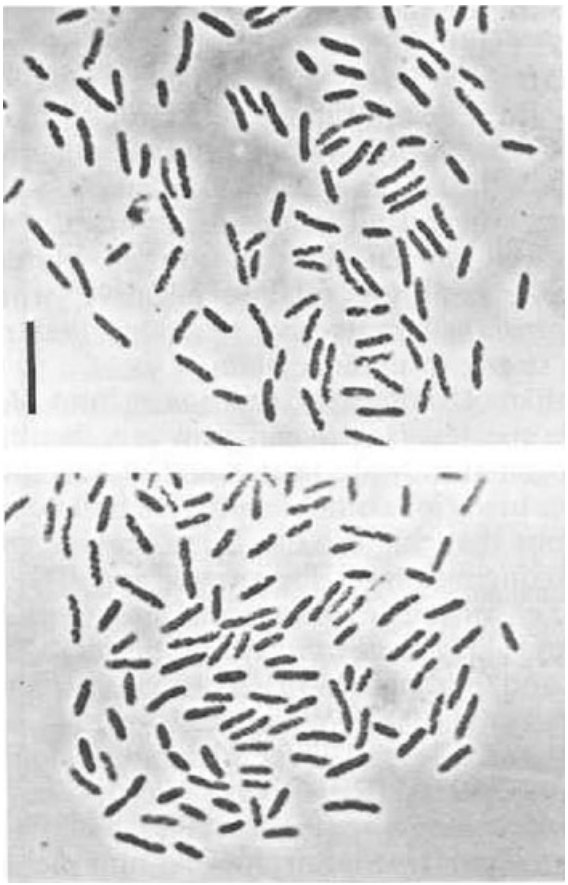

Fig. 2. Three-week-old cells of *Derxia gummosa* on nitrogen-free glucose agar, showing shrinkage of the cells. Phase contrast microscopy. Bar = 10 µm.

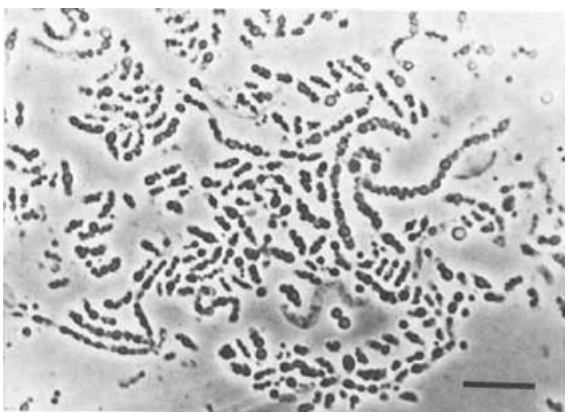

Fig. 3. Ten-day-old cells of *Derxia gummosa* on peptone agar with 2% glucose. Phase contrast microscopy. Bar = 10 µm.

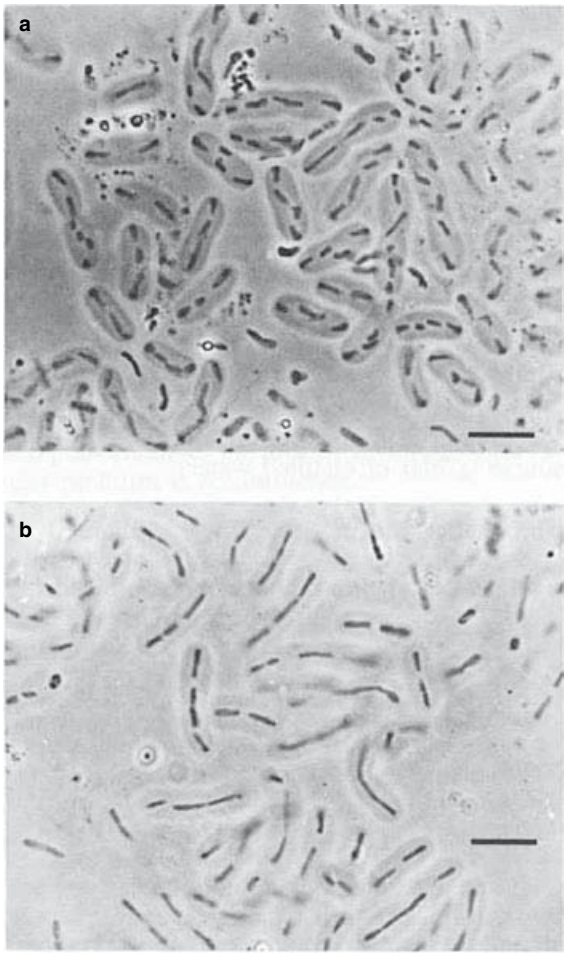

Fig. 4a. Three-month-old cells of *Derxia gummosa* on nitrogen-free glucose agar. The cells show shrinkage and are enclosed by a thick slime envelope. Phase contrast microscopy. Bar = 10 μm. Fig. 4b. More pronounced shrinkage of cells of a four-month-old *Derxia gummosa* culture on nitrogen-free glucose agar. Note the thick slime envelopes enclosing the rows of cells. Bar = 10 μm.

illum and Herbaspirillum in the second edition), *Derxia* cells are mainly straight rods and the lipoid bodies are more numerous. *Derxia* colonies are far more slimy than those of *Azospirillum*, and the mahogany-brown color they eventually acquire is in contrast to the pink or whitish color of *Azospirillum* colonies. Moreover, there are some minor physiological differences. *Derxia* strains can exhibit nitrogen-dependent growth on glucose, whereas only some strains of *Azospirillum* (i.e., only those belonging to the species *A. lipoferum*) can do so. On the other hand, *Derxia* strains generally do not grow well on malate, whereas all strains of *Azospirillum* can grow well on this carbon source. Moreover, *Derxia* strains are catalase negative, whereas *Azospirillum* strains give reactions that range from strong to undetectable.

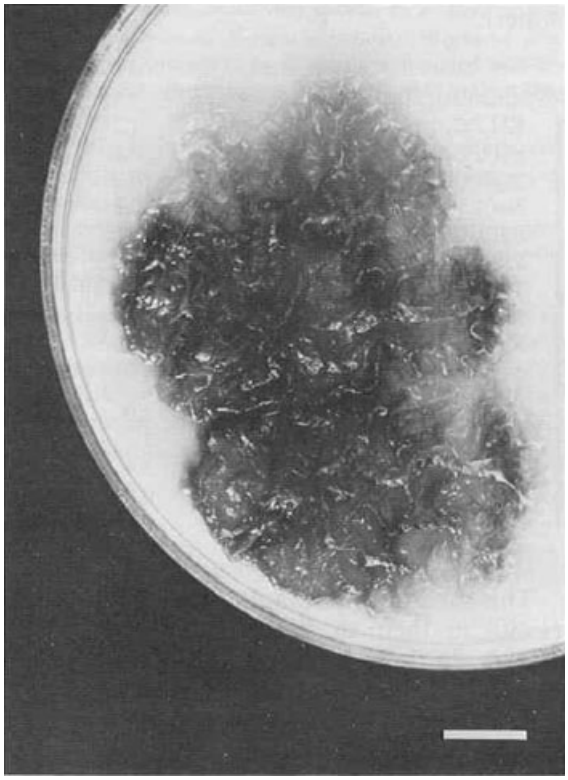

Fig. 5. Colony of *Derxia gummosa* on nitrogen-free glucose agar with calcium carbonate showing the coarse and wrinkled colony surface. Bar = 1 cm.

Unlike *Azotobacter*, *Azomonas*, and *Beijerinckia* species, *Derxia* species can grow as a facultative hydrogen autotroph. In this ability, they show affinities to various other facultative hydrogen autotrophs that can also use H_2 to provide energy and reducing power for growth and CO_2 fixation, i.e., various *Pseudomonas* and *Alcaligenes* species ("*Hydrogenomonas*" species) (Buchanan and Gibbons, 1974), *Xanthobacter* species (Wiegel et al., 1978; Wiegel and Schlegel, 1984; Malik and Claus, 1979), nitrate-reducing *Paracoccus* species (Rittenberg, 1969), *Bradyrhizobium japonicum* (Hanus et al., 1979), and *Azospirillum lipoferum* (Malik and Schlegel, 1981; Sampaio et al., 1981) (see also The Mesophilic Hydrogen-Oxidizing (Knallgas) Bacteria in the second edition). For further details on facultative hydrogen autotrophy of *Derxia*, see section "Physiological and Biochemical Properties" in this Chapter.

Species Description

Derxia gummosa Jensen, Petersen, De and Bhattacharya, 1960.

Cells are Gram-negative, rod-shaped with rounded ends, 3.0–6.0 μm in length, and 1.0–

1.2 µm wide, occurring singly or in short chains. Cells are rather pleomorphic, depending on age and the medium. In aging cultures, cells often remain together, forming long filaments of sometimes locally swollen or distorted cells. Some cells may assume enormous sizes (up to 30 µm). Young cells have a homogeneous cytoplasm; older cells typically show large refractile bodies throughout the whole cell. Resting stages are not known. Cells are motile by a short polar flagellum; motile cells are numerous in liquid glucose media containing combined nitrogen, but are rare on nitrogen-deficient solid media. The organism is aerobic, having a strictly respiratory type of metabolism with oxygen as the terminal electron acceptor. Molecular nitrogen is fixed under aerobic conditions and also under decreased oxygen pressures (microaerophilic conditions). Optimum temperature is 25–35°C; growth is slow at 15°C, feeble at 40°C; no growth occurs at 50°C. Growth occurs from pH 5.5 to about 9.0; no growth occurs at pH 4.4. Liquid cultures turn into a gelatinous mass, but growth near the surface is more luxuriant and forms a thick, tough pellicle. Colonies on agar media are at first slimy and semitransparent, later massive and opaque, highly raised with a wrinkled surface. Older colonies develop a rust-brown to dark mahogany-brown color. They are catalase negative. A wide range of sugars, alcohols, and organic acids are oxidized, mostly to CO_2, but a small amount of acid, probably acetic acid, is produced during growth in an alkaline medium. They can grow as a facultative hydrogen autotroph. The GC content of the DNA in three strains of *Derxia gummosa* ranges from 69.2–72.6 mol% (T_m) (De Smedt et al., 1980). In the type strain, it is 70.4 ± 1.7 mol% (T_m) (De Ley and Park, 1966).

The appearance of cells from young cultures is depicted in Fig. 1. Older cells on sugar-rich media contain large refractile bodies. Especially on glucose-peptone agar, very elongated cells are produced containing many refractile bodies (Fig. 3). The refractile material is probably poly-β-hydroxybutyrate, since it stains with Sudan III and Sudan black, but some vacuoles which do not stain may also be involved. On nitrogen-free glucose agar, older cells undergo shrinkage (Fig. 2) and are finally enclosed by a slime envelope (Fig. 4).

Motile cells may become numerous in liquid glucose media containing ammonia or glutamate as the nitrogen source. The cells usually have a single polar flagellum, but some may have a flagellum at each pole. According to Thompson and Skerman (1979), the single polar flagellum is less than a full wave and is less than 3 µm in length.

Growth in liquid media usually starts as a ring at the glass-liquid interface and develops into a thick, wrinkled, tough pellicle. Shallow layers of medium change into a firm gelatinous mass after a couple of weeks. The color gradually becomes a dark red-brown.

Growth on nitrogen-deficient agar media begins as thin, whitish, or semitransparent scattered colonies. Later, more massive, highly raised, or dome-shaped colonies emerge which rapidly assume a diameter of 1 cm or more (giant colonies) (Fig. 5). These colonies are very reminiscent of those of *Beijerinckia* species. Colonies are at first whitish or dull yellow with a smooth surface, but the surface soon becomes coarse and wrinkled, and the color deepens to a dark mahogany brown. The slime of these colonies is very tenacious and gumlike, but in the other developmental stages, it is softer and smeary.

Physiological and Biochemical Properties

In the original description, Jensen et al. 1960 mentioned the appearance of *Derxia gummosa* on nitrogen-free, mineral glucose agar as a few "massive" colonies among many "thin," whitish colonies. The type of colony used as inoculum affected neither the relative numbers nor the distribution of the two colony types. They reported further that the "massive" colonies fixed nitrogen, whereas the "thin" colonies did not. Tchan and Jensen (1963) observed that the formation of "massive" colonies was stimulated by the addition of small quantities of combined nitrogen to the medium and that dinitrogen fixation could not be initiated in a medium completely free of combined nitrogen.

Hill and Postgate (1969) found that, with a small quantity of combined nitrogen, batch cultures of *Derxia gummosa* in otherwise nitrogen-free media could be established with agitation in air. However, this supplement was unnecessary if the cultures were left stagnant or if the atmospheric oxygen concentration was lowered to 0.1 atm or less. Once established, continuous cultures could be maintained in air, provided vigorous stirring was avoided. Hill (1971) demonstrated in more detail that *D. gummosa* is very sensitive to oxygen and that the presence of oxygen markedly affects its colony morphology. At an oxygen concentration of less than 0.2 atm, only the "massive"-colony type is produced on nitrogen-free, mineral agar media; the "thin"-colony type which predominates in air was absent. Only the "massive" colonies reduced acetylene. Apparently, the copious production of a viscous and tenacious slime inhibits the penetration of oxygen and therefore stimulates nitrogen fixation. The colonial dimorphism on agar probably arises because only when the local oxygen concentrations on the agar surface are

depressed can dinitrogen fixation and subsequent growth to the "massive" colony type take place.

The efficiency of nitrogen fixation by *D. gummosa* varies between 9 and 25 mg N/g of glucose consumed, but in most strains it is distinctly lower than in *Azotobacter* or *Beijerinckia*.

Growth on nitrogen-deficient media or under nitrogen-fixing conditions is stimulated by small amounts of combined nitrogen (nitrate, ammonia), particularly at the start (Tchan and Jensen, 1963). There is no requirement for amino acids under nitrogen-fixing conditions. However, small amounts of yeast extract are stimulatory for growth under nitrogen-fixing conditions (J. H. Becking, unpublished observations), and although there is no apparent requirement for vitamins or growth factors, it is possible that small amounts of biotin are stimulatory for growth of some strains (J. H. Becking, unpublished observations).

As sole source of carbon, growth is good to excellent on glucose, fructose, ethanol, glycerol, mannitol (only utilized by some strains), and sorbitol; growth on lactate is scant. No growth or only a trace of growth occurs on lactose, galactose, maltose, sucrose, formate, acetate, propionate, pyruvate, succinate, malate, fumarate, dulcitol, and sometimes starch. Butyrate, citrate, benzoate, and xylose suppress growth. Growth on methane or methanol as the sole carbon source has also been demonstrated for *D. gummosa* (Sampaio et al., 1981).

Growth with combined nitrogen sources is much faster than with molecular nitrogen and is completely uniform, in contrast to the uneven growth on nitrogen-free agar. Colonies change from a pale yellow through rust-brown to almost black (darkest if nitrate is present), and sometimes a light brown, water-soluble pigment is produced. Growth with glutamic acid, ammonium acetate, alanine, sodium nitrate, and urea decreases from abundant to good in approximately the same sequence. Aspartic acid, asparagine, and peptone give a much slower growth, which is uneven and mostly confined to scattered colonies. Glycine seems to be toxic.

Nitrate is not reduced to nitrite or N_2 in a glucose-nitrate medium. Indole is not produced from tryptophan.

Trace elements, particularly molybdenum, are required for dinitrogen fixation, but vanadium cannot replace molybdenum (Jensen et al., 1960). Thus, *Derxia* apparently does not have an alternative vanadium-activated nitrogenase.

D. gummosa has been shown to grow as a hydrogen autotroph in an atmosphere containing $H_2 + CO_2 + O_2$, with either N_2 or NH_4^+ as the nitrogen source (Pedrosa et al., 1980). Indeed, it appears to grow nearly as well autotrophically as it does heterotrophically. Ribulose-1,5-bisphosphate carboxylase activity, which mediates CO_2 fixation, occurs in autotrophically-grown cells but not in cells grown heterotrophically.

A medium for testing the autotrophy has the following composition (g/liter of distilled water):

Medium for Testing Autotrophy

KH_2PO_4	1.2
K_2HPO_4	0.8
$MgSO_4 \cdot 7H_2O$	0.2
NaCl	0.2
$CaCl_2 \cdot 2H_2O$	0.02
$FeSO_4 \cdot 7H_2O$	0.002
Trace element solution (see below)	2.0 ml
Biotin	10 µg
Agar	15.0

Trace element solution (g/liter)

$Na_2MoO_4 \cdot 2H_2O$	1.0
$MnSO_4 \cdot H_2O$	1.75
H_3BO_3	1.4
$CuSO_4 \cdot 5H_2O$	0.04
$ZnSO_4 \cdot 7H_2O$	0.12

This medium was employed by Pedrosa et al. (1980) in their studies on the autotrophy of *Derxia*. In these studies, a very low concentration of potassium malate (0.1 g/liter) was sometimes added to the medium. It should be noted that most strains of *Derxia* (including the type strain) give only scant growth with malate. Thompson and Skerman (1979) reported no growth on DL-malate in all of the six strains that they tested.

Applications

No studies have yet been done on the occurrence and significance of this organism in the rhizosphere of crop plants. However, Campêlo and Döbereiner (1970) found *Derxia* more frequently on agar plates inoculated with roots (33% positive for *Derxia*) compared to those inoculated with soil (26%).

CHAPTER 3.2.11

The Genera *Leptothrix* and *Sphaerotilus*

STEFAN SPRING

Introduction

Representatives of the genera *Leptothrix* and *Sphaerotilus* were among the first microorganisms to be recognized in the environment and described in detail by scientists. The type species of the genus *Leptothrix*, *L. ochracea*, was already observed in the late eighteenth century and described by Roth (1797) under the synonym "*Conferva ochracea*." Later, Kützing (1843) proposed to place this species within the genus *Leptothrix*. Ten years earlier, the same author had published a description of the species *Sphaerotilus natans* (Kützing, 1833), which is today still known under this name. These early publications were probably evoked by the observation of ocherous deposits (clearly visible to the naked eye) in ponds or slowly running water. A microscopic examination of these suspicious aggregates led then to the discovery of filamentous microorganisms, which were obviously responsible for the deposition of iron or ferromanganese oxides in a slimy matrix, resulting in the typical color of the formed amorphous flocs or surface films.

Further investigations of the *Sphaerotilus-Leptothrix* group were induced by their potential economic importance. The massive growth of these microorganisms at industrial sites can lead to technological problems like clogging of water distribution systems or the bulking of activated sludge (Dondero, 1975). More recently, the significance of *Leptothrix* species in the corrosion of steel could be demonstrated (Olesen et al., 2000; Rao et al., 2000). On the other hand, a potential application of these microorganisms in the biological clearance of heavy metals from contaminated water supplies is being discussed (Nelson et al., 1999; Solisio et al., 2000).

Both genera, *Leptothrix* and *Sphaerotilus*, have been always considered as closely related because of the conformity of some suspicious morphologic traits (Mulder and Van Veen, 1963). Later, their close relationship was confirmed by phylogenetic and phenotypic data, thereby justifying their treatment as a group. Characteristic traits, which distinguish members of this group from other phylogenetically related species, are the capability to form tubular sheaths and the precipitation of copious amounts of oxidized iron or manganese.

Phylogeny and Taxonomy

Phylogeny and Related Genera

Members of the genera *Leptothrix* and *Sphaerotilus* comprise a phylogenetically coherent cluster within the β1-subgroup of the Proteobacteria. The similarity values among 16S rRNA gene sequences representing strains of the *Sphaerotilus-Leptothrix* group are in the range between 96.3 and 99.8% (Pellegrin et al., 1999). It has to be noted, however, that to date no 16S rRNA sequence of *L. ochracea* (the type species of the genus *Leptothrix*) is available. In addition, the physiology of this species is largely unknown, because it could not be isolated in pure culture. Hence, it cannot be excluded that the type species of *Leptothrix* is phylogenetically only distantly related to the other species of this genus.

Representatives of the genera *Aquabacterium*, *Ideonella*, *Rubrivivax*, *Roseateles* and two misclassified species, *[Alcaligenes] latus* and *[Pseudomonas] saccharophila*, are phylogenetically closely related to the *Sphaerotilus-Leptothrix* group. Together they form the *Rubrivivax* line of descent, which is tightly associated with the Comamonadaceae (Wen et al., 1999). The relative branching order of most species within the *Rubrivivax* group is difficult to determine, mainly because of the restricted number of varying positions available for the estimation of phylogenetic distance values. Depending on the method and database used for tree reconstruction, it may happen that representatives from other genera get intermixed with species from the *Sphaerotilus-Leptothrix* group. Therefore, it is difficult to decide if the capability of sheath-formation within this group evolved from a common ancestor, i.e., if it is a monophyletic trait. Despite the close phylogenetic relationship of members of the *Rubrivivax* branch, a differentiation is easily possible based on phenotypic

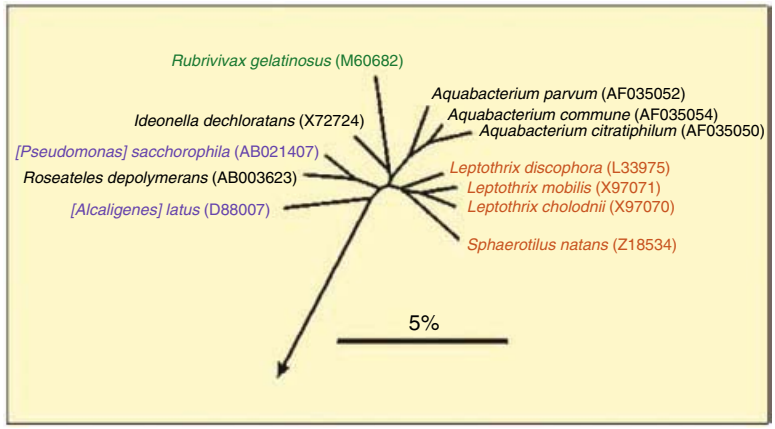

Fig. 1. Phylogenetic tree showing the position of members of the *Sphaerotilus-Leptothrix* group among representatives of the *Rubrivivax*-branch of the β-Proteobacteria. Sheath-forming species are labeled in red, photoautotrophic species in green, and facultatively chemolithoautotrophic species in blue. The GenBank/EMBL accession number for each sequence is shown in parentheses. With the exception of *Sphaerotilus natans* (DSM 565) and *Leptothrix cholodnii* (CCM 1827), sequences of type strains were used. This tree was reconstructed using the ARB program package (Ludwig and Strunk, 1997). It is derived from a distance matrix on a selection of 16S rRNA sequences using the neighbor-joining method of Saitou and Nei (1987). Phylogenetic distances were calculated as described by Felsenstein (1982). The sequence of *Escherichia coli* was used as an outgroup (not shown). The bar indicates 5% estimated sequence divergence.

characteristics. It is noteworthy that the genera in this tight assemblage represent three basically different metabolic types, namely photoautotrophs (*Rubrivivax*), facultative chemolithoautotrophs (*[Alcaligenes] latus* and *[Pseudomonas] saccharophila*) and respiratory chemoorganotrophs (e.g., *Ideonella* and *Sphaerotilus*). In Figure 1, a representative phylogenetic tree based on 16S rRNA gene sequence data has been selected which adequately reflects the phenotypic classification within this group.

Important phenotypic characteristics useful for distinguishing members of the genera *Leptothrix* and *Sphaerotilus* from other species belonging to the *Rubrivivax*-lineage are listed in Table 1.

Phenotypic Characteristics

Common Traits Some important phenotypic traits are shared by all members of the genera *Leptothrix* and *Sphaerotilus*: Cells are straight rods, Gram-negative and motile by flagella. Growth is filamentous under natural conditions, owing to the formation of tubular sheaths that surround single and linear chains of cells. Sheaths are produced by excretion of fibrillar polymeric substances that are crosslinked to form a mesh-like fabric closely fitting to the cells. In contrast to slimes or capsules, this matrix is not in intimate contact with the cells. In aquatic habitats rich in iron and manganese, sheaths get incrusted with ferric hydroxide (*Sphaerotilus*) or ferromanganese oxides (*Leptothrix*). Without these incrustations, they appear as very thin, almost transparent structures and are therefore not easily recognized by phase contrast microscopy. Occasionally, cells move out of the sheath or lyse and leave behind an empty space or gap within the filament, thereby facilitating the observation of the sheath. Treatment of slide preparations with ethanol may improve the visibility of sheaths under phase contrast.

Further conspicuous morphological features of members of this group include the formation of slime, holdfasts, and false branching of filaments. These traits are frequently recognized in the genus *Sphaerotilus*, but are less common among representatives of the genus *Leptothrix*. The sheaths of *S. natans* and several *Leptothrix* species are surrounded by a slime layer that may be involved in the accumulation of iron hydroxide and in the oxidation of Mn(II). Holdfasts are sticky, disc-like evaginations or blebs formed at one cell pole opposite to the flagellum by which organisms attach to walls of containers, submerged plants, stones and other surfaces. Holdfast formation can be easily observed in pure cultures of *Sphaerotilus natans* and *Leptothrix lopholea*, but is absent or variable in other cultured *Leptothrix* species. False branching is characteristic for *Sphaerotilus natans* and several *Leptothrix* strains. It develops if a cell attaches to an existing filament and forms a new filament, thereby forming a branch.

Metabolism is strictly aerobic, respiratory and chemoorganoheterotrophic. The possibility of an autotrophic or mixotrophic growth of these bacteria with ferrous iron as electron acceptor has been discussed for many years, but up to now no

Table 1. Differential characteristics of genera and misclassified species belonging to the *Rubrivivax* group of the β-Proteobacteria.

Characteristic	*[Alcaligenes] latus*	*[Pseudomonas] saccharophila*	*Roseateles*	*Rubrivivax*	*Ideonella*	*Aquabacterium*	*Leptothrix*[a]	*Sphaerotilus*

Symbols: +, present in all species; –, absent in all species; and NR, not reported.
[a]Physiological data for *Leptothrix lopholea* and *L. ochracea* are not available.
From Kersters and De Ley (1984); Palleroni (1984); Mulder and Deinema (1992); Malmqvist et al. (1994); Spring et al. (1996); Kalmbach et al. (1999); and Suyama et al. (1999).

definite evidence could be presented which would support this assumption. Representatives of both genera, *Leptothrix* and *Sphaerotilus*, require vitamin B_{12} as an essential growth factor in mineral media. A number of *Leptothrix* strains have been found to require in addition thiamine and biotin as growth factors (Rouf and Stokes, 1964). In broth culture, a flocculent growth is typical. Poly-β-hydroxybutyrate is stored as reserve material. The major quinone type detected is ubiquinone Q8 (>90% of total quinones). The four major components of the cellular fatty acids are *cis*-9 hexadecanoic acid (*cis*-9 16:1), hexadecanoic acid (16:0), *cis*-9,11 octadecanoic acid (*cis*-9,11 18:1) and decanoic acid (12:0). In all strains tested, the hydroxylated fatty acid 3-hydroxydecanoic acid (3-OH 10:0) can be detected, however in some cases, only in low amounts (Kämpfer, 1998). The G +C content of DNA is similar in both genera and ranges between 68 and 71 mol%. In general, chemotaxonomic features characteristic for the *Sphaerotilus-Leptothrix* group are very similar in other organisms belonging to the *Rubrivivax* group and Comamonadaceae, so that a clear differentiation of species or even genera within this phylogenetic group is hardly possible based solely on chemotaxonomic traits.

Distinguishing Traits Albeit closely related, several phenotypic characteristics allow the differentiation of the genera *Leptothrix* and *Sphaerotilus*. The ability to oxidize soluble manganese (Mn^{2+}) compounds to solid manganic (Mn^{4+}) oxides is restricted to *Leptothrix* species. This trait has been originally used for differentiation because it can be easily observed in Mn^{2+}-containing media or habitats. Further distinguishing traits, however, were only revealed by a detailed taxonomic study of cultured strains of both genera. They include the storage of polysaccharides as reserve material only by *Sphaerotilus* strains, size of cells, structure of the sheath surface (*Leptothrix* sheaths show a rough surface when viewed by electron microscopy, in contrast to the sheaths of *Sphaerotilus* strains which have a smooth surface), utilization of carbon sources, and the pronounced response of *S. natans* to an increase of organic nutrient concentration in contrast to a poor response of most *Leptothrix* species.

A summary of phenotypic characteristics useful for the classification of both genera is presented in Table 2.

Table 2. Main morphological and physiological characteristics of the genera *Leptothrix* and *Sphaerotilus*.

Characteristic	*Leptothrix*[a]	*Sphaerotilus*
Cell dimensions		
Width (μm)	0.6–1.5	1.2–2.5
Length (μm)	1.5–14	1–10

Problems in the Taxonomy of Members of the *Sphaerotilus-Leptothrix* Group

The Proposal of Pringsheim Members belonging to the *Sphaerotilus-Leptothrix* group share some important phenotypic characteristics which are easily recognized. On the other hand, distinguishing traits are sometimes difficult to determine and require the investigation of defined pure cultures. Certain strains of this group show a considerable morphological variability, depending on the respective environmental conditions, leading to the effect that virtually identical or similar strains were described under different species names. These circumstances probably led Pringsheim (Pringsheim, 1949a; Pringsheim, 1949b) to believe that all strains of this group should be placed in the genus *Sphaerotilus*. He also concluded that *L. ochracea* would be a morphological variant of *S. natans*

because both species lack visible deposits of manganese oxides on their sheaths. The investigations which led to these conclusions were however inadequate because they were based on only a few partly described strains or on the observation of uncultured bacteria in natural environments. Several studies in the following years clearly revealed the mistakes in Pringsheim's nomenclature. Nevertheless, his assumptions produced a lot of confusion in the taxonomic literature on the *Sphaerotilus-Leptothrix* group between the 1950s and 70s. In that time, for instance, a variety of manganese-oxidizing strains, which probably belong to different *Leptothrix* species, were described under the name *Sphaerotilus discophorus* (e.g., Rouf and Stokes, 1964).

Instability of Phenotypic Characteristics Several difficulties regarding the taxonomy of this group are due to the loss of important phenotypic traits upon cultivation (Van Veen et al., 1978). The reversible or nonreversible loss of physiological and morphological characteristics of strains in pure culture caused divergent descriptions of species, which were originally described on the basis of observations in the natural environment (e.g., *L. discophora*, see below). The ability to form sheaths has been irreversibly lost by several strains of *Sphaerotilus natans* and by most *Leptothrix* strains available from public culture collections, with the exception of *L. cholodnii* (formerly "*L. discophora*") SP-6 (= LMG 8142). Gaudy and Wolfe (1961) reported that sheath formation in *Spaerotilus natans* is affected by the composition of the culture medium and inhibited at high concentrations of peptone. The colony morphology of freshly isolated strains corresponds to the ability of sheath formation and can be smooth (sheathless cells) or rough and filamentous (sheath-forming cells). Sometimes even various colony morphologies of the same strain can be observed on one agar plate. The manganese-oxidizing activity in *Leptothrix* strains is independent from the formation of sheaths and more stable in most strains, but loss of this trait has also been reported.

A report on the disc- or holdfast-formation of an uncultured sheathed bacterium, which was tentatively identified as *L. discophora* (Carlile and Dudeney, 2001), illustrates the taxonomic problems within this group. Interestingly, the formation of basal discs or holdfasts at one end of the filament (*discophora* means disc-bearing) was mentioned in the original description of this species by Schwers (1912), which was based on photomicrographs of cells in natural environments. In later studies, however, disc formation was never again observed in pure cultures of this morphotype, so that it was concluded that the presence of this trait within the genus *Leptothrix* was confined to the species *L. lopholea* (Mulder, 1989a). If the authors of the abovementioned studies have in fact described the same species, the ability to form discs would not distinguish between *L. discophora* and *L. lopholea*, this trait being more stable in the latter. To avoid this kind of confusion, descriptions of new strains should be based on freshly isolated pure cultures that were studied, if possible, under conditions most similar to natural habitat conditions.

Lack of Reference Strains A major problem in the taxonomy of the genus *Leptothrix* is the availability of reference strains. The type species of the genus *Leptothrix*, *L. ochracea*, is not cultured and the description is based only on morphological observations. Although the description of "*L. pseudo-ochracea*" was based on pure cultures, no type strain was designated. On the other hand, the type strains of *L. lopholea*, LVMW 124, and *L. cholodnii*, LVMW 99, are not available from public culture collections and have apparently been lost. The strain LMG 7171 can be used as reference strain for *L. cholodnii* until a neotype is designated, but for *L. lopholea*, no other strains are available, preventing detailed taxonomic studies on this species.

Ecology

Ecology of Sheath Formation

The production of a sheath takes place at the expense of energy and requires synthesis and excretion of a large amount of cellular material. Therefore, it can be assumed that sheath formation was developed by microorganisms under a selective pressure and offers several ecological and nutritional advantages in the environment. A linear arrangement of single cells within a tubular sheath enables bacteria to form filaments, without actual enlargement of cell size. It has been shown that filamentous growth is an effective strategy of bacteria to exceed the size limit of particles edible by protozoa, thereby allowing them to escape from grazing (Sommaruga and Psenner, 1995). In addition, sheaths provide cells with physical protection from infection by bacteriophages (Winston and Thompson, 1979), bacterial predators (Venosa, 1975), and bacterivorous metazoa. Obviously tough sheaths impregnated with ferric oxides cannot be consumed by metazoa and are not penetrated by bdellovibrios or phages.

Rigid sheaths in combination with extracellular slime represent an ideal matrix for the rapid

build-up of biofilms in the form of floating aggregates or dense layers on solid surfaces. The ecological advantages of biofilm formation for bacteria are well known and include reduction of flow rates in running waters, adsorption of nutrients, and establishment of heterogenous microniches characterized by various chemical gradients. The reversible inhibition of sheath formation by high nutrient concentrations in some *Sphaerotilus* strains may be an indication for the important role played by the sheath surface in the accumulation of nutrients (Gaudy and Wolfe, 1961).

The sheath provides cells with an additional compartment close to their outer surface. Enzymes and proteins which are secreted by the cell can be incorporated in the sheath matrix, thereby allowing the extracellular production or degradation of compounds. It is possible that members of both genera use the sheath or the space between sheath and outer cell surface for the oxidation of iron and/or manganese to avoid toxic concentrations of metal compounds within the cell.

Methods for Studying Distribution and Abundance

Members of the *Sphaerotilus-Leptothrix* group are not only abundant in natural environments, but also may play a role in industrial processes leading to several technical problems. They were associated with bulking of activated sludge (Wagner et al., 1994), corrosion of stainless steel (Olesen et al., 2000), clogging of water distribution systems (Dondero, 1975), and slime formation in paper mill factories (Pellegrin et al., 1999). To prevent damage caused by the prolific growth of these organisms, it could be advantageous to monitor them in environmental samples without time-consuming enrichment and cultivation steps. Although in some samples the affiliation of bacteria to the *Sphaerotilus-Leptothrix* group may be assigned on the basis of phase-contrast microscopic appearance, distinction between genera or single species is hardly possible. Consequently, culture-independent methods for the identification and detection of these species were developed. Two approaches could be promising: whole cell hybridization with fluorescently labeled oligonucleotide probes and polymerase chain reaction (PCR) detection of *Leptothrix* species using primers targeting *mofA*, an enzyme gene involved in manganese oxidation.

Whole Cell Hybridization Fluorescence in situ hybridization (FISH) using oligonucleotide probes is a well established technique for the identification and in situ detection of microorganisms based on signature regions of their 16S rRNA genes (Amann et al., 1995). Several probes were developed targeting 16S rRNA sequences of members of the *Sphaerotilus-Leptothrix* group. A check of published probe sequences against a current database of 16S rRNA gene sequences (Ludwig and Strunk, 1997) revealed, however, that some probes which were originally intended to be specific for a single species are in fact targeting a variety of different species, partly not even belonging to the *Sphaerotilus-Leptothrix* group. To minimize the risk of mistaken identification of uncultured bacteria by crossreactivity of probes, it is advisable to use simultaneously at least two different specific probes, distinguishable by fluorescence label. Suitable combinations of probes for the *Sphaerotilus-Leptothrix* group can be found in Table 3.

Table 3. Specificity of oligonucleotide probes targeting 16S rRNA sequences of members of the *Sphaerotilus-Leptothrix* group.

Sequence of:			Hybridization with probe[a]

Symbols: +, hybridization of probe; –, no hybridization of probe under stringent conditions; and ^{T}, type strain.
[a]Reactivity of the probe was either checked experimentally or determined by sequence comparison.
[b]Data from Wagner et al. (1994).
[c]Data from Siering and Ghiorse (1997).
[d]Only sequences of cultured strains available in public data bases were counted.

The identification of distinct species by FISH is still difficult, even by using a combination of specific probes, but the combined observation of morphological features (e.g., sheath formation) and hybridization signals should at least enable the identification of uncultured bacteria at the genus level. In Figure 2, the in situ detection of uncultured *Leptothrix* bacteria in an environmental wetland sample is shown.

Low signal intensities of labeled cells and samples with low numbers of target cells represent frequently encountered problems of the FISH method. In habitats with low numbers of sheathed bacteria, e.g., water distribution systems or sediments, the application of microscope slides can be a promising approach to obtain suitable samples for hybridization experiments. Microscope slides were successfully used for the enrichment of sheathed bacteria by employing to advantage their ability to adhere efficiently to smooth surfaces (Spring et al., 1996; Carlile and Dudeney, 2001). After removal and cleaning, the overgrown side of these slides can be used for FISH experiments. To improve signal intensities of labeled cells, it may help to treat samples prior to hybridization with diluted hydrochloric or oxalic acid, to remove iron and manganese oxides from sheaths, which could otherwise prevent efficient penetration of oligonucleotide probes into cells.

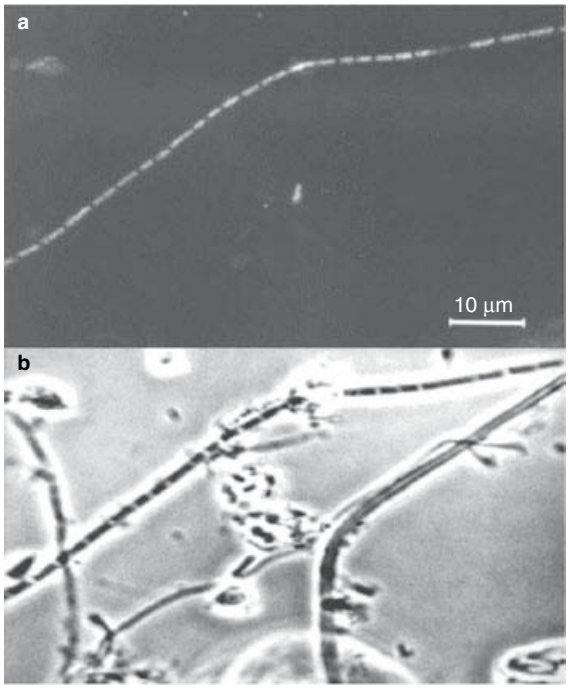

Fig. 2. Laser scanned epifluorescence (a) and matching laser scanned phase contrast image (b) of previously unidentified filamentous bacteria labeled by the PS-1 oligonucleotide probe in a sample of particulate material from the Sapsucker Woods wetland, Ithaca, NY. From Ghiorse et al. (1996), with permission.

Diagnostic PCR An alternative approach for the detection of *Leptothrix* bacteria was developed by Siering and Ghiorse (1997b). They used specific PCR primers for the amplification of the gene *mofA*, encoding a putative multi-copper oxidase involved in manganese oxidation by *Leptothrix* species (see section "Oxidation of Fe^{2+} and Mn^{2+}" in this Chapter).

The gene *mofA* was originally retrieved by cloning a DNA fragment of *Leptothrix discophora* SS-1, but homologous genes were identified also in several other *Leptothrix* species (Siering and Ghiorse, 1997b). The application of nondegenerate PCR primers enabled the in vitro amplification of a 706-bp portion of the gene *mofA* from a pure culture of *L. discophora* SS-1 and extracted nucleic acids from a water sample of a wetland iron seep, but not from nucleic acids extracted from a sediment sample of the same site. The obtained results were in agreement with previous observations which indicated that in this habitat, the growth of *Leptothrix* bacteria is restricted to ferromanganese surface films and the root zone of *Lemna* species in the water column. Potential advantages of this protocol are an increased specificity and sensitivity compared to the FISH method. However, in contrast to the latter method, no information on the morphology of the detected cells can be obtained.

The Genus *Leptothrix*

Habitats

Leptothrix species are widely distributed in the environment and can be easily found at sites which are characterized by a circumneutral pH, an oxygen gradient and a source of reduced iron and manganese minerals. Typical habitats include iron seeps of freshwater wetland areas, forest ponds, iron springs and the upper layers of sediments (Ghiorse and Ehrlich, 1992). At suitable sites, the massive growth of these organisms can be easily observed with the naked eye as ocherous masses emerging as surface films, solid mats or fluffy, dispersed material. Depending on the amount of oxidized manganese, the color can vary from yellowish-orange to dark brown. A wetland iron seep, shown in Fig. 3, is characterized by a pronounced ocherous color originating from a prolific growth of *Leptothrix* bacteria.

An iron-oxidizing microbial mat that developed at an iron seep where anoxic groundwater (rich in ferrous iron) flows over a stone wall was described in detail by Emerson and Revsbech (1994). They could demonstrate that *Leptothrix*

species represent a significant fraction of the active biomass in the upper few millimeters of this dense microbial mat.

Further studies presented indirect evidence for the association of *Leptothrix* bacteria with lacustrine ferromanganous micronodules (Stein et al., 2001) or microbial mats in areas of possible deep-lake hydrothermal venting (Dymond et al., 1989).

Most *Leptothrix* species are restricted to natural, unpolluted environments with low concentrations of easily degradable organic nutrients. A prominent exception is *L. cholodnii*, which is frequently detected in sewage sludge (Kämpfer, 1997).

Isolation

Several methods for the enrichment of *Leptothrix* species from the environment are based on the tendency of these filamentous organisms to attach to surfaces. Mulder and Van Veen (1963) used continuous flow devices to imitate the natural growth conditions of these organisms. A schematic of such an apparatus is shown in Fig. 4.

For producing iron-containing ditch water, an iron-cylinder is filled with iron-stone soil supplemented with 1 to 2 g of ferric carbonate/kg of soil. After an incubation period of about 3 weeks, during which the soil is kept saturated with water, enough ferric iron is reduced to ferrous iron to start a continuous flow of tap water percolating through the soil. The soil extract running off the iron cylinder from the upper outlet is sterilized by filtration and supplied dropwise to the upper Erlenmeyer flasks, which can be inoculated with various samples containing *Leptothrix* bacteria. To avoid rapid nonbiological oxidation of ferrous iron, the upper Erlenmeyer flasks can be aerated with a gas mixture of low oxygen content. Comparable to the situation in unpolluted slowly running water, bacteria which are able to attach to solid surfaces have a selective advantage within this device because they obtain more nutrients than bacteria moving with the medium. The described apparatus can be also applied for the observation of pure cultures of *Leptothrix* bacteria under conditions similar to their natural environment.

A less laborious enrichment method was introduced by Rouf and Stokes (1964), who filled glass cylinders with water taken from the environment and added extracted alfalfa straw as nutrient source, $MnCO_3$, and freshly precipitated $Fe(OH)_3$. After several days, the flocculent growth of sheathed bacteria adhering to the walls of the cylinder indicated the enrichment of *Leptothrix* bacteria.

An alternative method, which is also based on the capability of *Leptothrix* species to attach to smooth surfaces, was applied by Spring et al. (1996). Microscope slides were put into a sample of freshwater sediment, and after several weeks, sheaths of filamentous bacteria encrusted with ferric oxides covered parts of the slides. The slides can be removed from the sediment and used for isolation after washing in sterile tap water to remove loosely attached sediment bacteria.

Isolation of pure cultures can be achieved by streaking material from enrichment cultures on previously dried agar plates containing low levels of nitrogen and carbon sources. Enrichment cul-

tures may not be necessary if natural environments are studied in which *Leptothrix* bacteria can be detected by their flocculent growth. Flocculent cell material from these sites can be washed several times with sterile tap water and streaked directly on solid media.

The isolation medium used by Rouf and Stokes (1964) has the following composition (per liter of tap water): Peptone, 5.00 g; ferric ammonium citrate, 0.15 g; $MgSO_4 \cdot 7\ H_2O$, 0.20 g; $CaCl_2$, 0.05 g; $MnSO_4 \cdot H_2O$, 0.05 g; $FeCl_3 \cdot 6\ H_2O$, 0.01 g; and agar, 12.00 g. The plates are incubated at 25°C for 5–14 days in the dark. Colonies of *Leptothrix* strains can be easily distinguished from most contaminating bacteria on this medium by their dark-brown color.

Identification

So far six different species of *Leptothrix* can be distinguished on the basis of phenotypic characteristics. Reference strains for taxonomic studies are only available for three species, viz., *L. cholodnii, L. discophora* and *L. mobilis*. Descriptions of the remaining species are incomplete because they are based solely on microscopic observations (*L. ochracea*) or poorly characterized isolates (*L. lopholea* and "*L. pseudo-ochracea*"), hence preventing an accurate identification of newly isolated strains using culture-dependent methods. The name of "*Leptothrix pseudo-ochracea*" was not included in the *Approved Lists of Bacterial Names* (Skerman et al., 1980) and has therefore no formal taxonomic status. Differential characteristics of the known *Leptothrix* species are listed in Table 4. Detailed morphological descriptions follow below.

L. OCHRACEA *Leptothrix ochracea* is the most common iron-precipitating ensheathed bacterium that probably occurs all over the world in slowly running ferrous iron-containing waters, poor in readily decomposable organic matter. Low oxygen tensions seem to be required for prolific growth of this species (Emerson and Revsbech, 1994). The pronounced development and activity of *L. ochracea* in iron- and manganese-containing waters give rise to the accumulation and deposition of large masses of ferric oxide and, probably, manganese dioxide (MnO_2), which are thought to be responsible for the formation of bog ore (see for instance, Ghiorse and Chapnick, 1983).

Descriptions of this species are based on observations in the natural environment or in the laboratory on enrichment cultures of slowly running soil extract. The most typical characteristic of *L. ochracea* is the formation of large numbers of almost empty sheaths within a relatively short time. The mechanism of this procedure can be followed in a slide culture of the organism, in an iron-containing soil extract medium, under a phase-contrast microscope. In this way, the behavior of *L. ochracea* in crude culture can be observed continuously. It will be seen that chains of cells leave their sheath at the rate of 1–2 μm/min, continuously producing a new smooth and hyaline sheath connected with the old envelope (Fig. 5a). Impregnation and covering of the sheaths with iron probably take place after the

cells have left the envelopes. Aged golden-brown and highly refractile sheaths are brittle, so that they are easily broken into relatively short fragments. Viewed under phase contrast, such fragments are very characteristic and appear similar to broken glass capillaries (Fig. 5b, c). In Mn(II)-containing environments or enrichment cultures, sheaths of this species can be easily distinguished from sheaths of the other *Leptothrix* species which are characterized by irregular encrustations of granular MnO_2. In contrast, the sheaths of *L. ochracea* are only impregnated with ferric oxides and lack MnO_2 deposits, leading to a smooth and slender appearance of aged sheaths. The lack of MnO_2 encrustations in sheaths of *L. ochracea* can be detected either by using an electron microscope equipped with an X-ray energy dispersive microanalysis system (Ghiorse and Ehrlich, 1992) or by treatment with oxalic acid (Carlile and Dudeney, 2001). A diluted solution (1%) of oxalic acid, a solvent for hydrated ferric oxide, can make the sheaths of *L. ochracea* transparent and almost disappear, whereas sheaths of other *Leptothrix* species are unaffected owing to the impregnation with manganese oxides.

Investigators who have studied and described *L. ochracea* under natural conditions were unable to obtain pure cultures (Cholodny, 1926; Charlet and Schwartz, 1954). Others who thought they had isolated *L. ochracea* had, in fact, described one of the other species of this genus (Winogradsky, 1888; Winogradsky, 1922; Molisch, 1910; Lieske, 1919; Cataldi, 1939; Prüße, 1957). In some instances, an organism resembling *L. ochracea* has been isolated, viz., "*L. pseudo-ochracea*." A potential lithoautotrophic metabolism of *L. ochracea* with Fe(II) as electron donor could, therefore, never be proved with pure cultures and is uncertain, since the organism normally grows at a pH value of 6–7, at which Fe(II) is readily oxidized nonbiologically. In addition, its Mn (II)-oxidizing capacity, which probably occurs under natural conditions, has never been confirmed. It is, however, possible that in this species, the Mn(II) oxidizing factors are secreted into the surrounding environment leading to the precipitation of MnO_2 granules away from the sheath surface.

"*L. pseudo-ochracea*" Cells are more slender than those of the other *Leptothrix* species (Table 4), and are very motile by one thin polar flagellum. Even chains of 6–10 cells may show an undulatory locomotion after leaving their sheath. This characteristic may account for the relatively large number of empty sheaths in culture, compared with the number found in cultures of most other *Leptothrix* species; however, *L. ochracea* possesses even more empty sheaths. In slowly flowing ferrous iron-containing soil extract, the sheaths become impregnated with ferric oxide and appear yellow-brown. In this respect, the organism resembles *L. ochracea*. However, in media with added manganese compounds, the sheaths are covered with small granules of MnO_2, enabling an easy distinction from

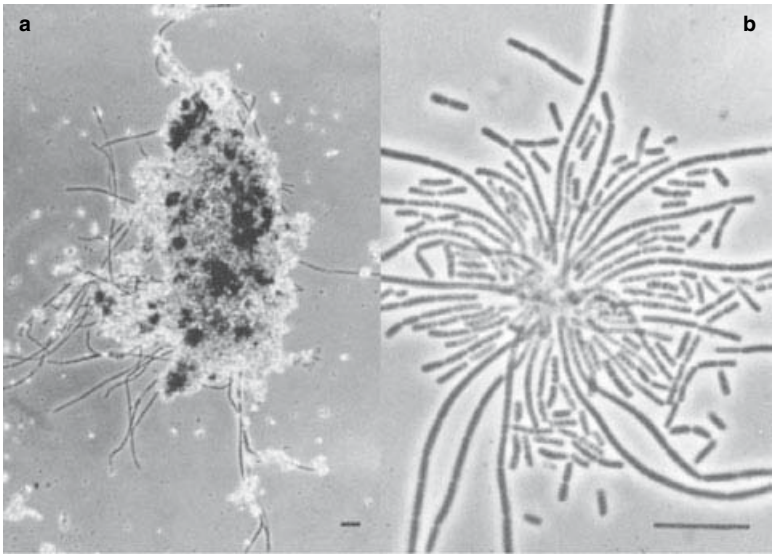

Fig. 6. *Leptothrix lopholea*. (a) Bacterial flocs with black-brown MnO_2 deposits. Reproduced with permission from Mulder and Deinema (1992). (b) Many trichomes radiating from common holdfasts. Bar = 10 µm. From Van Veen et al. (1978), with permission.

the sheaths of *L. ochracea* which are not impregnated with manganese oxides.

On Mn(II)-containing agar, the black-brown colonies are very filamentous and may exceed a width of 10 mm. On basal agar media containing 0.1% peptone and 0.1% glucose, the organism may grow in concentric rings.

The normal habitat of "*L. pseudo-ochracea*" is the slowly running, unpolluted, iron- and manganese-containing freshwater of ditches and brooklets. This species may also be found in slightly polluted water.

L. LOPHOLEA *Leptothrix lopholea* resembles *S. natans* to a greater extent than do the other *Leptothrix* species. It produces polytrichous subpolar flagellation and forms holdfasts and false branches. Strains may grow also in rich media. Cells usually develop short-sheathed filaments radiating from a cluster of holdfasts, giving rise to many tiny flocs when the cells are grown in liquid media (Fig. 6).

Deposition of iron and manganese oxides is more pronounced on holdfasts than on filaments. On Mn(II)-containing agar media, encrustation of sheaths with MnO_2 is retarded, so that colonies at first are white and later become black-brown. Cell growth responds poorly to an increased supply of organic nutrients. Strains that do show a good response oxidize manganese more slowly.

This species may be isolated from slowly flowing, unpolluted or polluted freshwater and from activated sludge.

L. CHOLODNII Cells of freshly isolated strains are usually found in long chains inside the sheaths. Single motile cells may be seen outside the sheaths. In the presence of Mn(II), the sheaths become covered with granular MnO_2 (Fig. 7a). At some sheath locations, the MnO_2 deposits may even exceed 10 µm. *Leptothrix cholodnii*, in contrast to other *Leptothrix* species, responds to an increased supply of organic nutrients (Table 2). This results in relatively large colonies (up to 5 mm in diameter) on nutrient-rich agar media. On Mn(II)-containing agar, black-brown hairy colonies are formed (Fig. 7b), particularly when the organism is seeded densely.

Most strains display a strong tendency to dissociate spontaneously and to produce smooth rather than the typical rough colonies (Fig. 7c). Such mutant strains are largely sheathless and oxidize manganese slightly or not at all (Mulder and Van Veen, 1963; Rouf and Stokes, 1964; Stokes and Powers, 1965).

In agreement with its nutritional requirements, *L. cholodnii* is found in slowly running iron- and manganese-containing unpolluted waters or in polluted waters, particularly in activated sludge.

L. DISCOPHORA Cells are relatively small compared to those of the other *Leptothrix* species described (Table 4). They may occur in narrow sheaths or be free-swimming; free cells are motile by a thin polar flagellum at one or both poles. The manganese-oxidizing and ferric oxide-storing capacities of this organism are very pronounced. In the presence of Mn(II), the sheaths are heavily but irregularly encrusted with MnO_2, giving rise to sheaths of sometimes 10 µm thickness. Under natural conditions, holdfasts may be formed and sheaths are covered with a slime capsule which tapers toward the growing tip and is impregnated with hydrated ferric oxides (Carlile and Dudeney, 2001). In enrichment media with both manganese (II) and iron (II), as in slowly

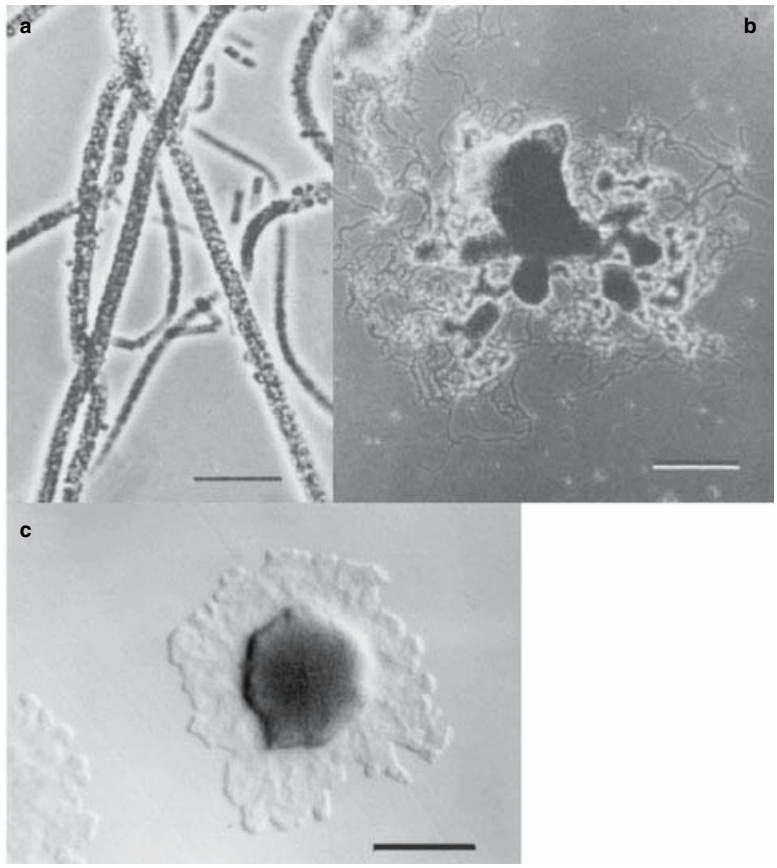

Fig. 7. *Leptothrix cholodnii*. (a) Sheaths encrusted with MnO_2. Bar = 10 μm. Reproduced with permission from Mulder and Deinema (1992). (b, c) Colony morphologies. (c) Smooth colony on the agar medium of Rouf and Stokes (1964). Bar = 500 μm.

flowing soil extract, the sheaths become covered with a thick, dark brown, fluffy layer of ferric oxide and MnO_2 which may increase the diameter of the trichomes up to about 20–25 μm (Fig. 8a).

Following isolation, the ability to form sheaths is easily lost in this species (Adams and Ghiorse, 1986). False branching is regularly observed, even with sheathless strains (Fig. 8b). In older cultures, coccoid bodies and cell evaginations are formed. Colonies on the solid medium of Rouf and Stokes (1964) are about 1 mm in diameter, more or less circular in shape, flat, and dark-brown (Fig. 8c). Under certain conditions, filamentous colonies may be formed. Increasing the supply of nutrients such as glucose, peptone, methionine, purine bases, vitamin B_{12}, biotin and thiamine only increases growth slightly. Visible aggregates are formed when grown in liquid media.

The normal habitat is slowly running, unpolluted, iron- and manganese-containing water of ditches, rivers or ponds.

L. MOBILIS Cells are similar in width to *L. discophora* cells (Fig. 9a), but are usually shorter in length. False branching, which is typical for *L. discophora*, is absent in cultures of *L. mobilis*. Cells are highly motile by a single polar flagellum. Sheaths are not formed under laboratory conditions. Colonies on the agar medium of Rouf and Stokes (1964) are about 1 mm in diameter, circular sometimes with frayed edges, flat, smooth and dark-brown (Fig. 9b). Visible aggregates are formed when grown in liquid media.

The species description is based on only one strain isolated from the sediment of a freshwater lake (Spring et al., 1996).

Preservation

Stock cultures can be stored on agar slants of the medium of Rouf and Stokes (1964) for about two months at 4°C. Rouf and Stokes (1964) reported a better survival of their strains if stored at room temperature instead of refrigerated. Most *Leptothrix* strains do not survive lyophilization. For the long-term preservation of these strains, freezing in liquid nitrogen is recommended using suspensions of cells in freshly prepared medium supplemented with 5% dimethyl sulfoxide (DMSO) as cryoprotectant.

Physiology

The genus *Leptothrix* is characterized by two remarkable metabolic activities: Formation of sheaths and oxidation of iron and manganese.

OXIDATION OF Fe^{2+} AND Mn^{2+} It could be demonstrated in several studies that the deposition of metal-oxides in *Leptothrix* species is biologically controlled. Oxidation of manganese and iron is catalyzed by various metal-oxidizing factors actively secreted by the cell (De Vrind-de Jong et al., 1990).

At circumneutral pH, biological oxidation of iron is difficult to distinguish from the chemical oxidation by oxygen. Only with the identification of an iron-oxidizing protein with a molecular weight of 150 kDa in spent culture medium of the sheathless strain *Leptothrix discophora* SS-1, the capability of biological iron-oxidation in *Leptothrix* species could be clearly demonstrated (Corstjens et al., 1992). The function of iron-oxidation is still unknown, but it seems unlikely to play a role in the generation of energy. It has to be noted, however, that *Gallionella ferruginea*, which is also neutrophilic and microaerophilic, thrives in the same habitats as *L. ochracea* and is able to gain energy from chemolithoautotrophic iron-oxidation (Hallbeck et al., 1993).

Several manganese-oxidizing factors could be identified in culture supernatants of *Leptothrix* species. One component with an estimated molecular weight of 110 kDa could be purified and partly characterized. It is called "manga-

nese-oxidizing factor" (MOF) and consists of protein and probably polysaccharide (Emerson and Ghiorse, 1992). It is assumed that this component is part of a larger complex that originates from membranous blebs and is associated with the sheath structure (Brouwers et al., 2000). Antibodies raised against the MOF protein of *L. discophora* SS-1 allowed retrieval of the gene *mofA*, encoding a putative multi-copper oxidase. A strong indication for an active role of this copper-dependent enzyme in manganese-oxidation is the observation that addition of small amounts of copper to actively growing cultures enhances the rates of manganese oxidation considerably (Brouwers et al., 2000). In addition to multi-copper oxidases, *c*-type hemes could be involved in metal-oxidation by *Leptothrix* species. Genes encoding proteins with potential heme-binding sites were identified as part of the operon encoding *mofA*.

So far, the beneficial effects of manganese oxidation are largely unknown, but it is unlikely that the deposition of manganese oxides has been developed without conferring an important advantage to these bacteria. The benefits of manganese oxidation are probably so difficult to determine because they are only effective under natural conditions difficult to imitate in the laboratory. Traditionally, it was assumed that the positive effects of Mn(II)-oxidizing enzymes and manganese oxides are based on the detoxification of harmful oxygen species (superoxide and peroxide) or on the adsorption of toxic compounds (e.g., heavy metals). Recently, an interesting new perspective was introduced by Sunda and Kieber (1994). They found that manganese oxides are strong chemical oxidants able to attack complex organic compounds (e.g., humic substances), thereby leading to the release of small organic molecules which can be easily assimilated by bacteria.

Structure and Composition of the Sheath

The overall structure and chemical composition of sheaths formed by *Leptothrix* species resemble those of *Sphaerotilus natans*, although several distinguishing traits were found. One characteristic which can be used for the differentiation between both genera is the structure of the sheath surface. In electron micrographs of unstained preparations, the sheath surface appears rough in *Leptothrix* species and smooth in strains of *Sphaerotilus* (Figs. 10 and 12b).

Emerson and Ghiorse (Emerson and Ghiorse, 1993a; Emerson and Ghiorse, 1993b) performed a detailed investigation of the ultrastructure and chemical composition of the *Leptothrix* sheath with the sheath-forming strain *L. cholodnii* (formerly "*L. discophora*") SP-6. They reported that it consists of a condensed fabric of 6.5-nm-diameter fibrils underlying a more diffuse outer capsular layer. The inner sheath layer has a thickness of 30–100 nm and seems to be associated with the outer layer of the Gram-negative cell wall by membrane evaginations. The purified sheath substance contains approximately 34% polysaccharide, 24% protein, 8% lipid, and 4% inorganic material. As major components of the polysaccharide moiety, uronic acids and amino sugars, which are probably in the N-acetylated form, were identified, whereas neutral sugars could not be detected. The sheath proteins are rich in cysteine residues (6 mol%), which confer numerous disulfide- and sulfhydryl-groups to the sheath. The heteropolysaccharide and protein moieties appear to be tightly associated or connected. On the basis of these findings, it was concluded that the principal structural elements of the sheath are proteoglycan fibrils that are covalently linked to each other by interfibril disulfide bonds resulting in a stable fabric. It is possible that the difference between the condensed inner layer and diffuse capsular layer is caused by an increased amount of free sulfhydryl groups in the exterior sheath-layer. A further characteristic of the sheath is its negative charge due to free carboxyl groups, originating mainly from the uronic acids of the sheath-proteoglycans. Both chemical groups, the free sulfhydryl and the free carboxyl groups, provide the sheath with numerous sites for binding of metal cations, especially Mn^{2+} and Fe^{2+}. According to the working model

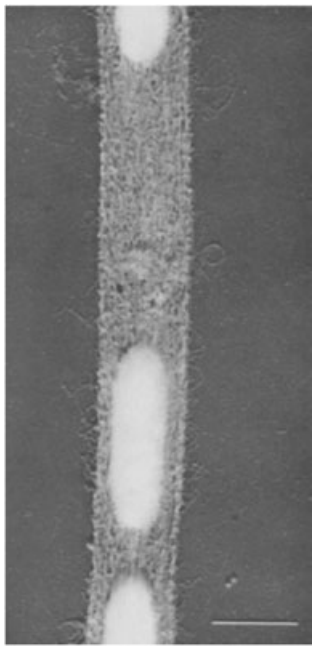

Fig. 10. Electron micrograph of a *Leptothrix* sheath showing a rough surface. Bar = 1 μm. Reproduced with permission from Mulder and Deinema (1992).

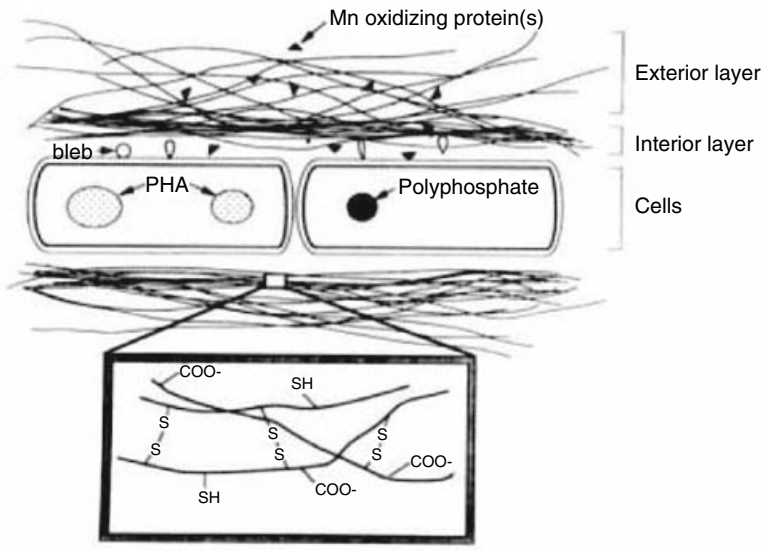

Fig. 11. Schematic model of the architecture and potential function of the sheath in *L. cholodnii* SP-6. PHA, polyhydroxyalkanoate. From Emerson and Ghiorse (1993a), with permission.

presented in Fig. 11, the anionic sheath-fibrils capture and concentrate soluble Mn(II) ions within the sheath, where they can be efficiently oxidized by excreted manganese-oxidizing factors associated with the sheath (Emerson and Ghiorse, 1993a). Manganese- and iron-oxidizing factors are probably excreted from the cell and transported to the sheath as membranous blebs containing protein complexes consisting of multi-copper oxidases and cytochromes (Emerson and Ghiorse, 1992).

The Genus *Sphaerotilus*

Habitat

Members of the genus *Sphaerotilus* are part of the natural microbial community in slowly running freshwater streams, ditches and ponds (Stokes, 1954). In contrast to *Leptothrix* sp., massive growth is typical in freshwater streams that receive high levels of organic pollution from sewage or industrial wastes, especially from paper, potato, dairy or other agricultural industries. When *Sphaerotilus* becomes established in a polluted river, it frequently proliferates so extensively that it lines the riverbed for long distances with a wooly, filamentous carpet (Dondero, 1975).

In poor settling activated sludge (so-called "bulking sludge"), *Sphaerotilus* is frequently found among other filamentous microorganisms (Eikelboom, 1975). Bulking or foaming of activated sludge is a common problem in water purification plants and prevents a ready separation of bacterial sludge flocs from the treated water. It appears that conditions which stimulate the growth of *Sphaerotilus natans* and/or other filamentous bacteria favor also the bulking of activated sludge. The correlation of conditions which favor the prolific growth of a distinct bacterial species with sludge bulking is however hardly possible owing to the high phenotypic diversity of filamentous bacteria which may be involved in this phenomenon (Kämpfer, 1997).

The uncontrolled growth of *Sphaerotilus* in artificial environments bears several risks of economic importance. It can contribute pyrogenic material to purified water for medical injection (Dondero, 1975) and cause damage to technical equipment or machines (Pellegrin et al., 1999). On the other hand, beneficial effects of the growth of *S. natans* are also discussed, e.g., the biosorption of heavy metals in wastewater at low pH values (Solisio et al., 2000; Esposito et al., 2001).

Isolation

Enrichment Procedures In many environments sheathed bacteria occur only in low numbers, for instance in activated sludge or nonpolluted water samples. The use of of enrichment cultures may facilitate the successful isolation of *Sphaerotilus* sp. from such habitats. For that purpose, variations of Winogradsky's hay infusion technique have been used (Mulder and Deinema, 1992). Extracted alfalfa straw (Stokes, 1954) or extracted pea straw (Mulder and Van Veen, 1963) serve as the nutrient material. Most of the soluble organic matter should be removed to prevent proliferation of undesirable organisms. This can be achieved by boiling and extracting the straw after it has been cut into small pieces. Suspensions of the extracted straw in tap water (1–8% [w/v]) are distributed in Erlenm-

eyer flasks and used as enrichment medium. After inoculation with 5–20% of a water sample or activated sludge and incubation for about one week at 22–25°C, filaments of *Sphaerotilus* may be seen in the medium upon microscopic observation. Often tufts of filaments can be found attached to the pieces of straw and also to the side of the flasks at or near the surface of the medium, thereby enabling easy removal using glass capillaries.

Pure cultures can be obtained from homogenized portions of the enriched material as described in the following paragraph.

DIRECT ISOLATION Often slimy masses of *Sphaerotilus* are found attached to submerged surfaces in polluted, slowly running water. Material from such sites can be successfully used for the direct isolation of *S. natans* or related strains by streaking on agar plates. To remove contaminating cells, the collected material should be washed with sterile tap water several times. Homogenization of the washed flocs by blending for a very short time may be useful. However, activated sludge flocs containing many filaments of *Sphaerotilus* should be streaked directly on the agar plates without homogenization step to avoid release of numerous, nonfilamentous cells by destroying the floc structure. The agar plates used should be dry and contain only low levels of nitrogen and carbon to limit the size of undesirable bacterial colonies, leaving large areas for the filamentous organisms. A further reason for the use of nutritionally poor media is the observation that *Sphaerotilus* often forms smooth colonies on nutrient-rich agar, instead of the typical rough colonies, which can be easily recognized. To inhibit the growth of contaminating fungi, the agar medium can be supplemented with cycloheximide (0.005 $g \cdot liter^{-1}$; Pellegrin et al., 1999).

A suitable isolation medium was proposed by Mulder (1989b), having the following basal composition per liter of distilled water: KH_2PO_4, 27 mg; K_2HPO_4, 40 mg; $Na_2HPO_4 \cdot 2\ H_2O$, 40 mg; $CaCl_2$, 50 mg; $MgSO_4 \cdot 7\ H_2O$, 75 mg; $FeCl_3 \cdot 6\ H_2O$, 10 mg; $MnSO_4 \cdot H_2O$, 5 mg; $ZnSO_4 \cdot 7\ H_2O$, 0.1 mg; $CuSO_4 \cdot 5\ H_2O$, 0.1 mg; $Na_2MoO_4 \cdot 2\ H_2O$, 0.05 mg; cyanocobalmin, 0.005 mg; peptone, 1 g; glucose, 1 g; and agar, 7.5 g.

Upon inoculation and incubation of these plates at 20–30°C, colonies of *Sphaerotilus* may be seen and tentatively identified within a few days by their characteristically flat, dull, cotton-like appearance. Confirmation of the identification may be achieved by microscopic observation.

Sphaerotilus may also be isolated by spread plate techniques with or without a previous centrifugation or homogenization step on a variety of agar media (Eikelboom, 1975; Williams and Unz, 1985; Ziegler et al., 1990), including the commercially available R2A agar (Seviour et al., 1994).

Identification

The genera *Sphaerotilus* and *Leptothrix* are closely related and share many phenotypic characteristics. Nevertheless, a clear differentiation of both genera is possible on the basis of phenotypic traits summarized in Table 2. The only recognized species of *Sphaerotilus* is currently *S. natans*. Typical morphological characteristics of this species are false branching of filaments, extensive slime production, attachment of filaments to solid surfaces by holdfast formation (Fig. 12a), deposition of hydrated ferric oxides on sheaths, and motility of cells by means of a bundle of subpolar flagella (Fig. 12b). In contrast to those of *Leptothrix*, the sheaths of *Sphaerotilus* occurring in natural habitats are usually thin and hyaline without encrustations by ferric or manganese oxides (Fig. 12c). However, the capability of Fe(II) oxidation can be easily demonstrated in this species by cultivation in media containing soluble iron compounds and low nutrient concentrations, e.g., soil extract enriched with ferrous iron. Under these growth conditions, the sheaths of *S. natans* turn yellow-brown and resemble in appearance those of *Leptothrix ochracea*. Most of the pronounced morphological characteristics of *S. natans* are largely dependent on the strain and cultivation conditions. Sheath formation can be inhibited by high levels of nutrients in the medium—peptones being more effective than carbohydrates—resulting in the formation of smooth instead of rough, filamentous colonies (Mulder and Van Veen, 1963). This loss of sheath-forming capability is reversible and can occur also spontaneously.

Growth of pure cultures in liquid media is usually flocculent, but sometimes pellicular or homogenous (Pellegrin et al., 1999). Upon prolonged incubation, large, circular bodies resembling protoplasts may appear in broth cultures. Their formation is probably due to the production of enzymes involved in the decomposition of cell walls during the death phase (Phaup, 1968).

The nutritional versatility of *S. natans* and related strains is remarkable. They can utilize a variety of carbon and nitrogen sources, tolerate a wide range of nutrient concentrations and can grow under low partial pressures of oxygen. Utilization of fructose, glucose, maltose, sucrose, lactate, pyruvate, and succinate as sole sources of carbon was reported by Stokes (1954), Mulder and Van Veen (1963), Kämpfer (1998), and Pellegrin et al. (1999). Numerous other carbon

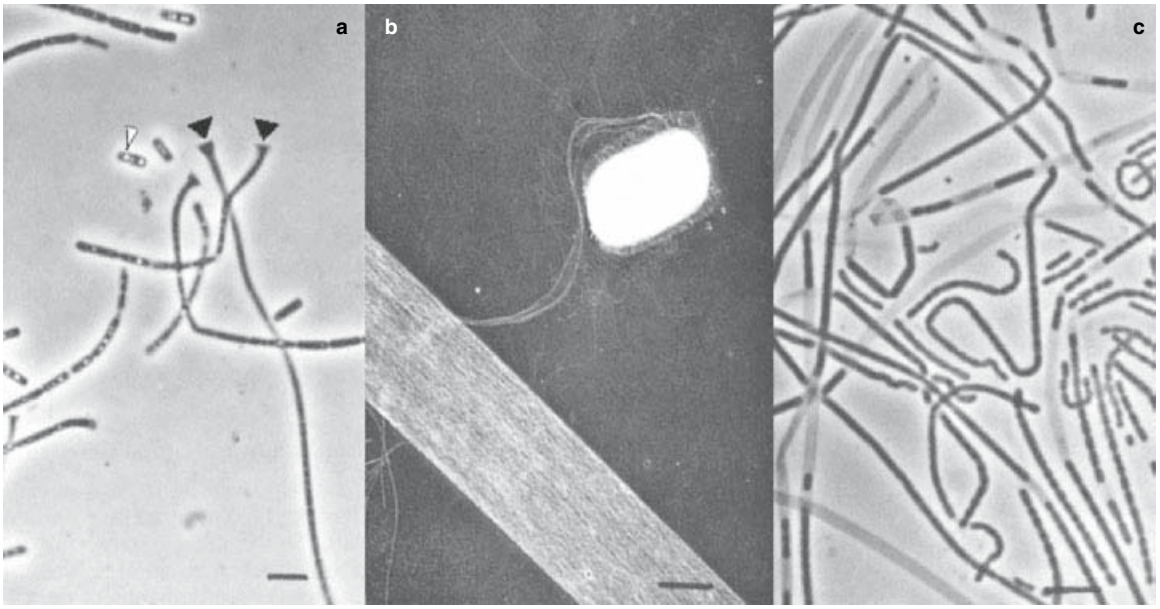

Fig. 12. *Sphaerotilus natans*. (a) Cells with internal granules of poly-β-hydroxybutyrate (white arrowhead) and filaments showing holdfasts (black arrowheads). Bar = 10 μm. (b) Electron micrograph of a single cell with a subpolar tuft of flagella and sheath with smooth surface. Bar = 1 μm. (c) Cells with and without a sheath and empty sheaths. Bar = 10 μm. All figures reproduced with permission from Mulder and Deinema (1992).

sources can be assimilated by strains of *S. natans*, but the substrate utilization patterns of strains within this species differ widely. In contrast to most *Leptothrix* strains, *S. natans* is able to assimilate relatively high concentrations of substrates from which it synthesizes considerable amounts of cellular material. Cells may contain large amounts of poly-β-hydroxybutyrate either as numerous small globules or as a few large globules (Fig. 12a). Polysaccharides may also accumulate. The synthesis of both reserve compounds is stimulated by a high carbon/nitrogen ratio in the medium or by oxygen deficiency (Mulder and Van Veen, 1963).

Preservation

Stock cultures of *S. natans* on agar slants of the previously described media can be stored for about 3 months at 4°C. Addition of 2–3 ml of sterile tap water to the agar slants may prolong the viability for another 3 months. Preservation for longer periods is accomplished by common lyophilization techniques; however, it must be stressed that some *Sphaerotilus* strains do not survive lyophilization. For the long-term preservation of these strains, freezing in liquid nitrogen can be applied.

Physiology

Metabolism *Sphaerotilus* is rarely found associated with deposits of metal oxides in natural environments and typically thrives in habitats with normal concentrations of ferrous iron. So far, the mechanism of iron oxidation in this microorganism is poorly understood and it could be that in *S. natans*, iron oxidation is only a side effect of a biological reaction with a different metabolic function.

Sphaerotilus natans is obligately aerobic and respiratory, but it can grow well with low concentrations of oxygen. It can readily adapt to various nutrient concentrations, growth temperatures (10–40°C) and pH values (pH 5.4–9.0), but seems to be sensitive to an increase in NaCl concentration (upper limit between 0.3 and 0.7%; Dondero, 1975). Glucose is dissimilated via the phosphogluconoate pathway and the tricarboxylic cycle. In the presence of glucose, the oxidation of other sugars, amino acids, and compounds of the tricarboxylic acid cycle seems to be repressed (Dondero, 1975).

Structure and Composition of the Sheath The sheath of *S. natans* is, like the sheath of *Leptothrix*, resistant to proteases and composed of a complex of polysaccharide, protein and lipid. Romano and Peloquin (1963) detected in purified sheath material 36% carbohydrate, 28% protein and 5.2% lipid, whereas Takeda et al. (1998) obtained values of 54.1, 12.2 and 1–3%, respectively. These discrepancies may be due to the investigation of different strains of *S. natans* or the application of various cultivation conditions or sheath purification methods. The surface

of the *S. natans* sheath is smooth and covered with an acidic exopolysaccharide composed of fucose, galactose, glucose and glucuronic acid (Gaudy and Wolfe, 1962). Slime production by exopolysaccharide secretion is much more pronounced in this species than in members of the genus *Leptothrix*. In contrast to the exopolysaccharide of the slime capsule, the sheath carbohydrate is free of acidic sugars and contains only glucose and galactosamine which is probably in its N-acetylated form. A heteropolysaccharide composed of glucose and galactosamine (in a molar ratio of 1 : 4) can be released from the sheath by hydrazine treatment which completely degrades the sheath structure (Takeda et al., 1998). The sheath of *S. natans* can be also degraded enzymatically by a kind of eliminase (produced by a *Paenibacillus* sp.) which attacks the polysaccharide moiety of the sheath (Takeda et al., 2000).

Although the sheath structure is resistant to protease treatment, part of the sheath protein appears to be sensitive to protease attack and can be removed from the sheath by treatment with agents that reduce disulfide bonds. However, in contrast to the *Leptothrix* sheath, disulfide bonds apparently do not play a role in maintaining the sheath structure of *S. natans*. In sheaths treated with protease, the most abundant amino acids were glycine and cysteine. Only three or four other major amino acids were detected, and it was concluded that the sheath protein may consist of repeating subunits of a small peptide which is crosslinked with a polysaccharide backbone (Takeda et al., 1998).

The revealed differences in the fine structure and composition of sheaths from *Sphaerotilus* and *Leptothrix* may be an indication for different functions of these structures for the respective microorganisms.

CHAPTER 3.2.12

The Lithoautotrophic Ammonia-Oxidizing Bacteria

HANS-PETER KOOPS, ULRIKE PURKHOLD, ANDREAS POMMERENING-RÖSER, GABRIELE TIMMERMANN AND MICHAEL WAGNER

Introduction

The lithoautotrophic ammonia-oxidizing bacteria (AOB) are well defined by their fundamental metabolism. Ammonia serves as the sole energy source and carbon dioxide is used to fulfill the carbon need. Together with the lithotrophic nitrite-oxidizing bacteria (see the chapter Nitrite Oxidizing Bacteria in this Volume), the AOB catalyze the so-called "nitrification process" ($NH_3 \rightarrow NO_2^- \rightarrow NO_3^-$), which has a key position in natural nitrogen cycling. Details of the biochemistry of the AOB are reported in the chapter on Oxidation of Inorganic Nitrogen Compounds as an Energy Source in Volume 2. This chapter focuses on the phylogeny, taxonomy, and diversity of AOB as well as on their distribution in nature.

Winogradsky in his fundamental investigations on AOB already postulated the existence of a great diversity of species within this guild (Winogradsky, 1892; Winogradsky and Winogradsky, 1937; Winogradsky and Winogradsky, 1933). However, isolation of AOB turned out to be difficult and was neglected for several decades after Winogradsky's classical studies. Therefore, *Nitrosomonas europaea* was the only species in culture for a long period. Beginning in the 1960s, S. W. Watson from the Woods Hole Research Center (Woods Hole, MA, United States) and others started a new era of isolation and culturing of novel species of AOB. Since that time, 16 species of AOB have been described and named (Watson, 1965; Watson et al., 1971c; Harms et al., 1976; Jones et al., 1988; Koops et al., 1990; Koops et al., 1991), and the existence of many other cultured species has been reported in the literature (Koops and Harms, 1985; Stehr et al., 1995a). Meanwhile, the phylogeny of the described species and the majority of the yet unnamed cultured species has become well established (Woese et al., 1984; Woese et al., 1985; Head et al., 1993; Teske et al., 1994; Pommerening-Röser et al., 1996; Purkhold et al., 2000; Purkhold et al., 2003; see the section on Phylogeny of AOB in this Chapter), providing a sufficient basis for investigations of natural AOB populations employing classical as well as molecular techniques. In particular, the polymerase chain reaction (PCR)-assisted retrieval of 16S rRNA gene or *amoA* gene (encoding the active site subunit of the AOB key enzyme ammonia monooxygenase) sequences from the environment (e.g., Stephen et al., 1996; Purkhold et al., 2000) and the direct identification of AOB via fluorescence in situ hybridization FISH (e.g., Juretschko et al., 1998) allow the diversity of AOB to be monitored and their abundance in situ to be quantified. Results obtained from such investigations together with results from laboratory studies of cultured species have led to a better understanding of the ecology of this bacterial guild.

The following sections describe enrichment and isolation techniques of AOB (see the section on Enrichment, Isolation, and Maintenance in this Chapter), summarize the present knowledge on their taxonomy (see the section on General Characteristics of the Genera and Species of AOB in this Chapter) and phylogeny (see the section on Phylogeny of AOB in this Chapter), and provides an overview of available techniques for investigating AOB (see the "Methods Useful for In Situ Detection of AOB" in this Chapter). The last section aims to reveal possible correlation between ecophysiological characteristics and distribution patterns of the distinct species or groups of species of AOB (see the section on Dominant Populations of AOB in Different Environments in this Chapter).

Enrichment, Isolation, and Maintenance

Isolation procedures in general are targeted to the numerically most abundant AOB of the respective sample site. Therefore, the first step of enrichment should be a most probable number (MPN) dilution series in media, as far as possible reflecting the conditions of the environment under investigation. For example, in enrichments from acidic environments, low pH of the medium and addition of urea as the sole substrate for

energy generation is useful to isolate members of the dominant subpopulation of AOB. In general, the most important factors are the ammonia and the salt concentration in the medium. In some cases, temperature also may be of importance. Two alternative second steps on the way to isolation have been most successful. One option is additional series of dilutions, always using the highest positive dilution of the foregoing MPN series as inoculum. The other option is plating of the bacteria from the highest positive dilution of the original MPN dilution series. It is important to keep in mind that AOB sometimes grow extremely slowly. Therefore, a positive reaction in the highest dilution of an MPN series sometimes may become visible (via pH indicator) not before incubation for two or three weeks, and colony picking from agar plates should await a minimum growth period of 6–8 weeks.

Standard media, useful for enrichment cultures or pure cultures, are presented in Tables 1A and 1B. For stock cultures, calcium carbonate (5 g per liter) or *N*-(2-hydroxyethyl)piperazine-*N*′-2-ethanesulfonic acid (HEPES; 4.77 g per liter) can be used as a pH buffer. In working cultures, the pH should be adjusted by addition of a 10% solution of sodium hydrogen carbonate. This addition is either performed manually (with the aid of a pH indicator) or by using an automatic pH controller. Since ammonia and not ammonium is the substrate of AOB, the pH optimum in part depends on the concentration of the added ammonium salt. Ten mM ammonium salts at a pH of about 8.0 can be regarded as good standard for sufficient growth of AOB cultures. Large volume cultures should be stirred to guarantee a sufficient supply with oxygen. In general, 30°C is a suitable growth temperature. Stock cultures should be transferred to fresh medium every 3–4 months. Storage of AOB cells in liquid nitrogen is possible, whereas freeze-drying of AOB cells in general has not been successful.

General Characteristics of the Genera and Species of AOB

The taxonomic framework of the AOB stems from early investigations of Winogradsky (Winogradsky, 1892; Migula, 1900; Buchanan, 1917; Winogradsky and Winogradsky, 1933). The

Table 1A. Different growth media for lithotrophic ammonia oxidizers.

[a]Suitable buffers are 5.0 g/l $CaCO_3$ and 4 g/l HEPES, respectively.
[b]Medium no. 1 is from Soriano and Walker (1968), for terrestrial strains. Medium no. 2 is from Watson (1971b), for terrestrial strains. Medium no. 3 is from Krümmel and Harms (1982), for terrestrial strains. Medium no. 3 is from Watson (1965), for marine strains. Medium no. 5 is from Koops et al. (1976), for brackish-water strains.

isolates originally were categorized into genera on the basis of the shape of cells. Later, the arrangement of their intracytoplasmic membranes was introduced as a second basic character. Using these criteria, the genera *Nitrosomonas*, *Nitrosococcus*, *Nitrosospira*, *Nitrosolobus* and *Nitrosovibrio* have been established (Watson et al., 1981; Watson et al., 1989; Koops and Möller, 1992). In the following, a brief listing of the distinguishing morphological features of the five recognized genera of AOB is given and the distinct csultured species are described. Differential characteristics of the genera of AOB and of the species of AOB are presented in Tables 2 and 3, respectively.

The Genera

Genus *Nitrosomonas* (Winogradsky, 1892) Cells generally are rod shaped, but sometimes spherical. Extensive intracytoplasmic membranes are arranged as peripherally located flattened vesicles. Sometimes intrusions of membranes into the protoplasm are observed (Fig. 1).

Genus *Nitrosospira* (Winogradsky and Winogradsky, 1933) Cells are tightly closed spirals and occasionally vibrio shaped. Extensive intracytoplasmic membranes are missing. Intrusions of membranes into the protoplasm are sporadically observed (Fig. 2).

Genus *Nitrosovibrio* (Harms et al., 1976) Cells are vibrio shaped. Extensive intracytoplasmic membranes are missing. Intrusions of membranes into the protoplasm are documented (Fig. 3).

Genus *Nitrosolobus* (Watson et al., 1971c) Cells are pleomorphic lobes compartmentalized by the cytoplasmic membrane (Fig. 4).

Genus *Nitrosococcus* (Winogradsky, 1892) This genus solely represents the gamma-proteobacterial AOB. Both described species, *N. oceani* and *N. halophilus*, are characterized by large spherical to ellipsoidal cells revealing extensive intracytoplasmic membranes, arranged as a central stack of vesicles (Fig. 5).

Table 1B. Different media used to ascertain that cultures of ammonia oxidizing bacteria are free of heterotrophic contaminants.

	Medium no.[b]		
Ingredient	1	2	3
Distilled water	1,000ml	600ml	250ml
Seawater		400ml	750ml
Yeast extract (Difco)	0.5g	0.5g	0.5g
Peptone (Difco)	0.5g	0.5g	0.5g
Beef extract (Difco)	0.5g	0.5g	0.5g

[a]The pH of these media should be adjusted to 7.3.
[b]Media no. 1, 2 and 3 are from Koops et al. (1976). Medium no. 1 is for terrestrial and freshwater strains, respectively; no. 2 for brackish-water strains; and no. 4 for marine strains.

The Cultured Species

Since all AOB possess the same fundamental metabolism and morphological differences are per se limited within this group, identification on the species level often is difficult if exclusively phenotypic characters are used. The three genera *Nitrosolobus*, *Nitrosovibrio* and *Nitrosospira*, which phylogenetically form the *Nitrosospira* lineage (see the section on Phylogeny of AOB in this Chapter), are severely affected by this limitation. *Nitrosomonas* species within one of the distinct lineages of this genus often cannot be unambiguously identified using phenotypic characters, while species affiliated with different lineages can more easily be distinguished. In general, DNA-DNA hybridization is the method of choice to define closely related species. The above-mentioned phenotypic similarities among closely related AOB has hampered in many cases formal description of genotypically well-defined, cultured species. Below, important features of AOB species are listed.

Table 2. Characteristics of the genera of the ammonia-oxidizing bacteria.

Characteristics	*Nitrosococcus*	*Nitrosolobus*	*Nitrosomonas*	*Nitrosospira*	*Nitrosovibrio*
Cell shape	Spherical to ellipsoidal	Pleomorphic lobate	Straight rods	Tightly coiled spirals	Slender curved rods
Cell size (μm)	1.5–1.8 × 1.7–2.5	1.0–1.5 × 1.0–2.5	0.7–1.5 × 1.0–2.4	0.3–0.8 × 1.0–8.0	0.3–0.4 × 1.1–3.0
Flagellation of motile cells	Tuft of flagella	Peritrichous	Polar to subpolar	Peritrichous	Polar to subpolar
Arrangement of intracytoplasmic membranes	Central stacks of vesicles	Compartmentalizing membranes	Peripheral flattened vesicles	Invaginations	Invaginations

Table 3. Characteristics and preferred habitats of described species of the ammonia-oxidizing bacteria.

Species	G+C (mol%)	Carboxysomes	Urease activity	Substrate (NH_3) affinity (K, in µM)	Maximum ammonia tolerance NH_4Cl (in mN; pH 8.0)	Salt requirement	Maximum salt tolerance (in mM)	Preferred habitats
Nitrosomonas europaea	50.6–51.4	–	–	30–61	400	–	400	Sewage disposal plants, eutrophic freshwater and brackish water
Nitrosomonas eutropha	47.9–48.5	+	–		600	–	400	
Nitrosomonas halophila	53.8	+	–		400	+	900	
Nitrosococcus mobilis	49.3	–	–		250	+	500	
Nitrosomonas communis	45.6–46.0	–	–	14–43	250	–	250	Soils (not acid) eutrophic freshwater
Nitrosomonas nitrosa	47.9	+	+	19–46	100	–	300	
Nitrosomonas ureae	45.6–46.0	–	+	1.9–4.2	200	–	200	Oligotrophic freshwater and natural soils
Nitrosomonas oligotropha	49.4–50.0	–	+		50	–	150	
Nitrosomonas marina	47.4–48.0	–	+	50–52	200	+	800	Marine environments
Nitrosomonas aestuarii	45.7–46.3	–	+		400	+	600	
Nitrosomonas cryotolerans	45.5–46.1	–	+	42–59	400	+	550	Marine environments
Nitrosolobus multiformis	53.5	ND	+/–	ND	50	–	200	Soils (not acid)
Nitrosovibrio tenuis	53.9	ND	+/–	ND	100	–	100	Soils, rocks and freshwater
Nitrosospira briensis	54	ND	+/–	ND	200	–	250	Soils, rocks and freshwater
Nitrosococcus oceani	50–51	ND	+	ND	1000	+	1100	Marine environments
Nitrosococcus halophilus	50–51	ND	–	ND	500	+	1800	Marine environments and salt lakes

Symbols and Abbreviations: +, present; –, not present; +/–, present in some strains; and ND, no data.

The Species of the Betaproteobacterial AOB

The Nitrosomonas *Group* The cultured species of this genus can be assigned to six distinct, phylogenetically definable lineages (see the section on Phylogeny of AOB in this Chapter), comprising 11 described species. Several further genospecies are in culture but cannot sufficiently be discriminated by phenotypic properties (e.g., Koops and Harms, 1985; Stehr et al., 1995a). In general, described species belonging to different lineages of *Nitrosomonas* are phenotypically well distinguishable (Table 3). However, within the distinct *Nitrosomonas* lineages, species discrimination in many cases is as impossible as observed for the *Nitrosospira* lineage.

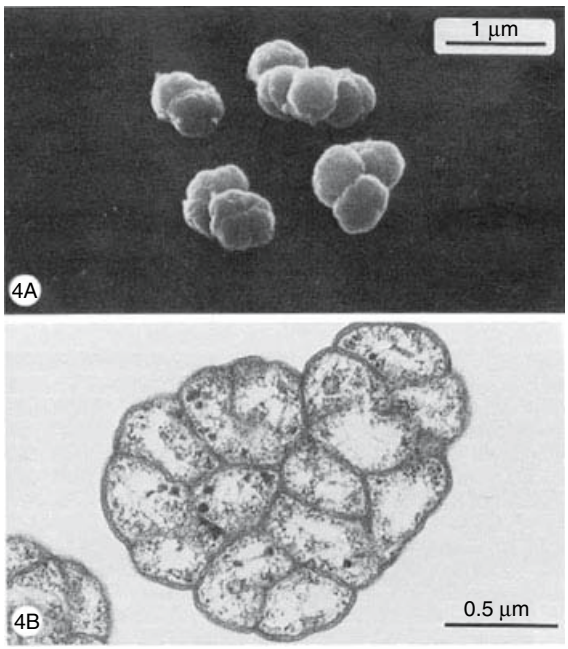

Fig. 4. The genus *Nitrosolobus*. Scanning electron micrograph (A) and electron micrograph of thin sections (B) of cells of *Nitrosolobus* species.

The Nitrosomonas europaea/Nc. mobilis *Lineage* This lineage comprises four described species, all being characterized by a relatively high salt tolerance. Two of these species, *N. halophila* and *Nc. mobilis*, have an obligatory but moderate salt requirement. All reveal relatively high affinity constants for ammonia (50–100 µM), and all cultured strains are urease negative. Consistent with these findings the members of this group seem to prefer eutrophicated aquatic environments with heightened ionic strength. The levels of phylogenetic interrelationships among the four species of this lineage are different. While *N. europaea* and *N. eutropha* reveal absolute close relationship with each other (15–16% DNA-DNA similarity), they show only minimal DNA-DNA similarity values with *N. halophila*, and DNA-DNA similarities are even missing with *Nc. mobilis*, as measured with the S1 nuclease technique (Pommerening-Röser et al., 1996).

Nitrosomonas europaea (Winogradsky, 1890; Watson, 1971a) Cells (0.8–1.1 × 1.0–1.7 µm) are short rods with pointed ends. Motility is not observed, and carboxysomes are missing. Often found in sewage disposal plants, cells are occasionally observed in eutrophicated freshwaters or fertilized soils. They have no obligate salt requirement, but do have a striking tolerance for

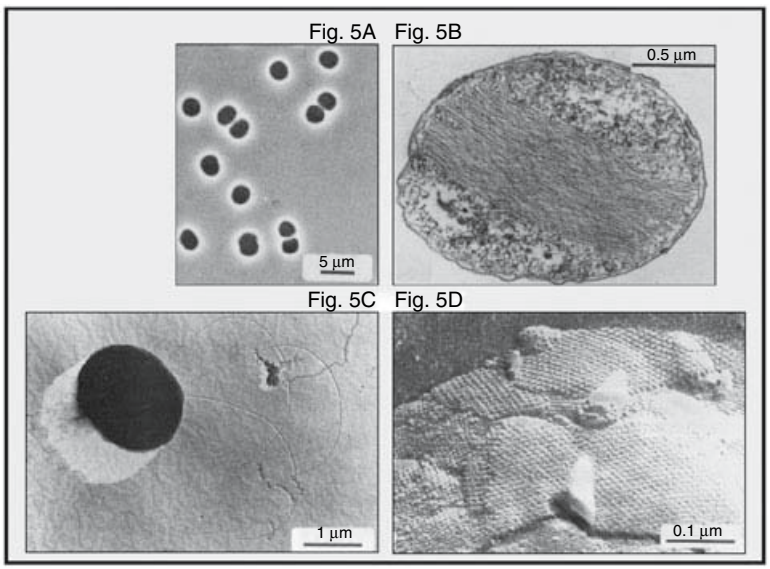

Fig. 5. The genus *Nitrosococcus*. Phase-contrast photomicrographs of whole cells (A) and electron micrographs of thin sections of cells (B) of *Nitrosococcus halophilus*. (D) Freeze-etch electron micrograph of *Nitrosococcus oceani* showing the macromolecular arrangement of the two layers outside of the envelope.

increasing salt concentration up to 400 mM NaCl. The G+C content of DNA is 50.6–51.4 mol%.

Nitrosomonas eutropha (Koops et al., 1991) Cells occur singly or as short chains and are pleomorphic, rod- to pear-shaped, with one or both ends are pointed. Cells (1.0–1.3 × 1.6–2.3 μm) are motile, and carboxysomes are observed. The species is commonly distributed in sewage disposal plants, and occasionally it has been isolated from other eutrophicated environments. The species has no salt requirement but is tolerant to high salt concentration up to 400 mM NaCl. The G+C content of DNA is 47.9–48.5 mol%.

Nitrosomonas halophila (Koops et al., 1991) Cells (1.1–1.5 × 1.5–2.2 μm) occasionally appear coccoid. Motile cells possess a tuft of flagella, and carboxysomes are observed. Cells have an obligate salt requirement, and some isolates are alkali tolerant up to pH 10. Cells tolerate high salt concentration (up to 900 mM NaCl). Strains were isolated from the North Sea and from soda lakes located in Mongolia (Sorokin et al., 2001). The G+C content of DNA is 53.8 mol%.

Nitrosococcus (*Nitrosomonas*) *mobilis* (Koops et al., 1976) Cells (1.5–1.7 × 1.5–2.1 μm) are coccoid or rod shaped. Carboxysomes have not been observed. Motile cells possess a tuft of flagella. Cells have an obligate salt requirement. Isolates originate from the North Sea (Koops and Harms, 1985) and from an industrial wastewater treatment plant (Juretschko et al., 1998). The species seems to prefer eutrophic, aquatic environments. The G+C content of DNA is 49.3 mol%.

The Nitrosomonas communis *Lineage* According to phenotypic properties, this lineage is divided into two sublineages. This division is also supported by DNA-DNA similarity data (Pommerening-Röser et al., 1996). One subgroup contains *N. communis* together with two undescribed cultured genospecies (see the section on Phylogeny of AOB in this Chapter) that are phenotypically not well distinguishable. These three species are urease negative and prefer agricultural soils with neutral pH. The other subgroup is represented by a single species, *N. nitrosa*. In contrast to the first subgroup, all isolates of *N. nitrosa* are urease positive, and aquatic environments are the preferred habitats.

Nitrosomonas communis (Koops et al., 1991) Cells (1.0–1.4 × 1.7–2.2 μm) are relatively large rods with rounded ends. Motility is not observed, and carboxysomes are missing. Moderately eutrophicated, pH neutral soils seem to be the preferred habitat and freshwater only an occasional habitat. The G+C content of DNA is 45.6–46.0 mol%.

Nitrosomonas nitrosa (Koops et al., 1991) Cells (1.3–1.5 × 1.4–2.2 μm) are spheres or rods with rounded ends. Motility is not observed. Carboxysomes are present. Although eutrophicated freshwaters seem to be the preferred habitats, strains occasionally have been isolated from marine environments and a wastewater treatment plant. The G+C content of the DNA is 47.9 mol%.

The Nitrosomonas oligotropha *Lineage* Two described species and several undescribed genospecies (e.g., *Nitrosomonas* sp. Nm47, *Nitrosomonas* sp. Nm86, *Nitrosomonas* sp. Nm84, and *Nitrosomonas* sp. Nm59) belonging to this lineage exist in culture (see the section on Phylogeny of AOB in this Chapter). The absolute majority of strains originate from oligotrophic freshwaters, and only occasional isolates are from natural, often moderately acidic (pH about 6.0) soils. All strains investigated thus far reveal strikingly low affinity constants for ammonia (few μM) and almost all isolates are urease positive. All studied strains turned out to be salt sensitive.

Nitrosomonas oligotropha (Koops et al., 1991) Cells (0.8–1.2 × 1.1–2.4 μm) are rod shaped or spherical with rounded ends. Cell aggregates, obviously caused by extensive production of exopolymeric materials, are observed in the environment as well as in pure culture. Carboxysomes are missing, motility is not observed. The G+C content of DNA is 49.4–50.0 mol%.

Nitrosomonas ureae (Koops et al., 1991) Phenotypically very similar to *N. oligotropha* but distinguishable by a lower G+C content of the DNA (45.6–46.0 mol%).

The Nitrosomonas marina *Lineage* This lineage is represented by two described species and one undescribed genospecies (represented by the isolates Nm51 and Nm63; see the section on Phylogeny of AOB in this Chapter). All isolates originate from marine environments and reveal an obligate salt requirement. In general, isolates are urease positive.

Nitrosomonas marina (Koops et al., 1991) Cells (0.7–0.9 × 1.7–2.2 μm) are slender rods with rounded ends. Motility is not observed, and carboxysomes are missing. The G+C content of DNA is 47.4–48.0 mol%.

Nitrosomonas aestuarii (Koops et al., 1991) Phenotypically, this species is very similar to *N. marina*. Cells (1.0–1.3 × 1.4–2.0 μm) are rod shaped. The G+C content of DNA is 45.7–46.3 mol%.

The Nitrosomonas cryotolerans *Lineage* Only one species has yet been described, and only one strain is available in culture. The only cultured strain of *Nitrosomonas cryotolerans* (Jones et al., 1988) originates from surface water of the Kasitsna Bay (Alaska). The rod shaped cells (2.0–4.0 × 1.2–2.2 μm) requires salt and is urease positive. Carboxysomes are missing. Motility has not been observed. Intracytoplasmic membranes are not exclusively peripherally arranged, as is typical for the other members of the genus *Nitrosomonas*, but sometimes membranes intrude deep into the cytoplasm and often surround the nucleoplasm. Cultures can grow at temperatures as low as –5°C. The G+C content of DNA is 45.5–46.1 mol%.

The Nitrosomonas *sp. Nm143 Lineage* In total four isolates belonging to this lineage are available in culture (Ward, 1982; Ward and Carlucci, 1985; Purkhold et al., 2003; see the section on Phylogeny of AOB in this Chapter) but were not described by name. All isolates were obtained from marine systems.

The *Nitrosospira* Lineage Within this group of microorganisms, the three genera *Nitrosospira*, *Nitrosolobus*, *Nitrosovibrio* (each encompassing a single described species) and several genospecies (see the section on Phylogeny of AOB in this Chapter) have been described. While the genera show discriminative morphological characters, phenotypic species discrimination within the distinct genera is very difficult. However, the DNA G+C content differs significantly among genospecies or groups of genospecies (Koops and Harms, 1985). Different affinity constants for the binding of ammonia and different tolerances for increasing ammonia or salt concentrations could eventually serve as distinguishing features. Furthermore, temperature was observed as a factor that could be used to discriminate among species (Jiang and Bakken, 1999). However, no robust phenotypically based system for discriminating between species of the distinct genera is currently available. Unfortunately, this situation is consistent with the lack of sufficient resolution within 16S rRNA gene-based phylogenetic trees of the *Nitrosospira* lineage (see the section on Phylogeny of AOB in this Chapter).

THE GENUS *NITROSOSPIRA* This genus contains many cultured genospecies (see the section on Phylogeny of AOB in this Chapter) that cannot sufficiently be discriminated by phenotypic characteristics (Koops and Harms, 1985). However, two groups, containing two and three distinct species, respectively, can be distinguished on the basis of DNA G+C values around 53.5 and 55.2 mol%, respectively. The existence of these two groups later has been confirmed by DNA-DNA hybridizations applying the S1 nuclease technique (Pommerening-Röser, 1993). Unfortunately, only a few of the numerous cultured species have yet been included in such investigations. All cultured species are more or less pleomorphic, varying in shape between tightly closed spirals and vibrio-forms. All species, thus far studied, have urease-positive as well as -negative strains at similar frequencies. Species are commonly distributed in natural soils and, occasionally, occur in freshwater environments. Via molecular studies, representatives of *Nitrosospira* have also been detected in marine environments (McCaig et al., 1994; Stephen et al., 1996; Phillips et al., 1999; Bano and Hollibaugh, 2000; Horz et al., 2000; Hollibaugh et al., 2002; Nicolaisen and Ramsing, 2002). However, marine isolates do not exist and salt requirement has not yet been observed among cultured *Nitrosospira* strains.

Cells of *Nitrosospira briensis* (Winogradsky and Winogradsky, 1933) are motile cells and possess 1–6 peritrichous flagella. Strains of this species have been isolated from soils. The type strain is urease negative, but other isolates of this species are urease positive. The G+C content of DNA is about 54 mol%.

THE GENUS *NITROSOVIBRIO* Only one species is in culture. All strains of this species have exclusively vibrio-shaped cells. Pleomorphy, as observed with several genospecies of the genus *Nitrosospira*, has not yet been detected.

The three cultured strains of *Nitrosovibrio tenuis* (Harms et al., 1976) were isolated from natural soils and are urease positive. Cells are slender curved rods (0.3–0.4 × 1.1–3.0 μm). Motile cells possess 1–4 subpolar flagella. The G+C content of DNA is 53.9 mol%.

THE GENUS *NITROSOLOBUS* The genus is characterized by the pleomorphic, lobate cells which are compartmentalized by the cytoplasmic membrane. One described species and one genospecies (*Nitrosolobus* sp. NL5) are available. Both species are distinguishable by cell size and by a significantly different DNA G+C content of 53.5 and 56.5%, respectively (Koops and Harms, 1985). Most of the isolates of both species originate from soils, generally being pH-neutral and agriculturally used. One strain of *Nitrosolobus* sp. was obtained from a sewage disposal plant.

The cells of *Nitrosolobus multiformis* (1.0–1.5 × 1.0–2.5 µm; Watson et al., 1971c) are pleomorphic, motile, and possess 1–20 peritrichous flagella. Cell division is by constriction. The G+C content of DNA is about 53.5 mol%.

The Species of the Gammaproteobacterial AOB

The gammaproteobacterial AOB are represented by only two species of the genus *Nitrosococcus*: *N. oceani* and *N. halophilus*. Both species have a similar morphology. However, both are different in salt requirement, salt tolerance, and ammonia tolerance (Table 3). Moreover, the observation that all cultured strains of *N. oceani* possess urease whereas the two isolates of *N. halophilus* are urease negative indicates another discriminating character. However, more strains must be studied to verify these distinguishing features. A third species, *N. nitrosus*, is no longer available in culture.

Nitrosococcus nitrosus (Migula, 1900) This species is no longer available in culture, and nothing is known about its ecophysiology or its phylogenetic position. This species should be placed on the list of rejected names.

Nitrosococcus oceani (Watson, 1965; Watson, 1971a; Trüper and de Clari, 1997) This species originally was described as *Nitrosocystis oceanus* (Watson, 1965) and later renamed "*Nitrosococcus oceanus*" (Watson, 1971a), before the presently accepted name *Nitrosococcus oceani* was established (Trüper and de Clari, 1997). Spherical or ellipsoidal cells (1.8–2.2 µm in diameter) occur singly or as pairs. Motile cells possess 1–20 flagella (tuft). Two surface layers exist, being composed of subunits arranged in rectilinear and hexagonal arrays (Fig. 5). Intracytoplasmic membranes are arranged as a stack of parallel, flattened vesicles (Murray and Watson, 1965; Watson, 1965; Watson and Remsen, 1970). All cultured strains originate from marine environments, and all are urease positive. The G+C content of DNA is between 50 and 51 mol%.

Nitrosococcus halophilus (Koops et al., 1990) Both species are morphologically not distinguishable from *N. oceani*, but differ in salt requirement and salt tolerance as well as in ammonia tolerance (Table 3). The two cultured strains were isolated from an inland salt lake and from a salt lagoon in the Mediterranean Sea, respectively. In contrast to the cultured strains of *N. oceani*, the two isolates of *N. halophilus* are urease negative. The G+C content of DNA is 50–51 mol%.

Phylogeny of AOB

The phylogenetic framework of AOB has been established by comparative 16S rRNA gene sequence analysis of the cultured species. During the last years, this system has been significantly extended by including environmentally retrieved 16S rRNA gene sequences.

The Cultured AOB

The first phylogenetic analyses of AOB were carried out by Woese and co-workers in the 1980s (Woese et al., 1984; Woese et al., 1985) and demonstrated that two phylogenetically distinct groups of AOB exist. The major group, containing the genera *Nitrosomonas*, *Nitrosospira*, *Nitrosovibrio* and *Nitrosolobus*, belongs to the class Betaproteobacteria, while the second group of AOB, represented by two species of the genus *Nitrosococcus*, is affiliated with the class Gammaproteobacteria (see the chapter Oxidation of Inorganic Nitrogen Compounds as an Energy Source in Volume 2). These results, obtained from 16S rRNA oligonucleotide catalogues, were later confirmed and extended via comparative 16S rRNA gene sequence analysis (Head et al., 1993; Teske et al., 1994; Utaaker et al., 1995; Purkhold et al., 2000). Today, almost complete 16S rRNA gene sequences are available for the 14 described species of AOB affiliated with the Betaproteobacteria. Furthermore, more than 100 16S-rRNA gene sequences of other AOB isolates belonging to this class have been determined. Within the Betaproteobacteria, the AOB form a well-supported monophyletic evolutionary group (Head et al., 1993; Teske et al., 1994). The minimal 16S rRNA gene sequence similarity between recognized members of this group is 89.4% (*Nitrosococcus mobilis*/*Nitrosomonas nitrosa*). Figure 6 shows a phylogenetic 16S rRNA-based tree of those AOB (15 nitrosospiras and 19 nitrosomonads) demonstrated to represent different genospecies (DNA-DNA similarity less than 60% and/or 16S rRNA sequence similarity less than 97.5%). The genera *Nitrosospira*, *Nitrosolobus* and *Nitrosovibrio* are closely related, and 16S rRNA phylogeny provides no convincing support for subdivision of this lineage into three genera, although morphological and ecophysiological differences exist between the different genera (see the section on General Characteristics of the Genera and Species of AOB in this Chapter). It has therefore been suggested these genera be lumped into the single genus *Nitrosospira* (Head et al., 1993). In contrast, the cultured nitrosomonads can be subdivided into six lineages which are consistently

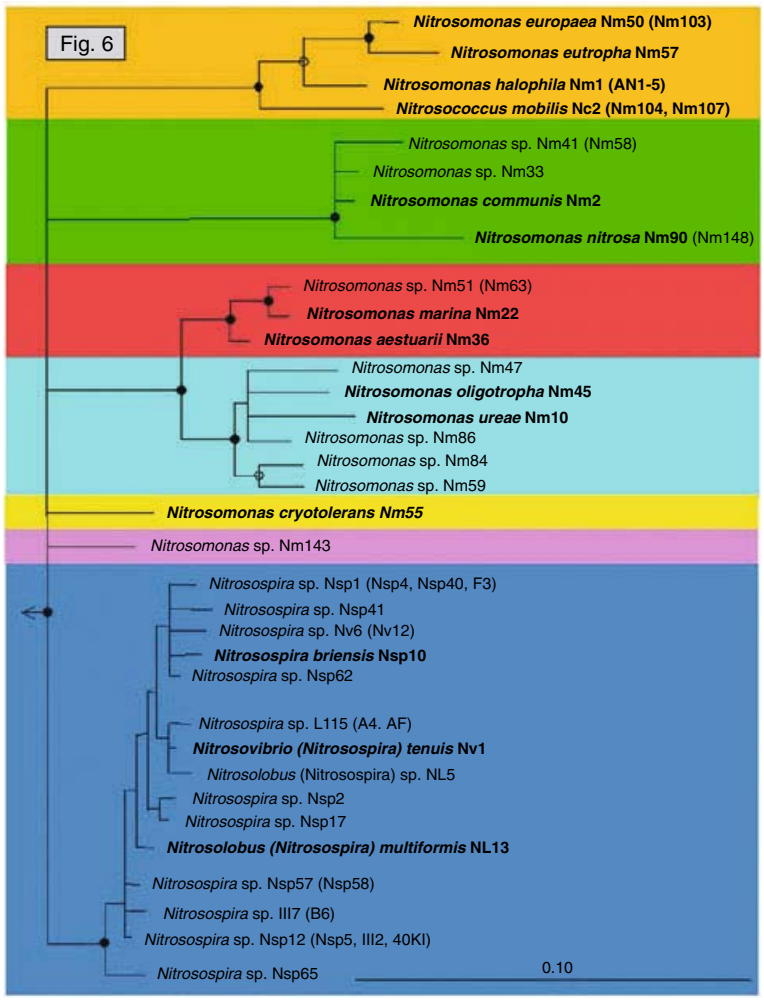

Fig. 6. 16S rRNA-based phylogenetic tree of the betaproteobacterial AOB. The tree includes only those AOB which have been demonstrated to represent different genospecies (DNA-DNA similarity < 60%) and for which 16S rRNA gene sequences longer than 1000 nucleotides are available. Strains with DNA-DNA similarity > 60% with each other are given in parenthesis after the respective species name. Described species are depicted in bold. Maximum likelihood, maximum parsimony, and neighbor-joining trees were calculated and merged. Multifurcations connect branches for which a relative order cannot be unambiguously determined by applying different treeing methods. Filled and empty dots indicate parsimony bootstrap values (100 resamplings) above 90% and 70%, respectively. Scale bar represents 10% estimated sequence divergence.

retrieved using different treeing methods and which (if consisting of more than one sequence) have parsimony bootstrap support of above 90%. This phylogenetic substructure is also retrieved if all betaproteobacterial AOB isolates (56 nitrosomonads and 48 nitrosospiras), for which a 16S rRNA sequence longer than 1000 bases has been determined, are included in the treeing analysis (Figs. 7 and 8). For the different groups within the nitrosomonads, different nomenclature systems are used in the literature (Pommerening-Röser et al., 1996; Stephen, 1996; Purkhold et al., 2000; Aakra et al., 2001b; see also Fig. 7). To avoid confusion, we herein propose a hierarchical system for subdivision of the betaproteobacterial AOB as displayed below for further use. New lineages should only be postulated if 1) almost full-length 16S rRNA sequences for the respective AOB exist and 2) the lineages can be retrieved with all treeing methods with high bootstrap support. The lineages are subdivided into recognized species and genospecies with each of these units possibly containing several strains. In the following, a brief list (consistent with the above rules) of those units within the betaproteobacterial AOB is presented:

Betaproteobacterial AOB
- Nitrosospira lineage
  - (Genus *Nitrosospira*)
  - (Genus *Nitrosolobus*)
  - (Genus *Nitrosovibrio*)
- *Nitrosomonas* group
  - *N. europaea*/*Nc. mobilis* lineage
  - *N. communis* lineage
  - *N. marina* lineage
  - *N. oligotropha* lineage
  - *N. cryotolerans* lineage
  - *Nitrosomonas* sp. Nm143 lineage

Although 16S rRNA phylogeny of the nitrosospiras does not reveal an obvious substructure, Stephen et al. (1996) suggested subdivision of this group into three "clusters" (clusters 2, 3 and 4, Fig. 8; cluster 1 contains no cultured species,

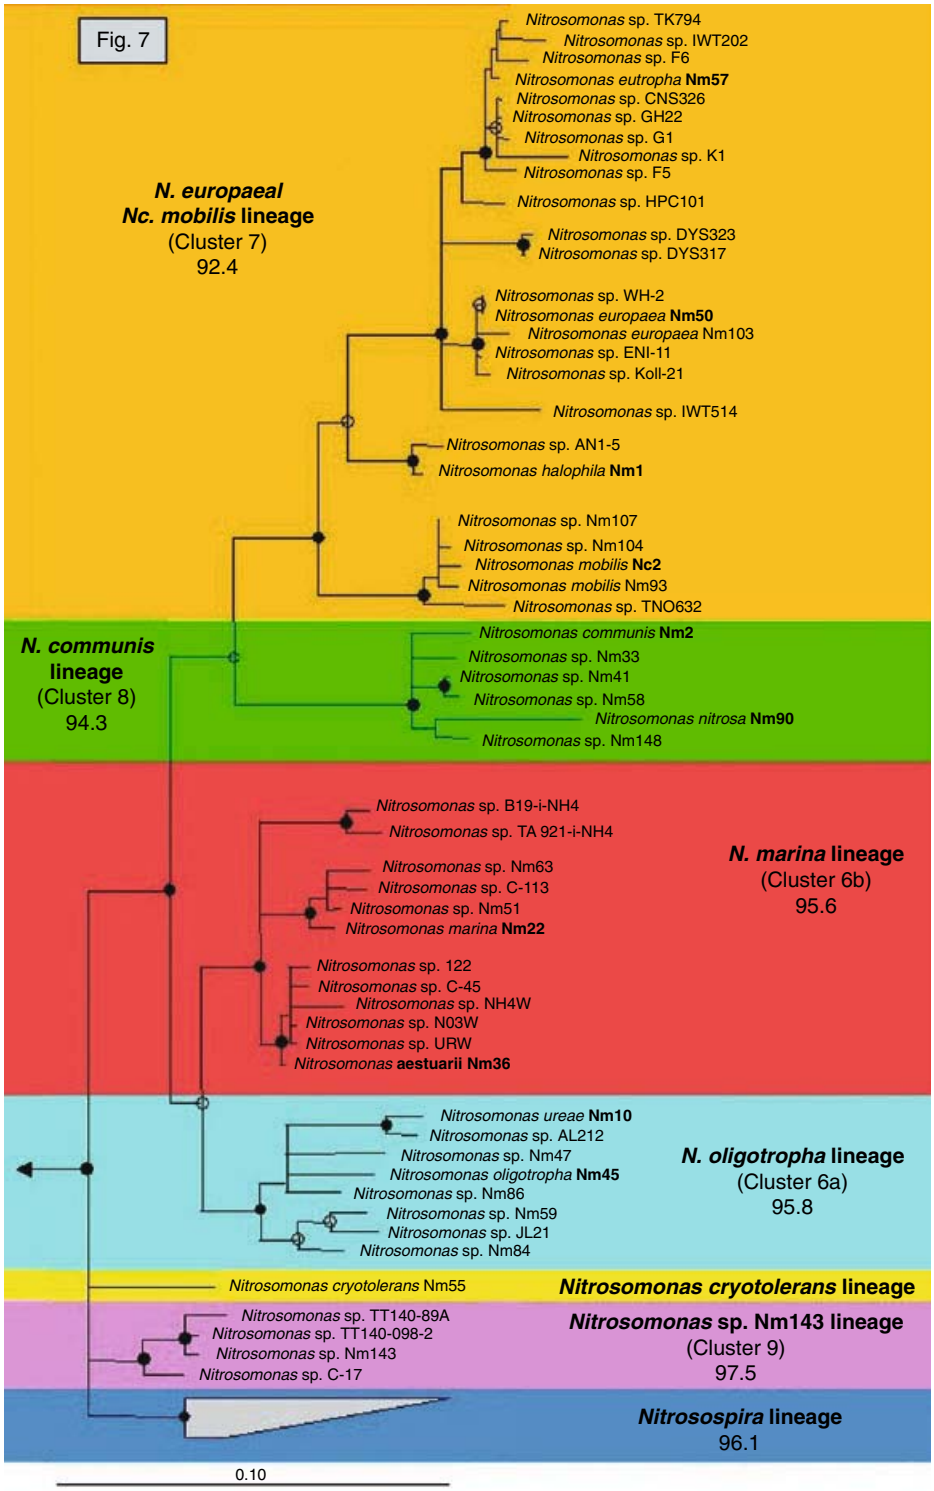

Fig. 7. 16S rRNA based phylogenetic tree of the nitrosomonads. The tree includes all isolates for which 16S rRNA gene sequences longer than 1000 nucleotides are available. Described species are depicted in bold. Maximum likelihood, maximum parsimony, and neighbor-joining trees were calculated and merged. Multifurcations connect branches for which a relative order cannot be unambiguously determined by applying different treeing methods. Filled and empty dots indicate parsimony bootstrap values (100 resamplings) above 90% and 70%, respectively. For each cluster, the minimum 16S rRNA sequence similarity between two of its members is depicted. Sequences included in the analysis were published by Head et al. (1993), Suwa et al. (1997), Juretschko et al. (1998), Sorokin et al. (1998), Aakra et al. (1999a), Aakra et al. (1999b), Yamagata et al. (1999), Purkhold et al. (2000), and Purkhold et al. (2002). Sequences of strains CNS326, G1, K1, IWT202, TK794, WH-2, Koll-21, DYS317, DYS323, IWT514, TNO632, marine bacteria C-45, NH4W, 122, URW, NO3W, C-113, TT140-098-2, TT140-89A, and estuarine bacteria TA 921-i-NH4, B19-i-NH4, C-17 are unpublished but available at GenBank. Scale bar represents 10% estimated sequence divergence.

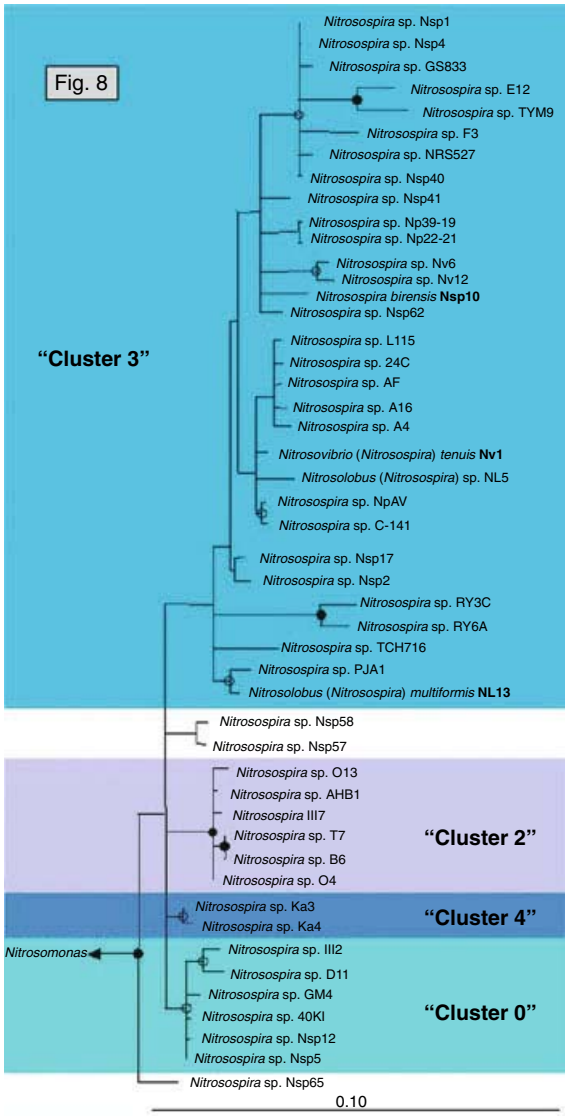

Fig. 8. 16S rRNA-based phylogenetic tree of the highly related genera *Nitrosospira*, *Nitrosolobus*, and *Nitrosovibrio*. The tree includes all isolates for which 16S rRNA gene sequences longer than 1000 nucleotides are available. Described species are depicted in bold. Maximum likelihood, maximum parsimony, and neighbor-joining trees were calculated and merged. Multifurcations connect branches for which a relative order cannot be unambiguously determined by applying different treeing methods. Filled and empty dots indicate parsimony bootstrap values (100 resamplings) above 90% and 70%, respectively. Sequences included in the analysis were published by Head et al. (1993), Teske et al. (1994), Utaaker et al. (1995), Tokuyama et al. (1997), Aakra et al. (1999a), Aakra et al. (1999b), Aakra et al. (2001b), and Purkhold et al. (2002). Sequences of strains GS833, E12, NRS527, NpAV, RY6A, RY3C, TCH716, and PJA1 are unpublished but available at GenBank. Scale bar represents 10% estimated sequence divergence.

see the section on Environmental Sequences in this Chapter). Purkhold et al. (2000) subsequently extended this system by the proposing cluster 0. These nitrosospira clusters are found with all treeing methods but not all of them are well supported by bootstrap analysis. Therefore, clusters of the *Nitrosospira* lineage are not comparable with the distinct lineages within the *Nitrosomonas* group. This reflects the fact that the minimum 16S rRNA sequence similarity of 96.1% within the entire *Nitrosospira* group is higher than those within the individual, described *Nitrosomonas* lineages (Fig. 7). It should also be noted that DNA-DNA hybridization analyses suggest that the *Nitrosospira* clusters 0, 2 and 4 might each represent only one single species (H.-P. Koops, unpublished observation). Taken together, it is thus questionable whether subdivision of the *Nitrosospira* lineage into the above-mentioned clusters or other subdivisions (Aakra et al., 2001b) is justified.

Owing to the limited discriminatory power of comparative 16S rRNA analysis, in particular for the *Nitrosospira* lineage, other phylogenetic marker molecules were tested for phylogeny inference of AOB. Aakra and co-workers determined the 16S–23S rRNA gene intergenic spacer region (ISR) of several AOB and used these sequences for phylogenetic analysis (Aakra et al., 2001b). In that study, the authors postulated highly consistent ISR- and 16S rRNA-based tree topologies for AOB and thus suggested the usefulness of the ISR for future studies on AOB diversity and evolution. However, careful inspection of the phylogenetic trees presented in that publication reveal significant topological incongruencies between 16S rRNA and ISR trees. Owing to the high variability of the ISR, these sequences are very difficult to align and not suitable to reliably determine evolutionary relationships above the species level.

Recently, the *amoA* gene coding for the active site polypeptide of the ammonia monooxygenase has been used as an additional phylogenetic marker molecule for AOB (McTavish et al., 1993; Klotz and Norton, 1995; Rotthauwe et al., 1995; Suwa et al., 1997; Hommes et al., 1998; Alzerreca et al., 1999; Yamagata et al., 1999; Horz et al., 2000; Purkhold et al., 2000; Aakra et al., 2001a; Casciotti and Ward, 2001; Purkhold et al., 2003). PCR primers that allow amplification of a 453-bp fragment of this gene are generally used in these studies (Rotthauwe et al., 1997; modified by Stephen et al., 1999). Phylogeny inference based on the deduced amino acid sequence of the *amoA* gene fragment is overall consistent with the 16S rRNA phylogeny of AOB. Members of the genera *Nitrosospira*, *Nitrosolobus* and *Nitrosovibrio* form a tight monophyletic grouping with no obvious substructure. Within the

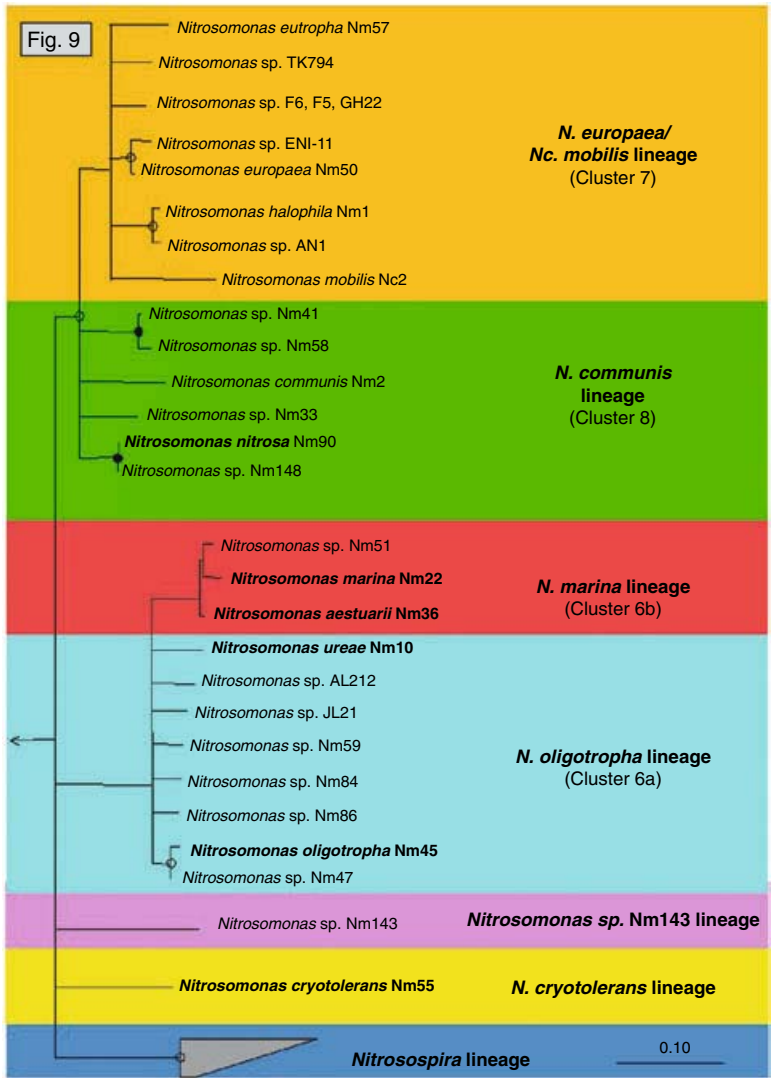

Fig. 9. AmoA-based phylogenetic tree of the betaproteobacterial AOB. Described species are depicted in bold. The 453-bp gene fragment obtainable with the most commonly used amoA PCR primers (Rotthauwe et al., 1995) was used for phylogeny inference. AmoA sequences shorter than 414 nucleotides were excluded from the analysis. Protein maximum likelihood, protein maximum parsimony, neighbor-joining, and Fitch trees were calculated and merged. Multifurcations connect branches for which a relative order cannot be unambiguously determined by applying different treeing methods. Filled and empty dots indicate parsimony bootstrap values (100 resamplings) above 90% and 70%, respectively. Sequences included in the analysis were published by McTavish et al. (1993), Holmes et al. (1995), Rotthauwe et al. (1995), Suwa et al. (1997), Yamagata et al. (1999), Aakra et al. (2001a), Casciotti et al. (2001), Sorokin et al. (2001), Norton et al. (2002), and Purkhold et al. (2003). Sequences of *Nitrosospira* sp. C-57 and *Nitrosomonas* sp. TK794 are unpublished but available at GenBank. Scale bar represents 10% estimated sequence divergence.

nitrosomonads the *N. europaea*/*Nc. mobilis* lineage and the *N. marina* lineage are also found with all treeing methods, while the *N. communis* and the *N. oligotropha* lineage are not always monophyletic (Fig. 9). If *amoA* nucleic acid sequences are used for phylogenetic analysis, basically the same picture emerges with the exception that the *N. europaea*/*eutropha* lineage is no longer monophyletic (data not shown). If compared to the 16S rRNA-based phylogeny of AOB, AmoA analysis does provide less resolution, reflecting that a relatively short (151 positions) and highly conserved (93 positions have an identical amino acid in at least 98% of the betaproteobacterial AOB) amino acid sequence stretch is used as marker. The information content of AmoA sequences could be significantly extended in future studies by the development of primers that allow the amplification of more complete *amoA* gene fragments. First attempts in this direction were recently published by Norton et al. (2002).

Correlation plots of *amoA* and AmoA similarity versus 16S rRNA similarity of all possible pairs of betaproteobacterial AOB isolates (Fig. 10) demonstrate that 1) 16S rRNA is more conserved than *amoA* or AmoA and 2) AOB showing below 80% *amoA* nucleic acid similarity (or 85% AmoA amino acid similarity) always possess less than 97.0% 16S rRNA sequence similarity (the currently accepted 16S rRNA threshold value for bacteria genospecies assignment; Stackebrandt and Goebel, 1994). AmoA sequences of a new AOB isolate with less than 80% nucleic acid similarity (or 85% amino acid similarity) to described AOB species are thus indicative of a previously undiscovered species. An *amoA* or AmoA sequence with a higher similarity to a described AOB species can represent multiple gene copies, different strains

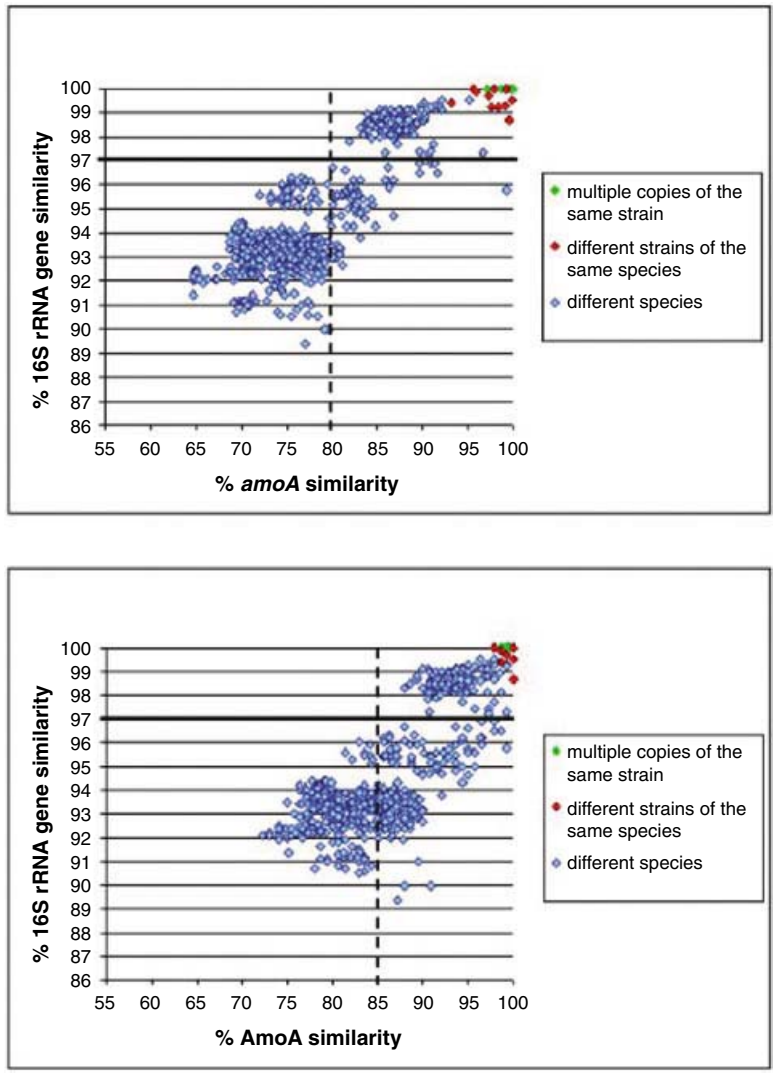

Fig. 10. Correlation plots of 16S rRNA similarity with amoA (panel A) and AmoA (panel B) similarity values. Solid lines indicate 16S rRNA threshold values for species delineation. Dotted lines indicate the amoA and AmoA threshold values below which amoA and AmoA sequences are indicative of novel AOB species.

of this species, or a novel AOB species. The latter possibility exists since 16S rRNA similarities between different species can be higher than 97%.

Environmental Sequences

Molecular diversity surveys of AOB almost exclusively focussed on betaproteobacterial AOB. Stephen et al. (1996) were the first to investigate the diversity of these bacteria in an environmental sample using directly retrieved 16S rRNA gene sequences (see the section on Molecular Techniques in this Chapter). Since then, AOB species richness of numerous natural and engineered systems has been analyzed by the 16S rRNA approach. However, the PCR primers applied in several of these studies do not cover all recognized AOB and thus probably provided a biased view of the natural AOB diversity and their environmental distribution (see the section on Molecular Techniques in this Chapter). Interestingly, of the 508 16S-rRNA clones affiliated with betaproteobacterial AOB (status August 2002), more than 83% cluster with cultured representatives of this guild. The remaining clones form two novel clusters, one within the nitrosomonads (environmental lineage 5) and one within the nitrosospiras (cluster 1; Fig. 11). On the basis of the results of the various AOB 16S rRNA diversity surveys, environmental distribution patterns of the different AOB clusters can be revealed and compared to the findings obtained with cultivation-based methods (Fig. 12). A more detailed discussion of environmental distribution patterns of the different AOB is provided in a separate section (see the section on Distribution of AOB in Nature in this Chapter).

The natural diversity of ammonia oxidizers in various environments also has extensively been studied by comparative sequence analysis

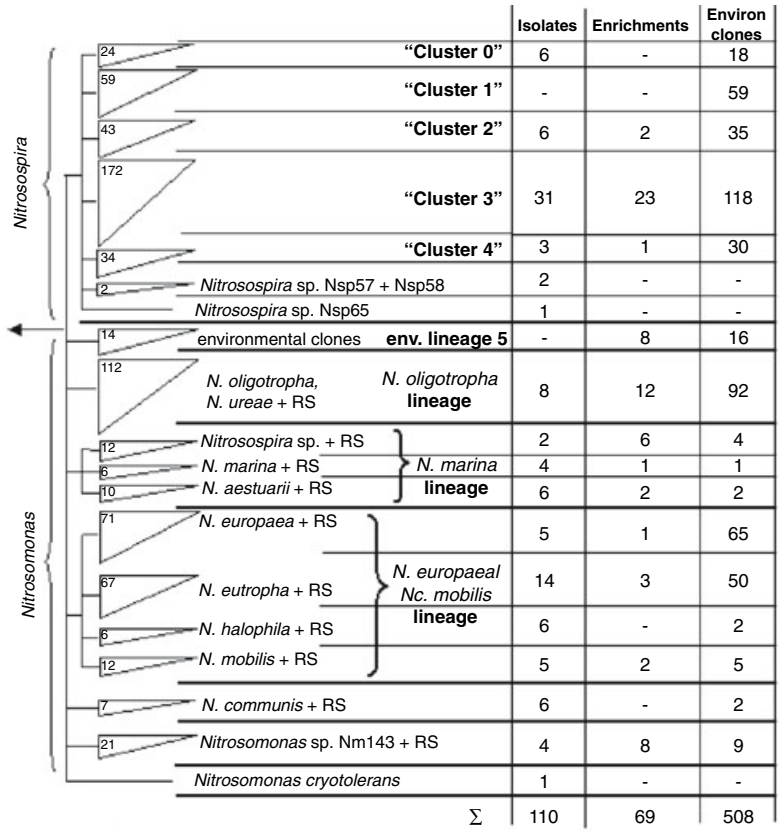

Fig. 11. Schematic 16S rRNA-based phylogenetic classification of the betaproteobacterial AOB. Multifurcations connect branches for which a relative order could not be unambiguously determined by applying different treeing methods. The height of each triangle represents the number of sequences in the cluster. It should be noted that 16S rRNA sequences shorter than 1000 nucleotides were only considered if they could be unambiguously assigned to one of the lineages. All other short 16S rRNA sequences had to be omitted because their phylogenetic analysis cannot reliably be performed (Ludwig et al., 1998). The 16S rRNA sequences used in this analysis were published by Takahashi et al. (1992), Head et al. (1993), McCaig et al. (1994), McCaig et al. (1999), Teske et al. (1994), Rotthauwe et al. (1995), Utaaker et al. (1995), Pedersen et al. (1996), Stephen et al. (1996), Kowalchuk et al. (1997), Kowalchuk et al. (1998), Kowalchuk et al. (2000a), Kowalchuk et al. (2000b), Suwa et al. (1997), Tokuyama et al. (1997), Juretschko et al. (1998), Logemann et al. (1998), Princic et al. (1998), Speksnijder et al. (1998), Aakra et al. (1999a), Aakra et al. (1999b), Aakra et al. (2000), Aakra et al. (2001b), Bruns et al. (1999), Mendum et al. (1999), Philips et al. (1999), Philips et al. (2000), Radeva et al. (1999), Whitby et al. (1999), Whitby et al. (2001a), Whitby et al. (2001b), Yamagata et al. (1999), Abd El Haleem et al. (2000), Bano et al. (2000), Ward et al. (2000), Bollmann et al. (2001), Burrell et al. (2001), Chang et al. (2001), de Bie et al. (2001), Daims et al. (2001a), Gieseke et al. (2001), Smith et al. (2001), Sorokin et al. (2001), Hollibaugh et al. (2002), Nicolaisen et al. (2002), Regan et al. (2002), and Purkhold et al. (2003). In addition, unpublished 16S rRNA sequences (Accession numbers: AF107527, AJ441258, AJ441259, AJ441260, AJ441261. AJ441262, AJ441263, AJ441264, AJ441265, AJ441266] AJ441267, AJ441268, AJ441269, AJ441270, AJ441271, AJ441272], AJ441273, AJ441274, AJ441275, AJ441276, AJ441277, AJ441278, AJ441279, AJ441280, AJ441281, AJ441282, AJ441283, AJ441284, AJ441285, AF034139, AF034140, AF034141], AF034142, AF034143, AF034144, AF034147, AJ318197, U57617, AF510862, AF510863, AF510864, AF510865, AJ245751, AJ245752, AJ245753, AJ245754, AJ245755, AJ245756, AJ245757, AJ245758, AJ245759, AJ245760, AJ431350, AJ431351], AF414581, Y10128, Y10127, AJ224941, AF353155, AF353156, AF353157, AF353158, AF353159, AF353161, AF353162, AF353163, AF353164, AF359341, AF363287, AF363289, AF363290, AF363291, AF363292, AF363293, and A036898) available in GenBank were analyzed. RS: related sequences.

of environmentally retrieved *amoA* clones (Rotthauwe et al., 1997; Helmer et al., 1999; Stephen et al., 1999; Baribeau et al., 2000; Horz et al., 2000; Ivanova et al., 2000; Nold et al., 2000; Purkhold et al., 2000; Schmid et al., 2000; Chang et al., 2001; Gieseke et al., 2001; Oved et al., 2001; Dionisi et al., 2002; Sakano et al., 2002). In total, 383 *amoA* clones are currently available from these studies (status August 2002). Consistent with the 16S rRNA-based AOB diversity surveys, most *amoA* clones obtained are affiliated with sequence clusters

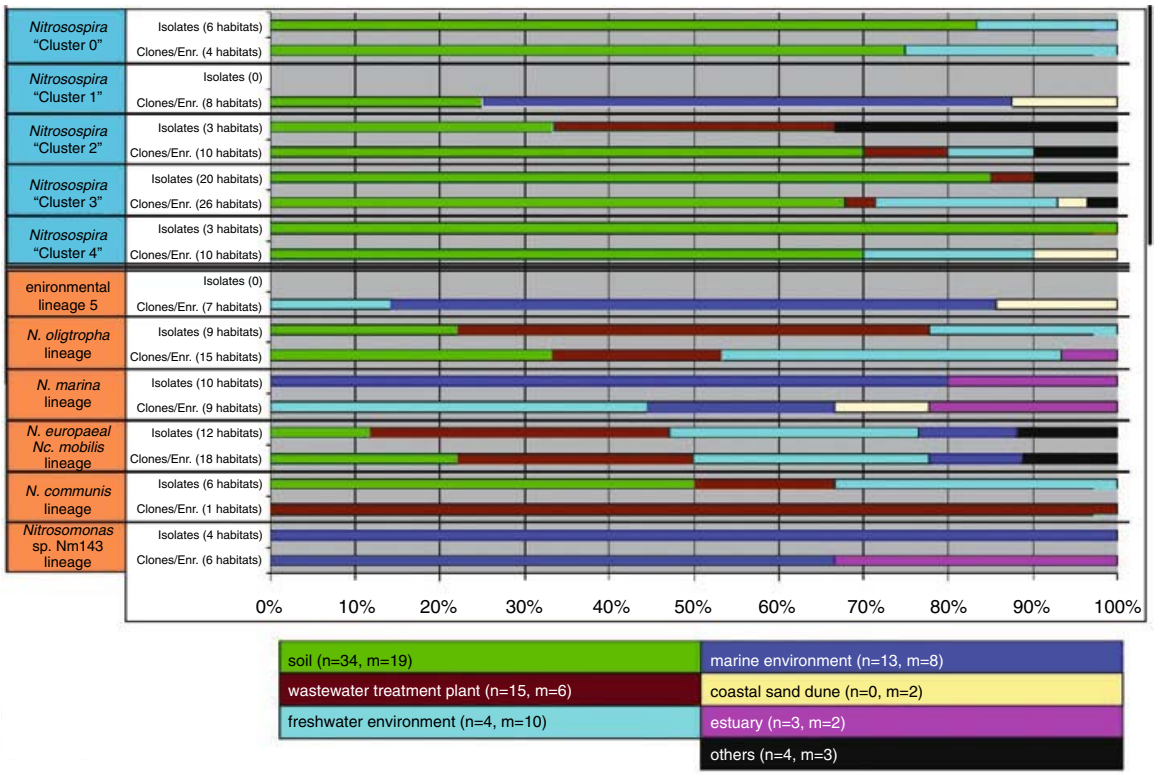

Fig. 12. Environmental distribution patterns of AOB clusters. For each cluster, the origin (sampling site) of each 16S rRNA sequence belonging to this cluster was determined. Subsequently, we counted the number of different sampling sites in which members of a particular cluster were detected. This number of habitats, which is given in parentheses, was set to 100%. In the next step, the sampling sites were grouped into the categories wastewater treatment plants, soil (including a rhizoremediation plant), freshwater (including sediment), marine (including sediment), estuary, and coastal sand dune. All other habitats were lumped together. For each cluster the proportion of each category is shown. For comparison, an identical analysis was performed of the available isolates for each cluster. The displayed legend explains the color-coding of the habitats. In addition, the number of different samples of a particular habitat category analyzed by the 16S rRNA approach (n) or cultivation (m) is given. For example, 16S rRNA AOB clones are available from 34 different soil samples and 19 soils were examined by AOB cultivation.

defined by cultured ammonia oxidizers (Table 4). The environmental distribution patterns of AOB inferred from AmoA analysis (Fig. 13) confirm the results from the 16S rRNA studies (Fig. 12), although the limited resolution provided by AmoA does not allow specific data for the individual *Nitrosospira* clusters to be extracted or the *N. oligotropha* to be distinguished from the *N. marina* cluster. According to the threshold values inferred from the *amoA*/16S rRNA correlation plots (Fig. 10), only two (clone GLII-9 from a wastewater treatment plant [wwtp] and clone Plus8ee from a lake) of the environmental *amoA* clones probably represent novel AOB species. These observations confirm that ammonia oxidizers already deposited in culture collections might be surprisingly representative of the natural diversity within this guild. However, it is important to stress that the sequences from 16S rRNA or *amoA* gene libraries from environmental samples rarely contain sequences completely identical to those of cultured organisms. Since no DNA-DNA hybridization data can be obtained for noncultured organisms, it can, according to the current species definition in bacteriology (Stackebrandt et al., 1988), not be decided whether these sequences represent novel or known ammonia oxidizer species. In this context, one should however bear in mind that PCR and cloning procedures introduce microvariation artifacts in cloned sequences (Speksnijder et al., 2001) and thus might cause (at least a part of) the high degree of microheterogeneity observed for AOB sequence clusters detected in environmental 16S rRNA and *amoA* clone libraries.

Although the 16S rRNA and *amoA* library approaches provided valuable insights into the natural diversity of AOB, the dependency of these techniques on nucleic acid extraction, PCR and cloning heavily biases the results (Wintzigerode and Goebel, 1997). Understand-

Table 4. Phylogenetic affiliation of amoA sequences obtained from environmental samples. AmoA-sequences analyzed for this Table were obtained from Baribeau et al. (2000), Chang et al. (2001), Dionisi et al. (2002), Gieseke et al. (2001), Ivanova et al. (2000), Helmer et al. (1999), Henckel et al. (1999), Holmes et al. (1999), Horz et al. (2000), Nold et al. (2000), Oved et al. (2001), Purkhold et al. (2000), Purkhold et al. (2003), Rotthauwe et al. (1997), Sakano et al. (2002), Schmid et al. (2000), and Stephen et al. (1999). In addition, unpublished environmental amoA sequences determined by the authors or available in GenBank (Accession numbers: AJ277459], AF338319, AF338320], AF239878, AF239879, AF239880, AF239881, AF239882, AF239883, AF239884], AJ388568, AJ388569, AJ388570, AJ388571, AJ388572, AJ388573, AJ388574, AJ388575, AJ388576, AJ388577, AJ388578, AJ388579, AJ388580, AJ388581, AJ388582, AJ388583, AJ388588, and AJ388589) were used.

	Total	Isolates	Enrichments	Environmental clones
Nitrosospira cluster	152	37	3	112
N. marina and *N. oligotropha* cluster	116	16	0	100
N. europaea/Nc. mobilis cluster	156	16	0	140
N. communis cluster	37	6	0	31
Nitrosomonas sp. Nm143 cluster	1	1	0	0
N. cryotolerans cluster	1	1	0	0
Σ	463	77	3	383

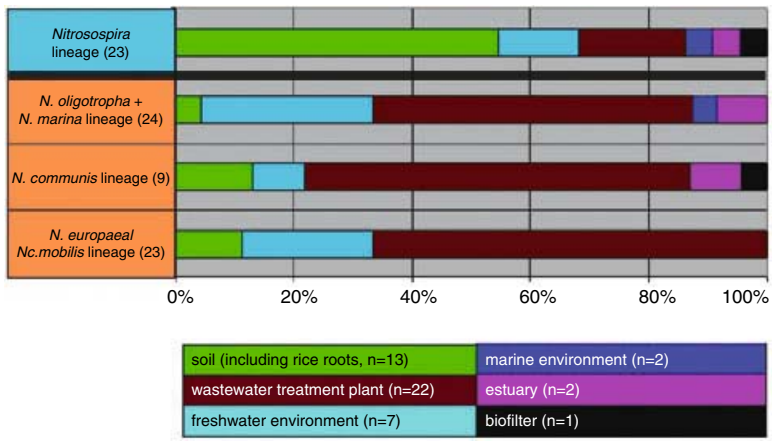

Fig. 13. Environmental distribution patterns of AOB clusters based on AmoA analysis. For each cluster, the origin (sampling site) of each AmoA sequence belonging to this cluster was determined. This analysis only included sequences from enrichments and sequences directly retrieved from the environment. Subsequently, we counted the number of different sampling sites in which members of a particular cluster were detected. This number, which is given in parentheses after the cluster designation, was set to 100%. In the next step, the sampling sites were grouped into the categories wastewater treatment plants, soil, freshwater (including sediment), estuary, biofilter, and marine (including sediment). For each cluster, the proportion of each category is shown. The displayed legend explains the color-coding of the habitats. In addition, the number of different sampling sites of a particular habitat category analyzed by the 16S rRNA approach (n) is given. Please note that the depicted grouping does not reflect the phylogenetic relation but results from the poor resolution of the amplified amoA gene fragment.

ing the ecology of AOB requires quantitative data on their in situ abundance and activity in ecosystems. The AOB community composition in a system can be quantitatively analyzed by using rRNA-targeted probes in combination with dot blot or in situ hybridization techniques (see the section on Molecular Techniques in this Chapter). However up to now, the AOB composition of only wastewater treatment reactors and full-scale plants has been characterized with these methods (Wagner et al., 1995; Mobarry et al., 1996; Juretschko et al., 1998; Schramm et al., 1999; Schramm et al., 2000; Daims et al., 2001b).

Methods Useful for In Situ Detection of AOB

Classical Techniques

Traditionally, the abundance, diversity and ecology of AOB were investigated by cultivation-dependent methods. For the enumeration of

viable AOB, the most probable number (MPN) technique often has been used, sometimes in parallel with other techniques. The efficiency of MPN has been calculated from comparisons with results obtained with fluorescent antibody (FA) counting (Belser, 1979; Ward, 1982) or calculations of activity per cell (Belser and Mays, 1982). Results obtained from these comparisons have led to the suggestion that the MPN efficiency may range between 0.001 and 0.05% (Hall, 1986). One important reason of underestimating AOB with MPN may be that AOB often form cell aggregates in the environment (Wagner et al., 1995; Stehr et al., 1995b; Juretschko et al., 1998; Koops and Pommerening-Röser, 2001). Another reason may be that the media used in MPN counting of AOB often have not been well adapted (ammonia concentration, salinity, and pH value) to the conditions in the environment under investigation (Koops and Pommerening-Röser, 2001).

Qualitative characterization of natural AOB populations is a very time consuming process. This especially holds true if classical methods are applied. The isolation of numerically dominant species will take at least some months (see the section on Enrichment, Isolation, and Maintenance in this Chapter). Moreover, considerable experience in working with AOB in the laboratory is required. However, this approach is currently the only option that allows the physiological properties of those species representing the numerically dominant AOB population in the respective environment to be completely investigated. These findings can help determine why distinct species of AOB are dominant in certain environments.

Phenotypic identification of new isolates of AOB is possible if the strain belongs to one of those species already being described in the literature. Useful parameters are the physiological properties (Ks values of ammonia-oxidation, requirement or tolerance of increased salt concentrations, and possession of urease), morphological characteristics (shape and size of cells, arrangement of intracytoplasmic membranes, and possession of carboxysomes), and G+C content of the DNA. For unambiguous identification, DNA-DNA hybridization with the type strain of the respective species should be carried out.

Immunological Techniques

In the 1970s, the cultivation-dependent approach was complemented by the fluorescent antibody technique, which allowed (for the first time) members of this guild to be detected in situ. Generally, polyclonal antibodies against several AOB were produced by injecting rabbits with the respective cells. Several studies demonstrated in situ visualization of AOB in environmental samples using these antisera for immunofluorescence and claimed that this approach allows a more rapid and accurate enumeration of AOB compared to enrichment culture methods (Belser, 1979; Ward and Perry, 1980; Ward and Carlucci, 1985; Abeliovich, 1987; Völsch et al., 1990). Although the fluorescent antibody (FA) approach represented a significant step forward in the history of research on nitrifier ecology, this technique has several disadvantages. Most importantly, pure cultures of AOB from the environment under investigation are required to produce the antibodies, since different serological groups exist within at least some of the AOB species. Therefore, the FA-technique, although allowing direct in situ detection of AOB, is indirectly dependent on successful cultivation of the target organisms. Consequently, this technique will not allow identification of novel, previously uncultured AOB species. Furthermore, the various polyclonal antibodies raised in different laboratories against different AOB are not easily available and thus their use is often restricted to a few laboratories. Another major disadvantage of the FA-technique is that the specificity of the obtained antibodies cannot be tailored in silico (i.e., using a computer) and must be determined in time-consuming experimental screening assays using different pure cultures. Finally, the FA-technique potentially suffers from false negative and false positive signals. The false negative signals might result from penetration problems of the relatively large antibodies in dense flocs or biofilms. False-positive signals were described as a result from nonspecific antibody binding to extracellular material or detritus (Szwerinski et al., 1985).

Recently, polyclonal antibodies against the purified β subunit of the ammonia monooxygenase (AmoB) of *Nitrosomonas eutropha* were shown to target all betaproteobacterial AOB by Western blot analysis (Pinck et al., 2001). After appropriate AOB cell permeabilization (Bartosch et al., 1999), the α AmoB antibodies are also suitable for immunofluorescence-based group-specific detection of betaproteobacterial AOB (E. Spieck, personal communication). Since these polyclonal antibodies target a key enzyme of the betaproteobacterial AOB, this assay is expected to be highly specific and will probably also allow yet unknown members of this group to be targeted. In the future, this technique most probably can be standardized to become the first choice method for general counting of betaproteobacterial AOB in those environmental samples that are well suited for FA application.

Molecular Techniques

After the establishment of 16S rRNA-based phylogeny of cultured AOB (Head et al., 1993; Teske et al., 1994; Pommerening-Röser et al., 1996; see the section on Phylogeny of AOB in this Chapter), many different 16S rRNA-targeted PCR primers and probes for dot blot or fluorescence in situ hybridization (FISH) have been developed (Table 5). Most frequently the natural diversity of AOB has been investigated by comparative analyses of PCR amplified and cloned AOB 16S rRNA gene fragments (see the section on Distribution of AOB in Nature in this Chapter). Apparently, the specificity of the applied PCR primers dramatically determines the outcome of such molecular AOB diversity surveys. In this context, it is important to note that the actual specificity of many primers used in previous investigations significantly differs from the indicated (intended) specificity listed in the original publications (Tables 6 and 7). These inconsistencies were detected after re-evaluating the primer/probe specificities based on the current, encompassing AOB 16S rRNA gene database. For example the PCR primer NitA, which is frequently used for AOB diversity surveys (Abd El Haleem et al., 2000; Ward et al., 2000; Hollibaugh et al., 2002), shows mismatches to all cultured nitrosospiras, all members of the *N. communis* and *N. oligotropha* lineage, and most members of the *N. marina* lineage. To avoid such pronounced biases, the use of PCR primers with high sensitivity (targeting all known or at least most betaproteobacterial AOB) but relatively low specificity (not perfectly excluding other bacteria) is recommended. Furthermore, the amplified 16S rRNA gene fragment must have a size larger than 1000 nucleotides to allow reliable phylogeny inference. The above-mentioned criteria are currently best fulfilled by the β AMOf and β AMOr primer pair. This approach accepts the amplification of non-AOB 16S rRNA gene fragments, which subsequently have to be identified by phylogenetic analysis or hybridization with probes with excellent specificity (e.g., probe Nso1225).

Recently, the toolbox for AOB detection has been extended by analyzing PCR amplified 16S rRNA gene fragments with denaturing gradient gel electrophoresis (DGGE; Kowalchuk et al., 1997; Nicolaisen and Ramsing, 2002). This fingerprinting approach allows a rapid comparative assessment of AOB diversity in many samples but requires subsequent controls like cloning and sequencing of bands or hybridization of membrane-blotted DGGE gels with suitable probes. Furthermore, the length of PCR amplificates that can be analyzed is limited to approximately 500 bp, which limits primer selection and hampers phylogeny inference.

Quantitative analysis of AOB community composition and abundance in the environment requires the use of methods not affected by PCR biases (Wintzigerode and Goebel, 1997). For this purpose, both dot blot and FISH methods have been developed and applied for AOB diversity research (Wagner et al., 1995; Mobarry et al., 1996; Schramm et al., 1996; Juretschko et al., 1998; Okabe et al., 1999; Liebig et al., 2001; Nogueira et al., 2002). The major advantage of dot blot analysis is that it can be applied to almost all environmental samples, while FISH does not work quantitatively in samples having a high autofluorescence or containing nontransparent particles (like soils). On the other hand, FISH allows visualization of the target bacteria and quantification of the AOB community composition and absolute AOB cell numbers (Daims et al., 2001c), while dot blot analysis only provides information on the relative or absolute abundance of probe target rRNA molecules. Whether, for example, a high rRNA content of a certain AOB species in an environmental sample originates from many target cells with a low rRNA concentration or a few cells with a high rRNA concentration cannot be figured out by dot blot hybridization.

It has been postulated that the rRNA content of a bacterial cell is directly related to its physiological activity. It must however be noted that this link does not always hold true for AOB. Quantitative FISH experiments showed that AOB have high cellular ribosome contents even after prolonged complete physiological inhibition (Wagner et al., 1995) or starvation (Morgenroth et al., 2000). Therefore, physiological activity of AOB cannot reliably be inferred from the above-mentioned methods and must be determined for example by combining FISH and microautoradiography (Lee et al., 1999), FISH and microelectrodes (Schramm et al., 1999), or stable isotope probing (Whitby et al., 2001a).

In addition to rRNA-based methods, the gene encoding the active site polypeptide of the ammonia monooxygenase (*amoA*) is frequently used as phylogenetic marker for AOB in environmental diversity surveys. Like the 16S rRNA database, the database of *amoA* sequences of cultured AOB is encompassing (see the section on Phylogeny of AOB in this Chapter). Several primer pairs for specific amplification of *amoA* have been published (Holmes et al., 1995; Rotthauwe et al., 1995; Sinigalliano et al., 1995; Mendum et al., 1999; Webster et al., 2002) but only the primer pair described by Rotthauwe et al. (1995), amplifying 55% of the *amoA* gene and slightly modified later by Stephen et al. (1999), has been shown to be suitable for detecting all tested betaproteobacterial AOB (Purkhold et al., 2000). The *amoA* approach for

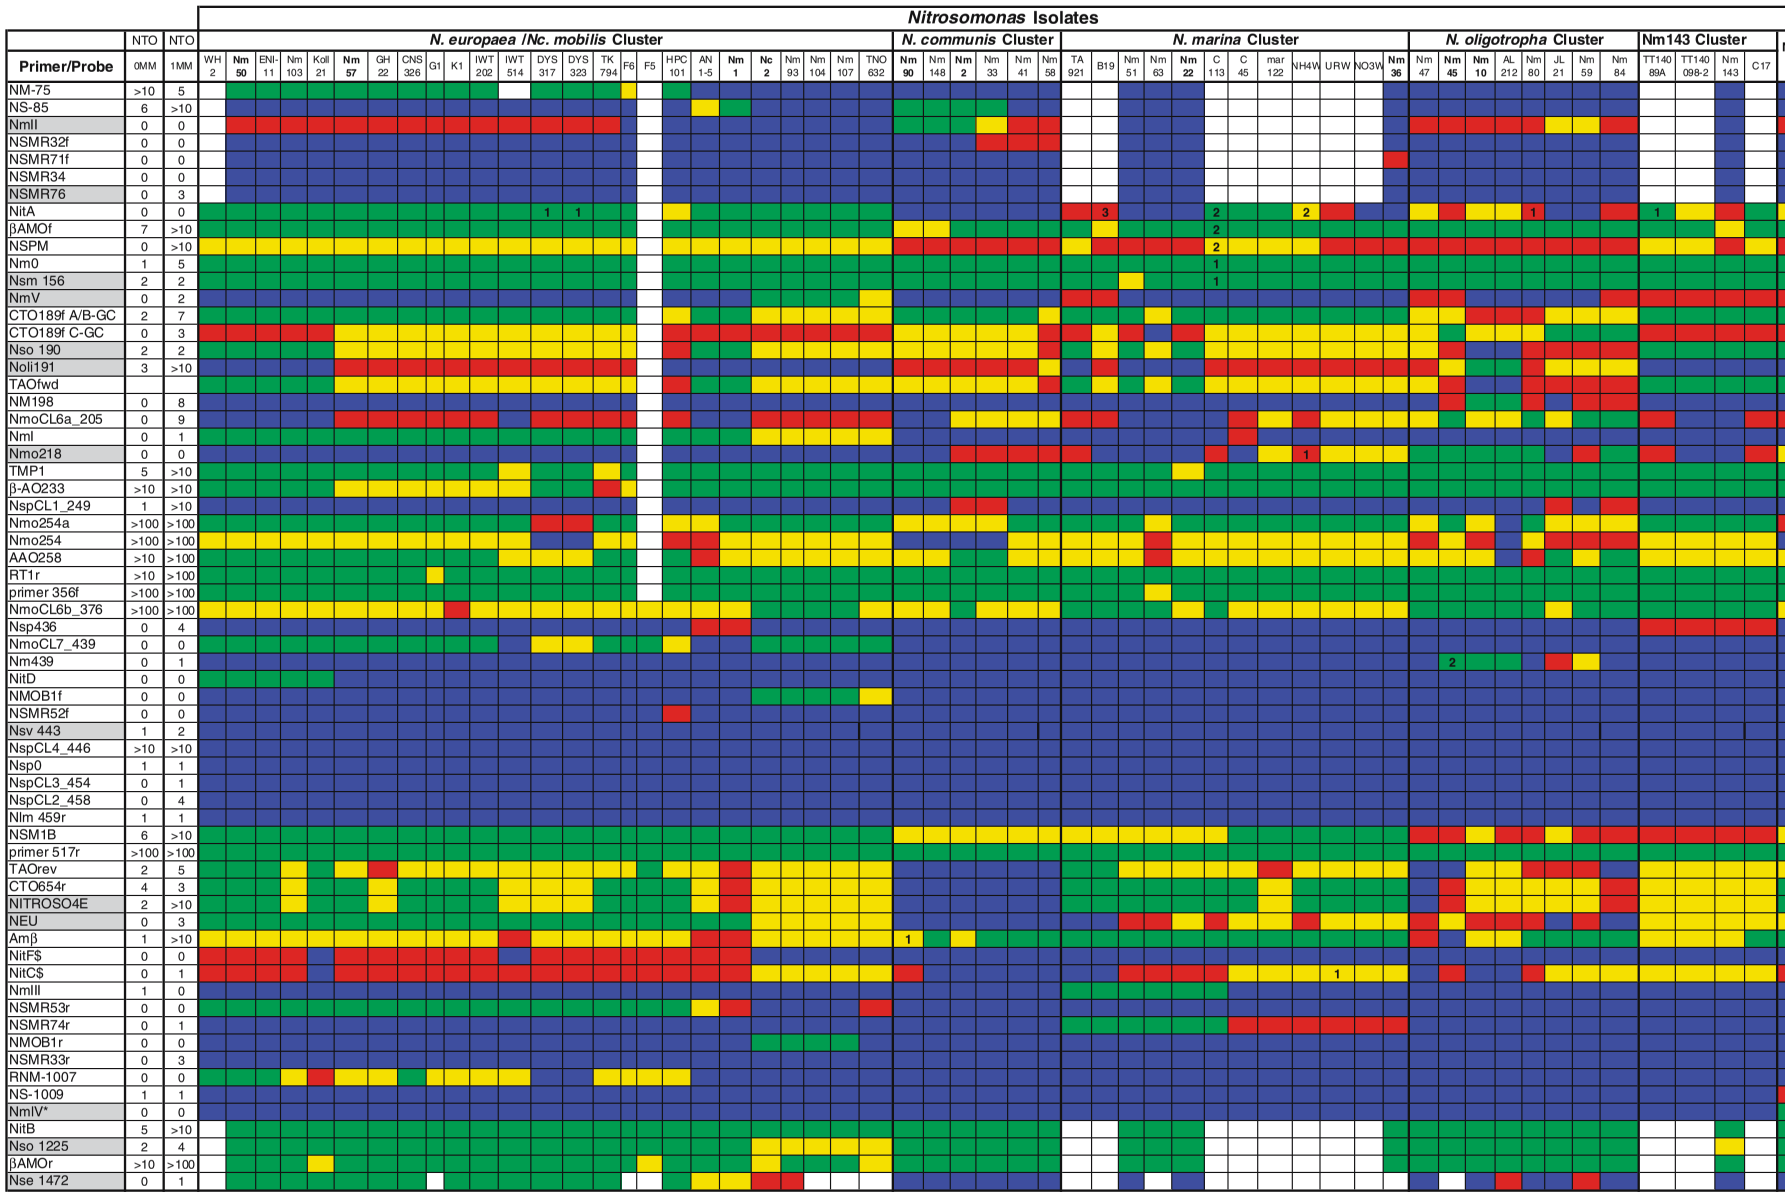
Table 7. Specificity and sensitivity of published 16S rRNA (gene) targeting PCR primers and hybridization probes for nitrosomonads. Abbreviations: NTO, number of non-target organisms outside the AOB with no mismatch (0 MM) or one mismatch (1 MM) in its 16S rRNA (gene) to the respective primer/probe.[a]



AOB diversity research impresses by its specificity and sensitivity but suffers from PCR-biases and relatively low phylogenetic information content (see the section on Phylogeny of AOB in this Chapter). Several fingerprinting techniques like gel retardation, DGGE, and terminal restriction fragment length polymorphism (T-RFLP) have been combined with the *amoA* approach and allow first insights into the diversity of an *amoA* PCR amplificate without time-consuming cloning and sequencing analysis (Kowalchuk et al., 1998; Horz et al., 2000; Schmid et al., 2000; Nicolaisen and Ramsing, 2002). Furthermore, an in situ PCR technique is available which allows direct detection of the *amoA* gene in AOB (Hoshino et al., 2001).

Significant method development for AOB diversity research is underway. Several quantitative PCR methods for AOB detection in the environment have been developed (Mendum et al., 1999; Dionisi et al., 2002). Furthermore, absolute AOB numbers in complex samples can also be determined by applying a novel FISH method in combination with confocal laser scanning microscopy and digital image analysis (Daims et al., 2001c). In the future, DNA microarrays composed of several hundred rRNA- or *amoA* -targeted oligonucleotide probes will almost certainly become available for parallel analyses of AOB community structures. Studies on first generation microarrays carrying a relatively limited number of AOB-targeted probes have already been published (Guschin et al., 1997; Wu et al., 2001).

Distribution of AOB in Nature

The distribution of AOB in the environment has traditionally been analyzed by cultivation-dependent methods (see the section on Classical Techniques in this Chapter). Recently, these studies were complemented by molecular diversity surveys of various man-made and natural systems (see the section on Molecular Techniques in this Chapter). The combination of both approaches is strongly recommended because each approach is characterized by its specific limitations. MPN-based isolation of AOB target the numerically most important AOB but might overlook not yet cultured AOB species that cannot thrive in the cultivation medium offered (although any clear indication for that is missing in the literature). On the other hand, it is important to interpret PCR-based molecular AOB distribution data with caution because the mere retrieval of a 16S rRNA sequence of an AOB proves neither that this organism is abundant nor that it is physiologically active. This problem is particularly severe for AOB (compared to many other bacteria) because they can survive very long time periods under unfavorable conditions (Johnstone and Jones, 1988; Wilhelm et al., 1998; Pinck et al., 2001). Therefore, molecular studies aiming at identification of dominant AOB species in an environment should focus on PCR amplificates of the highest positive DNA dilution, an approach analogous to the MPN technique (Feray et al., 1999), or even better include quantitative techniques (see the section on Molecular Techniques in this Chapter). Independent of the method used, the distinction between autochthonous and allochthonous AOB of a particular ecosystem is not trivial, making the natural distribution patterns of the distinct AOB species difficult to define. This problem is particularly severe because many of the environments are strongly influenced by human activity that eventually causes transmission of significant amounts of AOB to foreign systems. For example, AOB typically found in activated sludge also might be detectable in freshwater systems, if effluents of a wastewater treatment plant are disposed close to the sampling site. In this context, the importance of a careful selection of representative sampling sites is obvious. It is also interesting to note that isolations of strains via MPN series in general define more restricted distribution patterns of the distinct species of AOB than obtained from comparable molecular investigations.

AOB are present in most aerobic environments including rocks and building stones but can also survive in anaerobic systems (see the section on Dominant Populations of AOB in Different Environments in this Chapter). Since ammonia is the essential energy source for these organisms, their distribution in nature is coupled to geological, biological and anthropogenic sources of reduced nitrogen. Consequently, they have adapted to a broad range of different ammonia concentrations in the diverse environments, reflected by different affinity constants for ammonia. This is one of the most important aspects influencing the distribution patterns of AOB in nature (Suwa et al., 1994; Suwa et al., 1997; Stehr et al., 1995a; Koops and Pommerening-Röser, 2001). On the other side, ammonia is a toxic compound. Therefore, the tolerance of increasing ammonia concentrations (Table 3) is another aspect shaping the distribution patterns of AOB (Bollmann and Laanbroek, 2001).

Furthermore, the presence or absence of urease activity was observed to be of ecophysiological relevance for AOB. This property is of special importance in acidic environments, where free ammonia is missing as substrate because it is nearly quantitatively ionized to ammonium. Under such conditions, only those AOB species that can use urea as an alternative

ammonia source can build up stable populations (De Boer and Laanbroek, 1989; De Boer et al., 1991; Jiang and Bakken, 1999; Burton and Prosser, 2001). Possession of urease seems also to be an essential property for AOB that successfully colonize oligotrophic soils or aquatic environments.

Distribution of AOB in nature also is affected by different salt requirements, salt tolerances and salt sensitivities of the distinct species (Table 3). This is of special importance for their distribution patterns in aquatic systems (such as rivers, lakes, estuaries, marine environments and salt lakes) that significantly differ in salinity (Koops et al., 1990; Koops et al., 1991).

The AOB are aerobes. Although their oxygen affinity constants are relatively high (Painter, 1986), AOB possess nitrifying activity not only at oxygen saturation but also at extremely low oxygen concentrations (Goreau et al., 1980). Even ammonia oxidation under anaerobic conditions is being discussed (Schmidt and Bock, 1997; Schmidt and Bock, 1998; Zart et al., 2000). However, specific selection of distinct AOB species by different oxygen concentrations has not yet been reported in the literature.

Temperature also may be of importance for distribution patterns of AOB in nature. This has been indicated in some publications (Golovacheva, 1976; Jones et al., 1988; Jiang and Bakken, 1999). Beside environments characterized by constant high or low temperatures, such as hot springs or permafrost soils, environments showing pronounced temperature changes, such as rock surfaces, might harbor interesting AOB. However, these systems have not been studied intensively enough to allow general conclusions on their AOB diversity.

The Betaproteobacterial AOB

The betaproteobacterial AOB are divided into two main subgroups, the *Nitrosomonas* group (containing six distinct lineages) and the *Nitrosospira* lineage (containing the genera *Nitrosospira*, *Nitrosovibrio* and *Nitrosolobus*). Within the *Nitrosomonas* group, a relatively strong correlation between the phylogenetically defined lineages (see the section on Phylogeny of AOB in this Chapter) and the distribution patterns of the respective species exists. Within the *Nitrosospira* lineage, this correlation is not as obvious.

The *Nitrosomonas* Group

The N. europaea/Nc. mobilis *Lineage* The four cultured species of the *N. europaea/Nc. mobilis* lineage are moderately halophilic and all show striking halotolerance (Table 3). Most of the cultured strains of the three species *N. europaea*, *N. eutropha* and *Nitrosococcus mobilis* (which is phylogenetically a member of the genus *Nitrosomonas*) have been isolated from wastewater treatment plants and their molecular signatures are also frequently retrieved from these systems (Figs. 12 and 13). In addition, quantitative FISH results demonstrated that *Nc. mobilis* and *N. europaea* are dominant in several wastewater treatment plants (Juretschko et al., 1998; Daims et al., 2001b). Some isolates of this lineage were obtained from strongly fertilized agricultural soils. All these environments are more or less eutrophicated and influenced by anthropogenic activity, frequently rendering the conditions more favorable for these AOB. The successful colonization of these systems requires tolerance of increasing ionic strength and, in particular, of high concentrations of toxic compounds such as ammonia. Consequently, these properties are found in all members of these AOB lineages (Table 3). The natural habitat for members of these lineages has not yet been identified. However, in a recent molecular investigation the presence of *N. europaea* -like and *N. eutropha* -like organisms in a salt lake was shown (Ward et al., 2000). This is of interest, since strains belonging to the fourth species of the *N. europaea/Nc. mobilis* lineage, *N. halophila*, recently could be isolated from salt lakes in Mongolia (Sorokin et al., 2001). Sporadically, isolates of the *N. europaea/Nc. mobilis* lineage were obtained from the North Sea (*N. halophila* and *N. mobilis*), from the river Elbe estuary (*N. europaea*) and from freshwater sediments (*N. europaea* and *N. eutropha* ; Stehr et al., 1995a; Koops and Pommerening-Röser, 2001). Consistent with these findings, molecular investigations detected members of the *N. europaea/Nc. mobilis* lineage in fertilized soils or natural fresh water environments (Voytek, 1996; Holmes et al., 1999; Campbell, 2000; Horz et al., 2000; Ivanova et al., 2000; Phillips et al., 2000; Burrell et al., 2001; Oved et al., 2001; Smith et al., 2001; Whitby et al., 2001a; Morris et al., 2002; Radajewski et al., 2002; Webster et al., 2002).

The N. communis *Lineage* The *N. communis* lineage comprises two entities, the *N. communis* and the *N. nitrosa* sublineages, which are currently phylogenetically not clearly distinguishable but have significantly different distribution patterns in nature. The *N. communis* sublineage contains, in addition to *N. communis*, three other cultivated species, not yet described by name (Fig. 9). The majority of strains of this sublineage were isolated from approximately pH neutral soils, often agriculturally utilized. Since all three species of this sublineage possess relatively high

affinity constants for ammonia and lack urease activity, they probably need relatively high ammonia concentrations in the environment. Most likely this is an important reason that these species seem to be missing in oligotrophic natural soils and in substrate-low natural freshwaters. In contrast to the above subgroup, strains of the *N. nitrosa* subgroup are commonly distributed in more or less eutrophicated freshwaters. Since the affinity constants for ammonia are similar to those of the species of the *N. communis* sublineage, the possession of urease might be responsible for this different distribution. Strains of *N. nitrosa* also have been isolated from marine environments, a fact which is in apparent contrast to the relatively low salt tolerance of these strains observed in laboratory studies (Table 3). Surprisingly, only two 16S rRNA gene clones of the *N. communis* lineage have been detected in environmental diversity surveys (Gieseke et al., 2001; Fig. 11). This low retrieval rate may have been caused by the fact that many of the commonly applied primers possess mismatches with the 16S rRNA gene of members of this lineage (Table 7). In contrast, *amoA* sequences affiliated with this lineage were detected in soil, freshwater and wastewater treatment plants (Ivanova et al., 2000; Purkhold et al., 2000; Gieseke et al., 2001; Oved et al., 2001; Dionisi et al., 2002; Nogueira et al., 2002; Fig. 11).

The N. oligotropha *Lineage* The *N. oligotropha* lineage comprises several species, although only *N. oligotropha* and *N. ureae* are described by name. A total of six species of this lineage is available in culture (Fig. 7), and the existence of more species has been indicated by molecular environmental studies (Speksnijder et al., 1998) and several unpublished sequences publicly accessible via GenBank. The majority of cultured strains have been isolated from rivers and lakes (Koops and Pommerening-Röser, 2001). Some isolates originate from sewage disposal plants (Koops and Harms, 1985; Suwa et al., 1997) and from soil samples. The 16S rRNA sequences of this cluster were frequently detected in soil and freshwater (Stephen et al., 1996; Speksnijder et al., 1998; Bruns et al., 1999; Radeva et al., 1999; Kowalchuk et al., 2000b; Phillips et al., 2000; Bollmann and Laanbroek, 2001; Whitby et al., 2001b; Regan et al., 2002). Among the cultivated species of AOB, the representatives of the *N. oligotropha* lineage reveal the lowest affinity constants for ammonia, being in the range of a few μM. All investigated strains are urease positive. These observations are in accordance with the generally low ammonia concentration in their natural habitats. It is also notable, that representatives of this lineage often occur floc- or biofilm-attached in the environment (Stehr et al., 1995a), as well as in laboratory studies (Bollmann and Laanbroek, 2001). Consistent with this observation, at least some members of this lineage can produce remarkable amounts of exopolymeric substances (Stehr et al., 1995b).

The N. marina *Lineage* The *N. marina* lineage comprises three cultivated species, *N. marina*, *N. aestuarii* and *Nitrosomonas* sp. (represented by the isolates Nm 51 and Nm 63). All isolates originate from marine environments. Molecular signatures of this lineage have also been detected in marine samples (Stephen et al., 1996; Casciotti and Ward, 2001) as well as in enrichment cultures from such environments (Stephen et al., 1996). The presence of members of this lineage has been observed with molecular techniques in estuarine environments, coastal sand dunes and even in freshwater (aquaria) and a wastewater treatment plant (Kowalchuk et al., 1997; Speksnijder et al., 1998; Purkhold et al., 2000; Burrell et al., 2001; de Bie et al., 2001; Nicolaisen and Ramsing, 2002). Some authors, unfortunately, have lumped together the *N. oligotropha* lineage and the *N. marina* lineage (Kowalchuk and Stephen, 2001), although both lineages are phylogenetically distinct (Figs. 6 and 7) and the species of the two lineages show pronounced differences in ecophysiological characteristics and distribution patterns.

The N. cryotolerans *Lineage* The *N. cryotolerans* lineage is represented by only one species, *N. cryotolerans*, and only one isolate exists in culture. This strain has been isolated from a marine environment and is obligatorily halophilic and urease positive. In molecular in situ analyses of AOB populations, *N. cryotolerans* has not yet been detected, although most of the commonly applied 16S rRNA gene primers do match this species.

The Nm 143 Lineage Recently, a new lineage was identified within the genus *Nitrosomonas* (Purkhold et al., 2003; Fig. 7). This lineage has been provisionally named after *Nitrosomonas* sp. Nm143 and contains three additional isolates. It is not known whether these four isolates represent one or more than one species. All isolates were obtained from marine systems. Molecular signatures of this lineage were found in several marine and estuary systems (McCaig et al., 1994; Stephen et al., 1996; de Bie et al., 2001; Nicolaisen and Ramsing, 2002).

Uncultured Lineage The so-called "environmental lineage 5" is the only major evolutionary lineage within the *Nitrosomonas* group which does not yet contain a cultured representative

(Stephen et al., 1996; Purkhold et al., 2000). The 16S rRNA sequences of this lineage were obtained from freshwater environments, marine systems and a coastal sand dune (McCaig et al., 1994; McCaig et al., 1999; Stephen et al., 1996; Kowalchuk et al., 1997; Speksnijder et al., 1998; Bano and Hollibaugh, 2000).

The Nitrosospira *Lineage* Members of the *Nitrosospira* lineage were postulated by some authors to be the dominant AOB in nature (Hiorns et al., 1995; Hastings et al., 1997; Ceccherini et al., 1998). However, this postulate is rather unsecured because it is based on findings obtained with nonquantitative PCR-dependent methods often involving primers and probes not sufficiently covering some of the *Nitrosomonas* lineages (Tables 6 and 7). The *Nitrosospira* lineage represents a phylogenetically young group of AOB. Therefore, no highly reproducible phylogenetic substructure can be revealed within this group based on comparative 16S rRNA or *amoA* sequence analysis (see the section on Phylogeny of AOB in this Chapter). Nevertheless, a provisional subdivision system of this group has been suggested (Stephen et al., 1996; extended by Purkhold et al., 2000; Fig 8) and widely applied for interpretation of data from molecular AOB diversity surveys (for a review, see Kowalchuk and Stephen, 2001). However, it is questionable whether the suggested clustering defines units characterized by particular ecophysiological traits.

Most isolates of the *Nitrosospira* lineage were obtained from terrestrial systems. Consistent with this finding, the current molecular dataset suggests that members of the *Nitrosospira* clusters 0, 2, 3 and 4 are predominantly found in terrestrial habitats (Fig. 12). Whether the reported occurrence of these clusters in freshwater habitats reflects that these bacteria are autochthonous freshwater inhabitants or soil-borne organisms transferred to the water bodies cannot be decided. Nitrosospiras of cluster 1, for which no isolate exists, also occur in soil but are more frequently found in marine systems. The analyzed wastewater treatment plants rarely harbored nitrosospiras, and only members of clusters 2 and 3 were detected. Constructed wetlands might represent an exception to this rule, since mainly *Nitrosospira* -related 16S rRNA sequences were retrieved from a plant using rhizoremediation technology (Abd El Haleem et al., 2000). *Nitrosospira* strains Nsp57, 58 and 65, which were isolated from masonry and form two novel branches within this group (Fig. 8), are the only *Nitrosospira* isolates for which yet no closely related sequences were directly obtained from an environment.

At least within the so-called "*Nitrosospira* cluster 3," profound differences regarding physiology and distribution patterns exist because this cluster, in contrast to the other four clusters, comprises many morphologically as well ecophysiologically different species.

The Gammaproteobacterial AOB

The cultured strains of the two species of the genus *Nitrosococcus*, representing the gammaproteobacterial AOB, have been isolated from marine environments (all strains of *N. oceani*) and from a salt lagoon or from a salt lake (two isolates of *N. halophilus*), respectively. This habitat range is in accordance with the salt requirements and with the salt tolerances of the two species in laboratory experiments. Using immunological methods and molecular techniques, *N. oceani* was detected exclusively in marine environments but shown to be widely distributed (Ward and Perry, 1980; Ward, 1982; Ward and O'Mullan, 2002). *Nitrosococcus halophilus* has not yet been observed in nature via molecular techniques.

Dominant Populations of AOB in Different Environments

Attempts to describe the dominant AOB populations of an environment should always take into careful consideration whether the retrieved species are autochthonous or allochthonous members of the analyzed ecosystem. Often species are introduced into environments from adjacent habitats. Since ecophysiological characteristics of distinct species of AOB often differ only minimally, introduced populations have a good chance to survive in the novel environment. Moreover, anthropogenic influence has created many new environments colonized by AOB that had no or only little time to adapt evolutionarily to these systems. In such cases, the sum of ecophysiological parameters will determine finally which of the species competing with each other will become the dominant representative.

Marine Environments

A relatively clear situation is found in marine environments. In these ecosystems, generally those AOB are dominant which have a compatible salt requirement and a suitable salt tolerance. Consequently, the gammaproteobacterial AOB, *N. oceani* together with representatives of the *Nitrosomonas marina* lineage are the only AOB isolated with high frequency from marine environments. The second species of *Nitrosococ-*

cus, *N. halophilus*, seems to prefer environments with higher salt concentrations (salt lagoons or even salt lakes). Most of the above-mentioned organisms (except *N. halophilus*) can also be detected in marine systems using molecular methods (Stephen et al., 1996; Ward and O'Mullan, 2002). It is not clear why only one strain of *N. cryotolerans*, which also is ecophysiologically well adapted to these systems, has been isolated from marine samples. Members of the Nm143 lineage also seem to be distributed exclusively in marine environments. However, the ecophysiological properties of the latter group have not yet been investigated.

Occasionally, species of the *Nitrosomons europaea*/*Nc. mobilis* lineage, owing to their relatively pronounced salt tolerance, were cultured from marine samples (Koops et al., 1976; Koops and Pommerening-Röser, 2001). Using quantitative dot blot, Hovanec and DeLong (1996) found that *N. europaea* -like bacteria were a major component of the microbial community in filters from seawater aquaria, but the primer (NSM1B) used for this analysis also has a full match to several members of the *N. marina* lineage (Tables 6 and 7). The 16S rRNA sequences of the *Nitrosomonas* environmental lineage 5 and *Nitrosospira* cluster 1, which both contain no cultured representatives, were frequently detected in marine environments (McCaig et al., 1994; McCaig et al., 1999; Stephen et al., 1996; Phillips et al., 1999; Bano and Hollibaugh, 2000; Hollibaugh et al., 2002; Fig. 12), but quantitative molecular data are missing. The retrieval of nitrosospiras in systems with elevated salt concentrations is surprising, since all cultured species of this lineage have a low salt tolerance in laboratory studies. The mere detection of 16S rRNA sequences of *Nitrosospira* cluster 1 in a marine environment does not prove that these organisms indeed possess a high salt tolerance and thrive in these systems. Alternatively, these nitrosospiras might be allochthonous inhabitants able to survive for extended periods in the ocean without significant physiological activity. It is thus important 1) to isolate and study a strain of this cluster and/or 2) to prove physiological activity of members of this cluster in situ for example by combination of FISH and microautoradiography (Lee et al., 1999).

Salt Lakes

In salt lakes, the pH as well as the composition and concentration of salts vary significantly (Ward et al., 2000; Sorokin et al., 2001) thus creating different niches for AOB. Accordingly, different AOB were found in different salt lakes. From a salt lake in Saudi Arabia, a strain of *Nitrosococcus halophilus* was obtained (Koops et al., 1990), and from soda lakes located in Mongolia, alkali tolerant representatives of *Nitrosomonas halophila* have been isolated (Sorokin et al., 2001). In molecular analyses, *N. europaea* -like and *N. eutropha* -like organisms were detected in the hypersaline Mono Lake in California (Ward et al., 2000). However, the PCR primers used in this study (NitA and NitD) were not suited for a general AOB diversity study (Tables 6 and 7). To get a more general view of the AOB community composition in such environments, more investigations must be carried out.

Freshwater Environments

In natural freshwater environments, members of the *Nitrosomonas oligotropha* lineage are generally the dominant AOB representatives. This is indicated by repeated isolation of members of this lineage from high MPN dilutions (Koops and Harms, 1985; Stehr et al., 1995a; Koops and Pommerening-Röser, 2001). Quantitative PCR-independent molecular data on AOB community composition in these systems are not available, but at least 16S rRNA sequences of this lineage were frequently detected in freshwater water bodies and sediments (Speksnijder et al., 1998; Radeva et al., 1999; Bollmann and Laanbroek, 2001; Whitby et al., 2001b; Regan et al., 2002) as well as in the Schelde estuary (Belgium and The Netherlands; de Bie et al., 2001). In addition, 16S rRNA sequences of *Nitrosospira* clusters 0, 2, 3 and 4 were harvested in molecular analyses of these habitats (Kowalchuk et al., 1998; Speksnijder et al., 1998; Whitby et al., 1999; Whitby et al., 2001b) and in a freshwater aquarium (Burrell et al., 2001). Moreover, using immunological methods, nitrosospiras were found in a eutrophic lake sediment (Smorzewski and Schmidt, 1991). However, these results do not necessarily indicate *Nitrosospira* dominance in freshwater systems because quantitative data are lacking, and several of the PCR primers applied in these studies do not sufficiently cover the *N. oligotropha* cluster (Purkhold et al., 2000; Tables 6 and 7).

Occasionally, strains of *N. europaea*, *N. eutropha* and *N. nitrosa* have been isolated from eutrophicated rivers and eutrophic lakes (Koops and Pommerening-Röser, 2001). Furthermore, 16S rRNA sequences of *N. europaea*/*Nc. mobilis*, of *Nitrosomonas* environmental lineage 5 and of the *N. marina* lineage were retrieved from freshwater systems (Speksnijder et al., 1998; Whitby et al., 1999; Bollmann and Laanbroek, 2001; Burrell et al., 2001), but the significance of these findings remains unclear.

Artificial Aquatic Environments

Urea and ammonia are the most frequently found nitrogen compounds in sewage. In wastewater treatment plants, AOB oxidize ammonia to nitrite, which is subsequently converted to nitrate by the nitrite-oxidizing bacteria. Nitrate is then removed from the sewage by denitrifying bacteria via anaerobic respiration. The slow growth rate of AOB and their susceptibility to pH- and temperature swings as well as to several sewage compounds is responsible for frequent failure of the nitrification in municipal and industrial wwtps.

Isolation techniques indicate that in standard municipal wwtps, *N. eutropha* seems to be the dominant representative (Watson and Mandel, 1971b; Koops and Harms, 1985), but *N. europaea* and *Nc. mobilis* have also been repeatedly cultivated (Juretschko et al., 1998; Koops and Pommerening-Röser, 2001). All these species belong to the same *Nitrosomonas* lineage (Fig. 7)

In industrial wwtps, the cultivation of representatives of members of the *N. oligotropha* lineage as well as *N. nitrosa* has been regularly reported (Koops and Harms, 1985; Suwa et al., 1997). In laboratory experiments, a remarkable high tolerance of members of the *N. oligotropha* lineage to heavy metals was observed, and the production of significant amounts of exopolymeric materials by these species was suggested to be the major reason for this tolerance (Stehr et al., 1995b). This resistance to heavy metals may be responsible for the presence of members of this lineage in special wwtps.

During the last decade, molecular techniques were extensively applied to characterize AOB community structure and activity in activated sludge and biofilm from various wwtps. FISH revealed that AOB generally occur in tight microcolonies formed of up to several thousand individual cells (Fig. 14). These microcolonies cannot be easily dispersed using ultrasonic or Ultraturrax homogenizer treatments and thus contribute to the underestimation of AOB numbers in MPN assays. Typically, the AOB are detected in situ in close proximity to nitrite oxidizers reflecting the mutualistic relationship between both guilds (Mobarry et al., 1996; Schramm et al., 1996; Schramm et al., 1998; Juretschko et al., 1998; Okabe et al., 1999). Experiments using a combination of FISH with ^{14}C-bicarbonate microautoradiography demonstrated that almost all AOB microcolonies in activated sludge are physiologically active. Furthermore, AOB in wwtps can incorporate pyruvate (Daims et al., 2001a). Using quantitative FISH data, the specific activity of a single AOB cell in activated sludge has been estimated to be 2.3 ± 0.4 fmol of ammonia per hour (Daims et al., 2001c). According to FISH analyses, nitrosomonads are predominant over nitrosospiras in most activated sludge and biofilm systems (Mobarry et al., 1996; Schramm et al., 1996; Schramm et al., 2000; Juretschko et al., 1998; Okabe et al., 1999; Daims et al., 2001b; Gieseke et al., 2001). With the exception of *Nitrosomonas cryotolerans*, *Nitrosomonas halophila* and *Nitrosomonas* sp. Nm143, relatives of all other *Nitrosomonas* species occur in wwtps (Purkhold et al., 2000). *Nitrosococcus mobilis*, originally thought to be restricted to brackish water, is abundant in many wwtps (Juretschko et al., 1998; Daims et al., 2001b). Some nitrifying wwtps are dominated by a single AOB species (Juretschko et al., 1998), while other plants harbor a high diversity of AOB (Purkhold et al., 2000; Daims et al., 2001b; Gieseke et al., 2001). Whether and how differences in diversity of ammonia oxidizers are linked to the stability of the nitrification process is a yet unanswered question. Investigations of AOB populations in the raw sewage most probably also could give important insight into AOB diversity in sewage disposal plants.

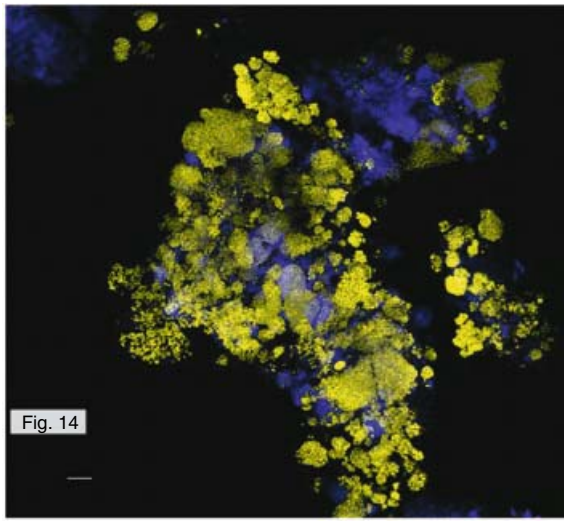


Fig. 14. FISH detection of an AOB microcolony in a nitrifying biofilm from a sequencing batch biofilm reactor. AOB were stained by probe NEU, and the fluorescence signals were recorded by confocal laser scanning microscopy. Probe-conferred fluorescence is shown in yellow, while autofluorescence of the biofilm is depicted in blue. Bar = 10 µm. The picture was kindly provided by Holger Daims.

Soils

In acidic soils (heathlands, grasslands, forest soils, and marshy lands), where sufficient amounts of free ammonia are missing, urease-positive species seem to be the exclusive representatives of the AOB. This has become obvious

via isolations as well as from molecular investigations (Kowalchuk and Stephen, 2001). Exclusively, species of the genera *Nitrosospira* and *Nitrosovibrio* could be detected. Molecular studies confirmed the predominance of nitrosospiras in acidic soils (Stephen et al., 1996; Smith et al., 2001) and indicated that, in particular, members of the *Nitrosospira* cluster 2 are well adapted to low pH terrestrial habitats (Kowalchuk et al., 1997; Stephen et al., 1998). A more detailed up-to-date summary of these findings can be found in Kowalchuk and Stephen (2001). However, urease-positive strains of *Nitrosolobus multiformis* and of the genus *Nitrosomonas*, respectively, are missing in acidic soils.

In more neutral soils, especially if agriculturally used, members of the *N. communis* lineage together with strains of *Nitrosolobus multiformis* are absolutely dominant in high MPN dilutions (MacDonald, 1986; Koops and Pommerening-Röser, 2001). In oligotrophic natural soils, especially if moderately acidic (pH around 6.0), strains of the *N. oligotropha* lineage as well as strains of the genera *Nitrosospira* or *Nitrosovibrio* have also been isolated (Koops and Pommerening-Röser, 2001).

Rocks and Building Stones

AOB are also common on surfaces of rocks or building stones. Many strains have been isolated, and all were found to be members of the genera *Nitrosospira* or *Nitrosovibrio* (Spieck et al., 1992). Neither the closely related genus *Nitrosolobus* nor any of the lineages of the genus *Nitrosomonas* seem to be represented in these environments. Currently, the selective factors leading to these distribution patterns are speculative. Most likely, the acidic pH caused by the nitrification process is a crucial factor. Periodically appearing dryness or drastic change in temperature also may be selective for members of the genera *Nitrosospira* or *Nitrosovibrio*.

CHAPTER 3.2.13

The Genus *Thiobacillus*

LESLEY A. ROBERTSON AND J. GIJS KUENEN

Introduction

Ever since the genus *Thiobacillus* was first described in 1904, the ability to grow while using a reduced sulfur compound as a source of energy has been considered sufficiently important taxonomically to merit classifying all Gram-negative, sulfur-oxidizing, nonphototrophic rods in this genus. However, as studies using modern taxonomic methods began to reveal that some of the species are only superficially related, virtually every paper describing a new *Thiobacillus* species in the last decade has mentioned the need to reorganize the genus. Most of this reorganization has now been done (Kelly and Wood, 2000a), and the authors are grateful to D.P. Kelly and A. Wood for permission to see and use their resulting manuscripts prior to publication.

The effect of the reorganization is dramatic (Table 1). In the last edition of *The Prokaryotes*, the genus *Thiobacillus* included 17 species. There are now only three species left—all autotrophs, and all members of the β-subclass of the Proteobacteria. The 4 or 5 facultative autotrophs that fall into the β-subclass have now been assigned to a new genus—*Thiomonas*. Most of the other former *Thiobacillus* species fall into the γ-subclass, together with the members of the genus *Thiomicrospira*. This includes both the well-known acidiphilic and recently discovered alkaliphilic "*Thiobacillus*" species, as well as the marine species. However, because the reorganization is still so new and most researchers will look for these organisms in one group, many of them will be dealt with in this chapter, with the exception of the γ group. *Thiobacillus acidophilus* and *Thiobacillus versutus* have both been transferred to existing genera (see Table 1). Similarly, *Thiosphaera pantotropha* has now been reclassified as *Paracoccus pantotrophus* and will be described in the chapter on that genus. The last member of the γ group, *Thiobacillus novellus*, is now *Starkeya novella*. Within this chapter, the generic terms "thiobacilli" and "colorless sulfur bacteria" refer to the whole group, regardless of their new classification.

Habitats

In nature, the distribution of reduced inorganic sulfur compounds is only one of the factors governing the presence and activity of the colorless sulfur bacteria, and a complex of chemical, physical, and microbial interactions is almost as important a controlling force. One crucial factor is the requirement for the simultaneous presence of an electron donor (the reduced sulfur compound) and electron acceptor (i.e., oxygen or nitrogen oxides). Sulfide is one of the most important natural substrates, and many of the colorless sulfur bacteria grow in the narrow zones and gradients where sulfide and oxygen coexist (Nelson and Jannasch, 1983). Such gradients can be found, for example, in stratified lakes and at the interface between aerobic water and an anaerobic sediment, but may be even more common in microniches in environments that contain anaerobic pockets (e.g., sediments and wet soils). It must be realized that extremely high turnover rates of sulfide can be observed at very low levels of sulfide and oxygen ($<10^{-6}$ mM; Nelson et al., 1986). In fact, it is thanks to these low oxygen concentrations that the sulfide-oxidizing bacteria can successfully compete with the spontaneous oxidation of sulfide. This implies that even where environmental sulfide concentrations are very low, the actual sulfide flux may be very high. Similarly, other gradients can influence the growth and selection of sulfur oxidizers. Thus, it has been shown that thiobacilli respond differently to varying redox potentials (Sokolova and Karavaiko, 1968; Timmer ten Hoor, 1975). The occurrence of acidophilic bacteria in apparently neutral environments indicates the existence of pH gradients associated with acidic microniches. Sulfur oxidizers have been enriched and isolated from natural sites chosen by the obvious presence of inorganic sulfur or iron compounds (e.g., sediments from rivers, canals, estuaries and tidal flats, acid sulfate soil, [hot] acid springs, mine drainage effluent, hydrothermal vents, hyperalkaline soda lakes, and wastewater treatment systems). The thiobacilli, especially the specialized chemolithotrophs, have long

been viewed as one of the most important groups of organisms contributing to the transformation of sulfur in soils and sediments, although only a few systematic studies on their occurrence and distribution have been carried out. However, there is evidence that, depending on the particular environmental conditions, the mixotrophic and heterotrophic sulfur oxidizers may be at least equally important in the overall conversion of reduced sulfur compounds to a more oxidized state (Guitoneau and Keiling, 1932; Kuenen, 1975; Mason and Kelly, 1988; Robertson et al., 1989). In general, sulfur and iron oxidizers are ubiquitous in soil, sediments, and freshwater and marine environments. They grow over a wide range of pH values and temperatures (see Tables 2 and 3). Thus, it is relatively easy to find them in nature. An obvious factor that limits their growth is the availability of reduced inorganic sulfur compounds, a limitation that is especially important for the obligate autotrophs that completely depend on these compounds for growth. A special case is the spontaneous oxidation of sulfide by tetrathionate, which is controlled by thiosulfate-recycling bacteria such as *Catenococcus thiocyclus*. This organism oxidizes thiosulfate to tetrathionate at concentrations as low as 1–10 μmol/liter. The tetrathionate is then chemically reduced to thiosulfate by sulfide, making it available to *C. thiocyclus* again. Thus, even where sulfide or thiosulfate levels appear to be very low, it has been shown that such thiosulfate-recycling heterotrophs can contribute significantly to the turnover within the local sulfur cycle (Sorokin et al., 1996).

Despite their ability to incorporate some organic compounds into cell material, the contribution of the obligate autotrophs to the

breakdown of organic compounds in nature is probably negligible. Gottschal and Kuenen (1980) showed that the versatile species are generally favored in freshwater environments when the turnovers of available inorganic and organic substrates are approximately equivalent. When the inorganic substrates are dominant, obligate autotrophs should be favored, and similarly, heterotrophs will be favored when organic compounds make up the bulk of the available substrate (Fig. 1). However, this does not necessarily hold true for marine situations (Kuenen et al., 1985). Further work remains to be done to discover what other selective pressures are operative in the marine milieu. It should also be remembered that groups of benthic sulfur-oxidizing bacteria such as *Beggiatoa* and *Thiovulum*, described elsewhere, are especially important in such situations (Otte et al., 1999).

Because many of the colorless sulfur bacteria produce sulfuric acid or ferric iron, they are often associated with the oxidative corrosion of concrete and pipes and have been implicated in the corrosion of buildings and ancient monuments. Acid and metal pollution can also be a result of the activities of thiobacilli in mine wastes (Tuovinen and Kelly, 1972). On the more positive side, the production of acid contributes, for example, to the leaching of metals from poor ores that are unsuitable for extraction by conventional metallurgical methods (Boon, 1996). In addition, the potential application of the pyrite-oxidizing capacity of *Acidithiobacillus ferrooxidans* and related organisms for the desulfurization of coal has been successfully explored (Bos et al., 1988; Bos and Kuenen, 1990). However, the problem of the acid waste stream from this process, which contains ferric hydroxysulfate has not yet been solved.

In soils, thiobacilli may sometimes be responsible for the solubilization of sulfur compounds such as pyrite and other metal sulfides, thus making sulfur available (as sulfate) for assimilation by other microorganisms and plants. In soil reclaimed from the sea, the oxidation of pyrite may lead to the formation of "cat clay." The sulfur budget and the role of microorganisms in the sulfur cycle of cultivated soils are, of course, important for assessing fertility. In Australia, for example, thiobacilli are scarce in sulfur-deficient areas. Under suitable climatic conditions (e.g., in the tropics), rock phosphate pelleted with sulfur and seeded with thiobacilli has been shown to be a useful, slow release source of phosphate and sulfate for soil fertilization (Swaby, 1975).

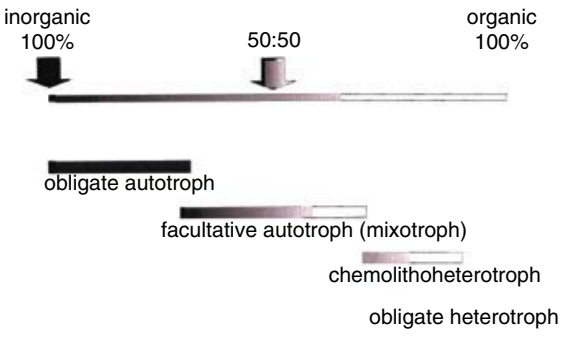

Fig. 1. A "spectrum" showing the ratios of inorganic to organic substrates most likely to favor the four physiological types of colorless sulfur bacteria.

Marine thiobacilli have been isolated from oceans, soda lakes, hydrothermal vents, and coastal and tidal areas and classified by reference to nonmarine cultures. Characteristically, some (but not all) marine forms have a requirement for (sodium) chloride levels comparable with the salinity of their natural environment. It is difficult to explain their presence in the open oceans; perhaps they are able to scavenge volatile sulfur compounds released from bottom sediments during the process of decomposition. At the hydrothermal vents, they are believed to be important producers of organic compounds at the start of the geochemically based food chain (Jannasch, 1985a). However, as they are, on the whole, dependent on oxygen generated by photosynthesis for electron acceptors, they cannot therefore be considered "primary producers" in the strict sense of the term.

Many *Thiomicrospira* species were isolated from estuarine mud rich in sulfides and from the waters of hydrothermal vents (Jannasch et al., 1985b; Brinkhoff et al., 1999a; Brinkhoff et al., 1999b). Some, but not all, require NaCl for growth.

Moderately thermophilic thiobacilli (optimum growth around 50°C) have been isolated from hot springs in geothermal areas (Williams and Hoare, 1972; Le Roux et al., 1977; Wood and Kelly, 1985), and from copper-leaching operations (Brierley and Lockwood, 1977; Brierley et al., 1978). The sulfur transformations in hot springs involve some unique microbiological features. Sulfur oxidizers found at high temperatures (up to 85°C) are typically acidophilic and lack a rigid cell wall structure because of a lack of peptidoglycan. These organisms are all classified as belonging to the genus *Sulfolobus*. One sulfur-oxidizing member of the genus *Acidianus* has been reported to grow at temperatures up to 100–105°C (Stetter, 1988).

At the other end of the pH scale, the range of extremely alkaliphilic bacteria present in environments such as soda lakes has only recently become apparent, and sulfur-oxidizing bacteria (Table 3) make up a significant population within these communities (Sorokin et al., 2001).

Another source of colorless sulfur bacteria is the rich mixture of microbial populations found in wastewater treatment systems. Indeed, *Paracoccus pantotrophus* was isolated from a denitrifying, sulfide-oxidizing, fluidized bed reactor (Robertson and Kuenen, 1983a; Robertson and Kuenen, 1983b), and it has been claimed that *Thiobacillus denitrificans* has been isolated from others (e.g., Batchelor and Lawrence, 1978). As these reactors can, in many ways, be regarded as enrichment cultures on the large scale, they may be a rich source of other strains with novel physiological traits.

Physiology

By definition, all of the species described in this chapter can derive energy for growth from the oxidation of reduced sulfur compounds if provided with a terminal electron acceptor, but the conditions required (e.g., low pH) may vary somewhat. Moreover, the ability of all of the colorless sulfur bacteria to oxidize certain sulfur compounds has not been rigorously tested. Until this is done, caution should be exercised when basing differentiation of the species on which sulfur compounds they can oxidize or accumulate. Some of the reactions can be summarized as follows:

$$H_2S + 2O_2 \rightarrow H_2SO_4 \quad (1)$$

$$2H_2S + O_2 \rightarrow 2S^\circ + 2H_2O \quad (2)$$

$$2S^\circ + 3O_2 + 2H_2O \rightarrow 2H_2SO_4 \quad (3)$$

$$Na_2S_2O_3 + 2O_2 + H_2O \rightarrow Na_2SO_4 + H_2SO_4 \quad (4)$$

$$4Na_2S_2O_3 + O_2 + 2H_2O \rightarrow 2Na_2S_4O_6 + 4NaOH \quad (5)$$

$$2Na_2S_4O_6 + 7O_2 + 6H_2O \rightarrow Na_2SO_4 + 6H_2SO_4 \quad (6)$$

$$2KSCN + 4O_2 + 4H_2O \rightarrow (NH_4)_2SO_4 + K_2SO_4 + 2CO_2 \quad (7)$$

$$5H_2S + 8KNO_3 \rightarrow 4K_2SO_4 + H_2SO_4 + 4N_2 + 4H_2O \quad (8)$$

$$5S^\circ + 6KNO_3 + 2H_2O \rightarrow 3K_3SO_4 + 2H_2SO_4 + 3N_2 \quad (9)$$

$$2FeS_2 + 2H_2O + 7O_2 \rightarrow 2FeSO_4 + 2H_2SO_4 \quad (10)$$

$$4FeSO_4 + O_2 + 2H_2SO_4 \rightarrow 2Fe_2(SO_4)_3 + 2H_2O \quad (11)$$

The complete oxidation of reduced sulfur compounds to sulfate is common to all of the obligate and facultatively autotrophic sulfur oxidizers, and the ability of a culture to lower its pH while growing on thiosulfate is one of the criteria that has been used for the detection of these bacteria. The pH often rises in cultures of heterotrophs able to partially oxidize inorganic sulfur compounds because of the formation of polythionates (e.g., tetrathionate from thiosulfate). It should be noted, however, that a lack of acid production is not a decisive criterion for the differentiation between the chemolithotrophic and chemoorganotrophic sulfur oxidizers because under unfavorable cultural conditions, even the chemolithotrophs accumulate intermediates in significant amounts. For example, it has been observed that *Acidithiobacillus ferrooxidans*, when growing on thiosulfate, trithionate or sulfide, produces sulfur which is detectable not only outside the cells, but also as a finely dispersed precipitate outside the cell membrane (Hazeu et al., 1988). *Halothiobacillus neapolitanus* and its probable relatives known as "*Thiobacillus* strains O and W" produce sulfur during growth on reduced sulfur compounds under various environmental stresses (e.g., oxygen tension), but do not appear to accumulate sulfur internally (Stefess and Kuenen, 1989; Visser et al., 1997).

Enrichment, Isolation, and Cultivation Techniques

Within certain limits (e.g., NaCl requirement), most of the colorless sulfur bacteria discussed in this chapter appear to have similar requirements for inorganic salts. All of the known species can be cultivated in chemically defined media. However, many of their nutritional needs have not been quantitatively established, and the chemical composition of the basal media used in different laboratories varies enormously. For example, their requirements for trace elements have not been studied in detail and many recipes are variations of the trace element solution described by Vishniac and Santer (1957). Small quantities of yeast extract have sometimes been used as a source of trace elements and vitamins, but it should be remembered that yeast extract does not contain vitamin B_{12}. Marine enrichment cultures are best made in artificial seawater or by supplementing a mineral medium with sodium chloride (20–40 g/liter). Nitrogen assimilation and dissimilation have received relatively little attention, but ammonium (NH_4^+) and/or nitrate (NO_3^-) ions can usually serve as nitrogen sources, and some species have more than one pathway for nitrogen assimilation (e.g., *Halothiobacillus neapolitanus* has both the glutamate synthase (GOGAT) and alanine dehydrogenase pathways; Beudeker, 1982). However, most species (*Thermothiobacillus tepidarius*, *Acidithiobacillus thiooxidans* and *A. albertis* are exceptions) can

also use organic nitrogen compounds such as urea and glutamate. Several species are capable of dissimilatory nitrate reduction to nitrite, but only a few can denitrify completely to nitrogen gas (see Tables 2 and 3; see also the chapter on the genus *Paracoccus*). With the exception of *Paracoccus pantotrophus*, the known mixotrophic colorless sulfur bacteria are all unable to grow on reduced sulfur compounds when they denitrify (i.e., they can only denitrify heterotrophically or, as with *Paracoccus denitrificans*, with hydrogen as the electron donor). Because of this, a combination of denitrifying conditions with reduced sulfur compounds as substrate can be employed for the selective enrichment of the obligately autotrophic species and strains with a physiological resemblance to *Pa. pantotrophus*. Care should be taken, however, as *Thiobacillus thioparus* (which can only reduce NO_3^- to nitrite [NO_2^-]) sometimes appears in denitrifying enrichments in coculture with bacteria that can only denitrify from NO_2^-.

The enrichment and isolation procedures for the colorless sulfur bacteria are based on their chemolithotrophic properties and their ability to grow autotrophically or mixotrophically. Thiosulfate is the most commonly used substrate for their growth because it is soluble and reasonably stable over much of the required pH range. However, chemical degradation of thiosulfate results in the formation of (colloidal) sulfur. This is enhanced in acid media (Roy and Trudinger, 1970). An important factor in the selection of sulfur oxidizers is the presence of organic material that can support the growth of mixotrophic or heterotrophic organisms (Fig. 1). All other factors being equal, the specialized chemolithoautotrophs are generally dominant in batch enrichment cultures, even if organic compounds have also been added. This dominance is due to the fact that these chemolithoautotrophs have higher maximum specific growth rates on reduced sulfur compounds than do their facultative counterparts, which in batch culture will also exhibit diauxy. In addition to the truly facultative autotrophs (or mixotrophs), many other strains are able to oxidize reduced sulfur compounds, frequently carrying out incomplete oxidations (e.g., thiosulfate to tetrathionate; Trudinger, 1967; Vitolins and Swaby, 1969; Tuttle and Jannasch, 1972; Tuttle and Jannasch, 1973; Sorokin et al, 1996). Many such strains do not seem to be able to gain energy from the reaction, and there is probably a range of heterotrophs with varying efficiencies for deriving energy from the oxidation of the various reduced sulfur compounds (Trudinger, 1967; Tuttle et al., 1974; Kuenen, 1975; Kuenen, 1989a; Kelly and Harrison, 1989). *Thiomonas perometabolis* was previously believed to be the only validly named chemolithoheterotroph, but it has now been shown to grow autotrophically under specialized conditions. *Catenococcus thiocyclus* is thus one of the few named chemolithotrophs that has been shown to gain energy from thiosulfate oxidation (Sorokin, 1992; Sorokin et al, 1996), although other well-documented (albeit unnamed) chemolithoheterotrophs exist (Suylen et al., 1986; Gommers and Kuenen, 1988). An alternative benefit to energy generation might be gained if the sulfide is used to detoxify hydrogen peroxide generated during aerobic growth (Kuenen et al., 1985).

A successful method of enriching for facultatively autotrophic sulfur bacteria from freshwater sources is to use chemostat cultures under double substrate (e.g., acetate and thiosulfate) limitation (Gottschal and Kuenen, 1980). In these cultures, because of the limitation, the concentrations of the two substrates are very low and diauxy does not occur. The facultative chemolithotrophs can therefore grow mixotrophically and can successfully compete with the specialists for thiosulfate. Depending on the ratio of inorganic to organic substrates used, enrichments for chemolithoheterotrophs can also be made (Fig. 1). However, as mentioned above, marine species do not always follow this pattern, and denitrifiers can also behave differently. Growth within a biofilm may also produce anomalous results, with versatile species appearing where obligate chemolithotrophs might be expected (M.Verbeek et al., unpublished observations).

The media shown for individual species are generally intended for batch cultures and the preparation of agar plates. Chemostat media tend to be less strongly buffered because the pH of the culture can be controlled by automatic titration. This can be an advantage in the cultivation of some species. For example, *Thiobacillus* strain Q tends to accumulate large deposits of polyphosphate when grown even at the phosphate levels found in normal chemostat media (Gommers and Kuenen, 1988). The chemical constitution of chemostat medium varies depending on which nutrient is intended to be limiting. Care should be taken that the limiting factor is indeed that which was intended, since bacterial requirements for different nutrients vary. The putative limiting factor can be confirmed by altering (e.g., doubling or halving) its concentration and then checking whether the biomass yield indeed changes proportionately.

Many of the colorless sulfur bacteria have not yet been studied in the chemostat. However, the technique presents several advantages, including defined conditions and growth rates and the possibility of using potentially toxic substrates (e.g., sulfide) by keeping their concentrations low. In

addition, the sulfur-oxidizing capacity of some mixotrophs and chemolithoheterotrophs can be inhibited by the amounts of sulfite present in batch culture media supplied with reduced sulfur compounds (especially if heat-sterilized), and chemostat cultures may provide the only option for discovering whether the oxidation of these compounds does indeed generate energy (Gommers and Kuenen, 1988). Examples of media that have been used with success for growing neutrophilic, alkaliphilic and acidiphilic colorless sulfur bacteria in continuous culture are therefore given here. They can be adapted to specific needs by a careful selection of electron donors and electron acceptors and by controlling (slightly changing) the pH of the culture with an autotitrator. Titration can be done with bicarbonate (especially where obligate autotrophs are concerned) as it can serve as a source of CO_2, NaOH, and H_2SO_4 (where it will not interfere with the making of sulfur balances) or dilute HCl. The disadvantage of using HCl is its corrosive nature.

For neutrophilic bacteria, the following basic mineral salts medium can be used (concentrations in g/liter): K_2HPO_4, 0.8; KH_2PO_4, 0.3; NH_4Cl, 0.4; $MgSO_4 \cdot 7\ H_2O$, 0.4; and 2 ml of trace element solution (see below). To avoid precipitation during autoclaving at 110–120°C, the $MgSO_4$ and trace element solution must be sterilized separately. Alternatively, the medium can be made up in two parts, supplied to the chemostat by separate pumps, and mixed in the culture vessel. If this is done, the mineral salts medium listed above is made up double strength, and concentrated H_2SO_4 (1.25 ml/liter) is added to prevent precipitation during autoclaving. The substrates are then supplied, also double strength, in a second bottle to which NaOH (0.15 g/liter) has been added.

A range of substrates can be used. Concentrations in the range of 20 mM acetate or 10 mM succinate are suggested for heterotrophic cultures. Forty mM thiosulfate or sulfide can be used for autotrophic cultures. It should be noted that if sulfide is to be used, it must be sterilized separately and then aseptically added to a medium that has been cooled under N_2 or argon to exclude oxygen. The medium bottle should then be kept under a slight N_2 or argon over-pressure, even when in use, to prevent chemical oxidation of the sulfide. For denitrifying cultures, KNO_3 or KNO_2 can be used at concentrations calculated from the stoichiometry of the oxidations (e.g., for 20 mM thiosulfate, 32 mM nitrate would be more than sufficient as 10–20% of the electrons would be used for CO_2 fixation and thus are not available for electron acceptor reduction). Where organic substrates must be included in the calculation, allowance should be made for assimilation. It is necessary to add bicarbonate (to serve as a carbon source) to the substrate bottle when growing autotrophic cultures under anaerobic conditions, unless CO_2 is supplied in another way, perhaps in the gas stream.

For growing acidiphiles, a modified 9K medium (Silverman and Lundgren, 1959) has been used successfully with *Acidithiobacillus ferrooxidans* (Hazeu et al., 1986; Hazeu et al., 1988). This medium contains (in g/liter): $(NH_4)_2SO_4$, 1.0; KCl, 0.1; $Ca(NO_3)_2$, 0.01; $MgSO_4 \cdot 7\ H_2O$, 0.2; K_2HPO_4, 0.5, and 1 ml/liter of trace element solution. As with the neutrophilic medium, a range of substrates including 20 mM thiosulfate or 10 mM tetrathionate can be added. If the medium is to contain reduced sulfur compounds, they must either be sterilized separately, or the medium should be autoclaved at pH 7.0 to avoid chemical reactions. The pH of the culture is then adjusted by autotitration with 2N H_2SO_4.

The trace element solution (Vishniac and Santer, 1957) used with these chemostat media contains (in g/liter): ethylene diamine tetraacetate (EDTA), 50; $ZnSO_4$, 2.2; $CaCl_2$, 5.5; $MnCl_2 \cdot 4\ H_2O$, 5.06; $FeSO_4 \cdot 7\ H_2O$, 5.0; $(NH_4)_6Mo_7O_{24} \cdot 4\ H_2O$, 1.1; $CuSO_4 \cdot 5\ H_2O$, 1.57; and $CoCl_2 \cdot 6H_2O$, 1.61. It should be noted that the original description contains 10 times the concentration of $ZnSO_4$ or 22 g/liter.

Both obligately and facultatively chemolithotrophic strains are generally purified by streaking on thiosulfate or sulfur agar. Thus far, there is no specific isolation technique for the facultative chemolithotrophs. They are generally isolated from enrichment cultures by streaking on inorganic thiosulfate agar and subsequent isolation and testing for heterotrophic potential or by plating on media with a mixture of thiosulfate and an organic substrate such as acetate. Chemolithoheterotrophs must, of course, be purified on medium containing both thiosulfate and an organic substrate. The inclusion of a suitable indicator in the agar permits the detection of colonies actually using the thiosulfate (and where neutrophilic bacteria are concerned, can indicate sulfate or polythionate production). Solid media generally contain thiosulfate, but sulfur plates may sometimes be appropriate. Alternatively, plates can be incubated in an atmosphere of H_2S gas. A crude method of generating the H_2S is to mix Na_2S crystals with acid, but remember that H_2S is 10 times more toxic than HCN. As H_2S oxidizes spontaneously in air, a more sophisticated method is to continuously generate an air, nitrogen and H_2S mixture, which is then passed over the cultures (Visser et al., 1997). If desired, organic compounds can be included, as they are not toxic for the obligate

chemolithotrophs. Some amino acids may, however, inhibit growth when added as the sole organic substrate in an inorganic medium. It is likely that the inhibition is caused by an imbalance in the amino acid synthesis in the organism (Kelly, 1969; Lu et al., 1971). Obviously, when acid-producing bacteria are being grown in batch cultures, it is necessary to control the pH. This can be done in several ways including strong buffers, the addition of solid calcium carbonate, and periodic or automatic adjustment with carbonate solution. Solid calcium carbonate dissolves at pH values below 6.0–6.5, and it is therefore only useful for the neutrophiles. It can also be used in solid media. Suitable pH indicators, such as bromocresol purple (pH 5.2–6.8), bromthymol blue (pH 6.0–7.6) and phenol red (pH 6.8–8.7), can be used.

One of the most common problems in obtaining pure cultures of chemolithotrophs is the extreme persistence of heterotrophic contaminants in association with the chemolithotrophic colonies on agar plates (e.g., Taylor et al., 1971; Harrison, 1984). This is partly due to the presence of trace amounts of soluble organic material in virtually all agar brands and partly due to the fact that many obligate chemolithotrophs excrete organic compounds (Schnaitman and Lundgren, 1965; Borichewski, 1967; Cohen and Kuenen, 1976). An example of this frequently occurs during enrichment for *Thiobacillus denitrificans*. Anaerobic batch cultures containing nitrate and thiosulfate often yield mixed populations of *T. thioparus* and heterotrophic denitrifiers, rather than *T. denitrificans* (Taylor et al., 1971). *Thiobacillus thioparus* can only reduce nitrate to nitrite, but it also excretes organic material that may then be used by heterotrophic, nitrite-reducing bacteria. An analogous problem has been found in the enrichment and isolation of *Acidithiobacillus ferrooxidans*, which may occur in close association with the facultatively chemolithotrophic *Acidiphilium acidophilum* (Guay and Silver, 1975; Tuovinen et al., 1978; Harrison, 1984). The low pH required by these acidophilic bacteria can result in partial hydrolysis of agar and the release of organic compounds into the medium. Critical endpoint dilutions to obtain pure cultures of obligate chemolithotrophs should only be used with extreme caution, as often only the highest dilution that contains both the chemolithotroph and heterotrophic contaminant will show growth. A new technique that avoids organic support media has been successfully used for the isolation of acidophilic and neutrophilic obligate autotrophs (De Bruyn et al., 1990). This method involves passing the inoculum through a sterile, inert, polycarbonate membrane filter. The filter is then floated on the surface of a suitable mineral medium (see below) and incubated at an appropriate temperature. Substrate can be supplied as dissolved thiosulfate or as H_2S. By eliminating the use of agar, the presence of all organic compounds can be avoided and overgrowth by heterotrophs thus prevented. This method is both faster and simpler than other wholly inorganic methods such as silica gel plates. It should also be remembered that some microorganisms may not be able to tolerate the high concentrations of substrate (or possible contaminants such as sulfite in some grades of thiosulfate) generally required in batch cultures, and a continuous culture or fed batch culture might be more appropriate.

It is important to note that the enrichment or isolation technique will often define the type of isolate obtained. For example, in a study of the microbial community in a sulfide-oxidizing wastewater treatment system (Visser et al., 1997), it was found that direct streaking of samples onto agar gave a number of colonies equivalent to only 0.2% of the number obtained from direct counts. Even though a mineral salts agar with thiosulfate had been used, 80% of these colonies proved to be heterotrophic. Serial dilution methods gave an even lower count, equivalent to 0.06% of the direct count. When isolations were made using an adaptation of the floating filter technique and sulfide, however, the number of autotrophic colonies obtained was equivalent to 15% of the direct count. Different autotrophs dominated the cultures obtained from the serial dilutions and the floating filters. These organisms, known as "*Thiobacillus* strains W and W5" (and on the basis of 16S RNA sequences, related to *Halothiobacillus neapolitanus*) behaved differently to the extent that the original isolate W5 would not grow on agar plates. Comparison of these isolates with the original microbial community, using denaturing polyacrylamide gel electrophoresis of the total protein of these cultures, showed that isolate W5 was most probably the dominant organism in the original bioreactor. Because the results from the filter technique are so dramatically different from those of conventional methods, it is worth saying more about it here. For the work described above, 0.2-mm polycarbonate filters (Poretics Corporation, Livermore, CA) were used. Twenty-five mm diameter filters were incubated in sterile tissue culture clusters (Costar, Cambridge, MA) with wells (35 mm in diameter) filled with a medium suitable for autotrophic growth. The clusters were placed in dessicators, but any vessel allowing the controlled flushing of the headspace would do. Also, H_2S was continually circulated through the headspace by sparging an acid solution of sodium sulfide with air.

Identification

By definition, none of the colorless sulfur bacteria are phototrophic, and bacteria possessed of photopigments belong in other genera (e.g., *Chromatium* or *Thiocapsa*) even if they can grow lithoautotrophically on reduced sulfur compounds in the dark. The basic taxonomic features of the members of this group are shown in Tables 2 and 3. For detailed descriptions of most of the species, the reader is referred to Kelly and Wood (2000b), where the currently known physiological and taxonomic features of most of the members of these genera are shown.

It cannot be stressed too strongly that before identification, cultures should be rigorously checked for purity, since heterotrophic contaminants are both common and persistent in autotrophic cultures. "Normal" heterotrophic contaminants should be sought not only in rich media at neutral pH values, but also using a range of environmental conditions (e.g., pH, dissolved oxygen, and denitrification) as close to those conditions under which the culture is normally grown. Bearing in mind that even some of the contaminants may be fastidious, several different organic substrates should be checked with the mineral salts media suggested for use with colorless sulfur bacteria.

Enrichment, isolation, and enumeration procedures for sulfur-oxidizing bacteria were at one time almost invariably based on the use of either thiosulfate or elemental sulfur as substrates. As a result, potential isolates may not have been found, as some colorless sulfur bacteria preferentially or even exclusively use sulfide (W. J. Bijleveld et al., unpublished observations). Equally, the use of agar plates selects for bacteria able to cope with the organic substrates and with those substrates supplied in relatively high concentrations. Diffusion through the gel is the only way by which oxidation products including H_2SO_4 are removed. As already mentioned (see the discussion of "*Thiobacillus* W5" above), a very different isolation pattern emerged when the bacterial community in a wastewater treatment reactor was cultivated on inorganic filters floating on mineral medium (used as a support). The ability to oxidize reduced sulfur compounds is not routinely included in standard taxonomic tests, and species, which might otherwise be considered hydrogen bacteria (e.g., *Pa. denitrificans*) or methylotrophs (e.g., *Hyphomicrobium* EG), are now found capable of oxidizing (and gaining energy from) reduced sulfur compounds (Friedrich and Mitrenga, 1981; Suylen et al., 1986). Thus the ability to oxidize reduced sulfur compounds, especially sulfides, may be much more widespread in nature than indicated by currently employed methodology.

Some commonly used media are described in the references given. It must be emphasized that for most thiobacilli, these media do not ensure selective enrichments. Isolation procedures generally involve colony development. However, because the morphological characteristics of the thiobacilli are similar, and because the colony shape and color are, to some extent, subject to the medium and growth conditions, their appearance is of little identification value. Identification procedures should involve reference to relevant previously described strains and studies at the physiological and molecular levels. Further details can be found below, in the original descriptions of the different species, and in Kelly and Harrison (1989), Kuenen and Robertson (Kuenen and Robertson, 1989b; Kuenen and Robertson, 1989c), and Kelly and Wood (2000a).

As discussed in the introduction, the taxonomy of the colorless sulfur bacteria was originally based on the classical taxonomic tests that are largely founded on physiological reactions. The most critical requirements for inclusion in the genus *Thiobacillus* have been that the organism is a Gram-negative rod with the ability to use reduced sulfur compounds as an energy source for growth. In recent years, the heterogeneity of the genus became apparent, (Kuenen and Robertson, 1987; Mason et al., 1987; Robertson et al., 1989), and a need for some form of reorganization became apparent (Kelly and Harrison, 1989; Kuenen, 1989a). Writing for the previous edition of *The Prokaryotes*, we said "More data are necessary before the taxonomic world is turned upside down." As can be seen from Table 1, this was not an understatement; the genus *Thiobacillus* alone was split into five new genera once the molecular taxonomy was done. However, while it is tempting to rely only on molecular analysis, this reliance would lead to an equally inaccurate or uninformative picture; thus, it is far better to use a mixture of classical and new methods. After enrichment and isolation on the basis of their ability to derive energy from the oxidation of reduced sulfur compounds, physiological factors such as the ability to fix CO_2, pH range, temperature range and denitrification capability should all be checked in addition to the 16S mRNA analysis, %G+C content, and DNA:DNA hybridization with possibly related organisms. It is also desirable to check such isolates on substrates such as H_2, methane and methanol as well as more traditional heterotrophic substrates such as acetate or glucose and alternative reduced sulfur compounds. Electron microscopy is important not only to establish the presence and number of flagellae, but also to identify intracellular inclusions such as sulfur particles, carboxysomes, and stored carbohydrates. It should be noted that suspected

chemolithoheterotrophic bacteria should really be checked in continuous cultures under electron donor limitation to confirm that they can gain energy from the oxidation and that they can't fix CO_2. Sometimes bacteria do not respond well to the relatively high substrate concentrations in batch cultures, or to the presence of contaminants (e.g., SO_3^{-2} frequently contaminates thiosulfate, and can be produced in thiosulfate solutions during heat sterilization).

The Bacteria

The γ-Subclass of the Proteobacteria

These four species were all listed as members of this physiological grouping in earlier editions of *The Prokaryotes* and *Bergey's Manual*. They have now all been transferred to other genera and will be described in the chapter on their respective genera.

Acidiphilium acidophilum synonyms: *Thiobacillus acidophilus* and *Thiobacillus organoparus.*

Paracoccus versutus synonyms: *Thiobacillus versutus*, *Thiobacillus rapidicrescens* and *Thiobacillus* A2.

It is worth noting that *Pa. versutus* was originally isolated from enrichment cultures inoculated from freshwater sediments and designed to produce *Thiobacillus denitrificans*. Anyone aiming to make such enrichments should be aware of the possibility.

Paracoccus pantotrophus synonym: *Thiosphaera pantotropha*.

Starkeya novella synonym: *Thiobacillus novellus*.

The β-Subclass of the Proteobacteria

THE GENUS *THIOBACILLUS* All members of this genus (for synonyms, see Table 1) are Gram-negative rods, some of which are motile. They are also obligately or facultatively autotrophic. Detailed taxonomic descriptions can be found in Kelly and Wood (2000a). However, see Table 2 for general characteristics.

Thiobacillus aquaesulis *Type Strain ATCC 43788 (Wood and Kelly, 1988)* This moderately thermophilic species was isolated from the thermal spring at Bath, Avon, Great Britain. In batch culture containing thiosulfate, this species accumulates sulfur. However, accumulation is not observed under thiosulfate limitation in the chemostat. Although *T. aquaesulis* can grow heterotrophically on complex substrates such as yeast extract, it cannot grow if supplied sugars, organic acids, or methylamine as its sole substrate. NH_4^+ can be used as a source of nitrogen.

Thiobacillus denitrificans *Neotype Strain NCIB 8327 (Beijerinck, 1904; Kelly and Harrison, 1989) Thiobacillus denitrificans* is an obligate autotroph and depends on the oxidation of inorganic reduced sulfur compounds and carbon dioxide fixation. It can assimilate a limited amount of organic carbon. Under anaerobic conditions, these bacteria couple the oxidation of sulfur compounds to the respiratory reduction of nitrogen oxides (such as nitrate or nitrite) to nitrogen gas (denitrification). Their enrichment and isolation can thus be made selective by the use of anaerobic media and cultural conditions. This species contains ubiquinone Q8.

The taxonomic status of *Thiobacillus denitrificans* has recently been evaluated by Kelly and Wood (2000b).

Thiobacillus thioparus *Type Strain ATCC 8158 (Beijerinck, 1904) Thiobacillus thioparus* is the type species of the genus *Thiobacillus*. Like all obligately chemolithotrophic thiobacilli, it has a limited capacity for incorporating organic carbon (e.g., acetate and succinate) into cellular material, but its energy generation for growth obligately depends on the oxidation of inorganic, reduced sulfur compounds. It is differentiated from the similar *T. neapolitanus* by 1) its ability to grow anaerobically in the presence of nitrate (which is only reduced to nitrite), 2) its ability to grow on thiocyanate, and 3) the immediate formation of sulfur in the batch culture medium described for *T. novellus*. Some newly isolated strains can grow chemolithoautotrophically on dimethyl disulfide, dimethyl sulfide, carbon disulfide, and carbonyl sulfide (Smith and Kelly, 1988a; Smith and Kelly, 1988b; Smith and Kelly, 1988c). NH_4^+ and NO_3^- can both be used as nitrogen sources. *Thiobacillus thioparus* contains ubiquinone Q8.

Thiobacillus thioparus can be isolated from fresh water and estuarine and marine sediments (Vishniac and Santer, 1957) a suitable inorganic medium and the enrichment and isolation procedures discussed above.

THE GENUS *THIOMONAS* (MOREIRA AND AMILS, 1997) This newly described genus contains many of the facultatively autotrophic members of the old genus, *Thiobacillus*. They are thus Gram-negative rods, some of which might be motile under suitable grow conditions. For synonyms, see Table 1.

THIOMONAS CUPRINA TYPE STRAIN DSM 5495 (HUBER AND STETTER, 1989) This is a facultatively chemolithotropic, mesophilic acidophile (pH optimum for growth, 3–4) capable of growth on a variety of sulfidic ores and sulfur, but not

on ferrous iron. It can also grow on yeast extract, peptone and pyruvate.

Thiomonas intermedia Type Strain ATCC 15466 (London, 1963) Autotrophic growth of *Ts. intermedia* is slow, and mixtures of glucose and thiosulfate give a much faster growth rate (London and Rittenberg, 1966; Matin and Rittenberg, 1970). While able to grow heterotrophically, *Ts. intermedia* requires a reduced sulfur compound as a source of sulfur. Thiosulfate can be replaced by yeast extract or by a mixture of thiamin pyrophosphate, reduced glutathione, lipoic acid, methionine, cysteine (each at a final concentration of 0.15 mM) together with biotin and coenzyme A (both at final concentrations of 0.015 mM; Smith and Rittenberg, 1974). This organism contains ubiquinone Q8.

Although many thiobacilli will grow in media designed for *Ts. intermedia*, the enrichment of *Ts. intermedia* may be promoted if the pH is allowed to fall below 4.0, as it is relatively acid tolerant. In addition to NH_4^+ and NO_3^-, organic nitrogen compounds can be used as a source of nitrogen. Marine and freshwater strains are known. *Thiomonas intermedia* has been isolated from freshwater sediments. For further details, see London (1963) and London and Rittenberg (1966).

Thiomonas perometabolis Type Strain ATCC 23370 (London and Rittenberg, 1966) It was formerly believed that *Ts. perometabolis* was unable to fix carbon dioxide and was thus unable to grow autotrophically. Its ability to gain energy from the oxidation of reduced sulfur compounds was undisputed, and *Ts. perometabolis* was therefore considered to be a chemolithoheterotroph. However, Harrison (1983) and Katayama-Fujimura et al. (Katayama-Fujimura et al., 1983; Katayama-Fujimura et al., 1984) showed that if relatively large inocula were used, *Ts. perometabolis* could grow chemolithoautotrophically in batch cultures on thiosulfate, and the first enzyme of the Calvin cycle, ribulose-bisphosphate carboxylase, was detected in these cultures.

Thus far, chemostat cultures with a carefully chosen mixture of inorganic and organic components in the medium (Fig. 1) appear to be the most successful selective technique for the cultivation of this type of organism, and at least one chemolithoheterotroph, "*Thiobacillus*" strain Q, has been isolated from this type of culture (Gommers and Kuenen, 1988). Since great care is required to grow this type of organism chemolithoautotrophically, the use of substrate ratios expected to favor chemolithoheterotrophs might more successfully enrich for *Ts. perometabolis* than those expected to favor mixotrophs. For batch culture, the basic medium described for *Ts. intermedia* may be used, with yeast extract or casein hydrolysate supplements.

"*Thiobacillus rubellus*," a strain which appears to differ from *Ts. perometabolis* only in its colony color, was described by Mizoguchi et al. (1976).

Thiomonas thermosulfata Type Strain ATCC 51520 (Schooner et al., 1996) This organism grows autotrophically on thiosulfate, tetrathionate and sulfur, heterotrophically on yeast extract, glutamate and succinate, and mixotrophically. It does not grow on ferrous iron or formate. As its name suggests, it is a moderate thermophile. In thiosulfate medium, the pH can fall as low as 2.8. *Thiomonas thermosulfata* contains ubiquinone Q8.

"*Thiobacillus plumbophilus*" Type Strain DSM 6690 (Drobner et al., 1992) This organism was isolated from a German uranium mine. It is obligately autotrophic, able to grow on H_2S, PbS or H_2, but not sulfur, thiosulfate or many other metal sulfides. It is strictly aerobic. It contains 96.5% ubiquinone Q8. As it has little or no DNA hybridization with *Ts. cuprina*, this species is probably not a member of the genus *Thiomonas*. Physiologically, it resembles *Acidithiobacillus ferrooxidans*, which is a member of the γ-subclass. Moreover, there is no DNA hybridization between the two. The status of *T. plumbophilus* therefore requires further consideration.

The γ-Subclass of the Proteobacteria

The range of environmental optima shown by the species listed here serves to emphasize the fact that the ability to metabolize reduced sulfur compounds is a fairly loose taxonomic criterion. In fact, it is in the γ-subclass that the extremophilic colorless sulfur bacteria are found.

The genus *Acidithiobacillus* All members of this genus (for synonyms see Table 1) are Gram-negative rods, some of which are motile. They are obligate acidiphiles. The full description of this genus is given in Kelly and Wood (2000a), but the basic characteristics are summarized in Table 3. These are generally the species previously known as the autotrophic, acidiphilic *Thiobacilli*.

Acidithiobacillus albertensis *Type Strain ATCC 35403 (Bryant et al., 1983; Kelly and Wood, 2000a)* Although physiologically similar to *A. thiooxidans*, the G+C content of this strain differs significantly (Table 3), and it must therefore be considered a separate species. *Acidithiobacil-*

lus albertensis was isolated from the acid soil adjacent to a sulfur stockpile. The cells have a condensed glycocalyx and, like *A. ferrooxidans*, have been observed to accumulate internal sulfur deposits.

As the two species are so similar, *A. albertensis* can be cultured on the media described for *A. thiooxidans*. However, it should be noted that the pH range of *A. albertensis* does not extend to the low level associated with *A. thiooxidans*, and its lower limit is pH 2.0. NH_4^+ is used as a source of nitrogen. Further details can be found in Bryant et al. (1983).

Acidithiobacillus caldus *Type Strain: Strain KU; DSM 8584; ATCC 51756 (Hallberg and Lindström, 1994; Kelly and Wood, 2000a)* Short, motile, rods that can grow on reduced sulfur compounds and hydrogen, but not on ferrous iron or metal sulfides. They can grow mixotrophically if provided with tetrathionate and glucose or yeast extract.

Acidithiobacillus ferrooxidans *Type Strain ATCC 23270 (Temple and Colmer, 1951; Kelly and Wood, 2000a) Acidithiobacillus ferrooxidans* is an obligate autotroph that is able to derive energy from the oxidation of ferrous iron as well as reduced sulfur compounds. During growth on thiosulfate, trithionate, tetrathionate and sulfide, *A. ferrooxidans* has been observed to accumulate fine sulfur deposits, which are predominantly associated with the cell wall (Hazeu et al., 1988). Early reports of facultatively autotrophic *A. ferrooxidans* strains are now believed to have been due to the presence of facultatively autotrophic (see *Acidiphilium acidophilum*) or heterotrophic contaminants, some of which have been difficult to remove, as their presence can stimulate the growth of the autotroph (Harrison, 1984). The ability to oxidize Fe^{2+} is the key characteristic that is generally employed in isolation procedures. Initial enrichments with reduced sulfur compounds frequently produce mixtures of various acidophilic thiobacilli, whereas enrichment on Fe^{2+} can result in almost pure cultures of *A. ferrooxidans*.

Ferrous Sulfate Medium for the Isolation and Batch Culture of *A. ferrooxidans* (Temple and Colmer, 1951; Tuovinen and Kelly, 1973)

Solution I

$K_2HPO_4 \cdot 7\ H_2O$	0.5 g
$(NH_4)_2SO_4$	0.5 g
$MgSO_4 \cdot 7\ H_2O$	0.5 g
H_2SO_4, 15 N solution	5.0 ml

Dissolve in 1 liter of deionized water and sterilize by autoclaving.

Solution II

$FeSO_4 \cdot 7\ H_2O$	167 g
H_2SO_4, 15 N solution	50 ml

Dissolve in 1 liter of deionized water and sterilize by filtration. Four parts of solution I and 1 part of solution II are mixed to give a medium containing 120 mM Fe^{2+}. Should it be necessary to prevent iron precipitates from forming in the medium, the pH of the cultures can be lowered in successive subcultures to a value of 1.3 with H_2SO_4.

To prepare solid media, high purity agar or agarose must be used at low concentrations. Most brands solidify sufficiently at concentrations of 0.3–0.4% (w/v). Better results are obtained if the agar is previously washed with distilled water to remove inhibitory substances. Membrane filters that have been previously washed in distilled water can be used to support the bacteria on solid or liquid media, as described in the section on enrichment and isolation (De Bruyn et al., 1990).

Medium for the Growth of *A. ferrooxidans* on Reduced Sulfur Compounds in Batch Culture

Solution III (per liter):

KH_2PO_4	3.0 g
$(NH_4)_2SO_4$	3.0 g
$MgSO_4 \cdot 7\ H_2O$	0.5 g
$CaCl_2 \cdot 2\ H_2O$	0.5 g

Dissolve in 1 liter of deionized water and sterilize by autoclaving. After sterilizing, 0.15 ml of solution II can be added, together with one of the following substrates: $Na_2S_2O_3 \cdot 7\ H_2O$, 10 g; $K_2S_4O_6$, 3.0 g; or flowers of sulfur, 5.0 g.

For growth on reduced sulfur compounds, the initial pH should be around 3.8–4.4. *Thiobacillus ferrooxidans* can use NH_4^+ and NO_3^- as nitrogen source and has been reported to be able to fix N_2 (McKintosh, 1978).

Acidithiobacillus thiooxidans *Type Strain ATCC 19377 (Waksman and Joffe, 1922; Kelly and Wood, 2000a)* These obligately autotrophic bacteria are typically found in acidic environments where they account for the production of copious amounts of sulfuric acid from reduced sulfur compounds. They have been isolated from soil, sulfur deposits, and mine refuse. *Acidithiobacillus thiooxidans* may be easily enriched in acid media with elemental sulfur as substrate, but this is not a specific medium, and the other acidophiles may also appear. *Acidithiobacillus thiooxidans* can grow at lower pH values (down to pH 0.5) than any other known species in this group.

Medium for the Isolation and Batch Culture of *A. thiooxidans* (Waksman and Joffe, 1922; Starkey, 1935)

K_2HPO_4	3.5 g
$(NH_4)_2SO_4$	0.3 g
$MgSO_4 \cdot 7\ H_2O$	0.5 g
$FeSO_4 \cdot 7\ H_2O$	0.018 g
CaCl	0.25 g
Flowers of sulfur	5.0 g

Dissolve in 1 liter of deionized water, adjust to pH 4.5 with HCl, and sterilize by autoclaving.

Solid media can be prepared for *A. thiooxidans* using thiosulfate (10 g/liter) or colloidal sulfur (Wieringa, 1966):

Mix 25–30 ml of molten, sterile mineral salts medium (containing 15 g/liter agar) with 1–1.5 ml of 0.15 N HCl in a 10-cm Petri dish and allow to set. Then pour 10 ml of mineral medium supplemented with polysulfide solution on top (2 ml/liter). The HCl diffuses upwards and precipitates sulfur as a fine suspension. The H_2S is removed and the surface of the agar is dried by warming the plate. Polysulfide solution can be prepared by mixing a saturated H_2S solution in water with a saturating amount of sulfur, followed by autoclaving.

These plates can be prepared with different mineral salts media for the growth of other sulfur bacteria at different pH values. NH_4^+ can be used as a nitrogen source.

"Thiobacillus prosperus" *Type Strain DSM 5130 (Huber and Stetter, 1989)* This organism is a member of the γ-subclass and therefore not a true member of the genus *Thiobacillus*, but requires further study before it can be assigned to its new genus. However, because it is an acidophile, it is most appropriately listed with the other acidophiles until such time as its correct genus is established.

"*Thiobacillus prosperus*" was first isolated from a marine hydrothermal area off Italy (Huber and Stetter, 1989). It is an obligate autotroph that can grow aerobically on pyrite, sphalerite, chalcopyrite, arsenopyrite, and galena as well as on H_2S. Growth on Fe^{2+} and sulfur is poor, and thiosulfate, tetrathionate, and synthetic versions of the different ores do not generally support growth. This species is markedly less sensitive to salt (grows at NaCl concentrations up to 6%) than *A. ferrooxidans* is (does not grow at NaCl concentrations above 1%; Huber and Stetter, 1989), but it should be regarded as halotolerant rather than halophilic because a concentration of 1% NaCl nearly doubled its doubling time. As it is physiologically similar to *A. ferrooxidans* (although the amount of DNA hybridization between them was negligible), "*T. prosperus*" can be grown in the media described for *A. ferrooxidans*.

CHAPTER 3.2.14

The Genera *Simonsiella* and *Alysiella*

BRIAN P. HEDLUND AND DAISY A. KUHN

Introduction

The genera *Simonsiella* and *Alysiella* are filamentous, aerobic, chemoorganotrophic members of the Neisseriaceae in the Betaproteobacteria. *Simonsiella* is part of the normal flora of the oral cavity of a variety of phylogenetically and ecologically diverse warm-blooded vertebrates (Table 1). *Simonsiella* is distinguished from other bacteria on the basis of morphology (Fig. 1). Individual cells are wide (1.9–6.4 μm), short (0.5–1.3 μm), and relatively flat (0.5–1.3 μm) and attach to form monoseriate filaments that are 8 or more cells long. Cells at either end of the filament are often narrower than cells in the center, giving the filament a tapered appearance. In some strains, filaments of 8 or more cells remain attached, giving rise to "super" filaments that reach 50 or more μm in length. *Simonsiella* cells are crescent-shaped, which causes filaments to bend, yielding a watchband shaped filament with convex-dorsal and concave-ventral asymmetry. This dorsal-ventral asymmetry is functional since *Simonsiella* attach to squamous epithelial cells exclusively via their ventral surface and glide along the long axis of the filament (Fig. 1e). Chemotaxonomic and phylogenetic studies of *Simonsiella* isolates from the mouths of different mammals suggest that each mammal may host a unique species of *Simonsiella*.

Alysiella is similar to *Simonsiella* except filaments are composed of oblong disk-shaped cells that are neither dorsoventrally differentiated nor tapered toward the ends (Fig. 1f). Currently there is only one confirmed isolate of *Alysiella* and this isolate is related to *Simonsiella* on the basis of 16S rDNA sequence analysis. Other strains previously referred to as *Alysiella* belong to the genus *Moraxella* in the Gammaproteobacteria.

Phylogeny

Rossau et al. (1989) and Dewhirst et al. (1989) showed that isolates of *Simonsiella* and the type strain of *Alysiella filiformis* are closely related to the genera *Neisseria*, *Kingella* and *Eikenella* by DNA-DNA hybridization (Rossau et al., 1989), rRNA-DNA hybridization (Rossau et al., 1989), and 16S rRNA sequencing and phylogenetic analysis (Dewhirst et al., 1989); therefore, the family Neisseriaceae was emended to include these genera (Dewhirst et al., 1989). Rossau et al. also showed that two other strains deposited in culture collections as *Alysiella*, American Type Culture Collection (ATCC 29468) and Hygiene Institut, Universitä Marburg, Marburg, Germany (HIM 1018-2), actually belong to the Gammaproteobacteria (Rossau et al., 1989; Rossau et al., 1991), and this led to an erroneous report that *Alysiella* is a member of the Gammaproteobacteria (Stackebrandt et al., 1988). More recently the 16S rRNA gene has been sequenced from ATCC 29468 and this sequence confirms that this strain is a member of the genus *Moraxella* (C. Xie and A. Yokota, unpublished data). Apparently certain filamentous morphotypes of *Moraxella* are morphologically and chemotaxonomically very similar to the type strain of *Alysiella*.

The first study of the phylogeny within the genus *Simonsiella* was by Hedlund and Staley (2002), who sequenced the 16S rRNA gene from four isolates from each of four different animal hosts: humans, sheep, dogs and cats. The resulting phylogeny showed that the genus *Simonsiella* is paraphyletic within the Neisseriaceae, a result that could be considered surprising given the distinctive morphology of the genus. There are many plausible explanations for the paraphyly of *Simonsiella* (see Funk and Omland, 2003). One possible explanation for the paraphyly of the genus is that horizontal transfer of 16S rRNA genes has occurred within the Neisseriaceae through transformation and recombination, partly obscuring the record of the vertical evolution of the group. Indeed, members of the genus *Neisseria* are well known for their natural competence, and this genus cohabits the oral cavity with *Simonsiella* (see The Genus Neisseria in this Volume). Alternatively, it is possible that *Simonsiella* morphology is unstable on an evolutionary scale.

Table 1. Known occurrence of *Simonsiella* in the oral cavities of warm-blooded vertebrates.

Despite the apparent paraphyly of the genus, *Simonsiella* isolates from each host animal form a well-supported monophyletic group (Hedlund and Staley, 2002), suggesting that each species of mammal hosts a unique species of *Simonsiella*, as originally suggested by Kuhn and coworkers (Jenkins et al., 1977; Kuhn et al., 1978) and supported by chemotaxonomic studies (Kuhn et al., 1978), distinct ranges of DNA G+C content (Kuhn et al., 1977), distinct fatty acid content (Jenkins et al., 1977), and distinct cellular carbohydrate content (Heiske and Mutters, 1994; see the section Identification in this Chapter). These host-specific *Simonsiella* groups correspond to the three validly described *Simonsiella* species: *S. muelleri* from humans, *S. crassa* from domestic sheep, and *S. steedae* from domestic dogs. Although the *Simonsiella* strains isolated from domestic cats form a well-supported monophyletic group, they have not been assigned a species since this group is more phylogenetically diverse than the described *Simonsiella* species and since these strains are phenotypically similar to *S. steedae*. Furthermore, *S. steedae* and the isolates from cats have not been tested by DNA-DNA hybridization.

If the pattern of host animal-*Simonsiella* specificity is confirmed with studies of *Simonsiella* isolates from other hosts, this would indicate that the barriers to *Simonsiella* transfer between hosts of different animal species are much higher than the barriers to *Simonsiella* transfer among members of a single host species. Kuhn (1981) suggested that these host-specific *Simonsiella* groups could be considered ecospecies and that the *Simonsiella* that normally inhabit the oral cavity of a particular animal might evolve to thrive within the mouth of its host through adaptations to the nutrition provided by the host animal, to the microbial community within the mouth of the host animal, or to other host-specific factors.

It has been suggested that the divergence of *Simonsiella* into host-specific groups may have been forced by the divergence of the host animals (Hedlund and Staley, 2002). Evidence in support of this hypothesis is that the *Simonsiella* isolates from carnivores—domestic dogs and cats—are more closely related to each other than they are to *Simonsiella* strains from humans and sheep. This pattern is predicted by the co-divergence hypothesis because dogs and cats are together in the order Carnivora and are thought to have diverged about 45 million years ago, whereas the carnivores are thought to have diverged from primates and artiodactyls 80–100

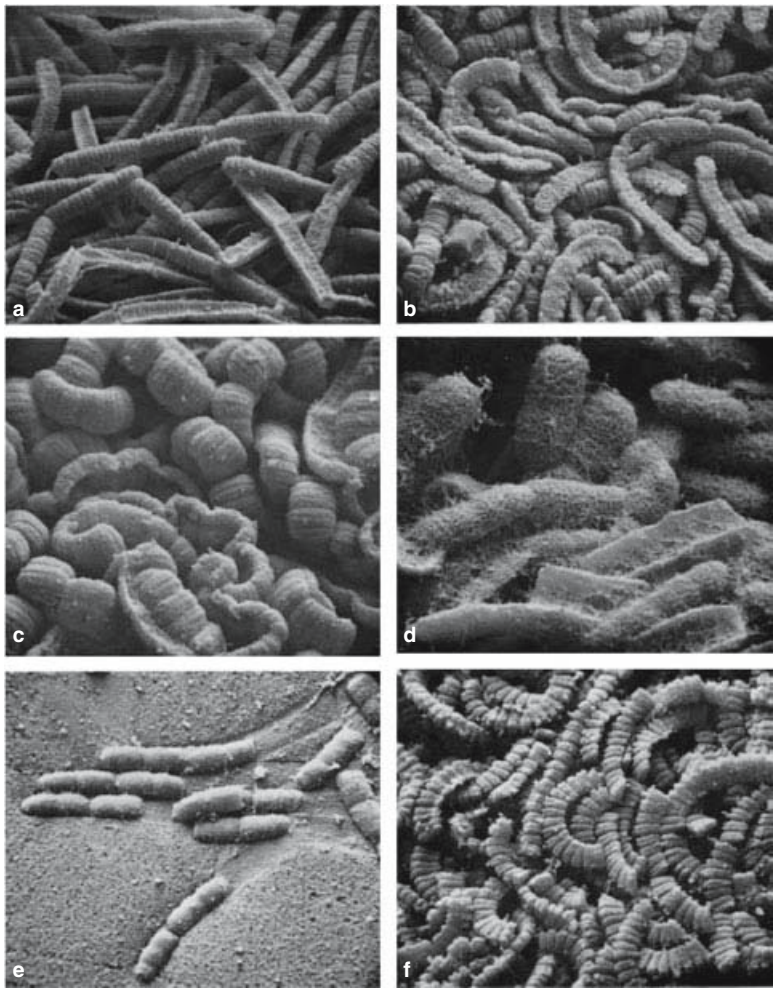

Fig. 1. Scanning electron micrographs illustrating the morphology of four *Simonsiella* strains and one *Alysiella* strain cultivated on BSTSY agar at 37°C for 10 h (a, b, c, d and f) and 4 days (e). a) *Simonsiella crassa* neotype ATCC 27504 of sheep origin forms straight, relatively slender filaments with rounded ends; the individual crescent-shaped cells can be recognized on both the convex dorsal and the concave ventral sides of the filaments; compare with Fig. 7a. b) *Simonsiella* sp. ATCC 27381 of cat origin shows lateral curvature of the filaments with large amounts of irregularly structured ("fuzzy") extracellular material obscuring the cells on the concave ventral side of the filaments; compare with Fig. 7g. c) *Simonsiella steedae* ATCC 27396 of dog origin forms broad filaments with dorsal curvature that causes the filaments to lie on edge. Some filaments are apposed to each other on their ventral sides. d) *Simonsiella steedae* ATCC 27411 of dog origin possesses copious amounts of extracellular capsular material obscuring entirely the multicellular nature of the *Simonsiella* filaments; compare with Fig. 7f. e) *Simonsiella steedae* ATCC 27411 of dog origin showing gliding tracks impressed in the agar surface. In the hydrated state the tracks are filled with liquid and can be seen with a light microscope at low magnification. The dorsal capsular material obscures the multicellular structure of the filaments. f) *Alysiella filiformis* neotype ATCC 29469 of sheep origin. The multicellular filaments are flat and are composed of closely apposed pairs of oblong disk-shaped cells; *Alysiella* filaments lack the dorsal-ventral and the terminal differentiations characteristic of the genus *Simonsiella*. Compare with Fig. 7b. × 2250 (a, b, c, d and f). × 1125 (e). (a, b, c, d and e from Pangborn et al., 1977.)

million years ago (Kumar and Hedges, 1998). We believe that the co-divergence hypothesis should be tested with *Simonsiella* strains isolated from wild animals since it seems that host switching is more likely to occur in domestic and zoo animals than in natural populations and since presumed transient *Simonsiella* strains have occasionally been isolated from domestic animals (Kuhn et al., 1978; D. A. Kuhn, unpublished observations).

The 16S rRNA gene of type strain of *Alysiella filiformis* was recently sequenced by two groups (K. K. Garborg, et al., unpublished data; C. Xie and A. Yokota, unpublished data) and shown to form a well-supported monophyletic group with the sequences from *S. crassa* (Fig. 2). It is interesting that both *A. filiformis* and *S. crassa* are of sheep origin. Given the close phylogenetic position of the type strain of *A. filiformis*

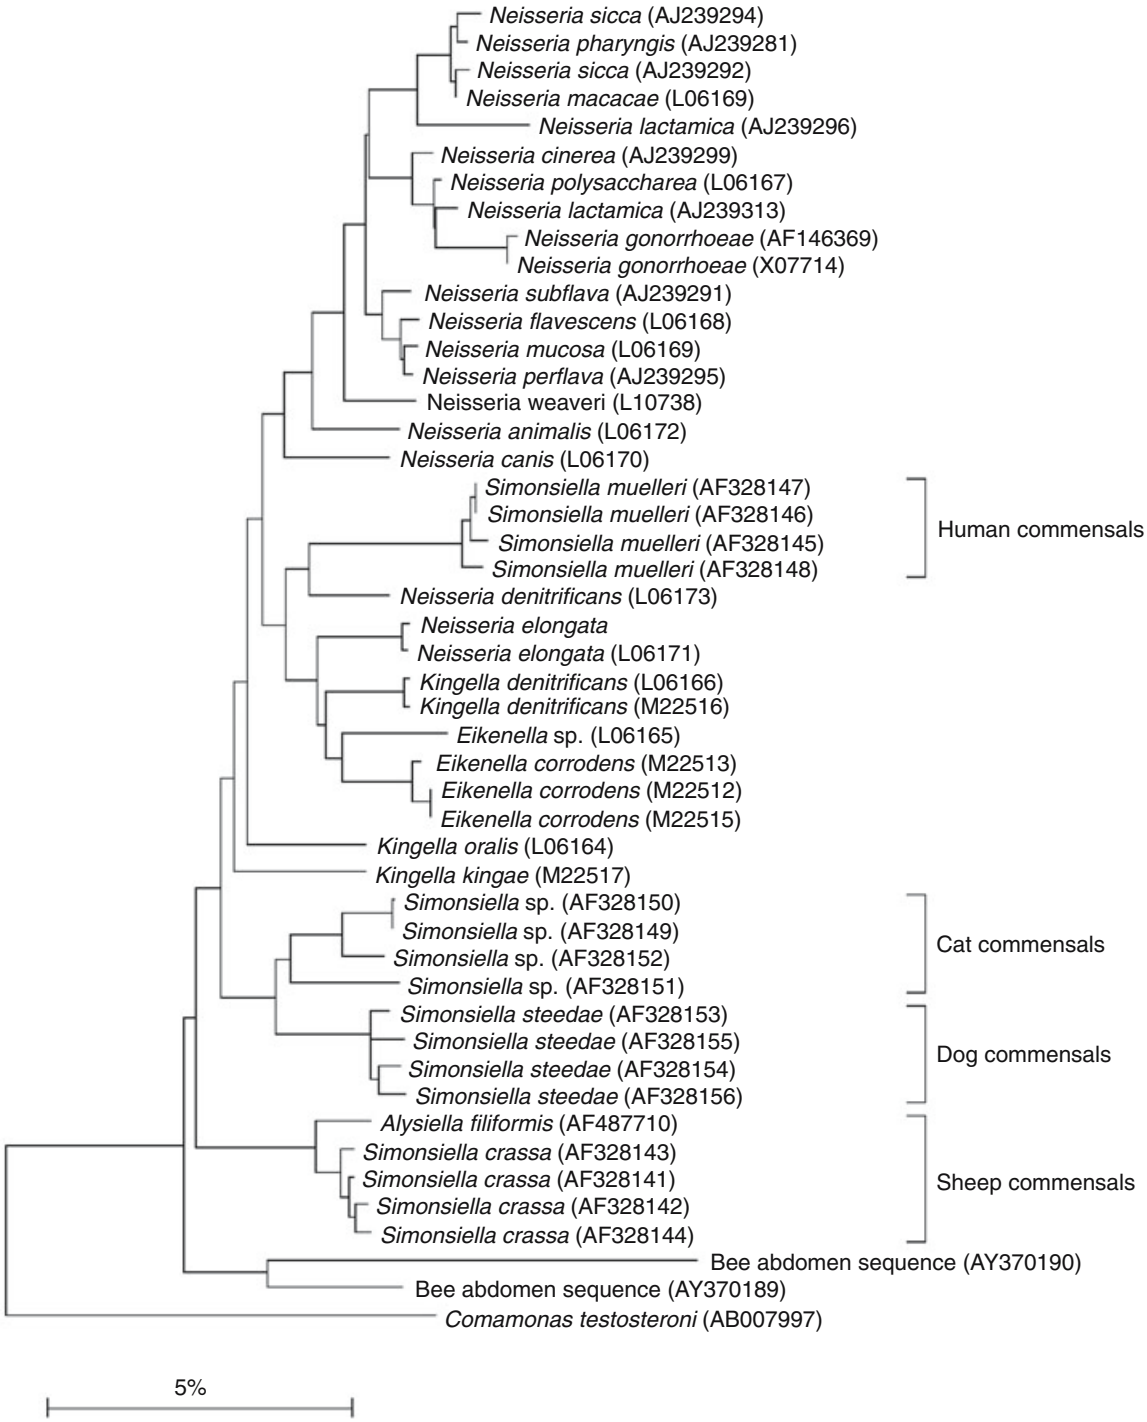

Fig. 2. 16S rRNA gene phylogenetic tree showing the position of *Simonsiella* and *Alysiella* among some other members of the Neisseriaceae. The tree was created using Treecon (Van de Peer and de Wachter, 1994) with a Kimura 2-parameter correction and the neighbor-joining algorithm of tree construction. Similar phylogenies were obtained with parsimony and maximum-likelihood methods (Hedlund and Staley, 2002).

with *Simonsiella crassa*, along with the confusion in identifying *Alysiella*, it may be prudent to dissolve the genus *Alysiella* and emend the description of *Simonsiella* and *S. crassa* to include the type strain of *A. filiformis*. However, we believe further study is warranted to address this issue.

Given the paraphyly of *Simonsiella* and the poor representation of *Alysiella* 16S rRNA gene sequences in public databases, caution should be

used when identifying members of these genera via culture-independent 16S rRNA gene surveys. *Simonsiella*-like sequences have recently been recovered from material from the abdomens of worker bees (Jeyaprakash et al., 2003); however, these two sequences group together at the base of the Neisseriaceae and there are no data on whether these sequences come from bacteria phenotypically similar to *Simonsiella*; thus, these bacteria are unlikely to belong to the genus *Simonsiella* sensu stricto.

Taxonomy

Currently, three species of *Simonsiella* have been validly described: *S. muelleri* from humans (Kuhn and Gregory, 1978), *S. crassa* from domestic sheep (Steed, 1962), and *S. steedae* from domestic dogs (Kuhn and Gregory, 1978). These species are each monophyletic (see the section Phylogeny in this Chapter) and can be distinguished chemotaxonomically (Kuhn et al., 1978; Heiske and Mutters, 1994; Table 2). A fourth monophyletic group from domestic cats has not been assigned a species designation due to its phenotypic similarity with *S. steedae* and the fact that the cat *Simonsiella* isolates have not been compared with *S. steedae* by DNA-DNA hybridization.

Only a single species of *Alysiella* has been described, *A. filiformis* (Steed, 1962). It seems likely that study of *Simonsiella* and *Alysiella* from more diverse hosts could greatly expand the taxonomy of the group.

Habitat

To date, representatives of the genera *Simonsiella* and *Alysiella* have been found exclusively in the oral cavities of warm-blooded vertebrates. The earliest recorded observation of *Simonsiella* was made by Miller in 1906 (Simons, 1922) in the throat mucus of a diphtheritic chicken and in plaque and saliva of humans. Since then, many of these organisms have been discovered inhabiting the mouths of a wide variety of mammals (Table 1) and Simons (1922) mentions that Schmid may have seen such organisms in the mouths of donkeys, elephants, hippopotami, monkeys, and other animals. *Simonsiella* has also been observed in an oral smear from an orangu-

Data generally from Kuhn et al. (1978).

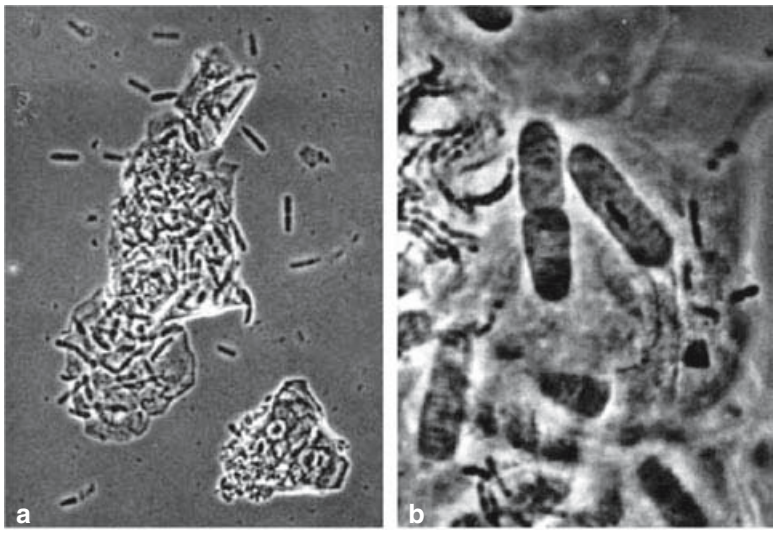

Fig. 3. Phase-contrast photomicrographs of a wet mount in saliva of an oral swabbing from the hard palate of a youth. a) At low magnification (×260) with a 10× objective lens, numerous rod-shaped *Simonsiella* filaments are seen on and near the epithelial cells. b) At high magnification (×1825) with an oil-immersion 100× objective lens, the multicellular (striated) structure of the *Simonsiella* filaments can be recognized. Their enormous size is apparent by comparison with the adjacent streptococci.

tan at the Los Angeles Zoo (R. Bledsoe, unpublished observations). Simons (1922) found *Simonsiella* in every oral specimen from every animal species he examined.

Simonsiella and *Alysiella* colonize the mouth by adhering to the mucosal squamous epithelium. In wet mounts or stained smears of oral swabbings, the multicellular filaments are seen attached to desquamated cells, often in great numbers; generally, there are few free filaments (Fig. 3). Stereoscopic scanning electron micrographs show the flat *Simonsiella* filaments oriented with their concave ventral side toward the surface of the epithelial cells (Nyby et al., 1977). The ventral capsule with its fibrillar components (the dorsal capsule of *Simonsiella* filaments lacks these structures) is probably involved in the adhesion to and the gliding locomotion on the cells of the oral mucosa (Figs. 1a–d and 4). Such structures are also present on the type strain of *A. filiformis* (Kaiser and Starzyk, 1973; J. Pangborn et al., unpublished observations). These organisms likely maintain themselves in the oral cavity by gliding and adhering to new epithelial cells during the ongoing desquamation of these cells and their elimination in the flow of saliva.

The preferred site of colonization in the mouth appears to be the palate, although *Simonsiella* has also been found in samples from the buccal cavity, gingival margin, tongue, throat, and base of the mouth (Miller, 1911; Simons, 1922; Fellinger, 1924; Berger, 1963; Richardson et al., 1966; Saphir and Carter, 1976; Nyby et al., 1977; Kuhn et al., 1978). *Simonsiella* has been seen neither in tubercular sputum nor on teeth (Fellinger, 1924). Fellinger (1924) attributed the abundant occurrence of *Simonsiella* in the mouth to the ready access of air to that site. Today, the strict aerobic nature of *Simonsiella* has been established in axenic culture.

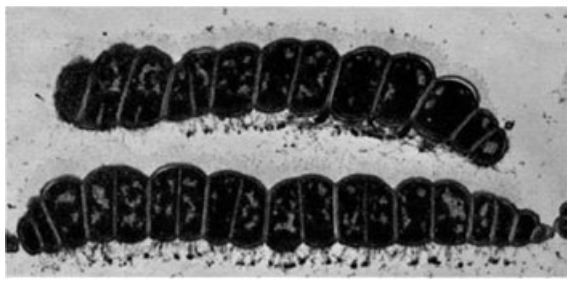

Fig. 4. Transmission electron micrograph of a longitudinal thin section of multicellular filaments of *Simonsiella steedae* ATCC 27411 situated within a colony showing the dorsal-ventral differentiation of *Simonsiella* at the cytological level. The prokaryotic cells possess Gram-negative-type cell walls that form asymmetrically from the ventral side. The dorsal capsule is undifferentiated; the ventral capsule contains fibrils emerging from the cells at right angles; within the cytoplasm there are fewer ribosomes and more membranes in the ventral region. Compare with Fig. 1. ×19,400. (From Pangborn et al., 1977.)

In healthy human populations, the incidence of *Simonsiella* is in the range of 30–40% (Simons, 1922; Kuhn et al., 1974; Gregory et al., 1985), while it is 4% or less in individuals with oral pathologies (Simons, 1922; Bruckner and Fahey, 1969). A study comparing the diets of *Simonsiella* carriers versus noncarriers indicated that carriers have a significantly higher daily intake for 13 dietary variables, including four fat components; however, the carbohydrate intakes were not statistically different between carriers and noncarriers (Gregory et al., 1985). Children possibly have a higher incidence than adults (Fellinger, 1924; Richardson et al., 1966). Some people consistently harbor large numbers—literally masses—of *Simonsiella*, especially after waking up in the morning; others carry few or none. Antibiotic (ampicillin) treatment for a res-

piratory ailment has been known to eliminate *Simonsiella* from the mouth of a long-term carrier (Gregory, 1975).

In dogs and cats, the incidence and abundance of *Simonsiella* are very high, the incidence approaching 100% in specimens from the palate or from the buccal cavity (Nyby et al., 1977). *Simonsiella* is less likely to be found in specimens from oral fluids and gingival margins (about 20% incidence; Saphir and Carter, 1976; Bailie et al., 1978).

Note, however, that the preceding survey provides only a rough estimate of the occurrence of *Simonsiella*. The figures vary not only with the site in the mouth from which the specimens are obtained, but also with the method of observation. Direct microscopic observation of oral specimens on plates (see Kuhn et al. [1974], Nyby et al. [1977], Kuhn et al. [1978] and the section Isolation) yields higher percentages than the detection of macroscopic colonies after prolonged incubation (Richardson et al., 1966; Saphir and Carter, 1976; Bailie et al., 1978). As previously mentioned, the sampling of animals for these bacteria has been limited to a phylogenetically and ecologically limited group of animals so the breadth of habitats for *Simonsiella* and *Alysiella* may not be currently appreciated.

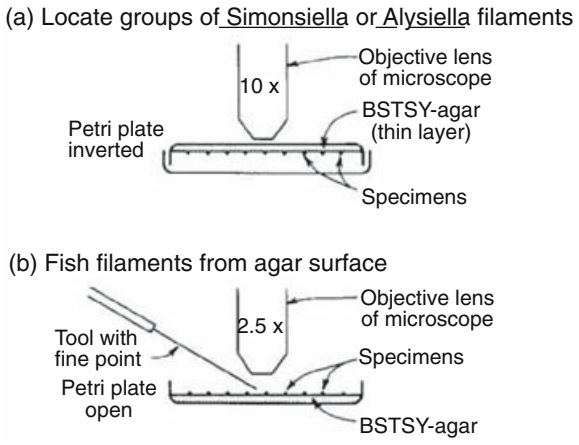

Fig. 5. Procedure for the isolation of *Simonsiella* and *Alysiella*. a) After a brief incubation period, the oral swabbings on the agar surface can be surveyed microscopically for suitable specimens with the Petri plates covered (to prevent microbial contamination from the air) and inverted. b) The use of a 2.5× objective lens facilitates the "fishing" process because it affords a greater working distance and a wider field of view with the microscope. Figure 5 shows oral specimens at low magnification.

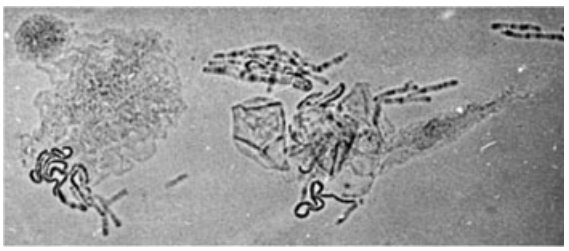

Fig. 6. General appearance of oral specimens after 6 h of incubation at 37°C on a thin layer of BSTSY agar in a Petri plate viewed microscopically with a 10× objective lens. Several groups of *Simonsiella* filaments, seen on broad side and on edge, are located near epithelial cells (center) and microcolonies of "ordinary-sized" bacteria (upper left and right). The group at top center is located in a suitable position for isolation of axenic cultures of *Simonsiella*. ×200.

Isolation

Enrichment culture techniques to facilitate the isolation of *Simonsiella* and *Alysiella* have as yet not been developed. Preliminary attempts to design selective media with antibiotics and dyes (e.g., crystal violet) in the hope of encouraging the growth of these Gram-negative organisms while suppressing or inhibiting the numerous Gram-positive members of the oral flora have not met with success (Nyby, 1974). Therefore, the most direct and least time-consuming approach for isolating axenic cultures relies on the microscopic recognition of the morphologically conspicuous *Simonsiella* and *Alysiella* organisms amid the great diversity of other oral bacteria (Steed, 1962; Kuhn et al., 1978). This approach has also been used to determine the incidence of *Simonsiella* in humans (Kuhn et al., 1974) and in dogs (Nyby et al., 1977).

Oral samples are obtained by rubbing sterile cotton swabs over the animals' palates. The swabs are then rolled directly and without delay (without the use of a transport medium in laboratory as well as in field situations) over the surface of thin layers of BSTSY agar in plastic Petri plates. The plates are then incubated aerobically at 37°C for 6–10 h. This brief incubation period allows the *Simonsiella* and *Alysiella* filaments to multiply and glide from the oral squamous epithelial cells onto the agar surface so that they can be more readily detected. Longer incubation causes the filaments to be overgrown, especially by streptococci. The agar surface is then scanned microscopically with a 2.5× or 10× objective in combination with a 10× or 12.5× ocular lens. Well-isolated microcolonies are transferred to BSTSY agar plates of normal thickness with a flame-sterilized dissection needle or other tool with a fine point (Figs. 5 and 6). Successful transfers result in macroscopic colonies after 16–20 h of aerobic incubation at 37°C.

Simonsiella and putative *Alysiella* can be readily recognized microscopically at low magnification. The filaments are generally attached to

or located near epithelial cells; they are broad, 2–10 μm wide, and the intercellular septations give the filaments the appearance of cross-striation (Fig. 3). After a few hours of incubation, a second microscopic examination generally reveals more numerous filaments and evidence of gliding locomotion from the epithelial cells onto the agar surface. Researchers must take care in identifying putative *Alysiella* isolates. The identity of such cultures should be confirmed with some genetic approach, preferably by 16S rRNA gene analysis, to distinguish this genus from morphologically and phenotypically similar *Moraxella* strains which also inhabit the oral cavity (see the section Phylogenetics in this Chapter).

The tool with a fine point that is used for isolation of filaments has to fit the manual dexterity of the individual operator while the plates are being viewed under the microscope. Individual preferences have called for tools differing in weight and shape (e.g., a dissecting needle, a dental probe, or an inoculating needle with or without a holder).

The incubation temperature of 37°C is an important factor, because newly isolated strains tend to have a narrow temperature tolerance range. However, in attempts to isolate *Simonsiella* or *Alysiella* from a new animal host, the incubation temperature should probably match the oral temperature of the host. An aerobic atmosphere (air without the addition of, e.g., 5% CO_2) is advantageous in selecting the strictly aerobic *Simonsiella* and *Alysiella*. Also, newly isolated strains need to be transferred at 2- to 3-day intervals. Refrigeration is not recommended.

Great abundance of filaments in a given oral cavity aids isolation. However, it is not necessarily an indicator of probable success. Some filaments are difficult to "fish" and transfer. Furthermore, filaments from a known carrier have been known to lyse after a mere 2–3 h of incubation on BSTSY agar (Kuhn et al., 1978). The cultural requirements are evidently not yet known for some members of the genera *Simonsiella* and *Alysiella*.

Another approach for isolating axenic cultures of *Simonsiella* and *Alysiella* depends on picking macroscopic colonies that develop from oral samples. This is, however, a more random process because it is difficult to identify the correct colonies among the many colonies of other oral organisms. Also, if the original sample consisted of a relative minority of *Simonsiella* or *Alysiella*, these bacteria may become crowded out or overgrown by other bacteria. On blood agar, small (0.2–0.3 mm diameter), oxidase-positive colonies with a narrow zone of hemolysis may on microscopic examination be *Simonsiella*, although hemolysis is not necessarily a reliable guideline for detecting these colonies. As the colonies expand, they cover the area of hemolysis and thus obscure it (Berger, 1963). Various types of blood (e.g., sheep, rabbit and horse) may not be hemolyzed equally by all *Simonsiella* strains. Finally, some strains, especially from dogs and cats (Berger, 1963; Bailie et al., 1978), may not be hemolytic.

BSTSY Agar for Isolation of *Simonsiella* and *Alysiella* (Kuhn et al., 1978)

Tryptic soy broth without dextrose (Difco)	2.75% w/v
Yeast extract (Difco)	0.4% w/v
Agar (Difco)	1.5% w/v
Distilled water	90% v/v
Sterile bovine serum	10% v/v

Add the sterile bovine serum aseptically after autoclaving the rest of the medium and cooling it to 45°C in a water bath. Pour the medium into plastic Petri plates in thin layers to facilitate microscopic examination during the isolation procedure or in layers of normal thickness for cultivation of axenic strains.

Identification

Identification of the genus *Simonsiella* can be made by careful microscopic examination; axenic cultures are not necessary for generic identification. The filaments of *Simonsiella* possess distinctive dimensions for bacteria: Cells are ≥2 μm × ≥10 μm, and filaments as wide as 10 μm or as long as 90 μm have been observed (Fig. 7). The scanning electron micrographs in Fig. 1 clearly depict the morphology of *Simonsiella* and some of its variations. With these images in mind, one can readily recognize the distinctive features of these bacteria via light microscopic examination, preferably with a phase-contrast microscope, of wet mounts or agar surfaces (e.g., to photograph the bacteria; Kuhn and Starr, 1972). In contrast to *Simonsiella*, putative *Alysiella* strains identified by microscopy must be confirmed by some genetic technique, such as 16S rRNA gene analysis.

Caution should be practiced in identifying *Simonsiella* cells stained with routine bacteriological stains, especially the Gram stain. Firstly, the filaments fall flat onto the microscope slide when a smear is dried, and their three-dimensional ribbon-like structure can be overlooked. Secondly, the Gram stain procedure may give erroneous results on this large organism because of incomplete decolorization. Thus, the flat, Gram-negative *Simonsiella* may be mistakenly identified as the cylindrical, Gram-positive *Caryophanon* (see Smith and Trentini [1973] for discussion of Gram staining in *Caryophanon*).

While *Simonsiella* and *Alysiella* have been classified on the basis of their gliding capacity

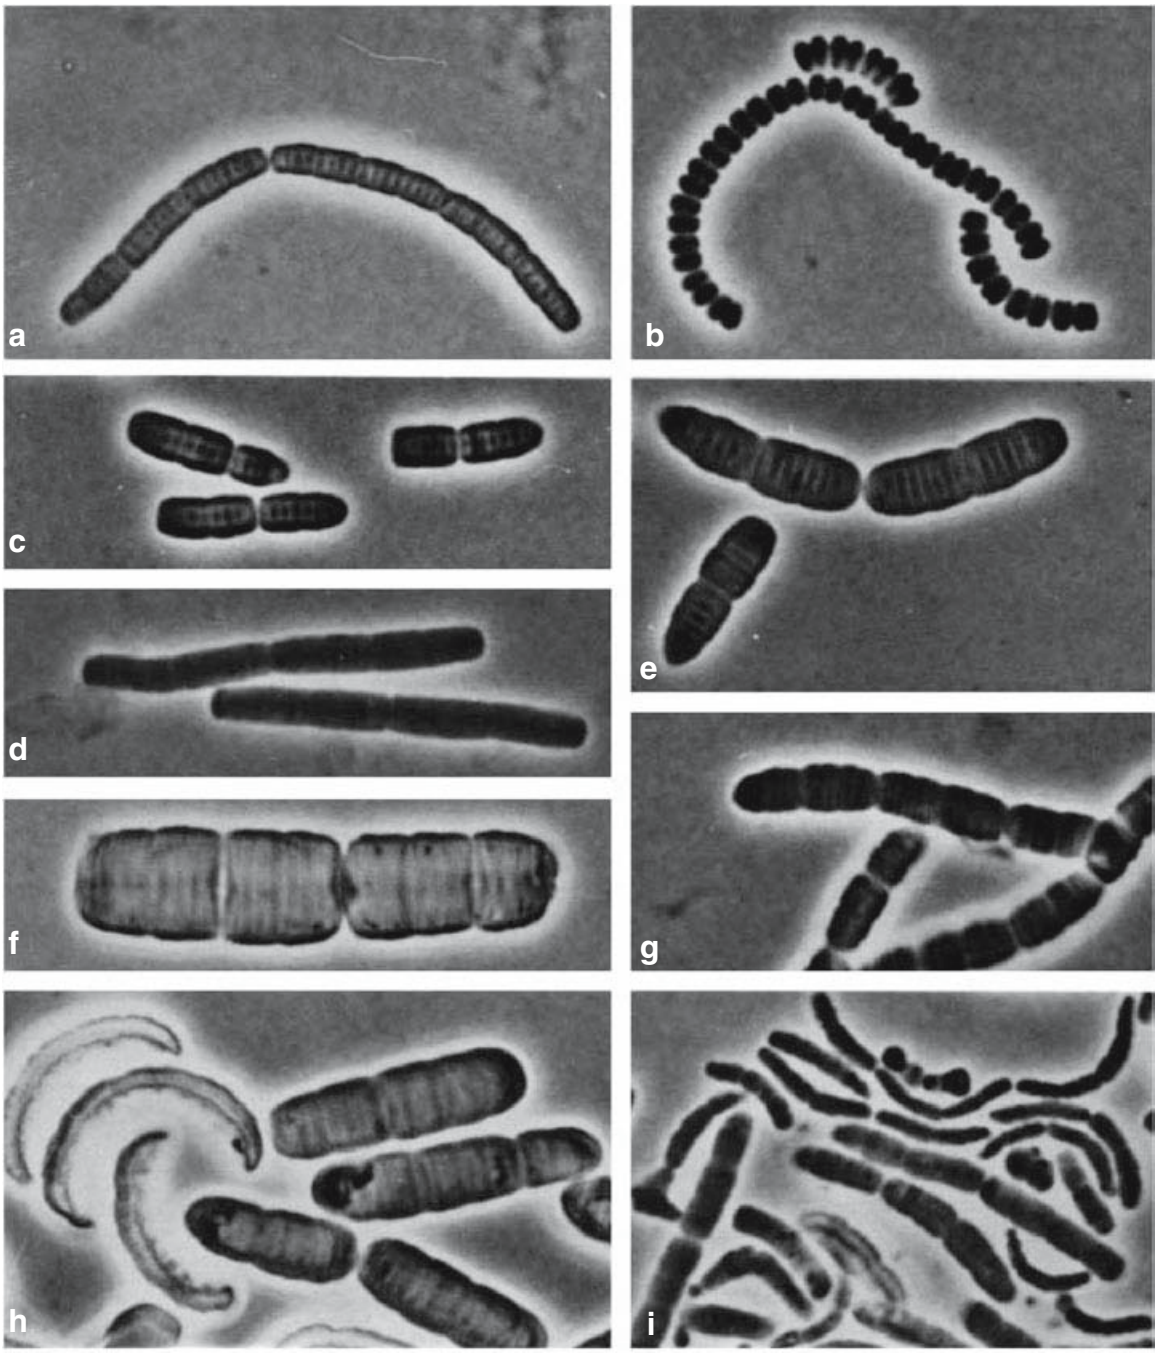

Fig. 7. Comparative morphology of *Simonsiella* and *Alysiella* seen in phase-contrast microscopy with a 100× Neofluar objective on a Zeiss photomicroscope. All strains had been cultured on BSTSY agar at 37°C. Magnification: ×1850. a) *Simonsiella crassa* neotype ATCC 27504 of sheep origin forms straight, relatively slender filaments with rounded ends; compare with Fig. 1a. b) *Alysiella filiformis* neotype ATCC 29469 of sheep origin forms long, flat filaments of closely apposed pairs of cells; compare with Fig. 1b. c) *Simonsiella muelleri* neotype ATCC 29453 of human origin. d) *Simonsiella muelleri* ATCC 29432 of human origin forms long, slender filaments. e) *Simonsiella* strain ATCC 29437 of cat origin forms bullet-shaped filaments because the terminal cells diminish in size. f) *Simonsiella steedae* ATCC 27411 of dog origin possessed broadest filaments yet observed when recently isolated. The filaments became narrower after many transfers of the strain in vitro; compare with Fig. 1d and e. g) *Simonsiella* sp. ATCC 27381 of cat origin shows long, more frequently segmented filaments with less regular contours. h) *Simonsiella steedae* ATCC 29429 of dog origin shows dorsal curvature with edgewise position of filaments and large amounts of irregularly structured extracellular material on the ventral side; compare with Figs. 1c and 3. i) *Simonsiella muelleri* ATCC 29458 of human origin develops many involution forms; it grows poorly under the environmental conditions provided for all strains displayed in this figure.

(Steed-Glaister, 1974), the actual gliding locomotion may not always be readily detectable in the process of identification. *Simonsiella* glides only when the concave ventral side of its filaments is in contact with a solid surface (e.g., epithelial cell, agar or glass). It cannot glide when its filaments are curled and on edge or when they are suspended in liquid media, as in wet mounts (Steed, 1962; Buchanan and Kuhn, 1978). Also, the rate of gliding locomotion is relatively slow (2–28 μm/min) and demands expertise and patience in microscopy. Some axenic strains of *Simonsiella* have never been observed to glide, and others have lost their gliding capacity in vitro with time (Buchanan and Kuhn, 1978).

In addition to habitat, morphology, Gram-stain behavior, and motility, the genera *Simonsiella* and *Alysiella* possess the following traits: They are strict aerobes that decompose H_2O_2 and possess cytochrome-oxidase. Nutritionally, they are chemoorganotrophs that require complex media and may require serum.

On BSTSY agar, their surface colonies are opaque, pale-yellow, and have entire, low-convex form, diameters from ≤1 mm to ≥2 mm, and a smooth, glistening, butyrous texture. On blood agar, they are generally hemolytic. They grow well between 33°C and 40°C, at 1% NaCl, pH 7.2, and 5% sucrose. They do not grow at 45°C and 2% NaCl.

The DNA G+C content of *Simonsiella* and *Alysiella* is 40–55 mol%. The genome sizes of several of these bacteria have been determined by renaturation rate experiments of DNA: *S. crassa* ATCC 15533^T, 2.4×10^9; *S. muelleri* ATCC 29453^T, 2.3×10^9; *S. steedae* ATCC 27409^T, 2.2×10^9; *A. filiformis* ATCC 15532^T, 2.7×10^9 (Rossau et al., 1989).

The fatty acid contents of *Simonsiella* are typical of Gram-negative Proteobacteria, in that even numbered saturated and monounsaturated fatty acids predominate. In all 48 strains studied, the predominant fatty acids are tetradecanoic acid, 9-hexadecenoic acid, an unidentified fatty acid with equivalent chain length of 20, and dodecanoic acid. Certain fatty acids are elevated in certain species of *Simonsiella* including hexadecanoic acid in the *Simonsiella* isolates from cats and 9-octadecenoic acid in *S. crassa*, allowing the species of *Simonsiella* to be identified by fatty acid profiles (Jenkins et al., 1977).

The cell wall ultrastructures also appear to be typical of Proteobacteria, and electron microscopy studies show that the cell wall forms asymmetrically from the ventral side of the cell (Pangborn et al., 1977; Fig. 4).

The species of the genera *Simonsiella* and *Alysiella* can be identified by the physiological and biochemical properties in Table 2, preferably coupled with 16S rRNA gene sequencing. They cannot be identified unequivocally by the dimensions of their filaments (Kuhn et al., 1978). Detailed descriptions of the *Simonsiella* species, *S. crassa*, *S. muelleri* and *S. steedae*, are presented in the papers by Jenkins et al. (1977), Kuhn et al. (1977) and Kuhn et al. (1978). The physiological data of *Alysiella filiformis* are for its neotype strain; they have been determined by Steed (1962) and concurrently with 50 strains of *Simonsiella* by Kuhn et al. (1978). The media compositions and procedures of the diagnostic tests are described in the paper by Kuhn et al. (1978). In addition, the cellular carbohydrates of *Simonsiella* and *Alysiella* have been described by Heiske and Mutters (1994), and have been found to be unique among the Neisseriaceae.

Preservation

Strains of *Simonsiella* and *A. filiformis* have been lyophilized at the ATCC. In addition, *Simonsiella* strains have been preserved by freezing a liquid culture with glycerol as a cryoprotectant (35% [v/v] final concentration).

Ecology

The ecological niche or role of *Simonsiella* and *Alysiella* in their habitat, the oral cavity, is not known at the present time. They appear to be residents of the healthy, normal oral cavity and not transient inhabitants, as has been suggested (Bruckner and Fahey, 1969). The reports of *Simonsiella* in mouths with obvious pathologies are relatively rare (Carandina et al., 1984; Whitehouse et al., 1987; Hodgin, 1988), and a causal relationship between *Simonsiella* and the pathologies is not obvious. In fact, the incidence of *Simonsiella* in human populations with obvious oral pathologies appears to be considerably lower than in groups of healthy people (Simons, 1922; Bruckner and Fahey, 1969). Thus, the presence of *Simonsiella* and *Alysiella* might be considered an indication of a normal flora and good health.

The mode of transmission of *Simonsiella* and *Alysiella* to new hosts has never been studied, though the most likely possibility would seem to be direct mouth-to-mouth contact, either vertically from parents to offspring or horizontally between mates. These bacteria have never been observed in the intestines or in stool, so a fecal-oral route of transmission seems unlikely. Although the mouth is usually considered sterile at birth, Whitehouse et al. (1987) reported isolating a *Simonsiella* strain from the gastric aspirate or oral cavity of a human neonate, 15 min postpartum. The mother's membranes had burst

24 h before delivery and it was speculated that this was the source of the *Simonsiella* inoculum; however, *Simonsiella* has never been reported from the urogenital tract.

Acknowledgment. We sincerely thank Jim Staley for critically reviewing drafts of the manuscript.

CHAPTER 3.2.15

Eikenella corrodens and Closely Related Bacteria

EDWARD J. BOTTONE AND PAUL A. GRANATO

Introduction

Eikenella corrodens was first isolated by Henriksen (1948), who described the organism as a slow-growing, anaerobic, Gram-negative rod. Because the organism appeared to pit or corrode the agar surface, producing colonies that grew in depressions, the organism was called "the corroding bacillus" (Holm, 1950) and was classified by Eiken (1958) as *Bacteroides corrodens*. Subsequent studies by Henriksen (1969) showed that the organism described by Eiken as *B. corrodens* was not an obligate anaerobe. In fact, careful genetic, biochemical, and serologic studies by Jackson and Goodman (1972) demonstrated that the term *B. corrodens* had been applied to two genotypically dissimilar groups of organisms, each of which warranted separate taxonomic classification even though both groups shared the common characteristic of pitting the surface of agar media. They, therefore, proposed the name "*Eikenella corrodens*" for the facultatively anaerobic Gram-negative rod and placed it within the family Brucellaceae. *Bacteroides ureolyticus* became the new species designation for the Gram-negative rods that grew as obligate anaerobes and were previously known as *B. corrodens* (Jackson and Goodman, 1978). Furthermore, *Eikenella corrodens* also became the accepted designation for the "HB-1" group of organisms described by King and Tatum (1962), since these isolates were shown to be biochemically and serologically identical (Riley et al., 1973). As now established, the genus *Eikenella* consists of a single, genetically uniform species, *E. corrodens*, with a G+C content of 56–58 mol%, (Coykendall and Kaczmarek, 1980) and has been placed within the Neisseriaceae family.

Habitat

Eikenella corrodens is part of the resident microflora of mucous membrane surfaces in humans. The organism is associated most commonly with the normal flora of the respiratory tract but also is recognized as a mucous membrane commensal of the gastrointestinal and urogenital tracts. Apparently no animal or environmental reservoirs exist for the microorganism (Decker, 1986a).

The predominance of *E. corrodens* in the mouth and gingival surfaces appears to be associated with the adherence of the organisms to human buccal epithelial cells. Yamazaki et al. have shown that the adherence of *E. corrodens* to human buccal epithelial cells may require the interaction of lectin-like proteins on the bacterial cell surface with galactose-like receptors on the surface of epithelial cells (Yamazaki et al., 1981; Yamazaki et al., 1988). Coaggregation of *E. corrodens* with other bacterial species in the oral cavity is also lectin mediated (Ebisu et al., 1988).

Isolation

Media for Selection

Eikenella corrodens is a facultatively anaerobic (microaerophilic), Gram-negative rod, which usually fails to grow on most selective media, such as MacConkey or eosin methylene blue (EMB) agars. When incubated aerobically, *E. corrodens* appears to have a definitive requirement for hemin upon primary isolation, with growth developing slowly on media such as Mueller-Hinton or Brucella agar supplemented with 5% blood or on chocolate agar (Goldstein et al., 1981). Upon subculture of the primary isolate, however, variants may be selected that do not require hemin for growth. Growth of *Eikenella* may be stimulated by incubating the culture plates in a 3–10% CO_2 environment, even though the organism does not require CO_2. Interestingly, when incubated anaerobically, *E. corrodens* does not have an obligate requirement for hemin. The anaerobic growth that occurs on non-heme-containing media, such as brain heart infusion agar, is comparable to that observed with growth on blood or chocolate agar plates incubated in air and/or a CO_2 environment.

Because *E. corrodens* is a slow-growing organism and is usually recovered from polymicrobic samples, its growth may be obscured by faster-

growing bacteria, which makes its detection difficult, if not impossible. Recovery of *Eikenella* from such polymicrobic specimens may be improved significantly by adding clindamycin (5 μg/ml) to the blood-supplemented isolation medium (Slee and Tanzer, 1978).

Growth Characterization

Within 19–24 hours of incubation at 35–37°C in 5% CO_2, tiny, pinpoint colonies (0.2–0.5 mm) may be detected on a blood or chocolate agar plate. Occasionally, prolonged incubation for 2–3 days may be required before colony size increases sufficiently for the colonies to become readily apparent (1.0–3 mm). Colonies of *E. corrodens* may appear either smooth or rough when grown on blood or chocolate agar media. The ability of the organism to pit or corrode the agar surface is an important distinguishing feature and is a useful identifying characteristic. However, this colonial characteristic is not universally present since only 45% of clinical isolates exhibit this corroding phenomenon on primary isolation. When present, pitting of the agar surface is usually detected by observing the agar surface at different angles with oblique lighting. Occasionally, however, some colonies may have to be moved to detect the underlying depression caused by their growth. Optimum pH for growth is 7.3.

In addition to pitting the agar surface, when grown on blood agar, *E. corrodens* produces a distinctive colonial morphology consisting of a dry, flat, radially spreading, pale yellow-pigmented colony with an irregular periphery and a moist central core. When observed under a stereoscopic microscope, three distinct zones of colonial growth are evident: 1) a clear, moist, glistening center zone; 2) a highly refractile, speckled, pearl-like circle of growth resembling mercury droplets; and, 3) an outer nonrefractile perimeter of spreading growth (Bottone et al., 1973). The typical colonial morphology is shown in Figs. 1 and 2. Microscopic (500×) observation of radially spreading colonies shows bacilli translocating for short distances from a central inoculum. Termed "twitching motility" (Henrichsen, 1975a; Henrichsen and Blom, 1975b; Schröter, 1975), this form of surface translocation takes place by intermittent "jerks" as the bacilli migrate away from a point inoculum. This phenomenon is not flagellum-mediated but is dependent on a thin film of water provided by cultures incubated in a humid atmosphere. Penetration into the agar media by *E. corrodens* during translocation may account for the corroding colonial characteristics, as well as the colony imprint when surface growth is removed. *Eikenella corrodens* strains lacking twitching motility produce translucent, dome-shaped, nonspreading colonies 0.5–1.0 mm in diameter. As noted above, such colony morphology may be encountered on primary isolation or by careful selection from corroding colony types.

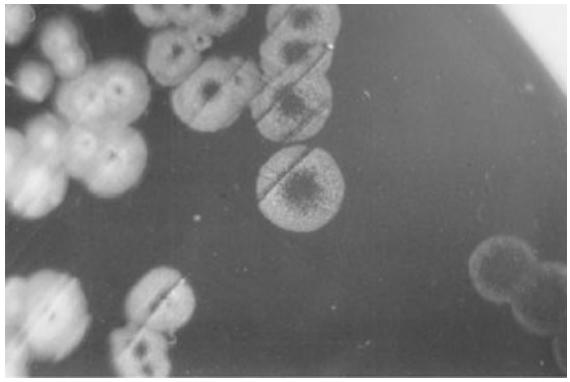

Fig. 1. Characteristic appearance of colonies of *E. corrodens* after growth on sheep blood agar for 48 h. From Bottone et al. (1973).

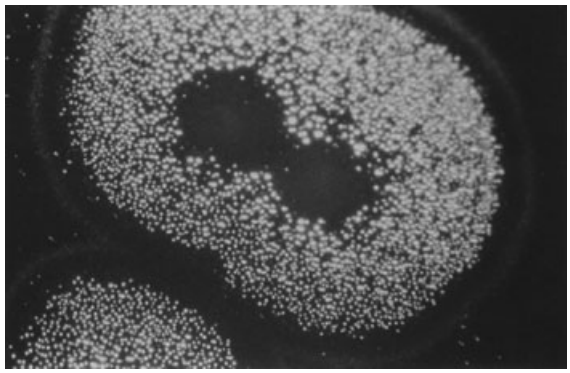

Fig. 2. Appearance of an *E. corrodens* colony at higher magnification showing the three characteristic zones of growth. From Bottone (1973).

When grown on chocolate agar, the characteristic three zones of growth are less pronounced. Additionally, growth of *E. corrodens* on blood or chocolate agar is accompanied by either an odor similar to hypochlorite bleach, or a musty odor reminiscent to that produced by *Pasteurella* or *Haemophilus* species. Upon prolonged incubation on blood agar, the medium surrounding the colonies becomes slightly green.

In liquid media, growth rates of individual strains may vary, and growth may be improved by the addition of 0.1–0.2% agar or cholesterol (10 μg/ml) to the broth medium. In thioglycolate broth supplemented with yeast extract, a band of growth usually develops a few centimeters below the surface of the medium after 3 days of incubation. When grown in a glucose broth with yeast extract, growth may develop as a uniform tur-

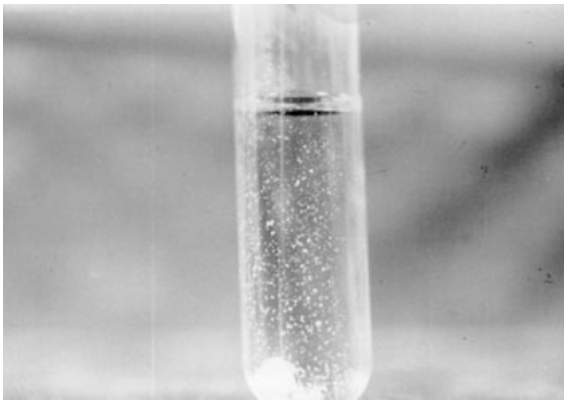

Fig. 3. Granular growth of *E. corrodens* in supplemented glucose broth, showing adherence to the side of the tube.

bidity or, as shown in Fig. 3, as discrete granules adhering to the side of the tube. Using scanning electron microscopy of 7-day-old cultures, Progulske and Holt (1980) showed that a fibrillar material connects *E. corrodens* cells, and this material may account for a surface hydrophobicity resulting in granule formation in liquid media. *Eikenella corrodens* also produces pili composed of type IV pilin (Hood and Hirschberg, 1995) and possesses an enteric type of lipopolysaccharide (Progulske and Holt, 1984a). Piliated isolates form corroding colonies, whereas nonpiliated variants form large smooth noncorroding colonies (Villar et al., 2001).

Microscopic Morphology

Eikenella corrodens is a small (0.3–0.5 by 1.0–3.0 μm), straight, nonsporeforming, nonencapsulated, nonmotile, Gram-negative coccobacillus. The organism has a uniform morphology with rounded ends, although occasional short filaments of up to 12 μm may be observed (Jackson et al., 1971). In direct smears of clinical material, however, *E. corrodens* is more coccobacillary, resembling *Haemophilus* species, and may even possess a capsule (Decker et al., 1986b).

Identification

The biochemical characteristics that distinguish *E. corrodens* are listed in Table 1. Generally, the organism is biochemically inactive, lacking oxidative and fermentative capabilities and failing to produce urease, indole, or hydrogen sulfide (H_2S). All isolates are oxidase positive and most isolates are capable of reducing nitrate to nitrite. Catalase is usually negative, although rare catalase-positive isolates may be encountered (Kasten et al., 1998). Tests separating *E. corrodens* from other corroding bacilli are shown in Table 2.

Table 1. Biochemical characteristics of *Eikenella corrodens*.

Characteristics	% Positive[a]

[b]Weakly positive reaction.
[c]64% give a positive.

Antigenic Structure

Eikenella corrodens has been found to possess four major antigenic components (Jackson et al., 1971). All strains of *E. corrodens* appear to be antigenically related, but differences in the amounts of each antigen type may exist among strains. In fact, some strains may even lack one or two of the four major antigenic components, as detected by immunodiffusion studies (Wong and Jackson, 1971). A type-specific antigen (Maliszewski et al., 1983) and a group antigen with endotoxin activity (LPS), and containing 0.5% ketodeoxyoctonate, have been found in *E. corrodens*, and the latter is distinct from outer-membrane, type-specific protein antigens (Progulske et al., 1984b).

Pathogenicity

Even though *E. corrodens* is generally regarded as an organism of low virulence and lacks animal

Table 2. Differentiation of *E. corrodens* from similar species showing gliding motility and/or producing colonies that "pit" the agar surface.

pathogenicity (Klairat, 1967; Bottone et al., 1973), it has become increasingly recognized as a cause of human infection (Bottone et al., 1973; Brooks et al., 1974; Dorff et al., 1974; DeMello and Leonard, 1979; Suwanagool et al., 1983; Tami and Parker, 1984; Drake et al., 1986; Tveteras et al., 1987). Human infections usually result from some predisposing factor, such as trauma to a mucous membrane surface that compromises normal host defense mechanisms and allows the organism to gain access to surrounding tissue. Once primary infection occurs, hematologic dissemination may establish foci of infection in other parts of the body.

In intravenous drug abusers, *E. corrodens* endocarditis, osteomyelitis, and septicemia have been reported in association with the practice of licking needles or injection sites prior to drug inoculation (Angus et al., 1994; Olopoenia et al., 1994; Swisher et al., 1994). *Eikenella corrodens* osteomyelitis has been reported subsequent to a toothpick puncture to a foot (Robinson and Kourtis, 2000); vertebral osteomyelitis and a liver abscess occurred secondary to a fishbone piercing the patient's pharynx (Lehman et al., 2000) and liver (Kessler and Kourtis, 2001).

In normal human hosts, *Eikenella* is usually involved in mixed bacterial infections, often with viridans group streptococci, and less frequently with various members of the Enterobacteriaceae (Bottone et al., 1973; Brooks et al., 1974; Badger et al., 1979). Infections frequently involve the head, neck (Goodman, 1977; Jones and Romig, 1979; Knudsen and Simko, 1995), or abdominal area (Tami and Parker, 1984; Drake et al., 1986; Tveteras et al., 1987). Severe *E. corrodens* and viridans streptococcal cellulitis and septic arthritis of the knee subsequent to dental manipulation also has been reported in a patient with a history of hemarthrosis (Flesher and Bottone, 1989). Jacobs et al. (1993) offer compelling evidence that most concomitant streptococcal isolates are members of the *S. anginosis* group, which presently consists of three species, *S. anginous*, *S. constellatus* and *S. intermedius* (Whiley and Beighton, 1991). *Eikenella* are also responsible for 7–29% (Bilos et al., 1978; Goldstein et al., 1978a; Peeples et al., 1980; Faralli and Sullivan, 1986; Brook, 1987) of human hand-bite wound infections, as well as clenched-fist injuries, which are frequently complicated by bone resorption and osteomyelitis. Additionally, a severe *E. corrodens* genital ulcer occurred after a human bite to the penis (Rosen and Conrad, 1999). Other studies have reported that *Eikenella* may be an important periodontal pathogen with resultant severe alveolar bone loss (Socransky, 1977; Irving et al., 1978; Johnson et al., 1978; Listgarten et al., 1978; Behling et al., 1979). This bacterial species is often recovered from subgingival plaque in patients with severe periodontitis (Mueller et al., 1997); *E. corrodens* coaggregates with other bacterial species in plaque and elaborates a toxin in gingival sulcus, which contributes to periodontal disease (Levine and Miller, 1996; Young, 1996). Production of

hydrolytic enzymes also may contribute to periodontal disease (Allaker et al., 1994).

Eikenella corrodens also may be the sole infecting pathogen in cases of endocarditis, meningitis, brain abscesses, subdural empyema, septic arthritis, pneumonia, postsurgical infections, and soft-tissue diseases (Johnson and Pankey, 1976; Sheng et al., 2001). Several reports (Suwanagool et al., 1983; Tami and Parker, 1984; Tveteras et al., 1987; Sheng et al., 2001) have shown that *E. corrodens* may have an accentuated potential to cause disease in immunocompromised patients and, as such, may serve as an opportunistic pathogen in that patient population.

In a review of *E. corrodens* pleuropulmonary infections, Joshi et al. (1991) reported that this infectious complication occurs in two groups of patients: adults 44 years old with underlying medical conditions (immunosuppression, lung disease, alcoholism, intravenous drug use, or propensity to pulmonary aspiration) and in children ≥ 14 years of age. *Eikenella corrodens* septic pulmonary embolization secondary to internal jugular vein phlebitis after oropharyngeal infection also has been described (Celikel and Muthuswamy, 1984).

Antimicrobial Susceptibility

In vitro antimicrobial susceptibility studies (Goldstein et al., 1978b; Goldstein, 1986; Sheng et al., 2001) indicate that *E. corrodens* infections can be successfully treated with a wide variety of agents including penicillin, ampicillin, amoxicillin, but not cephalothin or cefuroxime. *Eikenella corrodens* is susceptible in vitro to cefoxitin, ceftriaxone, cefotetan, ciprofloxacin, moxalactam, imipenem and tetracycline. Resistance to clindamycin, lincomycin, and metronizadole is constant, but variable with regard to aminoglycosides. Two β-lactamase-producing strains have been isolated from patients with infectious complications in Spain (Trallero et al., 1986). *Eikenella corrodens* in vitro antibiotic susceptibility may be determined by disk-agar diffusion, agar dilution, and E-test methods (Luong et al., 2001). Alcala and colleagues (1998) found a microdilution method using *Haemophilis* test medium correlated well with the agar dilution method using Mueller-Hinton sheep blood agar.

Gram-Negative Species Capable of Forming Corroding Colonies

Species placed in this category are for the most part neither genotypically, morphologically, nor biochemically related to *E. corrodens*. They are enjoined with *E. corrodens* mainly because they, on occasion, may produce colonies that pit the agar surface. By and large, they comprise the HACEK group of organisms (*Haemophilis aphrophilus*, *H. paraphrophilus*, *Actinobacillus actinomycetemcomitans*, *Cardiobacterium hominis*, *Eikenella corrodens* and *Kingella* species). Although not a HACEK group microorganism, oral *Capnogtophaga* species also may give rise to corroding colonies and demonstrate twitching motility.

Haemophilis paraphrophilus was first described by Zinnemann et al. (1968) as a V-dependent *Haemophilus* species that grows preferentially under 10% CO_2 tension. In air without CO_2 supplementation, two types of colonies develop: a small, smooth colony and a larger colony with an irregular contour and a dry, crinkled surface resembling breadcrumbs. Microscopically, analogous to *E. corrodens*, *H. paraphrophilus* may present as either a small coccobacillus after growth in CO_2, or as a more bacillary form in ambient air. Part of the normal oral flora, on occasion, these species have caused endocarditis and brain abscesses and may be isolated from vaginal specimens. Distinguishing characteristics of *H. paraphrophilus* are shown in Table 2. Although generally regarded as catalase negative in several references (Weyant et al., 1996), Zinneman (1968) originally reported all 16 of his strains studied as catalase positive "though rather slow to develop."

Cardiobacterium hominis was the name proposed by Slotnick and Dougherty (1964) for a pleomorphic, teardrop-shaped, Gram-negative bacterium isolated from patients with endocarditis. *Cardiobacterium hominis*, in addition to demonstrating a swollen terminus, may occur also as rosettes comprising clusters of bacilli, as well as long serpentine filaments, and may retain some crystal violet during Gram staining. Stick-like bacillary forms with rounded ends similar to those observed with *E. corrodens* may occur after growth on media containing yeast extract.

Colonies of *C. hominis* when viewed microscopically show a roughened surface comprised of an intertwining network of bacilli extending from the colony core to its periphery. From the colony edge, a streaming of slender bacilli may be observed, which often articulate with other bacillary forms from proximal colonies (Wormser and Bottone, 1983). Such surface translocation of bacillary forms may be attributed to a gliding motility of individual cells, especially evident after growth under CO_2 enrichment and in a humid atmosphere.

Biochemically, *C. hominis* anaerogenically ferments glucose, maltose, mannitol and sucrose, usually within 48 h, especially after

serum or hemin enrichment of the carbohydrate-containing medium. Lactose is not degraded (Table 2). Indole production is a major distinguishing feature of *C. hominis* (Table 2) and is best demonstrated by the addition of Kovac's reagent to a 48-hour-old peptone broth culture supplemented with fetal bovine serum (Wormser and Bottone, 1983). Hydrogen sulfide production may be detected by suspending a lead acetate strip over inoculated triple sugar or Kliger iron agar slants.

Via cryptogenic bacteremia, *Cardiobacterium hominis* (part of the normal nasopharyngeal flora) causes mainly endocarditis in individuals with prior cardiac disease or in patients with prosthetic heart valves. A rare β-lactamase-producing strain with high-level resistance (minimal inhibitory concentration [MIC]: ≥256 μg/ml) to penicillin and reduced susceptibility to vancomycin (MIC: 8 μg/ml) has recently been reported isolated from a patient with endocarditis (Lu et al., 2000).

The genus *Kingella* within the family Neisseriaceae is comprised of three species (*K. kingae*, *K. denitrificans* and *K. indologenes*). All three species show similar microscopic morphology, namely short, stout, Gram-negative rods with rounded or square ends. This morphologic characteristic is shared with *Moraxella* species, as is the tendency to resist decolorization and appear partially Gram positive. On blood agar incubated at 35–37°C, two colonial morphotypes may develop: one a spreading, corroding colony associated with twitching motility and fimbriation, and in the absence of fimbriation and twitching motility, a smooth, convex colony. *Kingella kingae* produces colonies surrounded by a zone of β hemolysis. *Kingella* species colonize mucous membranes of the upper respiratory tract from where they may become blood-borne and gain access to various body sites, especially joints of young children (Abuamara et al., 2000).

In 1962, King and Tatum reported on the isolation of small Gram-negative rods with fastidious growth requirements, which they categorized as members of the HB group because they morphologically and culturally fell between *Haemophilus* and *Brucella* species (King and Tatum, 1962). Designated HB-1, HB-2, HB-3 and HB-4, members were subsequently accorded genus status with, as noted earlier, HB-1 becoming *E. corrodens* and HB-2 and HB-3 being designated "*Haemophilus aphrophilus*" and "*Actinobacillus actinomycetemcomitans*," respectively. Because these latter two species are closely related genetically and phenotypically, they are discussed conjointly.

Actinobacillus actinomycetemcomitans (as the name implies) has long been recognized in conjunction with *Actinomyces* infections, since both are derived from the oral flora. Furthermore, both *H. aphrophilus* and *E. corrodens* also have been documented in association with actinomycotic lesions (Page and King, 1966; Blake and Haburchak, 1982).

Microbiologically, both *A. actinomycetemocomitans* and *H. aphrophilus* are small, Gram-negative coccobacilli that bear a remarkable resemblance to *Brucella* species, with which they may be confused on initial isolation. On 5% sheep blood agar, colonies are initially smooth after a 24-h incubation but may become rough and adherent with prolonged incubation; such colonies, when viewed microscopically, may show a star-shaped formation in the center of the colony (Page and King, 1966; Meyers et al., 1971; Bottone et al., 1973). In liquid media, compact colonies will develop adherent to the sides of the tube, while the remainder of the liquid media is clear. Biochemical tests that distinguish these two species from each other and from *E. corrodens* are shown in Table 2. Clinically, both species have been associated with a variety of human infectious complications, most notably endocarditis and abscesses (Page and King, 1966).

CHAPTER 3.2.16

The Genus *Burkholderia*

DONALD E. WOODS AND PAMELA A. SOKOL

Introduction

The genus *Burkholderia* contains organisms that are important causes of human, animal and plant disease, as well as organisms useful in promoting plant growth and bioremediation. The type species, *Burkholderia cepacia*, is important in all of these activities. Originally identified as a plant pathogen that caused soft rot in onions (Burkholder, 1950), *B. cepacia* has emerged in the last 20 years as an opportunistic pathogen in nosocomial infections, particularly in individuals with cystic fibrosis (CF) or chronic granulomatous disease (Gilligan, 1991; Govan et al., 1996b; LiPuma, 1998; Speert et al., 1994). Other significant human and animal pathogens include *B. pseudomallei*, the cause of melioidosis, and *B. mallei*, the cause of glanders (Sanford, 1995). A newly described nonpathogenic species, *B. thailandensis* (Brett et al., 1998), has been useful in defining the pathogenesis of diseases caused by *B. pseudomallei* and *B. mallei* (Brett et al., 1997).

Burkholderia cepacia is a serious pathogen in CF patients because many strains have been determined to be easily transmitted from person to person (Govan et al., 1993; LiPuma et al., 1990) and intrinsically resistant to many antibiotics (Goldman and Klinger, 1986; Prince, 1986). Once acquired, *B. cepacia* infection rarely is eradicated from the lungs of CF patients. In addition, a proportion of patients who acquire *B. cepacia* infection develop the so-called "cepacia syndrome," a rapidly fatal pneumonia and sepsis, with a high mortality (Govan and Deretic, 1996a; Isles et al., 1984). The pathogenic mechanisms involved in this syndrome remain unclear. Indeed, the nature of the virulence factors that contribute to the pathogenicity of *B. cepacia* in CF remains largely unknown.

Aside from its potential as a human pathogen, *B. cepacia* and the related species in the *B. cepacia* complex have tremendous potential for agricultural and environmental use. Because it has anti-fungal and anti-nematodal properties, *B. cepacia* is very attractive as a biocontrol agent for the enhancement of crop yields (Govan et al., 1996b). *Burkholderia cepacia* also is a natural colonizer of the rhizophere and therefore considered by many to be preferable to the toxic compounds currently used as fertilizers. Because of its nutritional versatility, *B. cepacia* also has applications for bioremediation of contaminated soils.

Burkholderia pseudomallei is a common cause of human pneumonia and fatal bacteremias in endemic areas (Chaowagul et al., 1989). The organism is an opportunistic pathogen, and those individuals with underlying conditions such as diabetes or renal disease are particularly susceptible to *B. pseudomallei* infection (Chaowagul et al., 1989; Woods et al., 1993). Clinical manifestations of *B. pseudomallei* infection, a disease known as melioidosis, vary from an asymptomatic state, to benign pneumonitis, to acute or chronic pneumonia, to overwhelming septicemia (Smith et al., 1987). Treatment of melioidosis can involve up to 9 months of antibiotic therapy (Tanphaichitra and Srimuang, 1984), and relapse is common. Additionally, the latency period of the organism ranges from 2 days to 26 years (Smith et al., 1987; Mays and Ricketts, 1975).

Burkholderia pseudomallei occurs as a soil organism in Southeast Asia and northern Australia. Incidence of melioidosis generally is confined to these endemic areas (Chaowagul et al., 1989). Recent surveys, however, show that the organism is much more prevalent worldwide than previously believed. Isolation of *B. pseudomallei* from the environment and in clinical situations in parts of Africa, the Middle East, Europe, and in Central and South America has been documented (Dance, 1991). Subclinical and clinical disease is evident in humans, as well as wild and domestic animals, residing in the areas subtended by latitude 20 degree north to 20 degrees south (Dance, 1991), and as many as 10 to 30% of Southeast Asian population have serum antibodies to the organism. Likewise, individuals who travel to, through, and reside in endemic areas are susceptible to infection. One to two percent of healthy soldiers and up to 9% of wounded individuals who served in Vietnam are seropositive. Thus, the approximately 3 million American soldiers who traveled and lived in that

endemic region include a significant number who have latent infection, often recrudescing after a latent period of months to years (Sanford, 1995). More recently, a report from India indicates *B. pseudomallei* is present and is responsible for a significant level of disease in that country (Bharadwaj et al., 1994).

Burkholderia mallei is the causative agent of glanders, a disease which primarily affects horses, mules or donkeys (Sanford, 1995). The mode of infection in animals remains controversial; considerations include inhalation, ingestion or inoculation through breaks in the skin. Glanders in humans has never been common, but its importance is tremendous due to the serious nature of the infection. The pathogenesis of this disease is unknown. It is recognized from earlier studies that *B. mallei* (an organism with tremendous infectivity) poses a significant hazard to humans exposed to aerosols containing this organism (Howe, 1949). At present, no effective vaccines are available against this organism, and information on the treatment with antibiotic therapy also is not available.

Reports in the literature suggest that *B. pseudomallei*-like species exist that are nonpathogens in animals (Brett et al., 1997; Smith et al., 1995; Wuthiekanum et al., 1996a; Wuthiekanum et al., 1996b). To definitively assess relatedness, more than 95% of the 16S rDNA from *B. pseudomallei* 1026b (a virulent clinical isolate) and *B. pseudomallei-like* E264 (an avirulent environmental isolate) has been cloned and sequenced. The results of these studies, based upon a 16S rDNA phylogenetic analysis, confirmed the presence of a new *Burkholderia* for which the name *Burkholderia thailandensis* has been proposed (Brett et al., 1998).

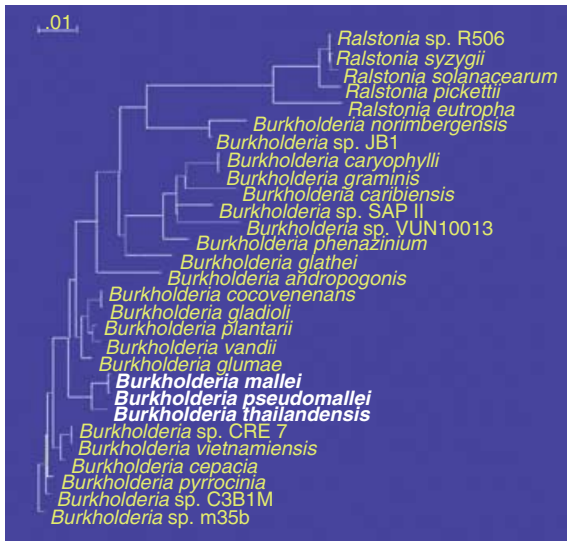

Fig. 1.

Taxonomy

In 1992, Yabuuchi and colleagues (Yabuuchi et al., 1992) established the genus *Burkholderia* and transferred seven species of the genus *Pseudomonas* homology group II to the new genus, with the type species designated as *Burkholderia cepacia* (Palleroni and Holmes, 1981). The rationale for the new genus was based on the 16S rRNA sequences, DNA-DNA homology values, cellular lipid and fatty acid composition, and phenotypic characteristics. Thus, seven new species were created: *Burkholderia cepacia* (Palleroni and Holmes, 1981), *Burkholderia mallei* (Zopf, 1885), *Burkholderia pseudomallei* (Whitmore, 1913), *Burkholderia caryophilli* (Burkholder, 1942), *Burkholderia gladioli* (Severini, 1913), *Burkholderia picketii* (Ralston et al., 1973), and *Burkholderia solanaceareum* (Smith, 1896). Based on biochemical, immunological and genetic data, *B. pseudomallei*, *B. mallei*, *B. cepacia* and *B. thailandensis* are relatively closely related (Fig. 1). Two *Burkholderia* species and an *Alcaligenes* species have been subsequently reclassified in a new genus *Ralstonia* on the basis of 16S rRNA analysis, DNA homology, and cellular lipid composition (Yabuuchi et al., 1995). *Burkholderia pickettii* and *B. solanacearum* are now members of the genus *Ralstonia*.

During the last 15–20 years, *B. cepacia* has been isolated frequently from respiratory cultures of CF patients with a variety of clinical outcomes. Some patients infected with *B. cepacia* suffer a necrotizing pneumonia followed by a rapid and often fatal clinical deterioration. Other patients are colonized chronically and experience a slow deterioration of lung function (Govan and Deretic, 1996a; Govan et al., 1996b; Isles et al., 1984). During investigations to identify properties that might account for differences in clinical outcomes, it was discovered that strains classified as *B. cepacia* were very heterogeneous. A detailed genotypical and phenotypical analysis of properties including whole-cell protein profiles, DNA-rRNA hybridization, DNA-DNA hybridization, fatty acid analysis and biochemical tests resulted in the determination that *B. cepacia* was actually made up of five closely related but distinct genomic species. This group of five phenotypically related species often is referred to as the *B. cepacia* complex (Vandamme et al., 1997). These species were originally classified as genomovars I–V. Genomovars are phenotypically similar, genotypically distinct groups of strains that share a low level of DNA hybridization and are considered distinct species,

but are not given an official species name until differential diagnostic tests have been established. The *B. cepacia* complex consists of *B. cepacia* genomovar I, which contains the type strain of *B. cepacia*, *B. cepacia* genomovar III, the recently described species *B. multivorans* (formerly genomovar II), *B. stabilis* (formerly genomovar IV), and *B. vietnamensis* (formerly genomovar V; Vandamme et al., 1997).

Habitat

B. cepacia and the related species are soil bacteria that are found most commonly on plant roots or the immediately adjacent area (the rhizosphere) and in moist environments (Nijhuis et al., 1993). Although considered opportunistic pathogens, they rarely are isolated from the hospital environment in CF centers and are not commonly recovered from respiratory equipment used for CF patients (Govan et al., 1996b; Mortensen et al., 1995). In non-CF patients, however, outbreaks have occurred due to the presence of *B. cepacia* in contaminated nebulizers, disinfectants and drinking water (Pegues et al., 1996; Riboli et al., 1996). All five species of the *B. cepacia* complex have been isolated from patients (Vandamme et al., 1997). *Burkholderia cepacia* genomovar I is more frequently isolated from soils and plants, and *B. multivorans* primarily has been isolated from the sputum of CF patients. *Burkholderia vietnamiensis* originally was identified as a nitrogen-fixing organism isolated from the rice rhizosphere (Gillis et al., 1995).

Burkholderia pseudomallei is predominantly found in Southeast Asia and northern Australia (Chaowagul et al., 1989). Because *B. pseudomallei* is nutritionally diverse and is capable of resisting a variety of environmental extremes, it is puzzling that the global distribution of *B. pseudomallei* is not more uniform (Smith et al., 1987). The organism can be readily isolated from environmental niches such as rice paddies, still or stagnant waters, and moist soils that predominate in the tropics, and it is believed these habitats are the primary reservoirs from which susceptible hosts acquire infections (Ellison et al., 1969; Leelarasamee and Bovornkitti, 1989).

Isolation

Three different selective media have been developed and are currently used to isolate organisms belonging to the *B. cepacia* complex. These media are designed for the isolation of organisms (e.g., *B. cepacia* complex) that use lactose or sucrose and are resistant to antibiotics such as polymyxin, gentamycin and vancomycin. These antibiotics inhibit the growth of *Pseudomonas aeruginosa*. *Pseudomonas cepacia* agar (PCA) is composed of DeCicco holding medium with 300 U of polymyxin per ml and 100 mg ticarcillin per ml and has been used in clinical laboratories since approximately 1985 (Gilligan et al., 1985). Oxidation-fermentation polymyxin bacitracin lactose agar (OFPBL) is composed of oxidation-fermentation agar supplemented with lactose, 300 U of polymyxin per ml, and 0.2 U bacitracin per ml and has been widely used since approximately 1987 (Welch et al., 1987). Recently a new selective medium, *Burkholderia cepacia* selective agar (BCSA), has been developed that is more enriched for the growth of the *B. cepacia* complex and is more selective against the growth of other organisms than either PCA or OFPBL (Henry et al., 1997; Henry et al., 1999). Commonly misidentified organisms on OFPBL or PCA include *Stenotrophomonas maltophilia*, *Alcaligenes xylosoxidans* and *Comamonas acidovorans*. The selective medium BCSA contains a base of casein and yeast extract supplemented with 1% lactose, 1% sucrose, 600 U polymyxin per ml, 10 mg gentamycin per ml, and 2.5 mg vancomycin per ml. *Burkholderia cepacia* complex strains grow more quickly on BCSA and are readily visible in 24 hours. This medium is more effective at suppressing the growth of non-*B. cepacia* complex organisms than either PCA or BCSA or OFPBL (Henry et al., 1999). Addition of vancomycin to this medium reduced the rate of false positives, particularly due to *Staphylococcus* sp. and *Pseudomonas aeruginosa*.

Isolation and identification of *B. pseudomallei* by the culture method is still the method of choice for definitive diagnosis of melioidosis. It is relatively simple and economical to perform. The use of a modified Ashdown medium containing colistin further helps to increase the efficiency of isolation (Dance et al., 1989).

Identification

Burkholderia cepacia colonies appear smooth and slightly raised on blood agar or selective medium. Owing to the oxidation of lactose on MacConkey agar, colonies will become dark red or pink after extended incubation. Key biochemical tests include a positive oxidase reaction, lysine decarboxylase activity, oxidation of glucose and xylose, and usually oxidation of maltose, lactose, and/or sucrose. Members of this complex also have multitrichous polar flagella and are motile (Gilligan and Whittier, 1999). *Burkholderia multivorans* can be differentiated from *B. cepacia* genomovars I and III by its lack of sucrose utilization and variable

lysine decarboxylase activity (Vandamme et al., 1997). *Burkholderia multivorans* can be differentiated from *B. stabilis*, which also does not oxidase sucrose, by its ability to grow at 42°C. *Burkholderia stabilis* does not grow at 42°C and can be differentiated from all the other genomovars by the absence of β-galactosidase activity (Vandamme et al., 1997; Vandamme et al., 2000).

DNA-based assays also have been developed to facilitate identification and discrimination between members of the *B. cepacia* complex (Bauernfeind et al., 1999; Segonds et al., 1999). Polymerase chain reaction (PCR) primers based on 16S and 23S ribosomal RNA sequences are able to differentiate *B. multivorans* and *B. vietnamiensis* from *B. cepacia* genomovars I and III and *B. stabilis* (Bauernfeind et al., 1999). The PCR primers, based on *recA* gene sequences, can differentiate between all five members of the *B. cepacia* complex (Vandamme et al., 2000).

Availability of an API 20NE test panel has considerably simplified the identification of *B. pseudomallei*. However, this API panel of tests has been reported to misidentify *B. pseudomallei* for *Chromobacter violaceum* and others (Inglis et al., 1998). A PCR procedure for the discrimination of *B. mallei* and *B. pseudomallei* has been developed. Identificaton is based on a single nucleotide difference T 2143 C (T versus C at position 2143) in the 23S rDNA sequence of *B. malle* and *B. pseudomallei*. In comparison with conventional methods, the procedure allows more rapid identification (Bauernfeind et al., 1998). *Burkholderia mallei* has no unusual nutritional requirements, grows slower on laboratory media than *B. pseudomallei*, and can be differentiated from *B. pseudomallei* by being nonmotile.

Epidemiology

Acquisition of *B. cepacia* infections in CF patients can occur either from the environment or via patient-to-patient transmission. Transmission between patients may depend on several factors including properties of the strain, the patient, and the treatment center. Several molecular typing methods, which include ribotyping (LiPuma et al., 1988), pulse-field gel electrophoresis (Govan et al., 1993), and PCR-based random amplified polymorphic DNA (RAPD) typing (Mahenthiralingam et al., 1996), have facilitated epidemiological analysis of *B. cepacia* infections. The RAPD typing method has proven to be reproducible, discriminatory and versatile, allowing both clinical and research laboratories to perform fingerprint analysis of *B. cepacia* strains (Mahenthiralingam et al., 1996). These molecular typing methods have led to the observation that some *B. cepacia* strains infect multiple patients and appear to be transmissible; other strains appear to be unique isolates that may be acquired from the environment. It is not known what factors account for the transmissibility of epidemic *B. cepacia* isolates, although two properties have been shown to correlate with at least some epidemic strains. Isolates from one epidemic strain prevalent in eastern Canada and the United Kingdom were shown to possess the cable pilin subunit gene *cblA*, although other epidemic strains do not carry this marker (Mahenthiralingam et al., 1997; Sun et al., 1995). A DNA marker (BCESM = *B. cepacia* epidemic strain marker), identified by RAPD typing analysis, has been shown to be conserved among epidemic isolates of *B. cepacia* and only occasionally is present in unique clinical or environmental isolates (Mahenthiralingam et al., 1997). All of the isolates that contain the BCESM marker belong to *B. cepacia* genomovar III (Mahenthiralingam et al., 2000). The functions of any genes associated with the BCESM marker have not yet been determined, although this region contains an open reading frame with homology to negative transcriptional regulators (Mahenthiralingam et al., 1997). Most of the strains that infect multiple patients belong to genomovar III, although one strain of *B. multivorans* also has been reported to be an epidemic strain. Most strains of *B. multivorans* appear to be unique isolates that may have been acquired from the environment (Vandamme et al., 1997). Most strains that infect non-CF patients belong to *B. cepacia* genomovar I. *Burkholderia stabilis* has been isolated from CF sputum, blood and ear and from non-CF respiratory infections, as well as from the hospital environment (Vandamme et al., 2000).

Though epidemiological surveys have demonstrated that *B. pseudomallei* is endemic to regions that typically border 20° north and south of the equator, the incidence of disease is particularly high in South-East Asia and northern Australia (Chaowagul et al., 1989; Leelarasamee and Bovornkitti, 1989; Dance, 1991). In northeastern Thailand alone, an estimated 20% of community acquired septicemia and approximately 40% of deaths due to the complications of bacterial sepsis can be attributed to *B. pseudomallei* (Chaowagul et al., 1989). Although the organism is not strictly confined to the equatorial regions, the probability of acquiring melioidosis outside of these geographic domains is exceedingly low (Howe et al., 1971).

Burkholderia mallei is an obligate mammalian pathogen (Pitt, 1990; Sanford, 1990). Glanders is endemic in the Far and Middle East, Northern Africa, eastern Mediterranean and southeastern

Europe (Benenson, 1995; Kovalev, 1971). The Western Hemisphere is currently free of the disease (Benenson, 1995; Howe et al., 1971; Parker, 1990), and the United States has been glanders-free since 1937.

Disease

B. cepacia was originally identified as a plant pathogen that caused soft rot in onions (Burkholder, 1950). In the last 20 years it has emerged as an opportunistic pathogen in nosocomial infections, particularly in individuals with cystic fibrosis (CF) or chronic granulomatous disease (Gilligan, 1991; Govan et al., 1996b; LiPuma, 1998; Speert et al., 1994). The incidence of *B. cepacia* infections in CF patients varies geographically, but prevalence has been reported as high as 40% in some North American centers. Approximately 20% of CF patients colonized with *B. cepacia* experience a rapid and often fatal pulmonary decline, sometimes associated with septicemia, even in patients with previously mild disease (Govan and Deretic, 1996a; Govan et al., 1996b). Other patients are chronically colonized with a slow deterioration of lung function; however, some patients appear to experience no adverse affects following colonization with *B. cepacia* (Govan et al., 1996b; Isles et al., 1984). A 20-year study of Canadian CF patients concluded that colonization with *B. cepacia* significantly increased the risk of mortality at all levels of pulmonary function and that the risk was significantly higher in children (Corey and Farewell, 1996). A recent study comparing two-year and long-term survival rates in patients colonized with *B. cepacia* also concluded that colonization is associated with reduced long-term survival (Frangolias et al., 1999). *Burkholderia cepacia* infections are difficult to treat effectively due to the organism's multidrug resistance to potent antibiotics (Gilligan and Whittier, 1999; Simpson et al., 1994). There is considerable evidence, which has led to great concern in the CF community, that *B. cepacia* can be transmitted from person to person through nosocomial or social contacts (Govan et al., 1993; Johnson et al., 1994; Pegues et al., 1994; Smith et al., 1993). A recent study in the United Kingdom reported a hospital outbreak with an epidemic strain of *B. cepacia* that infected both CF and non-CF patients (Holmes et al., 1999), suggesting that transmission is possible between these patient groups. Acquisition of this strain in the CF patient group was associated with significantly increased mortality rates (Holmes et al., 1999).

Diagnosis of *B. cepacia* is normally based on culture and identification on selective medium (including BCSA, OFPBL and PCA) of the organism from respiratory secretions or sputum from CF patients. In other patient populations, diagnosis also depends on culture of *B. cepacia* from blood, respiratory secretions, indwelling catheters or urine.

All five genomovars and species of the *B. cepacia* complex have been isolated from the sputum of CF patients (Vandamme et al., 1997). The majority of isolates from CF patients are *B. multivorans, B. cepacia* genomovar III and *B. stabilis*. The majority of the epidemic or transmissible strains belong to genomovar III, although one epidemic clone has been identified as *B. multivorans*. Most environmental and soil isolates are either *B. cepacia* genomovar I or *B. vietnamiensis* (Vandamme et al., 2000). The recent differentiation of the *B. cepacia* complex into different species has not yet been followed by clinical data that might predict outcomes of infections by various species or genomovars. Currently, it also is not known if these *Burkholderia* species possess different virulence factors or regulate virulence factors differently and subsequently vary in their potential pathogenicity in CF or immunocompromised individuals.

The manifestations of melioidosis commonly are represented by acute, subacute and chronic illnesses, with the clinical indications of some forms of the disease often being mistaken for malaria, plague, pneumonia and miliary tuberculosis (Howe et al., 1971; Smith et al., 1987; Leelarasamee and Bovornkitti, 1989). Thus, melioidosis should be considered in any febrile patient with a history of residence in a major endemic region. If Gram-negative bipolar staining bacilli are observed in sputum, the organism can be readily cultured and identified (Sanford, 1990). In acute cases, blood and urine cultures are frequently positive; whereas, if chronic or subacute forms of the disease are suspected, biopsy may be required (Sanford, 1990). Serological studies can be helpful for diagnosing active and recrudescent disease, and an immunoglobulin M (IgM) immunofluorescence test is often positive in recent infections (Dance, 1991). Also, indirect hemagglutination and complement fixation tests are available but require the testing of paired sera over several weeks to confirm the presence of an active infection (Smith et al., 1987; Chaowagul et al., 1989).

Melioidosis is primarily acquired via the inoculation of compromised surface tissues by soil and water contaminated with *B. pseudomallei*, the highest incidence of disease occurring during the monsoon and rainy seasons (Chaowagul et al., 1989; Leelarasamee and Bovornkitti, 1989). It is believed that during these periods, rising water tables percolate the organism up through the underlying soil to the surface, thus enhancing their potential for exposure to humans and ani-

mals. This route of transmission tends to explain the prevalence of disease amongst rice farmers and their families who labor in the rice paddies without the benefit of protective clothing (Chaowagul et al., 1989; Leelarasamee and Bovornkitti, 1989). Another important route of infection appears to be the inhalation and aspiration of contaminated fomites. During the Vietnam War, a disproportionate number of helicopter crewmen contracted *B. pseudomallei* infections as compared to other soldiers stationed in the same regions. To explain this phenomenon, it has been proposed that the helicopter rotors acted to disturb infectious dust particles around landing zones and thus facilitated the pulmonary inoculation of the crewmen with *B. pseudomallei* (Howe et al., 1971; Sanford, 1990). Alternatively, ingestion of the organism and human-to-human transmission, although to much lesser extents, have been implicated as routes of inoculation (McCormick et al., 1975). To date, there have been no reports of transmission of disease between animals and humans (Leelarasamee and Bovornkitti, 1989; Dance, 1990).

A number of physiological abnormalities have been correlated with the predisposition of certain populations to *B. pseudomallei* infections. In particular, during a one-year study of patients admitted to a hospital in northeastern Thailand for treatment of septicemic melioidosis, 32% demonstrated preexisting diabetes mellitus (Chaowagul et al., 1989). Similarly, it has been shown in a diabetic, infant-rat model of infection that such animals are far more sensitive to challenge with *B. pseudomallei* isolates than are the healthy, non-diabetic rats (Woods et al., 1993). The reasons for this increased susceptibility, however, are still being investigated. Other health-related factors that appear to increase the probability of acquiring melioidosis include impaired cellular immunity, leukemia, lymphomas, HIV infections, renal disorders, and debilitating afflictions such as alcoholism and parenteral drug abuse (Whitmore and Krishnaswami, 1912; Whitmore, 1913; Leelarasamee and Bovornkitti, 1989; Tanphaichitra, 1989). Although *B. pseudomallei*-related illnesses are documented in apparently healthy individuals, the organism probably is still best described as an opportunistic pathogen.

Glanders is a zoonotic disease primarily of horses, donkeys and mules; however, nearly all mammals are susceptible to the causative agent, *B. mallei*. Natural infections of humans have been sporadic and usually are subclinical. Disease can result from a low infectious dose by aerosol, oral or parenteral routes. The incubation period is short, and nonspecific signs and symptoms confound definitive diagnosis of glanders. There are two major presentations of the disease: the nasal-pulmonary form (glanders) and the cutaneous form (farcy). These two forms may present simultaneously and usually are accompanied by systemic disease (Howe et al., 1971; Steele, 1973; Von Graevenitz, 1973). The route of infection, dose and virulence of *B. mallei* determine the severity of the disease. Clinically evident disease may be acute or chronic (Hornick, 1982; Parker, 1990; Steele, 1973), but subclinical and even latent infections may occur. The acute form of the disease most often afflicts humans (Freeman, 1985) and is characterized by a rapid onset of pneumonia, bacteremia, pustules and death within days. The chronic form of the disease, in contrast, is characterized by intermittent recrudescence and milder signs and symptoms and may last up to 25 years.

Pathogenicity

Despite the severity of *B. cepacia* infections in some patients, the virulence of this organism remains an enigma. Several potential virulence factors have been identified, including siderophores, proteases, hemolysins, lipase, and an extracellular toxic complex (Govan et al., 1996b). Bacterial pathogens must contend with an iron-restricted environment when colonizing mammalian hosts inasmuch as iron is bound to transferrin and lactoferrin and the binding of iron renders it essentially unavailable to microbial invaders (Crosa, 1989; Mietzner and Morse, 1994). Pathogenic bacteria require specialized iron acquisition systems to overcome the iron limitation imposed by the host. The most common mechanism of iron acquisition is the secretion of small chelators called "siderophores," which bind ferric iron and return it to the cell via specific outer membrane receptors (Crosa, 1989). *Burkholderia cepacia* produces four different siderophores (pyochelin, salicylic acid, cepabactin and ornibactins). Salicylic acid and ornibactins are the most prevalent siderophores produced, whereas cepabactin rarely is produced by CF isolates of *B. cepacia* (Darling et al., 1998). Approximately 50% of *B. cepacia* isolates from CF patients produce pyochelin (Sokol, 1986). Pyochelin-positive strains were more frequently isolated from patients with severe pulmonary disease, whereas pyochelin-negative strains were more frequently isolated from patients with moderate or mild infections. Genes have been identified that are required for the biosynthesis of the siderophore ornibactin (Sokol et al., 1999). The *pvdA* gene that codes for the enzyme L-ornithine N^5-oxygenase is required for effective colonization and persistence in acute and chronic *B. cepacia* respiratory infection models (Sokol et al., 1999).

Burkholderia cepacia produces at least one extracellular zinc metalloprotease that is similar to *Pseudomonas aeruginosa* elastase (Kooi et al., 1994; McKevitt et al., 1989). Purified protease has been shown to induce bronchopneumonia in rats (McKevitt et al., 1989). We recently have determined that anti-protease antibodies can reduce lung injury in chronic lung infections in rats (Sokol et al., 2000). Lipase activity has been reported in 67–100% of *B. cepacia* isolates (Gilligan, 1991; McKevitt and Woods, 1984; Nakazawa et al., 1987); however, purified lipase is not toxic to mice or Hela cells (Lonon et al., 1988). We have identified a quorum-sensing system in a *B. cepacia* genomovar III strain (Lewenza et al., 1999). The *cepI* gene directs the synthesis of the autoinducer molecule, *N*-octanoylhomoserine lactone. The *cepR* gene codes for a transcriptional regulator that positively regulates genes required for protease production or secretion and negatively regulates genes involved in ornibactin biosynthesis (Lewenza et al., 1999). Hemolysin production in *B. cepacia* is rare, with most studies reporting a 4% or lower incidence of hemolysin production in clinical isolates (Gilligan, 1991; McKevitt and Woods, 1984; Nakazawa et al., 1987). Recently, a low-molecular–weight (>3,000 Da) hemolytic activity was described in one strain of *B. cepacia* that was able to induce nucleosomal degradation (consistent with apoptosis) in human neutrophils and in a mouse macrophage cell line (Hutchison et al., 1998). There does not appear to be any correlation between production of extracellular virulence factors and transmissibility of epidemic *B. cepacia* isolates. Some strains of the *B. cepacia* complex have been shown to invade and survive in cultured epithelial cells and macrophages (Burns et al., 1996; Martin and Mohr, 2000; Saini et al., 1999). *Burkholderia cepacia* also has been reported to be resistant to growth inhibition by epithelial cell β-defensins and resistant to nonoxidative neutrophil-killing mechanisms compared to *P. aeruginosa* (Baird et al., 1999; Speert et al., 1994).

The ability to acquire iron from host sources is a prerequisite for the successful establishment and maintenance of most bacterial infections. Yang et al. have demonstrated that 84 : 84 *B. pseudomallei* strains examined during their studies tested positive for siderophore production using the chrome azurol S (CAS) assay. A structural and chemical analysis of the siderophore synthesized by *B. pseudomallei* U7 confirmed the molecule was approximately 1,000 Da in size, was water soluble with a yellow-green fluorescence, and belonged to the hydroxamate class (Yang et al., 1991). Furthermore, studies also have demonstrated the siderophore was capable of scavenging iron from both lactoferrin and transferrin in vitro (Yang et al., 1993). The name malleobactin has been proposed for this compound (Yang et al., 1991).

Although *B. pseudomallei* isolates can express an impressive array of both secreted and cell-associated antigens, the role(s) of these products in the pathogenesis of disease to date have been relatively ill defined. One of the primary reasons for this has been the lack of suitable techniques for genetically manipulating the organism. Owing to the recent application of a transposon-based mutagenesis system for use in *B. pseudomalle*, genetic loci, which encode a number of these putative virulence determinants and protective antigens, have been identified and characterized (DeShazer et al., 1997; DeShazer et al., 1998).

It has been shown previously that *B. pseudomallei* isolates can secrete antigens that demonstrate biological activities consistent with proteases, lecithinases, lipases and hemolysins (Esselman and Liu, 1961; Ashdown and Koehler, 1990; Sexton et al., 1994). However, though the importance of these factors has been implicated in the pathogenesis of the disease, only the protease has been characterized to date. Studies conducted by Sexton et al. (1994) have confirmed the presence of a 36-kDa antigen with associated proteolytic activities in *B. pseudomallei* culture supernatants. In particular, a protease expressed by *B. pseudomallei* (isolate 319a) was found to be a metalloenzyme requiring iron for maximal protease activity and to be optimally active at pH 8.0 and 60°C (Sexton et al., 1994). Furthermore, monoclonal antibodies (MAb) raised against a *Pseudomonas aeruginosa* alkaline protease were cross-reactive with this antigen (Sexton et al., 1994).

Most recently, an 11.8-kb chromosomal locus in *B. pseudomallei* has been identified that demonstrates a high degree of homology to operons that encode for the products of the main terminal branch of the general secretory pathway (GSP; Pugsley, 1993). Further characterization of the open-reading frames in this locus have confirmed that their orientation and physical arrangement are virtually identical to the *pul* gene cluster of *Klebsiella oxytoca* (Pugsley, 1993). Not surprisingly, the phenotypic analysis of individual transposon mutants also has confirmed their inability to secrete antigens associated with protease, lipase and lecithinase into the extracellular milieu. Interestingly, although the protease, lipase and lecithinase may play a small role in the pathogenesis of acute melioidosis, mutants deficient in their ability to secrete these particular exoenzymes were not severely attenuated in their ability to cause a fulminating illness (DeShazer et al., 1999).

In the mid-1950s, several studies demonstrated that filter-sterilized *B. pseudomallei* culture

supernatants were lethal for mice and hamsters when administered parenterally (Nigg et al., 1955; Heckly and Nigg, 1958; Heckly, 1964). These results were consistent with the fulminating illnesses observed in animals following inoculation with viable bacteria and suggested that *B. pseudomallei* strains might be capable of secreting a lethal toxin. In studies conducted by Ismail et al. (1987), mouse lethal, thermolabile toxin was presumably purified to homogeneity and characterized as a 31-kDa protein. Haase et al. (1997) have also described the presence of cytotoxic activity in culture filtrates. Their results, however, suggest that the antigen is only 3 kDa in size and that the cytotoxic activity in this instance most likely is due to the presence of a small peptide. Recently it has been reported that a rhamnolipid purified from *B. pseudomallei* culture supernatants demonstrates a cytotoxic effect against HL60 and HeLa cell lines (Haubler et al., 1998). Because this activity can be neutralized by albumin, however, it is unlikely to be of consequence in the pathogenesis of *B. pseudomallei* infections. These results have not been reproduced in animal models, even when using preparations concentrated by lyophilization (Brett et al., 1997; Brett et al., 1998).

Burkholderia pseudomallei strains can synthesize capsular antigens (Smith et al., 1987; Leelarasamee and Bovornkitti, 1989), and they may play an important role in the pathogenesis of melioidosis. Whereas in vitro studies have determined that encapsulated *B. pseudomallei* strains are as susceptible to phagocytic uptake by polymorphonuclear leukocytes (PMNs) as non-encapsulated variants, evidence tends to suggest that the presence of exopolysaccharide confers upon them the ability to resist the bactericidal effects of the phagolysosomal environment (Smith et al., 1987; Pruksachartvuthi et al., 1990). This feature of *B. pseudomallei* strains may help to explain why these organisms are able to remain latent in a host for as long as 26 years.

Recently, Steinmetz et al. isolated and purified a high-molecular-weight capsular antigen (150 kDa) from *B. pseudomallei* NCTC 7431 and succeeded in raising a Mab against it (Steinmetz et al., 1995). They were able to demonstrate the reactivity of both mucoid and non-mucoid strains with the MAb, suggesting that the capsular antigen is constitutively expressed by *B. pseudomallei* strains. Interestingly, temperature appeared to have little effect on the synthesis of the exopolysaccharide inasmuch as *B. pseudomallei* strains grown at both 15 and 37°C were Mab-reactive. Furthermore, an assay utilizing a variety of *Pseudomonas spp.* and *Burkholderia spp.* as controls was able to confirm the specificity of the MAb for *B. pseudomallei* and *B. mallei* strains only (Steinmetz et al., 1995). More recently, Masoud et al. (1997) have been successful at elucidating the chemical and structural characteristics of a capsular polysaccharide isolated from the virulent clinical isolate *B. pseudomallei* 304b. Their results demonstrated that the exopolysaccharide was a linear unbranched polymer of repeating tetrasaccharide units having the structure (-3)-2-*O*-Ac-β-D-Gal*p*-(1-4)-α-D-Gal*p*-(1-3)-β-D-Gal*p*-(1-5)-β-D-KDO*p*-(2-) (where KDO is 3-deoxy-D-manno-2-octulosonic acid). Similarly, Nimtz et al. (1997) have demonstrated that a structurally identical capsular antigen is expressed by *B. pseudomallei* NCTC 7431. Studies by both groups have also shown that patient sera reacted strongly with the purified carbohydrate antigens, indicating that this carbohydrate polymer is most likely expressed in vivo (Steinmetz et al., 1995; Masoud et al., 1997). Previous studies have confirmed that the lipopolysaccharide (LPS) antigens expressed by *B. pseudomallei* strains are highly conserved throughout this species (Pitt et al., 1992). In fact, serological evidence suggests only one serotype of *B. pseudomallei* (Bryan et al., 1994). To investigate this phenomenon, Perry et al. have characterized the LPS antigens isolated from a number of *B. pseudomallei* strains (Perry et al., 1995). Their results demonstrated that *B. pseudomallei* strains coordinately express two distinct somatic *O*-antigens (PS) on their cell surface. The type I antigen consists of a high-molecular-weight unbranched 1,3-linked homopolymer of 2-*O*-acetylated 6-deoxy-β-D-manno-heptopyranosyl residues, while the type II antigen is an unbranched heteropolymer consisting of (-3)-β-D-glucopyranose-(1-3)-6-deoxy-α-L-talopyranosyl-(1)-disaccharide repeats (L-6dTal*p*: __33% *O*-4 acetylated and *O*-2 methylated; __66% *O*-2 acetylated; Knirel et al., 1992; Perry et al., 1995). Even though the simultaneous expression of two or more LPS moieties is not an uncommon feature associated with Gram-negative bacteria, the degree to which the two PS antigens are conserved amongst *B. pseudomallei* strains is quite remarkable (Perry et al., 1995).

It has been reported that *B. pseudomallei* strains are resistant to the bactericidal effects of normal human serum (Ismail et al., 1988). Type II PS is essential for conferring this resistance phenotype. A 17.5-kb region of the chromosome, which is required for the synthesis of the type II antigen, confers the serum-resistance phenotype (DeShazer et al., 1998). Type II PS is probably a significant determinant in the pathogenesis of melioidosis because the LD50 value associated with a type II PS mutant is approximately 140-

fold higher than that of the wild-type strain (Woods et al., 1993; DeShazer et al., 1998).

Flagella are commonly recognized as important virulence determinants expressed by bacterial pathogens because the motility phenotype imparted by these organelles often correlates with the ability of an organism to cause disease (Penn and Luke, 1992; Moens and Vanderleyden, 1996). A significant degree of size and antigenic homogeneity exists amongst flagellins expressed by *B. pseudomallei* isolates. Furthermore, flagellin-specific antiserum can passively protect diabetic infant rats against a *B. pseudomallei* challenge (Brett et al., 1994). Curiously, there was no significant difference between the virulence capacities associated with a wild-type strain of *B. pseudomallei* and nonmotile mutants in either the diabetic infant rat or Syrian hamster models of infection (DeShazer et al., 1997). These results indicate that though flagella and/or motility may not be major virulence determinants in the pathogenesis of melioidosis, purified flagellin might still be a protective immunogen against *B. pseudomallei* infections.

Although glanders is a serious life-threatening zoonotic disease, relatively little is known about the pathogenesis, virulence factors, strain and the host immunopathological responses to infection (Fritz et al., 1999).

Treatment

Burkholderia cepacia is resistant to most antibiotics, making treatment of CF patients very difficult. It usually is susceptible only to piperacillin, axlocillin, cefoperazone, ceftazidime, chloramphenicol and trimethoprim-sulfamethoxazole (TMP-SMX; Pitkin et al., 1997). Strains isolated from CF sputum from patients treated with several courses of antibiotic therapy are often resistant to all known antimicrobial agents (Gilligan and Whittier, 1999). Resistance to a variety of antimicrobial agents including penicillins, first- and second-generation cephalosporins and many of the aminoglycosides is characteristic of *B. pseudomallei* clinical isolates (Dance et al., 1988; Leelarasamee and Bovornkitti, 1989; Godfrey et al., 1991; Weinberg and Heller, 1997). With this in mind, accurate identification of the organism, evaluation of the severity of the infection and antibiotic susceptibility testing are of paramount importance in devising an effective chemotherapeutic strategy. Whereas the newer therapies that utilize combinations of ceftazidime–cotrimoxazole or amoxicillin–clavulanate for treatment of disease are proving beneficial, the mortality rates associated with the acute septicemic and pulmonary forms of melioidosis are still unacceptably high (Smith et al., 1987; Leelarasamee and Bovornkitti, 1989; Kanai and Kondo, 1994; Weinberg and Heller, 1997; Ho et al., 1997). Typically, prolonged oral therapy also is recommended to assure the full clinical resolution of infections while reducing the potential for recrudescence of disease.

Antibiotic therapy for glanders is complex (Batmanov, 1991); however, there have been reports that ceftazidime, imipenem, doxycycline and ciprofloxacin are active against both *B. mallei* and *B. pseudomallei* (Kenny et al., 1999). Antibiotics clinically proven to be effective in the treatment of melioidosis may therefore be effective for treating glanders.

CHAPTER 3.2.17

The Nitrite-Oxidizing Bacteria

AHARON ABELIOVICH

Introduction

Nitrite-oxidizing bacteria are a small group of primarily organo and/or chemoautotrophs that are difficult to grow and work with. For many years they drew very little attention, although it was realized that they provide a key link in the global nitrogen cycle between the ammonia-oxidizing bacteria, which generate nitrite, and the various denitrifying microorganisms that remove nitrate by reducing it to ammonia or molecular nitrogen, thus completing the global nitrogen cycle.

The growing public awareness relating to issues of environmental pollution in recent decades brought renewed interest in this group of bacteria, as their role in the transformation of nitric oxides became apparent. In addition, these bacteria cause economic damage to agriculture and to ground water quality by contributing to the leaching of nitrogen fertilizers (distributed in the form of ammonia) from surface soils, thus polluting aquifers with increasing concentrations of nitrites and nitrates.

Owing to their key role in the global cycling of nitrogen and their activities both as prime contributors to and scavengers of nitric oxides in the biosphere, nitrite-oxidizing bacteria became in recent years the focus of intensive ecophysiological research, in spite of the difficulties in cultivating and maintaining many of these bacteria in the laboratory.

In addition to this group of autotrophic nitrifyers, there is also a diverse group of heterotrophic bacteria capable of heterotrophic nitrite oxidation. Thus, in one such study (Sakai et al., 1996), the nitrite transforming activities of heterotrophic bacterial strains from various culture collections as well as isolates from activated sludge were studied. Of the 48 strains tested, 17 strains consumed 1–5 mM of nitrite and accumulated corresponding amounts of nitrate. Heterotrophic microorganisms are rather flexible in determining the fate of the consumed nitrite. For instance, in *Bacillus subtilis* strain I-41 (a denitrification-positive isolate), the ratio of the amount of nitrate accumulated to that of nitrite consumed varied from 0 to 100%, depending on the culture conditions. However, the mechanism of oxidation of nitrite to nitrate in these heterotrophic bacteria is very different from that in the autotrophic bacteria (Sorokin, 1991), as heterotrophic nitrite oxidation requires catalase and hydrogen peroxide (H_2O_2) generated through oxidation of organic electron donors. Also, aeration affects the nitrite- and nitrate-transforming activities of various heterotrophic bacteria. For example, *Pseudomonas pavonaceae*, a denitrification-positive strain, metabolizes both nitrite and nitrate to more reduced compounds at low oxygen pressure, and the direction of the conversion changes from reduction to oxidation at high oxygen pressure. This switching might be caused by inhibition and repression of the nitrite-reducing activity and by stimulation of nitrite-oxidizing activity by oxygen (Sakai et al., 1997).

Historic Background

Nitrite-oxidizing bacteria carry the second stage of the nitrification process, that of oxidation of nitrite to nitrate. Because nitrate is an essential ingredient of gunpowder, nitrate and nitrification were the focus of interest both to scientists and politicians for many centuries. Nitrification protocols for the manufacture of nitrates by composting organic matter in soil have existed for many centuries: from the tenth century in China and from the twelfth century in Europe (Macdonald, 1986). However, the process was considered to be of a chemical and not biological nature until the late nineteenth century. It was only in 1862 that Pasteur suggested that nitrification was of biological origin (Pasteur, 1862), and it was only when Winogradsky in 1891 succeeded in isolating a nitrite-oxidizing bacterium that the debate about whether nitrification is a one-stage process (carried by a single bacterium) or a two-stage process (carried by two distinct classes of microorganisms) was settled (Macdonald, 1986).

Nitrite Oxidation

A detailed account of the mechanism of nitrite oxidation as an energy source has been described previously (Bock et al., 2001). The key enzyme that makes the nitrite-oxidizing bacteria so important in the global nitrogen cycle is nitrite oxidoreductase (NOR), which carries out the stoichiometric reaction:

$$NO_2^- + H_2O \Leftrightarrow NO_3^- + 2H^+ + e^- \quad (1)$$

$$2H^+ + 2e^- + 0.5O_2 \rightarrow H_2O \quad (2)$$

Reaction (1) is reversible, and many nitrite oxidizers are capable of reducing nitrate to nitrite under anaerobic conditions, but the significance of the reverse reaction to their survival is not clear, as both nitrite and nitrate are rapidly reduced in anaerobic environments.

Nitrite oxidoreductase was isolated from various *Nitrobacter* strains, such as from mixotrophically grown cells of *Nitrobacter hamburgensis*; the enzyme purified from heat-treated membranes was homogeneous by the criteria of polyacrylamide gel electrophoresis and size exclusion chromatography. The monomeric form consisted of two subunits with molecular weights of 115 kDa and 65 kDa, respectively. The dimeric form of the enzyme contained 0.70 molybdenum, 23.0 iron, 1.76 zinc and 0.89 copper gram-atoms per molecule. The catalytically active enzyme was investigated by visible and electron paramagnetic resonance spectroscopy (EPR) under oxidizing (as isolated), reducing (dithionite), and turnover (nitrite) conditions. As isolated, the enzyme exhibited a complex set of EPR signals between 5–75 K, originating from several iron-sulfur and molybdenum (V) centers. Addition of the substrate nitrite or the reducing agent dithionite resulted in a set of new resonances. The molybdenum and the iron-sulfur centers of nitrite oxidoreductase from *Nitrobacter hamburgensis* were involved in the transformation of nitrite to nitrate (Meincke et al., 1992).

Systematics

As late as 1981, all bacteria capable of chemolithotrophic growth using ammonia ornitrite as energy source and capable of assimilating CO_2 via the Calvin cycle were grouped in one family, the Nitrobacteraceae (Watson et al., 1981). This classification was based on the fact that all the bacteria grouped in this family carry out oxidation reactions of inorganic nitrogen compounds, and all are capable of chemolithotrophic growth using these as energy sources. All are Gram-negative bacteria and usually found in association; as a physiological interdependence exists between the two groups, inasmuch as the ammonia oxidizers provide the substrate for the nitrite oxidizers, whereas the nitrite oxidizers are inhibited by excess ammonia.

With the advent of molecular biology and classification of bacteria through sequencing of 16S ribosomal RNA genes and other specific DNA sequences, as well as the use of monoclonal antibodies, it became evident that the two groups are not related, and that there is no phylogenetic relationship between ammonia and nitrite oxidizers. Almost all nitrite oxidizers (with the exception of *Nitrospira moscoviensis*, which seems to occupy an intermediate position; Schramm et al., 1998) are a homogenous group belonging to the α-subdivision of the Proteobacteria and are very closely related to the nonsulfur purple photosynthetic bacterium *Rhodopseudomonas palustris*. None of the ammonia-oxidizing bacteria belong to the α-subdivision, and they are all distributed between the β- and γ-subdivisions (Woese et al., 1984; Woese et al., 1985).

Comparative 16S rDNA sequencing was used to evaluate phylogenetic relationships among selected strains of ammonia- and nitrite-oxidizing bacteria (Teske et al., 1994). All characterized strains were shown to be affiliated with the proteobacteria. The study extended recent 16S rDNA-based studies of phylogenetic diversity among nitrifiers by the comparison of eight strains of the genus *Nitrobacter* and representatives of the genera *Nitrospira* and *Nitrospina*. The latter genera were shown to be affiliated with the δ-subdivision of the proteobacteria but did not share a specific relationship to each other or to other members of the δ-subdivision. All characterized *Nitrobacter* strains constituted a closely related assemblage within the α-subdivision of the Proteobacteria. As previously observed, all ammonia-oxidizing genera except *Nitrosococcus oceanus* constitute a monophyletic assemblage within the β-subdivision of the proteobacteria. Consideration of physiology and phylogenetic distribution suggests that nitrite-oxidizing bacteria of the α- and γ-subdivisions are derived from immediate photosynthetic ancestry. Each nitrifier retains the general structural features of the specific ancestor's photosynthetic membrane complex. Thus, the nitrifiers, as a group, apparently are not derived from an ancestral nitrifying phenotype.

Watson et al. (1981) identified three genera of nitrite-oxidizing bacteria (the *Nitrospira* being discovered only in 1986; Watson, 1986) and classified them on the basis of morphology and nutritional requirements. Bartosch et al. (1999) also divided the nitrite-oxidizing bacteria into four genera, *Nitrobacter*, *Nitrospina*, *Nitrococcus* and

Nitrospira, according to their reactions with monoclonal antibodies prepared against the nitrite oxidoreductase of the genus *Nitrobacter*. Among these, *Nitrobacter* and *Nitrospira* strains are capable of heterotrophic or mixotrophic growth, the rest being strict chemolithotrophs.

Because of the difficulties in culturing nitrifying bacteria on solid media, the methods for enumerating and identifying nitrifiers in environmental samples conventionally depended on incubating serial dilutions for very long periods, and then testing these for appearance of nitrate. Thus, the dominant nitrite-oxidizing species in an environmental sample was usually identified only after incubation of 3–6 months and was acertained on the basis of morphological and physiological properties such as sensitivity to salts and nutrient concentration. These observations led over the years to a general consensus that *Nitrobacter* strain were the dominant nitrite-oxidizing organisms in practically all tested environments such as soil, marine waters, wastewater treatment plants, fresh water and reservoirs; *Nitrococcus* and *Nitrospina* were rarely identified (Watson et al., 1981).

In 1995, a Gram-negative, nonmotile, nonmarine, nitrite-oxidizing bacterium was isolated by enrichment culture of a sample from a partially corroded area of an iron pipe located in a heating system in Moscow, Russia (Ehrich et al., 1995). The cells (0.9–2.2 μm × 0.2–0.4 μm in size) were helical to vibroid-shaped and often formed spirals with up to three turns 0.8–1.0 μm in width. The organism possessed an enlarged periplasmic space and lacked intracytoplasmic membranes and carboxysomes. The cells excreted extracellular polymers and formed aggregates. The bacterium grew optimally at 39°C and pH 7.6–8.0 in a mineral medium with nitrite as sole energy source and carbon dioxide as sole carbon source. The doubling time was 12 h in a mineral medium with 7.5 mM nitrite. The cell yield was low; only 0.9 mg of protein/liter was formed during oxidation of 7.5 mM nitrite. Under anoxic conditions, hydrogen could be used as electron donor with nitrate as electron acceptor. Organic matter (yeast extract, meat extract and peptone) supported neither mixotrophic nor heterotrophic growth. At concentrations as low as 0.75 g of organic matter/liter or higher, growth of the nitrite-oxidizing cells was inhibited. The cells contained cytochromes of the *b*- and *c*-type. The G+C content of DNA was 56.9 ± 0.4 mol%. This chemolithoautotrophic nitrite-oxidizer differed from the terrestrial members of the genus *Nitrobacter* with regard to morphology and substrate range and was similar to *Nitrospira marina* in both characteristics. The isolated bacterium was designated as a new species of the genus *Nitrospira*. Recent studies suggest that this genus dominates most of the nitrite oxidation activities in natural as well as artificial habitats (see below).

With the introduction of molecular technologies to environmental microbiology, the true dominant nitrite oxidizers could be identified in situ in environmental samples, either by polymerase chain reaction (PCR, using specific rDNA primers) or fluorescence in situ hybridization (FISH, using specific probes). These studies led to the surprising conclusion that *Nitrospira* strains are the dominant nitrite oxidizers in most environmental samples tested so far, whereas *Nitrobacter* sp. are seldom identified without prior enrichment (Burrell et al., 1998; Burrell et al., 1999; Schramm et al., 1998; Juretschko et al.,1998; Okabe et al., 1999).

There is, however, no doubt that within the next years, with the advent of oligonucleotide microchip technology, oligonucleotide microchips will dominate as genosensors for determinative and environmental studies in microbiology (Guschin et al., 1997). Precise identification of bacterial communities and of the genes switched on by each member of these communities under various environmental conditions will become routine in the environmental microbiology lab, and these procedures will enable the fine resolution of the community of nitrifying bacteria and its activities in different biotopes.

DNA sequencing methodologies also were used to identify bacteria in situ, in biofilms and activated sludge particles (Schramm et al., 1998). Bacterial aggregates from a chemolithoautotrophic, nitrifying fluidized bed reactor were investigated with microsensors and rDNA-based molecular techniques. The microprofiles of O_2, NH_4^+, NO_2^- and NO_3^- demonstrated the occurrence of complete nitrification in the outer 125 μm of the aggregates. FISH analysis showed that the dominant populations were of *Nitrospira* spp. and *Nitrosospira* sp. and that they formed separate, dense clusters which were in contact with each other and occurred throughout the aggregate. Significantly, no ammonia- or nitrite-oxidizing bacteria of the genera *Nitrosomonas* or *Nitrobacter*, respectively, could be detected by FISH. To identify the nitrite oxidizers, a 16S ribosomal DNA clone library was constructed and screened by denaturing gradient gel electrophoresis (DGGE), and selected clones were sequenced. The organisms represented by these sequences formed two phylogenetically distinct clusters affiliated with the nitrite oxidizer *Nitrospira moscoviensis*. The dominant *Nitrospira* sp. formed clusters with the nitrosospira sp. and occurred throughout the aggregate while the second, smaller, morphologically and genetically different population of *Nitrospira* sp. was

restricted to the outer nitrifying zones. The phylogeny of bacteria belonging to the genus *Nitrobacter* was investigated by sequencing the whole 16S rRNA gene (Orso et al., 1994). The average level of similarity for three *Nitrobacter* strains examined was high (99.2%), and the similarity level between *Nitrobacter winogradsky* and *Nitrobacter* sp. strain LL, which represent two different genomic species, was even higher (99.6%). When all of the *Nitrobacter* strains and their phylogenetic neighbors *Bradyrhizobium* and *Rhodopseudomonas* species were considered, the average similarity level was 98.1%. When complete sequences were used, *Nitrobacter hamburgensis* clustered with the two other *Nitrobacter* strains, though this was not the case when partial sequences were used. The two *Rhodopseudomonas palustris* strains examined exhibited a low similarity level (97.6%) and were not clustered.

In another study (Okabe et al., 1999), the in situ spatial organization of ammonia-oxidizing and nitrite-oxidizing bacteria in domestic wastewater biofilms and autotrophic nitrifying biofilms was investigated by using microsensors and FISH, performed with 16S rDNA-targeted oligonucleotide probes. The combination of these techniques made it possible to relate in situ microbial activity directly to the occurrence of specific nitrifying bacterial populations. In situ hybridization revealed that bacteria belonging to the genus *Nitrobacter* were not detected; instead, *Nitrospira*-like bacteria were the main nitrite-oxidizing bacteria in both types of biofilms. *Nitrospira*-like cells formed irregularly shaped aggregates consisting of small microcolonies, which bound the clusters of ammonia oxidizers. Whereas most of the ammonia-oxidizing bacteria were present throughout the biofilms, the nitrite-oxidizing bacteria were restricted to the active nitrite-oxidizing zones, which were inside the biofilms. Microelectrode measurements showed that the active ammonia-oxidizing zone was located in the outer part of a biofilm, whereas the active nitrite-oxidizing zone was located just below the ammonia-oxidizing zone and overlapped the location of nitrite-oxidizing bacteria, as determined by FISH.

The use of fluorescent monoclonal antibodies was also very useful for the rapid quantification and in situ detection of specific nitrifiers in a mixed bacterial habitat such as a biofilm (Noda et al., 2000). In that study, 12 monoclonal antibodies against *Nitrosomonas europaea* (IFO14298) and 16 against *Nitrobacter winogradsky* (IFO 14297) enabled a direct cell count of *N. europaea* and *N. winogradsky*. Moreover, the distribution of N. europaea and N. winogradsky in a biofilm could be examined. Most of *N. winogradsky* existed near the surface and most of *N. europaea* existed within the polyethylene glycol (PEG) gel pellet.

Using DNA sequences from the intergenic spacer (IGS) region of the ribosomal operon, and two primers derived from 16S and 23S rDNA conserved sequences, Navarro et al. (1992a) amplified these sequences by PCR. The PCR products, cleaved by four base cutting restriction enzymes, were used to differentiate *Nitrobacter* strains. This method is convenient for the genotypic characterization of *Nitrobacter* isolates and was successfully used to characterize natural populations of *Nitrobacter* from various soils and a lake. Considerable diversity was demonstrated in various soils, and in both water and sediments of the lake.

Navarro et al. (1992b) also studied the genomic diversity of *Nitrobacter* strains by determining rDNA gene restriction patterns as well as hybridization characteristics and DNA base compositions. The DNA hybridization (S1 nuclease method) revealed five DNA genomic groups, and these groups formed three genomic *Nitrobacter* species.

Mobarry et al. (1996) prepared a hierarchical set of five 16S rRNA-targeted DNA probes for phylogenetically defined groups of autotrophic ammonia- and nitrite-oxidizing bacteria. Their environmental application was demonstrated by quantitative slot blot hybridization and whole-cell hybridization of nitrifying activated sludge and biofilm samples. In situ hybridization experiments revealed that *Nitrobacter* and *Nitrosomonas* species occurred in clusters and frequently were in contact with each other within sludge flocs.

The nitrite oxidoreductase (NOR) from the facultative nitrite-oxidizing bacterium *Nitrobacter hamburgensis* X14 was used to develop a probe for the gene *norB* (Kirstein and Bock, 1993). Sequence analysis of DNA fragments revealed three adjacent open reading frames in the order *norA*, *norX* and *norB*. The deduced amino acid sequence of protein NorB contained four cysteine clusters with striking homology to those of iron-sulfur centers of bacterial ferredoxins. Protein NorB shares significant sequence similarity to the β-subunits (NarH and NarY) of the two dissimilatory nitrate reductases (NRA and NRZ) of *Escherichia coli*. Additionally, the derived amino acid sequence of the truncated open reading frame of norA showed striking resemblance to the α-subunits (NarG and NarZ) of the *E. coli* nitrate reductases. Additionally, the derived amino acid sequence of the truncated open reading frame of norA showed resemblance to the α-subunits of the *E. coli* nitrate reductases.

Monoclonal antibodies prepared against nitrite oxidoreductases of nitrite oxidizers also

were used successfully for the identification of nitrite oxidizers (Bartosch et al., 1999). Immunoblot analyses performed with three monoclonal antibodies (MAbs) that recognized the nitrite oxidoreductase (NOR) of the genus *Nitrobacter* were used for taxonomic investigations of nitrite oxidizers. These MAbs were able to detect the nitrite-oxidizing systems (NOS) of the genera *Nitrospira*, *Nitrococcus* and *Nitrospina*. When the genus-specific reactions of the MAbs were correlated with 16S rDNA sequences, they reflected the phylogenetic relationships among the nitrite oxidizers. In ecological studies, the immunoblot analyses demonstrated that *Nitrobacter* or *Nitrospira* cells could be enriched from activated sludge by using various substrate concentrations.

The microbiology of the biomass from a nitrite-oxidizing sequencing batch reactor (NOSBR) as well as the seed sludge used were investigated by microscopy, by culture-dependent methods, and by molecular biological methods (Burrell et al., 1998). The NOSBR was fed with an inorganic salts solution and nitrite as the sole energy source. It was operated for 6 months, and 16S ribosomal DNA clone libraries were prepared both from the seed sludge and from the reactor. Analysis of the seed sludge revealed that it contained three clones (4% of biomass) that were closely related to the autotrophic nitrite-oxidizer *Nitrospira moscoviensis*, whereas the NOSBR sludge itself was overwhelmingly dominated by bacteria closely related to the *N. moscoviensis* (89%). Only two clone sequences were similar to those of the genus *Nitrobacter*. Near-complete insert sequences of eight clones of *N. moscoviensis* isolated from the NOSBR and one clone from the seed sludge were determined and phylogenetically analyzed. This report was the first to show the presence of bacteria from the *Nitrospira* genus in wastewater treatment systems.

Nitrite-oxidizing bacteria belonging exclusively to the genus *Nitrospira* also dominated the nitrite-oxidizing community of a phosphate-removing biofilm from a sequencing batch biofilm reactor (Gieseke et al., 2001).

In another study (Burrell et al., 1999), a sequencing batch reactor (SBR) was operated to selectively grow a nitrite-oxidizing microbial community, and it was found that the nitrite oxidation was due the presence of bacteria from the *Nitrospira* genus and not the *Nitrobacter* genus, which were in very low numbers. It was hypothesized that the unknown nitrite-oxidizing bacteria in wastewater treatment plants are a range of species related to *Nitrospira moscoviensis*.

Oxidation of nitrite to nitrate in aquaria is typically attributed to bacteria belonging to the genus *Nitrobacter* that are members of the α-subdivision of the class Proteobacteria. To identify bacteria responsible for nitrite oxidation in aquaria, clone libraries of rRNA genes were developed by Hovanec et al. (1998) from biofilms from several freshwater aquaria, and analysis of the rDNA libraries, along with results from denaturing gradient gel electrophoresis (DGGE) on frequently sampled biofilms, indicated the presence of putative nitrite-oxidizing bacteria closely related to other members of the genus *Nitrospira*. Hybridization experiments with rRNA from biofilms of freshwater aquaria demonstrated that *Nitrospira*-like rRNA comprised nearly 5% of the rRNA extracted from the biofilms during the establishment of nitrification. Nitrite-oxidizing bacteria belonging to the α-subdivision of the class Proteobacteria (e.g., *Nitrobacter* spp.) were not detected in these samples. Aquaria that received a commercial preparation containing *Nitrobacter* species did not show evidence of *Nitrobacter* growth and development but did develop substantial populations of *Nitrospira*-like species. Time series analysis of rDNA phylotypes on aquaria biofilms by DGGE, combined with nitrite and nitrate analysis, showed a correspondence between the appearance of *Nitrospira*-like bacterial ribosomal DNA and the initiation of nitrite oxidation. In total, the data suggest that *Nitrobacter winogradsky* and close relatives were not the dominant nitrite-oxidizing bacteria in freshwater aquaria. Instead, nitrite oxidation in freshwater aquaria appeared to be mediated by bacteria closely related to *Nitrospira* sp.

Isolation and Nutritional Requirements

The information in this section is compiled from the chapter by Bock and Koops (1992) on Nitrobacter in the second edition published in the previous edition of {The Prokaryotes}.

Obligate and facultative lithoautotrophic nitrite oxidizers can be successfully isolated only if mineral nitrite media free of any organic contaminants are used, otherwise heterotrophs will overgrow nitrite oxidizers. A sample of 1–2 g (soil, stone, mud etc.) is placed in 100 ml of enrichment medium selective for the growth of either terrestrial or marine strains (Table 1). For the enrichment of dominant nitrifiers, a combination of the most probable number (MPN) technique followed by the serial dilutions method is suitable. In the highest dilutions, nitrite oxidation can be detected only after several months because of the slow growth of the nitrite oxidizers. Plating samples from enrichment cultures on rich and poor solid agar media

Table 1. Four culture media[a] for lithoautotrophic and mixotrophic growth of nitrite oxidizers.

Ingredient	1a	2b	3b	4c
Distilled water (ml)	1,000	1,000	1,000	300

can check contamination by heterotrophs. It may take a year to obtain pure cultures with the technique described above.

Medium 1a for terrestrial strains is from Aleem and Alexander (1958), media 2b and 3b also for terrestrial strains are from Bock and Stackebrandt (1983), and medium 4c for marine strains is from Watson and Waterbury (1971).

Habitats

As described earlier, the nitrite-oxidizing bacteria are ubiquitous, and are usually found in association with the ammonia-oxidizing bacteria, which provide them with their energy source. In spite of many reports describing their sensitivity to light (Guerrero and Jones, 1996; Guerrero and Jones, 1997) and various toxicants (Deni and Penninckx, 1999; Jenicek et al., 1996), nitrite-oxidizing bacteria are abundant in practically all terrestrial, marine and fresh water habitats. Nitrifying bacteria play a significant role in erosion of rocks (Lebedeva et al., 1978) primarily because they release nitrates, which dissolve carbonates, in exchange for CO_2 they assimilate. This process was found to be a major cause of deterioration of historic monuments in Europe (Mansch and Bock, 1998). Proliferation of nitrifiers in sewage is also the basis for nitrogen removal from domestic and industrial waste in water treatment plants, including chemical industry wastewater. Nitrite oxidizers grow within a wide range of pH values up to 10 (Sorokin, 1998a; Sorokin et al., 1998b) and salinities (limits are difficult to determine as nitrifying bacteria resist very low water activities, such as occur when living within desiccated rocks).

Although nitrite oxidizers are considered obligate aerobes (even though many can utilize nitrate in absence of oxygen as an electron acceptor), growth of nitrite oxidizers can be observed in totally anaerobic environments such as deep in the mud at the bottom of deep anaerobic wastewater reservoirs, in the absence of nitrate or oxygen, in presence of significant concentrations of sulfides (Abeliovich, 1987). Also, nitrifying bacteria were isolated from a marine anaerobic sediment at depths of up to 8 cm (Blackburn, 1983). Nothing is at present known about the metabolism and survival mechanisms of these nitrite-oxidizing bacteria living under strict anaerobic, reducing conditions.

Light (particularly blue light) is frequently mentioned as an inhibiting factor for the nitrification process. However, the reports on the effects of light are sometimes contradictory. Nitrifiers are found in all habitats exposed to sunlight, either at the surface of fresh water or marine habitats, so obviously they must have efficient protection mechanisms to overcome photoinhibition and damage caused by direct sunlight.

Sorokin et al. (1998b) and Sorokin (1998a) have isolated five strains of lithotrophic, nitrite-oxidizing bacteria from sediments of three soda lakes after enrichment at pH 10 with nitrite as sole energy source; these strains were described as a new species of the genus *Nitrobacter*, *N. alkalicus*. Nitrite oxidation to nitrate occurred at pH 10. The nitrifiers had pear-shaped budding cells morphologically similar to those of *Nitrobacter* and formed tiny colonies on mineral nitrite agar at pH 10.

In a study aimed at evaluating the potential of wastewater treatment plants to contaminate receiving waterways, survival of *Nitrobacter* cells associated with particles in water treatment plant discharges was studied using immunofluoresence methods (Bonnet et al., 1997). It was found that *Nitrobacter* colonies can settle in freshwater sediments in a week (10^6 cells per gram of dry sediment) and can therefore colonize river sediments.

Chemolithotrophic nitrifying bacteria are dependent on the presence of oxygen for the oxidation of ammonium via nitrite to nitrate. The success of nitrification in oxygen-limited environments largely depends on the oxygen sequestering abilities of both ammonium- and

nitrite-oxidizing bacteria. Oxygen consumption kinetics were determined with cells grown in mixed culture in chemostats at different growth rates and oxygen tensions (Laanbroek and Gerards, 1993). Reduction of oxygen tension in the culture was found to repress the oxidation of nitrite before the oxidation of ammonium was affected, and hence nitrite accumulated.

In addition to the competition between ammonium- and nitrite-oxidizing bacteria, there is competition with organotrophic bacteria for the available oxygen as well. The outcome of the competition is determined by their specific affinities for oxygen as well as by their population sizes. The effect of mixotrophic growth of nitrite-oxidizing *Nitrobacter hamburgensis* on the competition for limiting amounts of oxygen was studied in mixed continuous culture experiments with the ammonium-oxidizing *Nitrosomonas europaea* at different oxygen concentrations (Laanbroek et al., 1994). The specific affinity for oxygen of *N. europaea* was in general higher than that of *N. hamburgensis*, and in transient state experiments, when oxic conditions were switched to anoxic, *N. hamburgensis* was washed out and nitrite accumulated. However, at low oxygen concentration, the specific affinity for oxygen of *N. hamburgensis* increased and became as great as that of *N. europaea*, and owing to its larger population size, the nitrite-oxidizing bacterium became the better competitor for oxygen and ammonium accumulated. Therefore Laanbroek et al. suggest that continuously oxygen-limited environments present a suitable ecological niche for the nitrite-oxidizing *N. hamburgensis*.

Biofilms

Biofilms present a unique biotope for using molecular DNA techniques as well as FISH and various sensors. The combination of microsensor and molecular techniques is highly useful for studies on the microbial ecology of biofilms in general, and in particular for the identification of activity sites of nitrifying bacteria.

Thus, the distribution of nitrifying bacteria of the genera *Nitrosomonas*, *Nitrosospira*, *Nitrobacter* and *Nitrospina* was studied by Schramm et al. (2000) in a membrane-bound biofilm system in which gradients of oxygen, pH, nitrite and nitrate were determined by means of microsensors, while the nitrifying populations along these gradients were identified and quantified using FISH in combination with confocal laser scanning microscopy. It was found that the oxic part of the biofilm was dominated by ammonia oxidizers and by members of the genus *Nitrobacter*, and *Nitrospira* sp. were virtually absent in this part of the biofilm, whereas they were most abundant at the oxic-anoxic interface. In the totally anoxic part of the biofilm, cell numbers of all nitrifiers were relatively low. These observations suggest the microaerophilic behavior of an as yet uncultured *Nitrospira* sp. as a factor affecting its environmental competitiveness.

De Beer and Schramm (1999), using microsensors and molecular techniques (such as in situ hybridization with 16S rDNA-targeted oligonucleotide probes), showed that there exists in biofilms grown in bioreactors a complex nitrifying community, consisting of members of the genera *Nitrosomonas*, *Nitrosospira*, *Nitrobacter* and *Nitrospira*.

In nitrifying biofilms from a trickling filter of an aquaculture water recirculation system, it was found that nitrification was restricted to a narrow zone of 50 μm of the very top of the film. Ammonia oxidizers formed a dense layer of cell clusters in the upper part of the biofilm, whereas the nitrite oxidizers showed less-dense aggregates in the proximity of the ammonia oxidizers. Both ammonia and nitrite oxidizers were not restricted to the oxic zone of the biofilm but were also detected in substantially lower numbers in the anoxic layers and even occasionally at the bottom of the biofilm (Schramm et al., 1996).

Enumeration

Conventional methodologies for counting nitrifiers are gradually being replaced by new technologies, although the MPN method still dominates, this because all methods based on specific probes or antibodies still leave open the possibility that some species do not crossreact with the probe used. On the other hand, the issue of optimal conditions for maximal yields using MPN counts has not been yet resolved.

One example is a new amperometric enzyme-linked immunoassay for specific enumeration of *Nitrobacter*, which uses an electrode made of glassy carbon on which an immunological reaction is carried out. The detection limit was approximately 3×10^6 *Nitrobacter* cells/ml (Sanden and Dalhammar, 2000). It was shown that this method could be applied for the enumeration of *Nitrobacter* in activated sludge and other environmental samples. The reason for the attempts to develop new methodologies is the lengthy incubation periods required for stable MPN counts: maximum most probable numbers of the ammonia-oxidizing group were attained in 20–55 days (median, 25) and MPN estimates of nitrite oxidizers required a much longer incubation (103–113 days; Matulewich et al., 1975). In addition, Both et al. (1990a) and (1990b) studied the effect of two concentrations of nitrite in the

incubation medium, 0.05 and 5.0 mM, and found that numbers of nitrite-oxidizing bacteria were highly dependent on the nitrite concentration as well as on the soil sampled.

Neither the influence of pH or nitrite concentration in the incubation medium could account exclusively for the MPN-enumeration result, which raises the issue of whether to use more than one incubation medium for the enumeration of nitrite-oxidizing bacteria. Enumeration of nitrite-oxidizing bacteria in soil samples by the MPN technique often showed relatively high cell number at a low nitrite concentration, when compared to the number of ammonium-oxidizing bacteria. When different *Nitrobacter* species as well as nongrowing cells differing in age were incubated 5 months at 20°C in presence of various nitrite concentrations and pH values, it appeared that the growth of cells taken from an early stationary phase culture of all these species was not affected by high nitrite concentrations or low pH. Growth of 8- and 18-month-old nongrowing cells of *Nitrobacter hamburgensis* was also insensitive to high nitrite concentration (5 mM). The growth of 8- and 18-month old resting cells of *N. vulgaris* was repressed only by a combination of 5 mM nitrite and a low pH. Growth of 8-month-old nongrowing cells of *N. winogradsky* was sensitive to 5 mM irrespective of pH, but growth of 18-month-old cells were inhibited by 5 mM nitrite only at a low pH. The growth of 8- and 18-month-old resting cells of *N. winogradsky* serotype *agilis* was repressed by low pH rather than by high nitrite concentration (Laanbroek and Schotman, 1991). These results emphasize the problems associated with using MPN counts for estimating size of nitrifier populations in natural samples.

A molecular approach based on PCR that was expected to detect and quantify nitrifying bacteria was also tested using specific primers of the genus *Nitrobacter*. In this study, coupled in parallel was a ^{14}C-radiotracing method used to measure potential nitrification; it was shown that *Nitrobacter* represented less than 0.1% of the total bacterial community (Berthe et al., 1999).

In another study, also aimed at counting *Nitrobacter* populations in situ by PCR, two primers from the 16S rDNA gene were used to generate a 397-bp fragment by amplification of *Nitrobacter* species DNA, and it was found that the PCR had a lower detection threshold (10^2 *Nitrobacter* cells per gram of soil) than did the MPN or fluorescent antibody method (Degrange and Bardin, 1995). In contrast, another study (Feray et al., 1999) found the best recovery yield was obtained with the immunofluorescence technique (21.3%), and the poorest detection level was reached with the MPN method (3.1%).

Wastewater

Tertiary wastewater treatment, aimed at removing all nitrogen wastes from the effluents, is costly in terms of the oxygen required for oxidizing ammonia to nitrate. However, as far as the nitrification—denitrification process is concerned, oxidation of nitrite to nitrate is an unnecessary step, as denitrification can just as well proceed from nitrite. Therefore, attempts are being made to devise operational parameters that will inhibit the activity of nitrite-oxidizing bacteria in wastewater treatment plants.

Thus, it was found (Rhee et al., 1997) that accumulation of nitrite occurred during the aerobic phase of a sequencing batch reactor (SBR) operating to remove nitrogen from synthetic wastewater: the activity of autotrophic nitrite oxidizers was reduced in the SBR and the free ammonia was the main inhibitor of nitrite oxidation.

It has been shown experimentally (Garrido et al., 1997) that it is possible to convert all ammonium to approximately 50% nitrate and 50% nitrite in the effluent of a biofilm air-lift suspension reactor, this with oxygen concentrations between 1 and 2 mg/liter. The ammonia- and nitrite-oxidizing bacterial populations occurring in the nitrifying activated sludge of an industrial plant treating sewage with high ammonia concentrations were also studied using in situ hybridization with a set of hierarchical 16S rDNA-targeted probes (Juretschko et al., 1998). Although a *Nitrobacter* strain was isolated, members of the genus *Nitrobacter* were not detectable in the activated sludge by in situ hybridization. A specific 16S rDNA-targeted probe for *Nitrospira* demonstrated that a *Nitrospira*-like bacterium was present in significant numbers (9% of the total bacterial counts).

According to Blackall (2000), even though it is common knowledge that *Nitrosomonas* and *Nitrobacter* are the major ammonia and nitrite oxidizers, today we know that these organisms may not play any role in the transformations for which they have achieved such acclaim. Using the above-mentioned methodologies, *Nitrospira*-like bacteria were found to be the dominant nitrite oxidizers in both enriched and full scale nitrifying systems.

Resistance, Inhibition and Biodegradation

Because inhibition of nitrite oxidation is economically advantageous in wastewater treatment plants, procedures were developed for identification of nitrification inhibitors in wastewater.

These include fractionation of wastewater samples and a nitrification inhibition assay with pure cultures of *Nitrobacter* to identify the inhibitory effect. In such a study, a series of unsaturated fatty acids and two monoterpenes were found to be inhibitory in an industrial wastewater sample (Svenson et al., 2000).

A shorter nitrification-denitrification cycle occurs in the presence of free ammonium. Although the occurrence of this cycle depends on both a high ammonia concentration and high pH, it was found that the pH of the wastewater is the decisive parameter (Surmacz-Gorska et al., 1997). However, a study aimed at identifying nitrification at high pH values in soda lakes and soda soils with pH 9.5–11 led to the isolation of a nitrifier morphologically similar to *Nitrobacter* that formed tiny colonies on mineral nitrite agar at pH 10 (Sorokin, 1998a).

Hwang et al. (2000), in a detailed study of the inverse relation between alkalinity and ammonia with respect to inhibition of nitrite oxidation, showed that when the molar ratio of carbonate alkalinity to ammonia increased from 4.1 to 9.4 (thus increasing the concentration of free ammonia), the ammonium removal rate doubled. At the same time the higher concentration of free ammonia in the medium was a selective inhibitor for *Nitrobacter*, causing an enhanced nitrite build-up in a biofilm reactor.

As for the effect of heavy metals, laboratory evaluations were conducted to study the toxic effects of copper and nickel on a culture of strictly obligatory nitrifiers (*Nitrosomonas* sp. and *Nitrobacter* sp.) in continuous flow stirred tank reactors. *Nitrosomonas* sp. was found to be equally or more sensitive than *Nitrobacter* sp. (Lee et al., 1997).

Attempts were made to develop a process for the simultaneous removal of organic halogens and nitrogen from kraft pulp mill effluents. A nitrifying biofilm reactor removed organic halogens from bleached kraft pulp mill effluents including chlorophenols from synthetic wastewater (Kostyal et al., 1997; Kostyal et al., 1998). In another study, none of several chemicals tested (nonylphenol, naphthalene, 2-methylnaphthalene, di-2-ethylhexylphthalate and toluene) inhibited nitrification when added to soil at various concentrations (Kirchmann et al., 1991). However, in many cases municipal wastewater did contain substances that inhibited nitrification to varying degrees (Jonsson et al., 2000).

Reports conflict on the effect of toluene on indigenous microbial populations. Nitrite oxidation potential (NOP) was reduced after incubation with high toluene concentrations for 45 days (Fuller and Scow, 1996). Trichloroethylene is also inhibitory to the soil indigenous nitrifying population (Fuller and Scow, 1997).

Volatile fatty acids such as formic, acetic, propionic, *n*-butyric, isobutyric, *n*-valeric, isovaleric and *n*-caproic acid as well as trimethylamine are inhibitory to nitrification, but only at high concentrations, suggesting that volatile fatty acids and trimethylamine alone cannot account for the inhibition of the nitrification activity in domestic wastewater (Eilersen et al., 1994).

Nitrifying bacteria were also found to be resistant to monochloramines, and the combination of increased concentrations of oxidized nitrogen with decreased total chlorine in treated water was used as an indicator of bacterial nitrification (Cunliffe, 1991).

The need to set limits on nitrite oxidation in wastewater treatment plants created a demand for assays to determine the degree of inhibition of nitrification. One such assay, developed by Grunditz and Dalhammar, was based on inhibition of pure cultures of *Nitrosomonas* and *Nitrobacter* isolated from sewage sludge (Grunditz and Dalhammar, 2001).

As for the effects of light, nitrifying bacteria (both ammonia and nitrite oxidizers) are capable of recovery from photoinhibition in the dark (see above). Recovery of oxidizing activities is both dose and wavelength dependent (Guerrero and Jones, 1996). The light-absorbing pigment was identified as a porphyrin-like pigment with an absorption maximum at 408 nm, accumulating at the late exponential phase of growth. This photoreceptor was found at higher concentrations in ammonia oxidizers than in nitrite oxidizers (Guerrero and Jones, 1997).

Lithotrophy

An evaluation of field data from historical buildings in Germany, carried on by Mansch and Bock (1998), showed that ammonia and nitrite oxidizers were found in 55 and 62% of the samples, respectively, and that nitrifying bacteria will colonize natural stone within several years of exposure. The highest cell numbers were in some cases found underneath the surface. Nitrifying bacteria showed a preference for calcareous material with a pore radius of 1–10 μm. Cell numbers of nitrifying bacteria did not correlate with the nitrate content of the stone material. Their data strongly suggest that microbial colonization of historical buildings is enhanced by anthropogenic air pollution. A comparison of samples taken between 1990 and 1995 from buildings throughout Germany showed that in eastern Germany significantly more colonization with facultatively methylotrophic bacteria and nitrifying bacteria existed. The same was true for natural stone from an urban exposure site when compared to material from a rural exposure site.

CHAPTER 3.2.18

The Genera *Azoarcus*, *Azovibrio*, *Azospira* and *Azonexus*

BARBARA REINHOLD-HUREK AND THOMAS HUREK

Introduction

The genera *Azoarcus*, *Azospira*, *Azovibrio* and *Azonexus* harbor mostly nitrogen-fixing Betaproteobacteria. In their first taxonomic description, several strains which were later assigned to the genera *Azovibrio*, *Azospira* (Reinhold-Hurek et al., 1993) and *Azonexus* (Hurek et al., 1997b) were included in the genus *Azoarcus* sensu lato. Therefore, they are discussed in one chapter. Except for one strain, all these diazotrophic bacteria had been isolated from a similar source, roots of a pioneer grass in Pakistan or fungal resting stages from the same field; they had many physiological features in common, and they were phylogenetically related. Therefore, three groups of bacteria were included into *Azoarcus* although they were located on the *Azoarcus* rRNA branch at low $T_{m(e)}$ values (Reinhold-Hurek et al., 1993) or showed a low 16S rDNA similarity (Hurek et al., 1997b). Isolation of additional strains, which made possible a better phenotypic description, and sequencing of almost complete 16S rDNA sequences allowed the reassessment of the taxonomic structure of *Azoarcus* sensu lato. The unnamed groups C and D (Reinhold-Hurek et al., 1993) obtained the rank of different genera *Azovibrio* and *Azospira*, respectively (Reinhold-Hurek and Hurek, 2000); *Azoarcus* sensu lato group E (Hurek et al., 1997b) was proposed as *Azonexus* (Hurek et al., 1997b). Strains of these genera deserve special recognition as endophytes of grass roots or as degraders of aromatic compounds.

The Genus *Azoarcus*

Introduction

The genus *Azoarcus* harbors two ecologically different groups of bacteria: 1) soil-borne strains which can degrade aromatic hydrocarbons under denitrifying conditions, and 2) bacteria associated with grass roots epi- or endophytically, which apparently do not survive well in root-free soil. They will be referred to as "soil-borne" or "plant-associated" species, respectively, in this chapter. *Azoarcus* was originally described with two valid species of grass-associated diazotrophs (Reinhold-Hurek et al., 1993). However, a growing number of species of soil-borne strains has been added in recent years.

Phylogeny

Azoarcus spp. are members of the Betaproteobacteria in the Rhodocyclales according to phylogenetic analysis of almost complete 16S rRNA gene sequences. They are phylogenetically most closely related to *Thauera* with which they form the *Azoarcus/Thauera* branch (Fig. 1). *Azoarcus* species are located on two different clades, which in part reflects their physiology and ecology: the soil-borne species *A. tolulyticus*, *A. toluclasticus*, *A. toluvorans*, *A. evansii*, *A. buckelii* and *A. anaerobius* and the plant-associated species *A. indigens*, *A. communis* and *Azoarcus* sp. strain BH72. The analysis of phylogenetic relationships within the *Azoarcus*/*Thauera* 16S rDNA cluster is rendered difficult because the branching pattern between *Thauera*, the soil-borne and the plant-associated *Azoarcus* species is unstable when tested with different tree-building methods. This was also observed previously (Hurek et al., 1997b; Reinhold-Hurek and Hurek, 2000). Also in other taxa closely related to each other, like *Rhizobium* and related genera, the resolution of phylogenetic analysis is sometimes limited. Nevertheless, all named species in the genus *Thauera* cluster in one clade with highly significant support levels (Fig. 1), allowing a reliable assignment to this genus. Also most soil-borne species or strains of *Azoarcus* fall into one clade with significant support levels, and none of the species containing plant-associated strains are located on this branch. The 16S rDNA phylogenetic distances within these three clades are similar. Within the genus *Azoarcus*, they are up to 6%, while *Thauera* is 6–7% distant. Thus *Azoarcus* spp. represents a rather heterogeneous group. Moreover, since the phylogenetic distances within the three clades in the *Azoarcus*/*Thauera* group are similar, both subgroups of

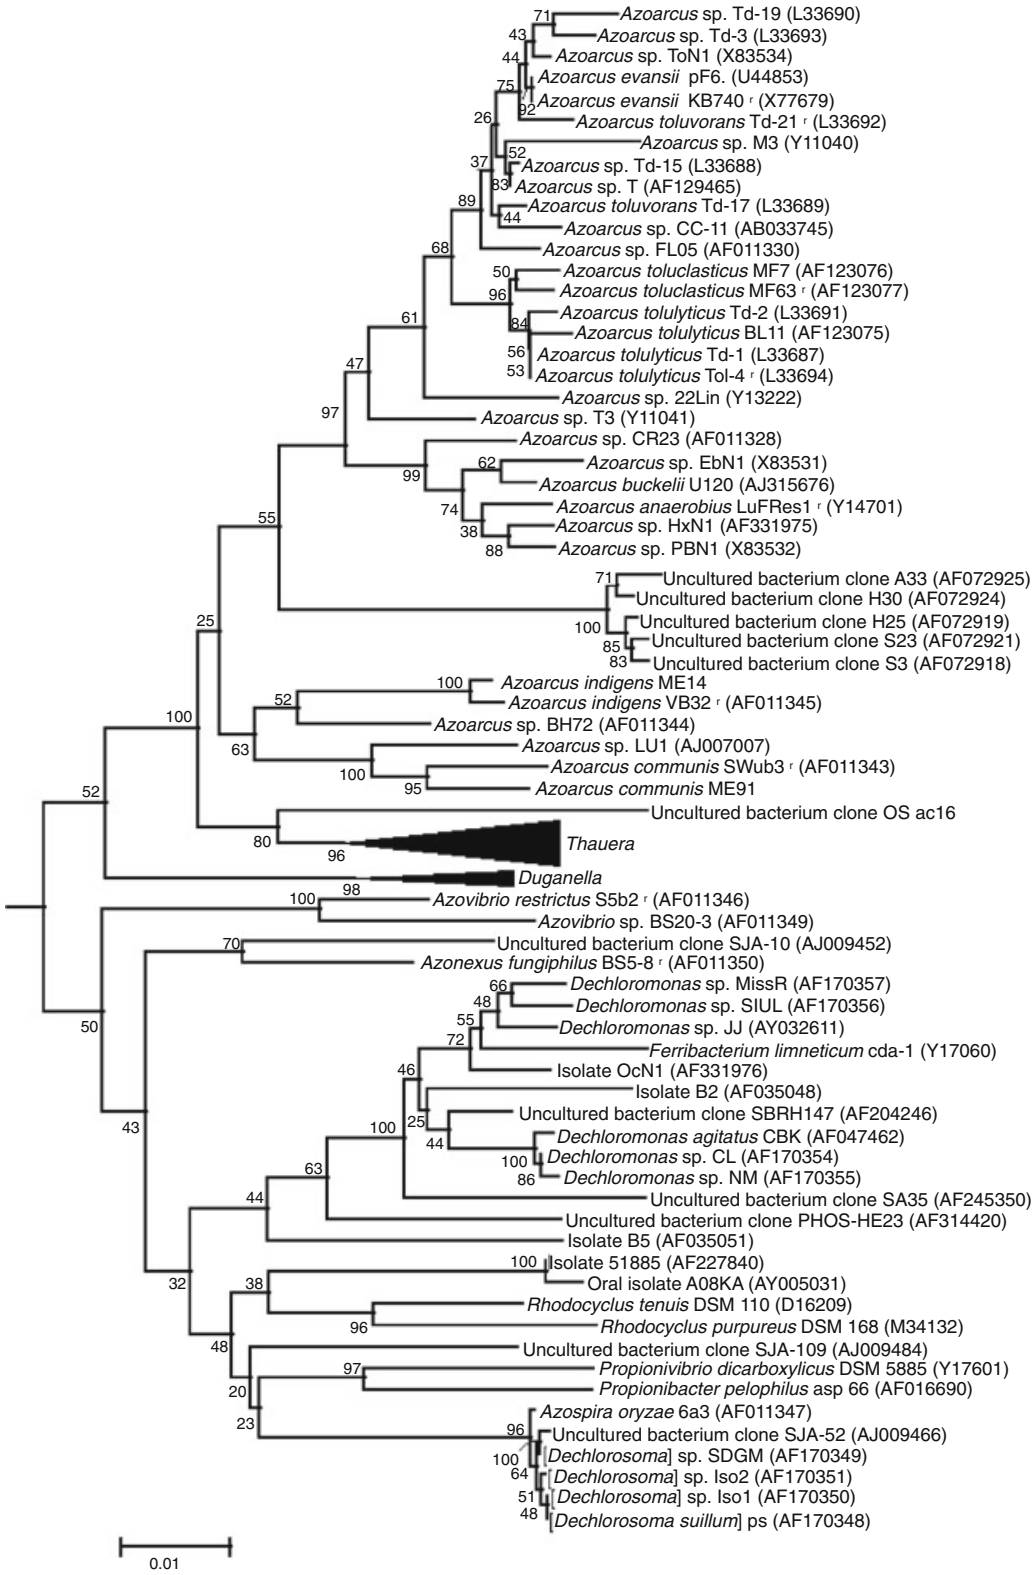

Fig. 1. Phylogenetic analysis of 16S rDNA sequences (1358 positions) of a subgroup of the Betaproteobacteria. Subtree of the *Rhodocyclus*/*Thauera*/*Azoarcus* group derived from an analysis of 159 sequences. Tree inference was carried out using the neighbor-joining algorithm and a Jukes-Cantor correction with 125 bootstrap repetitions. Sequence accession numbers are given in parentheses.

Azoarcus might also deserve the rank of different genera in the future. However, this will require a rigid polyphasic taxonomic analysis.

On the basis of 16S rDNA sequence analyses, all of the validly described species of *Azoarcus* are well resolved except for the two strains of *A. toluvorans*, which are interdispersed with several strains of uncertain affiliation (Fig. 1). Former members of *A. tolulyticus*, Td-3 and Td-19, have recently been removed from this species owing to low DNA-DNA similarity (below 40%), which is also reflected in our phylogenetic analysis (Fig. 1).

Interestingly, also a deeply-branching clade of as yet uncultured bacteria detected in nitrifying-denitrifying activated sludge of an industrial wastewater treatment plant (Juretschko et al., 2002) is localized within the *Azoarcus* cluster (Fig. 1).

Taxonomy

The definition of the genus *Azoarcus* is quite complex. It includes strains with a variety of physiological and ecological properties, which place them into at least two groups. In addition to their ecology, the species containing plant-associated strains differ from the soil-borne species in some nutritional features, e.g., in their inability to use carbohydrates as sole carbon source or, under conditions of denitrification, a wide range of aromatic compounds. The genus *Azoarcus* consists of the following eight validly described species, mostly based on polyphasic taxonomic approaches including DNA-DNA hybridization, protein profiles, fatty acid analysis, and nutritional profiles: *A. indigens* (type species) and *A. communis* (Reinhold-Hurek et al., 1993), *A. tolulyticus* (Zhou et al., 1995), *A. toluclasticus* and *A. toluvorans* (Song et al., 1999), *A. evansii* (Anders et al., 1995), *A. anaerobius* (Springer et al., 1998) and *A. buckelii* (Mechichi et al., 2002). One isolate (BH72) is different from these at the species level according to DNA-DNA similarity studies (≤25% DNA binding); however, a species name was not given because it is only a singular strain (Reinhold-Hurek et al., 1993). Numerous additional soil-borne strains are localized in the *Azoarcus* clade according to 16S rDNA sequence analysis (examples given in Fig. 1). Most have been isolated under conditions of denitrification with aromatic hydrocarbons as a C-source, but the lack of nutritional/physiological data and DNA-DNA similarity values does not yet allow a species assignment.

The phylogenetic distances within the three clades in the *Azoarcus*/*Thauera* group are similar (Reinhold-Hurek and Hurek, 2000), and the soil-borne and plant-associated species show considerable phenotypic differences (Reinhold-Hurek and Hurek, 2000; see also the section on Identification in this Chapter). Therefore, both subgroups of *Azoarcus* might deserve the rank of different genera in future. However, this will require a rigid polyphasic taxonomic analysis. As can be seen from the descriptive table (Table 3), many features have not been tested for all species or strains. There appears to be a bias in testing, e.g., nitrogen fixation and aerobic nutritional profiles are not excessively tested in soil-borne strains, whereas nutritional profiles under conditions of denitrification are missing for plant-associated species. These studies should also include the numerous soil-borne isolates not yet assigned to any species. As some strains are deeply branching in the phylogenetic analysis (e.g., 22Lin, T3 and M3; Fig. 1), the description of new species might be expected.

Habitat

Azoarcus spp. occur in terrestrial ecosystems; however, both groups of *Azoarcus* spp. strongly differ in their habitats and ecology. Members of *A. indigens*, *A. communis* and *Azoarcus* sp. BH72 occur inside roots or on the root surface of Gramineae and have never been isolated from root-free soil so far (Reinhold-Hurek and Hurek, 1998b), except for members of *A. communis* originating not from plants but from French refinery oily sludge (S2; Laguerre et al., 1987; Reinhold-Hurek et al., 1993) or from a compost biofilter in Canada (Lu1; Juteau et al., 1999). In contrast, all isolates localized in the clade of *A. tolulyticus*, *A. toluvorans*, *A. toluclasticus*, *A. evansii*, *A. buckelii* or *A. anaerobius* do not originate from living plants but mostly from soil and sediments. Therefore, their habitats will be treated separately.

The plant-associated strains were originally isolated from Kallar grass (*Leptochloa fusca* [L.] Kunth), a flood-tolerant salt marsh grass grown as a pioneer plant on salt-affected, flooded, low-fertility soils in the Punjab of Pakistan since the 1970s (Reinhold et al., 1986; Reinhold-Hurek et al., 1993). These nitrogen-fixing bacteria were found in high numbers in surface-sterilized roots or culms and rarely on the root surface (*A. communis*). Only much later, the host range was found to be extended to rice (*Oryza sativa*) from Nepal (Engelhard et al., 2000) or to resting stages (sclerotia) of a plant-associated basidiomycete found in rice field soil from Pakistan (Hurek et al., 1997b).

Soil-borne species of *Azoarcus* are very widespread but not plant-associated. Strains belonging to the validly described species have been isolated from noncontaminated soils (Song et al., 1999) or contaminated soils, either with unknown contaminations in industrial areas

(Song et al., 1999) or with petroleum contaminations (Fries et al., 1994; Zhou et al., 1995). Many strains were also cultured from sediments of creeks (uncontaminated or contaminated; Anders et al., 1995), aquifers (Fries et al., 1994; Fries et al., 1997; Zhou et al., 1995), or even from activated sewage sludge (Springer et al., 1998). Soil-borne *Azoarcus* spp. are also widespread with respect to their geographical distribution: they have been found for example in North America (United States, Canada and Puerto Rico), South America (Brazil), or Europe (Germany and Switzerland).

Isolation

Plant-associated and soil-borne members of *Azoarcus* spp. will be treated separately. Plant-associated strains are best enriched on media free of combined nitrogen. Washed or surface-sterilized roots are macerated aseptically in wash medium (enrichment medium free of a carbon source).

To avoid overgrowth by faster growing diazotrophs, inoculate enrichment cultures with serial dilutions of this material. N-free semisolid synthetic malate medium (SM-N) is used for enrichment, composed of (per liter of distilled water): $MgSO_4 \cdot 2H_2O$, 0.2 g; NaCl, 0.1 g; $CaCl_2$, 0.02 g; $MnSO_4 \cdot H_2O$, 0.01 g; $Na_2MoO_4 \cdot 2H_2O$, 0.002 g; Fe(III)-EDTA, 0.066 g; KH_2PO_4, 0.6 g, and K_2HPO_4, 0.4 g, adjusted to pH 6.8; DL-malic acid, 5 g, and KOH, 4.5 g adjusted to pH 6.8; agar, 2 g; and vitamin solution, 1 ml. The vitamin solution contains (mg per liter of distilled water) myo-inositol, 10,000; niacinamide, 100; pyridoxine HCl, 100; thiamine HCl, 100; calcium pantothenate, 50; folic acid, 20; choline chloride, 50; riboflavin, 10; ascorbic acid, 100; *p*-aminobenzoic acid, 1; vitamin A, 0.5; vitamin D_3, 0.5; vitamin B_{12}, 0.5; and D-biotin, 0.5. Add phosphate buffer and vitamin solution after autoclaving. Inoculate medium solidified in screw-cap tubes with 10 µl of macerate or root pieces below the medium surface. Incubate tubes without shaking at 30°C or 37°C, and check for development of a subsurface pellicle. Take samples for streaking before the pellicle has moved to the medium surface and become very dense. Isolate single colonies on SM-medium agar supplemented with 20 mg of yeast extract per liter. Use acetylene reduction method to analyze enrichment cultures or isolates for nitrogenase activity in semisolid medium. Check purity and colony color on complex medium, VM ethanol (which is based on SM medium but supplemented [per liter] with "Lab Lemco" powder [Oxoid] or Bacto Peptone [Difco], 3 g; yeast extract, 1 g; NaCl, 1 g; NH_4Cl, 0.5 g; and agar, 15 g). Alternatively, for salt-affected habitats, use SSM medium which is adapted to high salt concentrations of saline-sodic soil (Reinhold et al., 1986) instead of SM medium for enrichment and isolation.

For soil-borne strains, enrichment is routinely done under strictly anaerobic conditions, with nitrate as terminal electron acceptor. A variety of aromatic carbon sources have been used, depending on the species or strain under study. Preparation of media and cultivation of bacteria have to be carried out under strictly anoxic conditions.

Use a typical medium (for *A. evansii*), which consists of (per liter of distilled water): KH_2PO_4, 0.816 g; K_2HPO_4, 5.920 g; NH_4Cl, 0.530 g; $MgSO_4 \cdot 7H_2O$, 0.200 g; KNO_3, 0.5 g; and $CaCl_2 \cdot 2H_2O$, 0.025 g; dissolve phosphate and other ingredients separately from each other, adjust both to pH 7.8 for *A. evansii* or neutral pH for other strains, and combine both autoclaved solutions after cooling. Add 10 ml of sterile trace elements SL-10 and 5 ml of vitamin solution. SL-1 contains (per liter of distilled water): HCl (25%; 7.7 M), 10 ml; $FeCl_2 \cdot 4H_2O$, 1.5 g; $ZnCl_2$, 70 mg; $MnCl_2 \cdot 4H_2O$, 100 mg; H_3BO_3, 6 mg; $CoCl_2 \cdot 6H_2O$, 190 mg; $CuCl_2 \cdot 2H_2O$, 2 mg; $NiCl_2 \cdot 6H_2O$, 24 mg; and $Na_2MoO_4 \cdot 2H_2O$, 36 mg. First dissolve $FeCl_2$ in HCl, then dilute in water, add and dissolve the other salts. The vitamin solution contains (mg per liter of distilled water): vitamin B_{12}, 50 mg; pantothenic acid, 50 mg; riboflavin, 50 mg; pyridoxamine-HCl, 10 mg; biotin, 20 mg; folic acid, 20 mg; nicotinic acid, 25 mg; nicotinamide, 25 mg; α-lipoic acid, 50 mg; *p*-aminobenzoic acid, 50 mg; and thiamine-HCl $\cdot 2H_2O$, 50 mg. Add potentially toxic carbon sources at low concentrations (toluene, 5 ppm; phenol, 1 mM; and Na-benzoate, 5 mM) and spike cultures again with the carbon source after its degradation. Use ascorbic acid (4 mM) to reduce the medium. Carry out enrichment in anoxically sealed serum bottles. When using rich sediments as an inoculum, deplete when necessary from readily oxidizable carbon sources by repeated incubation in medium free of carbon sources (Fries et al., 1994). Plate the enriched samples on agar media such as M-R2A medium (Fries et al., 1994) or on agar used for dilution series (Widdel and Bak, 1992). M-R2A medium contains (per liter of distilled water): yeast extract, 0.5 g; peptone, 0.5 g; casamino acids, 0.5 g; glucose, 0.5 g; soluble starch, 0.5 g; sodium pyruvate, 0.3 g; K_2HPO_4, 0.4 g; KH_2PO_4, 0.25 g; KNO_3, 0.505 g; $CaCl_2 \cdot 2H_2O$, 0.015 g; $MgCl_2 \cdot 2H_2O$, 0.02 g; $FeSO_4 \cdot 7H_2O$, 0.007 g; Na_2SO_4, 0.005 g; NH_4Cl, 0.8 g; $MnCl_2 \cdot 4H_2O$, 5 mg; H_3BO_3, 0.5 mg; $ZnCl_2$, 0.5 mg; $CoCl_2 \cdot 6H_2O$, 0.5 mg; $NiSO_4 \cdot 6H_2O$, 0.5 mg; $CuCl_2 \cdot 2H_2O$, 0.3 mg; $NaMoO_4 \cdot 2H_2O$, 0.01 mg; and agar, 15 g. Adjust the pH to 7.0 before autoclaving.

For cultivation on poorly water-soluble compounds such as alkylbenzenes, special procedures are required (Rabus and Widdel, 1995).

Identification

Since members of the genus *Azoarcus* are quite heterogeneous with respect to ecology and physiology, the description of the genus is complex. The phenotypic characteristics of the genus *Azoarcus* are as follows: Cells are straight to slightly curved rods. Cell pairs often appear slightly S-shaped, with the exception of *A. buckelii* cells, which occur as cocci. Cell width is 0.4–1.5 μm and length 1.1–4.0 μm. In many species, some elongated cells (8–12 μm) occur in late-log or stationary-phase cultures on medium containing malic acid and molecular nitrogen (N_2) or ammonia as nitrogen source. Cells accumulate polyhydroxybutyrate granules and are Gram negative. Cells are highly motile by means of one, rarely two polar flagella. Many species fix nitrogen and then require microaerobic conditions for growth on N_2. On semisolid nitrogen-free media, microaerophilic growth can be observed as veil-like pellicles developing several mm below the surface and moving to the medium surface during growth. Colony morphology differs in plant-associated and soil-borne species. *Azoarcus communis*, *A. indigens* and *Azoarcus* sp. BH72 grow well on complex media such as trypticase soy agar (TSA) or VM medium containing beef extract or peptone, yeast extract, and ethanol (colony diameter 2–4 mm after 4 d); on the latter medium, they produce a yellowish, nondiffusible pigment. In contrast, the soil-borne species *A. tolulyticus*, *A. evansii*, *A. buckelii*, *A. toluvorans* and *A. toluclasticus* grow poorly or not at all on complex media, and some may show different pigmentation. *Azoarcus anaerobius* is an exception since it is strictly anaerobic and therefore does not develop colonies on aerobically incubated agar plates. Optimum temperature for growth is 28–40°C, and no growth occurs at 45°C (Fig. 2). The soil-borne species are chemoorganoheterotrophic. Bacteria have a strictly respiratory metabolism with O_2 as the terminal electron acceptor, except one species (*A. anaerobius* which is strictly anaerobic). Alternatively, under anaerobic conditions, nitrate can be used for dissimilatory nitrate reduction. Nitrate can be also assimilated. Bacteria are oxidase positive. They grow well on salts of organic acids (such as L-malate, succinate, fumarate and DL-lactate), ethanol and L-glutamate, but not on mono- or disaccharides except for species that are not plant-associated. These soil-borne species use few carbohydrates and a variety of aromatic substrates as sole carbon sources under denitrifying conditions. Growth factor requirement varies: some strains depend on *p*-aminobenzoic acid or on cobalamin. All investigated species have 16:1, and all except one *cis*-9 16:1 and 18:1 as major cellular fatty acids. The mol% G+C of the DNA is 62–68 (Tm). The type species is *Azoarcus indigens*.

Since the genera *Azovibrio*, *Azospira* and *Azonexus* were formerly included in *Azoarcus* sensu lato (Reinhold-Hurek and Hurek, 2000) and are physiologically very similar, some characteristics distinguishing these genera from each other are given in Table 1. Genera harboring plant-associated diazotrophs and *Thauera* were also included in Table 1. The genus *Thauera* (Macy et al., 1993; Anders et al., 1995), which is phylogenetically closely related, is physiologically similar to soil-borne species and thus difficult to distinguish by classical tests.

The validly described species of *Azoarcus* are *A. indigens* (type species) and *A. communis* (Reinhold-Hurek et al., 1993), *A. tolulyticus* (Zhou et al., 1995), *A. toluclasticus* and *A. toluvorans* (Song et al., 1999), *A. evansii* (Anders et al., 1995), *A. anaerobius* (Springer et al., 1998) and *A. buckelii* (Mechichi et al., 2002). These species can be distinguished from each other

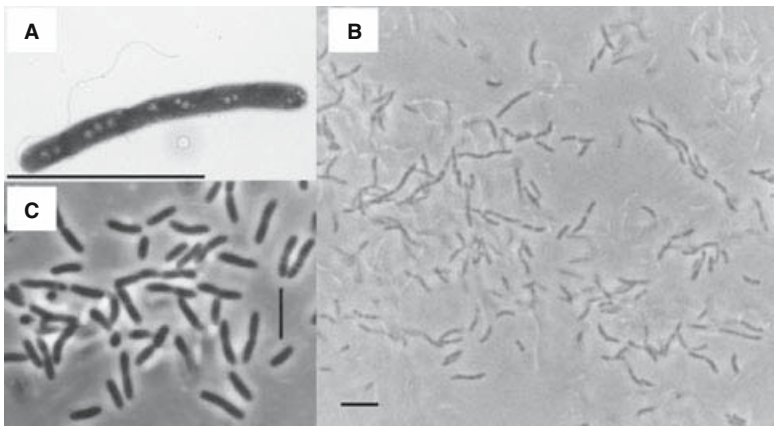

Fig. 2. Microcopic images of *Azoarcus* spp. Transmission electron (A) and phase contrast (B, C) images. A) *Azoarcus* sp. strain BH72 cultured in liquid VM medium for 24 h. [l]ND for *A. buckelii*.

by phenotypic characteristics given in Table 2. Strain BH72 is included in Table 2 and may represent a species of its own according to DNA-DNA-similarity studies (Reinhold-Hurek et al., 1993). It has to be noted, however, that in some cases characteristics have been tested for one strain only (see also Table 3). A more complete list of the characteristics of these species is given in Table 3. Further comments on the species are given in the text below.

Azoarcus indigens is the type species and can be differentiated from the others by its requirement for *p*-aminobenzoic acid, growth on itaconate, and a combination of characteristics given in Table 2. Cells are thin (0.5–0.7 μm wide) and curved, and cell pairs look slightly S-shaped. Colonies are very compact and difficult to disperse; growth in liquid media is clumpy; aggregation is very strong on peptone media. Optimum temperature for growth is 40°C. The major fatty acids are 3-OH-10:0, 12:0, *cis*-9 16:1, *cyclo*-17:0, and 18:1. *Azoarcus indigens* was isolated from roots and stem bases of *Leptochloa fusca* (L.) Kunth from the Punjab of Pakistan (Reinhold-Hurek et al., 1993), and black sclerotia of an *Ustilago*-related basidiomycete from rice soil in the Punjab of Pakistan (Hurek et al., 1997b) and from rice roots (*Oryza sativa*) from Nepal (Engelhard et al., 2000). The type strain is strain VB32 (=LMG 9092), which has a G+C content of 62.4 mol% (T_m). Accession number of the 16S rDNA sequence is AF011345 (www.ncbi.nlm.nih.gov/entrez/query.fcgi?db=nucleotide=search=AF011345).

Azoarcus anaerobius can be distinguished from others by its strictly anaerobic life style with nitrate as the only electron acceptor. Nitrate is quantitatively reduced to N_2 gas, nitrite accumulates intermediately, and nitrous oxide (N_2O) is not detected. Additional differences are given in Table 2. Optimum growth temperature is 28°C. Enhanced salt concentration impairs growth. Cells are superoxide-dismutase-positive. Sulfate, thiosulfate, sulfite, sulfur, trimethyl-amine *N*-oxide, dimethyl sulfoxide (DMSO), $Fe(OH)_3$, $K_3[Fe(CN)_6]$, or fumarate are not reduced, and oxygen is not reduced, not even at low pressures. Characteristics in addition to those given in Table 3 are: Sole carbon sources for growth are propanol, valerate, pyruvate, cyclohexane carboxylate, phenol, resorcinol, *p*-cresol; no growth with L-malate, formate, 5-oxocaproate, pimelate, catechol, hydroquinone, 2-hydroxybenzoate, *o*-cresol, and *m*-cresol. No autotrophic growth with hydrogen or thiosulfate. The pH range is 6.5–8.2 and optimum pH 7.2. Cells were isolated from sewage sludge. The species consists of only one strain, which is the type strain LuFRes1 (= DSM 12081). It has a G+C content of 66.5 ± 0.5 mol% (T_m). Accession number of the 16S rDNA sequence is Y14701 (www.ncbi.nlm.nih.gov/entrez/query.fcgi?db=nucleotide=search=Y14701).

Azoarcus buckelii can be distinguished from others by its cell shape and a combination of characteristics given in Table 2. Cells are coccoid of irregular size (1.5 ± 0.5 μm). Optimum temperature for growth is 28°C with a range from 4 to 40°C. It requires vitamin B_{12} for growth. Also nitrite can be used as terminal electron acceptor. Under oxic conditions, methanol and pyruvate are utilized in addition to carbon sources listed in Table 3. No growth occurs on formate, 2-aminobenzoate, catechol, pimelate, hexadecane, *o*-cresol, *p*-cresol, cyclohexane carboxylate, and phenol. Under denitrifying conditions, they utilize benzoate, 3-hydroxybenzoate, 4-hydroxybenzoate, 2-aminobenzoate, *o*-phtalate, protocatechuate, phenol, *o*-cresol, *p*-cresol, cyclohexane carboxylate, 4-hydroxyphenylacetate, heptanoate, 2-hydroxybenzaldehyde, 3-hydroxybenzaldehyde, 4-hydroxybenzaldehyde, 2-hydroxybenzoate, 3-hydroxybenzoate, 4-hydroxybenzoate, 2,4-dimethylphenol, 4-hydroxy-3-methylbenzoate, or for slow growth, 3-methylbenzoate, 2-fluorobenzoate, gentisate, phenylacetate, phenylpropionate, L-tyrosine, L-phenylalanine, and indole 3-acetate; no growth occurs on *m*-cresol, 3-aminobenzoate, 4-aminobenzoate, 2-methylbenzoate, 4-methylbenzoate, catechol, resorcinol, hydrochinone, cinnamate, *p*-anisate, L-tryptophan, indole, ethylbenzene, benzene, 3-chlorobenzoate, adipate, pimelate, D-glucose, D-fructose, D-ribose, lactose, cyclohexanol, cyclohexanone, 1,3-cyclohexanedione, D,L-mandelate, D,L-4-hydroxymandelate, and 2-hydroxybenzyl alcohol. The species consists of only one strain, which is the type strain U120 (= DSMZ 14744). It has a G+C content of 66 mol%. Accession number of the 16S rDNA sequence is AJ315676 (www.ncbi.nlm.nih.gov/entrez/query.fcgi?db=nucleotide=search=AJ315676).

Azoarcus communis can be distinguished from others by its cell width (0.8–1.0 μm) in combination with growth on D-mandelate, by growth on citrate, and a combination of characteristics given in Table 2. Cells are only slightly curved and plump. Optimum temperature for growth is 37°C. Some strains still grow well in 2% NaCl. The major fatty acids are 3-OH-10:0, 14:0, *cis*-9 16:1, 16:0, and 18:1. This species was isolated from roots of *L. fusca* (L.) Kunth from the Punjab of Pakistan ($SWub3^T$; Reinhold-Hurek et al., 1993; Engelhard et al., 2000) and from refinery oily sludge in France (Laguerre et al., 1987). The species affiliation of strain LU1 isolated from a compost biofilter in Canada (Juteau et al., 1999)

Symbols and abbreviations: +, positive for all strains; –, negative for all strains; ±, weak reaction for all strains; d, 11–89% of strains are positive; r, rarely; v, variable result; and ND, not determined.

[a]All strains have the following features: cells are straight to curved rods except *A. buckelii*; oxidase positive; no growth in the presence of 5% NaCl and no growth-rate increase when NaCl is added to medium (ND for *A. toluvorans*, *A. toluclasticus*, *A. anaerobius* and *A. buckelii*); denitrification (ND for *Azonexus* sp.); no spore formation; no starch hydrolysis (ND for *A. evansii*, *A. buckelii* and *A. anaerobius*).

[b]Marked characters were determined for *A. tolulyticus* strain Td-1 or *A. evansii* strain KB740^T (Reinhold-Hurek and Hurek, 2000).

[c]Growth on VM ethanol agar (VM) or Congo red agar (CR) at 37°C for 4 d.

[d]Not tested for strain pF6.

[e]All strains grow on DL-lactate, succinate, acetate, L-glutamate, butyrate (ND for *A. buckelii*), ethanol (ND for *A. toluvorans* and *A. toluclasticus*; no substrate but L-malate tested for *A. evansii* pF6); no growth on (ND for *A. buckelii*) D(+)-mannose, maltitol, *N*-acetyl-D-glucosamine, D-gluconate, and caproate; no growth on[b] (ND for *A. toluclasticus*, *A. toluvorans*, *A. anaerobius* and *A. buckelii*) D(+)-trehalose, L(+)-sorbose, ∀-D(+)-melibiose, D(+)-raffinose, lactulose, 1-0-methyl-β-galactopyranoside, 1-0-methyl-∀-galactopyranoside, D(+) cellobiose, β-gentiobiose, 1-0-methyl-β-D-glucopyranoside, ∀-L-rhamnose, ∀-L-fucose, D(+)-arabitol, L(–)-arabitol, xylitol, dulcitol, D-tagatose, *myo*-inositol, D-sorbitol, adonitol, hydroxyquinoline-β-glucuronide, D-lyxose, erythritol, 1-0-methyl-∀-D-glucopyranoside, 3-0-methyl-glucopyranose, D-saccharate, mucate, D-glucuronate, D-galacturonate, 2-keto-D-gluconate, 5-keto-D-gluconate, 3-phenylpropionate, caprylate, 4-aminobutyrate, DL-∀-amino-*n*-valerate, trigonelline, putrescine, ethanolamine, and D-glucosamine.

[f]Under denitrifying conditions.

[g]Tested with O_2 as terminal electron acceptor.

[h]Only glycerol tested.

From Reinhold-Hurek et al. (1993), Anders et al. (1995), Hurek and Reinhold-Hurek (1995a), Zhou et al. (1995), Hurek et al. (1997), Rhee et al. (1997), Springer et al. (1998), Song et al. (1999), Engelhard et al. (2000), Reinhold-Hurek and Hurek (2000), and Mechichi et al. (2002).

is currently not clear. The type strain is strain SWub3 (= LMG 9095), which has a G+C content of 62.4 mol% (T_m). Accession number of the 16S rDNA sequence is AF011343 (www.ncbi.nlm.nih.gov/entrez/query.fcgi?db=nucleotide=search=AF011343).

Azoarcus evansii can be distinguished from other species by a combination of characters given in Table 2. Cells are rods with rounded ends and motile by means of a subpolarly inserted flagellum. Yeast extract (0.1% [w/v]) inhibits growth. Optimum growth temperature is 35–37°C, and optimum pH is 7.8. During denitrifying growth with aromatic compounds, nitrite is an intermediate and is reduced mainly to N_2O (strain KB740^T). Characteristics in addition to those listed in Table 3 are: Under anaerobic conditions, strain KB740^T uses benzoate, phenylacetate, phenylglyoxylate, 3- and 4-hydroxybenzoate, 2-aminobenzoate, 4-hydroxyphenylacetate, L-phenylalanine, *p*-cresol, 2-fluorobenzoate, benzaldehyde, benzyl alcohol, indolylacetate, *o*-phtalate, adipate, pimelate, cyclohexane carboxylate, succinate, fumarate, L-malate, acetate, acetone, D-fructose, D-maltose, and slow growth occurs on glutarate, D-glucose, but not on toluene, phenol, 2-hydroxybenzoate, protocatechuate, *o*- and *m*-cresol, indole, ethanol, D-ribose, or D-lactose. Pyridine is used by strain pF6 under aerobic and anaerobic conditions. The major cellular fatty acids are *cis*-9 16:1, 16:0, 12:0, 3-OH 10:0, and *cis*-9, 11 18:1. The major quinone is ubiquinone 8. The species description is based on one strain isolated from creek sediment in the United States (Braun and Gibson, 1984); however, a second strain, pF6, sharing 100% 16S rDNA sequence identity was isolated on pyridine from industrial wastewater in Korea (Rhee et al., 1997). The type strain is strain KB740 (= DSM6898), which has a G+C content of 67.5 mol%. Accession number of the 16S rDNA sequence is X77679 (www.ncbi.nlm.nih.gov/entrez/query.fcgi?db=nucleotide=search=X77679).

Azoarcus toluclasticus can be differentiated from the other species by the lack of catalase activity despite aerobic growth and by a combination of characters given in Table 2. Cells are short motile rods. Optimum temperature for growth is 30°C. Under denitrifying conditions, they can grow on acetate, benzoate, pyruvate, succinate, D-xylose, L-arabinose, D-ribose, D-galactose, sucrose, lactose, maltose, adipate, lactate, mannitol, L-aspartate, L-proline or L-arginine. All strains except strain MF23 can use toluene as a growth substrate and strains MF58 and MF63^T can also grow on phenol under denitrifying conditions. The strains grow on brain-heart infusion, nutrient and trypticase soy agar (TSA), except for strain MF63^T, which does not grow on nutrient agar. The predominant cellular fatty acids are 16:0 and 16:1ω7*c*. DNA-DNA hybridizations show intermediate similarities (47–55%) among genomovar I (strains MF7 and MF23) and genomovar II (strains MF58, MF63^T and MF441). They were isolated from aquifer sediments in the United States. The type strain is strain MF63 (= ATCC 700605), which has a G+C content of 67.3 mol% (HPLC). Accession number of the 16S rDNA sequence is AF123077 (www.ncbi.nlm.nih.gov/entrez/query.fcgi?db=nucleotide=search=AF123077).

Azoarcus tolulyticus can be differentiated from the other species by a combination of characters given in Table 2. Cells are short motile rods, which are slightly elongated (to 2.8 μm) when grown on M-R2A agar. Optimum temperature for growth is 30°C, and growth still occurs at 37°C. Under denitrifying conditions they can utilize acetate, adipate, L-arginine, L-arabinose, L-aspartate, benzoate, fumarate, D-galactose, D-glucose, lactate, lactose, maltose, mannitol, L-proline, pyruvate, D-ribose, succinate, sucrose, toluene, D-xylose, or 4-hydroxybenzoate. The strains grow on brain-heart infusion agar, but not or only poorly on nutrient and TSA. The predominant cellular fatty acids are 16:0 and 16:1ω7*c*. Strains Td-19 and Td-3 (Zhou et al., 1995) have been removed from the species owing to low DNA-DNA similarity values (Song et al., 1999). The source of strains is aquifer sediments and petroleum-contaminated soils in the United States (Fries et al., 1994; Fries et al., 1997; Chee-Sanford et al., 1996). The type strain is strain Tol-4 (= ATCC 51758), which has a G+C content of 66.9 mol% (HPLC). Accession number of the 16S rDNA sequence is L33694 (www.ncbi.nlm.nih.gov/entrez/query.fcgi?db=nucleotide=search=L33694).

Azoarcus toluvorans can be differentiated from the other species by a combination of characters given in Table 2. Optimum temperature for growth is 30°C. Grow on brain-heart infusion, nutrient and TSA. Under denitrifying conditions, they can grow on acetate, benzoate, butyrate, fumarate, phenylacetate, pyruvate, succinate, toluene, D-xylose, L-arabinose, D-ribose, D-galactose, sucrose, maltose, adipate, lactate, mannitol, L-aspartate, L-proline, L-phenylalanine, L-arginine, 4-hydroxybenzoate or phenol, and under aerobic conditions, on benzene or ethylbenzene. They were isolated from soil from an industrial area in Brazil (Td17) or noncontaminated organic soil in the United States (Td21^T; Fries et al., 1994). The type strain is strain Td21 (= ATCC 700604), which has a G+C content of 67.8 mol% (HPLC). Accession number of the 16S rDNA sequence is L33692 (www.ncbi.nlm.nih.gov/entrez/query.fcgi?db=nucleotide=search=L33692).

Azoarcus sp. strain BH72 can be differentiated from the other species by its lack of growth on L-phenylalanine and a combination of characteristics given in Table 2. Cells are long, thin (0.6–0.8 μm wide) and slightly curved, elongated (8–12 μm) cells occurring in late-log or stationary phase culture on N-free or ammonium-supplemented SM-medium. Optimum temperature for growth is 40°C. The major fatty acids are16:0, *cis*-9 16:1, 18:1, 18:1, and 14:0. It was isolated from the root interior of *Leptochloa fusca* (L.) Kunth from the Punjab of Pakistan (Reinhold et al., 1986). The G+C content is 67.6 mol% (T_m). Accession number of the 16S rDNA sequence is AF011344 (www.ncbi.nlm.nih.gov/entrez/query.fcgi?db=nucleotide=search=AF011344).

Preservation

Although organic acids are typical carbon sources for many strains, medium containing organic acids becomes alkaline in the stationary phase. Thus, subculturing on organic acids should be avoided and VM ethanol medium should be used instead. Soil-borne strains may also be subcultured on M-R2A medium. Preservation by lyophilization is possible. Long-term preservation is achieved by storage in liquid nitrogen with 5% DMSO as a cryoprotectant.

Physiology

The optimum growth temperature is 30°C or 37–40°C, which is lower for *A. anaerobius* (28°C). Optimum pH is neutral, and the bacteria are not halophilic. All *Azoarcus* species have a strictly respiratory type of metabolism, and no fermentative abilities have been observed. All species except one, *A. anaerobius*, use oxygen as the terminal electron acceptor. In the original description of *Azoarcus* spp., standard procedures had failed to reveal the capacity for denitrification (Reinhold-Hurek et al., 1993). In a closer examination, the capacity to use nitrate as the terminal electron acceptor was demonstrated for these plant-associated strains (Hurek and Reinhold-Hurek, 1995a), a feature which they share with all other species (Anders et al., 1995; Zhou et al., 1995; Springer et al., 1998; Song et al., 1999). Most strains belonging to *A. tolulyticus*, *A. evansii*, *A. toluclasticus*, *A. toluvorans* and *A. anaerobius* were enriched or isolated anaerobically on nitrate, whereas the plant-associated species were enriched under conditions of nitrogen fixation.

In the original description of the genus *Azoarcus*, the capacity to fix nitrogen is listed as a genus character (Reinhold-Hurek et al., 1993). Nitrogen fixation (Fries et al., 1994; Zhou et al., 1995) or the occurrence of a nitrogenase gene *nifH* (Hurek et al., 1997a) has also been demonstrated for *A. tolulyticus*. However, owing to the addition of new species, this cannot be generalized for *Azoarcus* anymore. Nitrogen fixation was not detected in *A. anaerobius* (Springer et al., 1998) or *A. buckelii* (Mechichi et al., 2002). In the absence of physiological data (Anders et al., 1995), *A. evansii* was thought unlikely to be diazotrophic since no polymerase chain reaction (PCR)-amplifiable *nifH* fragment (T. Hurek and B. Reinhold-Hurek, unpublished observations) or hybridization with a *nifH* probe (Hurek et al., 1997a) occurs. However, recently this species was reported to fix nitrogen (Mechichi et al., 2002). For most other isolates enriched under denitrifying conditions, this character was not tested at all. In all diazotrophic strains (*A. indigens*, *A. communis*, *A. tolulyticus* and *Azoarcus* sp. strain BH72), nitrogenase activity occurs only under microaerobic conditions, probably due to the lack of efficient oxygen protection mechanisms. It was shown that nitrogen fixation is more tolerant to oxygen in strain BH72 than in *Azospirillum* spp., reaching steady states in an oxygen-controlled chemostat until dissolved O_2 exceeds 25 μM (Hurek et al., 1987). Similarly, the expression of nitrogenase genes is transcriptionally regulated in response to oxygen (fully repressed at 4% oxygen in the headspace) or combined nitrogen (repressed by 0.5 mM ammonium or nitrate; Egener et al., 1999). This strain shows augmented rates and efficiency of nitrogen fixation, called "hyperinduction," in empirically optimized batch cultures when shifting down to extremely low oxygen concentrations (30 nM; Hurek et al., 1994a). In the course of hyperinduction, novel intracytoplasmic membrane stacks are formed which might participate in efficient nitrogenase activity, since the iron protein of nitrogenase is mainly associated with these membranes (Hurek and Reinhold-Hurek, 1995a). The formation of these so-called "diazosomes" is most abundant and reproducible in coculture of strain BH72 and endophytic *Acremonium alternatum*, a mitosporic deuteromycete related to the Hypocreales within the euascomycetes and an isolate from Kallar grass (Hurek et al., 1995b; Hurek and Reinhold-Hurek, 1998). As in many Proteobacteria, nitrogenase genes are organized in an *nifHDK* operon (Egener et al., 2001). Phylogenetically, the nitrogenase in the genus *Azoarcus* follows either the organismic phylogenetic tree or appears to have been obtained by lateral gene transfer, depending on the species. In *A. indigens*, *A. communis* and *Azoarcus* sp. strain BH72, a fragment of the iron protein of nitrogenase encoded by the *nifH* gene is most closely related to nitrogenases occurring in diazotrophs of the γ-subclass of Proteobacte-

ria, while in *A. tolulyticus*, it is located within a clade of Alphaproteobacterial nitrogenases (*Bradyrhizobium* and *Azospirillum*; Hurek et al., 1997a).

In general, carbohydrates are not the preferred carbon sources of *Azoarcus* spp. None of the plant-associated species is able to utilize any out of 50 mono- and disaccharides or sugar alcohols tested (Reinhold-Hurek et al., 1993). *Azozrcus anaerobius* shows no growth on common carbohydrates such as D(+)-glucose or D(–)-fructose (Springer et al., 1998). In contrast, among the soil-borne species, all strains tested so far are able to utilize at least some carbohydrates (Table 1). All strains grow well on organic acids and a few amino acids (Table 1). The carbon sources listed here (except for *A. anaerobius*) were tested with O_2 as the terminal electron acceptor. For some strains, tests were also carried out under anaerobic conditions with nitrate as electron acceptor. For the majority of carbon sources, results were identical; however, for several carbon sources, strain-dependent differences were found (Song et al., 1999). In contrast to plant-associated species (Reinhold-Hurek et al., 1993; Hurek and Reinhold-Hurek, 1995a), most soil-borne species grow on aromatic compounds (such as toluene or phenol) under denitrifying conditions (Zhou et al., 1995; Song et al., 1999), benzoate (Anders et al., 1995), or resorcinol (Springer et al., 1998). Owing to the anaerobic degradation of aromatic compounds, this bacterial group receives particular attention for their biodegradation and biotransformation abilities. While aerobic metabolism is characterized by the extensive use of molecular oxygen (which is essential for the hydroxylation and cleavage of the ring structures), different strategies are necessary for the anaerobic degradation and are currently under study. Toluene, which can be decomposed anaerobically by three species, is activated by the addition to fumarate to form benzylsuccinate (Beller and Spormann, 1997) catalyzed by benzylsuccinate synthase via a glycyl radical (Krieger et al., 2001).

The aerobic metabolism of benzoate is unusual in *A. evansii* KB740^T. None of the known pathways, including the conversion of benzoate to catechol (1,2-dihydroxybenzoene) or protocatechuate (3,4-dihydroxybenzoate), appears to operate in this species (Mohamed et al., 2001). The first step is the activation of benzoate to benzoyl-CoA by a benzoate-CoA ligase, and the second step involves the hydroxylation of benzoyl-CoA by a novel benzoyl-CoA oxygenase (Mohamed et al., 2001). The first step of phenylacetate degradation is catalyzed by two different phenylacetate-CoA ligases under aerobic and anaerobic conditions, respectively (Mohamed, 2000). Strain PF6 degrades pyridine aerobically and anaerobically with nitrate as electron acceptor (Rhee et al., 1997). Benzoyl-CoA is also a central intermediate in the anaerobic degradation of aromatic compounds (Harwood et al., 1998). In *A. evansii* KB740, nucleotide sequence analysis of the gene cluster including a gene for benzoate-CoA ligase indicates that the degradation of benzoate is probably similar to the benzoate-CoA pathway in *Thauera aromatica* (Harwood et al., 1998). For further reading on anaerobic oxidation of aromatic compounds, the review of Boll et al. (2002) is recommended.

Resistance of *Azoarus* spp. to antibiotics has not been extensively tested. *Azoarcus indigens*, *A. communis* and strain BH72 are not resistant to ampicillin, kanamycin, streptomycin, spectinomycin or tetracycline (B. Reinhold-Hurek and T. Hurek, unpublished observation).

Genetics

For the three plant-associated species of *Azoarcus*, DNA reassociation experiments led to the estimation of a genome size from 4.5 to 5 Mb. The genome of *Azoarcus* sp. strain BH72 is currently sequenced (Hurek and Reinhold-Hurek, 2003), with an estimated genome size of 4.4 Mb.

Nothing is known about bacteriophages of the genus *Azoarcus*. Also the plasmid content is not well studied. In strain BH72, plasmids could not be detected in Eckhardt gels or by pulse field gel electrophoresis (B. Reinhold-Hurek and T. Hurek, unpublished observations). Several strains of *Azoarcus* spp. have been shown to be transformable. Broad host range plasmids based on RK2 such as pRK290 or pAFR3 can be transferred by triparental mating and are stably replicated in strain BH72 (Egener et al., 2001). Transformation can also be achieved by electroporation (Hurek et al., 1995b), and mutagenesis by allelic exchange (Hurek et al., 1995b) or transposon insertion (Dörr et al., 1998) is established.

Ecology

As already stated in the section on Habitat, the two phylogenetic clusters of *Azoarcus* strains appear to differ substantially in their ecology: the plant-associated and the soil-borne species. Among the plant-associated species (*A. indigens*, *A. communis* and strain BH72), most strains (except strain S2 from sludge [Laguerre et al., 1987] or strain LU1 from a compost biofilter [Juteau et al., 1999], both related to *A. communis* [Fig. 1]) appear to be strictly plant-associated and have never been isolated from root-free soil (Reinhold-Hurek and Hurek, 1998b). In contrast, no members of soil-borne species have been isolated from plant material as yet.

Plant-associated *Azoarcus* spp. have been up to now isolated from a limited number of samples, such as Kallar grass (*Leptochloa fusca* L. Kunth) from the Punjab of Pakistan (Reinhold et al., 1986; Reinhold-Hurek et al., 1993), rice roots (*Oryza* spp.) from Nepal (Engelhard et al., 2000), or resting stages of plant-associated fungi (Hurek et al., 1997b). However they may be more widely distributed than assumed; in molecular-ecological studies on root material or fungal spores, *Azoarcus* 16S rDNA genes (Hurek and Reinhold-Hurek, 1995a) or *nifH* genes (Ueda et al., 1995; Engelhard et al., 2000; Hurek et al., 2002) have been retrieved which did not correspond to genes of cultivated strains or species. Interestingly, the sequences retrieved up to now from plant material did not cluster with genes from soil-borne species, confirming that the latter do not appear to be plant associated. Since bacteria corresponding to the detected sequences could not be isolated from the same plant samples, they may occur in a state in which they are difficult to cultivate and thus overlooked by classical microbiological techniques. This is in agreement with the observation that in an inoculation experiment of Kallar grass with strain BH72, already two months after inoculation, attempts to reisolate the bacteria failed; however, nitrogenase gene (*nifH*) mRNA of this species was present at high levels in plant roots, suggesting high metabolic activity (Hurek et al., 2002). Using *nif*$^-$ and wild type BH72, it was demonstrated by N-balance and $^{15}N_2/^{14}N_2$ isotope studies that *Azoarcus* sp. can supply fixed nitrogen to its host plant Kallar grass (Hurek et al., 2002), an important observation with respect to the ecological role and possible applications of these bacteria.

Since plant-associated *Azoarcus* spp. cannot be isolated from root-free soil, the question arises how do they newly infect plants in nature. Survival in the absence of plants may be achieved in association with fungal resting stages in the soil (Hurek). Black sclerotia of a basidiomycete (a relative of *Ustilago hordei*) collected from a Kallar grass site in Pakistan harbored culturable strains of *Azoarcus indigens* and of the related genera *Azovibrio* spp., *Azospira oryzae* and *Azonexus fungiphilus* (Hurek). This suggests that plant-associated fungi might serve as shuttle vectors for plant-associated bacterial strains. Indeed, when these sclerotia were used to inoculate surface-sterilized rice seedlings in gnotobiotic culture, diazotrophs could be isolated from roots after 2–3 weeks of incubation. The abundant diazotrophs were identified as *Azospira oryzae* (B. Reinhold-Hurek, unpublished results).

Mechanisms of plant-microbe-interactions are best studied for *Azoarcus* sp. strain BH72, originating from the pioneer plant Kallar grass from Pakistan (Reinhold et al., 1986). In gnotobiotic cultures in the laboratory, these bacteria have a wider host range. They can invade rice roots and to a lesser extent stems (Hurek et al., 1994b), where they mainly colonize the root cortex tissue intercellularly and rarely the stele including xylem cells (Hurek et al., 1994b). Despite a high density of colonization of the root interior, the bacteria do not cause symptoms of plant disease (Hurek et al., 1994b) and thus have an endophytic and not a pathogenic lifestyle. Unlike rhizobia, they do not form an endosymbiosis in living plant cells (Reinhold-Hurek and Hurek, 1998a). Nevertheless they show endophytic nitrogen fixation, expressing nitrogenase genes in the apoplast of aerenchymatic air spaces of flooded rice seedlings (Egener et al., 1999) or field-grown Kallar grass plants (Hurek et al., 1997a).

Soil-borne species occur in a wide range of environments as stated in the section on Habitat. In most cases they were readily isolated under denitrifying conditions from nonmarine habitats such as contaminated or noncontaminated soils or sediments. Since many strains can degrade a wide range of aromatic compounds—which are the second most abundant class of organic compounds in nature—they can be expected to play an important role in carbon degradation in the biosphere. Their occurrence in anoxic sediments or sewage sludge indicates that their lifestyle in situ might be anaerobic (on nitrate as terminal electron acceptor), in contrast to the plant-associated strains that might be fixing nitrogen microaerobically. Besides the numerous isolates, there are also strains which have as yet escaped cultivation. One example is a deeply-branching clade of *Azoarcus* sp. found in high numbers in nitrifying-denitrifying activated sludge of an industrial wastewater treatment plant (Juretschko et al., 2002).

The Genera *Azovibrio*, *Azospira* and *Azonexus*

Introduction

Bacteria of these genera were first described to belong to the genus *Azoarcus* sensu lato (Reinhold-Hurek et al., 1993; Hurek et al., 1997b), to group C (*Azovibrio*), group D (*Azospira*) and group E (*Azonexus*). The availability of new isolates recently allowed a reassessment of the genus by a polyphasic taxonomic approach, leading to the proposal of three new genera. Since they are relatively similar in physiology and ecology, they are treated together.

Recently, perchlorate-reducing bacteria were described as a new genus (*Dechlorosoma suillum*; Achenbach et al., 2001); however, a polyphasic taxonomic analysis by us (Tan and Reinhold-Hurek, 2003) demonstrated that they are members of *Azospira oryzae*. Therefore, these bacteria are also included in this chapter.

Phylogeny

Analysis of almost complete 16S rDNA sequences placed all three genera into the Betaproteobacteria. Phylogenetic analyses using different algorithms showed that *Azoarcus* sensu lato was not monophyletic, but *Azoarcus* sensu stricto was divided from the other groups by the *Thauera* clade (Reinhold-Hurek and Hurek, 2000; see Fig. 1). The three new genera clearly represent different lineages, despite their exact phylogenetic relationships within the *Rhodocyclus* subgroup not being well resolved. Their phylogenetic distances from each other are similar to that of the *Thauera*/*Azoarcus* group or *Duganella* (formerly Zoogloea; Fig. 1). Other related genera are *Dechloromonas*, *Propionivibrio* and *Rhodocyclus*, and none are typically plant-associated bacteria.

Taxonomy

The three groups are divided from each other and to *Azoarcus* by a polyphasic taxonomic analysis including 16S rDNA sequence analysis, DNA-DNA hybridization, protein profiles, fatty acid analysis, and nutritional profiles. Each genus consists of only one validly described species: *Azovibrio restrictus*, *Azospira oryzae* and *Azonexus fungiphilus* (Reinhold-Hurek and Hurek, 2000). The members of each species are quite homogeneous in protein patterns and substrate utilization, except for *Azovibrio* sp. strain BS20-3. It shares only 97% 16S rDNA sequence identity with *Azovibrio restrictus* S5b2^T, which is strictly microaerobic and might thus deserve the rank of a separate species in future.

Azovibrio now harbors new members recently described as a misnamed genus "*Dechlorosoma suillum*" (Achenbach et al., 2001). The type strain shares almost 100% of 16S rDNA sequence identity (1433 out of 1435 bp) with *Azospira oryzae* 6a3, is very similar in sodium dodecylsulfate (SDS)-soluble protein patterns and carbon source profiles, and shows approx. 90% binding in DNA-DNA-hybridization studies; thus the type strain of *Dechlorosoma suillum* and *Azospira oryzae* have to be regarded as the same species (Tan and Reinhold-Hurek, 2003).

Habitat and Ecology

Bacteria of all three genera occur in terrestrial habitats. *Azovibrio* and *Azospira* strains have typically been isolated from surface-sterilized plant roots and are thus considered to be diazotrophic endophytes of grasses.

Members of both genera were found in roots of Kallar grass (*Leptochloa fusca* (L.) Kunth) in the Punjab of Pakistan (Reinhold-Hurek et al., 1993) and in roots of wild rice and cultured rice *Oryza sativa* in Nepal (Engelhard et al., 2000). *Azospira oryzae* also was found in roots of cultured rice in Italy (Engelhard et al., 2000) and wild rice in the Philippines (Hurek et al., 2000; Reinhold-Hurek and Hurek, 2000). Some strains of both genera and *Azonexus fungiphilus* were additionally found in another microniche, the resting stages (sclerotia) of a basidiomycete related to *Ustilago hordei* (Hurek et al., 1997b); they were collected in rice field soil at the site in the Punjab of Pakistan, where formerly Kallar grass had been grown. The finding that culturable bacteria appear to persist in fungal resting stages but not in soil suggests that plant-associated fungi may play a role as shuttle vectors for reinfection of plants by these diazotrophic endophytes. However, *Azonexus fungiphilus* was thought to be exclusively fungus-associated (Reinhold-Hurek and Hurek, 2000) but was recently cultured from surface-sterilized roots of wild rice, as well (B. Reinhold-Hurek and Z. Y. Tan, unpublished observations).

A new group of *Azospira oryzae* (Tan and Reinhold-Hurek, 2003), which was misnamed "*Dechlorosoma suillum*" has an entirely different habitat. It was isolated from a primary treatment lagoon of swine waste in the United States (Achenbach et al., 2001).

Isolation

Since all known strains are diazotrophic, enrichment and isolation are done on nitrogen-free media. The procedures are the same as described for plant-associated *Azoarcus* spp.

Identification

Azovibrio, *Azonexus* and *Azospira* are quite similar in physiological features but differ especially in cell morphology. Characters differentiating them from *Azoarcus* and other related genera are given in Table 1. More detailed phenotypic features are listed in Table 3. All three genera are diazotrophic. They do not use carbohydrates as sole carbon sources, but they do use a few organic and amino acids. Additional features are given below.

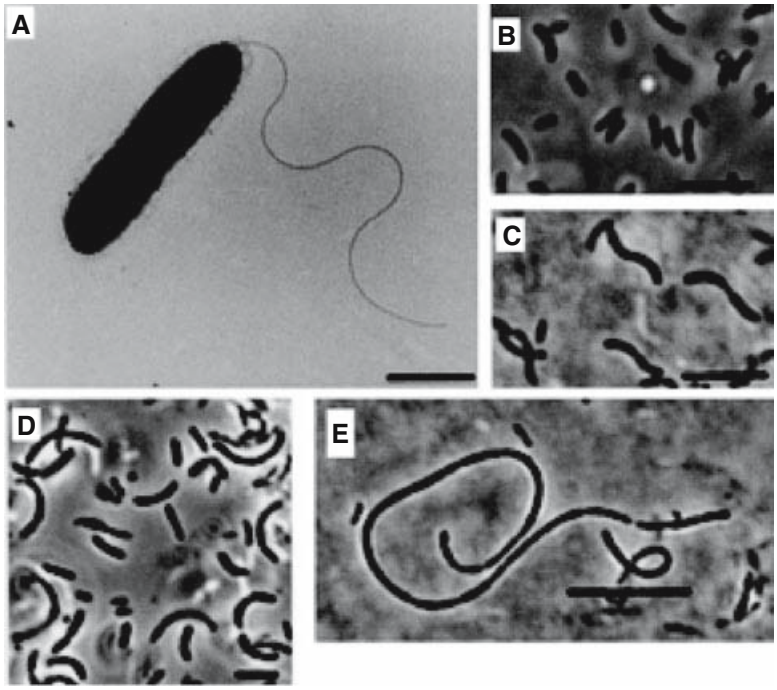

Fig. 3. Microscopic images of cells of the genera *Azovibrio*, *Azospira* and *Azonexus*. Transmission electron (A) and phase contrast (B-E) images of *Azovibrio* restrictus S5b2^T (A, B), *Azospira oryzae* 6a3^T (C), and *Azonexus fungiphilus* BS5-8^T (D, E). Cells were grown on N_2 in semisolid medium and photos taken during exponential (B), stationary (E) and late stationary (C, D) growth phase. Bars, 1 µm (A), 5 µm (B-D) or 10 µm (E). From Reinhold-Hurek and Hurek (2000).

Azovibrio cells are motile, slightly curved rods of 0.6–0.8 × 1.5–3.6 µm (Fig. 3), and elongated cells occur very rarely in stationary phase cultures. Cells grow well at 37°C. The major cellular fatty acids are *cis*-9-16:1, 16:0, 18:1, 14:0 and 3-OH-10:1. They have no dissimilatory nitrate reductase. The only validly described species is *A. restrictus*; however, strain BS20-3 (isolated from black sclerotia) might represent another species. In contrast to *A. restrictus*, BS20-3 requires cobalamin; it is also unusual because it is strictly microaerobic with negligible colony growth (Reinhold-Hurek and Hurek, 2000). The type strain is *A. restrictus* S5b2 (= LMG9099) which has a G+C content of 64.8 mol% and was isolated from surface-sterilized roots of Kallar grass. Accession number of the 16S rDNA sequence is AF011349 (www.ncbi.nlm.nih.gov/entrez/query.fcgi?db=nucleotide=search=AF011349).

Azospira cells are thin curved rods of 0.4–0.6 × 1.1–2.5 µm (Fig. 3), and elongated cells with one to several spiral windings of up to 8 µm occur rarely in late-stationary phase nitrogen-fixing cultures. Cells are highly motile with corkscrew-like motion. Growth is optimum at 37°C or 40°C. The major cellular fatty acids are *cis*-9-16:1, 16:0, 18:1 and 3-OH-10:1. They have no dissimilatory nitrate reductase. Plant-associated strains can use oxygen and nitrate as terminal electron acceptors, while strains originating from wastewater (formerly [*Dechlorosoma suillum*]) can also use perchlorate. The only validly described species is *Azospira oryzae*. The type strain is strain 6a3 (= LMG9096) which has a G+C content of 65.2 mol% and was isolated from surface-sterilized roots of Kallar grass. Accession number of the 16S rDNA sequence is AF011347 (www.ncbi.nlm.nih.gov/entrez/query.fcgi?db=nucleotide=search=AF011347).

Azonexus cells are highly motile, slightly curved rods of 0.6–0.8 × 1.5–4.0 µm; elongated straight to coiled cells of up to 50 µm length occur in the stationary phase of nitrogen-fixing cultures (Fig. 3). Cells grow well at 37°C and require cobalamin for growth. The only validly described species is *Azonexus fungiphilus*. The type strain is strain BS5-8 (= LMG 19178), which was isolated from resting stages (black sclerotia) of a basidiomycete related to *Ustilago* found in a rice field in Pakistan. Accession number of the 16S rDNA sequence is AF011350 (www.ncbi.nlm.nih.gov/entrez/query.fcgi?db=nucleotide=search=AF011350).

Preservation

Preservation and storage are carried out as for plant-associated species of *Azoarcus*.

Physiology

All three genera (even the perchlorate-reducing isolates from swine wastewater) are diazotrophic, showing microaerophilic nitrogen fixation (Tan and Reinhold-Hurek, 2003). As the plant-associated *Azoarcus* strains, cells require microaerobic conditions for nitrogen fixation

and form subsurface pellicles due to microaerophilic growth in semisolid media. The optimum growth temperature is 37–40°C. Optimum pH is neutral, and the bacteria are not halophilic. All genera have a strictly respiratory type of metabolism, and no fermentative abilities have been observed. All genera use oxygen or nitrate as the terminal electron acceptor, and some strains of *Azospira oryzae* also use perchlorate. All are oxidase and catalase positive. Similarly to plant-associated *Azoarcus* species, organic acids, amino acids, and ethanol but no carbohydrates are utilized.

Genetics

Extrachromosomal genetic elements have not been intensively studied in these genera. Transposon mutagenesis has been established for *Azonexus fungiphilus* (Gemmer and B. Reinhold-Hurek, unpublished), while *Azospira oryza* appears to be difficult to transform.

Neisseria, 624–25, 626, 630, 632
Rickettsia, 506
Spirillum, 707
Xanthobacter, 303
Antibiotic treatment
gonorrhea, 632
meningococcal disease, 632
pertussis, 651, 653
Antibody response, to pertussis, 665–66
Antigenic structure, *Eikenella corrodens*, 842
Antigens
Burkholderia, 854, 855
Neisseria, 617
Antimicrobial peptides, 664
Bordetella, 661–62
Antimicrobial susceptibility, *Eikenella corrodens*, 844
Antipyrin degradation, *Phenylobacterium*, 250–56
Appendicitis, *Bilophila*, 23
Appendix, *Comamonas*, 726
Apple habitat, Acetobacteraceae, 172–73
Applications
Acetobacter, 178
Achromobacter/Alcaligenes strains, 687–89
Acidomonas, 179
aerobic phototrophic bacteria, 580
Agrobacterium, 109–10
Azospirillum, 132–34
Beijerinckia, 161
Brucella, 429–31
Chromobacterium, 740–41
Comamonas, 732
Coxiella, 541
Derxia, 756
dimorphic prosthecate bacteria, 85–86
Gluconacetobacter, 185
Gluconobacter, 188–89
Herbaspirillum, 147
Janthinobacterium, 743
manganese-oxidizing bacteria, 229
methanotrophs, 284
Methylobacterium, 263
Ochrobactrum, 749
Paracoccus, 246
phototrophic alphaproteobacteria, 58–59
phototrophic betaproteobacteria, 599
Phyllobacterium, 749
Proteobacteria, 12
Spirillum, 707–8
Wolbachia, 516, 555–56
Xanthobacter, 307–9
Aquabacter, 290, 294
Aquabacter spiritensis, 294
Aquabacterium, 758
Aquaspirillum, 701, 703, 710–21, 723
differentiating characteristics of, 712–13
enrichment of, 711–18
habitat of, 711
identification of, 719–21
isolation of, 711–19
maintenance of, 711–18
morphology of, 719
motility of, 719
preservation of, 718–19
rRNA superfamily III species of, 719–20
rRNA superfamily IV species of, 720–21
taxonomy of, 719–21
type strains of, 714
Aquaspirillum anulus, 720
Aquaspirillum aquaticum, 711, 717, 719, 720, 725–26
Aquaspirillum autotrophicum, 710, 711, 717, 720, 742–43
Aquaspirillum bengal, 710, 717, 719
Aquaspirillum delicatum, 710, 719, 720
Aquaspirillum dispar, 719, 720
Aquaspirillum fasciculus, 710, 716, 719, 720
Aquaspirillum giesbergeri, 720
Aquaspirillum gracile, 710, 716, 719, 720
Aquaspirillum itersonii, 141, 703, 710, 719, 720
Aquaspirillum itersonii subsp. *itersonii*, 720

Aquaspirillum itersonii subsp. *nipponicum*, 718, 720
Aquaspirillum itersonii subsp. *vulgatum*, 720
Aquaspirillum magnetotacticum, 710, 717, 718, 719, 720
Aquaspirillum metamorphum, 715, 720
Aquaspirillum peregrinum, 719, 720
Aquaspirillum peregrinum subsp. *integrum*, 718
Aquaspirillum peregrinum subsp. *peregrinum*, 710
Aquaspirillum polymorphum, 710, 719, 720
Aquaspirillum psychrophilum, 710, 718, 720
Aquaspirillum putridiconchylium, 720
Aquaspirillum serpens, 710, 716, 717, 719, 720
Aquaspirillum sinuosum, 720
Aquaspirillum voronezhense, 701
Archangiaceae, 22
Archangium, 22
Arcobacter, 24–25
Arcobacter nitrofigilis, 25
Aromatic amine deamination, *Alcaligenes* strains, 682
Aromatic amine dehydrogenase, *Alcaligenes* strains, 682
Aromatic compound degradation
  Achromobacter/Alcaligenes strains, 683–84
  Azoarcus, 873, 886
  Comamonas, 728
  phototrophic betaproteobacteria, 598
Arphamenines A and B, 741
Arsenite resistance, *Achromobacter/Alcaligenes* strains, 686
Arthrobacter globiformis, 731
Arthropod habitat
  Alcaligenes, 677
  Anaplasma, 508–9
  Ancalomicrobium, 66
  Bartonella, 479
  Coxiella, 530, 536
  dimorphic prosthecate bacteria, 77
  Ehrlichia, 512–13
  Prosthecomicrobium, 66
  Rickettsia, 496, 500
  Wolbachia, 515–16, 547, 550–51, 553
Asaia, 13, 163–66, 172–73, 179–80
  characteristics of, 168, 180
  classification of, 167
  habitats of, 180
  identification of, 180
  isolation and cultivation of, 180
  taxonomy of, 180
Asaia bogorensis, 180, 190
Asaia krungthepensis, 180
Asaia siamensis, 180
Asticcacaulis, 72–86
Asticcacaulis biprosthecum, 74, 81, 84
Asticcacaulis excentricus, 74, 81, 84
ATP synthesis, *Brucella*, 367
Atrophic rhinitis, 651, 664
Autophagosomes, *Brucella*, 407–8
Autotransporter proteins, *Rickettsia*, 498–99
Auxotyping, *Neisseria*, 628
Azo dye degradation, *Pigmentiphaga kullae*, 689
Azoarcus, 17, 126, 873–88
  characteristics of, 878
  ecology of, 886–87
  genetics of, 886
  habitat of, 875
  identification of, 877–85
  isolation of, 876–77
  phylogeny of, 873–75
  physiology of, 885–86
  preservation of, 885
  species of, 880–83
  taxonomy of, 875
Azoarcus anaerobius, 873, 875, 877, 879, 885–86
Azoarcus buckelii, 873, 875, 877, 879, 885
Azoarcus communis, 873, 875, 877, 879–86
Azoarcus evansii, 873, 875–77, 884–86
Azoarcus indigens, 873, 875, 877, 879, 885–87
Azoarcus sp. strain BH72, 873, 875, 877, 879, 885–87
Azoarcus toluclasticus, 873, 875, 877, 884–85
Azoarcus tolulyticus, 873, 875, 877, 884–86
Azoarcus toluvorans, 873, 875, 877, 884–85
Azoarcus/Thauera branch, 873–75, 888
Azomonas, 21, 154–55, 751, 753–54
Azomonas agilis, 160
Azonexus, 873, 877, 887–90
  characteristics of, 878
  genetics of, 890
  identification of, 888–89
  isolation of, 888

Wolbachiae, 461
Wolbachia melophagi, 461–62, 547
Wolbachia persica, 461, 493, 547
Wolbachia pipientis, 461, 463, 494, 515–16, 547–56
Wolbachiae, *Wolbachia*, 461
Wolinella, 25
Wolinella succinogenes, 25
Wounds
Alcaligenes, 677
Aquaspirillum, 711
Ochrobactrum, 748

X

Xanthobacter, 290–310, 754
applications of, 307–9
characteristics of, 291
cultivation of, 299–300
cultures of, 309–10
habitats of, 295–97
identification of, 300–306
biochemical properties, 301–3
physiological properties, 304–6
isolation of, 297–99
phylogeny and taxonomy, 294–95
Xanthobacter agilis, 290, 298–99, 302–3
Xanthobacter aminoxidans, 290, 294, 299–301
Xanthobacter autotrophicus, 290–310
Xanthobacter flavus, 290–310
Xanthobacter methylooxidans, 290, 303–4
Xanthobacter polyaromaticivorans, 290, 293, 298, 300, 304
Xanthobacter tagetidis, 290, 293, 300–301, 308–9
Xanthobacter viscosus, 290, 294, 299–301
Xanthomonas, 18, 21, 689, 747
Xanthomonas autotrophicus, 151
Xenobiotic compound degradation, *Achromobacter/Alcaligenes* strains, 684–86
Xenorhabdus, 19
Xylella, 21
Xylella fastidiosa, 21
Xylophilus, 16, 723
Xylophilus ampelinus, 16

Y

Yersinia, 19, 28

Z

Zavarzinia compransoris, 725
Zeaxanthin dirhamnoside, *Xanthobacter*, 303
Zinc metalloprotease, *Burkholderia*, 854
Zoogloea ramigera, 17
Zoonosis
Brucella, 372, 374, 380–81
Coxiella, 530, 536
Ehrlichia, 460, 514
Rickettsia, 504
Zymobacter, 20
Zymomonas, 14, 151, 169, 201–14
characteristics of, 202–3
ethanol fermentation, 207–9
genetics and metabolic engineering, 212–14
growth and conservation of, 202
habitats of, 201
identification of, 202–3
isolation of, 201–2
metabolism of, 203–7
aerobic, 209–11
alcohol dehydrogenase isoenzymes, 206–7
carbohydrate transport, 203–4
glycolytic flux and regulation of, 204–6
pyruvate decarboxylase, 206
sugar and ethanol tolerance, 208–9
Zymomonas mobilis, 174, 201–14
Zymomonas mobilis subsp. *mobilis*, 202
Zymomonas mobilis subsp. *pomaceae*, 202
