Preface

Each of the first two editions of *The Prokaryotes* took a bold step. The first edition, published in 1981, set out to be an encyclopedic, synoptic account of the world of the prokaryotes—a collection of monographic descriptions of the genera of bacteria. The Archaea had not yet been formalized as a group. For the second edition in 1992, the editors made the decision to organize the chapters on the basis of the molecular phylogeny championed by Carl Woese, which increasingly provided a rational, evolutionary basis for the taxonomy of the prokaryotes. In addition, the archaea had by then been recognized as a phylogenetically separate and distinguishable group of the prokaryotes. The two volumes of the first edition had by then expanded to four. The third edition was arguably the boldest step of all. We decided that the material would only be presented electronically. The advantages were obvious and persuasive. There would be essentially unlimited space. There would be no restrictions on the use of color illustrations. Film and animated descriptions could be made available. The text would be hyperlinked to external sources. Publication of chapters would be seriati—the edition would no longer have to delay publication until the last tardy author had submitted his or her chapter. Updates and modifications could be made continuously. And, most attractively, a library could place its subscribed copy on its server and make it available easily and cheaply to all in its community. One hundred and seventy chapters have thus far been presented in 16 releases over a six-year period. The virtues and advantages of the online edition have been borne out. But we failed to predict the affection that many have for holding a bound, print version of a book in their hands. Thus, this print version of the third edition shall accompany the online version.

We are now four years into the 21st century. Indulge us then while we comment on the challenges, problems and opportunities for microbiology that confront us.

Moselio Schaechter has referred to the present era of microbiology as its third golden age—the era of "integrative microbiology." Essentially all microbiologists now speak a common language. So that the boundaries that previously separated subdisciplines from each other have faded: physiology has become indistinguishable from pathogenesis; ecologists and molecular geneticists speak to each other; biochemistry is spoken by all; and—mirabile dictu!—molecular biologists are collaborating with taxonomists.

But before these molecular dissections of complex processes can be effective there must be a clear view of the organism being studied. And it is our goal that these chapters in *The Prokaryotes* provide that opportunity.

There is also yet a larger issue. Microbiology is now confronted with the need to understand increasingly complex processes. And the modus operandi that has served us so successfully for 150 years—that of the pure culture studied under standard laboratory conditions—is inadequate. We are now challenged to solve problems of multimembered populations interacting with each other and with their environment under constantly variable conditions. Carl Woese has pointed out a useful and important distinction between empirical, methodological reductionism and fundamentalist reductionism. The former has served us well; the latter stands in the way of our further understanding of complex, interacting systems. But no matter what kind of synoptic systems analysis emerges as our way of understanding host–parasite relations, ecology, or multicellular behavior, the understanding of the organism as such is sine qua non. And in that context, we are pleased to present to you the third edition of *The Prokaryotes*.

Martin Dworkin
Editor-in-Chief

Foreword

The purpose of this brief foreword is unchanged from the first edition; it is simply to make you, the reader, hungry for the scientific feast that follows. These four volumes on the prokaryotes offer an expanded scientific menu that displays the biochemical depth and remarkable physiological and morphological diversity of prokaryote life. The size of the volumes might initially discourage the unprepared mind from being attracted to the study of prokaryote life, for this landmark assemblage thoroughly documents the wealth of present knowledge. But in confronting the reader with the state of the art, the Handbook also defines where more work needs to be done on well-studied bacteria as well as on unusual or poorly studied organisms.

This edition of *The Prokaryotes* recognizes the almost unbelievable impact that the work of Carl Woese has had in defining a phylogenetic basis for the microbial world. The concept that the ribosome is a highly conserved structure in all cells and that its nucleic acid components may serve as a convenient reference point for relating all living things is now generally accepted. At last, the phylogeny of prokaryotes has a scientific basis, and this is the first serious attempt to present a comprehensive treatise on prokaryotes along recently defined phylogenetic lines. Although evidence is incomplete for many microbial groups, these volumes make a statement that clearly illuminates the path to follow.

There are basically two ways of doing research with microbes. A classical approach is first to define the phenomenon to be studied and then to select the organism accordingly. Another way is to choose a specific organism and go where it leads. The pursuit of an unusual microbe brings out the latent hunter in all of us. The intellectual challenges of the chase frequently test our ingenuity to the limit. Sometimes the quarry repeatedly escapes, but the final capture is indeed a wonderful experience. For many of us, these simple rewards are sufficiently gratifying so that we have chosen to spend our scientific lives studying these unusual creatures. In these endeavors many of the strategies and tools as well as much of the philosophy may be traced to the Delft School, passed on to us by our teachers, Martinus Beijerinck, A. J. Kluyver, and C. B. van Niel, and in turn passed on by us to our students.

In this school, the principles of the selective, enrichment culture technique have been developed and diversified; they have been a major force in designing and applying new principles for the capture and isolation of microbes from nature. For me, the "organism approach" has provided rewarding adventures. The organism continually challenges and literally drags the investigator into new areas where unfamiliar tools may be needed. I believe that organism-oriented research is an important alternative to problem-oriented research, for new concepts of the future very likely lie in a study of the breadth of microbial life. The physiology, biochemistry, and ecology of the microbe remain the most powerful attractions. Studies based on classical methods as well as modern genetic techniques will result in new insights and concepts.

To some readers, this edition of the *The Prokaryotes* may indicate that the field is now mature, that from here on it is a matter of filling in details. I suspect that this is not the case. Perhaps we have assumed prematurely that we fully understand microbial life. Van Niel pointed out to his students that—after a lifetime of study—it was a very humbling experience to view in the microscope a sample of microbes from nature and recognize only a few. Recent evidence suggests that microbes have been evolving for nearly 4 billion years. Most certainly those microbes now domesticated and kept in captivity in culture collections represent only a minor portion of the species that have evolved in this time span. Sometimes we must remind ourselves that evolution is actively taking place at the present moment. That the eukaryote cell evolved as a chimera of certain prokaryote parts is a generally accepted concept today. Higher as well as lower eukaryotes evolved in contact with prokaryotes, and evidence surrounds us of the complex interactions between eukaryotes and

prokaryotes as well as among prokaryotes. We have so far only scratched the surface of these biochemical interrelationships. Perhaps the legume nodule is a pertinent example of nature caught in the act of evolving the "nitrosome," a unique nitrogen-fixing organelle. Study of prokaryotes is proceeding at such a fast pace that major advances are occurring yearly. The increase of this edition to four volumes documents the exciting pace of discoveries.

To prepare a treatise such as *The Prokaryotes* requires dedicated editors and authors; the task has been enormous. I predict that the scientific community of microbiologists will again show its appreciation through use of these volumes—such that the pages will become "dog-eared" and worn as students seek basic information for the hunt. These volumes belong in the laboratory, not in the library. I believe that a most effective way to introduce students to microbiology is for them to isolate microbes from nature, i.e., from their habitats in soil, water, clinical specimens, or plants. *The Prokaryotes* enormously simplifies this process and should encourage the construction of courses that contain a wide spectrum of diverse topics. For the student as well as the advanced investigator these volumes should generate excitement.

Happy hunting!

Volume 1

1. ***Essays in Prokaryotic Biology***

1.1 How We Do, Don't and Should Look at Bacteria and Bacteriology 3
CARL R. WOESE

1.2 Databases 24
WOLFGANG LUDWIG, KARL-HEINZ SCHLEIFER and ERKO STACKEBRANDT

1.3 Defining Taxonomic Ranks 29
ERKO STACKEBRANDT

1.4 Prokaryote Characterization and Identification 58
HANS G. TRÜPER and KARL-HEINZ SCHLEIFER

1.5 Principles of Enrichment, Isolation, Cultivation, and Preservation of Prokaryotes 80
JÖRG OVERMANN

1.6 Prokaryotes and Their Habitats 137
HANS G. SCHLEGEL and HOLGER W. JANNASCH

1.7 Morphological and Physiological Diversity 185
STEPHEN H. ZINDER and MARTIN DWORKIN

1.8 Cell-Cell Interactions 221
DALE KAISER

1.9 Prokaryotic Genomics 246
B. W. WREN

1.10 Genomics and Metabolism in *Escherichia coli* 261
MARGRETHE HAUGGE SERRES and MONICA RILEY

1.11 Origin of Life: RNA World versus Autocatalytic Anabolism 275
GÜNTER WÄCHTERSHÄUSER

1.12 Biotechnology and Applied Microbiology 284
EUGENE ROSENBERG

1.13 The Structure and Function of Microbial Communities 299
DAVID A. STAHL, MEREDITH HULLAR and SEANA DAVIDSON

2. Symbiotic Associations

2.1 Cyanobacterial-Plant Symbioses 331
DAVID G. ADAMS, BIRGITTA BERGMAN, S. A. NIERZWICKI-BAUER, A. N. RAI and ARTHUR SCHÜßLER

2.2 Symbiotic Associations Between Ciliates and Prokaryotes 364
HANS-DIETER GÖRTZ

2.3 Bacteriocyte-Associated Endosymbionts of Insects 403
PAUL BAUMANN, NANCY A. MORAN and LINDA BAUMANN

2.4 Symbiotic Associations Between Termites and Prokaryotes 439
ANDREAS BRUNE

2.5 Marine Chemosynthetic Symbioses 475
COLLEEN M. CAVANAUGH, ZOE P. MCKINESS, IRENE L.G. NEWTON and FRANK J. STEWART

3. Biotechnology and Applied Microbiology

3.1 Organic Acid and Solvent Production 511
PALMER ROGERS, JIANN-SHIN CHEN and MARY JO ZIDWICK

3.2 Amino Acid Production 756
HIDEHIKO KUMAGAI

3.3 Microbial Exopolysaccharides 766
TIMOTHY HARRAH, BRUCE PANILAITIS and DAVID KAPLAN

3.4 Bacterial Enzymes 777
WIM J. QUAX

3.5 Bacteria in Food and Beverage Production 797
MICHAEL P. DOYLE and JIANGHONG MENG

3.6 Bacterial Pharmaceutical Products 812
ARNOLD L. DEMAIN and GIANCARLO LANCINI

3.7 Biosurfactants 834
EUGENE ROSENBERG

3.8 Bioremediation 850
RONALD L. CRAWFORD

3.9 Biodeterioration 864
JI-DONG GU and RALPH MITCHELL

3.10 Microbial Biofilms 904
DIRK DE BEER and PAUL STOODLEY

Index 939

Volume 2

1. Ecophysiological and Biochemical Aspects

1.1 Planktonic Versus Sessile Life of Prokaryotes 3
KEVIN C. MARSHALL

1.2 Bacterial Adhesion 16
ITZHAK OFEK, NATHAN SHARON and SOMAN N. ABRAHAM

1.3 The Phototrophic Way of Life 32
JÖRG OVERMANN and FERRAN GARCIA-PICHEL

1.4 The Anaerobic Way of Life 86
RUTH A. SCHMITZ, ROLF DANIEL, UWE DEPPENMEIER and GERHARD GOTTSCHALK

1.5 Bacterial Behavior 102
JUDITH ARMITAGE

1.6 Prokaryotic Life Cycles 140
MARTIN DWORKIN

1.7 Life at High Temperatures 167
RAINER JAENICKE and REINHARD STERNER

1.8 Life at Low Temperatures 210
SIEGFRIED SCHERER and KLAUS NEUHAUS

1.9 Life at High Salt Concentrations 263
AHARON OREN

1.10 Alkaliphilic Prokaryotes 283
TERRY ANN KRULWICH

1.11 Syntrophism among Prokaryotes 309
BERNHARD SCHINK and ALFONS J.M. STAMS

1.12 Quorum Sensing 336
BONNIE L. BASSLER and MELISSA B. MILLER

1.13 Acetogenic Prokaryotes 354
HAROLD L. DRAKE, KIRSTEN KÜSEL and CAROLA MATTHIES

1.14 Virulence Strategies of Plant Pathogenic Bacteria 421
BARBARA N. KUNKEL and ZHONGYING CHEN

1.15 The Chemolithotrophic Prokaryotes 441
DONOVAN P. KELLY and ANNE P. WOOD

1.16 Oxidation of Inorganic Nitrogen Compounds as an Energy Source 457
EBERHARD BOCK and MICHAEL WAGNER

1.17 The H_2-Metabolizing Prokaryotes 496
EDWARD SCHWARTZ and BÄRBEL FRIEDRICH

1.18 Hydrocarbon-Oxidizing Bacteria 564
EUGENE ROSENBERG

1.19 Cellulose-Decomposing Bacteria and Their Enzyme Systems 578
EDWARD A. BAYER, YUVAL SHOHAM and RAPHAEL LAMED

1.20 Aerobic Methylotrophic Prokaryotes 618
MARY E. LIDSTROM

1.21 Dissimilatory Fe(III)- and Mn(IV)-Reducing Prokaryotes 635
DEREK LOVLEY

1.22 Dissimilatory Sulfate- and Sulfur-Reducing Prokaryotes 659
RALF RABUS, THEO A. HANSEN and FRIEDRICH WIDDEL

1.23 The Denitrifying Prokaryotes 769
JAMES P. SHAPLEIGH

1.24 Dinitrogen-Fixing Prokaryotes 793
ESPERANZA MARTINEZ-ROMERO

1.25 Root and Stem Nodule Bacteria of Legumes 818
MICHAEL J. SADOWSKY and P. H. GRAHAM

1.26 Magnetotactic Bacteria 842
STEFAN SPRING and DENNIS A. BAZYLINSKI

1.2.6 Enterococcus 175
DONALD J. LEBLANC

1.2.7 The Genus *Lactococcus* 205
MICHAEL TEUBER and ARNOLD GEIS

1.2.8 The Genera *Pediococcus* and *Tetragenococcus* 229
WILHELM H. HOLZAPFEL, CHARLES M. A. P. FRANZ, WOLFGANG LUDWIG, WERNER BACK and LEON M. T. DICKS

1.2.9 Genera *Leuconostoc*, *Oenococcus* and *Weissella* 267
JOHANNA BJÖRKROTH and WILHELM H. HOLZAPFEL

1.2.10 The Genera *Lactobacillus* and *Carnobacterium* 320
WALTER P. HAMMES and CHRISTIAN HERTEL

1.2.11 *Listeria monocytogenes* and the Genus *Listeria* 404
NADIA KHELEF, MARC LECUIT, CARMEN BUCHRIESER, DIDIER CABANES, OLIVIER DUSSURGET and PASCALE COSSART

1.2.12 The Genus *Brochothrix* 477
ERKO STACKEBRANDT and DOROTHY JONES

1.2.13 The Genus *Erysipelothrix* 492
ERKO STACKEBRANDT, ANNETTE C. REBOLI and W. EDMUND FARRAR

1.2.14 The Genus *Gemella* 511
MATTHEW D. COLLINS

1.2.15 The Genus *Kurthia* 519
ERKO STACKEBRANDT, RONALD M. KEDDIE and DOROTHY JONES

1.2.16 The Genus *Bacillus*—Nonmedical 530
RALPH A. SLEPECKY and H. ERNEST HEMPHILL

1.2.17 The Genus *Bacillus*—Insect Pathogens 563
DONALD P. STAHLY, ROBERT E. ANDREWS and ALLAN A. YOUSTEN

1.2.18 The Genus *Bacillus*—Medical 609
W. EDMUND FARRAR and ANNETTE C. REBOLI

1.2.19 Genera Related to the Genus *Bacillus*—*Sporolactobacillus*, *Sporosarcina*, *Planococcus*, *Filibacter* and *Caryophanon* 631
DIETER CLAUS, DAGMAR FRITZE and MILOSLAV KOCUR

1.2.20 An Introduction to the Family Clostridiaceae 654
JÜRGEN WIEGEL, RALPH TANNER and FRED A. RAINEY

1.2.21 Neurotoxigenic Clostridia 679
CESARE MONTECUCCO, ORNELLA ROSSETTO and MICHEL R. POPOFF

1.2.22 The Enterotoxic Clostridia 698
BRUCE A. MCCLANE, FRANCISCO A. UZAI, MARIANO E. FERNANDEZ MIYAKAWA, DAVID LYERLY and TRACY WILKINS

1.2.23 *Clostridium perfringens* and Histotoxic Disease 753
JULIAN I. ROOD

1.2.24 The Genera *Desulfitobacterium* and *Desulfosporosinus*: Taxonomy 771
STEFAN SPRING and FRANK ROSENZWEIG

1.2.25 The Genus *Desulfotomaculum* 787
FRIEDRICH WIDDEL

1.2.26 The Anaerobic Gram-Positive Cocci 795
TAKAYUKI EZAKI, NA (MICHAEL) LI and YOSHIAKI KAWAMURA

1.2.27 The Order Haloanaerobiales 809
AHARON OREN

1.2.28 The Genus *Eubacterium* and Related Genera 823
WILLIAM G. WADE

1.2.29 The Genus *Mycoplasma* and Related Genera (Class Mollicutes) 836
SHMUEL RAZIN

1.2.30 The Phytopathogenic Spiroplasmas 905
JACQUELINE FLETCHER, ULRICH MELCHER and ASTRI WAYADANDE

1.3 Firmicutes with Atypical Cell Walls

1.3.1 The Family Heliobacteriaceae — 951
MICHAEL T. MADIGAN

1.3.2 *Pectinatus*, *Megasphaera* and *Zymophilus* — 965
AULI HAIKARA and ILKKA HELANDER

1.3.3 The Genus *Selenomonas* — 982
ROBERT B. HESPELL, BRUCE J. PASTER and FLOYD E. DEWHIRST

1.3.4 The Genus *Sporomusa* — 991
JOHN A. BREZNAK

1.3.5 The Family Lachnospiraceae, Including the Genera *Butyrivibrio*, *Lachnospira* and *Roseburia* — 1002
MICHAEL COTTA and ROBERT FORSTER

JOHANNES F. IMHOFF

3.1.2	The Genera *Prosthecomicrobium* and *Ancalomicrobium* GARY E. OERTLI, CHERYL JENKINS, NAOMI WARD, FREDERICK A. RAINEY, ERKO STACKEBRANDT and JAMES T. STALEY	65
3.1.3	Dimorphic Prosthecate Bacteria: The Genera *Caulobacter*, *Asticcacaulis*, *Hyphomicrobium*, *Pedomicrobium*, *Hyphomonas* and *Thiodendron* JEANNE S. POINDEXTER	72
3.1.4	The Genus *Agrobacterium* ANN G. MATTHYSSE	91
3.1.5	The Genus *Azospirillum* ANTON HARTMANN and JOSE IVO BALDANI	115
3.1.6	The Genus *Herbaspirillum* MICHAEL SCHMID, JOSE IVO BALDANI and ANTON HARTMANN	141
3.1.7	The Genus *Beijerinckia* JAN HENDRICK BECKING	151
3.1.8	The Family Acetobacteraceae: The Genera *Acetobacter*, *Acidomonas*, *Asaia*, *Gluconacetobacter*, *Gluconobacter*, and *Kozakia* KAREL KERSTERS, PUSPITA LISDIYANTI, KAZUO KOMAGATA and JEAN SWINGS	163
3.1.9	The Genus *Zymomonas* HERMANN SAHM, STEPHANIE BRINGER-MEYER and GEORG A. SPRENGER	201
3.1.10	The Manganese-Oxidizing Bacteria KENNETH H. NEALSON	222
3.1.11	The Genus *Paracoccus* DONOVAN P. KELLY, FREDERICK A. RAINEY and ANN P. WOOD	232
3.1.12	The Genus *Phenylobacterium* JÜRGEN EBERSPÄCHER and FRANZ LINGENS	250
3.1.13	*Methylobacterium* PETER N. GREEN	257
3.1.14	The Methanotrophs—The Families Methylococcaceae and Methylocystaceae JOHN P. BOWMAN	266
3.1.15	The Genus *Xanthobacter* JÜRGEN WIEGEL	290
3.1.16	The Genus *Brucella* EDGARDO MORENO and IGNACIO MORIYÓN	315
3.1.17	Introduction to the Rickettsiales and Other Intracellular Prokaryotes DAVID N. FREDRICKS	457
3.1.18	The Genus *Bartonella* MICHAEL F. MINNICK and BURT E. ANDERSON	467

3.1.19 The Order Rickettsiales 493
XUE-JIE YU and DAVID H. WALKER

3.1.20 The Genus *Coxiella* 529
ROBERT A. HEINZEN and JAMES E. SAMUEL

3.1.21 The Genus *Wolbachia* 547
MARKUS RIEGLER and SCOTT L. O'NEILL

3.1.22 Aerobic Phototrophic Proteobacteria 562
VLADIMIR V. YURKOV

3.1.23 The Genus *Seliberia* 585
JEAN M. SCHMIDT and JAMES R. SWAFFORD

3.2. Beta Subclass

3.2.1 The Phototrophic Betaproteobacteria 593
JOHANNES F. IMHOFF

3.2.2 The *Neisseria* 602
DANIEL C. STEIN

3.2.3 The Genus *Bordetella* 648
ALISON WEISS

3.2.4 *Achromobacter*, *Alcaligenes* and Related Genera 675
HANS-JÜRGEN BUSSE and ANDREAS STOLZ

3.2.5 The Genus *Spirillum* 701
NOEL R. KRIEG

3.2.6 The Genus *Aquaspirillum* 710
BRUNO POT, MONIQUE GILLIS and JOZEF DE LEY

3.2.7 *Comamonas* 723
ANNE WILLEMS and PAUL DE VOS

3.2.8 The Genera *Chromobacterium* and *Janthinobacterium* 737
MONIQUE GILLIS and JOZEF DE LEY

3.2.9 The Genera *Phyllobacterium* and *Ochrobactrum* 747
JEAN SWINGS, BART LAMBERT, KAREL KERSTERS and BARRY HOLMES

3.2.10 The Genus *Derxia* 751
JAN HENDRICK BECKING

3.2.11 The Genera *Leptothrix* and *Sphaerotilus* 758
STEFAN SPRING

3.2.12 The Lithoautotrophic Ammonia-Oxidizing Bacteria 778
HANS-PETER KOOPS, ULRIKE PURKHOLD, ANDREAS POMMERENING-RÖSER, GABRIELE TIMMERMANN and MICHAEL WAGNER

3.2.13 The Genus *Thiobacillus* 812
LESLEY A. ROBERTSON and J. GIJS KUENEN

3.2.14 The Genera *Simonsiella* and *Alysiella* 828
BRIAN P. HEDLUND and DAISY A. KUHN

3.2.15 *Eikenella corrodens* and Closely Related Bacteria 840
EDWARD J. BOTTONE and PAUL A. GRANATO

3.2.16 The Genus *Burkholderia* 848
DONALD E. WOODS and PAMELA A. SOKOL

3.2.17 The Nitrite-Oxidizing Bacteria 861
AHARON ABELIOVICH

3.2.18 The Genera *Azoarcus*, *Azovibrio*, *Azospira* and *Azonexus* 873
BARBARA REINHOLD-HUREK and THOMAS HUREK

Index 893

Volume 6

3. Proteobacteria

3.3. Gamma Subclass

3.3.1 New Members of the Family Enterobacteriaceae 5
J. MICHAEL JANDA

3.3.2 Phylogenetic Relationships of Bacteria with Special Reference to Endosymbionts and Enteric Species 41
M. PILAR FRANCINO, SCOTT R. SANTOS and HOWARD OCHMAN

3.3.3 The Genus *Escherichia* 60
RODNEY A. WELCH

3.3.4 The Genus *Edwardsiella* 72
SHARON L. ABBOTT and J. MICHAEL JANDA

3.3.5 The Genus *Citrobacter* 90
DIANA BORENSHTEIN and DAVID B. SCHAUER

3.3.6 The Genus *Shigella* 99
YVES GERMANI and PHILIPPE J. SANSONETTI

3.3.7 The Genus *Salmonella* 123
CRAIG D. ELLERMEIER and JAMES M. SLAUCH

3.3.8 The Genus *Klebsiella* 159
SYLVAIN BRISSE, FRANCINE GRIMONT and PATRICK A. D. GRIMONT

3.3.9 The Genus *Enterobacter* 197
FRANCINE GRIMONT and PATRICK A. D. GRIMONT

3.3.10 The Genus *Hafnia* 215
MEGAN E. MCBEE and DAVID B. SCHAUER

3.3.11 The Genus *Serratia* 219
FRANCINE GRIMONT and PATRICK A. D. GRIMONT

3.3.12 The Genera *Proteus*, *Providencia*, and *Morganella* 245
JIM MANOS and ROBERT BELAS

3.3.13 *Y. enterocolitica* and *Y. pseudotuberculosis* 270
ELISABETH CARNIEL, INGO AUTENRIETH, GUY CORNELIS, HIROSHI FUKUSHIMA, FRANÇOISE GUINET, RALPH ISBERG, JEANNETTE PHAM, MICHAEL PRENTICE, MICHEL SIMONET, MIKAEL SKURNIK and GEORGES WAUTERS

3.3.14 *Yersinia pestis* and Bubonic Plague 399
ROBERT BRUBAKER

3.3.15 *Erwinia* and Related Genera 443
CLARENCE I. KADO

3.3.16 The Genera *Photorhabdus* and *Xenorhabdus* 451
NOEL BOEMARE and RAYMOND AKHURST

3.3.17 The Family Vibrionaceae 495
J. J. FARMER, III

3.3.18 The Genera *Vibrio* and *Photobacterium* 508
J. J. FARMER, III and F. W. HICKMAN-BRENNER

3.3.19 The Genera *Aeromonas* and *Plesiomonas* 564
J. J. FARMER, III, M. J. ARDUINO and F. W. HICKMAN-BRENNER

3.3.20 The Genus *Alteromonas* and Related Proteobacteria 597
VALERY V. MIKHAILOV, LYUDMILA A. ROMANENKO and ELENA P. IVANOVA

3.3.21 Nonmedical: *Pseudomonas* 646
EDWARD R. B. MOORE, BRIAN J. TINDALL, VITOR A. P. MARTINS DOS SANTOS, DIETMAR H. PIEPER, JUAN-LUIS RAMOS and NORBERTO J. PALLERONI

3.3.22 *Pseudomonas aeruginosa* 704
TIMOTHY L. YAHR and MATTHEW R. PARSEK

3.3.23 Phytopathogenic Pseudomonads and Related Plant-Associated Pseudomonads 714
MILTON N. SCHROTH, DONALD C. HILDEBRAND and NICKOLAS PANOPOULOS

3.3.24 *Xylophilus* 741
ANNE WILLEMS and MONIQUE GILLIS

3.3.25 The Genus *Acinetobacter* 746
KEVIN TOWNER

3.3.26 The Family Azotobacteraceae 759
JAN HENDRICK BECKING

3.3.27 The Genera *Beggiatoa* and *Thioploca* 784
ANDREAS TESKE and DOUGLAS C. NELSON

3.3.28 The Family Halomonadaceae 811
DAVID R. ARAHAL and ANTONIO VENTOSA

3.3.29 The Genus *Deleya* 836
KAREL KERSTERS

3.3.30 The Genus *Frateuria* 844
JEAN SWINGS

3.3.31 The Chromatiaceae 846
JOHANNES F. IMHOFF

3.3.32 The Family Ectothiorhodospiraceae 874
JOHANNES F. IMHOFF

3.3.33 *Oceanospirillum* and Related Genera 887
JOSÉ M. GONZÁLEZ and WILLIAM B. WHITMAN

3.3.34 *Serpens flexibilis*: An Unusually Flexible Bacterium 916
ROBERT B. HESPELL

3.3.35 The Genus *Psychrobacter* 920
JOHN P. BOWMAN

3.3.36 The Genus *Leucothrix* 931
THOMAS D. BROCK

3.3.37 The Genus *Lysobacter* 939
HANS REICHENBACH

3.3.38 The Genus *Moraxella* 958
JOHN P. HAYS

3.3.39 *Legionella* Species and Legionnaire's Disease 988
PAUL H. EDELSTEIN and NICHOLAS P. CIANCIOTTO

3.3.40 The Genus *Haemophilus* 1034
DORAN L. FINK and JOSEPH W. ST. GEME, III

3.3.41 The Genus *Pasteurella* 1062
HENRIK CHRISTENSEN and MAGNE BISGAARD

3.3.42 The Genus *Cardiobacterium* 1091
SYDNEY M. HARVEY and JAMES R. GREENWOOD

3.3.43 The Genus *Actinobacillus* 1094
JANET I. MACINNES and EDWARD T. LALLY

3.3.44 The Genus *Francisella* 1119
FRANCIS NANO and KAREN ELKINS

3.3.45 Ecophysiology of the Genus *Shewanella* 1133
KENNETH H. NEALSON and JAMES SCOTT

3.3.46 The Genus *Nevskia* 1152
HERIBERT CYPIONKA, HANS-DIETRICH BABENZIEN, FRANK OLIVER GLÖCKNER and RUDOLF AMANN

3.3.47 The Genus *Thiomargarita* 1156
HEIDE N. SCHULZ

Index 1165

Volume 7

3. Proteobacteria

3.4 Delta Subclass

3.4.1 The Genus *Pelobacter* 5
BERNHARD SCHINK

3.4.2 The Genus *Bdellovibrio* 12
EDOUARD JURKEVITCH

3.4.3 The Myxobacteria 31
LAWRENCE J. SHIMKETS, MARTIN DWORKIN and HANS REICHENBACH

3.5. Epsilon Subclass

3.5.1 The Genus *Campylobacter* 119
TRUDY M. WASSENAAR and DIANE G. NEWELL

3.5.2 The Genus *Helicobacter* 139
JAY V. SOLNICK, JANI L. O'ROURKE, PETER VAN DAMME and ADRIAN LEE

3.5.3 The Genus *Wolinella* 178
JÖRG SIMON, ROLAND GROSS, OLIVER KLIMMEK and ACHIM KRÖGER

4. Spirochetes

4.1 Free-Living Saccharolytic Spirochetes: The Genus *Spirochaeta* 195
SUSAN LESCHINE, BRUCE J. PASTER and ERCOLE CANALE-PAROLA

4.2 The Genus *Treponema* 211
STEVEN J. NORRIS, BRUCE J. PASTER, ANNETTE MOTER and ULF B. GÖBEL

4.3 The Genus *Borrelia* 235
MELISSA J. CAIMANO

4.4 The Genus *Leptospira* 294
BEN ADLER and SOLLY FAINE

4.5 Termite Gut Spirochetes 318
JOHN A. BREZNAK and JARED R. LEADBETTER

4.6 The Genus *Brachyspira* 330
THADDEUS B. STANTON

5. Chlorobiaceae

5.1 The Family Chlorobiaceae 359
JÖRG OVERMANN

6. Bacteroides and Cytophaga Group

6.1 The Medically Important *Bacteroides* spp. in Health and Disease 381
C. JEFFREY SMITH, EDSON R. ROCHA and BRUCE J. PASTER

6.2 The Genus *Porphyromonas* 428
FRANK C. GIBSON and CAROLINE ATTARDO GENCO

6.3 An Introduction to the Family Flavobacteriaceae 455
JEAN-FRANÇOIS BERNARDET and YASUYOSHI NAKAGAWA

6.4 The Genus *Flavobacterium* 481
JEAN-FRANÇOIS BERNARDET and JOHN P. BOWMAN

6.5 The Genera *Bergeyella* and *Weeksella* 532
CELIA J. HUGO, BRITA BRUUN and PIET J. JOOSTE

6.6 The Genera *Flavobacterium*, *Sphingobacterium* and *Weeksella* 539
BARRY HOLMES

6.7 The Order Cytophagales 549
HANS REICHENBACH

6.8 The Genus *Saprospira* 591
HANS REICHENBACH

6.9 The Genus *Haliscomenobacter* 602
EPPE GERKE MULDER and MARIA H. DEINEMA

6.10 *Sphingomonas* and Related Genera 605
DAVID L. BALKWILL, J. K. FREDRICKSON and M. F. ROMINE

6.11 The Genera *Empedobacter* and Myroides 630
CELIA J. HUGO, BRITA BRUUN and PIET J. JOOSTE

6.12 The Genera *Chryseobacterium* and *Elizabethkingia* 638
JEAN-FRANÇOIS BERNARDET, CELIA J. HUGO and BRITA BRUUN

6.13 The Marine Clade of the Family Flavobacteriaceae: The Genera Aequorivita, Arenibacter, Cellulophaga, Croceibacter, Formosa, Gelidibacter, Gillisia, Maribacter, Mesonia, Muricauda, Polaribacter, Psychroflexus, Psychroserpens, Robiginitalea, Salegentibacter, Tenacibaculum, Ulvibacter, Vitellibacter and Zobellia 677
JOHN P. BOWMAN

6.14 Capnophilic Bird Pathogens in the Family Flavobacteriaceae: Riemerella, Ornithobacterium and Coenonia 695
PETER VAN DAMME, H. M. HAFEZ and K. H. HINZ

6.15 The Genus *Capnocytophaga* 709
E. R. LEADBETTER

6.16 The Genera *Rhodothermus*, *Thermonema*, *Hymenobacter* and *Salinibacter* 712
AHARON OREN

7. Chlamydia

7.1 The Genus *Chlamydia*—Medical 741
MURAT V. KALAYOGLU and GERALD I. BYRNE

8. Planctomyces and Related Bacteria

8.1 The Order Planctomycetales, Including the Genera *Planctomyces*, *Pirellula*, *Gemmata and Isosphaera* and the Candidatus Genera *Brocadia*, *Kuenenia* and *Scalindua* 757
NAOMI WARD, JAMES T. STALEY, JOHN A. FUERST, STEPHEN GIOVANNONI, HEINZ SCHLESNER and ERKO STACKEBRANDT

9. Thermus

9.1 The Genus *Thermus* and Relatives 797
MILTON S. DA COSTA, FREDERICK A. RAINEY and M. FERNANDA NOBRE

10. Chloroflexaceae and Related Bacteria

10.1 The Family Chloroflexaceae 815
SATOSHI HANADA and BEVERLY K. PIERSON

10.2 The Genus *Thermoleophilum* 843
JEROME J. PERRY

10.3 The Genus *Thermomicrobium* 849
JEROME J. PERRY

10.4 The Genus *Herpetosiphon* 854
NATUSCHKA LEE and HANS REICHENBACH

11. Verrucomicrobium

11.1 The Phylum Verrucomicrobia: A Phylogenetically Heterogeneous Bacterial Group 881
HEINZ SCHLESNER, CHERYL JENKINS and JAMES T. STALEY

12. Thermotogales

12.1 Thermotogales 899
ROBERT HUBER and MICHAEL HANNIG

13. Aquificales

13.1 Aquificales 925
ROBERT HUBER and WOLFGANG EDER

14. Phylogenetically Unaffiliated Bacteria

14.1 Morphologically Conspicuous Sulfur-Oxidizing Eubacteria 941
JAN W. M. LA RIVIÈRE and KARIN SCHMIDT

14.2 The Genus *Propionigenium* 955
BERNHARD SCHINK

14.3 The Genus *Zoogloea* 960
PATRICK R. DUGAN, DAPHNE L. STONER and HARVEY M. PICKRUM

14.4 Large Symbiotic Spirochetes: *Clevelandina*, *Cristispira*, *Diplocalyx*, *Hollandina* and *Pillotina* 971
LYNN MARGULIS and GREGORY HINKLE

14.5 *Streptobacillus moniliformis* 983
JAMES R. GREENWOOD and SYDNEY M. HARVEY

14.6 The Genus *Toxothrix* 986
PETER HIRSCH

14.7 The Genus *Gallionella* 990
HANS H. HANERT

14.8 The Genera *Caulococcus* and *Kusnezovia* 996
JEAN M. SCHMIDT and GEORGI A. ZAVARZIN

14.9 The Genus *Brachyarcus* 998
PETER HIRSCH

14.10 The Genus *Pelosigma* 1001
PETER HIRSCH

14.11 The Genus *Siderocapsa* (and Other Iron- and Maganese-Oxidizing Eubacteria) 1005
HANS H. HANERT

14.12 The Genus *Fusobacterium* 1016
TOR HOFSTAD

14.13 Prokaryotic Symbionts of Amoebae and Flagellates 1028
KWANG W. JEON

Introduction to the Proteobacteria

KAREL KERSTERS, PAUL DE VOS, MONIQUE GILLIS, JEAN SWINGS, PETER VANDAMME AND ERKO STACKEBRANDT

Introduction

Within the domain Bacteria, the phylum Proteobacteria constitutes at present the largest and phenotypically most diverse phylogenetic lineage. In 1988, Stackebrandt et al. named the Proteobacteria after the Greek god Proteus, who could assume many different shapes, to reflect the enormous diversity of morphologies and physiologies observed within this bacterial phylum. In 2002, the Proteobacteria consist of more than 460 genera and more than 1600 species, scattered over 5 major phylogenetic lines of descent known as the classes "Alphaproteobacteria," "Betaproteobacteria," "Gammaproteobacteria," "Deltaproteobacteria" and "Epsilonproteobacteria." The Proteobacteria account for more than 40% of all validly published prokaryotic genera and encompass a major proportion of the traditional Gram-negative bacteria, show extreme metabolic diversity, and are of great biological importance, as they include the majority of the known Gram-negatives of medical, veterinary, industrial and agricultural interest. Moreover, not only can the origin of mitochondria be traced back to the "Alphaproteobacteria," but several representatives are ecologically important because they play key roles in the carbon, sulfur and nitrogen cycles on our planet. In this context, the purple nonsulfur bacteria and the rhizobia (both members of the "Alphaproteobacteria") are two of the most apparent and well-known examples, because the former are purple-colored photosynthetic prokaryotes using light as energy source, and the latter are able to reduce atmospheric nitrogen gas when living in symbiosis with leguminous plants. Agriculture and life on earth would be very different in the absence of these nitrogen-fixing rhizobia!

The Proteobacteria, formerly known as "purple bacteria and relatives," are characterized by a bewildering diversity of morphological and physiological types: besides rods and cocci, curved, spiral, ring-shaped, appendaged, filamentous and sheathed bacteria occur among this phylum. Most Proteobacteria are mesophilic, but some thermophilic (e.g., *Thiomonas thermosulfata* and *Tepidomonas*) and psychrophilic (e.g., *Polaromonas*) representatives have been described. A great number of Proteobacteria are motile by means of polar or peritrichous flagella, whereas the myxobacteria (belonging to the "Deltaproteobacteria") display a gliding type of motility and show highly complex developmental lifestyles, whereby often remarkable multicellular and macroscopic structures (so-called "fruiting bodies") are formed. Most of the known Proteobacteria are free-living; some (such as the rhizobia) enter in symbiotic associations with specific leguminous plants, where they fix nitrogen in root or stem nodules. Others live as intracellular endosymbionts of protozoa and invertebrates (mussels, insects and nematodes), whereas the rickettsiae are obligate intracellular parasites of humans or mammals. The extreme diversity of energy-generating mechanisms is a unique biochemical characteristic of the Proteobacteria: some are chemoorganotrophs (e.g., *Escherichia coli*), others are chemolithotrophs (e.g., the sulfur-oxidizing bacteria such as the thiobacilli and the ammonia-oxidizing bacteria such as *Nitrosomonas*) or phototrophs (e.g., the purple colored *Chromatium*, *Rhodospirillum* and many others). Concerning their relationship towards oxygen, the Proteobacteria include strictly aerobic and anaerobic species as well as facultative aerobes and microaerophiles. Denitrifiers are reported among the "Alphaproteobacteria," "Betaproteobacteria," "Gammaproteobacteria," and the "Epsilonproteobacteria." To reveal the extreme phenotypic biodiversity among the Proteobacteria, Table 1 gives an overview of the distribution of the five phylogenetic proteobacterial groups among 13 major phenotypic groups as defined in the 9th edition of *Bergey's Manual of Determinative Bacteriology* (Holt et al., 1994). Table 1 clearly shows that only three of these 13 phenotypic groups are unique to any one of the current proteobacterial classes. Representatives of some of these 13 phenotypic groups occur also among several other prokaryotic phyla.

Table 1. The occurrence of major phenotypic groups among the five classes of the Proteobacteria.

Phenotypic group[a]	Group nr.[a]	Occurring in proteobacterial class:
Aerobic/microaerophilic, motile, helical/vibrioid Gram-negative bacteria	2	α, β, γ, δ and ε
Gram-negative aerobic/microaerophilic rods and cocci	4	α, β, γ, δ and ε
Facultatively anaerobic Gram-negative rods	5	α, β, γ, δ and ε
Anaerobic straight, curved, and helical Gram-negative rods	6	β, γ and δ
Symbiotic and parasitic bacteria of vertebrate and invertebrate species	9	α and γ
Anoxygenic phototrophic bacteria	10	α, β and γ
Aerobic chemolithotrophic bacteria and associated genera	12	β, γ and ε
Budding and/or appendaged nonphototrophic bacteria	13	α and γ
Nonphotosynthetic, nonfruiting gliding bacteria	15	β and γ
Nonmotile or rarely motile, curved Gram-negative bacteria	3	α and ε
Dissimilatory sulfate- or sulfur-reducing bacteria	7	δ
Sheathed bacteria	14	β
Fruiting gliding bacteria	16	δ

[a]Phenotypic groups and group numbers are according to *Bergey's Manual of Determinative Bacteriology* (Holt et al., 1994). See also Garrity and Holt (2001).

This chapter sketches how and why the Proteobacteria were recognized as a coherent but diverse phylogenetic group and summarizes its phylogenetic structure as well as its phenotypic and ecological diversity.

Towards a Phylogenetic Definition of the "Purple Bacteria and Their Nonphototrophic Relatives"

In the context of the above mentioned extreme biodiversity of the Proteobacteria, it is not surprising that some 50 years ago—when only phenotypic techniques were available for characterization and comparison of prokaryotes—it was impossible to foresee that morphologically and physiologically highly different bacterial groups such as the Enterobacteriaceae and the photosynthetic purple sulfur bacteria (e.g., *Chromatium*) would be phylogenetically more closely related to each other, whereas morphologically similar bacteria such as the Enterobacteriaceae and the flavobacteria would harbor widely different genomes. Microbiologists possessed in those years only tools to look at the tips of the evolutionary branches of the tree of life. About 15 years prior to the introduction of ribosomal RNA analysis as a suitable method for determining prokaryote evolution, two different approaches were followed aiming at the same goal. The physiologists used the deductive strategy, trying to establish the phylogeny of prokaryotes from selected metabolic properties (Broda, 1970; Broda, 1975), while geneticists and biochemists followed the inductive strategy, originating from the pioneering publication by Zuckerkandl and Pauling (1965).

The question about the origin of bacterial respiration placed the photosynthetic bacteria, especially the anoxygenic "purple bacteria," in the center of discussion. To be more precise, the problem was how respiration could evolve in parallel in so many groups of organisms and independently from that evolved in cyanobacteria. The similarity of the electron-flow chains in photosynthesis and respiration as an ordered assembly of flavoproteins, cytochromes, quinones and non-heme Fe-S proteins in connection with membranes has been noted (Olson, 1970), and it was proposed that the photosynthetic chain could have been modified and adapted to respiration. It was Broda (1970) who concluded that respiration evolved independently from different kinds of photosynthetic apparatus, and if photosynthetic bacteria themselves evolved in different lines of descent, so would the aerobic respiring bacteria. This "conversion" hypothesis placed significant emphasis on the presence of phototrophic bacteria in various lines of descent and focused on the evolution of electron chains from photosynthetic anaerobes, anaerobic respirers, and aerobes ranging from phototrophic aerobes to strictly aerobic respirers. Broda's hypothesis, later supported (though refined) by the general phylogenetic frame of ribosomal RNA/DNA sequences, is illustrated by two examples. Firstly, he postulated the existence of a Gram-positive phototroph, later proven by the isolation of the phylogenetically Gram-positive *Heliobacterium chlorum* (Gest and Favinger, 1983; Woese et al., 1985a), branching deeply in the *Clostridium* lineage. Secondly, early 16S rRNA cataloguing data indicated the high phylogenetic similarity between the nonsulfur purple bacterium *Rhodopseudomonas palustris* and the aerobic *Nitrobacter winogradskyi* (Seewaldt et al., 1982). However, Broda (1975) was not in a position to predict the specific phylogenetic clustering of the purple sulfur and the purple nonsulfur bacteria as opposed to the lin-

eages of green sulfur bacteria, the green nonsulfur bacteria, and the cyanobacteria. Also, as they had not been described in the 1970s, the aerobic bacteriochlorophyll *a*-containing bacteria (α-3 and α-4 groups and a few in the "Betaproteobacteria") are not mentioned in the conversion hypothesis. Modifications to the outline of biochemical pathways given by Broda have been made by Schwemmler (1989), combining rRNA-based phylogenetic relatedness between species and the biochemistry of components of electron chains involved in aerobic respiration and anaerobic and aerobic photosynthesis.

Zuckerkandl and Pauling (1965) highlighted the importance of using semantides, such as genomic DNA, its primary transcript RNA, and the translation product, the proteins, as evolutionary markers. They postulated that the path of evolution is laid down in the primary structure of nucleic acids and determination of the blueprint of evolutionary conservative genes would necessarily unravel the evolutionary history of organisms. Owing to methodological restrictions, proteins rather than DNA or RNA were accessible to sequence analyses, restricting early molecular studies to those proteins easily isolated and sequenced. Besides histones and fibrinopeptides, used in the determination of the rate of gene evolution in eukaryotes, primarily proteins such as ferredoxin and cytochrome *c* allowed the first glimpse of the evolution of prokaryotic genes. While the ferredoxin data were obtained for mainly Gram-positive anaerobic bacteria and cyanobacteria, cytochrome *c* sequences were generated for respiring organisms as well as for anaerobic and aerobic photosynthetic bacteria (Schwartz and Dayhoff, 1978; Ambler et al., 1979) as well as for mitochondria, the origin of which could be traced to members of the "Alphaproteobacteria." Surprising to taxonomists, the clustering of species according to the primary and tertiary structure of proteins (Dickerson, 1980) did not correlate with the traditional systematic groupings such as those laid down in *Bergey's Manual of Determinative Bacteriology* (Buchanan and Gibbons, 1974). It was especially the phylogenetic closeness between Gram-negative, nonphototrophic organisms and phototrophs that shed doubts on the correctness of the sequence-based findings. However, shortly afterwards, results from the 16S rRNA cataloguing approach, fully supporting the protein-based studies, demonstrated the obvious failure of the phenotype to mirror phylogenetic relatedness. Some 30 years ago, the pioneering studies on 16S rRNA oligonucleotide cataloguing by Woese and coworkers (Fox et al., 1977; Woese and Fox, 1977) revolutionized the insights in microbial evolution, in particular, and evolution of life on earth, in general. The purple bacteria (nowadays named Proteobacteria) were first recognized and circumscribed as a distinct division (phylum) of the eubacteria by Woese and coworkers on the basis of signature and sequence analyses of the 16S rRNA/rDNA (Gibson et al., 1979; Fox et al., 1980; Woese et al., 1985b; Woese, 1987). Because the purple photosynthetic phenotype was distributed throughout the group the trivial name "purple bacteria" seemed to be justified for this phylogenetic group of Gram-negatives (Woese, 1987), although many nonphotosynthetic species (such as the enterics, the pseudomonads, rhizobia, rickettsiae, etc.) grouped among the photosynthetic representatives. The oligonucleotide signature analysis of 16S rRNAs revealed already in the 1980s that the purple bacteria comprised at least three major subdivisions, arbitrarily designated as α, β and γ. The purple nonsulfur (PNS) bacteria (e.g., *Rhodospirillum*, *Rhodobacter* and *Rhodocyclus*) were found in two subdivisions (α and β; Woese et al., 1984a; Woese et al., 1984b), whereas the purple sulfur (PS) bacteria (e.g., *Chromatium* and *Ectothiorhodospira*) belonged to the γ-subdivision (Woese et al., 1985c). When more Gram-negatives were investigated by rRNA-cataloguing, rDNA-sequencing and also by the DNA/rRNA hybridization technique, it became clear that the majority of the so-called purple bacteria were in fact nonphotosynthetic prokaryotes. Without being able to trace the deeper phylogenetic relationships, De Ley and coworkers (reviewed by De Ley, 1992) studied hundreds of Gram-negatives by the DNA/rRNA hybridization technique, which allowed their relative phylogenetic position within the various rRNA-branches to be determined. The α, β and γ groups corresponded to the rRNA superfamilies IV, III and I+II, respectively, as defined by De Ley and coworkers (De Vos and De Ley, 1983; De Vos et al., 1985; De Vos et al., 1989; De Ley et al., 1986; Jarvis et al., 1986; Rossau et al., 1986; Willems et al., 1991a; De Ley, 1992). The DNA/rRNA hybridization approach together with the application of various genomic and phenotypic techniques (i.e., the polyphasic approach; Colwell, 1970; Vandamme et al., 1996) allowed improvement of the classification of various Gram-negative taxa, such as the pseudomonads (De Vos and De Ley, 1983; De Vos et al., 1985; De Vos et al., 1989; Willems et al., 1991a; De Ley, 1992; Kersters et al., 1996), *Alcaligenes* and *Bordetella* (Kersters and De Ley, 1984; De Ley et al., 1986), the Pasteurellaceae (De Ley et al., 1990), the Neisseriaceae and Moraxellaceae (Rossau et al., 1986; Rossau et al., 1991), the Acetobacteraceae (Gillis and De Ley, 1980; De Ley and Gillis, 1984; Swings, 1992), the Campylobacteraceae (Vandamme and De Ley, 1991) and many others.

During the last 15 years, the knowledge concerning the phylogeny of the Gram-negatives gradually became more comprehensive by the availability of an increasing number of nearly complete 16S rRNA sequences, indicating that the Gram-negative sulfur- and sulfate-reducing bacteria form a fourth group or δ-subdivision among the purple bacteria together with the myxobacteria and the bdellovibrios (Oyaizu and Woese, 1985; Woese, 1987). Because the majority of the genera belonging to the purple bacteria are not purple and not photosynthetic, Stackebrandt et al. proposed in 1988 the name "Proteobacteria" for a new higher taxon (at the level of class), including these purple bacteria and their relatives; the α to δ groups were temporarily considered as subclasses, pending further studies and nomenclatural proposals. Later some microaerophilic and helical-shaped bacteria such as the campylobacters were placed in the fifth or ε-subclass, corresponding to rRNA-superfamily VI of De Ley's research group (Vandamme and De Ley, 1991; Stackebrandt, 1992).

Each new issue of the *International Journal of Systematic and Evolutionary Microbiology* adds new genera and species to the Proteobacteria, entailing a more bush-like rRNA/rDNA-tree topology. Yet, the distinctness of the subclasses seems to be maintained, although the differentiation between the β- and the γ-group is becoming less clear, and some rDNA-based trees indicate that *Desulfurella* and allied bacteria of the δ-group may constitute a sixth subdivision (Rainey et al., 1993). In the second edition of *Bergey's Manual of Systematic Bacteriology* (Garrity, 2001a), the Proteobacteria have been elevated to the rank of phylum and the subclasses α to ε have been elevated to the rank of classes, corresponding to the names "Alphaproteobacteria," "Betaproteobacteria," "Gammaproteobacteria," "Deltaproteobacteria," and "Epsilonproteobacteria," respectively (see Table 2). In a recently revised megaclassification of the prokaryotes, Cavalier-Smith (2002) proposes a new classification and nomenclature for the five major subgroups of the Proteobacteria (see Table 2).

In the present chapter, we follow the classification of the major reference work, *Bergey's Manual of Systematic Bacteriology* (Garrity, 2001), and will use ranks and names as listed in Table 2 (2nd column).

Is the 16S-rRNA-based Phylogeny of the Proteobacteria Confirmed by Other Experimental Approaches?

The first indications that the traditional groupings of the Gram-negative bacteria according to the previous editions of *Bergey's Manual of Systematic Bacteriology* (Buchanan and Gibbons, 1974; Krieg and Holt, 1984) and *Bergey's Manual of Determinative Bacteriology* (Holt et al., 1994) were not phylogenetic came from comparative sequence analysis of some redox proteins, such as cytochrome *c* [Introduction]. Also studies by Byng et al. (1983) on the regulation of multibranched pathways for the biosynthesis of aromatic amino acids indicated that some members of the genus *Pseudomonas*, such as *P. testosteroni* and *P. solanacearum*, were more similar to other genera than to the group of species around the type species *Pseudomonas aeruginosa* (belonging to the "Gammaproteobacteria"), which is in perfect agreement with rRNA/rDNA data. Later, *Pseudomonas testosteroni* and *P. solanacearum* (both belonging to the "Betaproteobacteria") were indeed transferred to the genera *Comamonas* and *Ralstonia*, respectively (Tamaoka et al., 1987; Yabuuchi et al., 1995).

The definition of the Proteobacteria as a separate evolutionary lineage and the overall picture of the grouping in five classes are confirmed by comparative analysis of 23S rRNA-genes and alternative phylogenetic markers such as the genes coding for elongation factor Tu and

Table 2. Three systems of Proteobacteria classification: correspondence between the names of taxa above the rank of order.

Classification		
1[a]	2[b]	3[c]
Class Proteobacteria	Phylum Proteobacteria	Division Proteobacteria
		Subdivision Rhodobacteria
Subclass alpha	Class "Alphaproteobacteria"[d]	Class Alphabacteria
Subclass beta	Class "Betaproteobacteria"	Class Chromatibacteria
Subclass gamma	Class "Gammaproteobacteria"	
		Subdivision Thiobacteria
Subclass delta	Class "Deltaproteobacteria"	Class Deltabacteria
Subclass epsilon	Class "Epsilonproteobacteria"	Class Epsilobacteria

[a]From Stackebrandt et al. (1988b).
[b]From *Bergey's Manual of Systematic Bacteriology* (Garrity, 2001).
[c]From Cavalier-Smith (2002).
[d]Quotation marks are used for names that have not yet been validated.

ATPase (Ludwig et al., 1995; Ludwig and Schleifer, 1999; Ludwig and Klenk, 2001). Moreover, the comparative analysis of conserved insertions and deletions (so-called "signature sequences") found in different bacterial proteins yielded molecular means to define the phylum Proteobacteria and its various classes and improved the understanding of their evolutionary relationships to other groups of Bacteria and Eukarya (Gupta, 2000; Gupta, 2002). Proteins studied were, e.g., alanyl-tRNA synthetase, succinyl-CoA synthetase, Hsp 60 (GroEL), Hsp70 heat shock protein, and *recA* protein. The listing of extensive literature on this subject would be unjustifiable in the context of this chapter (see Gupta, 2000). The proteobacterial classes emerged in the following order during evolution (Gupta, 2000): epsilon and delta → alpha → beta → gamma, which is similar to the order proposed on the basis of RNA polymerase β and β′ subunits (Klenk et al., 1999). Indeed, the ribosomal DNA tree does not clearly resolve the order in which the majority of main lineages emerged during evolution. Proteobacteria, Gram-positive bacteria, *Cyanobacteria*, Cytophaga/Flavobacteria and some other minor lineages appear to evolve at the same node, giving the rDNA-tree a fork-like appearance. The branching order of the various main lines of descent as depicted by Gupta (2000) is different. Gupta places the low G+C Gram-positive bacteria (clostridia) at the base of bacterial evolution, while those organisms constituting the base of the bacterial 16S rDNA tree (*Aquifex*, *Deinococcus-Thermus*, and green sulfur bacteria) are described as having evolved later. Proteobacteria appear as the last evolutionary group. The importance of the proteobacterial cell is highlighted not only as the donor of the mitochondria (Margulis, 1993; Falah and Gupta, 1994), but also as one of the fusion partners (the other being a archaeal cell) giving rise to the ancestral eukaryotic cell (see Gupta [2000] for an extensive list of references). More genes and complete genomes will have to be sequenced to determine the extent and relative time of lateral gene transfer and to highlight those genes that represent the core of genes transmitted vertically, hence representing the evolutionarily stable component of the cell.

So far, no reliable phenotypic features were found that would be characteristic for the whole phylum of the Proteobacteria and differentiate it from other phyla of the domain Bacteria. It seems also very difficult to find stable phenotypic features for the differentiation of the five classes, which is not surprising in view of the enormous variety of morphological and physiological types existing in each of these five lineages. Phototrophy cannot be used as phylogenetic marker, except that PNS- and PS-bacteria are only reported so far among the Proteobacteria, which could indicate that this type of photosynthesis was common in the proteobacterial ancestors and was lost during evolution in a great number of sublineages. Support for the validity of some of the results of nucleic acid and protein sequencing came from chemotaxonomy. Within the "Alphaproteobacteria," *Rhodopseudomonas palustris*, *Nitrobacter winogradskyi*, *Blastochloris (Rhodopseudomonas) viridis*, *Phenylobacterium immobile*, certain thiobacilli, *Brucella melitensis* and *Brevundimonas (Pseudomonas) diminuta* exhibited an unusual lipid A, which lacked glucosamine but contained instead a 2,3-diamino-2,3-dideoxy-D-glucose (Stackebrandt et al., 1988a). This structure was not uniformly distributed among all members of the "Alphaproteobacteria" but was shared among closely related species. Lipid A composition also confirmed the phylogenetic distinctness of species hitherto affiliated to the same genus on the basis of their phenotype. For example, *Rhodocyclus tenue* and *Rhodocyclus gelatinosa* (members of the "Betaproteobacteria"; Imhoff et al., 1984) differed significantly in the chemistry of their lipid A, a finding that supported the reclassification of the latter species as *Rubrivivax gelatinosus* (Willems et al., 1991b). As far as we could determine from the literature, quinones and polyamines seem to be good marker molecules to differentiate the major proteobacterial lineages (Collins and Jones, 1981; Collins and Widdel, 1986; Busse and Auling, 1988; Auling, 1992; Hamana and Matsuzaki, 1993; Busse et al., 1996; Table 3; Directory, Databases and Dictionaries Compiled by WDCM website (http://www.wdcm.nig.ac.jp/cgi-bin/search.cgi)). Ubiquinones are typical for the α, β and γ lineages, whereas menaquinones are characteristic for the "Deltaproteobacteria" and "Epsilonproteobacteria," although some photosynthetic "Alphaproteobacteria" and "Betaproteobacteria" contain also MK-8, MK-9 or MK-10 (Hiraishi et al., 1984). Some members of the Pasteurellaceae ("Gammaproteobacteria") are characterized by demethylmenaquinones. Gas chromatographic analysis of the methylesters of cellular fatty acids (FAME) does not allow differentiation of the five major lineages. Of course, phenotypic and chemotaxonomic features (e.g., FAME) are very useful for the description and differentiation of species, genera and families, and the polyphasic taxonomic approach integrating all available data (Colwell, 1970; Vandamme et al., 1996) has been applied during the last decade to improve the classification of previously polyphyletic proteobacterial genera, such as *Erwinia* (Hauben et al., 1998), *Pseudomonas* (Kersters et al., 1996; Anzai et al., 2000), *Rhizobium* and allies (de Lajudie et al., 1998), *Thiobacillus* (Kelly and

No single nucleotide signature is found in the 16S rRNA that could serve unambiguously to define the proteobacterial phylum (sensu *Bergey's Manual*). However, specific 16S rRNA sequence signatures for the various classes of the Proteobacteria have been described and used for the construction of DNA probes (Woese, 1987; Stackebrandt et al., 1988b; Manz et al., 1992; Ludwig et al., 1998). Such probes were extensively applied for the detection and visualization of Proteobacteria and other prokaryotes in activated sludge (Wagner et al., 1993; Snaidr et al.,

Table 4. Some rRNA-targeted oligonucleotide probes for fluorescent in-situ hybridization.

Probe	Position	Probe sequence (5′ → 3′)	Specificity	Reference

1997; Juretschko et al., 2002). Table 4 lists the sequence of some representative rRNA-targeted oligonucleotide probes.

The Proteobacterial Classes: Morphological, Physiological, Ecological and Phylogenetic Diversity

Figure 1 is a simplified phylogenetic tree of the Proteobacteria based on the nearly complete 16S rDNA sequences of the type strains of the type species of the majority of proteobacterial genera. Only the names of the families and major groups are indicated. The "Deltaproteobacteria" and "Epsilonproteobacteria" form the deeper branches of the phylum; the "Alphaproteobacteria" are also clearly separated, whereas the closer relationship between the β and γ lineages may indicate the common origin of the latter groups (Ludwig and Klenk, 2001).

Phototrophic bacteria occur only in the "Alphaproteobacteria," "Betaproteobacteria" and "Gammaproteobacteria" (purple colored triangles in Fig. 1); these anoxygenic phototrophic purple bacteria can be subdivided into the purple sulfur (PS; e.g., *Chromatium* and *Ectothiorhodospira*) and purple nonsulfur (PNS) bacteria (e.g., *Rhodospirillum*). All known PS bacteria belong to the "Gammaproteobacteria" and use H_2S or S° as sole electron donor. The PNS bacteria occur among the "Alphaproteobacteria" and "Betaproteobacteria." A great number of phototrophic Proteobacteria are versatile and can easily switch from a phototrophic to a heterotrophic lifestyle in the absence of light. The results of comparative 16S rDNA sequence analysis have led to extensive taxonomic rearrangements within previously defined taxa of proteobacterial phototrophs (Imhoff, 2001a).

In this chapter, we briefly touch on the morphological, physiological, ecological and phylogenetic diversity of the major proteobacterial groups. The reader will find more detailed information in the chapters dealing with the individual families and genera of the Proteobacteria.

An incomplete survey of disease-causing Proteobacteria is given in Table 5 for the bacteria of clinical and veterinary interest and in Table 6 for the phytopathogens. Some examples of industrial and biotechnological applications are listed in Table 7.

The "Alphaproteobacteria"

The 16S rDNA-tree separates the α-class clearly from the other proteobacterial classes (Fig. 1). The bacterial taxa belonging to the "Alphaproteobacteria" (some140 genera and 425 species at present) are morphologically and metabolically extremely diverse. More detailed information can be found in the chapters dealing with the individual families and genera of this class. Table 8 provides an overview of the major phylogenetic groups (see also Fig. 1) and the names of the orders and families of the "Alphaproteobacteria" as they are listed in the 2nd edition of *Bergey's Manual of Systematic Bacteriology* (Garrity, 2001a).

The majority of the "Alphaproteobacteria" are rod-shaped, but cocci and curved, spiral, stalked, budding and prosthecate forms do also occur. Some are phototrophic purple nonsulfur (PNS) bacteria (such as *Rhodospirillum* and *Rhodobacter*), whereas others are chemolithotrophs (e.g., the nitrite-oxidizing *Nitrobacter*) or chemoorganotrophs (e.g., *Sphingomonas* and *Brucella*). Marine and halophilic phototrophic PNS bacteria seem to be restricted to the "Alphaproteobacteria" (Imhoff, 2001b), whereas a physiologically remarkable group of bacteria, containing bacteriochlorophyll (BChl) but unable to grow phototrophically under anaerobic conditions, belongs to various lineages of the "Alphaproteobacteria" (Yurkov and Beatty, 1998; Yurkov, 2001). Except for *Roseateles*, all aerobic BChl-containing bacteria investigated so far are exclusively found within the "Alphaproteobacteria" and appear to be related phylogenetically to aerobic purely chemoorganotrophic bacteria. This could indicate that the presence of

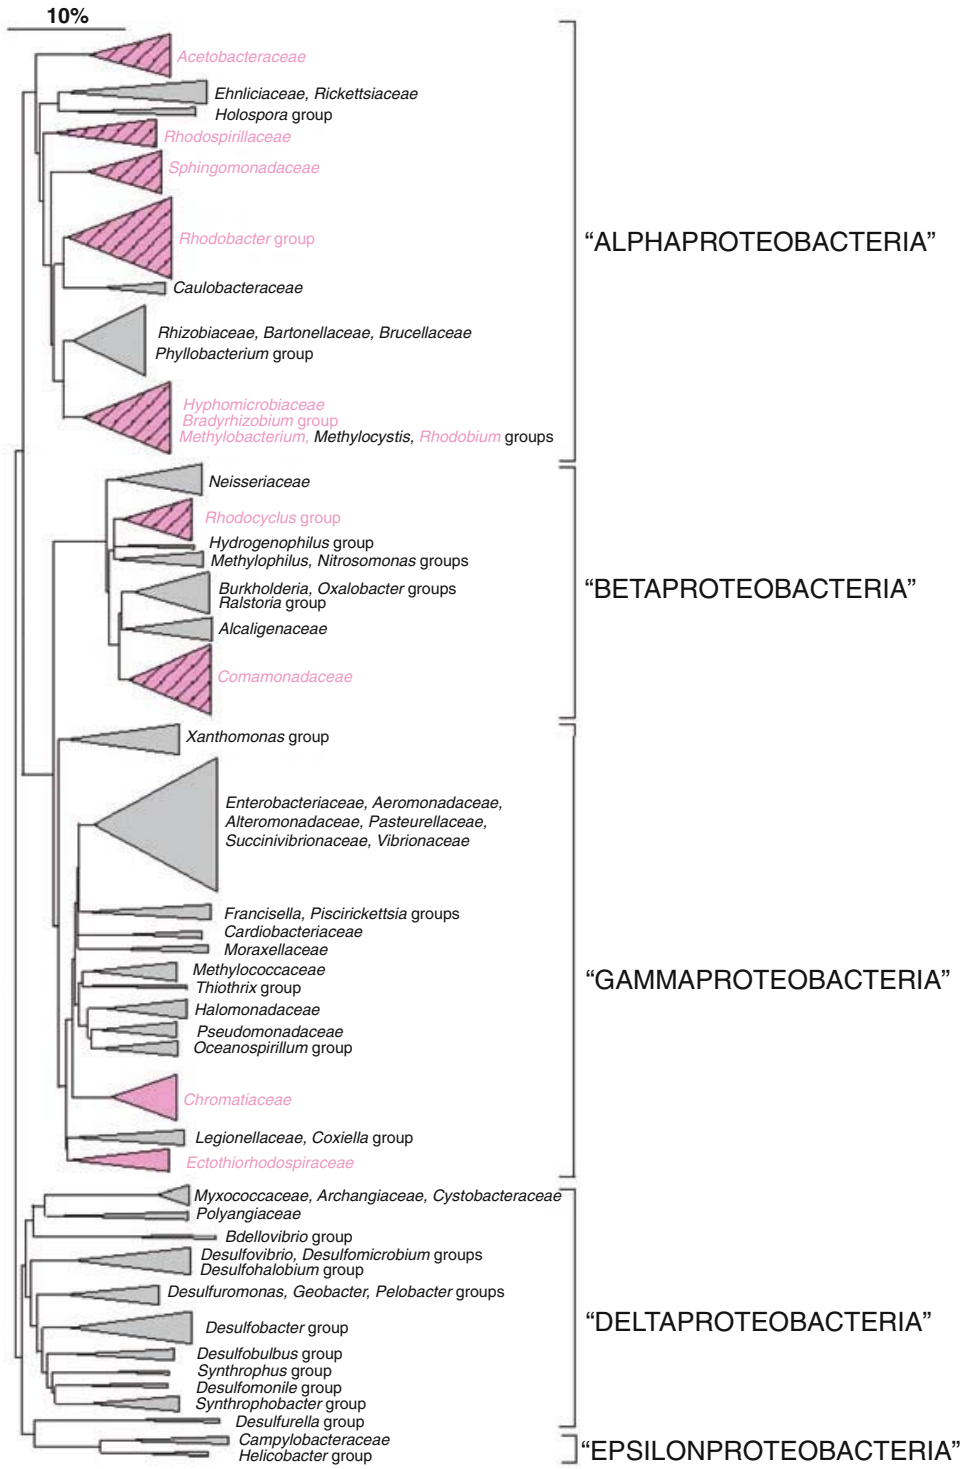

Fig. 1. Simplified neigbor-joining phylogenetic tree of the Proteobacteria based on the 16S rDNA sequences of the type strains of the proteobacterial genera. Distances were calculated using the substitution rate calibration method in TREECON 3.1 (Van de Peer and De Wachter, 1997). The bar indicates 10% estimated sequence divergence. *Bacillus subtilis* was used as outgroup (not shown). The width of the triangles is proportional to the number of genera within each cluster. The purple color indicates clusters where phototrophic bacteria occur: purple sulfur photosynthetics (Chromatiaceae and Ectothiorhodospiraceae) in the "Gammaproteobacteria," purple nonsulfur photosynthetics and aerobic phototrophs in the "Alphaproteobacteria" and "Betaproteobacteria." Shaded purple triangles indicate that most representatives of phototrophic "Alphaproteobacteria" and "Betaproteobacteria" are phylogenetically related to nonphototrophic, strictly chemotrophic bacteria belonging to the respective families or groups. Aerobic phototrophic Proteobacteria were reported among the Acetobacteraceae (sensu lato), the Sphingomonadaceae, the *Rhodobacter*, *Methylobacterium* and *Bradyrhizobium* groups (all "Alphaproteobacteria"), and in the genus *Roseateles* ("Betaproteobacteria," family Comamonadaceae).

Table 5. Some Proteobacteria involved in human and animal disease.

Proteobacterial class and species	Family[a]	Disease (site of action)	Risk group[b]
"Alphaproteobacteria"			
Bartonella henselae	Bartonellaceae	Cat-scratch disease, and bacillary angiomatosis	2
Bartonella quintata	Bartonellaceae	Trench fever	2
Brucella melitensis	Brucellaceae	Abortion (genital tract of animals), and brucellosis in man	3
Ehrlichia chaffeensis	Ehrlichiaceae	Human ehrlichiosis	2
Orientia tsutsugamushi	Rickettsiaceae	Scrub typhus	3
Rickettsia rickettsii	Rickettsiaceae	Rocky Mountain spotted fever	3
Rickettsia prowazekii	Rickettsiaceae	Typhus fever	3
"Betaproteobacteria"			
Bordetella pertussis	Alcaligenaceae	Whooping cough (respiratory tract)	2
Burkholderia mallei	"Burkholderiaceae"	Glander disease in equines	3
Burkholderia pseudomallei	"Burkholderiaceae"	Melioidosis	3
Neisseria gonorrhoeae	Neisseriaceae	Gonorrhoea (genital tract)	2
Neisseria meningitidis	Neisseriaceae	Meningitis (central nervous system)	2
Taylorella equigenitalis	Alcaligenaceae	Endometritis in mares	2
"Gammaproteobacteria"			
Coxiella burnetii	"Coxiellaceae"	Q-fever	3
Escherichia coli	Enterobacteriaceae		
intestinal variants		Diarrhea	2
uropathogenic variants		Urinary tract infections	2
verocytotoxigenic strains		e.g., O157:H7, causing hemorrhagic diarrhea and kidney failure	3
Francisella tularensis	"Francisellaceae"	Tularemia (skin and lymph nodes)	3
Haemophilus influenzae	Pasteurellaceae	Meningitis, pericarditis, and pneumonia	2
Legionella pneumophila	Legionellaceae	Legionnaires' disease (respiratory tract)	2
Pseudomonas aeruginosa	Pseudomonadaceae	Nosocomial infections (skin and respiratory tract, urinary tract)	2
Salmonella typhi	Enterobacteriaceae	Typhoid fever (gastrointestinal tract)	3
Shigella dysenteriae	Enterobacteriaceae	Dysenteria (gastrointestinal tract)	3
Vibrio cholerae	Vibrionaceae	Cholera (gastrointestinal tract)	2
Yersinia pestis	Enterobacteriaceae	Plague (blood)	3
"Epsilonproteobacteria"			
Campylobacter coli, *C. jejuni*	Campylobacteraceae	Diarrhea	2 2
Helicobacter pylori	"Helicobacteraceae"	Duodenal and gastric ulcers, and gastric carcinoma	2

Table 6. Some selected plant diseases caused by Proteobacteria.

Proteobacterial class and species	Family[a]	Disease (symptoms)
"Alphaproteobacteria"		
Agrobacterium rhizogenes	Rhizobiaceae	Hairy root
Agrobacterium tumefaciens	Rhizobiaceae	Crown gall
"*Candidatus* Liberibacter asiaticus"	in cluster of Rhizobiaceae, Bartonellaceae, etc.	Greening disease on citrus (a phloem-restricted disease)
"Betaproteobacteria"		
Acidovorax anthurii	Comamonadaceae	Leaf-spot on *Anthurium*
Burkholderia cepacia	"Burkholderiaceae"	Soft rot (sour skin on onion)
Burkholderia glumae	"Burkholderiaceae"	Sheath necrosis on rice
Ralstonia solanacearum	"Ralstoniaceae"	Moko disease on banana (vascular wilt)
Xylophilus ampelinus	Comamonadaceae	Necrosis and canker on grapevine
"Gammaproteobacteria"		
Brenneria (Erwinia) salicis	Enterobacteriaceae	Watermark disease on willow
Brenneria nigrifluens	Enterobacteriaceae	Bark canker on Persian walnut (*Juglans regia*)
Erwinia amylovora	Enterobacteriaceae	Fire blight on pome fruit (vascular wilt)
Erwinia stewartii	Enterobacteriaceae	Stewart's wilt on corn (vascular wilt)
Pectobacterium (Erwinia) carotovorum	Enterobacteriaceae	Soft rot
Pseudomonas agarici	Pseudomonadaceae	Spots on mushrooms
Pseudomonas marginalis	Pseudomonadaceae	Soft rot (pink eye) on potato
Pseudomonas savastanoi	Pseudomonadaceae	Galls on olive trees
Pseudomonas syringae	Pseudomonadaceae	Wildfire on tobacco, haloblight on beans, spots on tomato and pepper (blights and spots)

Table 6. *Continued*

Proteobacterial class and species	Family[a]	Disease (symptoms)
Pseudomonas syringae	Pseudomonadaceae	Canker on stone fruit
Xanthomonas campestris	"Xanthomonadaceae"	Black rot on crucifers (vascular wilt)
Xanthomonas citri	"Xanthomonadaceae"	Canker on citrus
Xanthomonas oryzae	"Xanthomonadaceae"	Blight on rice
Xanthomonas populi	"Xanthomonadaceae"	Canker on poplar trees
Xanthomonas translucens	"Xanthomonadaceae"	Blight on cereals
Xanthomonas vesicatoria	"Xanthomonadaceae"	Spots on tomato and pepper
Xylella fastidiosa	"Xanthomonadaceae"	Pierce's disease (e.g., on grapevine)

[a]According to *Bergey's Manual of Systematic Bacteriology* (Garrity and Holt, 2001). See also Fig. 1. Quotation marks are used for names which have not yet been validated (as of mid 2002).

Table 7. Some Proteobacteria involved in industrial and biotechnological processes.

Proteobacterial class, genus or species	Family[a]	Industrial product or process
"Alphaproteobacteria"		
Acetobacter aceti	Acetobacteraceae	Vinegar
Acetobacter xylinus	Acetobacteraceae	Cellulose membranes
Agrobacterium	Rhizobiaceae	Plant engineering (Ti-plasmid)
Gluconobacter oxydans	Acetobacteraceae	Oxidation of sorbitol (for vitamin C production)
Rhizobium	Rhizobiaceae	Inoculants for nodule formation on leguminous plants (N_2-fixation)
Rhodobacter capsulatus	"Rhodobacteraceae"	Production of hydrogen gas
Zymomonas mobilis	Sphingomonadaceae	Ethanol
"Betaproteobacteria"		
Ralstonia eutropha	"Ralstoniaceae"	Poly-β-hydroxybutyrate (bioplastics) and single-cell protein
"Gammaproteobacteria"		
Azotobacter	Pseudomonadaceae	Alginates (polysaccharide) and poly-β-hydroxybutyrate (bioplastics)
Chromatium	Chromatiaceae	Production of hydrogen gas
Erwinia herbicola	Enterobacteriaceae	Biological control of frost damage
Escherichia coli	Enterobacteriaceae	Production of heterologous proteins (e.g., insulin, interferon, and antiviral vaccines)
Photobacterium	Vibrionaceae	Luciferase (*lux*-genes)
Pseudomonas	Pseudomonadaceae	Oxidation of aliphatic and aromatic compounds
Acidithiobacillus ferrooxidans	Acidithiobacillus group	Active metal mining (bioleaching)
Xanthomonas campestris	"Xanthomonadaceae"	Xanthan (polysaccharide)

[a]According to *Bergey's Manual of Systematic Bacteriology* (Garrity and Holt, 2001). See also Fig. 1. Quotation marks are used for names which have not yet been validated (as of mid 2002).

Table 8. The "Alphaproteobacteria": orders, families and number of genera.[a]

Order	Family	Number of genera
Rhodospirillales	Rhodospirillaceae	10
	Acetobacteraceae	12
Rickettsiales	Rickettsiaceae	3
	Ehrlichiaceae	5

	"Beijerinckiaceae"	3
	"Bradyrhizobiaceae"	8
	Hyphomicrobiaceae	19
	"Methylobacteriaceae"	3
	"Rhodobiaceae"	1

[a]According to the second edition of *Bergey's Manual of Systematic Bacteriology* (Garrity and Holt, 2001). Quotation marks are used for names which have not yet been validated (as of mid 2002).

BChl in some members of the "Alphaproteobacteria" (e.g., *Erythrobacter* and *Roseobacter*) is an atavistic trait that remained functional after the aerobic bacteria evolved from their anaerobic phototrophic ancestors (Stackebrandt et al., 1996; Yurkov, 2001). Thus, aerobic phototrophic bacteria could represent an intermediate phase of evolution from anaerobic purple phototrophs to nonphotosynthetic aerobic chemotrophs. During the last decade, the classification of a number of classical phototrophic genera, such as *Rhodospirillum* and *Rhodopseudomonas*, underwent considerable changes, which are in agreement with 16S rDNA sequence data, morphological parameters, internal membrane structures as well as important chemotaxonomic parameters, such as the composition of cellular fatty acids, ubiquinones and cytochrome *c*-type structures. Most of the photosynthetic PNS bacteria are also capable of nitrogen fixation.

Classical chemoorganotrophs (such as *Sphingomonas*), as well as typical acidophiles (e.g., *Acetobacter*) and methylotrophs (e.g., *Methylobacterium*) belong to the "Alphaproteobacteria." A great number of α-class members live in association with eukaryotes: some are indeed pathogenic for humans and animals (e.g., *Brucella*) or plants (e.g., *Agrobacterium*), and others display an obligate parasitic lifestyle, cause diseases in humans and mammals, are transmitted by insect or tick bites (e.g., the Rickettsiaceae), or live symbiotically in the roots of leguminous plants (e.g., *Rhizobium* and *Bradyrhizobium*) and play a key role in atmospheric nitrogen fixation. Hence, these "Alphaproteobacteria" thrive in widely divergent habitats and exert a significant impact in the biosphere of our planet. The evolutionary roots of the mitochondrion are within the α-class (see Symbiotic, Parasitic and Not-Yet Cultured Proteobacteria, and the Alphaproteobacterial Origin of Mitochondria), and the understanding of the molecular aspects of plant tumor induction by *Agrobacterium tumefaciens* led to revolutionary applications in plant agriculture, where plant genetic engineers have used the natural transformation system of *Agrobacterium* as a vector for the introduction of foreign DNA into plants (Birch, 1997).

The Acetobacteraceae and the Rhodospirillaceae appear to be the deeper branching lineages among the "Alphaproteobacteria" (Ludwig and Klenk, 2001). In our analysis (Fig. 1), the Ehrlichiaceae and the Rickettsiaceae form also one of the deeper branches.

Acetobacteraceae and Related Groups The Acetobacteraceae form a clearly separate lineage of acidophilic bacteria encompassing the classical vinegar-producing *Acetobacter*, together with *Gluconobacter*, *Gluconacetobacter*, *Acidimonas*, *Acidiphilium*, *Asaia* and some other genera, as well as the phototrophic PNS bacterium *Rhodopila*. Some of the *Gluconacetobacter* species are able to fix nitrogen and live in association with sugar cane (*G. diazotrophicus*) or coffee plants (*G. azotocaptans*; Fuentes-Ramirez et al., 2001).

Rickettsiaceae, Ehrlichiaceae and the Holospora Group The Rickettsiaceae, the Anaplasmataceae and the Ehrlichiaceae form a distinct lineage among the "Alphaproteobacteria" and consist of small intracellular parasitic bacteria, such as *Rickettsia* (causing typhus and Rocky Mountain spotted fever), *Ehrlichia* (causing human granulocytic ehrlichiosis and Potomac fever in horses), *Anaplasma* (infecting erythrocytes of ruminants), and the remarkable *Wolbachia*, involved in parthenogenesis in various arthropods. Although these bacteria can infect various vertebrate hosts, their vectors and reservoirs are predominantly ticks and trematodes, except for the wolbachiae, which are highly promiscuous for diverse invertebrate hosts and are also found in a variety of helminths. On the basis of 16S rDNA gene and *groESL* operon sequence results, Dumler et al. (2001) proposed a reorganization of the genera into the families Rickettsiaceae and Anaplasmataceae: members of the Rickettsiaceae grow in the cytoplasm or nucleus of their eukaryotic host cells and the family is restricted to the genera *Rickettsia* and *Orientia*, whereas members of the Anaplasmataceae replicate while enclosed in a eukaryotic host cell membrane-derived vacuole, and the family was broadened to include all the alphaproteobacterial species of the genera *Ehrlichia*, *Anaplasma*, *Cowdria*, *Wolbachia* and *Neorickettsia* (Dumler et al., 2001). Various endosymbiotic bacteria of protozoa, such as *Paramecium*, were allocated to the genera *Holospora*, *Caedibacter* and *Lyticum* forming the *Holospora* rDNA lineage, which is distantly related to the group formed by the rickettsiae (Fig. 1). The evolutionary roots of the eukaryotic mitochondrion are among the rickettsiae (Symbiotic, Parasitic and Not-Yet Cultured Proteobacteria, and the Alphaproteobacterial Origin of Mitochondria).

Rhodospirillaceae The Rhodospirillaceae lineage corresponds to the α-1 subgroup of Woese et al. (1984a) and encompasses at least seven genera of spiral-shaped phototrophic PNS bacteria (e.g., *Rhodospirillum*, *Phaeospirillum*, *Rhodospira* and *Rhodovibrio*). Previously, these genera (except *Rhodospira*) were species assigned to the broad and heterogeneous genus *Rhodospirillum* (Imhoff et al., 1998). The phototrophic rhodospirillae practice a photoorganotrophic type of metabolism, where a simple fatty

acid or amino acid is the carbon source and light the energy source. Most of the phototrophic rhodospirillae can also fix nitrogen gas, a property that is also characteristic for members of the genus *Azospirillum*, belonging to the Rhodospirillaceae rDNA-lineage. The azospirillae are nonphototrophic N_2-fixing bacteria, widely distributed in the rhizosphere of tropical and subtropical grasses where they seem to enhance the growth of these plants. Magnetotactic bacteria belonging to the genus *Magnetospirillum* are also members of this phylogenetic lineage, together with some former *Aquaspirillum* species.

Sphingomonadaceae Proteobacteria containing glycosphingolipids in their cell envelopes belong to the phylogenetic lineage of the sphingomonads, forming a versatile group of aerobic bacteria occurring in various environments such as soil, water and clinical specimens. This lineage corresponds to the α-4 subgroup. The genus *Sphingomonas* contained at least 20 species and was recently split on the basis of phylogenetic and chemotaxonomic analyses into four different genera (*Sphingomonas* sensu stricto, *Sphingobium*, *Novosphingobium* and *Sphingopyxis*; Takeuchi et al., 2001). Some of the species belonging to these genera can metabolize various aromatic compounds and possess promising biotechnological properties. The Sphingomonadaceae comprise also the genera *Erythrobacter*, *Erythromicrobium* and *Porphyrobacter*, which are aerobic chemoorganotrophs, although their cells contain bacteriochlorophyll *a* and carotenoids. The genus *Zymomonas* is related to the sphingomonads. *Zymomonas* strains occur in palm sap and pulque, where they ferment sugars to high concentrations of ethanol by using the Entner-Doudoroff pathway, leading to the alcoholic beverages palm wine and tequila, respectively (Swings and De Ley, 1977; Sahm et al., 2001).

Rhodobacter Group The *Rhodobacter* group is a heterogeneous phylogenetic lineage among the "Alphaproteobacteria," including a number of photosynthetic rod-shaped PNS bacteria as well as numerous chemoorganotrophs. It corresponds to the α-3 group (Woese et al., 1984a). Typical photosynthetic PNS bacteria of this lineage belong to the genera *Rhodobacter* and *Rhodovulum*, containing freshwater and marine species, respectively. *Rhodobacter sphaeroides* and *R. capsulatus* were extensively used for genetic studies of bacterial photosynthesis. The facultative chemolithotroph *Paracoccus denitrificans* belongs also here; it is a remarkable and versatile bacterium, being able to grow chemolithoautotrophically at the expense of hydrogen gas or reduced inorganic sulfur compounds as electron donors, carbon dioxide and oxygen, but it can also grow chemoorganotrophically with various organic compounds as sole carbon source. Some hyphal, budding and prosthecate aerobic bacteria such as *Hyphomonas*, *Hirschia* and *Gemmobacter* belong to this lineage, as well as the budding *Staleya* and *Antarctobacter*, which were isolated from a hypersaline, heliothermal antarctic meromictic lake (Labrenz et al., 1998; Labrenz et al., 2000). Gram-negative cocci typically occurring in regular packages of tetrads and isolated from activated sludge biomass were assigned to the genus *Amaricoccus*, belonging to the *Rhodobacter* lineage (Maszenan et al., 1997). The *Rhodobacter* group is peripherally related to some of the most abundant cultured marine species and strains from some terrestrial halophilic lake environments. These organisms, frequently referred to as the *Roseobacter* group, include in addition to the aerobic bacteriochlorophyll-containing genera (such as *Roseobacter*, *Roseovarius* and *Rubrimonas*) the genera *Antarctobacter*, *Ketogulonicigenium*, *Methylarcula*, *Octadecabacter*, *Sagitulla*, *Silicibacter*, and *Sulfitobacter*, as well as the phylogenetically heterogeneous genus *Ruegeria*.

Caulobacteraceae The Caulobacteraceae are aquatic chemoorganotrophic and aerobic bacteria often attaching to surfaces with a stalk at one end and forming polarly flagellated swarming cells at the other end. Stalks of several cells may form rosettes. Caulobacters occur typically in freshwater and marine habitats with low nutrient levels. The rod-shaped *Brevundimonas* strains, which were previously allocated to the genus *Pseudomonas*, belong also to the Caulobacteraceae.

Rhizobiaceae, Bartonellaceae, Brucellaceae and Phyllobacterium Group This large and complex rDNA-cluster contains at present at least 15 genera and 70 species and corresponds to the α-2 subgroup of Woese et al. (1984a), together with the adjacent lineage formed by the Hyphomicrobiaceae and the *Bradyrhizobium*, *Methylobacterium* and *Methylocystis* rDNA groups (Fig. 1). One common trait of bacteria belonging to this cluster is that most of them interact with eukaryotes: agrobacteria are plant pathogens causing crown-gall or hairy-root disease (tumors) on various dicotyledonous plants; the rhizobia induce nodules on roots or stems of leguminous plants and live symbiotically in these nodules where they reduce atmospheric nitrogen; and the bartonellae and brucellae are pathogenic for humans or animals. The fast growing rhizobia classified in the genera *Rhizobium*, *Allorhizobium*, *Mesorhizobium* and *Sinorhizobium* form a major rDNA cluster, together with

the plant pathogenic genus *Agrobacterium* and the genus *Phyllobacterium*, whose members were isolated from leaf nodules of various plants belonging to the Myrsinaceae and Rubiaceae. The genus *Mesorhizobium* (more related to *Phyllobacterium*) and members of the genus *Sinorhizobium* form also a distinct clade among the rhizobia. According to 16S rDNA analysis, various *Rhizobium* species as well as *Allorhizobium* are highly related to the plant pathogenic agrobacteria. Recently, Young et al. (2001) proposed inclusion of all the species of *Agrobacterium* and *Allorhizobium* in the genus *Rhizobium*. The rRNA-based classification of the rhizobia is generally supported by sequence analysis of *atpD* and *recA* genes (Gaunt et al., 2001). The genes for nodule formation (*nod* genes), nitrogen fixation (*nif* genes) and tumor induction (in the case of agrobacteria) are localized on large plasmids. Species of the genus *Bartonella* occur in the blood of man and mammals; they are often vector borne, but can also be transmitted by animal scratches or bites. Bartonellae are considered to be emerging human pathogens. The type species *Bartonella bacilliformis* is a fastidious hemophilic organism that invades and destroys human red blood cells and is transmitted by a sandfly. *Bartonella quintana* (Brenner et al., 1993) was previously classified in the genus *Rochalimaea* and causes trench fever, a disease transmitted by lice and afflicting, e.g., soldiers during the First World War (1914–1918). *Bartonella henselae* (formerly *Rochalimaea henselae*) is nowadays recognized as the causative agent of cat scratch disease (Table 5). Brucellae develop intracellularly and cause worldwide infections (brucellosis) in humans and a great number of animals such as cattle, pigs, dogs, and even marine mammals.

Hyphomicrobiaceae, the Bradyrhizobium, Methylobacterium, Methylocystis and Related Groups The family Hyphomicrobiaceae contains hyphal, prosthecate and budding bacteria; most of them (e.g., *Hyphomicrobium* and *Pedomicrobium*) are chemoorganotrophs and prefer to grow on one-carbon compounds such as methanol, whereas others are phototrophic (e.g., *Rhodomicrobium*). *Hyphomicrobium* is well adapted to grow in oligotrophic freshwater habitats. Other members of the family are *Xanthobacter*, a versatile soil bacterium capable of nitrogen fixation and autotrophic growth in an atmosphere of hydrogen, oxygen and carbon dioxide, and *Azorhizobium caulinodans*, a nitrogen-fixing bacterium living symbiotically in the stem nodules of some leguminous plants such as *Sesbania*.

A large subcluster within this complex lineage is formed by the *Bradyrhizobium* group, including the slow-growing rhizobia nodulating soy bean and other leguminous plants and the stem-nodulating phototrophic bradyrhizobia (Molouba et al., 1999; Giraud et al., 2002), the photosynthetic PNS *Rhodopseudomonas*, the ecologically important chemolithotrophic nitrobacters oxidizing nitrite to nitrate, as well as the opportunistic *Afipia* species. The *Methylobacterium* and *Methylocystis* groups contain various methanotrophic and methylotrophic bacteria, mostly utilizing the serine pathway for the assimilation of one-carbon intermediates. Some of these methanotrophs may have biotechnological applications because they can utilize chloromethanes from polluted environments, whereas others such as *Methylocapsa* are acidophilic and can fix atmospheric nitrogen (Dedysh et al., 2002). A subgroup of the methylotrophic methylobacteria has been shown to nodulate *Crotolaria* legumes and fix nitrogen (Sy et al., 2001). Other members of this rDNA lineage are the genera *Beijerinckia*, consisting of aerobic, acid-tolerant free-living nitrogen-fixing rods occurring mainly in tropical acidic soils, and *Rhodobium*, which contains marine budding phototrophic PNS bacteria.

The "Betaproteobacteria"

The "Betaproteobacteria" (at least 75 genera and 220 species) clearly represent a monophyletic group within the larger phylogenetic lineage composed of the β-γ proteobacterial complex, named *Chromatibacteria* by Cavalier-Smith (Cavalier-Smith, 2002; Table 2). From the metabolic, morphological and ecological viewpoint, the "Betaproteobacteria" are very heterogeneous. They contain some purple nonsulfur (PNS) phototrophs (Fig. 1, purple triangles), various chemolithotrophs, some methylotrophs, a great number of chemoorganotrophs, some nitrogen-fixing bacteria, and some important plant-, human- and animal pathogens (see Tables 5 and 6). Their morphologies can vary from rods or cocci to spiral and sheathed cells. Some members of the "Betaproteobacteria" are of biotechnological interest owing to their biodegradation properties. Recently nitrogen-fixing "Betaproteobacteria" were described that nodulate the roots of legumes (Chen et al., 2001; Moulin et al., 2001). More detailed information concerning the group can be found in the chapters dealing with the individual families and genera of the "Betaproteobacteria." Table 9 gives an overview of the major phylogenetic groups (see also Fig. 1) and the names of the six orders and 12 families of the "Betaproteobacteria" as they are listed in the 2nd edition of *Bergey's Manual of Systematic Bacteriology* (Garrity, 2001a).

Table 9. The "Betaproteobacteria": orders, families and number of genera.[a]

Order	Family	Number of genera
"Burkholderiales"	"Burkholderiaceae"	4
	"Ralstoniaceae"	1
	"Oxalobacteraceae"	5
	Alcaligenaceae	6
	Comamonadaceae	15
"Hydrogenophilales"	"Hydrogenophilaceae"	2
"Methylophilales"	"Methylophilaceae"	3
"Neisseriales"	Neisseriaceae	14
"Nitrosomonadales"	"Nitrosomonadaceae"	2
	Spirillaceae	1
	Gallionellaceae	1
"Rhodocyclales"	"Rhodocyclaceae"	6

[a]According to the second edition of *Bergey's Manual of Systematic Bacteriology* (Garrity and Holt, 2001). Quotation marks are used for names which have not yet been validated (as of mid 2002).

Although the majority of the phototrophic PNS bacteria belong to the "Alphaproteobacteria," some PNS species are members of the *Rhodocyclus* group or the family Comamonadaceae of the "Betaproteobacteria." Similarly to the previously mentioned PNS "Alphaproteobacteria," the PNS betaproteobacterial phototrophs are phylogenetically intermingled with nonphototrophs (Fig. 1, visualized by purple shaded areas) and can be clearly differentiated from the PNS "Alphaproteobacteria" (e.g., *Rhodobacter*, *Rhodobium*, etc.) on the basis of fatty acid and quinone composition as well as cytochrome *c* sequences (Imhoff, 2001a).

Alcaligenaceae, Comamonadaceae, Burkholderia, Oxalobacter and Related Groups

The Alcaligenaceae, Comamonadaceae, and the *Burkholderia*-, *Ralstonia*- and *Oxalobacter*-groups are phylogenetically more closely related to each other than to other 16S rDNA branches of the "Betaproteobacteria" (Fig. 1). A number of clinically important taxa belong to this lineage: members of the genus *Alcaligenes* are mostly saprophytic, but behave often as nosocomial bacteria, whereas the closely related *Bordetella pertussis* (Table 5) causes whooping cough in humans (other *Bordetella* species are pathogenic for animals). *Taylorella* is responsible for endometritis in mares, *Pelistega* is associated with a respiratory disease in pigeons (Vandamme et al., 1998), and *Brackiella oedipodis* (Willems et al., 2002) was recently reported as the causal agent of endocarditis in a small neotropical primate.

The former "acidovorans" and "solanacearum" rRNA groups of the genus *Pseudomonas* sensu lato (i.e., respectively, rRNA groups III and II of Palleroni [1984]) belong to the "Betaproteobacteria." The "acidovorans" group has at present the status of the family Comamonadaceae, a phylogenetically coherent but physiologically heterogeneous group of prokaryotes encompassing genera such as *Acidovorax*, *Comamonas*, *Delftia*, *Hydrogenophaga*, *Variovorax*, *Xylophilus*, *Rhodoferax*, *Roseateles*, *Rubrivivax*, *Leptothrix* and *Sphaerotilus* (Willems et al., 1991a; Willems et al., 1991b). The latter two genera are heterotrophic sheathed bacteria, which may appear yellow or dark brown owing to the deposition of iron and manganese oxides, whereas *Rhodoferax* and *Rubrivivax* are typical PNS photosynthetic bacteria. Some Comamonadaceae, such as *Acidovorax facilis*, *Hydrogenophaga flava* and *Variovorax paradoxus*, are able to grow chemolithotrophically at the expense of hydrogen gas oxidation. *Xylophilus ampelinus* causes necrosis and canker on grapevines. Other representatives, e.g., belonging to *Comamonas* or *Delftia*, can degrade aromatic compounds (via the *meta*-cleavage of the aromatic ring) and are important in the biodegradation of toxic wastes. *Roseateles* was described as the first obligate aerobic betaproteobacterium containing bacteriochlorophyll *a* (Suyama et al., 1999). However, light does not support growth of *Roseateles* strains under anaerobic conditions and in this sense *Roseateles* resembles physiologically the aerobic bacteriochlorophyll *a*-containing "Alphaproteobacteria," such as *Erythrobacter* and *Erythromicrobium* (Sphingomonadaceae).

The former "*Pseudomonas solanacearum* group" is composed of the genera *Burkholderia*, *Ralstonia* and a few others. Some of these bacteria are typical plant pathogens (e.g., *Ralstonia solanacearum*, causing wilt on many cultivated plants; Table 6), whereas others are important animal and human pathogens. *Burkholderia mallei* and *B. pseudomallei* have been classified as risk group 3 organisms (Table 5) because they cause respectively glanders disease in horses and melioidosis, a disease endemic in animals and humans in Southeast Asia. *Burkholderia cepacia* seems ubiquitous and is both friend and foe to humans (Govan et al., 2000): it is associated with plants (the original isolate was reported by Burkholder [1950] as the causative agent of bacterial rot of onion bulbs), occurs in soil and water, protects crops from bacterial and fungal infections, and is also frequently reported in the environment of patients, particularly cystic fibrosis patients, where *B. cepacia* infections have a considerable impact on their morbidity and mortality, as well as on their social life. The remarkable genomic heterogeneity among the *B. cepacia* strains isolated from various ecological niches makes their correct identification problematic (Coenye et al., 2001). It was demonstrated that presumed *B. cepacia* strains isolated

from cystic fibrosis patients and other sources belong to at least nine distinct genomic species or genomovars (Vandamme et al., 1997; Coenye et al., 2001). At least two of these genomovars are often implicated in the transmission of *B. cepacia* between cystic fibrosis patients (Mahenthiralingam et al., 2000; LiPuma et al., 2001). The extreme metabolic versatilty of *B. cepacia* could be applied in the bioremediation of recalcitrant xenobiotics (Parke and Gurian-Sherman, 2001). However, more caution is undoubtedly needed in this area, because many strains used or under development for biocontrol or bioremediation purposes are taxonomically poorly characterized, causing a potential hazard to the cystic fibrosis community worldwide (Parke and Gurian-Sherman, 2001). The related genus *Ralstonia* is also unusual as it harbors important plant pathogens, opportunistic human pathogens, as well as organisms of considerable biotechnological interest because of their potential for biodegradation of xenobiotics and recalcitrant compounds. Moreover, Chen et al. (2001) described *Ralstonia taiwanensis* as a betaproteobacterium capable of root nodule formation and nitrogen fixation in a leguminous plant (*Mimosa*). Together with the *Burkholderia*-like strains described by Moulin et al. (2001), these are the first betaproteobacteria known to be capable of root nodule formation and nitrogen fixation. *Ralstonia eutropha* (previously classified as *Alcaligenes eutrophus*) is a well-known and intensely studied facultative chemolithotroph (a typical "Knallgas" bacterium) that can grow at the expense of hydrogen gas, CO_2 and O_2 (Aragno and Schlegel, 1992). When grown under appropriate conditions, *R. eutropha* is also an excellent producer of the bioplastic poly-β-hydroxybutyrate and similar polyhydroxyalkanoates (Table 7). Some toxic-metal-resistant bacteria isolated from industrial biotopes were recently allocated to the genus *Ralstonia* (Goris et al., 2001). The latter organisms can be exploited to recycle soils polluted by toxic metals, such as mercury, cadmium or nickel.

The *Oxalobacter* group is composed of *Herbaspirillum* (a diazotroph colonizing endophytically roots, stems or leaves of graminaceous plants), *Janthinobacterium* (one of the known violacein-producing organisms), *Oxalobacter* and a few other genera. *Oxalobacter formigenes* occurs in the rumen or the large bowel of humans and animals; it performs a unique fermentation of oxalate to formate and CO_2, whereby ATP is generated via a membrane-linked proton-translocating ATPase.

Hydrogenophilus Group The genus *Hydrogenophilus* harbors thermophilic (optimum growth temperature 50–60°C), facultatively chemolithoautotrophic hydrogen-oxidizing rods that form a distinct lineage among the "Betaproteobacteria" (Hayashi et al., 1999). The classification of the colorless chemolithotrophic S-oxidizing *Thiobacillus* species has been thoroughly revised by Kelly and Wood (2000). The type species *T. thioparus* together with a few other *Thiobacillus* species belongs to the "Betaproteobacteria" and is distantly related to the *Hydrogenophilus* group. The majority of the other *Thiobacillus* species belong to the "Gammaproteobacteria" and were reassigned to three other genera (see The "Gammaproteobacteria"). Because they are able to leach metals from ore, Thiobacilli (e.g., *Acidithiobacillus* species) are used in processing low-grade metal ores.

Methylophilus, Nitrosomonas and Related Groups The majority of the one-carbon utilizers (methanotrophs) belong either to the "Alphaproteobacteria" or to the "Gammaproteobacteria." However, three methylotrophic genera (*Methylobacillus*, *Methylophilus* and *Methylovorus*) group in the *Methylophilus* rRNA lineage of the "Betaproteobacteria." These are phylogenetically distantly related to the *Nitrosomonas* lineage. The aerobic chemolithoautotrophic ammonia-oxidizing bacteria such as the rod-shaped *Nitrosomonas* and the spiral-shaped *Nitrosospira* constitute a monophyletic lineage among the "Betaproteobacteria." *Spirillum volutans* is distantly related to this group, as well as the Fe^{2+}-oxidizing chemolithotrophic *Gallionella ferruginea*, already known since 1836 for its peculiar bean-shaped cells forming very long spiral stalks composed of ferric hydroxide (Ehrenberg, 1836).

Rhodocyclus Group The *Rhodocyclus* lineage harbors besides PNS bacteria (e.g., *Rhodocyclus purpureus*) also diazotrophic rhizosphere bacteria such as *Azoarcus* and *Azospira*. Several strains of *Azoarcus* and the related *Thauera* can degrade aromatic compounds including chlorobenzoates. *Thauera selenatis* is capable of nitrate and selenate respiration and another member of this group, *Zoogloea ramigera* (Rossellomora et al., 1993), is considered to be a typical floc-forming prokaryote during the activated sludge process in sewage treatment plants (Juretschko et al., 2002). Also *Quadricoccus* (a large coccus occurring in tetrads; Maszenan et al., 2002) is found in the activated sludge biomass where it synthesizes polyphosphate and polyhydroxyalkanoates.

Dechloromonas and *Dechlorosoma* are newly described genera of perchlorate-reducing bacteria, associated, e.g., with the manufacture and dismantling of ammunition (Achenbach et al., 2001).

Neisseriaceae The most prominent human pathogens of the "Betaproteobacteria" belong to the genus *Neisseria*, containing the two well-known species *N. gonorrhoeae* and *N. meningitidis*. Strains of these organisms have been extensively studied by multi-locus-sequencing-typing (MLST; Achtman, 1998; Maiden et al., 1998).

Other clinical bacteria, such as *Kingella* and *Eikenella*, belong also to this phylogenetic group together with *Chromobacterium*, which produces the purple pigment violacein. The mammalian oral commensals *Alysiella* and *Simonsiella* belong also to Neisseriaceae and are unique because their filament-forming cells show a dorsal-ventral asymmetry and display a gliding motility on the epithelial cells in the oral cavity and upper respiratory tract of their host. These bacteria might have coevolved with their mammalian hosts during the past 100 million years (Hedlund and Staley, 2002).

The "Gammaproteobacteria"

Most 16S rDNA trees show that the members of the "Gammaproteobacteria" represent a monophyletic group which includes in fact also the "Betaproteobacteria" as a major line of descent (see Fig. 1). The "Gammaproteobacteria" form the largest proteobacterial group (at least 180 genera and 750 species), including the phytopathogenic *Xanthomonas* group as a border-line member. Depending upon the rDNA-treeing method used, the *Xanthomonas* rDNA-group appears peripherally linked to either the β- or the γ-class and can be considered as a sister group of the "Betaproteobacteria" (Ludwig and Klenk, 2001). The major phylogenetic groups (Fig. 1) and the names of the 13 orders and 20 families of the "Gammaproteobacteria" as listed in the 2nd edition of *Bergey's Manual of Systematic Bacteriology* (Garrity, 2001a) are given in Table 10. The individual chapters on the families and genera of this class can be consulted for more detailed information.

The "Gammaproteobacteria" contain the photosynthetic purple sulfur (PS) bacteria (Chromatiaceae and Ectothiorhodospiraceae; Table 10; Fig. 1) together with a great number of familiar chemoorganotrophic bacterial groups, such as the Enterobacteriaceae, Legionellaceae, Pasteurellaceae, Pseudomonadaceae, Vibrionaceae, and also some chemolithotrophic mostly sulfur- or iron-oxidizing prokaryotes. The class harbors some important human and animal pathogens (Table 5). It is noteworthy that the family Enterobacteriaceae is known since 1937 as a classical phenotypic group (Rahn, 1937), which remains fully supported by modern molecular taxonomy. On the other hand, the tradional group of the pseudomonads turned out to be phylogenetically extremely heterogeneous, because its members are scattered over the "Alphaproteobacteria," "Betaproteobacteria" and "Gammaproteobacteria." The genus *Pseudomonas* is at present restricted to all species phylogenetically related to its type species *Pseudomonas aeruginosa*, a member of the "Gammaproteobacteria," whereas all the other pseudomonads belonging to the α- and β-classes have been allocated to new genera such as *Brevundimonas*, *Sphingomonas*, *Comamonas*, *Burkholderia*, *Ralstonia*, etc. (see The "Alphaproteobacteria," The "Betaproteobacteria"). An analogous taxonomic history concerns the genus *Thiobacillus*, whose members are chemolithotrophs oxidizing various inorganic sulfur-compounds. Its classification was recently clarified by Kelly and Wood (2000): thiobacilli related to the type species *T. thioparus* belong to the "Betaproteobacteria," whereas the *Thiobacillus* species belonging to the "Gammaproteobacteria" were reclassified in the genera *Acidithiobacillus*, *Halothiobacillus* and *Thermithiobacillus*.

Table 10. The "Gammaproteobacteria": orders, families and number of genera.[a]

Order	Family	Number of genera
"Chromatiales"	Chromatiaceae	22
	Ectothiorhodospiraceae	5
"Xanthomonadales"	"Xanthomonadaceae"	8
"Cardiobacteriales"	Cardiobacteriaceae	3
"Thiotrichales"	"Thiotrichaceae"	9
	"Piscirickettsiaceae"	5
	"Francisellaceae"	1
"Legionellales"	Legionellaceae	1
	"Coxiellaceae"	2
"Methylococcales"	Methylococcaceae	6
"Oceanospirillales"	"Oceanospirillaceae"	6
	Halomonadaceae	6
Pseudomonadales	Pseudomonadaceae	15
	Moraxellaceae	3
"Alteromonadales"	Alteromonadaceae	11
"Vibrionales"	Vibrionaceae	6
"Aeromonadales"	Aeromonadaceae	2
	Succinivibrionaceae	4
"Enterobacteriales"	Enterobacteriaceae	41
"Pasteurellales"	Pasteurellaceae	6

[a]According to the second edition of *Bergey's Manual of Systematic Bacteriology* (Garrity and Holt, 2001). Quotation marks are used for names which have not yet been validated (as of mid 2002).

Chromatiaceae and Ectothiorhodospiraceae The distribution of the anoxygenic photosynthetic purple sulfur (PS) bacteria is at present restricted to two clearly distinct phylogenetic lineages of the "Gammaproteobacteria" (Fig. 1): the Chromatiaceae (25 genera), which accumulate elemental sulfur globules inside their cells,

and the Ectothiorhodospiraceae (7 genera), which deposit sulfur outside their cells. These prokaryotes are mainly found in illuminated anoxic zones of lakes (particularly meromictic lakes) where H_2S accumulates and also in "sulfur springs," where biologically or geochemically produced H_2S can trigger the formation of massive blooms of purple sulfur bacteria (Imhoff, 2001a). All PS bacteria can utilize H_2S as an electron donor for CO_2 reduction, but many are also able to use other reduced sulfur compounds (e.g., thiosulfate) as photosynthetic electron donors. Ectothiorhodospiraceae are haloalkaliphilic sulfur bacteria possessing lamellar intracellular photosynthetic membrane structures, whereas most Chromatiaceae possess a vesicular type of intracellular membrane. Some nonphototrophic and alkaliphilic taxa belong also to the phylogenetic lineage of the Ectothiorhodospiraceae: for example, *Nitrococcus* is a halophilic nitrite-oxidizing chemolithotroph, *Thioalkalivibrio* (Sorokin et al., 2001) contains obligately chemolithotrophic sulfur-oxidizing bacteria, and *Alcalilimnicola* (Yakimov et al., 2001) is a halotolerant aerobic heterotroph.

Enterobacteriaceae, Aeromonadaceae, Alteromonadaceae, Pasteurellaceae, Succinivibrionaceae and Vibrionaceae The core of the γ-class is composed of the well-known enterics (see Introduction to the Family Enterobacteriaceae in the second edition), Vibrionaceae (see The Family Vibrionaceae in Volume 6), Aeromonadaceae (see The Genera Aeromonas and Plesiomonas in Volume 6), Pasteurellaceae (see The Genus Pasteurella in Volume 6) and the Alteromonadaceae (see The Genus Alteromonas and Related Proteobacteria in Volume 6), each including a large number of genera and species. Some representatives of these families are known as pathogens of humans and animals (Table 5). The Enterobacteriaceae include the well-known and thoroughly studied *Escherichia coli*, together with numerous inhabitants of the intestinal tract of warm-blooded animals (e.g., *Salmonella* and *Shigella*, the etiological agents of salmonellosis and shigellosis, respectively; see Table 5). *Escherichia coli* is an excellent indicator organism for water quality (fecal contamination). The Enterobacteriaceae comprise a relatively homogeneous phylogenetic group within this large cluster; they are mostly facultative anaerobic carbohydrate-degrading microorganisms; some perform a mixed acid fermentation, whereas others carry out the butanediol fermentation. The enterics comprise also plant pathogenic bacteria (e.g., *Erwinia*, *Pectobacterium* and *Brenneria*; see Table 6), the plague-causing *Yersinia pestis*, as well as *Xenorhabdus* and *Photorhabdus*, which are symbionts of entomopathogenic nematodes, where they live in the intestinal lumen. An interesting and somewhat distant member of the enterics is *Buchnera aphidicola*, a not-yet-cultured endosymbiont of aphids (Baumann et al., 1995). The symbiotic association between aphids and *Buchnera* seems to be obligate and mutualistic: *Buchnera* synthesizes tryptophan, cysteine and methionine and supplies these essential amino acids to the aphid host. A parallel evolution of *Buchnera* and aphids seems to have occurred, and Baumann et al. (1998) estimated the origin of this symbiotic association as 200–250 million years ago. The correlation of sequence diversity of 16S rDNA of symbionts with the age of their hosts has led to the calibration of the molecular clock of 16S rDNA in recent organisms (Moran et al., 1993), assumed to generate 1% sequence divergence within 25–50 million years (see also Stackebrandt, 1995). Also the endosymbionts of carpenter ants (*Camponotus* spp.) constitute a distinct taxonomic group within the "Gammaproteobacteria" and are phylogenetically closely related to *Buchnera* and symbionts of tsetse flies. Comparison of the phylogenetic trees of the bacterial endosymbionts and their host species suggests a highly synchronous cospeciation process of both partners (Sauer et al., 2000).

Vibrionaceae are facultative anaerobic inhabitants of brackish, estuarine and pelagic waters and sediments and form the dominant culturable microflora in the gut of molluscs, shrimps and fish. The family harbors several pathogens (e.g., *Vibrio cholerae*, the causal agent of cholera) as well as luminous bacteria (e.g., *Photobacterium* and several *Vibrio* species), occurring free-living in seawater, as well as being symbionts in the light organs of many fish and invertebrates (see Dunlap and Kita-Tsukamoto, 2001). Bioluminescent bacteria occur also among the genera *Photorhabdus* (Enterobacteriaceae) and *Shewanella*. The latter genus belongs to the Alteromonadaceae, which are strictly aerobic chemoorganotrophs requiring seawater for growth. Quorum-sensing plays an important role in the phenomenon of bioluminescence. Several representatives of the Pasteurellaceae are the etiological agents of various infectious diseases in humans and other vertebrates (cattle, sheep, goats and fowl). They encompass the following major genera: *Pasteurella*, *Haemophilus*, *Actinobacillus* and *Mannheimia. Haemophilus influenzae* was the first free-living organism whose entire genome (ca. 1.8×10^9 bp) was sequenced (Fleischmann et al., 1995). The Aeromonadaceae include the fish pathogen *Aeromonas salmonicida*. The Succinivibrionaceae (Hippe et al., 1999) are strict anaerobes fermenting glucose and other carbohydrates to succinate and acetate. They occur in the rumen of sheep and

cattle (*Ruminobacter*, *Succinomonas* and *Succinivibrio*) or in the feces or colon of dogs and humans (*Anaerobiospirillum*).

Francisella and Piscirickettsia Groups The *Francisella* and *Piscirickettsia* groups form a deeply branching lineage among the "Gammaproteobacteria." *Francisella tularensis* is the causal agent of tularemia, a plague-like zoonosis, spread to humans from rodents via direct contact or biting arthropods, whereas *Piscirickettsia salmonis* causes an epizootic disease in salmonid fishes. Members of the *Piscirickettsia* group display a great morphological and metabolic diversity: *Thiomicrospira* contains spiral-shaped chemolithotrophic sulfur-oxidizing bacteria, which are closely related to the alkaliphilic chemolithotrophic *Thioalkalimicrobium* (Sorokin et al., 2001). *Hydrogenovibrio* is a marine obligately chemolithoautotrophic hydrogen-oxidizing bacterium and *Cycloclasticus* harbors rod-shaped bacteria degrading aromatic hydrocarbons and occurring in marine sediments.

Cardiobacteriaceae The Cardiobacteriaceae are an example of a family created (Dewhirst et al., 1990) on the basis of 16S rDNA comparisons of three taxa, whose phylogenetic relationship was at first quite unexpected. *Cardiobacterium hominis* is an occasional resident of the human respiratory tract and has been recovered from blood samples of patients suffering from endocarditis. *Suttonella indologenes* (previously classified as *Kingella indologenes*) has been reported in human eye infections and blood of patients with endocarditis, whereas *Dichelobacter nodosus* (formerly *Bacteroides nodosus*) is the causative agent of footrot in ruminants. Authentic kingellae belong to the "Betaproteobacteria" and authentic bacteroideae belong to the Cytophaga-Flavobacterium-Bacteroides phylum (the so-called "Bacteroidetes" according to Garrity, 2001).

Moraxellaceae The Moraxellaceae encompass the genera *Moraxella*, *Acinetobacter* and *Psychrobacter* forming a separate lineage among the "Gammaproteobacteria" (Rossau et al., 1991). Moraxellae are commonly isolated from animals or humans and some of them are pathogenic, whereas the psychrophilic *Psychrobacter* species occur in the marine and antarctic environment (e.g., in antarctic ornithogenic soils; Bowman et al., 1996) and also in clinical material. The oxidase-negative acinetobacters are saprophytes occurring in soil, water and sewage, but also typically on the skin of healthy humans. Moreover, some acinetobacters can also cause nosocomial infections.

Methylococcaceae The Methylococcaceae form a distinct lineage (Bowman et al., 1995) encompassing methylotrophic bacteria such as the genera *Methylobacter*, *Methylococcus* and *Methylomonas*, which share the ribulose monophosphate cycle for the assimilation of reduced C1-compounds. Some of these methylotrophs form cysts as resting stages and possess internal membrane systems arranged as bundles of disc-shaped vesicles distributed throughout the cell, in contrast to some methylotrophs of the "Alphaproteobacteria," whose membrane systems run along the periphery of the cells. The moderately halophilic *Methylophaga* belong phylogenetically to the *Piscirickettsia* group.

Thiothrix Group The Thiothrix group contains a number of filamentous and gliding sulfur-oxidizing chemolithotrophs, such as *Thiothrix*, *Beggiatoa* and *Thioploca*. *Thiothrix* forms sheathed filaments, whereas *Beggiatoa* forms long filaments lacking a sheath. Sulfur granules generally accumulate in the cells. The not yet axenic *Thiomargarita* ("sulfur pearl") is related to *Thioploca* and is a real giant among the prokaryotic life forms (its spherical cells are about 500 μm wide!). *Thiomargarita* cells form thick mats near the coast of Namibia, where they perform an anoxic oxidation of H_2S coupled to the reduction of nitrate (Schulz et al., 1999; Schulz, 2002). *Leucothrix* can be considered as a chemoorganotrophic counterpart of *Thiothrix*. Some not yet cultured sulfur-oxidizing symbiotic bacteria of bivalves are closely related to the *Thiothrix* group and play an important role in the nutrition of such animals, living near hydrothermal vents.

Halomonadaceae The family Halomonadaceae is a large and complex group of moderately halophilic and marine bacteria encompassing the genera *Halomonas*, *Chromohalobacter*, *Zymobacter* and *Carnimonas*. Recent comparative sequence analysis of 16S and 23S rDNA of representative strains indicated (Arahal et al., 2002) that the genus *Chromohalobacter* forms a monophyletic group, whereas the genus *Halomonas* is clearly polyphyletic and needs a taxonomic re-evaluation based on a polyphasic taxonomic approach (Romanenko et al., 2002 [doi 10.1099/ijs.0.02240-0]).

Pseudomonadaceae In the past (Palleroni, 1984), the family Pseudomonadaceae contained an extremely heterogeneous group of aerobic, rod-shaped and mostly polarly flagellated bacteria, phylogenetically spread over the "Alphaproteobacteria," "Betaproteobacteria" and "Gammaproteobacteria." Nowadays the family is restricted to some 90 *Pseudomonas* species around the type species *Pseudomonas aeruginosa* and some related genera which form a

separate lineage within the "Gammaproteobacteria." The pseudomonads of the "Alphaproteobacteria" and "Betaproteobacteria" have been transferred to other genera (Willems et al., 1991a; Kersters et al., 1996; Anzai et al., 2000; Caulobacteraceae, Alcaligenaceae, Comamonadaceae, *Burkholderia*, *Oxalobacter* and Related Groups). Some authentic *Pseudomonas* species (e.g., *P. fluorescens*) produce fluorescent pigments. Most pseudomonads are versatile and can grow on a great variety of organic compounds, including aromatic hydrocarbons, because some of them possess efficient oxygenases. Such bacteria play key roles in the purification of wastewater and clean-up of oil spills. Some of the *Pseudomonas* species (e.g., *P. syringae*) are plant pathogens (Table 6), whereas *P. aeruginosa* and some other fluorescent pseudomonads can be involved in serious nosocomial infections (Table 5). The free-living nitrogen fixers of the genera *Azotobacter* and *Azomonas* belong also to this phylogenetic lineage, together with the cellulose-degrading *Cellvibrio* and a few other related genera.

Oceanospirillum Group The *Oceanospirillum* group encompasses six genera whose members are aerobic, are moderately halophilic and generally possess curved cells. Some representatives (e.g., *Neptunomonas*) can degrade polycyclic aromatic hydrocarbons or long chain alkanes. The taxonomy of the genus *Oceanospirillum* has recently been revised (Satomi et al., 2002). *Balneatrix alpica* was reported as a bacterium associated with a case of pneumonia and meningitis in a spa therapy center in France (Dauga et al., 1993).

Legionellaceae and Coxiella Group The clinically important legionellae occur in surface water, mud, thermally polluted lakes and streams and some (e.g., *Legionella pneumophila*) may enter the human respiratory tract when water is aerosolized in showers and air-conditioning systems. *Legionella pneumophila* is a pathogen for humans causing pneumonia (Legionnaires' disease). An obligate intracellular bacterial parasite of small free-living amoebae (previously classified as *Sarcobium lyticum*; Drozanski, 1991) belongs also to the genus *Legionella* (Hookey et al., 1996). The genera *Coxiella* and *Rickettsiella* belong to the same phylogenetic lineage as the legionellae. Although phylogenetically distinct, *Coxiella* and *Rickettsia* (the latter belonging to the "Alphaproteobacteria") share similarities in their parasitic lifestyle. *Coxiella burnetii*, an obligate parasitic bacterium growing preferentially in the vacuoles of the host cells, causes Q-fever, a pneumonia-like infection, transmitted among animals by insect bites (e.g., ticks) and occasionally causes disease in humans (originally called "abattoir fever"). Rickettsiellae are widely distributed intracellular pathogens of invertebrates, including insects, crustaceans and arachnids. They have not yet been cultivated in cell-free media and grow and multiply in cell vacuoles of the fat body and hepatopancreas of their invertebrate hosts.

Xanthomonas Group The plant pathogenic *Xanthomonas* species, *Frateuria* (phenotypically resembling the acetic acid bacteria of the α-class), *Xylella* (a phytopathogen living in the xylem of various plants) and *Stenotrophomonas*, together with some yellow-pigmented N_2O-producing bacteria isolated from ammonia-supplied biofilters (Finkmann et al., 2000), constitute a clearly separated phylogenetic lineage among the *Chromatibacteria* sensu Cavalier-Smith (2002), i.e., the large complex formed by the "Betaproteobacteria" and the "Gammaproteobacteria"; see Table 2). The ubiquitous *Stenotrophomonas maltophilia* is also involved in important nosocomial infections (Van Couwenberghe et al., 1997; Khan and Mehta, 2002). Depending on the treeing algorithms used and the number of rDNA-sequences included, the xanthomonads cluster peripherally linked either to the "Betaproteobacteria" or to the "Gammaproteobacteria" (Fig. 1). The first complete genome sequence published of a plant pathogenic bacterium (Simpson et al., 2000) was that of *Xylella fastidiosa*, a pathogen causing important diseases in citrus trees, grapevines and other plants.

The "Deltaproteobacteria"

From the viewpoint of lifestyle and morphology, the δ-class is most peculiar because it contains bacteria that are typical predators on other prokaryotes (bdellovibrios), whereas other "Deltaproteobacteria" belonging to the myxobacteria display complex developmental life cycles, forming multicellular structures called "fruiting bodies." Up to now, photosynthetic bacteria have not been reported among the δ-class. Menaquinones are the major electron carriers in the respiratory chain (Table 3). The major subgroups of the "Deltaproteobacteria" are: 1) the myxobacteria displaying gliding motility and forming multicellular fruiting bodies, which are often large enough to be observed with the aid of a hand lens or even by the naked eye (e.g., *Chondromyces*); 2) the bdellovibrios living as predators on other Gram-negative bacteria; 3) the dissimilatory sulfate- and sulfur-reducing bacteria (their genus names are mostly prefixed by *Desulfo-*); and 4) some synthrophic bacteria which ferment propionate (e.g., *Syntropho-*

bacter) or benzoate (e.g., *Syntrophus*) to acetate, CO_2 and hydrogen syntrophically in coculture with hydrogen-consuming methanogens.

Bdellovibrios and myxobacteria are strict aerobes, whereas the sulfate- and sulfur-reducers and the syntrophic bacteria are strictly anaerobic. One may speculate whether the bdellovibrios and the myxobacteria represent aerobic descendants of the sulfate- and sulfur-reducing bacteria. We consider here briefly the major phylogenetic groups of the "Deltaproteobacteria," containing at present some 60 different genera and 160 species. Table 11 summarizes the names of taxa above the rank of genus within the "Deltaproteobacteria" according to the new edition of *Bergey's Manual of Systematic Bacteriology* (Garrity, 2001).

Myxobacteria The myxobacteria constitute a fascinating group of strictly aerobic, chemoorganotrophic, gliding, generally pigmented rod-shaped cells, which under starvation conditions aggregate, forming multicellular and macroscopic fruiting bodies (see Dworkin and Kaiser [1993] and Dawid [2000]). Some of the cells within these fruiting bodies are often converted to resting stages called myxospores. The peculiar gliding movement of the vegetative cells is not restricted to myxobacteria as it occurs also amongst members of the genera *Cytophaga* and *Flexibacter*, both belonging to the Cytophaga-Bacteroides-Flavobacterium phylum (now called "Bacteroidetes"; Garrity, 2001). New molecular and genetic insights concerning gliding motility have been gathered from studies on *Myxococcus xanthus* (Spormann, 1999). The myxobacteria are grouped in the order Myxococcales, which is composed of the following four families: Myxococcaceae, Archangiaceae, Cystobacteraceae and the Polyangiaceae. Those fruiting myxobacteria whose rDNA sequence could be examined form a phylogenetically coherent group (Spröer et al., 1999; Fig. 1), consisting of two major phylogenetic lineages. One fairly homogeneous group is composed of the genera *Myxococcus*, *Angiococcus*, *Archangium*, *Cystobacter*, *Melittangium* and *Stigmatella*, whereas the second lineage is much more heterogeneous and is composed of three genera belonging to the family Polyangiaceae. Within the latter group, the genus *Nannocystis* seems to occupy the most separate position. The classification of the myxobacteria relies heavily on morphological features whose phylogenetic significance has been confirmed (Spröer et al., 1999). The myxobacteria occur in various habitats, such as soils and particularly on decaying organic material, including dung of herbivorous animals, rotting wood, and bark of living and dead trees. They obtain their nutrients primarily by causing lysis of other bacteria. The myxobacteria are mostly mesophilic, but some psychrophilic, acidophilic and alkaliphilic species have been described (Dawid, 2000). The sporangia of *Chondromyces crocatus* have been found to harbor a sphingobacterium-like organism which was described as "*Candidatus* comitans" by Jacobi et al. (1997).

Several myxobacteria produce potentially useful secondary compounds, such as antibiotics and cytostatic peptides (Reichenbach and Höfle, 1993; Reichenbach, 2001). The fruiting myxobacteria possess the most complex behavioral patterns and life cycles of all prokaryotes known so far and are therefore considered as a very interesting study object. They typically display social behavior expressed by collective food

Table 11. The "Deltaproteobacteria": orders, families and number of genera.[a]

Order	Family	Number of genera

uptake, cooperative motility (swarming), and social development (Crespi, 2001). Intercellular communication plays an important role in these phenomena. The analysis of the genome sequence of *Myxococcus xanthus* (9.5 Mb; twice as large as the *E. coli* genome) should enhance the understanding of the molecular and evolutionary basis of the peculiar life style of these myxobacteria.

Bdellovibrio Group The bdellovibrios are small vibrioid prokaryotes living as predators on other Gram-negative bacteria. They are widespread in nature and have been isolated from soil, sewage, freshwater and marine environments. Wildtype bdellovibrios show a biphasic life cycle, alternating between an extracellular "attack-phase" flagellated form and an intracellular nonflagellated reproductive phase. After a bdellovibrio cell penetrates the wall of a Gram-negative prey cell (such as *Pseudomonas* or *Erwinia*), it performs a number of modifications on the outer membrane and the peptidoglycan of the invaded bacterium. The resulting spherical structure, consisting of the killed invaded cell and the developing bdellovibrio, is called a "bdelloplast." The bdellovibrio cell grows and multiplies in the periplasmic space of the prey cell and digests the periplasmic and cytoplasmic contents of the invaded cell (for more details, see Jurkevitch, 2001). The parasitic life style of *Bdellovibrio* is reflected in the size of its genome, which is only half of that of *E. coli*. Genomic heterogeneity has been observed among the bdellovibrios (Seidler et al., 1972; Baer et al., 2000): the genera *Bdellovibrio* and *Bacteriovorax* constitute separate lineages among the "Deltaproteobacteria." The 16S rDNA sequences of two other genera (*Micavibrio* and *Vampirovibrio*) have not been analyzed yet. The latter genus attacks cells of the green alga *Chlorella*.

Sulfate- and Sulfur-reducing Bacteria Sulfate- and sulfur-reducing bacteria occur in various major phylogenetic lineages, such as the Archaea (e.g., *Archaeglobus*), the phylum of the thermophilic Thermodesulfobacteria, the order Clostridiales (the spore-forming *Desulfotomaculum* and *Desulfosporosinus*), and the "Deltaproteobacteria" (such as the genera *Desulfovibrio*, *Desulfobacter* and *Desulfuromonas*). The proteobacterial sulfate- and sulfur-reducing bacteria are mostly mesophilic and constitute a physiological group of an otherwise phylogenetically heterogeneous assemblage of bacteria (Fig. 1). The number of genera and species has significantly increased during the last decade: in 2002, the group encompassed some 40 validly published genera and some 120 species, as well as a number of not yet culturable bacteria which emerge from molecular environmental studies (Akkermans et al., 1994). The proteobacterial sulfate- and sulfur-reducers are widespread in aquatic and humid terrestrial environments that become anoxic as a result of microbial decomposition. They are for the most part strictly anaerobic, performing the complete or partial oxidation of small organic molecules (e.g., lactate, pyruvate, acetate, and in a few cases, also alkanes and aromatic compounds) with oxidized S-compounds (such as sulfate or elemental sulfur) as terminal electron acceptors generating hydrogen sulfide. They play a crucial role in the sulfur cycle. Some sulfate reducers (e.g., *Desulfonema* and *Desulfosarcina*) can also grow autotrophically with hydrogen gas as electron donor and CO_2 as sole carbon source. Multiheme cytochromes (of the *c*3 type) play a key role in electron-transport reactions in the periplasm of sulfate- and sulfur-reducing bacteria. Strictly sulfur-reducing bacteria occur among the genera *Desulfuromonas*, *Desulfuromusa*, *Desulfurella* and *Hippea* (Liesack and Finster, 1994; Miroshnichenko et al., 1999).

Phylogenetically the sulfate- and sulfur-reducing proteobacterial taxa display a significant diversity; at present at least five major phylogenetic lineages can be discerned within the "Deltaproteobacteria" (Fig. 1). To make the picture perhaps even more complex, not all the taxa belonging to these phylogenetic clusters metabolize with sulfate or sulfur as terminal electron acceptor. These five major rRNA clusters are the *Desulfovibrio*, *Desulfuromonas*, *Desulfobacter*, *Synthrophobacter* and *Desulfurella* groups.

The *Desulfovibrio* rRNA group (encompassing the genera *Desulfovibrio*, *Bilophila* and *Lawsonia*) is phylogenetically related to the *Desulfohalobium* group, *Desulfomicrobium* and *Desulfonatronum*. Desulfovibrios occur in aquatic biotopes but are also common inhabitants of the intestines of mammals, including humans. Interestingly, *Lawsonia intracellularis* is an obligately intracellular bacterium occurring in the intestinal epithelial cells of pigs with proliferative enteropathy, a major disease affecting the economics of pig industries worldwide. *Lawsonia* does not reduce sulfate, but is clearly related to the *Desulfovibrio* group (McOrist et al., 1995). Similarly *Bilophila wadsworthia* is a common inhabitant of the human colon and has been associated with human appendicitis and was also reported as a common infective agent in neonatal pigs (McOrist et al., 2001). One species of *Desulfomicrobium* (*D. orale*) has been described as being involved in peridontal disease.

The *Desulfuromonas* group is more related to the *Pelobacter* group, which is mainly composed of fermenting bacteria, such as *Malonomonas*

rubra, growing by the decarboxylation of malonate to acetate. Some of the sulfate-reducing bacteria can also utilize Fe^{3+} as electron acceptor, which is typical for the various *Geobacter* species, also belonging to this rRNA cluster.

The *Desulfobacter* group is quite diverse as it contains 14 genera and is phylogenetically related to the *Desulfobulbus* and the *Desulfomonile* (or "*Desulfoarculus*") groups. The *Desulfobacter* group harbors also some psychrophilic sulfate-reducing bacteria such as *Desulfofrigus* and *Desulfofaba*, which were isolated from cold Arctic marine sediments (Knoblauch et al., 1999).

Sulfate reducers occur also among the *Syntrophobacter* group (Fig. 1), which is composed of the syntrophs classified in the genus *Syntrophobacter* and the sulfate-reducers belonging to *Desulforhabdus* and *Desulfovirga* (Tanaka et al., 2000) together with the thermophilic marine genera *Desulfacinum* and *Thermodesulforhabdus*. The latter two genera form part of a subsurface microbial community; the former was isolated from hydrothermal vent systems and the latter from hot North Sea oil field water. Other syntrophs of the "Deltaproteobacteria" such as the benzoate-degrading *Syntrophus* species and the propionate-degrading *Smithella* belong to the *Syntrophus* group (Fig. 1).

The genera *Desulfurella* and *Hippea* seem to occupy a separate position within the Proteobacteria; they are anaerobic, moderately thermophilic, sulfur-reducing bacteria, isolated from respectively terrestrial hot springs or submarine hot vents. Pending further studies, it is possible that in the future the *Desulfurella* group might be considered as a sixth (zeta) class among the Proteobacteria (Rainey et al., 1993).

The "Epsilonproteobacteria"

This is the smallest and a more recently recognized line of descent within the Proteobacteria (6 genera and some 50 species). Compared to the multiple changes in the classification of the four other proteobacterial classes, the classification of the ε-class remained quite stable, because it is a fairly new group whose taxonomy was right from its recognition based on comparisons of 16S rDNAs. Up to now, photosynthetic bacteria have not been reported and key representatives are the genera *Campylobacter* and *Helicobacter*, encompassing enteropathogens for man and/or animals. Most species of the "Epsilonproteobacteria" are microaerophilic, chemoorganotrophic nonsaccharolytic spiral-shaped or curved bacteria, typically motile with a corkscrew-like motion by means of polar flagella. They obtain their energy mainly from amino acids or tricarboxylic acid cycle intermediates. Menaquinones are the characteristic respiratory quinones (Table 3). In the 1980s, interest in campylobacters and related bacteria increased owing to the availability of adequate isolation and cultivation procedures. Some species require indeed fumarate, or formate plus fumarate, or hydrogen plus fumarate for growth in microaerobic conditions. Numerous new taxa were described, and the gastritis-causing *Campylobacter pylori* was transferred together with *C. mustelae* (isolated from the gastric mucosa of ferret) to the new genus *Helicobacter* by Goodwin et al. (1989). Some not yet culturable "Epsilonproteobacteria" have been reported as symbionts of shrimps and polychaetes. The complete genome sequences of *Campylobacter jejuni* (Parkhill et al., 2000) and *Helicobacter pylori* (Alm et al., 1999) have been determined. For recent reviews emphasizing taxonomic aspects of the major genera of the "Epsilonproteobacteria," see Vandamme (2000), On (2001), and Solnick and Vandamme (2001), and also Wassenaar and Newell (2001). Table 12 summarizes the names of taxa above the rank of genus within the "Epsilonproteobacteria" according to the new edition of *Bergey's Manual of Systematic Bacteriology* (Garrity, 2001).

The Campylobacteraceae *Campylobacter coli* and *C. jejuni* are the most frequently identified causative agents of acute infective diarrhea in humans. Campylobacters can enter the food chain via raw milk and raw meat (particularly poultry). Other *Campylobacter* and *Arcobacter* species are involved in abortion and infectious infertility in various animals (e.g., sheep and cows), whereas some *Campylobacter* species are also found in large numbers in the periodontal pockets of diseased gums of man. Although primarily known as human and animal associated bacteria which are of relevance in food microbiology, arcobacters were shown to be abundantly present in certain environmental niches including water reservoirs, sewage, oil field communities, and certain saline environments. Their role in the environment is not well documented, but some of these organisms were shown to be sulfide oxiders (with the production of sulfur) and it has been suggested that they play a role in the sulfur cycle by reoxidizing sulfide formed by

Table 12. The "Epsilonproteobacteria": orders, families and number of genera.[a]

Order	Family	Number of genera
"Campylobacterales"	Campylobacteraceae	4
	"Helicobacteraceae"	2

[a]According to the second edition of *Bergey's Manual of Systematic Bacteriology* (Garrity and Holt, 2001). Quotation marks are used for names which have not yet been validated (as of mid 2002).

microbial sulfate or sulfur reduction (Teske et al., 1996; Voordouw et al., 1996; Snaidr et al., 1997; Wirsen et al., 2002). The type species *A. nitrofigilis* occurs in the roots and the rhizosphere of salt marsh plants, where these bacteria fix nitrogen. The genus *Sulfurospirillum* harbors microaerophilic sulfur-reducing curved bacteria occurring in freshwater or marine surface sediments. Two recently described *Sulfurospirillum* species (*S. barnesii* and *S. arsenophilum*) can even use arsenate or selenate as electron acceptor (Stolz et al., 1999). The strictly anaerobic "*Dehalospirillum multivorans*" was isolated from activated sludge and can dechlorinate tetrachloroethene, a volatile man-made pollutant (Scholz-Muramatsu et al., 1995). This organism seems to be phylogenetically related to *Sulfurospirillum*.

The Helicobacter Group The helicobacters constitute together with *Wolinella* a distinct phylogenetic lineage within the "Epsilonproteobacteria" (Fig. 1). *Helicobacter pylori* has received considerable attention for its role in gastric and duodenal ulcers and in gastric cancer in humans. *Helicobacter* encompasses at present some 20 species and more will likely be discovered when the stomach of other animals will be screened for bacteria similar to *H. pylori*. The phylogenetic and taxonomic position of various so-called "gastrospirilla" occurring in the stomachs of humans and animals will only be resolved when significant advances in the culture methods for these difficult bacteria are made. The pig and cattle strains now constitute two provisional candidate species: respectively *Candidatus Helicobacter suis* and *Candidatus Helicobacter bovis* (De Groote et al., 1999a; De Groote et al., 1999b; see also Table 13). Similarly, polyphasic investigations are needed in the group of "Flexispira rappini," which is a provisional name for the spindle-shaped bacteria with periplasmic fibers and bipolar tufts of sheathed flagella, isolated from a variety of clinical and veterinary sources. The name "Flexispira rappini" refers to a characteristic morphotype shared by several distinct taxa and not to a distinct well-defined species (Dewhirst et al., 2001; Vandamme and On, 2001).

Wolinella succinogenes (formerly *Vibrio succinogenes*), a commensal of the bovine rumen, belongs also to the *Helicobacter* group. This organism can grow on hydrogen as electron donor and fumarate as electron acceptor.

Likely the full extent of the ecological diversity of the "Epsilonproteobacteria" still remains to be discovered: 16S rDNA gene sequence data of symbionts of shrimps (*Rimicaris exoculata*) and polychaete annelids (*Alvinella pompejana*) suggest that some "Epsilonproteobacteria" may occupy important niches in the habitats of deep-sea hydrothermal vents, where they contribute to overall carbon and sulfur cycling at moderate thermophilic temperatures (Campbell et al., 2001; Corre et al., 2001). Recently, such a thermophilic sulfur-reducing bacterium isolated from the deep-sea hydrothermal vent polychaete, *Alvinella pompejana*, was allocated to a new genus, *Nautilia* (Miroshnichenko et al., 2002). Another remarkable member of the "Epsilonproteobacteria" is *Thiovulum*, whose phylogenetic relationship was shown by partial rDNA analysis (Romaniuk et al., 1987). The sulfur-oxidizing *Thiovulum* possesses large ovoid cells with a diameter often reaching 25 µm. The cytoplasm contains orthorhombic sulfur inclusions, and the bacterium is considered as a chemolithotroph occurring in marine and freshwater environments, where sulfide-containing water and mud layers are in contact with overlaying oxygen-containing water. The environmental *Thiomicrospira denitrificans* belongs also to the "Epsilonproteobacteria," whereas the other six *Thiomicrospira* species, including the type species *T. pelophila*, are affiliated to the *Piscirickettsia* group of the "Gammaproteobacteria" (Brinkhoff et al., 1999).

Symbiotic, Parasitic and Not-Yet Cultured Proteobacteria, and the Alphaproteobacterial Origin of Mitochondria

The application of molecular biological methods to study the diversity of genes from environmental DNA without the need to isolate prokaryotic strains prior to molecular analyses has broadened immensely our insight into community structure and must be considered a quantum leap in microbial ecology (Hugenholz et al., 1998). Though problems are still associated with its ability to qualify and quantify individual partners of the community, the molecular approach has circumvented problems recognized with pure culture studies—the "great plate count anomaly," as phrased by Staley and Konopka (1985). Hundreds of habitats and selected environmental sites have been subjected to the direct analysis of community structure by ribosomal rDNA sequencing and, more recently, of community function by the analysis of genes involved in metabolism (sulfur, nitrogen, methanogenesis, etc.) as well as degradation, bioremediation or heavy metal resistance.

Symbiosis between prokaryotic and eukaryotic organisms seems to play a major role in evolution (Gray and Doolittle, 1982; Margulis, 1993; Margulis, 1996). A classical example is the symbiotic association between some diazotrophic

Table 13. Published *Candidatus* taxa among the Proteobacteria (as of mid 2002).

Name of *Candidatus* Reference	Comments/host	References
"Alphaproteobacteria"		
"*Candidatus* Liberibacter africanus"	Phloem-restricted bacterium associated with greening disease in citrus	Jagoueix et al., 1994 Murray and Stackebrandt, 1995
"*Candidatus* Liberibacter africanus subsp. capensis"	Phloem-restricted bacterium associated with leaf mottle symptoms in *Calodendrum capense* (Cape chestnut)	Garnier et al., 2000
"*Candidatus* Liberibacter asiaticus"	Phloem-restricted bacterium associated with greening disease in citrus	Jagoueix et al., 1994 Murray and Stackebrandt, 1995
"*Candidatus* Odyssella thessalonicensis"	Endosymbiont of *Acanthamoeba* spp. Phylogenetically related to *Caedibacter* and *Holospora*	Birtles et al., 2000
"*Candidatus* Xenohaliotis californiensis"	Endosymbiont causing withering syndrome of *Haliotis* spp. (abalone). Belongs to the Rickettsiaceae	Friedman et al., 2000
"Betaproteobacteria"		
"*Candidatus* Procabacter acanthamoebae"	Endosymbiont of *Acanthamoeba* spp.	Horn et al., 2002
"Gammaproteobacteria"		
"*Candidatus* Arsenophonus triatominarum"	Endosymbiont of *Triatoma infestans*. Closely related to *Arsenophonus nasoniae* (the triatomine bug)	Hypsa and Dale, 1997
"*Candidatus* Blochmannia floridanus"	Endosymbiont of *Camponotus floridanus* (carpenter ants)	Sauer et al., 2000
"*Candidatus* Blochmannia herculeanus"	Endosymbiont of *Camponotus herculeanus* (carpenter ants)	Sauer et al., 2000
"*Candidatus* Blochmannia rufipes"	Endosymbiont of *Camponotus rufipes* (carpenter ants)	Sauer et al., 2000
"*Candidatus* Phlomobacter fragariae"	Phloem-restricted bacterium associated with marginal chlorosis of strawberry	Zreik et al., 1998
"Epsilonproteobacteria"		
"*Candidatus* Helicobacter bovis"	Occurs in pyloric part of the abomasum of cattle	De Groote et al., 1999a
"*Candidatus* Helicobacter suis"	Occurs in stomach of pigs	De Groote et al., 1999b

"Alphaproteobacteria" (e.g., *Rhizobium*, *Bradyrhizobium* and *Azorhizobium*) and leguminous plants, where the bacteria reduce atmospheric nitrogen in root or stem nodules. Some Proteobacteria live as obligate intracellular symbionts or parasites in animals. To study the long-term history of symbiotic associations, the phylogenetic trees of hosts and their symbionts have been compared. Few data only are available, the most convincing study being the one on the endosymbionts of aphids. The topology of the symbiont (*Buchnera aphidicola*) tree is completely concordant with host phylogeny, based upon morphology (Moran et al., 1993). The fossil and biogeographic time points for the host phylogeny have been used to calibrate the 16S rDNA of the closely related endosymbionts (>8% similarity). The value of 1% fixed substitutions per 25 to 50 milllion years (Moran et al., 1993) is similar to the value of 1% per 50 million years determined by Ochman and Wilson (1987) on the basis of a broader range of nonobligate symbiotic relationships (e.g., *Rhizobium*/legumes; *Photobacterium*/fish; and enterobacteria/mammals) and 1% per 60 million years suggested by Stackebrandt (1995) for the past 500 years.

The advantage to the host of the association has been unraveled in only a few cases (e.g., the removal of hydrogen produced from hydrogenosomes of ciliates, provision of nutritional carbon to the host bivalves by sulfur-oxidizing gill symbionts [Dando and Southward, 1986] or of essential amino acids to aphids by their endosymbionts [Baumann et al., 1995; Baumann et al., 1998]). Molecular tools have also been used to elucidate the transmission route of symbionts in tropical lunicid bivalves (Gros et al., 1998) and deep-sea bivalves (Krueger et al., 1996) by application of the polymerase chain reaction (PCR) techniques in ovaries, testis and gill tissue.

We can estimate that a considerable number of new proteobacterial taxa has not yet been detected or described, because suitable in vitro cultivation techniques do not yet exist for such endosymbiotic bacteria. However, DNA-based techniques allow the detection and visualization of such endosymbionts, and PCR amplification of their 16S rDNA by oligonucleotide probes (see Table 4), applied singly or in a combination of several probes, each representing a different taxonomic level, enables the determination of their phylogenetic position

(Manz et al., 1992; Amann et al., 1995; Amann and Ludwig, 2000).

An intracellular lifestyle has obvious advantages for a suitably adapted prokaryote, and the spread of intracellular bacteria seems to be guaranteed in hosts such as blood sucking insects. Hence, it is not surprising that intracellular bacteria have evolved in different phylogenetic groups. Classical examples among the Proteobacteria are *Coxiella*, *Rickettsiella* and the endosymbionts of aphids belonging to the genus *Buchnera* (all "Gammaproteobacteria") and various members of the Rickettsiaceae and allied groups (e.g., *Holospora* and *Caedibacter*), belonging to the "Alphaproteobacteria." Related to the Rickettsiaceae are the wolbachiae, which are symbionts of invertebrate hosts, affecting the reproduction of the host by induction of thelytokous parthenogenesis (i.e., male killing or feminization). The wolbachiae infect the reproductive cells of various insects and have thus the potential to be vertically transmitted by cytoplasmic inheritance. More details concerning intracellular prokaryotes can be found in the introductory chapter by Fredricks (Introduction to the Rickettsiales and other Intracellular Prokaryotes in this Volume) and some examples of symbiotic and not yet cultured Proteobacteria are shown in Table 14, together with their phylogenetic affiliation.

Most of these endosymbiotic bacteria cannot yet be cultivated and illustrate that only a very limited proportion of the bacterial species present in various habitats is actually known. Although a great part of the rDNA sequences of uncultured bacteria is available in public databases, no formal phenotypic description nor species names can be given for such organisms, and type strains cannot be made publicly available. Some of these uncultured bacteria have been partially described and provisionally allocated to the category of *Candidatus* (Murray and Schleifer, 1994; Murray and Stackebrandt, 1995). The proteobacterial *Candidatus* taxa together with some additional information are listed in Table 13 (see also the List of Bacterial Names with Standing in Nomenclature website).

The mitochondrion of eukaryotic cells can be considered as the ultimate prokaryotic endosymbiont. Like chloroplasts, mitochondria possess unique genomes that are distinct from the nuclear genomes of their associated eukaryotic cells, and mitochondrial ribosomes are clearly of the prokaryotic type and related to the "Alphaproteobacteria" (Lang et al., 1999). Among the many bacterial genomes that have now been sequenced, that of *Rickettsia prowazekii* (1.1 Mb) is most closely related to the mitochondrial genome (Andersson et al., 1998). *Rickettsia prowazekii* is the agent of epidemic

Table 14. Examples of symbiotic Proteobacteria and their phylogenetic affiliation.

Host species	Host trivial name	Phylogenetic affiliation of symbiont	Reference/EMBL accession number
Muscidifurax uiniraptor	House fly	α-class	Stouthamer et al., 1993
Bangasternus orientalis	Coleoptera, weevil	α-class	M85266
Rhinocyllus conicus	Coleoptera, weevil	α-class	M85267
Trichogramma deion	Parasite wasp of Lepidoptera	α-class	Stouthamer et al., 1993
Nasonia vitripennis	Parasitic wasp	α-class	Gherna et al., 1991
Crassostrea virginica	Eastern Oyster	α-class	Boettcher et al., 2000
Dysmicoccus neobrevipes	Homoptera, mealy bug	β-class	Munson et al., 1992
Acromyrmex octospinosus	Leave cutting ant	β-class	AF459796
Antonina crawii	Bamboo pseudococcoid, Homoptera	β, γ-class	Fukatsu et al., 2000
Solemya velum	Bivalve	γ-class	M90415
Heliothis virescens	Moth, tobacco budworm	γ-class	L22481
Bathymodiolus thermophilus	Bivalve	γ-class	Distel et al., 1988
Calyptogena elongata	Bivalve	γ-class	L25719
Calyptogena magnifica	Bivalve	γ-class	Distel et al., 1988
Vesicomya cordata	Bivalve	γ-class	L25713
Anodontia phillipiana	Bivalve	γ-class	L25711
Codakia orbicularis	Bivalve	γ-class	Distel et al., 1988
Thyasira flexuosa	Bivalve	γ-class	Distel and Wood, 1992
Lucina floridana	Bivalve	γ-class	L25707
Riftia pachyptila	Tube worm	γ-class	Distel et al., 1988
Anomalops katoptron	Deep sea anglerfish	γ-class	Z19081
Cryptosaras couesi	Deep sea anglerfish	γ-class	Haygood et al., 1992
Sitophilus zeamais	Coleoptera, maize weevil	γ-class	M85270
Acyrthosiphon sp.	Pea aphid	γ-class	Unterman et al., 1989
Camponotus floridanus	Giant ants	γ-class	Schröder et al., 1996
Glossina pallidipes	Tsetse fly	γ-class	Beard et al., 1993

louse-borne typhus in humans and multiplies in eukaryotic cells only. Most likely the genome types of mitochondria and rickettsiae have shared a common free-living alphaproteobacterial ancestor, which through genome reduction evolved via two descendent lineages (Gray, 1998; Gray et al., 1999). Studies on mitochondria of yeast reveal that the number of alphaproteobacterial descendents in the mitochondrial proteome is surprisingly small, and that a large number of novel mitochondrial genes likely originated from the eukaryotic nuclear genome complementing the remaining genes from the bacterial ancestor (Karlberg et al., 2000; Kurland and Andersson, 2000). Further genomic and proteomic analyses of other members of the "Alphaproteobacteria," such as *Bradyrhizobium* and *Rhodobacter*, may yield more information concerning the metabolic versatility of the proto-mitochondrion. Whether the origin of hydrogenosomes—the ATP-producing organelles of many anaerobic protists—is related to that of mitochondria remains to be investigated in more detail (Andersson and Kurland, 1999; Dyall et al., 2000).

Genome Analysis

The G+C content of genomic DNA of the Proteobacteria varies from 30 mol% (e.g., in *Campylobacter* and *Rickettsia*) to 70% (e.g., in *Alcaligenes*), indicating that almost the entire span of mol% G+C variation among living microorganisms is covered. Even within each of the proteobacterial subclasses, variation in G+C content of the genome is very large. Similarly the genome sizes of various Proteobacteria differ considerably. Commensals and free-living prokaryotic strains have a larger genome, ranging from 9.4 Mb (*Myxococcus xanthus*) to about 2.5 Mb (*Pasteurella multocida*), than that of obligate symbiotic and parasitic strains, e.g., *Buchnera aphidicola* (0.64 Mb) and *Rickettsia prowazekii* (1.1 Mb). Unexpectedly, the genome size of phylogenetically closely related species and even strains of the same species can differ significantly, as shown for three species of *Yersinia* (3.8–4.9 Mb) and various strains of *E. coli* (4.6–5.5 Mb) and *Burkholderia cepacia* (4.7–8.1 Mb; Lessie et al., 1996). Most Proteobacteria studied contain a single circular chromosome, but the presence of multiple chromosomes has been reported, particularly among the "Alphaproteobacteria": two different circular chromosomes in *Rhodobacter sphaeroides* (Suwanto and Kaplan, 1989) and *Brucella melitensis* (Michaux-Charachon et al., 1997); three circular chromosomes in *Rhizobium meliloti* (Sobral et al., 1991) and *Burkholderia cepacia* (Cheng and Lessie, 1994). Another unconventional organization has been detected in several strains of *Agrobacterium tumefaciens*, where the larger chromosome is circular (3.0 Mb), whereas the smaller (2.1 Mb) is linear (Jumas-Bilak et al., 1998). It should be noted that not all strains of *Brucella melitensis* or all species of the genus *Rhodobacter* contain multiple chromosomes, and the evolutionary significance of these peculiar genomic organizations remains to be unraveled (Jumas-Bilak et al., 1998).

A multitude of genes of various Proteobacteria have been sequenced; genetic and genomic aspects of *E. coli*, various *Pseudomonas* species, *Rhizobium* and many animal and human pathogenic Proteobacteria have been or are being studied in detail, and more importantly in recent years, considerable progress has been made in the sequencing of whole genomes of an increasing number of Proteobacteria. The first whole-genome sequence of a free-living microorganism was published in 1995 by Fleishmann et al. for the gammaproteobacterium *Haemophilus influenzae* (1.83 Mb). At present (mid 2002), the sequences have been completed for at least 9 α-, 3 β- (*Bordetella* and *Neisseria*), 17 γ- and 3 ε- (*Campylobacter* and *Helicobacter*) class members (sequenced genera are indicated by footnote "a" in Table 3; see also The Institute for Genomic Research website). Sequencing of a great number of proteobacterial genomes is in progress (see footnote "b" in Table 3 and The Institute for Genomic Research website, National Center for Biotechnological Information website, ([DOE Joint Genome Institute website] http://www.jgi.doe.gov/JGI_microbial/html and [GOLD Genome OnLine Database website] wit.integratedgenomics.com/GOLD/) and most of it pertains to bacteria of clinical or biotechnological importance. The sequencing projects will elucidate regulatory and structural functions of newly discovered genes and will also yield significant insights into the mechanisms of pathogenicity, bacterial photosynthesis, phylogeny and evolution.

Final Considerations

With the publication of the *Approved Lists of Bacterial Names* in 1980, the number of genera and species presently belonging in the Proteobacteria was approximately 130 and 500, respectively. Until 2002, the number of validly described genera and species increased to respectively about 460 and 1600, making the phylum Proteobacteria a heavily populated section

of the phylogenetic bacterial tree. Indeed, in terms of number of genera, the Proteobacteria encompass more than 40% of all prokaryotic genera. Recent insights into the community structure of as-yet uncultivated prokaryotes reveal that the vast majority of taxa have not yet been described. This is true not only for open environments, such as the open ocean (Giovannoni et al., 1990), soil (Liesack and Stackebrandt, 1992; Felske et al., 1999), deep subsurface (Chandler et al., 1997), waste treatment plants and bioreactors (Bond et al., 1995; Juretschko et al., 2002), and sediments of oceans and lakes (Bowman et al., 2000; Urakawa et al., 2000; Brambilla et al., 2001), but also for the microflora of eukaryotic hosts. Particularly the not-yet culturable Proteobacteria, the endosymbionts and those which are difficult to grow in axenic culture such as the helicobacters and allied taxa, are a goldmine for further studies on bacterial diversity. The most promising tools to explain the role of Proteobacteria in global cycling of gases and chemicals are: 1) for elucidating the phylogenetic structure of the community, DNA fragment electrophoresis, sequence analysis of universal and taxon-specific genes, and their identification in situ by FISH hybridization, and 2) for determining the physiological capacities of its members, identification of housekeeping genes by FISH techniques and by microautoradiography (Ouverney and Fuhrman, 1999; Lee et al., 1999). Horizontal transfer of genes (Klein et al., 2001) will shed light on the possible evolutionary history of the various large groups within Proteobacteria by tracing the origin of genes to the ancestors of recent species that are phylogenetically related to other prokaryotic phyla. The number of full genome sequences will continue to rise, providing microbiologists with an unparalleled wealth of information for scientific exploitation to the benefit of clinical, environmental, evolutionary and general microbiology. It is likely that the increasing number of genera and species as well as comparative studies on other semantic macromolecules will challenge the present five major subdivisions of the Proteobacteria: as the phylogenetic radiation of the proteobacterial lineages will become more complex, boundaries between the five major subgroups will become vague and the subgroups more ambiguous. On the other hand, information on orthologous genes other than ribosomal rRNA genes will provide systematicists with sets of molecules to be included in future studies on multi-locus sequence analysis. As recommended, this information will be used in the description of the taxon species (Stackebrandt et al., 2002) and possibly of higher taxa. Molecular studies and culture attempts will continue to go hand in hand. The scientific challenge in the near future will also include molecular determination of metagenomes from proteobacteria of selected sites as well as the cultivation of hitherto uncultured proteobacterial symbiotic and pathogenic organisms.

CHAPTER 3.1.1

The Phototrophic Alpha-Proteobacteria

JOHANNES F. IMHOFF

Introduction

The phototrophic purple α-Proteobacteria are purple nonsulfur bacteria able to perform anoxygenic photosynthesis. Owing to the presence of photosynthetic pigments, cell suspensions appear in various colors from beige, olive-green, peach-brown, brown, brown-red, red or pink and have characteristic absorption spectra. Photosynthetic pigments (bacteriochlorophyll *a* or *b* [esterified with phytol or geranylgeraniol] and various types of carotenoids) are located in the cytoplasmic membrane and internal membrane systems (vesicles, lamellae or membrane stacks).

Typically, phototrophic α-Proteobacteria grow under anoxic conditions in the light and their phototrophic growth, photosynthetic pigment synthesis and internal membrane formation are inhibited by oxygen but become derepressed at low oxygen tensions. Their metabolism is highly diverse and flexible. The preferred mode of growth is photoorganoheterotrophically, but many species also can grow photolithoautotrophically with molecular hydrogen, sulfide or thiosulfate as photosynthetic electron donor; some also can use ferrous iron. Growth factors are generally required, most commonly biotin, thiamine, niacin and *p*-aminobenzoic acid; growth of most species is enhanced by small amounts of yeast extract, and some have a complex nutrient requirement. Chemotrophic growth under microoxic to oxic conditions in the dark is common to most of these bacteria; some of them are very sensitive to minor levels of oxygen, while others grow equally well aerobically in the dark at the full atmospheric oxygen tension. Anaerobic dark growth by fermentation and oxidant-dependent growth also may occur.

Phylogeny

Phototrophic purple nonsulfur bacteria are a highly diverse and heterogeneous group of bacteria, both phenotypically and genetically. On the basis of 16S rDNA sequence similarities, phototrophic purple bacteria belong to the α-, β- and γ-Proteobacteria (Woese et al., 1984a; Woese et al., 1984b; Woese et al., 1985; Stackebrandt et al., 1988; Woese, 1987). While purple sulfur bacteria are γ-Proteobacteria, purple nonsulfur bacteria are found in the β- and α-Proteobacteria. The phototrophic purple β-Proteobacteria (including *Rhodocyclus* and relatives) are treated elsewhere in this volume (Imhoff). This chapter deals with the phototrophic purple α-Proteobacteria.

Three major phylogenetically distinct groups of phototrophic α-Proteobacteria are recognized (see Figs. 1–3). They are represented by *Rhodospirillum* and relatives (also called "α-1 Proteobacteria"; Fig. 1), by *Rhodopseudomonas* and relatives (also called "α-2 Proteobacteria"; Fig. 2) and by *Rhodobacter* and relatives (also called "α-3 Proteobacteria"; Fig. 3). While species of the α-3 group form a tight phylogenetic cluster, in the α-2 group *Rhodomicrobium* and *Rhodobium* species are at a greater distance to the other phototrophic species, and in the α-1 group, *Rhodovibrio*, *Rhodopila* and *Rhodothalassium* species form distinct lines separate from the cluster around *Rhodospirillum* and *Phaeospirillum* species. Close relatives of *Rhodovibrio* species and *Rhodothalassium salexigens* are not known and their assignment to the *Rhodospirillum* group is arbitrary. On the basis of 16S rDNA sequence similarities, chemotaxonomic characteristics and other properties, many representatives of the phototrophic α-Proteobacteria are very closely related to nonphototrophic, strictly chemotrophic bacteria. These similarities are taken as strong indication for the development of many nonphototrophic bacteria from phototrophic ancestors. A few examples of these relations are the following:

The acidophilic *Rhodopila globiformis* is closely related to other acidophilic bacteria including *Acidiphilium* species (Sievers et al., 1994).

Phaeospirillum species demonstrate a close relationship to *Magnetospirillum magnetotacticum* (Burgess et al., 1993).

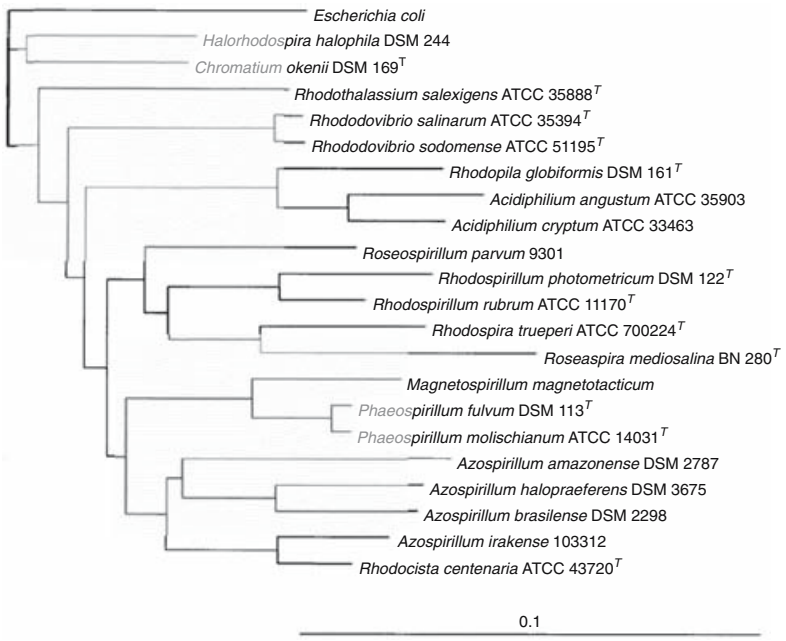

Fig. 1. Phylogenetic tree based on 16S rDNA sequences of the *Rhodospirillum*-group (α-1 Proteobacteria) in relation to other purple nonsulfur and purple sulfur bacteria and to representative close chemotrophic relatives.

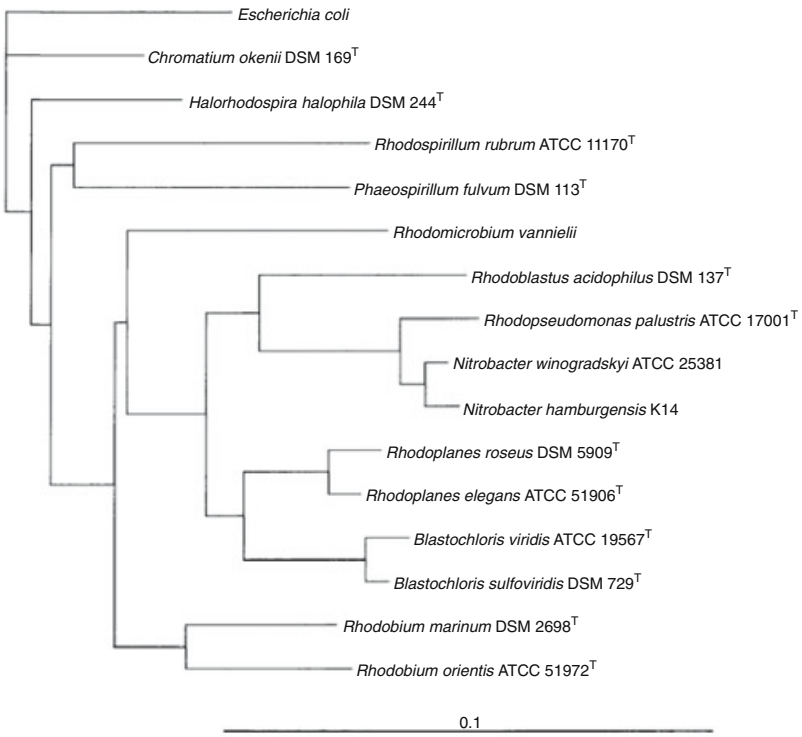

Fig. 2. Phylogenetic tree based on 16S rDNA sequences of the *Rhodopseudomonas*-group (α-2 Proteobacteria) in relation to other purple nonsulfur and purple sulfur bacteria and to representative close chemotrophic relatives.

Rhodocista centenaria has strong relations to *Azospirillum* species (Xia et al., 1994; Fani et al., 1995).

Within the α-2 Proteobacteria, *Rhodopseudomonas palustris* has strong relations to species of *Nitrobacter* (Seewaldt et al., 1982).

Rhodobacter and *Rhodovulum* species form a cluster closely associated to *Paracoccus denitrificans* (Imhoff, 1989a; Hiraishi and Ueda, 1994a).

Taxonomy

Since Molisch removed the purple sulfur bacteria from the Thiobacteria (Migula, 1900), pigmentation and ability to perform anoxygenic photosynthesis were considered of primary importance for assignment of bacteria to the Rhodobacteria (Molisch, 1907), later called "Rhodospirillales" (Pfennig and Trüper, 1971).

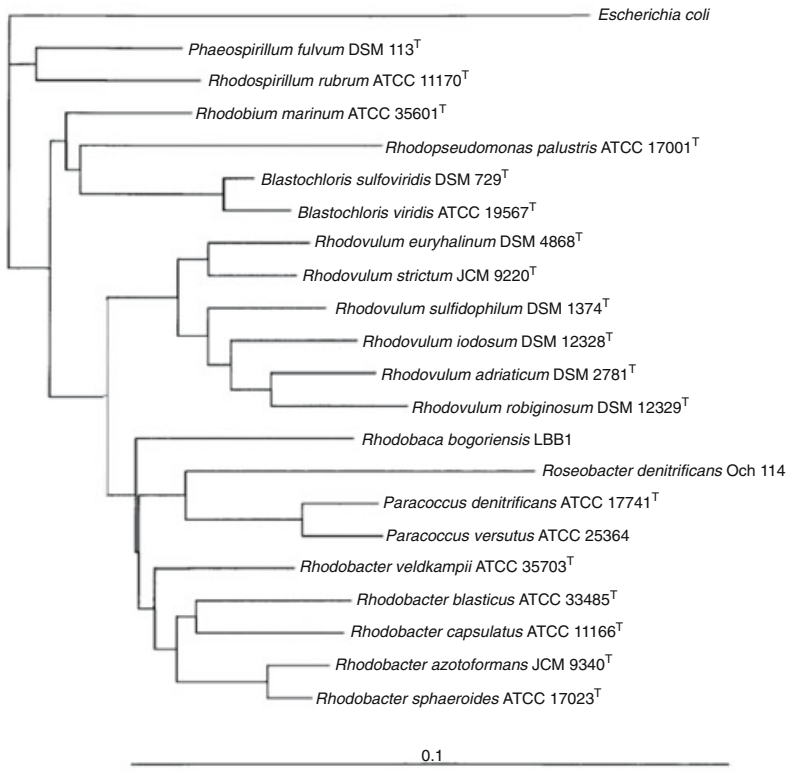

Fig. 3. Phylogenetic tree based on 16S rDNA sequences of the *Rhodobacter*-group (α-3 Proteobacteria) in relation to other purple nonsulfur and purple sulfur bacteria and to representative close chemotrophic relatives.

Because the Rhodospirillaceae (Pfennig and Trüper, 1971) do not represent a phylogenetically distinct group of bacteria, the use of the term "purple nonsulfur bacteria" (PNSB) was proposed for the α- and β-Proteobacteria that contain photosynthetic pigments and are able to perform anoxygenic photosynthesis under anoxic conditions (Imhoff et al., 1984b; Imhoff and Trüper, 1989b; Imhoff and Trüper, 1992b). Actual and historical aspects of the taxonomy of anoxygenic phototrophic purple bacteria have been discussed elsewhere (Imhoff, 1992a; Imhoff, 1995a; Imhoff, 1999; Imhoff, 2000).

Traditionally, purple nonsulfur bacteria have been classified into genera representing the rod-shaped *Rhodopseudomonas* species and the spiral-shaped *Rhodospirillum* species (Pfennig and Trüper, 1974b) and later into a third genus containing the half-circle- to circle-shaped *Rhodocyclus purpureus* (Pfennig, 1978). With the recognition of their genetic relationships and chemotaxonomic diversity, purple nonsulfur bacteria of the α- and β-Proteobacteria were taxonomically separated (Imhoff et al., 1984b; Imhoff and Trüper, 1989b). Later, bacteria within these groups were rearranged according to phylogeny, chemotaxonomic characteristics and ecophysiological properties. Despite the fact that many of the phototrophic purple nonsulfur bacteria are closely related to strictly chemotrophic relatives, the genus definitions of genera of the anoxygenic phototrophic bacteria still include phototrophic capability and content of photosynthetic pigments. At higher taxonomic ranks, phototrophic bacteria are treated together with nonphototrophic relatives.

Alpha-1 Proteobacteria

Most of the phototrophic bacteria that belong to the α-1 Proteobacteria (also known as the *Rhodospirillum* group) have been previously known as *Rhodospirillum* species and are of spiral shape. At present, the only nonspiral representative is *Rhodopila globiformis*. Genera included in this group are *Rhodospirillum*, *Phaeospirillum*, *Rhodospira*, *Roseospira*, *Rhodocista*, *Roseospirillum* and also *Rhodopila*, *Rhodothalassium* and *Rhodovibrio*.

In addition, 16S rDNA sequence data of purple nonsulfur bacteria implied that the spiral-shaped phototrophic α-Proteobacteria are phylogenetically quite distantly related to each other and do not warrant classification in one and the same genus (Kawasaki et al., 1993a; Imhoff et al., 1998). These bacteria also demonstrate great phenotypic diversity. Therefore, a reclassification of the spiral-shaped phototrophic α-Proteobacteria was proposed, based on distinct phenotypic properties and 16S rDNA sequence similarities. *Rhodospirillum centenum* was transferred to a new genus as *Rhodocista*

centenaria (Kawasaki et al., 1992). Other Rhodospirillum species were transferred to the new genera *Phaeospirillum*, *Rhodovibrio*, *Roseospira* and *Rhodothalassium* (Imhoff et al., 1998). Only *R. rubrum* and *R. photometricum* were maintained as species of the genus *Rhodospirillum*. In addition, new species were described of this group: *Rhodospira trueperi* was assigned to a new genus on the basis of significant phenotypic and genotypic differences from *Rhodospirillum rubrum* and other known PNSB (Pfennig et al., 1997); for similar reasons, the new bacterium *Roseospirillum parvum* was assigned to a new genus (Glaeser and Overmann, 1999).

Alpha-2 Proteobacteria

Most characteristic of phototrophic bacteria of the α-2 (*Rhodopseudomonas*) group is the budding mode of growth and cell division and the presence of lamellar internal membranes lying parallel to the cytoplasmic membrane. Most of these phototrophic bacteria have been previously known as *Rhodopseudomonas* species. Genera of this group now include *Rhodopseudomonas*, *Rhodoplanes*, *Rhodoblastus*, *Blastochloris*, *Rhodomicrobium* and *Rhodobium*.

After the removal of purple nonsulfur bacteria that contained vesicular internal photosynthetic membranes and those that were β-Proteobacteria from the genus *Rhodopseudomonas*, only those species remained within this genus that had lamellar internal membrane structures and grew and reproduced by budding (Imhoff et al., 1984b). The bacteria removed from *Rhodopseudomonas* are now recognized as species of *Rhodopila*, *Rhodobacter*, *Rhodovulum* and *Rubrivivax*. Thereafter, what remained of the genus *Rhodopseudomonas* (together with *Rhodomicrobium vannielii*) still represented a heterogeneous assemblage of species (Imhoff et al., 1984b) now recognized as genera of the α-2 Proteobacteria. Primarily due to the availability of sequence data of the 16S rDNA (Kawasaki et al., 1993a) and in part supported by the isolation and description of new species and additional data, the following proposals have been made. *Rhodopseudomonas marina* was transferred to the new genus *Rhodobium* as *Rhodobium marinum* together with the new species *Rhodobium orientis* (defined as the type species of this genus; Hiraishi et al., 1995b). *Rhodopseudomonas rosea* was transferred to the new genus *Rhodoplanes* and designated as the type species of this genus, *R. roseus* (Hiraishi and Ueda, 1994b). At the same time, *Rhodoplanes elegans* was described as a new species of this genus. *Rhodopseudomonas viridis* and *Rhodopseudomonas sulfoviridis* were assigned to the new genus *Blastochloris* as *B. viridis* and *B. sulfoviridis* (Hiraishi, 1997). Quite recently, *Rhodopseudomonas acidophila* was transferred to a new genus as *Rhodoblastus acidophilus* (Imhoff, 2001).

Rhodopseudomonas blastica was removed from this genus and transferred to *Rhodobacter blasticus* (Kawasaki et al., 1993b). Its 16S rDNA sequence is most similar to and clusters with those of the *Rhodobacter* species. *Rhodopseudomonas rutila* (Akiba et al., 1983) was considered as a later subjective synonym of *Rhodopseudomonas palustris* (Hiraishi et al., 1992). In addition to *Rhodopseudomonas palustris*, *Rhodopseudomonas julia* (Kompantseva, 1989) and *Rhodopseudomonas cryptolactis* (Stadtwald-Demchick et al., 1990) have been affiliated to this genus, though both species so far have not been validated and no 16S rDNA sequence of them is available.

Alpha-3 Proteobacteria

A characteristic feature of the phototrophic α-3 Proteobacteria (*Rhodobacter* group) is the presence of carotenoids of the spheroidene series and their extraordinary metabolic versatility and flexibility. These bacteria have been previously known as *Rhodopseudomonas* species and belong to the genera *Rhodobacter* and *Rhodovulum* (Pfennig and Trüper, 1974b; Imhoff et al., 1984b; Hiraishi and Ueda, 1994a). The former are freshwater bacteria and the latter true marine bacteria. Species of both genera have distinct 16S rDNA sequences (Hiraishi and Ueda, 1994a; Hiraishi and Ueda, 1995a; Hiraishi et al., 1996). Two new species, *Rhodovulum iodosum* and *Rhodovulum robiginosum*, have been described that use ferrous iron as photosynthetic electron donor (Straub et al., 1999). *Rhodobaca borogenensis*, a new isolate from an alkaline soda lake with low salt concentrations, has adapted in its salt response to this habitat (Milford et al., 2000).

Habitats

Ecological niches of phototrophic α-Proteobacteria are those anoxic parts of waters and sediments that receive light of sufficient quantity and quality to allow phototrophic development. Representatives of the purple nonsulfur bacteria are widely distributed in nature and are found not only in all kinds of stagnant water bodies, including lakes, waste water ponds, coastal lagoons, and in other aquatic habitats, but also in sediments, moist soils, and paddy fields. They live in aquatic habitats with significant amounts of soluble organic matter and low oxygen tension, but

rarely form colored blooms, like those of purple sulfur bacteria. However, often they are found accompanying the purple sulfur bacteria in stratified environments.

They have been found not only in freshwater, marine and hypersaline environments, and most frequently in habitats of moderate temperatures, but also in thermal springs and in cold polar habitats. Most purple nonsulfur bacteria have been isolated from all kinds of freshwater habitats where they also are most abundant. The greatest variety of species and the largest numbers of cells have been found in mud and water of eutrophic ponds, ditches and lakes. In the flat shore area of eutrophic lakes, 10^3 to more than 10^8 cells/ml of purple nonsulfur bacteria have been found in mud and water samples (Kaiser, 1966; Biebl and Drews, 1969). In pelagic water, the numbers usually are much lower (Biebl, 1973; Swoager and Lindstrom, 1971).

Quite a number of purple nonsulfur bacteria occur in marine and hypersaline environments. They are usually found in water bodies and sediments of intertidal flats, salt marshes, and polluted harbor basins, but not in the open sea. While freshwater isolates have a very low tolerance to sulfide, the sulfide tolerance of most marine species is much higher, and they even use sulfide and thiosulfate as photosynthetic electron donors. This is certainly an adaptation to this environment, which characteristically has a high activity of sulfate reduction and where consequently anoxic conditions are coincident with the presence of hydrogen sulfide. Although some isolates (strains of *Rhodopseudomonas palustris* and *Rhodomicrobium vannielii*) from marine habitats are not typical marine bacteria and do not require salt for optimum growth, most of the purple nonsulfur bacteria found in marine habitats are typical marine bacteria and are not found in freshwater habitats (Imhoff, 1988a). The marine forms include species of the genera *Rhodovulum* and *Rhodobium*, as for example *Rhodovulum sulfidophilum* (Hansen and Veldkamp, 1973), *Rhodovulum adriaticum* (Neutzling et al., 1984), *Rhodovulum euryhalinum* (Kompantseva, 1985), *Rhodobium marinum* (Imhoff, 1983a) and *Rhodobium orientis* (Hiraishi et al., 1995b). *Rhodospira trueperi* and *Roseospirillum parvum* are from a marine salt marsh and also represent typical marine bacteria. In addition, *Roseospira mediosalina* was isolated from a hot spring with low salt concentrations (2% salts) and is growing optimally between 5 and 7% NaCl (Kompantseva and Gorlenko, 1984).

Other halophilic species are well adapted to hypersaline environments. *Rhodothalassium salexigens* and *Rhodovibrio salinarum* are common to evaporated seawater pools and marine salterns and sometimes form colored layers in salt deposits or sediments (Drews, 1981; Nissen and Dundas, 1984; Rodriguez-Valera et al., 1985), whereas *Rhodovibrio sodomensis* is from Dead Sea sediments (Mack et al., 1993).

Some purple nonsulfur bacteria occur in acidic, boggy waters and soils. Most frequently, *Rhodoblastus acidophilus*, which grows optimally at pH 5.5–5.8, is found in such environments, often accompanied by *Rhodopseudomonas palustris* (Pfennig, 1969). *Rhodopseudomonas palustris* is very common and was isolated from all kinds of aquatic habitats (lakes, sewage and brackish waters), even from wet decaying leaves and from soils (Biebl and Pfennig, 1981; Imhoff and Trüper, 1992b). A preference for low pH values (pH 4.8-5.0) also is found in *Rhodopila globiformis* (Pfennig, 1974a).

Purple nonsulfur bacteria are found regularly in all stages of conventional sewage plants. Their numbers may increase dramatically from raw sewage to the activated sludge stage (from 2,000 to 100,000 cells/ml; Siefert et al., 1978). When anaerobic sewage is incubated in the light, it often spontaneously becomes red-brown in color owing to the presence of phototrophic bacteria. This suggests that it should be possible to easily direct the processes in the activated sludge towards photoassimilation of organic substrates by phototrophic bacteria. The first sewage treatment plant based on this principle was established in Japan (Kobayashi et al., 1971; see below).

Isolation

Two different strategies may be applied to isolate purple nonsulfur bacteria from their natural environment. Depending on the aims of the studies either the one or the other has clear preferences. According to classical enrichment techniques, phototrophic bacteria may be selectively enriched in suitable media under anoxic conditions and in the light; after visible growth, cells are separated in agar dilution series or on agar plates and isolated in pure culture. Alternatively pure cultures may be obtained by directly inoculating agar media from natural samples without prior enrichment.

The first strategy is the method of choice whenever the isolation of bacteria with particular physiological features is attempted. With a proper environmental sample and the right medium, bacteria with the desired properties may be selected and isolated. The second strategy has to be used whenever the natural diversity is to be analyzed and information on the natural abundance and distribution of the species in a sample is required. While specifically adapted

media are essential for the success of the first strategy, in the second one nonselective media are used with substrates (such as acetate, succinate or malate) that enable the development of most purple nonsulfur bacteria (Biebl and Pfennig, 1981; Imhoff and Trüper, 1992b). Even if the medium used can support only poor growth of a specific strain, after separation in or on agar and when the incubation time is adapted to the slow growth rates, it will grow out to a small colony and can be picked up for further transfers.

Selective Enrichment

Selective enrichment techniques for phototrophic bacteria were first used by Sergei Winogradsky (Winogradsky, 1888), and his technique is known as the "Winogradsky column." Variations of this column technique by other authors are discussed by Pfennig (1965) and Van Niel (1971). Van Niel (1944) elaborated the physiological basis for the enrichment of purple nonsulfur bacteria and was the first to develop a defined medium which could be used for their enrichment and cultivation.

For selective enrichment of purple nonsulfur bacteria, media have been used with lowered sulfate concentration to avoid production of sulfide by sulfate-reducing bacteria (Van Niel, 1944; Van Niel, 1971). An anaerobic enrichment culture using a common organic substrate and placed in the light usually will give rise to the development of purple nonsulfur bacteria. In many cases, in particular with marine samples, small Chromatiaceae—owing to their organotrophic capacity—compete with purple nonsulfur bacteria even if the sulfate concentration in the enrichment media is strongly reduced. The choice of the carbon source is not critical for the success of an enrichment culture because fermentative processes usually result in the formation of acetate or other acids (propionate, butyrate and lactate), which are good substrates for the majority of the purple nonsulfur bacteria. Some species of the purple nonsulfur bacteria, however, such as *Rhodovulum sulfidophilum* (Hansen and Veldkamp, 1973), *Rhodovulum adriacticum* (Neutzling et al., 1984) and *Blastochloris sulfoviridis* (Keppen and Gorlenko, 1975), tolerate and/or even require sulfide as a reduced sulfur source and/or photosynthetic electron donor.

Besides the mineral salts composition and the concentration of nutrients of the media, also the addition of vitamins, the pH, temperature, light intensity and light regime are of general importance for the selectivity of enrichment cultures. If samples from marine and hypersaline environments are investigated, the salinity and the mineral composition of the medium are of special importance.

A few examples of selective parameters for the enrichment of purple nonsulfur bacteria are the following:

Selective carbon sources for *Rhodopseudomonas palustris* are benzoate and formate (Qadri and Hoare, 1968). Because this species is very common in nature, many enrichments for purple nonsulfur bacteria will end up with the development of this species even without particularly selective conditions.

Enrichments under photoautotrophic conditions with hydrogen as electron donor favor growth of *Rhodobacter capsulatus*, which grows faster under these conditions than other phototrophic bacteria do (Klemme, 1968). Also this species often becomes predominant in unselective media.

Higher fatty acids like pelargonate and caproate (not more than 0.04% at pH 7.5) provide selective growth conditions for *Phaeospirillum fulvum* and *Phaeospirillum molischianum* (Pfennig, 1967; Van Niel, 1944).

For enrichment of *Rhodospirillum photometricum*, the anaerobic infusion method of Molisch (Giesberger, 1947) is still the best method (Biebl and Pfennig, 1981). Hay or other dried plant materials are suitable sources which may be used in large test tubes or cylinders under continuous illumination. *Rhodospirillum photometricum* also can be readily enriched from activated sludge incubated anaerobically in the light (1,000 lux, 30°C; Siefert et al., 1978).

The use of amino acids as carbon substrates favors the development of the *Rhodospirillum* species, in particular of *Rhodospirillum rubrum* (Biebl and Pfennig, 1981).

A succinate-mineral salts medium without growth factors and with an initial pH of 5.5 is highly selective for both *Rhodoblastus acidophilus* and *Rhodomicrobium vannielii* (Pfennig, 1969). If yeast extract or the required vitamins are present *Rhodopseudomonas palustris* may also develop under acidic conditions.

Enrichments in methanol bicarbonate medium select for *Rhodoblastus acidophilus* (and *Rubrivivax gelatinosus*).

Typical marine bacteria will not or only poorly grow in media without NaCl, though most freshwater species are inhibited by NaCl concentrations of sea water. Therefore, the addition of 3% NaCl is a selective factor for marine purple nonsulfur bacteria.

Salt concentrations of more than 10% are highly selective for moderately halophilic species like *Rhodothalassium salexigens*, *Rhodovibrio salinarum* and *Rhodovibrio sodomensis* that will not grow in media for freshwater or marine phototrophic bacteria.

Isolation Procedures

Direct Isolation. Methods of direct isolation of the phototrophic bacteria from a natural sample use agar dilution series or inoculation of agar plates to separate the cells prior to incubation. For isolation with solid media, water samples are most appropriate. A sample of mud, sludge, or soil may be used as a homogeneous suspension in medium or filter-sterilized water from the habitat. Samples containing less than 10 cells/ml need to be concentrated by centrifugation (agar dilution series) or filtration (agar plates). All methods for direct isolation are suitable for the determination of living cell counts, when known amounts of the sample are used in appropriate dilutions.

Preparation of Agar Dilution Series. Agar dilution series are prepared either with enrichment cultures or with promising natural samples by direct inoculation with an environmental sample. Selective media are not required and nonselective ones are preferred for a direct isolation without prior enrichment procedure.

In a modification of the method of Pfennig (Pfennig, 1965; Trüper, 1970), purified agar is dissolved (1.8%) and distributed in amounts of 3 ml into cotton-plugged test tubes. The agar is sterilized by autoclaving. The liquid agar is kept at 50°C in a water bath until use. A suitable medium is placed in the same water bath, and 6 ml of the prewarmed medium is added to each test tube. Medium and agar are mixed thoroughly by turning the tubes upside down and back and kept at 50°C. Eight tubes are sufficient for each dilution series. The first tube is inoculated with a natural sample or enrichment culture and mixed carefully; approximately 0.5 to 1.0 ml is transferred to a second tube, mixed carefully, and the procedure continued up to the last tube. The tubes are immediately placed into a cold water bath. After the agar has hardened, they are sealed with a paraffin mixture (3 parts paraffin oil and 1 part paraffin) and kept in the dark for several hours before they are incubated in the light (ca. 500–2,000 lux). After cells have grown to visible colonies, the paraffin layer is removed by melting, and well separated colonies are picked with a Pasteur pipette (the tip drawn out to a thin capillary) and transferred to a second dilution series. In general, three to four such dilution series are necessary to obtain pure cultures. When pure cultures have been obtained, single colonies are inoculated into liquid medium.

Cultivation on Agar Plates. Purple nonsulfur bacteria have quite often been successfully isolated on agar plates. When high numbers of phototrophic bacteria are present in the sample, streaking by conventional methods is appropriate. Samples containing low numbers of phototrophic bacteria can be easily concentrated on membrane filters (e.g., cellulose acetate or cellulose nitrate with 0.4 μm pore size; Biebl, 1973; Biebl and Drews, 1969; Swoager and Lindstrom, 1971; Westmacott and Primrose, 1975). The filter assembly is used after autoclaving, and the filters are transferred onto the agar surface with sterile tweezers. Samples with high numbers of purple nonsulfur bacteria (more than 100 cells/ml) may be diluted prior to filtration or distributed on the agar with a Drigalsky spatula (approximately 0.1 ml of a sample containing 100–300 cells/ml; Biebl and Drews, 1969).

Incubation of the plates is recommended in an anaerobic jar in which the air is replaced by an oxygen-free mixture of nitrogen with 5% carbon dioxide and 3% hydrogen. Remaining traces of oxygen are removed by reaction with hydrogen over a palladium catalyst. Alternatively the GasPak system (Becton, Dickinson and Co.) or comparable systems may be used. A more detailed description of these methods is given by Biebl and Pfennig (1981). Normally, an incubation time of five or more days is required before intensely colored colonies of purple nonsulfur bacteria become visible. Occasionally, unicellular green algae develop and form flat spots of grass-green color. Sometimes purple sulfur bacteria, in particular *Thiocapsa roseopersicina* and *Allochromatium vinosum*, also develop.

Media

A large number of media have been used for the enrichment and cultivation of purple nonsulfur bacteria (Biebl and Pfennig, 1981; Drews, 1965; Haskins and Kihara, 1967; Imhoff, 1982b; Imhoff and Trüper, 1976; Kaiser, 1966; Mack et al., 1993; Pfennig, 1969; Pfennig, 1978; Pratt and Gorham, 1970; Swoager and Lindstrom, 1971; Van Niel, 1944).

For the isolation and cultivation of purple nonsulfur bacteria from freshwater and marine sources, the AT medium (Imhoff and Trüper, 1976; Imhoff, 1982b; Imhoff, 1988c) with numerous slight modifications has been successfully used as a basic medium for more than 20 years in the author's laboratory. It can be used for cultivation of the great majority of the purple nonsulfur bacteria. It is also well suited for enrichment cultures of freshwater and marine purple nonsulfur bacteria. For the purpose of selective enrichment cultures, sulfate is omitted, a sulfate-free trace element solution (SLA) is used and selective carbon and nitrogen substrates are added. With nonselective carbon sources such as acetate, pyruvate, malate, succinate or fumarate, this medium is well suited for the isolation and enumeration of purple nonsul-

fur bacteria in agar dilution series or on agar plates. A vitamin solution (VA) is used that adds sufficient amounts of all vitamins required by known purple nonsulfur bacteria (Imhoff, 1988c; see below).

AT Medium

Dissolve in and dilute to 1 liter with distilled water:

KH_2PO_4	1.0 g
$MgCl_2 \cdot 6H_2O$	0.5 g
$CaCl_2 \cdot 2H_2O$	0.1 g
Na_2SO_4	0.7 g
NH_4Cl	1.0 g
$NaHCO_3$	3.0 g
NaCl	1.0 g
Na-acetate (or other carbon source)	1.0 g

Add: 1 ml of trace element solution SLA (see below)
1 ml of vitamin solution VA (see below)
10 ml of 5% sodium ascorbate
Adjust pH to 6.9.

The medium is filter-sterilized, collected in an autoclaved 2-liter Erlenmeyer flask with an outlet at the bottom and distributed from this vessel into sterile screw-cap bottles of desired volume (usually 50-ml and 1-liter bottles) under sterile conditions. These bottles are filled completely (not more than a pea-sized air bubble should be left) and can be stored for several months. To achieve anoxic conditions and to remove the oxygen from the medium, 0.05% sodium ascorbate is added. To avoid oxidation of the ascorbate prior to distribution into the bottles, it is added to the medium immediately before sterile filtration.

Yeast extract stimulates growth of most of the known purple nonsulfur bacteria. It is used as a source of growth factors and may be added at a concentration of 0.05%.

For *Phaeospirillum* and *Rhodospirillum* species addition of 0.01% Fe-citrate is growth stimulating. It may also be routinely added to the medium, except when sulfide is present.

For the cultivation of *Rhodoblastus acidophilus* and *Rhodomicrobium vannielli*, the pH is adjusted to 5.5.

For marine species, NaCl is added. A saline modification of the medium, the SAT medium, contains 3% NaCl.

For iron-oxidizing purple nonsulfur bacteria, 10 mM ferrous iron is added to completely anoxic media buffered with 20 mM bicarbonate at pH 7.0 (Ehrenreich and Widdel, 1994). An anoxic stock solution of $FeSO_4$ is autoclaved, maintained under nitrogen, and used to supplement the media. To increase the solubility of iron, chelators such as citrate or nitrilotriacetic acid may be added.

Some purple nonsulfur bacteria can tolerate sulfide to various degrees and/or use it as a photosynthetic electron donor. For these species, sodium sulfide is added at low concentrations of 0.4–1.0 mM (up to 2 mM for more tolerant strains). Some species even are dependent on the presence of reduced sulfur sources because they lack the ability to use sulfate as an assimilatory sulfur source. For these bacteria also low concentrations of sulfide may be used, or alternative sources of reduced sulfur such as thiosulfate, cysteine or methionine may be applied.

Vitamin Solution VA

(Modified after Imhoff and Trüper, 1977)

Biotin	10 mg
Niacin	35 mg
Thiamine dichloride	30 mg
p-Aminobenzoic acid	20 mg
Pyridoxolium hydrochloride	10 mg
Ca-panthothenate	10 mg
Vitamin B_{12}	5 mg

This vitamin solution meets the vitamin requirements of all purple nonsulfur bacteria. More specifically, for the culture of individual strains or species, the vitamins may be added individually or in desired combinations at the indicated concentration. Dissolve in 100 ml of distilled water, sterilize by filtration, keep refrigerated, and add 1 ml per liter of medium.

Trace Element Solution SLA

(Modified after Imhoff and Trüper, 1977)

$FeCl_2 \cdot 4H_2O$	1,800 mg
$CoCl_2 \cdot 6H_2O$	250 mg
$NiCl_2 \cdot 6H_2O$	10 mg
$CuCl_2 \cdot 2H_2O$	10 mg
$MnCl_2 \cdot 4H_2O$	70 mg
$ZnCl_2$	100 mg
H_3BO_3	500 mg
$Na_2MoO_4 \cdot 2H_2O$	30 mg

These salts are dissolved separately in a total of 900 ml of double-distilled water; the solutions are mixed, the pH is adjusted to about 2–3 with 1 N HCl, and the final volume is brought to 1 liter.

Medium for *Rhodopila globiformis*

(Modified after Pfennig, 1974a)

Mannitol	1.5 g
Gluconate	1.5 g
KH_2PO_4	0.4 g
NaCl	0.4 g
$CaCl_2 \cdot 2H_2O$	0.05 g
$MgCl_2 \cdot 6H_2O$	0.4 g
NH_4Cl	0.4 g
Na-thiosulfate	0.2 g

Dissolve the above in and dilute up to 1 liter with distilled water.

Add separately: 1 ml of SLA (or equivalent trace element solution)
1 ml of VA
5 ml of 0.1% Fe-citrate solution
Adjust pH to 4.9.

Complex Medium

(Modified after Nissen and Dundas, 1984)

$MgCl_2 \cdot 6H_2O$	3.5 g
KH_2PO_4	0.3 g
NaCl (depending on desired salinity)	100 g
Yeast extract (Difco)	1.5 g
Proteose peptone (Difco)	1.5 g
Na-malate	10 mM
Trace element solution SLA	1 ml

Dissolve the above in and dilute up to 1 liter of distilled water. Then adjust pH to 7.0. All strains of halophilic purple nonsulfur bacteria including our own isolates grow well in this medium. This and the complex medium described by Drews (1981) are suitable for growth of *Rhodothalassium salexigens* and *Rhodovibrio salinarum*.

Synthetic Medium for Halophilic (Purple Nonsulfur) Phototrophic α-Proteobacteria

(Modified from Imhoff, 1988c)

$NaHCO_3$	3.9 g
KH_2PO_4	0.5 g
KCl	1.0 g
$CaCl_2 \cdot 2H_2O$	0.05 g
$MgCl_2 \cdot 6H_2O$	3.5 g
Na_2SO_4	1.0 g
NaCl (depending on desired salinity)	40–150 g
Proline	5.0 mM
Acetate	2.0 mM
Pyruvate	2.0 mM
K_3 citrate	10.0 mM
Glycine betaine	10.0 mM
Na-glutamate	5.0 mM
Vitamin solution VA (see above)	1 ml
Trace element solution SLA (see above)	1 ml

Dissolve the above in and dilute up to 1 liter of distilled water. Adjust pH to 7.0. Sterilize by filtration.

For special biochemical and physiological studies, synthetic media (such as this one) are required. The NaCl concentration is varied according to the desired salinity.

Identification

Identification of new isolates can be obtained only by detailed studies of physiological and morphological properties together with chemotaxonomic information and genetic sequence data. To distinguish closely related strains and species of the same genus, often DNA-DNA hybridization studies are required.

Because of the great diversity of the phototrophic α-Proteobacteria, a tentative assignment to one of the known genera often is much easier. Owing to the different physicochemical requirements of the species (e.g., salinity, pH and possibly temperature) and their physiological potential, the choice of the medium and the culture conditions for enrichment and isolation restrict the number of possible species that will be able to develop. Important additional information can be obtained from the color, size and consistency of the colonies on agar plates, the color of cell suspensions, and microscopic examinations. The shape of the cells, cell width and length, motility, mode of division, formation of cell aggregates, and presence of slime capsules are relevant properties that can be recognized in the light microscope. The cell morphology of a few representative species using light microscopy is shown in Fig. 4. Ultrathin sections under the electron microscope reveal the fine structure of the cells, in particular the type of the internal membrane system.

In many species, the color of cell suspensions is indicative of the major type of carotenoids present (Schmidt, 1978). Spirilloxanthin as the major component gives a pink or red color, increasing amounts of additional rhodopin turn the color to brown-red, rhodopin without significant amounts of spirilloxanthin results in brown, okenone results in purple-red, and rhodopinal results in purple-violet. Carotenoids of the spheroidene series give colors from yellowish brown to brownish red (depending on the content of oxygenated derivatives formed in the presence of oxygen) and greenish to beige-brown under strongly reducing conditions. Carotenoidless mutants of *Rhodospirillum rubrum* and *Rhodobium marinum* are blue in color.

In addition to the color of cell suspensions, absorption spectra yield preliminary information on the predominant bacteriochlorophylls and on the kind of bacteriochlorophyll-protein complexes. The carotenoids absorb at 480–550 nm. Absorption bands of bacteriochlorophyll a in vivo are at 380, 590–600, and 800–900 nm. Owing to the formation of different light-harvesting complexes, absorption spectra show a remarkable variation in the long wavelength range from 800–900 nm. Absorption spectra of whole cells are measured with cell suspensions washed twice in medium or appropriate salt solutions and then suspended in 60% sucrose solution (Biebl and Drews, 1969). Better results are often achieved by using isolated internal membranes suspended in buffer. For this purpose, it is sufficient to break the cells by ultrasonication or with a French press and to separate whole cells and large cell fragments from the internal membranes by centrifugation at 15,000 g.

For the detailed description of a new bacterium, careful physiological studies are required, including the utilization of substrates, relations to oxygen, the ability to grow in darkness, respiratory and fermentative growth, vitamin requirement, and ranges and optima of salt concentration, pH and temperature.

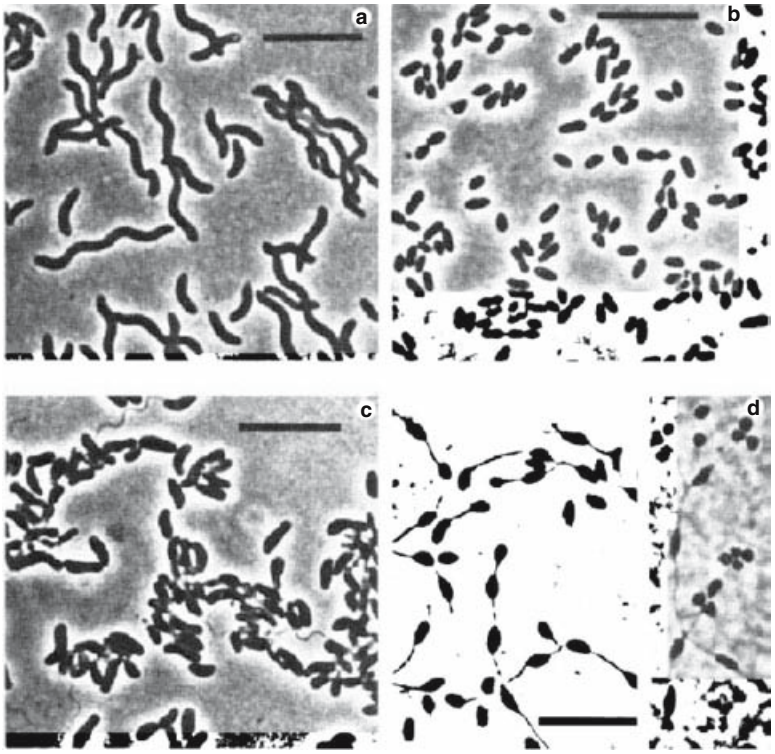

Fig. 4. Morphology of *Rhodospirillum rubrum* (a); *Rhodobacter sphaeroides* (b); *Rhodopseudomonas acidophilia* (c); *Rhodomicrobium vannielii* (d), left: Vegetative cells with polyhedral exospores; phrase contrast micrographs. (Bar = 10 μm.)

In addition to the phenotypic characterization, information on the genetic relatedness of a new isolate has to be obtained. To achieve a phylogenetic classification, 16S rDNA sequences are used and when the distinction of closely related strains and species is required (DeBont et al., 1981), DNA-DNA hybridization studies are performed. For the description of a new species, also the determination of the G+C content of the DNA is recommended.

Also chemotaxonomic properties have been found to be quite helpful to identify and classify new isolates of phototrophic bacteria (Hiraishi et al., 1984; Imhoff, 1984a; Imhoff, 1988b; Imhoff et al., 1982c; Imhoff et al., 1984b; 1998; Imhoff and Bias-Imhoff, 1995b; Thiemann and Imhoff, 1996; Imhoff and Süling, 1996; Pfennig et al., 1997). In particular the ring structure and the isoprenoid chain length of respiratory quinones and the fatty acid composition of the cell membranes are quite useful in identification (Hiraishi et al., 1984; Imhoff, 1984a). The structure and composition of polar lipids and lipopolysaccharides also are diagnostic properties of high value (Imhoff and Bias-Imhoff, 1995b; Weckesser et al., 1995). The need for sophisticated analytical methods, however, makes these properties less accessible for diagnosis.

Characteristic properties of presently known species of the phototrophic purple α-Proteobacteria that are of diagnostic value are shown in Tables 1–3. An arbitrary selection of outstanding properties of a few selected species follows:

Cultures of *Blastochloris viridis* and *Blastochloris sulfoviridis* are olive-green in color and contain bacteriochlorophyll β with an absorption maximum at 1020–1030 nm.

Cultures of *Rhodospira trueperi* are peach colored and reveal unusually low long-wavelength absorption maxima of bacteriochlorophyll b at 986 nm.

The in vivo absorption spectra of *Rhodospirillum rubrum* and *Rhodobium marinum* are characterized by an unusually low absorption maximum at approximately 803 nm and a single dominant peak without a shoulder (should be checked in derivative spectra) at 870–885 nm. This is taken as indication of the lack of peripheral light-harvesting complexes. Additional species with such spectra are *Rhodovibrio sodomensis*, *Rhodobaca bogoriensis* and *Rhodocista centenaria*.

For *Rhodomicrobium vannielii*, the peritrichous flagellation of swarmer cells, the formation of cell aggregates connected by thin filamentous tubes and the formation of exospore-like cysts of moderate heat resistance are typical.

Swarming motility on agar surfaces is characteristic for *Rhodocista centenaria*, which also forms desiccation- and heat-resistant cysts (Favinger et al., 1989).

A definitive growth requirement for salt is found in the marine species of *Rhodovulum* and *Rhodobium* and also in *Rhodospira trueperi*, *Roseospira mediosalina* and *Roseospirillum parvum*.

[a]Optimal growth in the absence of NaCl, but able to grow at 3% NaCl.

The tolerance of salt concentrations of more than 10% and growth under these conditions are characteristic for the halophilic species *Rhodothalassium salexigens*, *Rhodovibrio salinarum* and *Rhodovibrio sodomensis*.

Preservation

For short-term preservation, well-grown cultures may be kept in closed, air-tight screw-cap bottles at 6–10°C in a refrigerator (or cold room) or at room temperature for several months, even years. Maintenance transfer of liquid cultures should occur at intervals of 2–6 months. In particular *Rhodopseudomonas palustris* and some *Rhodobacter* species have been shown to maintain viable cells over very long time periods. Stock cultures of the brown-colored *Rhodospirillum* and *Phaeospirillum* species and of other oxygen-sensitive species should be grown in the presence of 0.05% sodium ascorbate and transfers should be made every 1–2 months. Also, stock cultures of *Blastochloris sulfoviridis* and *Rhodopila globiformis* should be transferred more frequently. Stock cultures are incubated anaerobically in screw-cap 50-ml bottles in the described media at 25–30°C and 2,000 lux and then taken from the light during late exponential growth phase. Stock cultures also may be maintained for prolonged times in agar stab cultures or in appropriate dilutions of agar dilution series, sealed with paraffin and kept in the dark.

For long-term storage, preservation in liquid nitrogen is recommended. Well grown cultures are supplemented with 50% dimethyl sulfoxide to give a final concentration of 5%, thoroughly mixed, dispensed in plastic ampoules, sealed and frozen in liquid nitrogen. Preservation and storage in liquid nitrogen are possible with all strains tested with either dimethylsulfoxide (5%) or glycerol (10%) as a protecting agent.

Several purple nonsulfur bacteria were succsessfully preserved by freeze-drying (Biebl and Malik, 1976). The best protecting agent was skim milk (20%) supplemented with 10% sucrose, but most strains also survived in 10% sucrose alone. The brown-colored *Phaeospirillum* and *Rhodospirillum* species could not be lyophilized successfully (Biebl and Malik, 1976).

Physiology

A comprehensive treatment of the various aspects of the physiology of purple nonsulfur bacteria including structure, function and genetics of the photosynthetic apparatus is found in various chapters of *The Photosynthetic Bacteria* (Clayton and Sistrom, 1978) and *Anoxygenic Phototrophic Bacteria* (Blankenship et al., 1995). A short overview on physiology and photosynthesis is given by Drews and Imhoff (1991). In the following, the basic principles and a few specific examples of metabolic properties of the phototrophic α-Proteobacteria are presented.

Photosynthesis

Purple nonsulfur bacteria are anoxygenic phototrophic bacteria, growing phototrophically under anoxic conditions in the light without producing oxygen. All species can grow photoorganoheterotrophically using organic substrates as photosynthetic electron donors and carbon sources. Many representatives also grow under photolithoautotrophic conditions with reduced sulfur compounds, with hydrogen or ferrous iron ions as electron donor and CO_2 as sole carbon source.

Anoxygenic photosynthesis depends on the presence of a complex membrane-bound photosynthetic apparatus, which includes reaction center and light harvesting (antenna) pigment-protein complexes. The proteins of reaction center and antenna noncovalently bind bacteriochlorophyll, carotenoids and other cofactors in stoichiometric ratios. Most purple nonsulfur bacteria have two antenna complexes. The complexes of the reaction center are surrounded by core antenna (a B870 or B890 antenna complex with bacteriochlorophyll a and a B1020 complex with bacteriochlorophyll *b*) and additional peripheral antenna (B800-850 and B800-820 complexes with bacteriochlorophyll *a*). Species such as *Rhodospirillum rubrum* and *Rhodobium marinum* lack peripheral antenna complexes and can be recognized by their minor absorption maxima at 803 nm. Most purple nonsulfur bacteria have one type of peripheral antenna complex (B800-850). The synthesis of multiple forms of peripheral antenna polypeptides with varying proportions under different growth conditions (as found in *Rhodoblastus acidophilus* and *Rhodopseudomonas palustris*) and the formation of different peripheral antenna complexes result in a complex pattern of absorption maxima that is only resolved in derivative spectra (Brunisholz and Zuber, 1992; Zuber and Cogdell, 1995).

The principal function of the photosynthetic apparatus is the light-mediated excitation of a bacteriochlorophyll molecule in the reaction center followed by charge separation and resulting in electron transfer through the membrane. Most purple nonsulfur bacteria have an internal membrane system in which the photosynthetic apparatus is integrated. These internal membranes form vesicles, tubules or lamellar structures and are interconnected to the cytoplasmic

membrane. They can be isolated by cell rupture and fractionated centrifugation. Quite characteristically, the production of photosynthetic pigments, pigment-protein complexes and of the photosynthetic membrane structures is suppressed by oxygen. A notable exception is *Rhodocista centenaria* (Yildiz et al., 1991).

(Note: We distinguish between the anoxygenic phototrophic purple nonsulfur bacteria [which use photosynthesis as primary energy source and are well adapted to the anoxic way of life] and the aerobic bacteriochlorophyll-containing bacteria [which primarily gain energy by aerobic respiration but are unable to grow by anoxygenic photosynthesis under anoxic conditions]. The latter are treated elsewhere.)

Respiration

Chemoorganoheterotrophic growth in the presence of oxygen is common among purple nonsulfur bacteria and most of the known species are facultatively chemotrophic. While some species are very sensitive to oxygen, others grow equally well under oxic conditions in the dark at the full oxygen tension of air. Also chemolithoautotrophic growth with hydrogen or reduced sulfur compounds as electron donors and oxygen as electron acceptor has been demonstrated (Madigan and Gest, 1979; Siefert and Pfennig, 1979). Under anoxic dark conditions, growth of several species is also supported by respiratory electron transport in the presence of nitrate, nitrite, and nitrous oxide. Denitrification is induced by nitrate, either in the dark or in the light, but is suppressed by oxygen. A single strain of *Rhodobacter sphaeroides*, described as a subspecies, *Rhodobacter sphaeroides* f. sp. *denitrificans* (Satoh et al., 1976), but later recognized as a regular strain of *Rhodobacter sphaeroides* (De Bont et al., 1981; Imhoff, 1989a), was the first phototrophic purple bacterium known to use nitrate as an electron acceptor under anoxic dark conditions. Later, nitrate reduction was found in additional strains of *Rhodobacter sphaeroides* (Michalski and Nicholas, 1988), in strains of *Rhodopseudomonas palustris* (Klemme et al., 1980), and in *Rhodobacter capsulatus* (McEwan et al., 1984). Some of these strains could not grow with nitrate as sole nitrogen source, but dinitrogen produced during denitrification might be assimilated under these growth conditions (Dunstan et al., 1982). Also, *Rhodobacter azotoformans*, *Rhodobium orientis* and *Rhodoplanes roseus* and *Rhodoplanes elegans* are able to denitrify (Hiraishi and Ueda, 1994b; Hiraishi et al., 1995b; Hiraishi et al., 1996).

Anaerobic growth on sugars with dimethylsulfoxide (DMSO) or trimethylamine-*N*-oxide (TMAO) as an additional oxidant has been observed first in *Rhodobacter capsulatus* (Yen and Marrs, 1977) and later also in other species. Energy generation during growth with fructose and TMAO was proposed to be due to anaerobic respiration (Schultz and Weaver, 1982), and the generation of a membrane potential under these conditions has been demonstrated (McEwan et al., 1983). Later it was questioned that a true electron transport chain is involved in DMSO and TMAO reduction. The physiological role of these external oxidants was discussed in detail (Ferguson et al., 1987; Zannoni, 1995).

Fermentation

In the absence of external electron acceptors, a number of purple nonsulfur bacteria can use fermentative processes for energy generation (Uffen, 1978). During fermentative growth, substrates or storage products are oxidized incompletely, and reduced organic compounds as well as CO_2 and H_2 are produced. *Rhodospirillum rubrum* forms succinate, acetate, propionate, formate, CO_2 and H_2 during fermentation of fructose (Schön and Biedermann, 1973), whereas acetate, formate and equimolar amounts of CO_2 and H_2 are produced from pyruvate (Uffen, 1973). *Rhodobacter capsulatus* produces succinate, lactate, acetate, CO_2 and H_2 under identical conditions (Schultz and Weaver, 1982).

Carbon Metabolism

Organic carbon sources have quite different functions under phototrophic, respiratory and fermentative metabolism. Under phototrophic growth conditions, they serve primarily as a source of cellular carbon, but in addition may function as an electron source for photosynthetic electron transport; in the presence of inorganic electron donors, they may be exclusively photoassimilated. During respiratory growth, the major part of the carbon sources is completely oxidized and only a minor fraction is assimilated into cell substance. Enzymatic reactions of the citric acid cycle involved in substrate oxidation would be expected at elevated levels under these conditions and indeed have been found to be increased during respiratory growth of *Rhodobacter capsulatus* (Beatty and Gest, 1981). During fermentation, substrates or storage products are oxidized incompletely on a large scale, and reduced organic compounds and hydrogen are excreted to achieve a redox balance of the cells.

Most of the purple nonsulfur bacteria can use a variety of different organic carbon sources. Intermediates of the tricarboxylic acid cycle in addition to acetate and pyruvate are generally used. A number of purple nonsulfur bacteria use straight-chain saturated fatty acids with 5–18 car-

bon atoms (Janssen and Harfoot, 1987). Also organic acids, amino acids, alcohols and carbohydrates support growth of many of these bacteria. Carbon substrates such as citrate and aromatic compounds are used by a few species only. Citrate for instance is used by *Rubrivivax gelatinosus* (a β-Proteobacterium), *Rhodobacter sphaeroides*, *Rhodobacter blasticus*, *Rhodovulum strictum*, *Rhodothalassium salexigens*, *Rhodoblastus acidophilus*, *Rhodoplanes roseus*, *Rhodoplanes elegans* and by some strains of *Blastochloris viridis*, *Rhodobium marinum* and *Rhodopseudomonas palustris*. Some of these bacteria grow weakly with citrate.

A small number of species (*Rhodopseudomonas palustris*, *Rubrivivax gelatinosus*, *Phaeospirillum fulvum*, *Rhodocyclus purpureus*, *Rhodoblastus acidophilus* and *Rhodomicrobium vannielii*) can grow at the expense of aromatic organic compounds, such as benzoate, 3-hydroxybenzoate, 4-hydroxybenzoate, 1,3,5-trihydroxybenzene and other hydroxylated, methoxylated aromatic acids and aldehydes (Dutton and Evans, 1978). The ability to use aromatic compounds is best developed in *Rhodopseudomonas palustris*. This species also metabolizes phenolic acids, phenylalkane carboxylates, 4-hydroxy-cinnamate and related compounds (Harwood and Gibson, 1988; Gibson and Harwood, 1995). Most of these compounds support both phototrophic (anoxic conditions in the light) and chemotrophic (oxic conditions in the dark) growth; some are degraded only under the one or the other condition. During phototrophic growth, a reductive pathway for cleavage of the aromatic ring structure is used (Dutton and Evans, 1969; Gibson and Harwood, 1995).

Acetate is assimilated by almost all purple nonsulfur bacteria. The metabolic pathways of acetate assimilation, however, are quite different among the species. In many phototrophic purple bacteria, the primary reaction of acetate metabolism is the ATP-dependent formation of acetyl CoA, which is the substrate for further reactions. The two key enzymes of the glyoxylate cycle, isocitrate lyase and malate synthase, are present in most of these bacteria and acetate is assimilated via this pathway. There is, however, some variance in the literature regarding the presence of isocitrate lyase, in particular in *Rhodospirillum rubrum* and *Rhodobacter sphaeroides* (Tabita, 1995). Certainly, alternative pathways of acetate assimilation are possible. For *Rhodospirillum rubrum*, the conversion of acetate to oxalacetate by two carboxylation reactions from acetate to pyruvate and further to oxalacetate has been postulated (Buchanan et al., 1967). In *Rubrivivax gelatinosus* (a β-Proteobacterium), photoassimilation of acetate is possible via the serine-hydroxypyruvate pathway (Albers and Gottschalk, 1976).

For purple nonsulfur bacteria, CO_2 is an important carbon source. Under autotrophic growth conditions with CO_2 as sole carbon source, the Calvin cycle with ribulose bisphosphate carboxylase (RubisCO) as key enzyme is employed (Tabita, 1995). This enzyme is well studied and constitutes a major fraction of the cellular protein in bacteria that grow with CO_2 as sole carbon source and use the Calvin cycle. Also, CO_2 is required under heterotrophic growth conditions during assimilation of several reduced organic substrates. A number of carboxylating enzyme activities are responsible for this "heterotrophic CO_2 fixation" (see Kondratieva, 1979; Tabita, 1995). For instance, assimilation of propionate is connected with a carboxylation to succinate. Also, long-chain fatty acids and other highly reduced substrates such as methanol require CO_2 to elevate the oxidation-reduction level of these substrates to that of the cell material.

One-carbon compounds, such as methanol and formate, also are used by strains of a limited number of species. *Rhodomicrobium vannielii*, *Rhodobium marinum*, *Rhodoblastus acidophilus*, *Rhodospirillum rubrum*, *Rubrivivax gelatinosus*, *Rhodocyclus tenuis* and several *Rhodobacter* and *Rhodovulum* species use formate as carbon source. Reasonable growth rates with methanol were found only in strains of *Rhodoblastus acidophilus* (Douthit and Pfennig, 1976). Apparently, the RubisCO pathway is involved in carbon assimilation of *Rhodoblastus acidophilus* also during growth on methanol and formate; both substrates are used as electron donors and are oxidized to CO_2, which in turn is assimilated (Quale and Pfennig, 1975; Sahm et al., 1976). *Rubrivivax gelatinosus* is able to grow anaerobically in the dark with CO as sole source as carbon and energy. Under these conditions, CO is transformed into CO_2 and H_2, and RubisCO could be involved in assimilation of the latter (Uffen, 1983). In *Rhodospirillum rubrum*, CO is used under anoxic conditions during phototrophic growth and induces an oxygen-sensitive CO dehydrogenase (Bonam et al., 1989).

Sulfur Metabolism

The role of reduced sulfur compounds as photosynthetic electron donors for purple nonsulfur bacteria was realized together with the recognition of their importance in the marine environment. Purple nonsulfur bacteria vary greatly in their sulfur metabolism.

Most purple nonsulfur bacteria, in particular freshwater species, are inhibited by sulfide even

at low concentrations. Some species, however, are quite tolerant to this toxic compound and use it as a photosynthetic electron donor (Hansen and Imhoff, 1985; Hansen and van Gemerden, 1972; Imhoff, 1982a; Imhoff, 1983a; Neutzling et al., 1984). The tolerance of *Rhodovulum sulfidophilum* is high and comparable to that of *Allochromatium vinosum*. *Rhodomicrobium vannielii* tolerates concentrations of 2–3 mM, whereas growth of *Rhodobacter capsulatus* is completely inhibited at 2 mM. At low concentrations of sulfide (0.4–0.8 mM), however, growth of this species is quite rapid. Growth of *Rhodopseudomonas palustris*, as of most of the purple nonsulfur bacteria, is inhibited at concentrations as low as 0.5 mM sulfide (Hansen and van Gemerden, 1972). In general, small amounts of yeast extract in the media increase the tolerance towards sulfide.

In addition to sulfide, some purple nonsulfur bacteria can use thiosulfate as an electron donor. Extracellular elemental sulfur is the final oxidation product during sulfide oxidation of a number of purple nonsulfur bacteria, such as *Rhodospirillum rubrum*, *Rhodobacter capsulatus*, *Rhodobacter sphaeroides* (Hansen and Veldkamp, 1973) and *Roseospira mediosalina* (Kompantseva and Gorlenko, 1984). Elemental sulfur occurs outside the cells. Only with *Rhodopseudomonas julia* elemental sulfur was microscopically observed outside as well as inside the cells (Kompantseva, 1989). Oxidation of elemental sulfur is found in a limited number of species, as in *Rhodobacter veldkampii*, *Rhodovulum euryhalinum*, *Rhodovulum adriaticum* and *Rhodopseudomonas julia*. In these species, elemental sulfur is an intermediate product during oxidation to sulfate (Hansen, 1974; Hansen and Imhoff, 1985; Neutzling et al., 1984; Kompantseva, 1985; Kompantseva, 1989). Sulfate is formed from sulfide without formation of elemental sulfur in *Rhodovulum sulfidophilum*, *Rhodovulum strictum*, *Rhodopseudomonas palustris* and *Blastochloris sulfoviridis* (Hansen, 1974; Hiraishi and Ueda, 1995a; Neutzling et al., 1985). Tetrathionate is the only oxidation product of *Rhodomicrobium vannielii* grown in a chemostat, but in batch culture, sulfide reacts with the tetrathionate formed, so that thiosulfate is the major product (together with minor amounts of elemental sulfur) accumulated under these conditions; sulfate is not formed under either condition (Hansen, 1974).

With a few notable exceptions, the purple nonsulfur bacteria can use sulfate as an assimilatory sulfur source. Apparently two different pathways occur in these bacteria, involving either adenosine 5′-phosphosulfate (APS) or 3′-phosphoadenosine 5′-phosphosulfate (PAPS; Imhoff, 1982b). In the presence of reduced sulfur compounds, these are preferentially assimilated and the energetically expensive assimilation of sulfate is repressed (Imhoff et al., 1983b). Common alternative assimilatory sulfur sources include sulfite, thiosulfate, cysteine, glutathione, methionine and sulfide. *Rhodovulum adriaticum*, *Rhodovulum iodosum*, *Rhodovulum robiginosum*, *Rhodovulum euryhalinum*, *Blastochloris sulfoviridis*, *Rhodopseudomonas julia*, *Rhodobacter veldkampii* and *Roseospirillum parvum* require reduced sulfur sources and are unable to assimilate sulfate (Keppen and Gorlenko, 1975; Kompantseva, 1985; Kompantseva, 1989; Neutzling et al., 1984; Hansen and Imhoff, 1985; Pfennig, 1974a; Straub et al., 1999; Glaeser and Overmann, 1999). Growth of *Rhodopila globiformis* is inhibited by high concentrations of sulfate although at low concentration this can serve as an assimilatory sulfur source (Imhoff et al., 1981). Also *Rhodobium marinum* grows poorly with sulfate as an assimilatory sulfur source, but much better in the presence of low concentrations of reduced sulfur sources.

Nitrogen Metabolism

Ammonia, dinitrogen, and several organic nitrogen compounds (e.g., glutamate, aspartate or yeast extract) are the most appropriate nitrogen sources of most purple nonsulfur bacteria. Nitrate is assimilated only by a few species (strains of *Rhodospirillum rubrum*, *Rhodobacter sphaeroides*, *Rhodobacter capsulatus* and *Rhodopseudomonas palustris*) and growth yields with nitrate are considerably lower than with other nitrogen sources (Göbel, 1978; Imhoff, 1982a). Nitrate assimilation is inducible by nitrate but repressed by ammonia and glutamate.

Assimilation of ammonia is strongly regulated and two different major pathways occur. The primary pathway in purple nonsulfur bacteria is via glutamine synthetase and glutamate synthase, which is active if cellular concentrations of ammonia are low and if growth is occurring at low concentrations of ammonia or on dinitrogen and nitrate (Drews and Imhoff, 1991). The second pathway present in most purple nonsulfur bacteria is via glutamate dehydrogenase, which is active when ammonia concentrations are high.

The ability to fix dinitrogen is a common property of most phototrophic purple bacteria (Madigan, 1995). Dinitrogen fixation occurs under phototrophic and chemotrophic growth conditions, and the activity and expression of nitrogenase underlie a complex regulatory cascade (Drews and Imhoff, 1991; Haselkorn, 1986; Ludden and Roberts, 1995; Madigan, 1995). It has been most intensively studied in *Rhodospirillum rubrum*, where it was first discovered by Kamen and Gest (1949), and in *Rhodobacter capsulatus*.

Nitrogenase activity is repressed and inactivated by oxygen as in other dinitrogen-fixing bacteria. Its synthesis is derepressed at low concentrations of ammonia, i.e., under conditions of nitrogen limitation.

Hydrogen Metabolism

A great number of phototrophic purple bacteria can photoproduce hydrogen. With dinitrogen, glutamate or aspartate as nitrogen source, a number of carbon substrates (lactate, acetate, butyrate, malate and others) may be completely transformed to CO_2 and H_2, and these in turn may serve as substrates for photoautotrophic growth. After consumption of the organic substrate, cell suspensions of *Rhodobacter capsulatus* that produced, e.g., H_2 from lactate, rapidly started to consume the produced H_2 (Kelley et al., 1977). Similar observations were obtained with *Rhodospirillum rubrum* (Schick, 1971). Photoevolution of H_2 is catalyzed by nitrogenase, which is inhibited by ammonia, high concentrations of yeast extract and amino acids degraded to produce ammonia. The reaction is not reversible, insensitive to CO (a common inhibitor of hydrogenases) and independent of the partial pressure of H_2.

Hydrogen evolution in purple nonsulfur bacteria also occurs during fermentative growth under anoxic dark conditions. This hydrogen evolution is catalyzed by a reversible hydrogenase or by formate hydrogenlyase and underlies similar regulatory rules as in other fermenting bacteria, i.e., it is strongly inhibited by CO (Drews and Imhoff, 1991; Sasikala et al., 1993).

Hydrogen is not only produced, but also serves as an excellent photosynthetic electron donor for many purple nonsulfur bacteria and enables these bacteria to grow photolithoautotrophically. Hydrogen uptake is catalyzed by a reversible, membrane-bound hydrogenase, which is induced by hydrogen and independent of the nitrogen source. The membrane-bound hydrogenase is not inhibited by ammonia, but strongly inhibited by CO. During growth conditions of dinitrogen fixation, this uptake hydrogenase recycles the hydrogen produced by nitrogenase, and mutants lacking this hydrogenase demonstrate an increased hydrogen production during nitrogen fixation (Drews and Imhoff, 1991).

Applications

Most prominent examples of the application of phototrophic purple nonsulfur bacteria are their use in sewage treatment processes and for production of biomass, biopolymers and molecular hydrogen. They may be used as a source for cell-free systems performing photosynthesis and ATP formation and for the production of vitamins and other organic molecules.

Sewage contains a complex mixture of small organic molecules that are good substrates for purple nonsulfur bacteria. Phototrophic bacteria are regularly found in conventional sewage treatment plants (Holm and Vennes, 1971; Siefert et al., 1978). Facultative chemotrophic purple phototrophic bacteria compete best under such conditions. Because light-driven energy generation enables them to use compounds produced during anaerobic degradation processes, these bacteria are good candidates for application to the final stages of sewage treatment. A highly advanced system using phototrophic bacteria in the purification of municipal and industrial waste water is that developed by Kobayashi (Kobayashi et al., 1971; Kobayashi and Tschan, 1973; Kobayashi, 1977; Kobayashi and Kobayashi, 1995). This process uses the natural sequence of aerobic and anaerobic degradation, followed by culture of anoxygenic phototrophic bacteria and of green algae in separated reaction tanks (bioreactors). Phototrophic bacteria used in Kobayashi's system include *Rhodopseudomonas palustris*, *Rhodobacter capsulatus*, *Rhodobacter sphaeroides* and *Rubrivivax gelatinosus*. The use of phototrophic bacteria for sewage treatment was recently summarized by Kobayashi and Kobayashi (1995).

A number of different sources and processes have been used to produce bacterial biomass of phototrophic bacteria. Animal wastes (Ensign, 1977; Sasaki et al., 1990), soybean wastes (Sasaki et al., 1981), wheat bran (Shipman et al., 1975), municipal and industrial waste waters (Kobayashi, 1977), and clarified effluents of a biogas plant (Vrati, 1984) have been used. The produced biomass of phototrophic bacteria is a valuable source of animal feed; it is rich in vitamins and in essential and sulfur-containing amino acids (Vrati, 1984) and has been used in plankton production, in the culture of shrimp, and as food for fish and chicken (Kobayashi, 1977; Mitsui, 1979). Addition of phototrophic bacterial cells to the food increased the survival of fish as well as the production and quality of hens' eggs (Kobayashi and Tchan, 1973). With similar success the cell biomass of phototrophic bacteria has been used as fertilizer in agriculture (Kobayashi and Tchan, 1973). It may be used also for the production of hydrogen (Vrati and Verma, 1983; Bolliger et al., 1985), of biotin (Fillipi and Vennes, 1971), and of 5-aminolevulinic acid (Sasaki et al., 1990) and for other purposes.

Under nitrogen starvation, almost all phototrophic bacteria are able to produce molecular hydrogen. This process is mainly due to hydrogen evolution from nitrogenase. A large number

of substrates has been used by different research groups and with different purple nonsulfur bacteria to produce hydrogen (Kumazawa and Mitsui, 1982; Sasikala et al., 1993). Several attempts also have been made to produce hydrogen with immobilized cells of phototrophic bacteria (Francou and Vignais, 1984; Planchard et al., 1989; Vincenzini et al., 1982; von Felten et al., 1985; Weetall et al., 1981). Cells of *Rhodospirillum rubrum* (e.g., immobilized in a packed column) produced hydrogen with lactate as electron donor for 3,000 hours, with an activity loss of 60% after this time (von Felten et al., 1985). During the first days, mean rates of hydrogen production were 18–24 µl H_2 per mg dry weight and hour. Also cell-free systems were applied in hydrogen production (Mitsui, 1975). A recent comprehensive discussion of the technology of hydrogen production from phototrophic purple bacteria is given by Sasikala et al. (1993).

Poly-β-hydroxy-butyrate has been known for long as a storage product of phototrophic purple bacteria. In fact, an array of similar substances collectively termed "poly-3-hydroxyalkanoates" (PHAs) is accumulated, of which poly-3-hydroxybutyrate (PHB) is the most common. The PHAs occur as inclusion bodies of the cells visible in the light microscope and can account for a major fraction of the cell dry weight under appropriate growth conditions. Under strong nitrogen starvation or other conditions that restrict protein synthesis, excess carbon is converted into PHAs. In both *Rhodospirillum rubrum* and *Rhodobacter sphaeroides*, large amounts of storage PHAs can be synthesized under controlled growth conditions. *Rhodobacter sphaeroides* can produce more than 60% of its mass as PHAs of which 98% was PHB and the remainder was poly-3-hydroxyvalerate (Brandl et al., 1991). *Rhodospirillum rubrum* can produce a number of copolymers including an interesting tetrapolymer consisting of C_4, C_5 and C_6 repeating units (Brandl et al., 1989). A flexible polymerase which uses a variety of substrates yielding PHAs with different properties may be useful for the production of biodegradable thermoplastic polyesters of commercial value (Fuller, 1995). A copolymer of PHB and poly-3-hydroxyvalerate is commercially produced using cells of *Ralstonia eutropha*. A recent summary of aspects of biopolymer production by phototrophic purple bacteria is given by Fuller (1995).

CHAPTER 3.1.2

The Genera *Prosthecomicrobium* and *Ancalomicrobium*

GARY E. OERTLI, CHERYL JENKINS, NAOMI WARD, FRED RAINEY, ERKO STACKEBRANT AND JAMES T. STALEY

The genera *Prosthecomicrobium* and *Ancalomicrobium* are heterotrophic prosthecate bacteria, which produce numerous prosthecae per cell extending in all directions. These prosthecae vary in size and number both within and among species. Morphologically *Prosthecomicrobium* and *Ancalomicrobium* resemble one another because of their budding division and multiple prosthecae, but the former group is obligately aerobic whereas *Ancalomicrobium* strains are facultative anaerobes. Images of the type species *Prosthecomicrobium pneumaticum* and *Ancalomicrobium adetum* are shown in Figs. 1 and 2, respectively.

Taxonomy

Phylogenetic analysis of the 16S ribosomal RNA gene sequences of *P. pneumaticum*, *P. enhydrum*, *P. hirschii*, *A. adetum*, and several uncharacterized *Prosthecomicrobium*-like and *Ancalomicrobium* strains demonstrate that these organisms belong to the Alphaproteobacteria (Fig. 3). This group contains other budding and prosthecate bacteria, including representatives of the bacterial genera *Rhodomicrobium* and *Rhodopseudomonas* as well as *Hyphomicrobium* and *Caulobacter*. These findings are consistent with earlier 16S rRNA cataloguing studies on these genera (Schlesner et al., 1989).

Ancalomicrobium comprises a coherent clade within this group. Notably, *Ancalomicrobium* carries out a mixed-acid type fermentation, the products of which are identical to those of *Escherichia coli*, a member of the Gammaproteobacteria (Van Neerven and Staley, 1988). *Ancalomicrobium* is the only member of the Alphaproteobacteria currently known to have a mixed-acid fermentation.

Analyses of the 16S rRNA genes demonstrate that the genus *Prosthecomicrobium* is polyphyletic (Fig. 3) as none of the type strains of the other two species clusters with the type species, *P. pneumaticum*. Three strains, including *P. enhydrum* (ATCC 23634) and two *Prosthecomicrobium*-like bacteria, AP4.6 and P3.12, cluster with *Devosia neptuniae* (LGM 21357), a nonprosthecate organism. SCH75 is a morphologically distinctive organism whose multi-appendaged cells produce a holdfast from one polar prostheca (Schlesner et al., 1989). This representative, along with SCH127, is more closely related to members of the *Mesorhizobium* genus than to other members of *Prosthecomicrobium*. *Prosthecomicrobium hirschii* (ATCC 27832) and SCH71 form deep branches unrelated to any named genera. Finally SCH235 clusters with members of several named genera. This analysis suggests that the genus *Prosthecomicrobium* should be revised taxonomically.

Chemical analysis of phospolipids from different *Prosthecomicrobium* strains indicated that there are at least five distinct groups (Sittig and Schlesner, 1993). Four of these groups are represented in Fig. 3, with members of each group clustering in distinct phylogenetic positions. Additionally, various species and several as yet unnamed strains show little or no intrageneric DNA-DNA hybridization with one another (Moore and Staley, 1976; Schlesner et al., 1989; Chernykh et al., 1990).

To our knowledge, 16S rRNA sequencing of the remaining characterized species (Table 1) *P. litoralum* (Bauld et al., 1983), "*P. polyspheroidum*," "*P. consociatum*," and "*P. mishustinii*," (Vasilyeva and Lafitskaya, 1976; Vasileva et al., 1991) has not yet been reported and will be important in assessing the extent of diversity within the *Prosthecomicrobium* genus.

Reclassification of the bacteria that have been analyzed is required, as they do not cluster with the type species of *Prosthecomicrobium*, *P. pneumaticum*. The named species should therefore be reassigned to different genera.

Habitats

Multi-appendaged bacteria have been reported from a variety of natural habitats. Many strains have been isolated from fresh water (Staley, 1968), brackish and marine water (Bauld et al., 1983; Schlesner et al., 1989), groundwater (Hirsch

and Rades-Rohkohl, 1983), soil (Vasil'eva et al., 1974), and pulp mill aeration ponds (Stanley et al., 1979), where they may occur in high concentrations (Fig. 4). In one report (Bianchi, 1989), what appears to be a species of *Ancalomicrobium* was unexpectedly found in high concentrations in seawater used for shrimp aquaculture. Apparently the long prosthecae make these bacteria resistant to grazing by protozoan predators. Bacteria with multiple appendages have also been reported in the intestinal tracts of insects (Cruden and Markovetz, 1981), possibly because of concentration by feeding.

The multi-appendaged prosthecate bacteria appear to be well adapted for growth in oligotrophic and mesotrophic soil and aquatic habitats. Chemostat studies of *Prosthecomicrobium hirschii* indicate that their maximum growth rates are low regardless of the concentration of carbon source (Semenov and Vasileva, 1986). However, they have a high affinity for certain substrates such as glucose, as well as a low rate of respiration. These data suggest that in environments with low sugar concentrations these bacteria can metabolize efficiently because they have high-affinity uptake systems, which provide them with their selective advantage. Thus, their slow growth and low respiration rates may be advantages in oligotrophic environments where they reside (Semenov and Vasileva, 1986; Semenov and Staley, 1993).

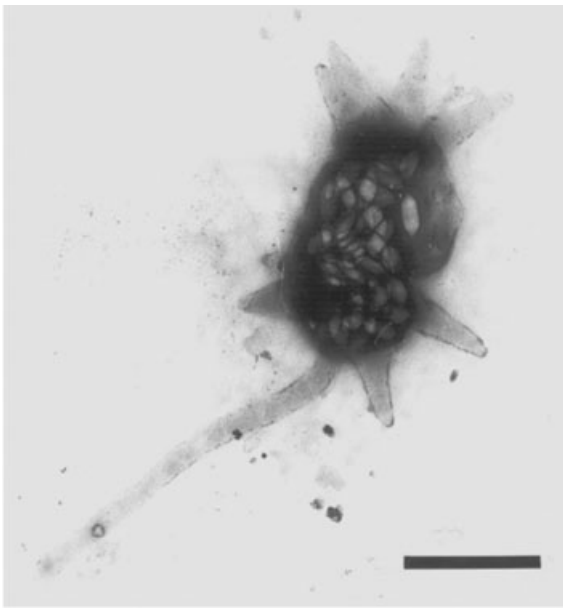

Fig. 1. *Prosthecomicrobium pneumaticum* (ATCC 23633). Transmission electron micrograph showing gas vesicles within the cell, many short prosthecae, and a single long prostheca. Bar = 1.0 μm.

Autoradiographic studies of acetate uptake in pulp mill aeration lagoons by *Ancalomicrobium* indicated that *Ancalomicrobium* was not as important as other bacteria in the metabolism of this substrate (Stanley and Staley, 1977). While their in situ uptake of sugars, which are abundant in this habitat, was not examined, it is clear that they are metabolically active in this environment.

Enrichment and Isolation

These bacteria occur in relatively low concentrations in natural habitats, typically 0.1–1 cell per ml (Staley et al., 1980), although they have been found in concentrations greater than 10^6 cells per ml in pulp mill aeration lagoons (Stanley et al., 1979). Generally, prior to isolation of pure cultures it is necessary to enrich for them. The usual procedure for enrichment entails using low-nutrient media. The most common procedure is to add a sterile peptone solution to a natural water sample to give a final concentration of 0.01% (Houwink, 1951). Schlesner et al. (1989) used a variety of carbohydrates (0.05% glucose,

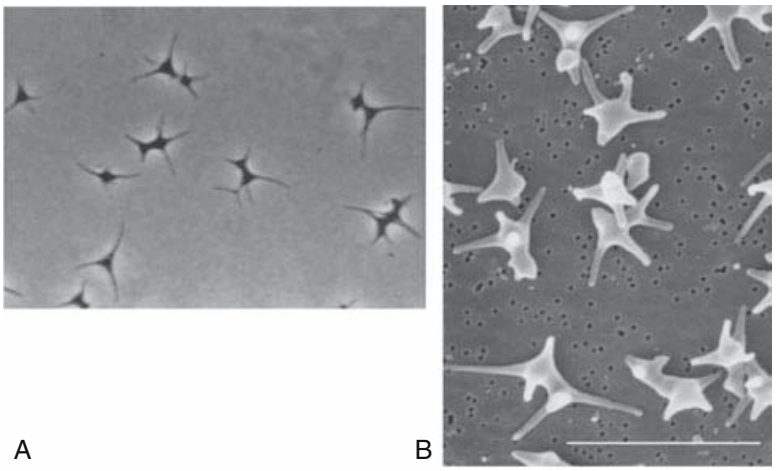

Fig. 2. *Ancalomicrobium adetum* (ATCC 23632). A) Phase contrast image of *A. adetum* cells showing long appendages and including one with a branch and B) scanning electron micrograph. Bar = 5.0 μm.

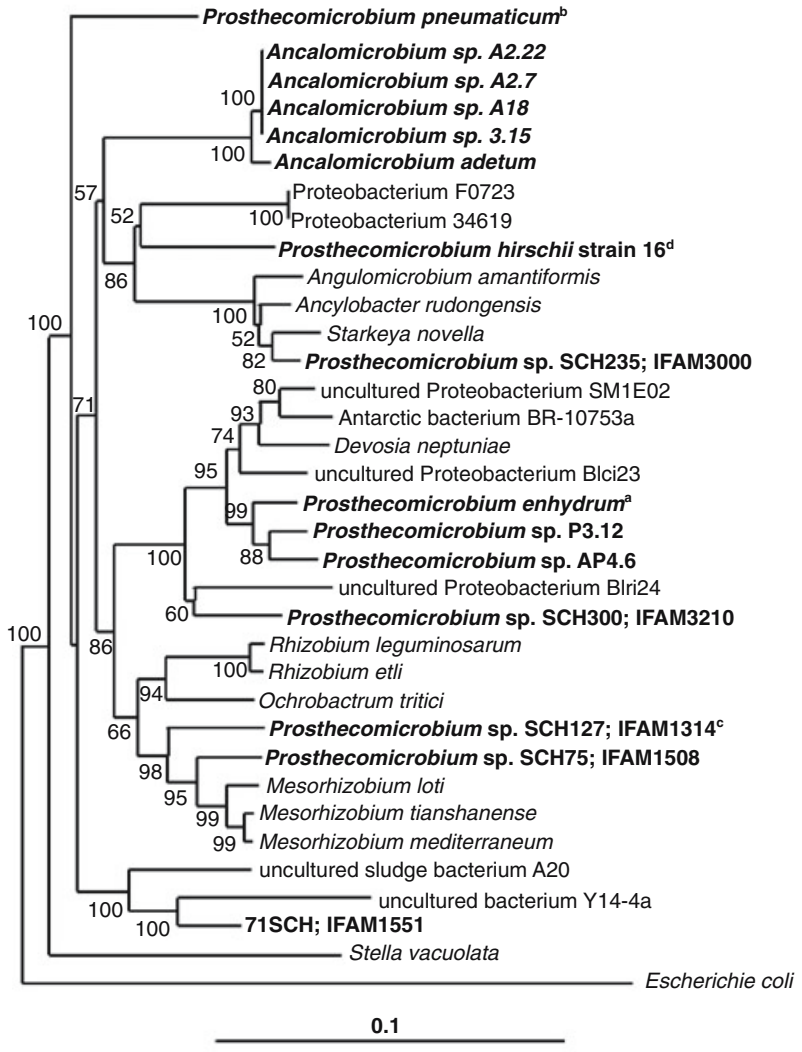

Fig. 3. Phylogeny of 16S rRNA genes from various *Prosthecomicrobium* and *Ancalomicrobium* isolates. Rooted neighbor-joining tree showing evolutionary relationships between various *Ancalomicrobium* and *Prosthecomicrobium* strains (bold). Reference sequences were picked by comparing these to 92,813 rRNA sequences in the RDP-II database using the sequence match tool (Cole et al., 2003), and complete sequences with the highest similarity to the query were used in our tree. Distances were calculated using the Kimura-2-parameter test over a total of 1137 characters. *Escherichia coli* was used as an outgroup. Percentages at nodes, with values greater than 50% shown, indicate bootstrap values for 1000 replications of the dataset; a-d indicate groups classified by their phospholipid composition as examined by Sittig and Schlesner (1993). a—group 1; b—group 2; c—group 3; and d—group 5. Bar represents the 10% 16S rDNA sequence distance.

Table 1. Species of *Ancalomicrobium* and *Prosthecomicrobium*.[a]

Species name	Type strain	Source
Ancalomicrobium adetum	4a (ATCC 23632)	Putah Creek, CA, USA
Prosthecomicrobium pneumaticum	3a (ATCC 23633)	Putah Creek, CA, USA
Prosthecomicrobium enhydrum	9b (ATCC 23634)	Putah Creek, CA, USA
Prosthecomicrobium hirschii	16 (ATCC 27832)	Pond, NC, USA
Prosthecomicrobium litoralum	524-16 (ATCC 35022)	Seawater, Puget Sound, USA
"*Prosthecomicrobium mishustinii*"	17	Soil, Colchis, Russia
"*Prosthecomicrobium consociatum*"	11	Compost, Shermetovo, Russia
"*Prosthecomicrobium polyspheroidum*"		Soil, Russia

[a]Although the species in quotation marks are in culture, their names have not been validly published.

or 0.01% lactate, or 0.1% glucosamine) or 0.25% $CaCO_3$ or 0.1% $NaNO_3$ in their enrichments.

A typical enrichment procedure is as follows: 10 mg of peptone is added to a 150-ml graduated beaker, which is covered with aluminum foil and autoclaved. Alternatively, a volume of an autoclaved peptone solution, equivalent to 10 mg, can be added to the beaker. A fresh- or marine-water sample is collected aseptically in a sterile bottle and 100 ml is transferred to one of the prepared beakers. This is then incubated at room temperature for 1–4 weeks, during which wet mounts are examined periodically using a phase microscope. When numbers of these organisms become appreciable, they may be isolated by streaking portions or spread-plating dilutions (10^{-3} to 10^{-5}) on dilute peptone agar (DPA). Additionally, these bacteria can be isolated from

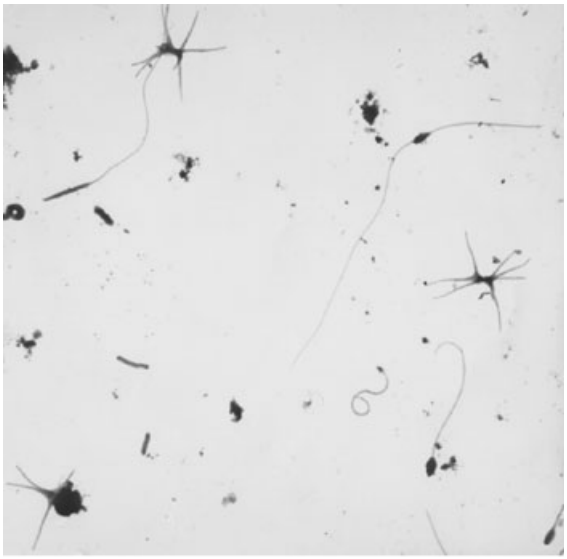

Fig. 4. Electron micrograph of a pulp mill environmental sample showing a high concentration of prosthecate bacteria.

liquid enrichment cultures by passing them through a column containing glass beads and plating eluted fractions (Staley, 1968).

Dilute Peptone Agar (DPA)

Peptone	0.1 g
Hutner's modified salts solution (see below)	20 ml
Vitamin solution (see below)	10 ml
Agar	15 g

Add distilled water up to a total of 1 liter.

Hutner's Modified Salts Solution

Nitrilotriacetic acid	10.0 g
$MgSO_4 \cdot 7H_2O$	29.7 g
$CaCl_2 \cdot 2H_2O$	3.3 g
$NaMoO_4 \cdot 2H_2O$	12.7 mg
$FeSO_4 \cdot 7H_2O$	99.0 mg
Metals "44"	50 ml

First neutralize the nitrilotriacetic acid with potassium hydroxide, then add the remaining ingredients. Adjust the pH to 7.2 with KOH and H_2SO_4. Add distilled water up to a total of 1 liter. Metals "44" contains per 100 ml: ethylene diamine tetraacetic acid, 250 mg; $ZnSO_4 \cdot 7H_2O$, 1095 mg; $FeSO_4 \cdot 7H_2O$, 500 mg; $MnSO_4 \cdot H_2O$, 154 mg; $CuSO_4 \cdot 5H_2O$, 39.2 mg; $CoCl_2 \cdot 6H_2O$, 20.3 mg; and $Na_2B_4O_7 \cdot 10H_2O$, 17.7 mg. Add a few drops of sulfuric acid to prevent precipitation before making to volume with distilled water, and store at 4°C.

Vitamin Solution

B_{12}	0.1 mg
Biotin	2 mg
Calcium pantothenate	5 mg
Folic acid	2 mg
Nicotinamide	5 mg
Pyridoxine HCl	10 mg
Riboflavin	5 mg
Thiamine HCl	5 mg

Add distilled water up to 1 liter and store at 4°C in a dark container.

The DPA plates should be incubated for about two weeks at room temperature prior to examination. Colonies are best located using a binocular dissecting microscope. The most likely colonies are small, have an entire margin, and may be a variety of colors (Table 1). Wet mounts of prospective colonies should be examined with a phase microscope, and when a presumptive colony has been located, it should be restreaked for purification. If the entire colony has been used in preparation of the wet mount, a loopful of the wet mount can be removed and used for streaking. This material may be streaked on DPA again, although a richer medium, MMB (Modified Medium B), will permit more rapid growth.

MMB Agar

Peptone	0.15 g
Yeast extract	0.15 g
Glucose	1.0 g
Ammonium sulfate	0.25 g
Hutner's modified salts solution	20 ml
Vitamin solution	10 ml
Agar	15 g

Add distilled water up to 1 liter. Adjust pH to 7.0–7.5 prior to autoclaving.

In habitats where their concentrations relative to other bacteria are much higher, isolation may be effected by streaking directly onto MMB agar. This practice has been used to isolate strains from pulp mill oxidation pond samples.

Cultivation and Maintenance

For routine cultivation and maintenance, cultures may be grown on MMB agar. Some strains tested seem to grow well on the richer and more easily prepared medium used for cultivation of caulobacters (Poindexter, 1964). This medium contains 0.2% peptone, 0.1% yeast extract, 0.02% magnesium sulfate, and 1.5% agar and is made to volume with tap water. Though higher yields may be obtained with this medium, pleomorphic forms occur with some strains. For example, *Ancalomicrobium adetum* produces high yields on this medium, but cells may form short chains and mini cells with one or two prosthecae. Alternatively a more concentrated version of MMB, termed "Super" MMB, has been found to work well for cultivation of *Ancalomicrobium* strains (Van Neerven and Staley, 1988).

These bacteria can also be grown on a defined medium containing ammonium sulfate as sole

nitrogen source and glucose as sole carbon source. The composition of this medium is as follows:

Defined Medium

Ammonium sulfate	0.25 g
Disodium phosphate	0.0005 M
Glucose	0.25 g
Hutner's modified salts solution	20 ml
Vitamin solution	10 ml

Add distilled water up to a total of 1 liter. For solid medium, add 1.5% agar.

This medium has been useful in ascertaining vitamin requirements using the single-deletion method (Staley, 1968). It has also been of limited use in determining carbon source utilization patterns, although MMB from which glucose has been deleted is generally more useful for that purpose.

Slant cultures maintain viability for at least one month at refrigerator temperatures. Lyophilization is satisfactory for longer periods of preservation. Frozen cultures made using 15% (w/v) glycerol and stored at –70°C have proven to be viable for at least 4 years. Storage of glycerol stocks at –20°C is not recommended.

Identification

Table 2 shows some of the major differences among the four validated and two nonvalidated species of *Prosthecomicrobium* and one species of *Ancalomicrobium* that have been described at this time.

The first step in determining whether an unidentified bacterium is a representative of one of these genera involves examination of a wet mount of a suspected colony under a phase microscope using an oil-immersion objective. Prosthecae on most strains can be detected by ordinary phase microscopy, but if there is any uncertainty, whole cells of the suspect strain must be examined using a transmission electron microscope (TEM). Most species of *Prosthecomicrobium* produce relatively short appendages (i.e., <1.0 μm) under normal growth conditions, but these can readily be seen by TEM. Following initial isolation and preliminary identification on the basis of aerobic growth and morphology, 16S rRNA gene sequencing and phylogenetic analysis may be helpful in the identification of isolates.

Once an isolate has been identified as a member of this group, it should be streaked for purification on MMB medium or PYG medium. To differentiate between the two genera, it is essential to conduct a test to determine whether the strains are able to grow as facultative anaerobes. This can be done on the Hugh-Leifson medium (Hugh and Leifson, 1953), using glucose as a carbon source.

Ancalomicrobium strains are facultative anaerobes whereas *Prosthecomicrobium* are obligate aerobes (Table 1). *Ancalomicrobium* cells have long appendages (Figs. 2a and 2b) when grown in dilute media such as MMB. *Ancalomicrobium adetum* also produces gas vacuoles under certain conditions such as late stationary growth phase. One species of *Prosth-*

Table 2. Characteristics of *Prosthecomicrobium* and one species of *Ancalomicrobium*.

Characteristic	*A. adetum*	*P. enhydrum*	*P. pneumaticum*	*P. litoralum*	*P. hirschii*	*P. polyspheroidum*	*P. consociatum*	*P. mushustinii*

Symbols: +, present; –, absent; and ±, present occasionally.

ecomicrobium, *P. pneumaticum*, also produces gas vacuoles. All species of *Prosthecomicrobium* reported to date produce cells with short appendages. However, some species of *Prosthecomicrobium*, such as *P. hirschii*, also produce long appendages, so the morphology of individual cells cannot be used for identification.

Prosthecomicrobium cells typically have short prosthecae, although, as mentioned previously, *P. hirschii* also produces long prosthecae as well. Only one species known to date, the type species *P. pneumaticum*, produces gas vesicles (Fig. 1). It is nonmotile.

Two members of *Prosthecomicrobium* are readily identified by their cellular morphology. *Prosthecomicrobium hirschii* has a dimorphic life cycle consisting of a short-appendaged prosthecate cell and a long-appendaged prosthecate cell (Fig. 5). Curiously the dimorphic lifecycle is not like *Caulobacter* spp. in which one cell type must change into another cell type. Instead, either the short-appendaged, motile, or long-appendaged, nonmotile, cell type can give rise to progeny of either cell type (Staley, 1984). The presence of a dimorphic population of cells is a reliable characteristic for classification of an isolate as *P. hirschii*.

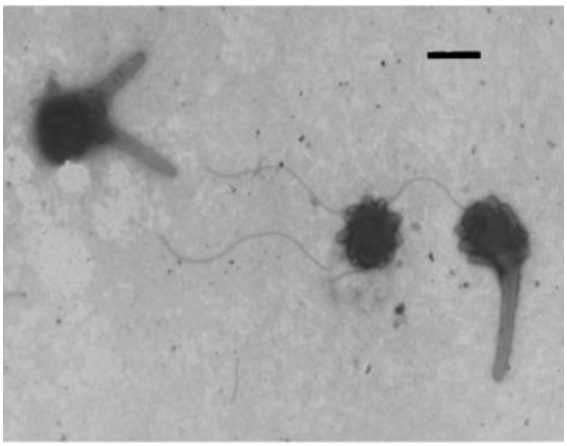

Fig. 5. *Prosthecomicrobium hirschii*. Electron micrograph showing the two typical morphologies of *P. hirschii* cells. Nonmotile cells lacking flagella with long appendages, and motile cells with a single polar flagellum and shorter appendages. Bar = 1.0 µm.

"*Prosthecomicrobium polyspheroidum*" is a long (>3 µm), rod-shaped bacterium with evenly spaced rows of short appendages giving it a "corn cob" appearance. This species as well as "*P. mishustinii*" and "*P. consociatum*" is not yet on the approved lists of bacterial species.

The remaining named species of *Prosthecomicrobium* are similar in morphology. *Prosthecomicrobium enhydrum* is motile and produces short appendages (Fig. 6). *Prosthecomicrobium litoralum* is a nonmotile, short-appendaged organism that inhabits brackish water and therefore has a requirement for moderate salinity. "*Prosthecomicrobium mishustinii*" is nonmotile, with moderately sized appendages. "*Prosthecomicrobium consociatum*" is nonmotile, with short appendages. All of these strains show some variability in the number and length of prosthecae (Fig. 6b).

Morphologically these bacteria resemble green sulfur phototrophic bacteria of the genera *Prosthecochloris* and *Ancalochloris.* Also, *Prosthecomicrobium* spp. resemble another organism, *Verrucomicrobium spinosum*, which has pili at the tips of its prosthecae (Schlesner, 1987). This organism, which has been placed in the genus *Verrucomicrobium*, falls into a completely different 16S rRNA group (Albrecht et al., 1987). Spinate bacteria superficially resemble these bacteria, but their noncellular appendages have many transverse striations and consist entirely of protein (Easterbrook and Coombs, 1976a; Easterbrook et al., 1976b).

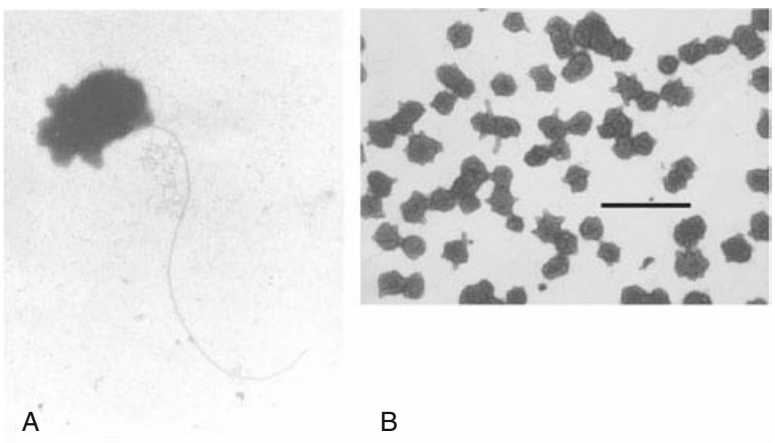

Fig. 6. *Prosthecomicrobium enhydrum*. A) Electron micrograph showing a single cell with a single subpolar flagellum, and B) electron micrograph of a field of *P. enhydrum* cells showing the variability in prosthecae length. Bar = 5.0 µm.

Dimorphic Prosthecate Bacteria: The Genera *Caulobacter*, *Asticcacaulis*, *Hyphomicrobium*, *Pedomicrobium*, *Hyphomonas* and *Thiodendron*

JEANNE S. POINDEXTER

Rationale for Clustering *Caulobacter*, *Asticcacaulis*, *Hyphomicrobium*, *Pedomicrobium*, *Hyphomonas* and *Thiodendron*

The genera treated together here comprise the *dimorphic prosthecate bacteria (DPB)*, in which reproduction regularly results in the separation of two cells that are morphologically and behaviorally different from each other (Fig. 1). One sibling is nonmotile and prosthecate, possessing at least one elongated, cylindrical appendage that is an outgrowth of the cell surface, including the outer membrane, the peptidoglycan layer, and the cell membrane, and that may also include cytoplasmic elements such as ribosomes; such an appendage is a *prostheca* (Staley, 1968). In natural populations, this prosthecate cell is usually also sessile by virtue of adhesive material associated with a cell pole or with the prostheca. The other sibling is flagellated, bearing (typically) one polar or subpolar flagellum, by means of which it is actively motile. This mode of reproduction is unique as a regular feature of a prokaryote reproductive cycle. It is regarded here as a reflection of an ecologic program common to these genera, viz., as a means of dispersing the population at each generation and thereby minimizing competition between siblings for resources.

In bacteria lacking motility, sibling separation in space depends on abiotic forces; if both are sessile, clones accumulate as cell clusters. In most motile unicellular bacteria, both siblings are motile; if they are also chemotactic, both cells will tend to follow the same gradients and so travel together. In the DPB, spatial separation is promoted by the motility of one cell and the immobility of its sibling.

Other prosthecate bacteria differ from those of the genera treated in this chapter either by lacking a motile stage (*Prosthecobacter*, *Filomicrobium*, *Ancalomicrobium*) or by producing motile cells only under certain environmental conditions (*Prosthecomicrobium*, *Rhodomicrobium*). *Thiodendron* is included in the DPB cluster even though its habit has so far been surmised only from polytypic populations in natural samples or enrichments; it bears one or two appendages that appear to be prosthecae, has been seen to form buds on those appendages, and is accompanied by motile cells that may be its own swarmers.*

Throughout the eukaryotic world, there are parallels for the asymmetric cell reproduction that is characteristic of the DPB, but very often with the consequence that only one of the two siblings continues to reproduce while the other differentiates and exhibits diminished or lost potential for subsequent reproduction. More relevant parallels are found at the organismic level, such as among fungi and invertebrate animals that are not freely mobile as adults but produce motile offspring or plants that produce propagules equipped for travel; the analogy to eukaryotes underlies the usage of the terms "mother" and "daughter" to refer to the nonmotile and motile siblings, respectively, of the DPB.

The parallel with dispersal units seems particularly apt as evidence accumulates that the motile siblings of DPB are in an analogously juvenile condition (Krasil'nikov and Belyaev, 1970; Matzen and Hirsch, 1982b; Moore, 1981; Moore and Brubaker, 1976; Moore and Hirsch, 1973; Morgan and Dow, 1985; Pate et al., 1973; Poindexter, 1964, 1981a; Swoboda and Dow, 1979; Wali et al., 1980). In each species so far studied, the motile cell is less actively growing than its prosthecate sibling; in *Asticcacaulis* and *Hyphomicrobium*, the swarmer is also typically considerably smaller than its prosthecate sibling.

This chapter was taken unchanged from the second edition.

* *Thiodendron* isolates have not been reported. The organism is known only from natural samples in which it has been interpreted as a sulfur-oxidizing prosthecate bacterium, probably with a motile stage. The absence of information regarding properties of monotypic populations does not justify a discussion beyond the excellent summary by Schmidt (1981).

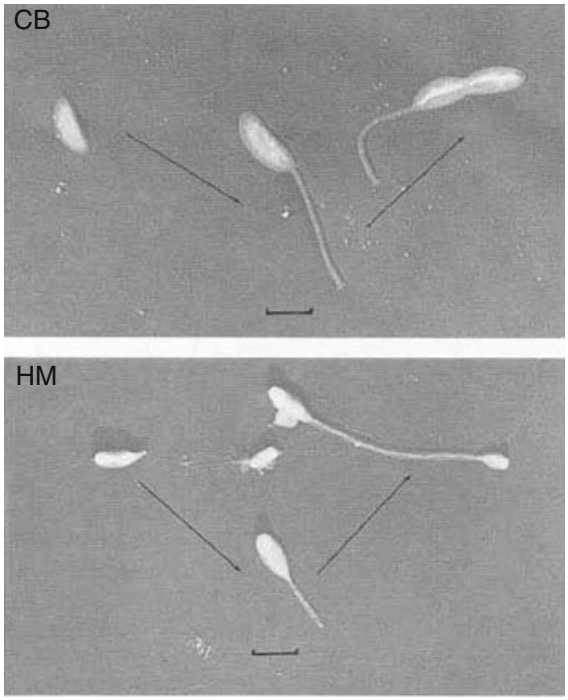

Fig. 1. Caulobacters (CB) and hyphomicrobia (HM). Left to right in each electron micrograph: swarmer, prosthecate cell, and reproducing cell. Transmission electron micrographs, Pt-shadowed cells. Bar = 1 μm.

Growth and progress toward reproduction are initiated in these swarmers only after a period in which their most evident activity is motility. The regulatory mechanisms by which growth and development are postponed have not been elucidated, although lipid, phosphorus, and nitrogen metabolism have been implicated as possibly influential metabolic processes (Chiaverotti et al., 1981; Emata and Weiner, 1983; O'Neill and Bender, 1989; Poindexter, 1984a; Mansour et al., 1980). Attachment is not necessary for the onset of development and growth, but presumably usually occurs prior to development in natural habitats. Although both swarmers and prosthecate cells are adhesive, attachment is probably initiated mainly in the swarmer stage (Hirsch, 1974; Leifson, 1962; Moore and Marshall, 1981; Zavarzin, 1961), since: 1) prosthecate cells are typically found attached, not afloat (although that may be because that is where they *can* be seen); 2) if pili are present in a strain, they occur predominantly or exclusively on swarmers (Schmidt, 1966; Umbreit and Pate, 1978); and 3) in laboratory-cultivated populations, the swarmer is demonstrably more active in initiating attachment (Newton, 1972). Moore and Marshall (1981) have suggested that, like pili, flagella may serve as a means of carrying adhesive material through the electrostatic barrier between cell and substratum, thereby aiding the establishment of stable contact (see Planktonic Versus Sessile Life of Prokaryotes in the second edition).

Thus, like the eukaryotes in which immotile organisms produce motile or transportable offspring, dispersal of DPB populations is the most reasonable interpretation of the major advantage of mobility in the juvenile stage. By fission or by budding, each normal reproductive event in these bacteria produces two siblings: one to grow and one to go. It is consistent with this developmental and reproductive habit that these bacteria exhibit the physiologic properties of oligotrophs (Poindexter, 1981b), most importantly: *tolerance of prolonged nutrient scarcity.* This is the principal physiologic property that can be exploited in their enrichment and isolation and is reflected in their distribution in nature. Once isolated, individual strains may tolerate much higher nutrient concentrations than are useful in their enrichment and isolation, but most isolates exhibit either growth inhibition or loss of control over cell form ("pleiomorphy") upon incubation in media designed for the cultivation of bacteria parasitic on plants or animals (see references in "Cultivation," this chapter). Such nutrient-rich media are generally suitable for the cultivation of copiotrophs, but morphology of those few DPB that are able to grow on such media may be so aberrant in such cultures that they may not be recognizable as DPB.

When cultivated under conditions that allow uniform dimorphic morphology and cell size from one generation to the next, cultivated DPB are morphologically identical to bacteria observed in natural materials. On the basis of the morphology of the reproductive stage, two fundamentally different types of DPB can be distinguished in natural samples, enrichment cultures, and pure cultures: caulobacters (*Caulobacter and Asticcacaulis*) and hyphomicrobia (*Hyphomicrobium*, *Pedomicrobium*, and *Hyphomonas*). Caulobacters reproduce by fission and hyphomicrobia by budding, almost always from the distal tips of prosthecae (hence the usage of the term "hyphae"). *Caulobacter* and *Asticcacaulis* can be distinguished from each other by the site of adhesion of sessile cells to substrata; *Caulobacter* cells adhere by the distal tip of the prostheca (hence "stalk"), while *Asticcacaulis* cells adhere by the cell pole and the prostheca is not adhesive. Among the hyphomicrobia, *Pedomicrobium* cells are distinguished morphologically from those of the other two genera by the production of buds whose long axes are perpendicular to the long axis of the hypha, rather than an extension of the hyphal axis; they also tend to produce more than one hypha per cell, but multiple prosthecae occur in stressed and aging populations of all DPB and are not a dependable morphological trait, particularly in

natural populations. Adhesiveness of a cell pole is typical of hyphomicrobia, but it is not a universal property of isolates under all conditions. The hyphae are not adhesive in any of the budding genera. The reverse orientation of sessile cells is helpful in distinguishing *Caulobacter* from hyphomicrobial cells in natural samples.

In addition to their developmental and reproductive habit and fundamentally oligotrophic physiology, these genera exhibit several other common properties that can be characterized only with pure populations. These properties are not unique to this group; on the contrary, they imply relationships to other eubacterial groups, particularly to pseudomonads, with which they often share their natural habitats. All are oxybiontic and grow in well aerated cultures; a tolerance of low pO_2 is exhibited by *Pedomicrobium* isolates, and a preference for such conditions is seen in *A. biprosthecum*. They seem universally cytochrome-positive and catalase-positive, although there are exceptional reports (e.g., Lapteva, 1977, 1987) of negative tests. Only one species (*C. crescentus*) has been examined for superoxide dismutase (SOD) activity; like certain *Pseudomonas* spp., *C. crescentus* possesses two SODs (Steinman, 1982). The Fe-SOD appears to be cytoplasmic, while the CuZn-SOD is periplasmic (Steinman and Ely, 1990). Unequivocal anaerobic growth is sustained only by *Hyphomicrobium* isolates, by dissimilatory respiration of nitrate to N_2.

All DPB are chemoheterotrophic, and variations in carbon-source preference are useful traits in generic and species differentiation. Ammonium ions are suitable as the sole source of nitrogen for isolates that can be cultivated in defined media; ammonia is assimilated by addition to glutamate or by reductive amination of pyruvate and glyoxylate (Doronina, 1985; Ely et al., 1978). Only *Hyphomicrobium* isolates have been reported able to use nitrate as the sole nitrogen source. In complex media, peptone is universally suitable as a nitrogen source. Poly-β-hydroxybutyrate (PHB) and polyphosphate are stored as reserves and may be detectable microscopically in cells in natural samples.

DPB possess outer membranes, and growing cells stain Gram-negatively. The outer membranes of the genera that have been characterized (*Asticcacaulis* [Jordan et al., 1974]; *Caulobacter* [Agabian and Unger, 1978]; *Hyphomonas* [Dagasan and Weiner, 1986; Shen et al., 1989]) exhibit a higher proportion of high-molecular-weight proteins than do those of other Gram-negative bacteria. Superficial layers of repeating protein subunits ("R-layers") are known in *Caulobacter* (Smit et al., 1981) and possibly in *Hyphomonas* (Dagasan and Weiner, 1986), in which two proteins account for more than half of the outer membrane proteins.

Most isolates are susceptible to antibiotics that inhibit prokaryotic protein synthesis (aminoglycosides, macrolides, tetracyclines), but may be resistant to synthetic antimicrobials such as sulfonamides; high concentrations of quinolones are required for inhibition of growth (J. S. Poindexter, unpublished observations). Any type of inhibitor, including mitomycin C, hydroxyurea, and cell wall synthesis inhibitors, may cause developmental aberrations (Haars and Schmidt, 1974; Koyasu et al., 1983; Moore and Brubaker, 1976; Moore and Duxbury, 1981; Weiner and Blackman, 1973).

Neutral to slightly alkaline reaction is optimal for growth, except for *Pedomicrobium* isolates, which grow well at pH 9.0. Moderate temperatures (20 to 30°C) are also generally optimal, but many isolates grow well at temperatures as low as 5°C, at least as primary isolates, and a few grow at temperatures above 35°C. Many isolates require vitamins, and growth is generally stimulated by B vitamins. When only one vitamin is required, it is biotin or B_{12}, while riboflavin and Ca-pantothenate are stimulatory for certain isolates.

The DNA base composition of bacteria of these genera is in the range of 59 to 67 mol% of GC, except in *A. excentricus* (55%) and *Hyphomonas hirschiana* (57%). RNA sequence analysis has revealed a closer relationship to pseudomonads than to other bacterial groups, although the relationship is "remote" (Stackebrandt et al., 1988); the presence of intracellular nucleases appears to interfere with the application of this analytic technique to phylogenetic interpretation of *Caulobacter* and *Hyphomonas*. Extensive studies of DNA-DNA hybridization have revealed little sequence similarity within the group, or even within a genus, except among isolates derived from the same initial sample, among variants of a single strain, or ~~in~~ only a few instances ~~among~~ isolates of clear phenotypic similarity (Gebers et al., 1984, 1985, 1986; Moore et al., 1978). Lack of DNA-DNA hybridization is not predictive of similarities among other molecules, such as outer-membrane proteins (Dagasan and Weiner, 1986). In the DPB, naturally-occurring plasmids have been detected only among caulobacters (Anast and Smit, 1988; Schoenlein and Ely, 1983). However, pseudomonad plasmids such as RP4 can be propagated and expressed in both *Caulobacter* and *Hyphomicrobium* (Anast and Smit, 1988; Chatterjee and Chatterjee, 1987; Dijkhuisen et al., 1984; Ely, 1979).

Possibly as an aspect of their oligotrophic nature, in the sense that they are not adapted to continual, well-supported growth, continuous

vegetative propagation of DPB results in diversification. This has been a persistent problem with all the genera and is perhaps best exemplified by Mevius' strain B; of the seven strains listed as *Hyphomicrobium aestuarii* in *Bergey's Manual* (Hirsch, 1989), six (MEV-533, MEV-533Gr, EA-617, EN-616, NQ-521 and NQ-528) are laboratory derivatives of one original isolate (Mevius, 1953). Most variations are detected as changes in colony morphology or texture and are presumably cell surface composition variants. This kind of change often occurs early in the purification of an isolate, especially of *Hyphomonas* (Moore et al., 1984). Pongratz (1957) reported one isolate of *H. polymorpha* as PR727 (rough) and PS728 (smooth); all five *Hyphomonas* isolates from the deep-sea vent community were all originally "rough," but two are now described as smooth (Moore and Weiner, 1989) and all have smooth variants (J. S. Poindexter, unpublished observations). Deposition of metal oxides is a trait that may be lost by initially positive isolates (Gregory and Staley, 1982; Tyler and Marshall, 1967a), reducing the usefulness of this characteristic in differentiating genera and species. Temperate bacteriophages also appear in long-cultivated strains (Driggers and Schmidt, 1970; Gliesche et al., 1988; Schmidt and Stanier, 1966), suggesting genetic perturbations during perpetual cultivation.

Despite this long list of similarities, there is no reason at present to regard this set of genera as a phylogenetically-related cluster. It is a group distinguished by its reproductive habit, which seems related to its ecology; its common ecologic program should be of sufficient advantage to have evolved more than once. The physiologic similarities arise largely from the oligotrophic nature of these organisms, which is consistent with a growth habit that promotes dispersal of successive generations.

Taxonomy by nucleic acid composition and sequence similarity has not resulted in a suggestion that these genera should be redistributed among bacterial groups differently from the placement inferred from traditional dependence on Gram-reaction, flagellation, cell morphology, nutrition, cytochrome content, and natural distribution. However, it has so far provided only scant evidence that they should be grouped together. Determination of rRNA cistron similarities revealed affinities among *Hyphomicrobium*, *Hyphomonas*, and *Caulobacter*, as well as between *Hyphomicrobium* and purple bacteria and nonmotile prosthecate bacteria (Moore, 1977). Similarities of rRNA sequences have also been detected among *Hyphomicrobium*, *Pedomicrobium*, and *Filomicrobium* (the last, a genus of nonmotile prosthecate bacteria), although this group appears to comprise a previously unrecognized fourth subgroup of the "alpha" subdivision of purple non-sulfur bacteria (Stackebrandt et al., 1988). Although presently inferred phylogenetic distances within this group seem great, they are smaller than the distance from any non-prosthecate bacteria.

Accordingly, aside from the possibility that the regular production of a motile stage is a late modification or a dispensable property among prosthecate bacteria, it seems appropriate at present to recognize the DPB as a cluster of genera that comprise a probably related subgroup of heterotrophic pseudomonads specialized for distribution in nature as uncrowded, oligotrophic populations.

Distribution of Dimorphic Prosthecate Bacteria

A single term can be used to describe the occurrence of DPB in waters: ubiquitous. This term applies without qualification to *Caulobacter* and is almost as appropriate for hyphomicrobia, as evidenced not just by the frequency of the detection of these two types within natural populations, but also by the relative ease of their enrichment and (with proper attention to their particular physiological traits) isolation. Lapteva (1987) has suggested that caulobacters, as typical aquatic bacteria, should be regarded as probably second only to pseudomonads in breadth of distribution and numbers. These two bacterial groups together may be responsible for the bulk of mineralization of dissolved organic material in aquatic environments, with caulobacters being especially important when nutrient concentrations and ambient temperatures are low (Allen, 1971; Staley et al., 1987).

When detected in unenriched samples, DPB are not found as crowds; even when total microbial density is high, DPB are usually sparse—with notable exceptions such as *Hyphomonas*-like organisms in some deep-sea hydrothermal vent samples (Jannasch and Wirsen, 1981) and *Pedomicrobium* in manganese concretions (Ghiorse and Hirsch, 1982; Marshall, 1980; Sly et al., 1988; Tyler and Marshall, 1967a, 1967b). Similarly, even when DPB are practically alone, as when total microbial counts are low or when they colonize submerged surfaces, they do not exploit the space by filling it with their progeny. Quantitative studies of their occurrence by direct plating, dilution for most-probable-number (MPN) calculation, or direct microscopic enumeration by scanning electron microscopy reveal population densities of 10^3 to 10^5 per ml of water or per gram of soil, detritus, or sediment; 10^6 DPB per such a unit, as reported by Lapteva (1987), is an exceptionally high density. By themselves, the

DPB have not been found responsible for turbidity of natural waters, nor are they detectable by sample odor as are, for example, sulfate-reducing bacteria and streptomycetes; microscopical examination of samples is required for their detection. The only macroscopic evidence of their possible presence is metal (Fe or Mn) oxide deposits on wet surfaces, but whether they cause or just adhere to such deposits remains to be established. Accordingly, "abundant" in referring to these organisms must be read as meaning 10^3 or more per ml or gram, "present" to mean detectable (usually microscopically and often only after enrichment), and "predominant" as relatively unaccompanied, but not necessarily "abundant."

Asticcacaulis is rarely sighted and even more rarely isolated. *Pedomicrobium* distribution is probably wider than evidence currently suggests, since a suitable method for enrichment and isolation of this type of hyphomicrobium has been developed only recently. *Hyphomonas* may be a type restricted to marine environments; its morphologic twin, *Hyphomicrobium*, is found in brackish waters (as well as soils and fresh water), but not marine sources. Distribution is discussed here principally with reference to *Caulobacter* and *Hyphomicrobium*.

Practically any type of seawater from harbors, estuaries, the open ocean, deep-sea hydrothermal vents, storage reservoirs contains *Caulobacter* and may also contain hyphomicrobia, probably *Hyphomonas*. *Caulobacter* may be the predominant form of aerobic chemoheterotrophic bacteria in oceanic samples (Jannasch and Jones, 1960), particularly in Antarctic waters (Takii et al., 1986; Waguri, 1976). DPB also occur in sediments, particularly if algal and/or plant material (including wood) has settled onto the bottom (Austin et al., 1979). DPB are typically found attached to submerged surfaces, whether or not they are detectable in bulk water, and so they settle with such materials.

They are also present in freshwater ponds, lakes, streams, rivers, and reservoirs (reviewed in Poindexter, 1981a), even temporary pools and puddles (Gebers, 1981; Masuda, 1957); in canals and lagoons of various trophic states (Lapteva, 1977, 1987; Staley et al., 1980, 1987; Stanley et al., 1979); in pipelines and water distribution systems, including domestic tap water; in wells (Masuda, 1957; Shah and Bhat, 1968); in home aquaria; in bottled spring water (Gonzalez et al., 1987); and in sewage. In short, if a site has been wet for any length of time, DPB will be present.

In this regard, it should be noted that the bulk of the carbon of some organic-rich sites in nature is insoluble, including plant litter and partly-treated sewage and activated sludge, as well as sediments, soils, and waters polluted with industrial wastes to the point of loss of translucency that is not due to microbial blooms. Such sites may support the growth of oligotrophic bacteria such as the DPB despite their "richness." Polymer-degrading bacteria such as cytophages are typical of such sites; presumably, the DPB subsist on soluble nutrients that are slowly released from insoluble organic materials by such bacteria.

Detection of DPB in sewage is sporadic, although they are known to occur in the highly aerobic type of sewage treatment known as activated sludge (Hartmans et al., 1986; Schmider and Ottow, 1986; Vedinina and Govorukhina, 1988), and phages lytic for DPB can be isolated from sewage effluents (Gliesche et al., 1988; Schmidt and Stanier, 1965). In anaerobic sewage treatment processes, only *Hyphomicrobium* appears to occur commonly, and then specifically in sewage carrying a high nitrate load. *Hyphomicrobium* is strongly favored in such sewage by the addition of methanol, which accelerates the removal of nitrate as N_2 as it selectively favors *Hyphomicrobium* multiplication (Claus and Kutzner, 1985).

Seasonal fluctuations have been characterized only for freshwater caulobacters; other DPB are not sufficiently abundant to allow meaningful quantitative determination of seasonal changes. Lapteva (1977, 1987) observed that caulobacters fluctuate with phytoplankton. Both types of aquatic organisms rise numerically in the springtime, may or may not decline (or descend in the water) during the summer, but definitely do so during the winter. They rise together again (in number and in location in the water, such as a lake) in the springtime, a pattern also noted by Staley et al. 1980. It seems likely that caulobacters respond readily to the release, in early spring, of nutrients immobilized during the winter and released abiotically during "spring turnover." They persist through the summer, but at that season are accompanied by a diversity of later-blooming bacteria.

The only clear limitation on the geographic distribution of DPB in fresh water is temperature; they have not been found in thermal springs.

DPB are found in soils, particularly from nutrient-poor soils such as "podzols."* They are also found in leaf-litter, in frequently-wetted agricultural and lawn soils (Belyaev, 1968; J. S. Poindexter, unpublished observations), and in metal ore deposits (Groudev et al., 1978).

* Podzol: a type of relatively infertile soil found typically in forests and consisting of a thin, ash-colored layer overlying a brown, acidic humus, the organic part of soil, resulting from the partial decay of leaves and other vegetable matter.

DPB are also found in the laboratory: *Hyphomicrobium* in enrichment cultures for nitrifying bacteria (Kingma Boltjes, 1936) and methane-oxidizers (Wilkinson and Hamer, 1972); *Caulobacter* in stock algal cultures (Bunt, 1961; Gromov, 1964; Klaveness, 1982; Li et al., 1984; Zavarzina, 1961); and both in enrichment cultures for N_2-fixing aerobes. Both *Caulobacter* and *Hyphomicrobium* can be isolated from laboratory water baths and distilled water (Callerio et al., 1983; reviewed in Poindexter, 1964). *Hyphomicrobium* is especially easy to detect and to isolate from any appended rubber tubing or plastic outlet of a distilled water reservoir, and *Caulobacter* is isolated from the outlets, the walls of the container, and the air-water interface.

With very few exceptions (*Hyphomonas polymorpha*, isolated from human nasal secretions [Pongratz, 1957]; *C. leidyi*, isolated from millipede hindguts [Poindexter, 1964]; and hyphomicrobia from turbot gills [Mudarris and Austin, 1988]), DPB are not detected in nor isolated from association with animals or decaying animal materials. They have not been reported as agents of food spoilage and are not pathogenic for laboratory animals~~ev~~en those that can persist long enough to stimulate an immune response (Famurewa et al., 1983).

In both soils and waters, DPB (and *Prosthecobacter*; see The Genera Prostheomicrobium, Ancalomicrobium and Prosthecobacter) are especially likely to be encountered as algal epibionts; examining the surfaces of algal thalli is often the most dependable way to detect DPB in a natural sample. Caulobacters are usually attached to algal structures, while hyphomicrobia are more often detected within algal jelly (Geitler, 1965; Hirsch, 1974). These associations are best observed by scanning electron microscopy (SEM) (Fig. 2). In living specimens examined by phase contrast microscopy, they are more difficult to discern; the phase halo of the relatively large algal cells interferes with the visibility of the stalks, while the *Caulobacter* cells may be overlooked waving on their stalks several micrometers away from the algal surface. Even in SEM images, very long stalks may not be traceable to their cells (Fig. 2; see also Tufail, 1987).

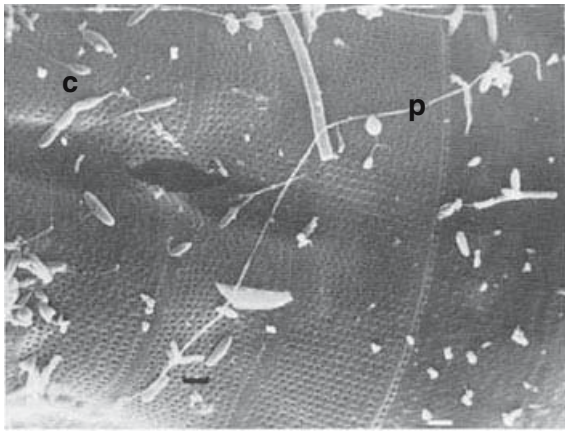

Fig. 2. Prosthecae (p) and prosthecate cells (c) attached to the filamentous diatom *Melosira.* Scanning electron micrograph. Bar = 1 µm.

As algal epibionts, DPB exhibit some preference for association with diatoms (Anderson and Poindexter, 1984; Nemec and Bystricky, 1962; Tufail, 1987). This may reflect any of: a preference of the caulobacters, at least, for siliceous surfaces (glass, sand grains, diatom frustules); strictly spatial coincidence, since diatoms are themselves common as epibionts of other algae and of plants; and environmental factors that favor, in common, the multiplication of these two types of organisms. In the laboratory, when mixed with an algal population, caulobacters attach readily to both phototrophic and heterotrophic diatoms and to algae with nonsiliceous walls (Fig. 3). In natural habitats, caulobacter numbers fluctuate in parallel with phytoplankton in general (Lapteva, 1987; Staley et al., 1987) and they are likely to be found on every kind of alga and on submerged plants as well (Kudryavtsev, 1978). Among the DPB, caulobacters in particular can be isolated from both natural and cultivated algal populations: from soil (Gromov, 1964), water (Gromov, 1964; Lapteva, 1987), and cultures (of *Nostoc* [Bunt, 1961], *Chlorella* [Zavarzina, 1961], *Phormidium, Tribonema, Chlorella,* and *Chlorococcum* [Gromov, 1964], *Anabaena* [Li et al., 1984], and *Cryptomonas* [Klaveness, 1982]).

The principal advantage of attachment to algae is presumed to be an immediate source of soluble organic substances in the algal exudate. During illumination, cyanobacteria and algae also release O_2, an environmental factor found by Lapteva (1987) to be a major positive influence on the occurrence of caulobacter populations. However, O_2 is also potentially toxic, and it has been suggested (Steinman and Eley, 1990) that algal association may have selected for the evolution in caulobacters of a periplasmic SOD in addition to their cytoplasmic SOD (see Steinman, 1982). Since O_2 can be especially damaging to phototrophs, epibiontic heterotrophs such as caulobacters may serve to consume sufficient O_2 to reduce the pO_2 in the immediate environment of photosynthetically active cells (Lupton and Marshall, 1981; Staley, 1971; Stanley et al., 1979), as well as to cycle carbon immediately (algal exudate to CO_2 to alga) through their oxidative metabolism (Allen, 1971). Such considerations suggest mutually beneficial association, not just coincidence.

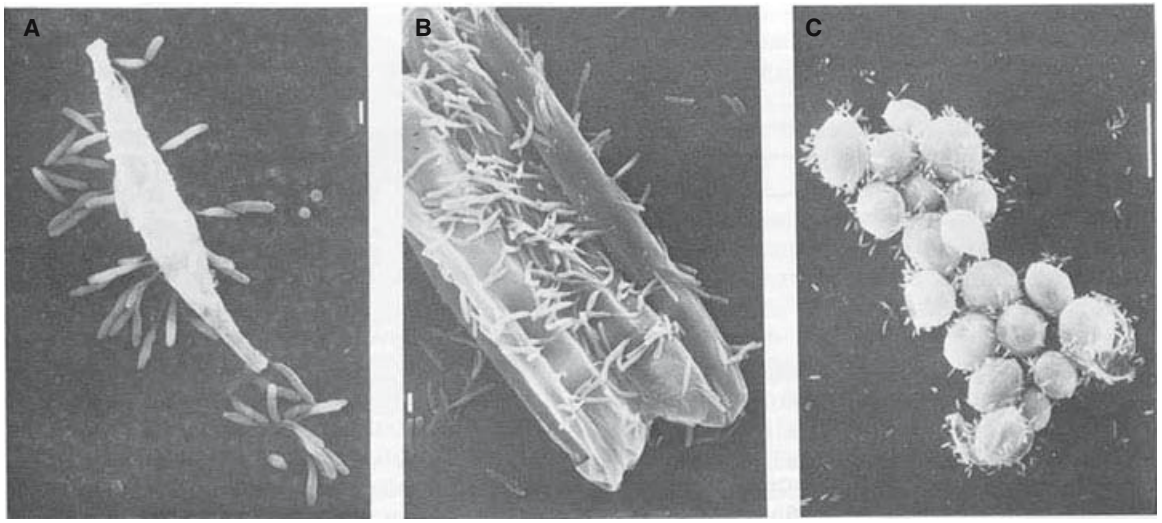

Fig. 3. Two-membered cultures of a marine caulobacter (VC13) attached to: (A) *Phaeodactylum tricornutum,* a phototrophic diatom; (B) *Nitschia* sp., a heterotrophic diatom; and (C) *Oöcystis* sp., a phototrophic green alga. Scanning electron micrographs by K. L. Anderson. Bar = (A and B) 1 μm; (C) 10 μm.

Enrichment and Isolation of Dimorphic Prosthecate Bacteria

Principles and General Procedure

The density of DPB in any natural sample will not be high and typically will be much lower than 10^6 per ml of water or per gram of solid material. Nevertheless, their tolerance of prolonged nutrient scarcity provides a dependable physiological basis for their enrichment. Successful enrichments from water, and from soil suspended in water, result when the sample is allowed to stand undisturbed for one to several weeks. Samples have often proved useful when stored for months and even years, and long-undisturbed samples can be regarded as pre-incubated enrichments.

Nevertheless, it is often more practical to promote microbial multiplication by supplementing the sample with organic nutrients; peptone added to 0.001 to 0.005% (w/v) is a suitable supplement, possibly indicating that microbial development in many natural samples is nitrogen-limited.

Periodic examination, by phase contrast microscopy, of the thin surface film (lifted with a loop, a slide, or a cover slip~~not~~ with a pipet), of growth scraped from the wall of the vessel, or of algal cells (if the culture has been illuminated) will reveal an accumulation of prosthecate cells. Other bacteria present may multiply, but they tend to die off or be consumed by protozoa; the prosthecate bacteria seem refractory to both of these processes.

At a point determined according to the proportion of accumulated prosthecate bacteria, a sample is streaked onto a suitable medium and incubated at room temperature (preferably) or at 30°C. A suitable plating medium for general purposes contains 0.05% peptone, plus possibly a vitamin mixture such as that formulated by Staley (1968), and 1.0 or 1.5% agar. As colonies become visible, they should be marked at two or three days and the plate reincubated. Colonies that become macroscopically visible at four to seven days will include *Caulobacter* and *Asticcacaulis* colonies, which are smooth, circular, and convex with an entire edge. Colonies that become visible only after seven days will include hyphomicrobia; development of *Hyphomicrobium* colonies can be accelerated by placing a flask or bottle of methanol in the incubator with the plates. Colonies of hyphomicrobia are initially hyaline, circular, cohesive, and often crateriform. Streaking on a mineral medium such as 337 (see "Cultivation," this chapter) and incubating in an atmosphere containing methanol vapors will increase selectivity of this step for *Hyphomicrobium*. Supplementation of the medium with 0.02% $MnSO_4$ or $FeSO_4$ (or iron powder or Fe-containing paper clips) may result in metal oxide deposition in the colonies, visible as brownish coloration. Many DPB deposit Fe and/or Mn oxides, at least upon primary isolation, and the presence of such deposits provides a macroscopic indication of possible DPB colonies.

At this point in the isolation of DPB, two major problems may be encountered. First, suitable samples often contain organisms that grow as a film on the surface of agar media; they may grow over and through colonies of DPB and be

carried onto subsequent streak plates. Their spreading can be retarded by the use of 2% agar, but this will also slow the development of DPB colonies. They can be avoided by transferring small, late-arising colonies as soon as possible (with the aid of a dissecting microscope, if necessary) to a secondary plate; the most suitable method is to transfer each colony with a sterile toothpick to a small area on a fresh plate. When growth accumulates in the inoculated patches, samples can be screened microscopically for DPB more conveniently than can the small colonies typical of the primary plates. Repeated restreaking from positive patches, then from isolated colonies, will eventually yield pure populations of DPB.

The second problem arises from the tendency of DPB to attach to other microbial cells, including other bacteria. As a consequence, initial colonies and patches containing DPB are often mixed with other bacteria (see, e.g., Harder and Attwood, 1978). This necessitates careful microscopic observation to avoid overlooking DPB, which may be only a minority in a mixed colony or patch, and repeated restreaking until all colonies on a plate contain only DPB, and only one type of DPB.

Microscopic screening is best accomplished in wet mounts examined with a phase contrast oil-immersion lens. This allows simultaneous evaluation of the presence of prosthecae and of motility. Prosthecae are less than 0.2 μm in diameter in caulobacters and only slightly wider in hyphomicrobia; they are not discernible in an ordinary light microscope. If phase contrast microscopy is not available, a droplet of crystal violet or methylene blue solution added to a wet mount will increase visibility of the prosthecae; the stain can be introduced from the edge of the cover slip after the mount has been examined for motility. Mordanted stains such as those used for visualizing flagella are also suitable for visualization of prosthecae.

Most DPB are adhesive, and in colonies and in pure cultures they tend to adhere to each other in rosettes united by a common mass of holdfast material. Only in *Caulobacter* is the holdfast located at the distal tip of the prostheca, resulting in rosettes in which the cells are at the periphery. In the other genera, adhesive isolates bear holdfast material directly on the cell surface, and cells in rosettes appear crowded while their prosthecae extend away from the cell cluster (Fig. 4). The presence of either type of rosette in colonies on primary isolation plates indicates the possible presence of DPB. Colonies and patches should be pursued to purity if rosettes of cells are present, even if prosthecae are not seen; such clones may eventually prove identifiable as *Asticcacaulis*.

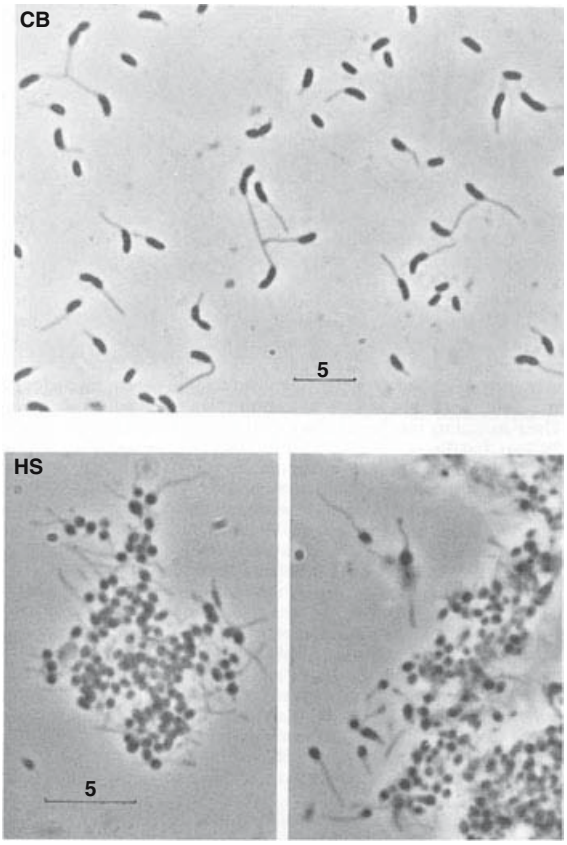

Fig. 4. (a) Caulobacterial (CB) and (b) hyphomicrobial (HS; lower panels) cell clusters formed in pure cultures. Phase contrast microscopy of cells in tannic acid + $HgCl_2$ (CB) or in seawater (HS). Bar = 5 μm.

Final identification of morphologic type should be made on the basis of electron microscopical examination of shadowed or negatively-stained specimens (see "Identification of DPB," this chapter).

The procedure just described is generally suitable for obtaining pure cultures of DPB. More specialized procedures for *Hyphomicrobium* and for *Pedomicrobium* are described below.

It is occasionally possible to isolate DPB without an enrichment step, and if the total microbial count of the sample is low because it was obtained from a strictly oligotrophic habitat, or if the sample is from a long-unused storage reservoir, direct streaking is worth attempting. A few useful guidelines are given below that can improve the development of a useful proportion of DPB and ensure their recognition once isolated.

1. Water samples should not be filtered to remove eukaryotic microbes and particulates. If filtration is for some reason desired, then the filter should also be used as inoculum for a separate enrichment culture. DPB are often more abundant on algal and fungal thalli and on

particles than in the ambient water, and the material on the filter may be a more suitable inoculum than the water.

2. Soil samples should be ground, not just shaken, to break up microbial clumps and to detach prosthecate cells from particles.

3. DPB can be collected on bait placed in the enrichment culture or in situ in the habitat. Glass surfaces such as microscope slides are the easiest to handle. (For simple observation of these organisms, this is the method used by Henrici and Johnson [1935]; somewhat more demanding, because of their physical delicacy, is the use of plastic-coated electron microscope grids [Hirsch and Pankratz, 1970].) To remove DPB, the bait should be rinsed well to remove casually-associated bacteria, then scraped (while wet) with a hard object to remove prosthecate cells. Breaking the prosthecae of caulobacters will not kill the cells, and hyphomicrobia do not attach by their prosthecae. Rubbing with a soft cotton swab will not detach these tightly-adhesive bacteria.

4. Dilution of the water sample or suspension of ground soil or sediment is often helpful. When DPB are present in sufficiently high proportion so that they will persist to higher dilutions than many of the other types present in a sample, dilution~~es~~pecially of samples to be supplemented with nutrients~~re~~duces the number of faster-multiplying bacteria and results in usefully high proportions of DPB after shorter incubation periods.

5. *Above all*, initial streaking must employ dilute media. Colony development will take several days, and colonies will be quite small, but the majority of DPB either do not grow on media containing 0.5% or more of soluble organic material or exhibit extreme pleiomorphy and absence of motility. Prosthecal development, in particular, is aberrant; in addition, cell shape is irregular, lysis is frequent, and viability in the colonies is low. Failure to accommodate this characteristic of DPB is probably the main reason they are so much more frequently sighted in natural samples than isolated from them; filtering them out before enrichment surely accounts for another major loss of DPB from natural samples prior to incubation. In addition, they are not reported in studies employing acridine orange (see, e.g., Kogure et al., 1979) because prosthecae fluoresce very weakly, or not at all, and most of the DPB strains tested either are not inhibited by nalidixic acid or develop aberrantly in its presence (see, e.g., Weiner and Blackman, 1973).

On the other hand, the purity of isolates can be checked by streaking on routine bacteriological "nutrient agar"(0.5% peptone plus 0.3% beef extract) for freshwater and soil isolates (Attwood and Harder, 1972; Gebers and Beese, 1988; Hirsch and Conti, 1964a) and on full-strength Zobell's 2216 (0.5% peptone, 0.1% yeast extract, 0.01% $FePO_4$ in 75% seawater) for marine isolates. Among marine DPB, only *Hyphomonas* will grow readily and with recognizable dimorphology on Zobell's medium, and even their growth is improved by diluting the medium three- to ten-fold (Havenner et al., 1979; Weiner et al., 1980).

Specific Enrichment Procedures for *Hyphomicrobium* and *Pedomicrobium*

Methanol-Nitrate Anaerobic Enrichment for *Hyphomicrobium* This method, developed independently by Sperl and Hoare (1971) and by Attwood and Harder (1972), is the only dependably rapid enrichment method for DPB. It yields a nearly pure population of *Hyphomicrobium* in three days to three weeks; the lower the organic content of the sample, the earlier the *Hyphomicrobium* population will develop (Attwood and Harder, 1972).

A sample of water or sewage (a few ml) or of mud or soil (not more than 1 gram) is added to a mineral medium (such as "337," see below) containing 0.5% KNO_3 and 0.5% methanol. The culture is incubated anaerobically, preferably in a tightly screw-capped vessel. When turbidity and bubbles (of N_2) appear, phase contrast microscopical examination usually reveals a high proportion (often more than 90%) of hyphomicrobia, which can then be purified by streaking on the same medium and incubating either aerobically or anaerobically. Methylotrophic denitrifying DPB isolated by this means, as well as strains isolated initially as aerobes but that are capable (sometimes only after adaptation [Sperl and Hoare, 1971]) of anaerobic growth with methanol and nitrate, have been assigned to four species of *Hyphomicrobium* (*H. vulgare*, *H. facilis*, *H. aestuarii* and *H. zavarzinii* [Hirsch, 1989]); thus, although highly selective for the genus *Hyphomicrobium*, the method yields several species among the isolates.

Humic Gel Selection for *Pedomicrobium* This method yields *Pedomicrobium* without a liquid enrichment step. Samples of soil or manganous deposits (e.g., from pipelines) suspended in water or saline, or of a water sample, are streaked on humic gel agar (for preparation, see Gebers and Hirsch, 1978) containing vitamins (to prevent pleiomorphy of *Pedomicrobium*) and cycloheximide (to inhibit fungi) at pH 5–6 (to inhibit other bacteria). After four to six weeks, yellow-brown cohesive colonies with dense cen-

ters and frayed edges appear. Isolation of *Pedomicrobium* requires vigorous disruption of these colonies (e.g., with the aid of a mechanical homogenizer) in a suspending medium and restreaking, since they are often overgrown by or contain other bacteria. After isolation, more rapid growth can be allowed by cultivation in acetate-yeast extract medium (PSM, below).

The principle underlying this direct isolation is the same as in the general procedure outlined above: during the first few weeks of incubation, other bacteria and fungi (and sometimes also algae and amebae) grow and multiply. *Pedomicrobium* colonies develop as the others decline (Gebers, 1981).

Identification of Dimorphic Prosthecate Bacteria

The genera of DPB are defined and therefore identified primarily on the basis of morphological traits. Accordingly, identification of an isolate as a representative of one of these genera requires microscopical examination, during the growth phase, of pure cultures that meet the following criteria.

1. Uniform dimorphic morphology.
2. Minimal to moderate accumulation of reserve polymers.
3. Not more than 50% of the population accounted for by swarmers.

These criteria are based on the following considerations.

1. Most isolates, particularly of hyphomicrobia, exhibit pleiomorphy even during the growth phase of a culture; all isolates do so in stationary phase. Pleiomorphy can often be reduced by vitamin supplementation of the medium (Gebers, 1981; Gebers and Beese, 1988; Gebers and Hirsch, 1978; Matzen and Hirsch, 1982a; Vedenina and Govorukhina, 1988) and is invariably reduced by the use of media containing not more than 0.2% soluble organic nutrients. "Uniform dimorphic morphology" means all prosthecate cells look alike, all swarmers look alike, and all reproductive cells (the link between the two forms) look alike.

2. DPB accumulate large quantities of carbon or phosphorus reserves when these nutrients are available in excess. Reduction of the carbon or phosphorus source that minimizes such accumulation typically also yields cultures of more uniform morphology and reduces the proportion of "bizarre" forms (Tyler and Marshall, 1967b).

3. Because swarmers of these bacteria arise by cell reproduction and do not themselves reproduce, a swarmer proportion greater than 50% indicates a failure of cell maturation and implies that aberrant development will be observed among the prosthecate cells present (see, e.g., Dow et al., 1983). *A. excentricus*, whose nonprosthecate cells can divide in some media (Larson and Pate, 1975), is an exception to this criterion.

In any pure culture that meets these criteria, there will be three types of cells: prosthecate cells, swarmer cells, and reproducing cells. Their definitive characteristics are best determined by electron microscopy of shadowed or negatively-stained specimens (Fig. 5). The bands typical of (although not universal among; Poindexter,

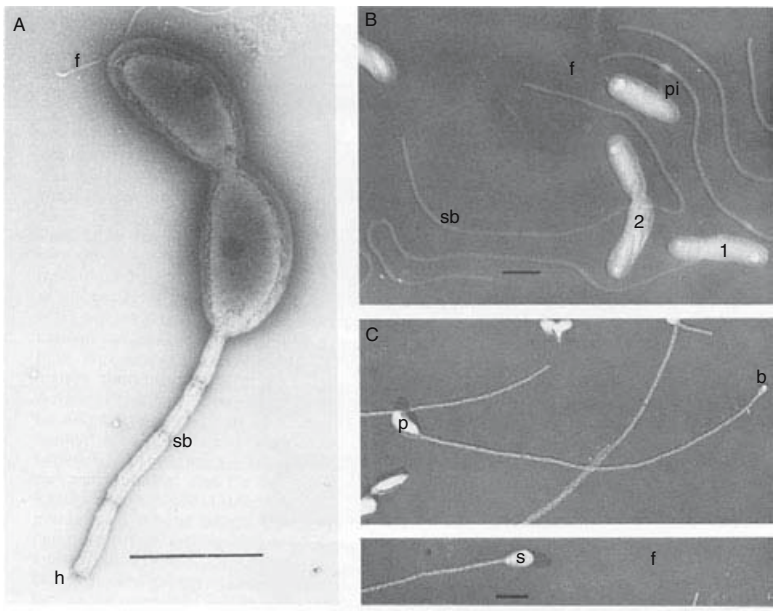

Fig. 5. (A) Negatively stained (K-PTA) *Caulobacter* cell. h, holdfast material; sb, stalk band; f, flagellum (with hook). (B) Pt-shadowed cells of *A. biprosthecum* with one (1) and two (2) prosthecae, and a swarmer with flagellum (f) and prosthecal initials (pi); sb, stalk band. The incipient swarmer of the dividing biprosthecate cell is flagellated. (C; two panels) Pt-shadowed *Hyphomicrobium* sp. cells; p, prosthecate ("mother") cell; b, very young bud; s, incipient swarmer with flagellum (f). Bar = 1 μm.

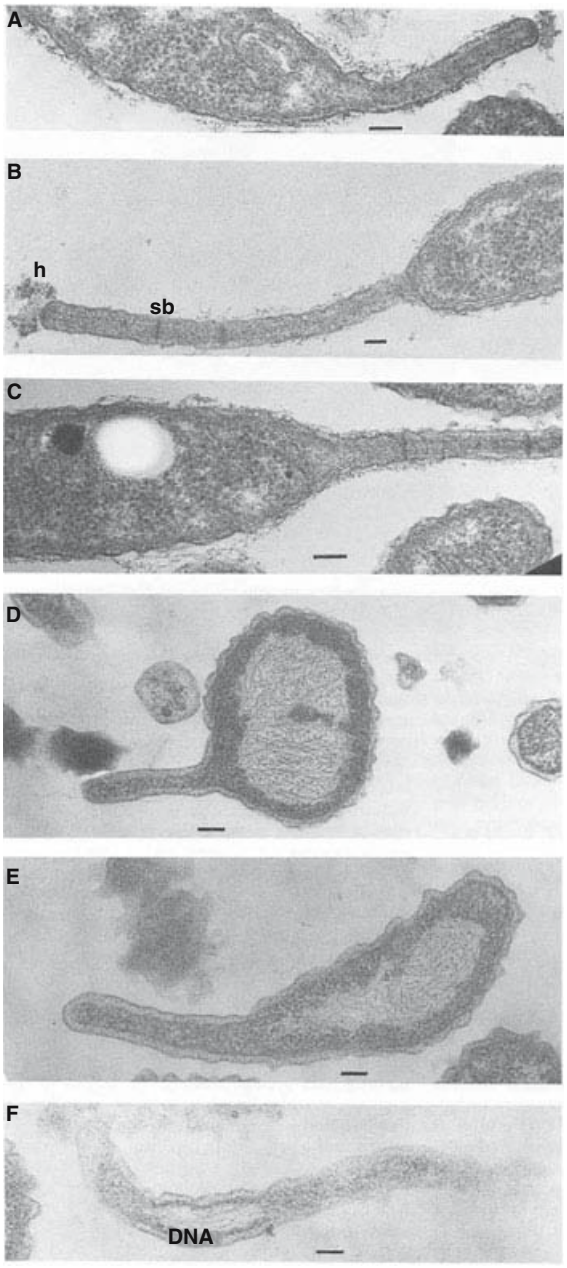

Fig. 6. Sections of prosthecae. (A–C) *Caulobacter* stalks; h, holdfast material; sb, stalk band. (D–F) *Hyphomonas* hyphae, with ribosome density as within the cell body cytoplasm; DNA, fibrils of DNA. Bar = 100 nm.

1989a, 1989b) caulobacterial prosthecae are discernible in such specimens. The identity of a cellular appendage as a prostheca can be established only by examination of thin sections (Fig. 6) that reveal the presence of all three components of the cell envelope: outer membrane, peptidoglycan layer, and cytoplasmic membrane. This technique also distinguishes the caulobacterial "stalk," which typically lacks cytoplasmic components through most or all of its length, from the (wider) hyphomicrobial "hypha," which includes cytoplasmic components throughout its length.

Cell shape is uniform in each developmental stage of each isolate, but variable within each genus. *Caulobacter* cells may be vibrioid, rod-shaped, or fusiform; *Asticcacaulis* cells are only rod-shaped. Known hyphomicrobia are rod-shaped or ovoid to nearly spherical, and incipient buds and swarmer cells may exhibit a shape different from that of mature, prosthecate cells. The morphology of the reproductive cell is distinctive for three of the genera; the fourth form is shared by two genera, as follows.

Caulobacter: approximately equatorial constriction; one pole prosthecate, one pole monoflagellate. There is one prostheca per cell.

Asticcacaulis: unevenly divided by septation; the prosthecate sibling is characteristically longer, with the prostheca subpolar or lateral, and the shorter sibling subpolarly monoflagellate. There may be one or two prosthecae per cell.

Pedomicrobium: the larger, prosthecate cell is the "mother" cell, and the smaller bud arises at the distal tip of the prostheca; as the bud grows, its long axis is perpendicular to the hyphal axis; the bud bears one subpolar flagellum. There may be one, two, or more prosthecae per cell.

Hyphomicrobium and *Hyphomonas*: morphology as in *Pedomicrobium* except that the long axis of the bud is a continuation of the hyphal axis. In *Hyphomicrobium*, the swarmer may possess more than one (polar or subpolar) flagellum. Typically one, rarely more than two prosthecae per cell.

Distinguishing among the genera of hyphomicrobia has long been difficult, particularly because of their tendency to pleiomorphy (Bauld and Marshall, 1971; Bauld and Tyler, 1971; Bauld et al., 1971). However, it is now apparent that this morphology occurs in at least three distinct physiotypes: 1) methylotrophs (now *Hyphomicrobium* [Hirsch, 1989]), among which requirements for organic growth factors are unknown, although vitamins may be stimulatory, and for which nitrate can serve as sole source of nitrogen; 2) non-methylotrophic organisms (now *Pedomicrobium* [Gebers, 1989]) that prefer organic acids as carbon sources, accept ammonia as sole source of nitrogen, and require organic growth factors; and 3) amino-acid-requiring isolates (now *Hyphomonas* [Moore and Weiner, 1989]), all of which are either marine isolates or can be maintained on marine media. Accordingly, distinction between the two genera that have similar morphology in the budding stage requires determination of dependence on amino

acids as macronutrients or of ability to grow with methanol or methylamines as the only organic substrates.

Cultivation of Dimorphic Prosthecate Bacteria

Although media designed to mimic the composition of animal tissues ("routine" bacteriological media) are unsuitable for the cultivation of these chemoheterotrophic bacteria (for example: Attwood and Harder, 1972; Bauld et al., 1971; Gebers, 1981; Gebers and Beese, 1988; Gebers and Hirsch, 1978; Gromov, 1964; Havenner et al., 1979; Hirsch and Conti, 1964a; Kingma Boltjes, 1936; Kudryavtsev, 1978; Lapteva, 1977, 1987; Larson and Pate, 1975; Li et al., 1984; Loeffler, 1890; Poindexter, 1964, 1981a; Weiner et al., 1980), such media are *qualitatively* suitable; they need only be diluted at least three- to ten-fold. The importance of reducing total solute concentrations—principally of organic compounds, phosphate, and ammonium—cannot be over-emphasized. Growth of DPB in "rich" media or in severely unbalanced media is extremely poor if it occurs at all, and the cells are structurally fragile and morphologically aberrant. *Hyphomonas* isolates are the only members of this group that tolerate 0.5% or more of complex organic material, but in such media, viability even of this group is lower than on more dilute media, and the populations exhibit considerable genetic as well as structural and developmental instability.

The importance of employing dilute media was discovered during the first reported isolation of *Caulobacter* (Loeffler, 1890). In a study of methods for staining bacterial flagella, Loeffler encountered "eines höchst merkwürdigen Organismus" in a strongly diluted cabbage ("Kohlrabi") infusion. He purified the organism on Kohlrabi infusion solidified with gelatin, which the organism did not digest. On transfer to a richer, meat extract-peptone-gelatin agar medium, its growth was slower and development of prosthecae (described by Loeffler as thick thread-like appendages) was sparse. On return to the very dilute medium, the organism developed extremely long prosthecae that extended across the microscopic field. The organism is illustrated in Figs. 7 and 8 of Loeffler (1890) as it appeared on the two media. Uncertain of its nature, Loeffler named the organism *"Vibrio* (?) *spermatozoides"*; the cell form and pale yellow color of the colonies suggest that it was the organism known today as *C. vibrioides*. Because of his study, nutrient sensitivity in *Caulobacter* is the longest-known physiologic property of these DPB.

Many DPB are also sensitive to chelating agents such as nitrilotriacetate, ethylenediamine tetraacetate, and citrate and to phosphate, which binds many cations with affinities comparable to those of organic chelators (Hirsh, 1974; Hirsch and Conti, 1964a; Larson and Pate, 1975; Poindexter, 1984b). Thus, if chelators are used, their concentrations must be not more than 1 mM. Similarly, substances added as pH buffers (e.g., phosphate, HEPES, imidazole) are inhibitory or interfere with development at concentrations that provide dependable buffering capacity; imidazole is tolerated at the highest concentration (5 mM), but not by all isolates. Phosphate is provided in some media for some strains at 10 to 20 mM, but development is impaired (as evidenced by the accumulation of swarmers in late exponential and stationary phases), and the cells are relatively fragile. The majority of isolates exhibit requirements for vitamins (biotin, riboflavin, B_{12} or pantothenate) or for organic growth factors that are still unidentified. Pleiomorphy, in particular, is frequent among hyphomicrobia unless vitamins are provided (Gebers, 1981; Gebers and Beese, 1988; Gebers and Hirsch, 1978; Matzen and Hirsch, 1982a; Vedinina and Govorukhina, 1988).

Detailed recipes for isolation and cultivation of DPB are presented below. However, dilute (less than 0.2%) peptone media will support the growth of all DPB (even of methylotrophic hyphomicrobia, which will obtain their principal carbon source from laboratory air [Kingma Boltjes, 1936]). For nonfastidious isolates, a general basal medium should provide (in distilled water or in 50 to 75% seawater) a mixture of amino acids, vitamins, trace minerals (with relatively high proportions of Mg and Ca [Harder and Attwood, 1978; Hirsch and Conti, 1964a; Johnson and Ely, 1977; Poindexter, 1984a, 1984b]), not more than 1 mM phosphate, and ammonia at a molarity not more than twice the molarity of amino acids. A principal carbon source could be added as: a sugar (for instance, glucose, xylose, fructose, or maltose; filter sterilized) for *Caulobacter* and *Asticcacaulis*; methanol or methylamine for *Hyphomicrobium*; acetate or ribose for *Pedomicrobium*; and amino acids for *Hyphomonas*, with a total organic concentration not more than 0.1 to 0.2%. A neutral pH, an incubation temperature of 25–30°C, and aerobic conditions will allow growth of all types of DPB.

Cultivation of *Caulobacter* and *Asticcacaulis*

Isolates from fresh water and soil can be cultivated on dilute peptone-yeast extract medium (PYE). However, prostheca development is somewhat inhibited by the yeast extract, and

morphology is more regular in dilute peptone medium supplemented with $CaC1_2$ (PCa). Marine caulobacters have been cultivated only in complex medium (CPS). The majority of isolates must be cultivated and maintained on PYE, PCa, or CPS. For *C. vibrioides*, PYE must also be supplemented with riboflavin (0.1 μg/ml) to ensure perpetual subcultivation.

Growth in liquid medium occurs as a surface film on stationary cultures and as evenly-suspended turbidity in agitated cultures.

PYE Medium (Poindexter, 1964)

Peptone	0.2%
Yeast extract	0.1%
$MgSO_4 \cdot 7H_2O$	0.02%

Use tap or distilled water.

PCa Medium (Poindexter, unpublished)

Peptone	0.2%
$MgSO_4 \cdot 7H_2O$	0.02%
$CaCl_2 \cdot 2H_2O$	0.015%

Use distilled water.

CPS Medium (Poindexter, 1964)

Peptone	0.05%
Casamino acids	0.05%
Seawater	75–80%

Isolates of *C. crescentus* and *C. leidyi* grow readily in defined HiGg medium (see below), and *A. excentricus* can be cultivated in this medium supplemented with biotin (2 μg/L). Glutamate is not required as a growth factor or as a source of carbon or of nitrogen. Its role appears to be primarily as ammonia acceptor, since *C. crescentus*, at least, lacks glutamate dehydrogenase (Ely et al., 1978); growth rate and yield are maximal when the medium provides equimolar amounts of glutamate and ammonium chloride and glucose as principal carbon source (Poindexter, unpublished observations).

HiGg Medium (Poindexter, 1978)

Glucose (filter sterilized)	5–10 mM
Monosodium glutamate (filter sterilized)	5–10 mM
Phosphate (Na and K salts)	0.1–1 mM
NH_4Cl	5–10 mM
Imidazole	5 mM

Use Hutner's mineral base (Cohen-Bazire et al., 1957), prepared without vitamins.

Cultivation of *A. biprosthecum* in defined medium is dependent particularly on the presence of amino acids. Growth is optimal when five amino acids are provided as well as glucose, ammonia, and biotin (MS-B-AA medium).

MS-B-AA Medium (Larson and Pate, 1975)

Glucose	0.1%
Alanine, glutamate, serine, proline, aspartate	100 mg/ml of each
$(NH_4)_2HPO_4$ (optional)	0.075 mM
$NaH_2PO_4 \cdot H_2O$	0.5 mM
KH_2PO_4	0.5 mM
$MgSO_4 \cdot 7H_2O$	0.01%
Sodium citrate	0.01%
D-Biotin	4 μg/l

Trace salts (prepared at 1,000×; see Larson and Pate, 1975, for preparation); final concentration per liter:

$CaCl_2 \cdot 2H_2O$	10 mg
$CuSO_4$	1 mg
$CoCl_2 \cdot 6H_2O$	1 mg
$FeSO_4 \cdot 7H_2O$	10 mg
$K_2B_4O_7 \cdot 4H_2O$	1 mg
MoO_3	1 mg
$MnSO_4 \cdot H_2O$	10 mg
$ZnSO_4 \cdot 7H_2O$	10 mg

Cultivation of *Hyphomicrobium*

Hyphomicrobium isolates generally do not require organic growth factors and can be cultivated aerobically on defined media that provide a mixture of minerals, including nitrate or ammonia as nitrogen source and C_1 compounds as carbon sources (methanol, methylamine, trimethylamine). Many isolates can also be cultivated anaerobically in mineral media supplemented with methanol and KNO_3 as terminal electron acceptor or with methylamine and thioglycollate. Most isolates do not grow evenly dispersed in liquid media; in stationary cultures, cells accumulate as a pellicle and as a film on the vessel wall, and growth of many isolates is not evenly suspended even in continuously-agitated liquid cultures. All known isolates will grow on freshwater media, and some will also grow on seawater media or in media containing up to 5.5% NaCl. Temperature optima are wide, and growth may occur at 5 to 45°C.

Of many versions of the mineral medium 337," variations relate to quantities of trace salts; optimal quantities vary with the isolate. The following recipe is based on the recipes of Hirsch and Conti (1964a, 1964b), Moore and Hirsch (1972), Moore (1981), and Matzen and Hirsch (1982a) and would seem to be an average composition of general suitability.

Medium 337 General

The following are added per liter of distilled water:

KH_2PO_4	1.36 g
Na_2HPO_4	2.13 g
$(NH_4)_2SO_4$	0.5 g
$MgSO_4 \cdot 7H_2O$	0.2 g
$CaCl_2 \cdot 2H_{20}$	2–10 mg
$FeSO_4 \cdot 7H_2O$	2 mg
$MnSO_4 \cdot 7H_2O$ (20 mg, to detect Mn oxidation)	0.4–0.8 mg
$Na_2MoO_4 \cdot 2H_2O$	0.5–2.5 mg
Methanol (or methylamine, 67.5% solution)	5 ml
Vitamin B_{12} or vitamin mixture (Staley, 1968)	
KNO_3 (for anaerobic growth)	5 g

Cultivation of *Hyphomonas*

A defined medium (GAMS) has been developed for one isolate (*Hyphomicrobium neptunium*, now regarded as *Hyphomonas neptunium*), although growth is much slower than in Zobell's marine broth. All other isolates have been cultivated only on complex media, for which one-third strength Zobell's appears to be particularly suitable (Havenner et al., 1979). As with *Hyphomicrobium*, growth is typically clumpy, but smooth variants that grow more evenly dispersed regularly arise in stock cultures of *Hyphomonas* (Pongratz, 1957; Moore and Weiner, 1989; J. S. Poindexter, unpublished observations). All known isolates are marine (Weiner et al., 1985) and do not grow on freshwater media.

GAMS Medium (Havenner et al., 1979)

Glutamate, aspartate, serine, methionine	125 mM of each
Calcium pantothenate	0.26 µM
Seawater	30%

Cultivation of *Pedomicrobium*

Pedomicrobium isolates have not been cultivated on defined media; they may, like most *Caulobacter* isolates, require organic growth factors not yet identified. A generally suitable complex medium will provide an organic acid (acetate, malate, pyruvate, succinate, gluconate) at 10 mM as carbon source, a complex organic mixture (peptone, casamino acids, yeast extract) at 0.05% as nitrogen source, and a mixture of vitamins.

In isolates that deposit oxides of iron or manganese on their cells, this property can be observed macroscopically as yellow or brown coloration in colonies grown on media containing ferrous or manganous salts. Such colonies will develop a blue color when flooded with acidified 2% $K_4[Fe(CN)_6]$ or 0.4% leukoberbelin blue I (see Gebers, 1989). The property of metal oxide deposition may, however, be lost on laboratory cultivation and seems to be a "spasmodic" property in individual isolates of both *Pedomicrobium* and *Hyphomicrobium* (Tyler and Marshall, 1967a).

PSM (Gebers, 1981; Gebers and Beese, 1988)

Sodium acetate	10 mM
Yeast extract	0.05%
Starch (or 0.4% gelatin)	0.2%
Metals 44 (Cohen-Bazire et al., 1957)	1 ml/l
Vitamins (Staley, 1968)	10 ml/l

Adjust to pH 9.0.

PYVM (Gebers and Beese, 1988)

Peptone	0.025%
Yeast extract	0.025%
Vitamins (Staley, 1968)	10 ml/l
Hunter's base (Cohen-Bazire et al., 1957)	20 ml/l
DL-Malate	10 mM

Adjust to pH 7.5.

Maintenance of Dimorphic Prosthecate Bacteria

All DPB can be maintained as vegetative stock cultures on dilute peptone medium of appropriate ionic composition, refrigerated between transfers. They can also be preserved as frozen suspensions, with a cryoprotectant such as glycerol (*Hyphomicrobium*, *Hyphomonas*) or without a cryoprotectant (*Caulobacter*, *Asticcacaulis*). Hyphomicrobia and some *Asticcacaulis* isolates are also dependably preserved by lyophilization, with or without milk; however, this process is not dependable for *Caulobacter* isolates, particularly marine strains. *Hyphomicrobium* and *Pedomicrobium* are tolerant of desiccation and can be preserved as slant cultures in screw-capped tubes stored at room temperature; if dry, they can be revived by rehydration with liquid growth medium.

Ecological Roles and Potential Applications of Dimorphic Prosthecate Bacteria

The DPB exhibit two characteristics that could be exploited in the purification of waters: the property of adhesiveness and the ability to metabolize organic materials available in extremely low quantities. A wide variety of materials are suitable substrata for their attachment, including glass—a durable material available in increasingly burdensome quantities that could support (physically) equally durable populations of bacteria such as *Caulobacter* and *Hypomicrobium* in purification beds for groundwater and other waters bearing low levels of pollutants. Caulobacters have been demonstrated to be capable of rapidly mineralizing agricultural pollutants present in very low concentrations (Grimes and Morrison, 1975). They rise to prominence in enrichment cultures provided with hydrocarbons, including aromatic compounds, as sole carbon sources (Moaledj, 1978; Murakami et al., 1976) and retain the ability to oxidize aromatic compounds after years of cultivation on peptone media (Chatterjee and Bourquin, 1987). Efforts are in progress to expand their catabolic versatility by the introduction of *Pseudomonas* genes (Chatterjee and Chatterjee, 1987) and other plasmids (Anast and Smit, 1988).

Hyphomicrobia can mineralize a variety of pollutants, including aromatic hydrocarbons (Moaledj, 1978), dimethyl sulfoxide and dime-

thyl sulfide (DeBont et al., 1981; Suylen and Kuenen, 1986), methyl chloride (Hartmans et al., 1986), and various alcohols (Köhler and Schwartz, 1982). The unique capability of *Hyphomicrobium* to denitrify sewage supported (metabolically) by methanol, a relatively inexpensive carbon source, has already proved practicable (Claus and Kutzner, 1985). Since anaerobic stages of sewage treatment plants generate methane and at least one isolate of *Hyphomicrobium* is known to utilize this compound (see Hirsch, 1989), it would seem reasonable to expect that denitrification and methane utilization could be combined in *Hyphomicrobium*~~in~~ an isolate or by genetic manipulation (Dijkhuisen et al., 1984)~~th~~ereby eliminating the need for methanol in the denitrification of sewage by *Hyphomicrobium*.

On the other hand, the same properties that would allow exploitation of these organisms probably enable them to foul submerged surfaces; they are particularly likely to become a nuisance in water distribution systems. Although often seen as members of biofouling communities on submerged surfaces, DPB have been regarded as relatively unimportant as pioneers, for two reasons, both based on microscopical studies. First, the microbial cells that appear earliest on experimental surfaces are not typically prosthecate (Corpe, 1978; Corpe et al., 1975; Marshall, 1976). Second, prosthecate bacteria do not predominate numerically at any stage of fouling. The first observation is consistent with the experimental evidence that attachment is initiated principally by the nonprosthecate, swarmer stage (Newton, 1972; Hirsch, 1974; Leifson, 1962; Moore and Marshall, 1981; Zavarzin, 1961), in which stage DPB are not distinguishable from other rods and vibrios by microscopy. The second is predictable, but does not preclude a significant role of DPB in initial conditioning or continued maintenance of the surface as suitable for attachment of other microorganisms and, later, of animals.

Beyond potential assistance from DPB in remedying problems of technological origin, their predictable presence in almost any sample of fresh or sea water and in many types of soils implies that their activities are compatible with~~an~~d possibly of benefit to~~di~~verse microbial communities. At present, the only significant role of which they seem capable is as mineralizers. However, the frequent occurrence of DPB attached to plant and algal remains may reflect their participation in mobilization of detritus as polymer-digesting microbes slowly free organic carbon from insoluble forms. As Lapteva (1987) has pointed out, although DPB may be responsible for the bulk of mineralization only in waters of low organic content, their total contribution in the vastness of the biosphere's waters may be considerable.

Similarly, the high frequency of the occurrence of DPB as algal epibionts may reflect an influence on primary productivity that is not yet appreciated. In quantitative studies of *Pseudomonas* and *Caulobacter* in association with algae (*Gomphonema*, *Cyclotella*, and *Chlorella*), Allen (1971) observed that total productivity~~al~~gal and bacterial~~wa~~s higher in two- or three-membered populations than when algae or bacteria were incubated as monotypic populations. Associations fared especially well when the source of carbon was organic material derived from a macrophyte *(Naxas)*. He inferred that within algal-bacterial associations, carbon could cycle between substratum and epibionts; such association would therefore be of mutual benefit to the associates. This intriguing possibility has not been pursued experimentally.

Nevertheless, the dimorphic habit of caulobacters and other DPB can be viewed as an adaptation particularly appropriate to attachment to living substrata. As new surface was generated by growth and reproduction of the substratum organism, each generation of epibiont would be prepared to relocate (by means of its swarmers) on virgin territory, while the substratum would not be overburdened by dense accumulations of epibionts. Clearly, the possibility that epibiontic prosthecate bacteria are advantageous to their algal associates and could have a direct and positive influence on primary productivity in aquatic (and possibly terrestrial) environments is worthy of exploration. Such a niche would be consistent with both the physiological properties and the unique developmental pattern of the dimorphic prosthecate bacteria.

CHAPTER 3.1.4

The Genus *Agrobacterium*

ANN G. MATTHYSSE

Introduction

The genus *Agrobacterium* is a group of Gram-negative soil bacteria found associated with plants. Many members of this group cause disease on plants. Infections of wound sites by *Agrobacterium tumefaciens* cause crown gall tumors on a wide range of plants including most dicots, some monocots, and some gymnosperms. Infections by *A. rhizogenes* cause hairy root disease. *A. vitis* causes tumors and necrotic lesions on grape vines and is commonly found in the xylem sap of infected plants. Despite the general perception that most of the agrobacteria cause disease, the member of this group most often isolated from soil, *A. radiobacter*, is avirulent.

Phylogeny

Earlier studies using physiological characteristics such as ability to grow on various carbon sources placed the agrobacteria with the rhizobia in the family *Rhizobiaceae*. More recent studies of both 16S rDNA and other chromosomal gene DNA sequence homologies suggest that these two groups of bacteria are indeed closely related (Willems et al., 1993). Both physiological characteristics and 16S rDNA sequence data place these bacteria in the α subgroup of the Proteobacteria. They appear to be closely related to members of the genus *Brucella*.

On the basis of genomic organization the agrobacteria appear to form a unique group within the α2 subgroup of the Proteobacteria (Jumas-Bilak et al., 1998; see also Genetics); Biovar 1 strains and *A. rubi* have both a circular and a linear chromosome. Biovar 2 and 3 strains also have 2 chromosomes, but both appear to be linear. Large plasmids (200–400 kb) are present in most strains. *Rhizobia*, although closely related to agrobacteria, appear to lack the linear chromosome present in biovar 1 agrobacteria.

Genetic experiments suggest that at least some members of the rhizobia are closely related to agrobacteria. The gene order on the circular chromosome appears to be conserved between *Sinorhizobium meliloti* and *A. tumefaciens* (Hooykaas et al., 1982). When plasmids from *Rhizobium phaseoli* were introduced into *A. tumefaciens* strain C58 (a biotype 1 strain; see also Taxonomy), the resulting bacteria were able to form nitrogen-fixing nodules on bean roots. This outcome suggests that all of the chromosomal genes required for the interaction of *R. phaseoli* with plants were present on the *A. tumefaciens* chromosomes (Martinez et al., 1987; see also Genetics, Chromosomal). Along similar lines, the *nodC* gene on the sym plasmid of *S. meliloti* can be induced when this plasmid is present in *A. tumefaciens* but not when the plasmid is transferred to *E. coli*, *Xanthomonas campestris* or *Pseudomonas savastanoi* (Yelton et al., 1987). All of these results suggest that the chromosomal genes of agrobacteria and *rhizobia* are so closely related they can substitute for each other. Sequencing of the genomes of *S. meliloti* and *A. tumefaciens* is currently in progress and should help to elucidate the relationship between these bacteria.

Taxonomy

The genus is divided into species largely based on pathogenic properties, although other physiological characteristics correlate with pathogenic properties. The major species are *A. radiobacter* (nonpathogenic), *A. tumefaciens* (the causative agent of crown gall tumors), *A. rhizogenes* (the causative agent of hairy root disease), and *A. vitis* (the causative agent of tumors and necrotic disease on grapevines). There are also less well studied proposed species such as *A. rubi* isolated from cane galls on *Rubrus* species.

Agrobacteria also have been divided into biotypes (biovars) based on physiological properties. Biovar 1, which includes most strains of *A. tumefaciens*, has no growth factor requirements and will grow in the presence of 2% NaCl. Most strains produce 3-ketolactose. All biovars produce acid from mannitol and adonitol. Biovar 1 bacteria also produce acid from dulcitol,

melizitose, ethanol, and arabitol. Some biovar 1 strains are able to grow at 37°C. However, they may lose the Ti plasmid, which is required for virulence, when grown at this temperature. Biovar 2 includes most strains of *A. rhizogenes*. These bacteria require biotin for growth. They fail to grow in the presence of 0.5% NaCl or at 37°C. Some biovar 2 strains can grow on tartrate, producing alkali. Biovar 3 strains include most *A. vitis* strains. Some authors also include some *A. tumefaciens* strains in this group. Like biovar 1 strains, these bacteria will grow in the presence of 2% NaCl but generally do not grow at 37°C. Both biovar 2 and 3 strains fail to produce 3-ketolactose. Biovar 3 strains can produce alkali from tartrate. Some biovar 3 strains require biotin for growth (Table 2). Selective growth media for various biovars have been reported and are described in the section on isolation of agrobacteria (Table 1). Biovars 1 and 3 contain both strains with wide and others with narrow host ranges (Kerr et al., 1977b).

Habitat

Agrobacteria usually are found in soil in association with roots, tubers, or underground stems. The bacteria also cause tumors from which they can be isolated. Tumors may be prevalent on grafted plants at the graft junction; examples include grapes, roses, poplars, and fruit trees. In some cases, the bacteria can be isolated from the xylem of infected plants. Thus it is often possible to isolate *A. vitis* from the xylem of infected grapevines.

Although agrobacteria are generally isolated from cultivated soils and plants, biovars 1 and 2 can be found in association with roots from uncultivated plants of the natural savanna and tall grass prairie which has never been cultivated (Bouzar et al., 1987). As is the case in most other field studies of agrobacteria, the majority of these isolates were nonpathogenic. Schroth et al. (1971) were able to isolate agrobacteria from almost every soil they tested in California by using selective media and enrichment culture methods. Thus the bacteria appear to be widely distributed regardless of the plants previously grown in the location. However, the number of bacteria pathogenic for a crop grown in a particular location was greater if the same crop had formerly been grown in that location.

Isolation

Agrobacteria can be isolated from soil obtained from the vicinity of infected plants, from galls formed by the bacteria, or, in the case of grapevines, from the xylem sap of infected plants. The bacteria are not numerous in older galls and may be easier to isolate from the surrounding soil than from the tumor tissue.

Agrobacteria grow readily in culture on complex or defined media (Table 1). Nutrient agar (with or without yeast extract [0.5%]) or yeast mannitol agar will support the growth of most strains. Some strains require B vitamins for growth, usually 0.2 mg/liter each of biotin, pantothenic acid and/or nicotinic acid. Many strains, including most *A. rhizogenes* isolates, are sensitive to salt and will not grow on media such as Luria-Bertani agar because this medium contains too much NaCl. The colonies are generally white or slightly cream or pale pink in color. No distinctive pigment is produced. Large amounts of extracellular polysaccharide may be produced on some media, giving the colonies a watery appearance. The bacteria grow at a moderate rate. *A. tumefaciens* will usually require 2 to 4 days to form colonies on complex media. Some strains of *A. rhizogenes* are slow growing and may require as much as 1 week to form colonies on complex media.

Optimal growth temperature for most strains is between 25 and 28°C, although the optimal temperature for plant infection may be lower (22°C).

Selective media may be used to isolate Agrobacteria (Table 1).

Identification

Agrobacteria have been traditionally identified as Gram-negative bacteria that don't produce fluorescent pigment on King's B medium and do produce tumors (or hairy roots) when inoculated onto test plants. The test plants most often used are tomato, sunflower, *Datura* spp., *Kalanchoë daigremontiana* (also called *Bryophyllum*), tobacco, and *Nicotiana glauca* (Figs. 1–4). These plants respond relatively readily and rapidly to inoculation of *Agrobacterium* strains by producing tumors in as few as 10 days. Sugar fermentations and production of ketolactose also have been used in identification of agrobacteria (Table 2). In recent years, lipid and fatty acid profiles have been used to identify both virulent and avirulent agrobacteria (Jarvis et al., 1996; Bouzar et al., 1993a). Polymerase chain reaction (PCR) has also been used in identification and to distinguish pathogenic from nonpathogenic strains. The PCR primers chosen from *vir* genes such as *virD2* (See Genetics) can be used to identify potentially pathogenic strains (Haas et al., 1995). Pathogenic strains have been identified by their ability to grow on different opines, and the

Table 1. Media for growth of agrobacteria.

General Media

Luria Agar (for biovar 1 and some biovar 3 strains)

Tryptone	10g
Yeast extract	5g
NaCl	5g
Water	1 liter
3M NaOH	1ml
Agar	14g

Yeast Mannitol Agar (for all biovars)

Mannitol	10g
Yeast extract	1g
K_2HPO_4	0.5g
$CaCl_2$	0.2g
NaCl	0.2g
$MgSO_4 \cong 7H_2O$	0.2g
$FeCl_3$	0.01g
Water	1 liter
Agar	15g

Adjust to pH 7.0. For biovar 2 add biotin, calcium pantothenate, and nicotinic acid, all at 200µg/liter.

Mannitol Glutamate Agar (for all biovars) (Roberts et al., 1974)

Mannitol	10g
L-Glutamic acid	2g
KH_2PO_4	0.5g
NaCl	0.2g
$MgSO_4 \cdot 7H_2O$	0.2g
Biotin	0.002g
Water	1 liter
Agar	15g

Adjust pH to 7.0 before autoclaving.

H4 Minimal Medium (for biovars 1 and 3; biovar 2 will grow very slowly on this medium) (Matthysse et al., 1976)

NH_4Cl	5g
NH_4NO_3	1g
Na_2SO_4	2g
K_2HPO_4	3g
KH_2PO_4	1g
$MgSO_4 \cdot 7H_2O$	0.1g
Water	1 liter

Dissolve salts in the order given; adjust pH to 7.2; add 10ml of sterile 20% glucose after autoclaving.

AB Minimal Medium

K_2HPO_4	3g
NaH_2PO_4	1g
NH_4Cl	1g
$MgSO_4 \cdot 7H_2O$	0.3g
KCl	0.15g
$CaCl_2$	0.005g
$FeSO_4 \cdot 7H_2O$	0.0025g
Water	1 liter

General Media

Dissolve salts in the order given; adjust pH to 7.2; add after autoclaving 10ml of sterile 20% glucose or sucrose.

Selective Media (Kerr, 1986)*

Selective Medium of Biovar 1*

L(-) Arabitol	3.04g
K_2HPO_4	1.04g
KH_2PO_4	0.54g
NH_4NO_3	0.16g
$MgSO_4 \cong 7H_2O$	0.25g
Sodium taurocholate	0.29g
Water	1 liter
1% Crystal violet	2ml
Agar	15g

Add after autoclaving 10ml of 2% cyclohexamide and 10ml of 1% $Na_2SeO_3 \cong 5H_2O$. On this medium colonies of agrobacteria are white, circular, raised, and glistening. They may become mucoid.

Selective Medium for Biovar 2*

Erythritol	3.05g
K_2HPO_4	1.04g
KH_2PO_4	0.54g
NH_4NO_3	0.16g
$MgSO_4 \cdot 7H_2O$	0.25g
Sodium taurocholate	0.29g
Yeast extract	0.01g
Malachite green	0.005g
Water	1 liter
Agar	15g

Add after autoclaving 10ml of 2% cyclohexamide and 10ml of 1% $Na_2SeO_3 \cong 5H_2O$. On this medium colonies of agrobacteria are white, circular, raised, and glistening. They may turn brown a they age.

Selective Medium for Biovar 3*

Adonitol	4.0g
K_2HPO_4	0.9g
KH_2PO_4	0.7g
NaCl	0.2g
$MgSO_4$	0.2g
Yeast extract	0.14g
Boric acid	1.0g
Water	1 liter
Agar	15g

Adjust pH to 7.2 before autoclaving. After autoclaving add 10ml of 2.5% cyclohexamide, 1ml of 8% triphenyltetrazolium chloride, 1ml of 2% D-cycloserine, and 1ml of 2% trimethoprin. On this medium colonies of agrobacteria have dark red centers with white edges.

*Note that these media are only semi-selective. Other organisms may grow. Additional tests are necessary to positively identify an isolate as *Agrobacterium*.

Table 2. Traits used for identification of biovars of *Agrobacterium*.

Characteristic	Biovar 1	Biovar 2	Biovar 3	*A. rubi*
Growth on selective medium 1A[a]	Yes			
2E[b]		Yes		
RS[c]				Yes
Growth factor requirements	None	Biotin	Biotin, some strains	Biotin, pantothenic acid, nicotinic acid
3-Ketolactose production	Most strains	No	No	No
Growth on 2% NaCl	Yes	No	Yes	Yes
Growth at 37°C	Yes	No	No	Yes
Acid production from mannitol	Yes	Yes	Yes	Yes
Adonitol	Yes	Yes	Yes	Yes
Erythritol	No	Yes	No	No
Dulcitol	Yes	Yes	No	No
Melizitose	Yes	No	No	No
Ethanol	Yes	No	No	No
Arabitol	Yes	No	No	No
Alkali production from tartrate	No	Yes	Yes	No

Data from Kerr (1986).

formation of particular opines by tumors caused by various strains has been used to group these strains. In general, grouping by sugar fermentations, fatty acid profiles, PCR, opine production and utilization, and genome organization all reach similar conclusions so that no one method of identification of agrobacterial species or biovars is preferable.

Preservation

The bacteria can be stored as stabs into vials of nutrient agar (all biovars) or Luria agar (biovars 1 and 3) at room temperature essentially indefinitely (more than 10 years). They can also be stored frozen in 25% glycerol at –70°C. Liquid cultures of biovars 1 and 3 can be spun down, resuspended in phosphate buffered saline containing 1 mM $MgSO_4$, and stored in the refrigerator for approximately 10 weeks.

Physiology

General

Agrobacteria are Gram-negative, nonspore–forming, short rods. They can use glucose as a carbon source, growing aerobically. Table 1 lists agrobacterial growth media formulations and Table 2 lists characteristics of different biovars.

Fig. 1. The stem of a tobacco plant wounded at two places and inoculated with *A. tumefaciens*. The tumors are shown at 6 weeks after inoculation.

Opines: Production and Utilization

Crown gall tumors produce specific substances (often substituted L-amino acids) called opines. The production of opines is catalyzed by enzymes encoded by genes introduced into crown gall tumor cells on the T DNA. These genes are usually expressed constitutively in the tumor tissue. Typical opines result from condensation reactions between compounds already

Fig. 2. Carrot root discs (A) uninoculated, (B) inoculated with *A. tumefaciens*, and (C) and (D) inoculated with *A. rhizogenes*. The discs are shown after 5 weeks incubation.

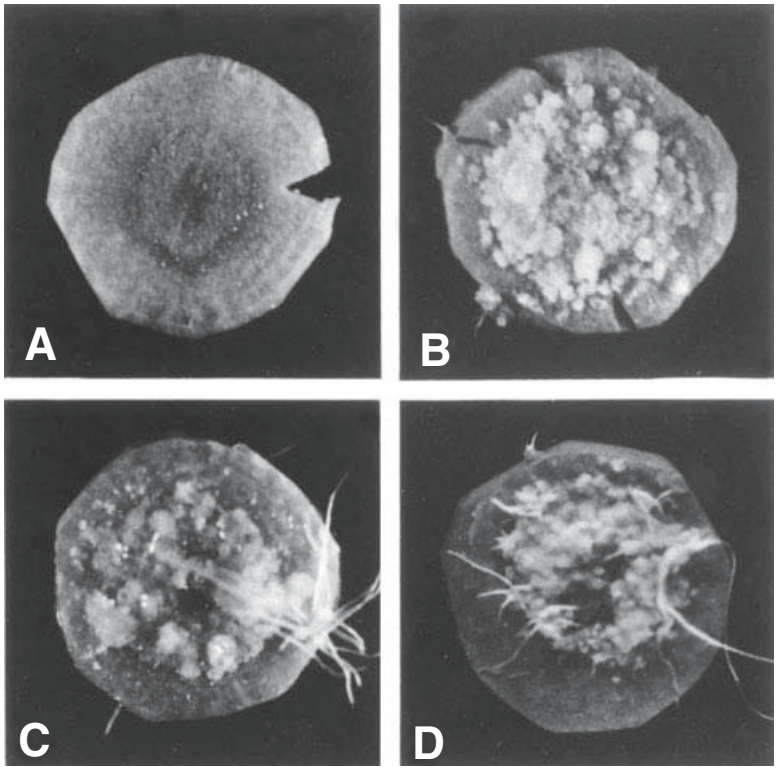

Fig. 3. A leaf of *Bryophyllum daigremontiana* (also called *Kalanchoë daigremontiana*) inoculated with *A. tumefaciens*. The site on the back right was inoculated with a strain lacking the Ti plasmid. Tumors are shown after 4 weeks growth.

Fig. 4. A leaf of *Bryophyllum daigremontiana* (also called *Kalanchoë daigremontiana*) inoculated with *A. rhizogenes*. Note that the roots formed at the wound sites are branching and ageotropic. The leaf is shown 5 weeks after inoculation.

present in plant cells. For example, octopine results from the reaction of the *a*-amino group of arginine and the keto group of pyruvate to form octopine [N_2-(1-D-carboxyethyl)-L-arginine]. The resulting compound (the opine) accumulates in the tumor tissue and can be used by the inciting bacteria as a carbon and nitrogen source. The genes encoding the enzymes for opine utilization are located on the Ti plasmid (pTi) outside the T DNA (the bacterial DNA which is transferred to the host cell) and on the chromosome. In the case of octopine, nitrogen appears to be recovered by the arginase-urease pathway. The genes for these enzymes are chromosomal. The carbon from octopine may be utilized by conversion of arginine to ornithine and then to proline via ornithine cyclase. The gene for this enzyme is located on pTi and, in some strains, a second copy is found in the chromosome (Dessaux et al., 1986). Other opines and their constituent compounds include lysopine (lysine and pyruvate), octopinic acid (ornithine and pyruvate), histopine (histidine and pyruvate), nopaline (arginine and *a*-ketoglutaric acid), nopalinic acid (ornithine and *a*-ketoglutaric acid), agrocinopine A (sucrose-4′-phosphate and arabinose-2-phosphate), agrocinopine C (glucose phosphate and sucrose phosphate), agropine (mannitol and glutamine), cucumopine [4-carboxyl-4-(2-carboxyl)spinacine], leucinopine (leucine and *a*-ketoglutaric acid), succinamopine (asparagine and a-ketoglutaric acid) and vitopine. Ti plasmids generally encode the enzymes for the synthesis of one or more opines in the T DNA and the enzymes for the utilization of the same opine elsewhere on the plasmid. Many Ti plasmids are named and grouped by the opine(s) that the plasmid-induced tumors produce (Dessaux et al., 1998).

Motility and Flagella

A. tumefaciens is motile by means of circumthecal flagella (Fig. 5). Some investigators have also observed polar and lateral flagella. There are four flagellar genes (*flaA*, *flaB*, *flaC* and *flaD*; Deakin et al., 1999). These genes are closely related to each other and to the *flaA* and *flaB* genes of *Sinorhizobium meliloti*. Deletion of the *flaA*, *flaB*, and *flaC* genes results in nonmotile bacteria that are slightly attenuated (tumors are about 70% the size of those induced by wild type bacteria) when inoculated directly into a wound site (Chesnikova et al., 1997). Bacteria, when inoculated into soil surrounding a wounded plant, must be able to move to wound sites on the plant to form tumors and thus must have flagella in order to be virulent. *A. tumefaciens* is chemotactic to a number of substances released by roots including sugars, amino acids and dicarboxylic acids. Genes involved in chemotaxis and motility have been sequenced (Wright et al., 1998; Deakin et al., 1997). These genes have a high level of homology with genes from *S. meliloti* and *Rhodobacter sphearoides*.

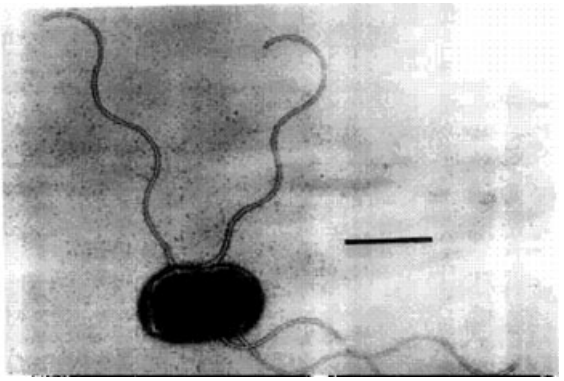

Fig. 5. *A. tumefaciens* as seen in the transmission electron microscope. Note the flagellae. The bar is 1 micron. From Brisbane et al. (1983).

Unique Aspects of *A. vitis*

Tartrate is found in grape sap. Most strains of *A. vitis* are able to degrade tartrate and use it as a carbon source. The genes for the metabolism of tartaric acid often are located on a plasmid, pTAR or pTr. A homologue of the *Pseudomonas ttuC* gene (encoding tartrate dehydrogenase) has been identified on these plasmids. Many of the tartrate plasmids are conjugative in *planta*, allowing their movement between strains (Otten et al., 1995; Salomone et al., 1996).

Genetics

General

Initial research on the agrobacteria suggested the presence of a circular chromosome and several large plasmids. More recent work has identified two chromosomes in *A. tumefaciens*. One is a roughly 3 Mbp circular chromosome that carries most of the known auxotrophic markers, and the other is a linear 2.1 Mbp chromosome to which some auxotrophic transposon mutants requiring adenine, threonine, serine, and pantothenic acid map (Jumas-Bilak et al., 1998; Goodner et al., 1999). Thus both DNA molecules can be considered chromosomes because they appear to contain genes required for normal cell functioning and metabolism. Most strains also have at least one large (approximately 300 kbp) cryptic plasmid, and virulent

strains have a Ti plasmid (approximately 200 kbp). Both the circular and linear chromosomes can be mobilized for conjugation by R68.41, a broad host-range conjugative plasmid (Goodner et al., 1999).

Chromosomal

A. tumefaciens Agrobacteria and *rhizobia* are closely related. The genetic maps of the circular chromosomes in *R. meliloti* and *A. tumefaciens* are very similar (Hooykaas et al., 1982). After *R. leguminosarum* plasmids were introduced into *A. tumefaciens*, the resulting bacteria could induce the formation of nitrogen-fixing nodules on the roots of beans. This finding suggested that all of the chromosomal genes required for the interaction of rhizobia with legumes are already present in the *A. tumefaciens* genome (Martinez et al., 1987). A variety of chromosomal genes from *A. tumefaciens* have been studied. Most of them are involved in the interaction of the bacterium with the plant. A summary of some of these genes is given below. They are grouped as follows: genes involved in exopolysaccharide synthesis, genes involved in attachment to plants, other genes required for virulence, and heat shock genes.

Genes Involved in Exopolysaccharide Synthesis
A. tumefaciens like *S. meliloti* makes a succinoglycan exopolysaccharide, which appears to have the same structure in both species. The pathway and the genes involved (named *exo* genes) for succinoglycan biosynthesis have been determined in *S. meliloti* (Reuber et al., 1993) and appear to be similar in *A. tumefaciens*. Mutations in the genes required for the synthesis of succinoglycan affect nodule formation in *S. meliloti*. However, similar mutations have been reported not to affect the virulence of *A. tumefaciens* (Cangelosi et al., 1987). Succinoglycan is also not required for colonization of tomato roots by *A. tumefaciens*, but mutations in *exo* genes did affect the ability of the bacteria to colonize legume roots (Matthysse, 2000).

In addition to succinoglycan, *A. tumefaciens* makes cellulose (Figs. 6–8). Genes required for cellulose synthesis (*cel* genes) are located on the bacterial chromosome near, but not adjacent to, the *att* genes (Robertson et al., 1988). Five genes organized into 3 operons (*celAB*, *celC* and *celDE*) have been identified. The *celD* and *celE* genes encode putative cytoplasmic proteins. The *celA*, *celB*, and *celC* genes encode putative membrane proteins. The CelA protein has homology to cellulose synthases from *Acetobacter xylinum*, *R. leguminosarum*, *P. fluorescens*, and plants. The C-terminal region of the CelC protein, which may be a glucosyl-transferase, has homology to endoglucanases from *E. chrysanthemi* and *A. xylinum*. The CelB, CelD, and CelE proteins have no significant homology with proteins in the databases (Matthysse et al., 1995). Although *A. tumefaciens* synthesizes some cellulose when grown in culture, the quantity increases markedly when the bacteria are grown with plant cells or roots. The mechanism by which the amount of cellulose synthesized is regulated is unknown. Mutants in *cel* genes are markedly reduced in virulence.

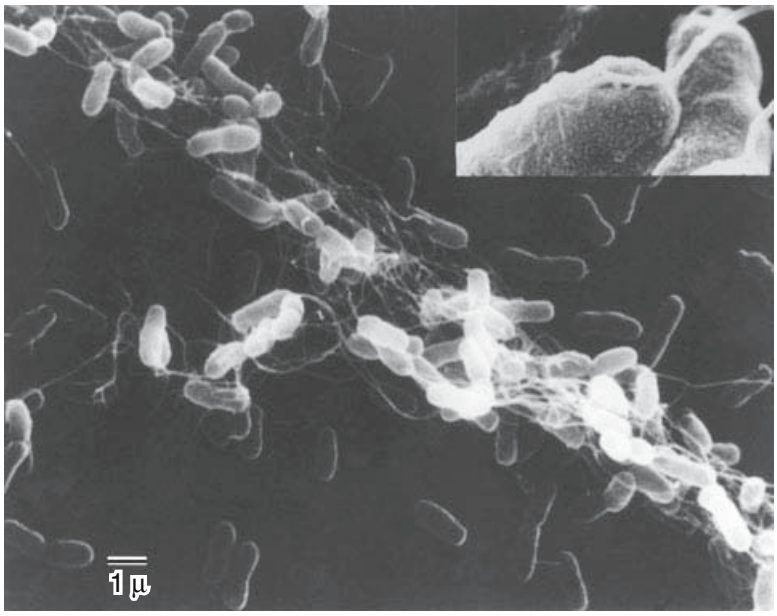

Fig. 6. Scanning electron micrograph showing *A. tumefaciens* grown with plant extract (soytone). The fibrils are cellulose made by the bacterium.

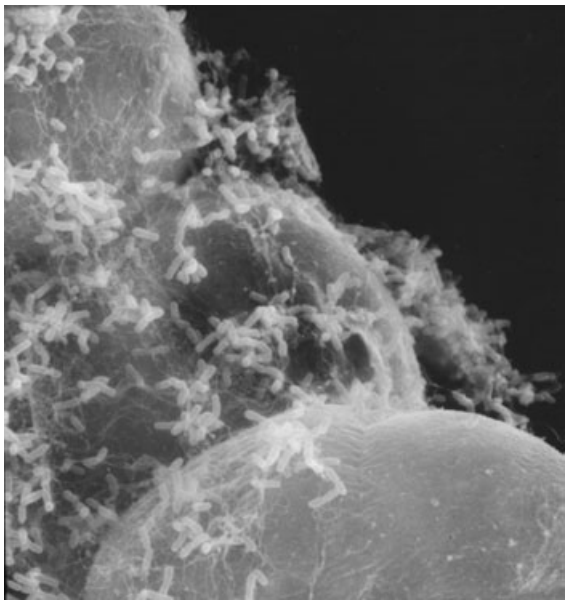

Fig. 7. Scanning electron micrograph of carrot suspension culture cells incubated with *A. tumefaciens* for 18 hours. Note the presence of both individually attached bacteria and clusters of bacteria on the surface of the plant cells. The fibrillar meshwork is cellulose fibrils made by the bacteria. From Matthysse et al. (1981).

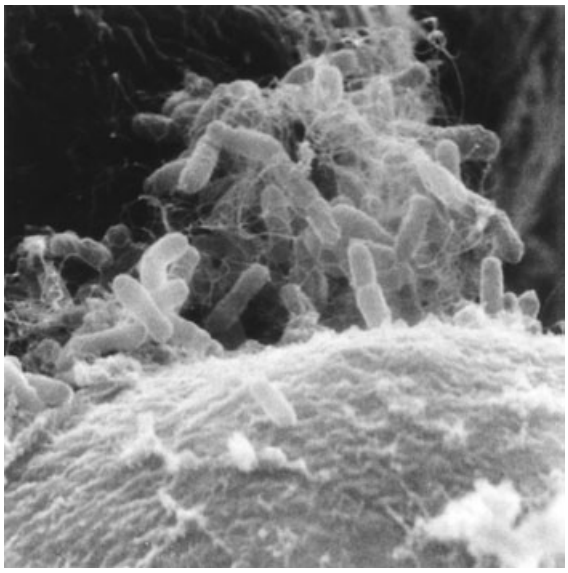

Fig. 8. Scanning electron micrograph of a carrot suspension culture cell incubated with *A. tumefaciens* for 18 hours. Note the presence of both individually attached bacteria and clusters of bacteria on the surface of the plant cells. The large cluster appears to be held together by cellulose fibrils produced by the bacteria. The majority of the bacteria adhering to the plant cell surface appear to be indirectly bound to the plant cell in large aggregates. From Matthysse et al. (1981).

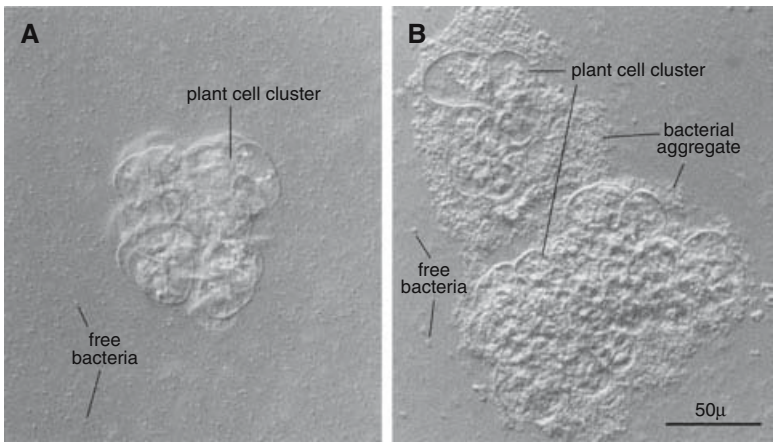

Fig. 9. Light micrographs showing bacteria (with and without attachment genes) incubated with carrot suspension culture cells for 24 hours. (A) A strain of *A. tumefaciens* lacking attachment genes. (B) Wild type *A. tumefaciens*.

Genes Involved in Initial Interactions with the Plant The region of the bacterial chromosome (*att*) in which transposon insertions result in an inability of the bacteria to attach to plants and thus in a lack of virulence is large (more than 35 kb). This region contains more than 32 open-reading frames (ORFs) organized in a minimum of 10 operons (based on the directions of the ORFs; Matthysse et al., 2000; Figs. 9–14). Many of these ORFs have no significant homology to any proteins in the databases. *Att* genes appear to fall into at least two categories: those that can be complemented by conditioned medium (CM) are presumably involved in signaling, and those that are not complemented by CM are presumably involved in the synthesis of the substance(s) that bind the bacteria to the plant surface. The *attA1–E* genes have homology to ABC transporters from a number of bacteria. Conditioned medium complemented the mutations in these genes. The genes are believed to be involved in signaling between the bacteria and the plant

(Matthysse et al., 1996). Conditioned medium also complemented several other *att* mutations. These genes are presumably also required for initial signaling. Conditioned medium did not complement mutations in *attJ*, *attK*, *attN*, *attO*, *attR*, or *attV-Z* genes. *AttR* mutants fail to make an acetylated capsular polysaccharide, which may be involved in binding of the bacteria to the plant surface (Reuhs et al., 1997). Three *att* ORFs products have homology to genes encoding DNA-binding proteins and may be involved in the regulation of gene expression. These ORFs are atrA, attJ and attO (Table 3).

Other known genes (aside from *att* and *cel*, which are required for the initial binding of the bacteria to the plant) appear to be involved in specifying for the general surface structure of the bacteria. These include the *chvAB* genes, which are required for the synthesis of β-1,2-D-glucan and the bacterial response to low external osmotic pressure, and the *pcsA* (*exoC*) gene, which encodes a phosphoglucomutase (Zorreguita et al., 1988; Thomashow et al., 1987; Leigh et al., 1992). Mutations in these genes, which are chromosomal, result in pleiotropic alterations in the bacterial surface. The *chvAB* mutants are avirulent on most but not all host plants. On some plants, they are virulent only at lower temperatures (19° but not 28°C; Banta et al., 1998). No Ti plasmid genes are known to be involved in the initial interactions of the bacteria with the plant.

Other Chromosomal Genes Involved in Pathogenesis Chromosomal genes involved in pathogenesis described elsewhere in this section include *att* genes, which are required for virulence; *cel* genes, which when mutated result in severe attenuation of virulence; *chvAB* genes, which are required for virulence on most hosts at normal (as opposed to cooler) temperatures; the *pscA* gene, which is required for virulence; and the *chvE* gene, which increases the induction

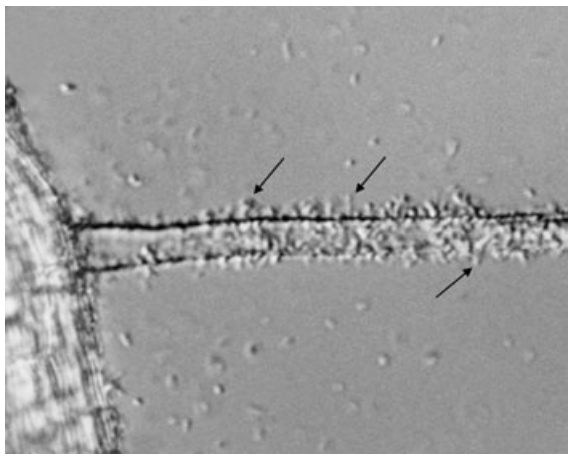

Fig. 10. Light micrograph showing *A. tumefaciens* strain C58 incubated with *A. thaliana* roots. Note the bacteria bound to the root hair surface preferentially in a vertical orientation (arrows). The orientation of bacterial binding varies with the strain examined.

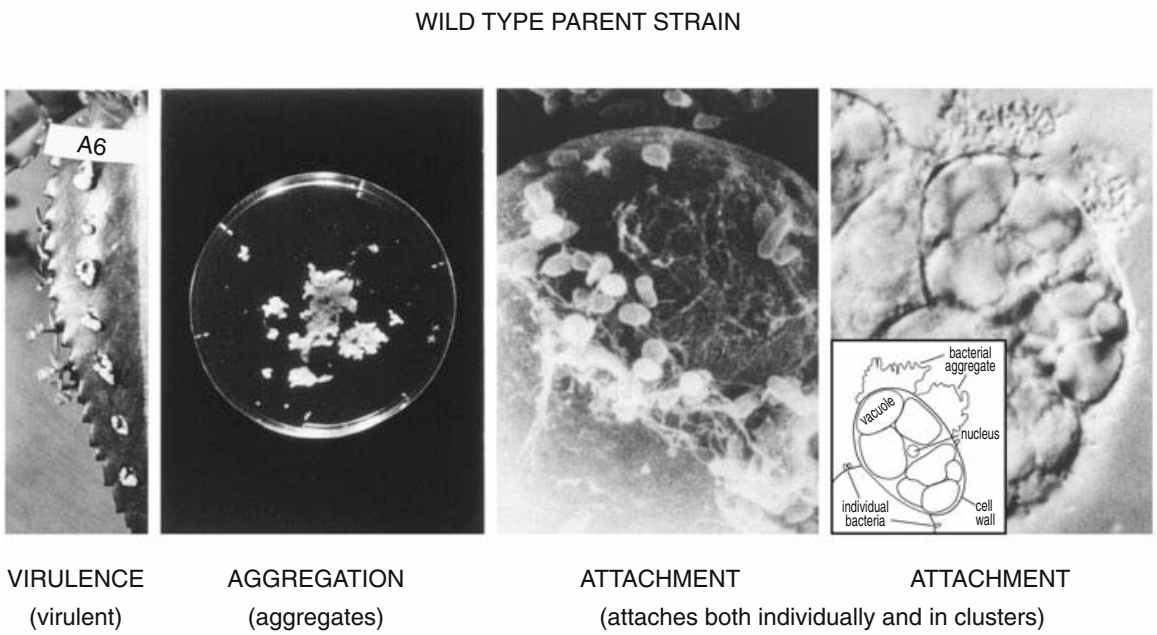

Fig. 11. Interactions of wild type *A. tumefaciens* with plants. From left to right: tumors on a leaf of *Bryophyllum daigremontiana*; aggregation of carrot suspension culture cells; scanning electron micrograph showing attachment to carrot cells; light micrograph showing attachment to carrot cells.

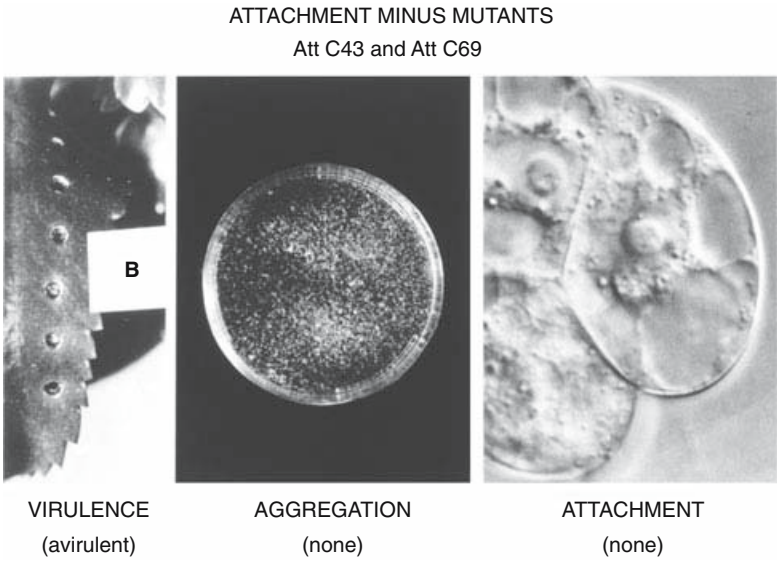

Fig. 12. Interactions of attachment-minus mutant *A. tumefaciens* with plants. From left to right: lack of tumor formation on a leaf of *Bryophyllum daigremontiana*; failure to aggregate carrot suspension culture cells; light micrograph showing lack of attachment to carrot cells. The concentrations of bacteria and plant cells in these incubations were the same as those used in Fig. 11 showing similar incubations of wild type bacteria.

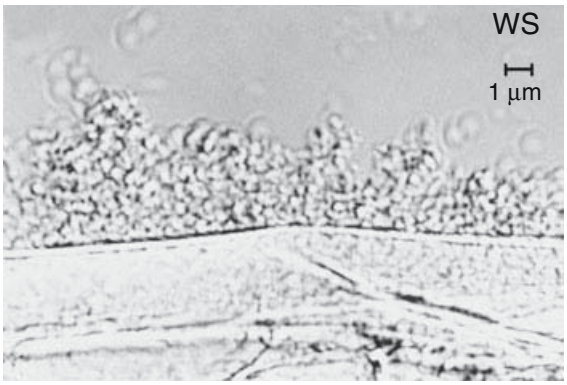

Fig. 13. Light micrograph showing *A. tumefaciens* bound to the surface of a root of *Arabidopsis thaliana*.

of *vir* genes by acetosyringone. Other chromosomal genes may affect the induction of *vir* genes. The *Ivr* (induction of *vir* genes) mutants are deficient in *vir* gene induction, although the mechanism is not understood (Metts et al., 1991). Some chromosomal genes are involved in *vir* gene induction on specific hosts. Thus some bacterial strains which are virulent on conifers carry a gene (*cbg*) that converts coniferin (which is not a *vir* gene inducer) to coniferyl alcohol (which is a *vir* gene inducer; Castle et al., 1992; Morris et al., 1990). Expression of *virC* and *virD* is regulated by a chromosomal gene *ros*, which encodes a repressor of these genes (Table 3). Ros mutants do not make succinoglycan, suggesting that *ros* is also involved in regulating the expression of *exo* genes. However, Ros mutants are still virulent on all hosts tested (Cooley et al., 1991a; Cooley et al., 1991b; Tiburtius et al., 1996; Hussain et al., 1997).

A two component system, *chvG*/*chvI*, is required for virulence and *vir* gene induction (Table 3). Mutations in these genes have pleiotropic effects; the mutant bacteria are sensitive to detergents and do not grow on complex medium. Because of the severely limited growth of these mutants, it is difficult to assess whether the requirement for *chvG*/*chvI* for virulence is due to a direct requirement for the gene products or to an indirect effect. The signal to which this system responds is unknown (Charles et al., 1993; Mantis et al., 1993).

Mutations in another chromosomal gene, *chvD*, reduce the induction of *virG* by acidic pH and phosphate starvation. This gene encodes a periplasmic ATPase (Winans et al., 1988). One gene, *acvB*, present only on the chromosome in nopaline strains, is required for virulence in these strains. In octopine strains, a second copy of this gene (*virJ*) is located on the Ti plasmid

Table 3. Regulatory genes in *A. tumefaciens* which affect expression of genes involved in the interaction with the host.

Gene	Location	Signals to which gene responds	Mutant phenotype	References
virG[a]	pTi	Acetosyringone and monosaccharides, acid pH, low phosphate	Avirulent, does not express *vir* genes	Winans et al., 1988 Roitsch et al., 1994 Stachel et al., 1985

attJ	Chromosomal	? Unknown	Avirulent, does not bind to plant	Matthysse et al., 2000
attO	Chromosomal	? Unknown	Avirulent, does not bind to plant	Matthysse et al., 2000

[a]Member of a two component system. The sensor genes are *virA* and *chvG*, respectively.

(Kalogeraki et al., 1995). In octopine strains, both genes must be mutated to observe a requirement for the gene for virulence.

Heat Shock Genes Two heat shock operons, *groESL* and *dnaKJ*, have been cloned from *A. tumefaciens* (Segal et al., 1995a; Segal et al., 1995b). The *groESL* operon contains an inverted repeat (IR) that appears to be involved in regulation of this operon's expression (Segal et al., 1995a). This inverted repeat is conserved in many bacteria (Segal et al., 1999). It acts as a transcription inhibitor, probably binding a protein repressor (Segal et al., 1996). Expression of the *groESL* operon is regulated not only at the level of transcription, but also at the level of translation by two different systems: the inverted repeat controls the stability of the transcript (Segal et al., 1996), and a temperature-activated RNA processing system specifically cleaves the mRNA of the operon, resulting in differential transcript stability (Segal et al., 1995c). In addition, the *rpoD* gene which encodes the vegetative transcription activator σ70 has been cloned (Segal et al., 1995d). This gene is a heat shock gene in *E. coli*, but it is not part of the heat shock regulon in *A. tumefaciens* (Segal et al., 1995d). A new heat shock promoter that is common to many α-purple bacteria, including *A. tumefaciens*, *Rhizobium meliloti* and *Bradyrhizobium*, has been identified. This promoter is recognized by a heat shock transcriptional activator, a homologue of σ32, which has been cloned from *A. tumefaciens* (Nakahigashi et al., 1995; Segal et al., 1995b).

A. rhizogenes There is relatively little work on the chromosomal genes of *A. rhizogenes*. They are generally believed to be similar to those of the other agrobacteria. However, differences in the binding of biotype 2 *A. rhizogenes* strains to plant cells suggest that at least some of the *att* genes must differ between biotype 1 *A. tumefaciens* and biotype 2 *A. rhizogenes* (Sykes et al., 1988). Differences of biotype 1 and 2 strains in their sensitivity to salt and in the sugars that they are able to metabolize suggest that there may be many differences in chromosomal genes between these strains.

A. vitis Genes are involved in the breakdown of pectin are important virulence factors in *A. vitis*. The genes affecting synthesis of polygalacturonase and endoglucanase are both chromosomal (McGuire et al., 1991). The *pehA* gene has been cloned and sequenced and appears to be closely related to *peh* from *Ralstonia solanacearum* and *Erwinia carotovora* (Herlache et al., 1997). Polygalacturonase mutants are reduced in virulence on grape (Rodriguez et al., 1991).

Ti Plasmid Genes

The *A. tumefaciens* Ti plasmid is about 200 kb. The complete sequences of 3 Ti plasmids are

available. Major groups of genes located on pTi include: the T DNA (the DNA transferred to the host cell), *vir* genes (genes required for, or associated with, virulence), and genes involved in quorum sensing, Ti plasmid conjugation, and opine metabolism.

T DNA The T DNA is the DNA fragment transferred to the host cell whose expression results in tumor formation. Located on the Ti plasmid, T DNA is bounded by 24 base-pair direct repeats referred to as the border sequences. Some Ti plasmids have two segments of T DNA (called TR and TL) with four border sequences. The segments bounded by the border sequences may be transferred individually or as an entire piece carrying both TR and TL. The T DNA carries genes for enzymes for plant growth hormone biosynthesis, for the modification of plant responses to growth hormones, and for the synthesis and secretion of opines. (See Physiology of Opines in this Chapter.)

Two enzymes encoded in the T DNA (tryptophan monooxygenase and indole-3-acetamide hydrolase) carry out the biosynthesis of auxin (indole-3-acetic acid, IAA). Tryptophan monooxygenase (encoded by *iaaM*) converts tryptophan into indole-3-acetamide, and indole-3-acetamide hydrolyase (encoded by *iaaH*) converts indole-3-acetamide into auxin. This pathway of auxin biosynthesis from tryptophan differs from that used by most plants and is the same as that used by some other plant pathogenic bacteria, notably *Pseudomonas savastanoi*, which infects olive and oleander, producing tumors. No DNA transfer is involved in this infection. The *P. savastanoi* genes are expressed in the bacterium, whereas the *A. tumefaciens* genes for auxin biosynthesis, which have eukaryotic promoters, are expressed in the plant host. Host biosynthesis of cytokinins is increased by the expression of the T DNA gene *ipt*, which encodes an isopentyl transferase. These genes encoding enzymes involved in plant hormone biosynthesis have constitutive eukaryotic promoters. Their expression and the resulting overprodution of auxin and cytokinins cause tumor formation. Two other genes carried on the T DNA appear to regulate the response of the plant to hormones, although their mechanism of action is not understood. These are gene 6b in which mutations give rise to large tumors and gene 5 in which mutations have a phenotype only in *iaa*$^-$ mutants. In this background gene 5 mutants produce an increased shoot-like tumor morphology. *Gene 5* encodes an indole lactate synthase. However, the role of indole-3-lactic acid in the plant is unknown (Binns et al., 1998).

The T DNA also encodes enzymes for the synthesis and secretion of opines, peculiar compounds made by the plant only in crown gall tumors. These genes are also preceded by constitutive eukaryotic promoters. It is thought that it is opine production by the tumor cells which results in the advantage to the bacteria in causing tumor formation. The bacteria possess genes for enzymes to metabolize these opines, which they can use as carbon and nitrogen sources. These genes are located outside the T DNA but on the Ti plasmid. Different Ti plasmids encode the enzymes for the production of different opines and their utilization. Ti plasmids and bacterial strains are often referred to by the opine(s) that they produce and use, e.g., octopine or nopaline strains.

The Ri plasmid of *A. rhizogenes* also contains a T DNA. Agropine Ri plasmids carry *iaaH* and *iaaM* genes in their T DNA, but hairy root formation by *A. rhizogenes* is not due to excess auxin production. Other Ri plasmids such as the mannopine and cucumopine plasmids don't contain *iaa* genes. Instead, the *rol* genes, particularly *rolB*, appear to be responsible for the growth of hairy roots (branched, ageotropic roots). There are four *rol* genes, *rolA*, *rolB*, *rolC*, and *rolD*. The mechanism by which they cause root formation and their biochemical activities are not understood, although their sequences are known (the whole of the T_L region of pRi has been sequenced). The *rol* genes appear to modify the hormone receptors or action of growth hormones in the plant. RolB alone is necessary and sufficient to cause full hairy root growth. Fertile plants can easily be regenerated from hairy roots on most species of plants. However, the regenerated plants have an altered morphology due to *rolA*, *rolB*, *rolC*, *rolD*, and ORF13. Ri plasmids contain genes for the synthesis of opines similar to those found on Ti plasmids (Binns et al., 1998).

vir Genes The transfer of T DNA to the host plant is dependent on *vir* genes and the presence of 24 bp direct repeats at the ends of the T DNA (called the border sequences). The particular sequences contained between the border sequences do not influence the DNA transfer. The *vir* genes include *virA* and *virG*, which are a two component system including a sensor for acetosyringone (VirA, an inner membrane protein) and a regulator (VirG, a DNA-binding protein that can be phosphorylated by VirA) which activates the expression of the other *vir* genes (Leroux et al., 1987). In addition to acetosyringone, expression of genes in the *vir* regulon is increased by acid pH and by the presence of monosaccharides. The latter response involves the binding of the sugar by the product of a chromosomal gene, *chvE* (Huang et al., 1990).

ChvE is a periplasmic galactose-binding protein and is required for chemotaxis to several sugars as well as influencing *vir* gene induction. ChvE mutants are avirulent on some but not all plants (Cangelosi et al., 1990; Huang et al., 1990). *VirD1* and *VirD2* encode an endonuclease that cuts the Ti plasmid DNA at the T DNA border sequences (Yanofsky et al., 1986). The *virE2* gene encodes a single-stranded DNA-binding protein (Christie et al., 1988). The *virB* operon encodes a DNA transfer system including a pilus analogous to that used by some conjugative plasmids including pRSF1010, pRP4, and pKM101, as well as to that used by the transport system for *Bordetella pertussis* toxin (Pohlman et al., 1994; Kado, 1994; Zupan et al., 1995; Shirasu et al., 1994; Lessi et al., 1994).

Of the *vir* genes, only *virA* and *virG* are expressed in the absence of inducers. These genes make up a two-component system. VirA, the sensor, is a plasma membrane protein that responds to phenolic compounds such as acetosyringone released by the plant. These inducers are most effective at low pH (5.3–6.0) and in the presence of monosaccharides. The sugars are bound by ChvE, which then interacts with VirA, increasing the response of VirA to the phenolic inducers. Low phosphate concentrations also increase the induction of vir genes. In response to the inducers, VirA autophosphorylates at a histidine residue and then transfers the phosphate to an aspartic acid in VirG. Phosphorylated VirG binds to specific DNA sequences referred to as *vir* boxes located 24 to 72 bp upstream of the *vir* operons and activates the *vir* genes' expression. VirG also binds to *vir* boxes located upstream of *virG* and thus increases its own synthesis (Johnson et al., 1998).

The *virB* and *virD* operons show considerable homology to genes required for conjugation between bacteria and they can mediate the conjugative transfer of other plasmids such as RSF1010. The *virD* operon contains five ORFs. VirD1 and VirD2 bind to the T DNA border sequences and nick the DNA between the third and fourth base of the repeat sequence on the bottom strand. VirD2 is covalently linked via a phosphotyrosine linkage to the 5′ end of the nicked DNA. DNA homology suggests that the border sequences and *virD2* belong to the P-family of conjugal transfer systems, which includes RP4, RK6, and R64. In some Ti plasmids, a sequence is located near the right border outside the T DNA, referred to as overdrive. VirC2 binds to this sequence and increases the efficiency of the formation of single-stranded nicks by VirD2. VirC1 (the other protein endcoded by the *virC* operon) may aid in this process. VirD4 is an integral membrane protein required for transfer of T DNA to host cells. It belongs to the class of TraG-like proteins, which are required for pilus formation. The *virB* operon contains 11 ORFs; nine of these encode membrane proteins. All except *virB1* are required for T DNA transfer. Mutants in *virB1* retain the ability to transfer T DNA but at a hundred-fold reduced efficiency. VirB1 is a secreted protein with an N-terminal region that resembles lysozyme. The remainder of the *virB* genes appears to be involved in the elaboration of a pilin and of a pore for the transfer of T DNA. This structure is formed best at cool temperatures (19–22°C). Sequence and structural studies suggest that VirB2 is the pilin. It may be processed after synthesis to a circular peptide. VirB7 is a lipoprotein and forms a tight complex with VirB4, VirB9, VirB10 and VirB11. VirB4 and VirB11 have ATP-binding sites and possess ATPase activity. The conjugation system encoded by *virD4* gene and the *virB* operon belongs to the group of bacterial conjugation systems that have their highest transfer efficiency on surfaces rather than in liquid suspension. This system is capable of transferring other DNAs as well as T DNA. Using this system, *A. tumefaciens* can transfer pRSF1010 to other bacteria or to plant cells (Johnson et al., 1998).

The *virE* operon contains two ORFs: *virE1* and *virE2*. VirE2 is a single-stranded DNA-binding protein. VirE2 is not required for T DNA transfer, although it is required for efficient tumor formation. VirE2 mutants can be complemented in trans by another *A. tumefaciens* strain, which does not have to contain T DNA, but must contain the *virB* and *virE* operons and *virD4*. Transgenic plants expressing *virE2* can also complement VirE2 mutants. It appears that the VirE2 (and VirF) proteins can be transferred to the host cell independently of the transfer of T DNA. This transfer requires the *virB* operon and *virD4* gene products as well as VirE1. VirE2, a single-stranded DNA-binding protein, may serve to protect the T DNA from degradation in the plant cell. Both VirE2 and VirD2 contain sequences that are similar to plant nuclear localization signals (NLS) and may aid targeting of the T DNA to the plant nucleus. Integration of the T DNA into the plant chromosomal DNA appears to proceed via illegitimate recombination into nonhomologous DNA at random and to involve proteins supplied by the plant rather than the bacterium (Johnson et al., 1998; de la Cruz et al., 1998; Rossi et al., 1998).

VirG regulates the expression of several other Ti plasmid operons. However, the role of these operons in tumorigenesis is unclear. These include *virF*, which is present in octopine Ti plasmids only. *VirF* mutants fail to cause tumors when a low number of bacteria are used in the

inoculation. They also fail to form tumors on some plants, including *Nicotiana glauca*. VirF appears to be transferred to the host cell along with VirE2. The *virH* operon contains four ORFs. Two of these have homology to cytochrome P450 enzymes. This operon is present in octopine and nopaline Ti plasmids and in some Ri plasmids (Deng et al., 1998).

The *virJ* gene is present on the Ti plasmid and in some strains also on the chromosome. The chromosomal copy of the gene is called *acvB*. VirJ may be associated with the T strand DNA (Kalogeraki et al., 1995). The *tzs* gene encodes a cytokinin prenyltransferase, which forms transzeatin. It is present in nopaline, agropine, and mannopine Ti plasmids but not in octopine and succinamopine Ti plasmids. It also is present in some Ri plasmids.

There is evidence to suggest that *virA*, *virC*, *virE*, *virF*, and *tzs* affect the host range of *A. tumefaciens*.

Genes Involved in Quorum Sensing *A. tumefaciens* like many other Gram-negative bacteria has a quorum-sensing system. The genes involved in this system are located on the Ti plasmid and are involved with the bacterial response to opines and with the conjugation of pTi between bacteria. They include *traR* and *traI*, which are homologues of the *luxI* and *luxR* genes of *Vibrio fisherii*. These genes have similar functions to the *V. fisherii* genes; *traI* encodes the enzyme for the synthesis of a homoserine lactone [N-(3-oxo-octanoyl)-L-homoserine lactone], which is the *Agrobacterium* autoinducer (AAI), and *traR* encodes a regulatory protein which binds AAI and DNA. The enzymatic activity of TraI has been demonstrated in vitro; it catalyzes the synthesis of AAI from 3-oxo-octanoyl-ACP (Acyl Carrier Protein) and S-adenosyl-methionine. The TraR protein plus AAI activates several promoters including the *traA* and *traC* promoters (to induce conjugation of bacteria which results in the transfer of pTi between bacteria), the *traI* promoter (a promoter upstream of an operon that includes *traR*) and the *traM* promoter. These observations suggest that the level of TraR in the cell is regulated by positive regulatory feedback loops involving the activation of TraI synthesis to make more AAI and the activation of *traR* expression. There is also apparently a negative feedback loop since TraM is an antagonist of TraR (Winans, 1998; Fuqua et al., 1996).

The expression of *traR* is controlled by *occR* in octopine and by *accR* in nopaline/agrocinopine Ti plasmids (see also Plasmid Conjugation) in response to the presence of octopine or agrocinopine. Thus the genes involved in quorum sensing are only expressed in the presence of the opine made by a crown gall tumor (or by plant cells which have received the opine synthesis genes from pTi). Why quorum sensing should only be necessary in the presence of transformed host cells is unclear (Winans, 1998; Fuqua et al., 1996).

Genes Involved in Plasmid Conjugation to Other Bacteria In addition to transferring a segment of DNA to the host cell (the T DNA), the Ti plasmid can be transferred from one bacterium to another. The genes for this conjugation are distinct from the *vir* genes involved in the transfer of T DNA, although both sets of genes are located on pTi. The *tra* and *trb* genes are required for this process. These genes show homology to the conjugation systems of other plasmids including the 11 *trb* genes of RP4, an IncP plasmid. The *tra* regulon of octopine Ti plasmids is positively regulated in a complicated manner. The *occR* gene product activates the transcription of *traR* in the presence of octopine. The *traR* gene product is homologous to *luxR* and activates the transcription of the *tra* genes in the presence of the *Agrobacterium* autoinducer (AAI), a homoserine lactone which is produced by *traI* (a *luxI* homologue). In nopaline Ti plasmids, AccR regulates the expression of *traR* by acting as a repressor. The inducer is agrocinopine. The result of this regulatory cascade is that conjugation of the Ti plasmid occurs only in the presence of transformed plant cells required to produce opines and a high bacterial population density required to produce a sufficient concentration of the autoinducer. These facts explain the early observations of Kerr et al. (1977a) that strains of *Agrobacterium* could only be induced to transfer the Ti plasmid by conjugation when the donor and recipient strains were inoculated together into a wound site on a susceptible host plant. The advantage to the bacterium in regulating the conjugation of pTi in this manner is unknown (Farrand, 1998).

A. vitis

The genetics and diversity of the Ti plasmids found in strains of *A. vitis* have been studied extensively. Three types of pTi have been characterized: plasmids with one large T DNA that encodes the enzymes for the synthesis of the opines octopine and cucumopine, plasmids with small T DNA that lead to octopine and cucumopine synthesis, and plasmids of the nopaline type Ti plasmids. Some of these Ti plasmids contain two T DNAs. The *vir* regions are conserved among all three types of pTi. One pTi from a vitopine strain (S4) belongs to a different incompatibility group than the other Ti

plasmids belong to (Szegedi et al., 1996). The limited host range of some *A. vitis* strains appears to be due to the *virA* gene since the host range can be extended by replacing this gene with *virA* from *A. tumefaciens* strain A6 (Yanofsky et al., 1985).

The genes of the T region of *A. vitis* include *iaaM*, whose product catalyzes the formation of indoleacetamide (IAM) from tryptophan, and *iaaH*, whose product catalyzes the conversion of IAM into the plant hormone indoleacetic acid (IAA). Wide host range strains also contain the *ipt* gene, which encodes an isopentenyl transferase required for the synthesis of cytokinins (Hoekema et al., 1984). Some limited host-range strains lack the *ipt* gene. Strong expression of *ipt* in grape is toxic to the cells unless *ipt* expression is accompanied by strong expression of the *iaa* genes, particularly *iaaM* (Huss et al., 1990). At least one pTi from *A. vitis* also carries the genes for the metabolism of tartaric acid. In other strains, these genes are carried on a separate plasmid. (See Physiology in this Chapter.)

Ecology

A. tumefaciens

Agrobacteria generally persist for long periods of time in the soil, particularly in the rhizosphere of susceptible host plants. When inoculated onto cherry, the bacteria established populations of about 10^5 CFU per gram of plant tissue and persisted for 2 years (the duration of the experiment). The biocontrol strain of *Agrobacterium* K84 (see Applications) also showed similar population densities and long persistence when inoculated onto several plants. However, bacterial persistence in fallow soil was much reduced; bacterial populations declined from 10^5 per gram soil to 10 in as short a time as 16 weeks. The bacteria could apparently move out from the inoculated rhizosphere and were recovered as far as 40 cm from the original plants (Stockwell et al., 1993). In other studies, agrobacteria were recovered from a fallow soil. The isolates were roughly evenly split between biotypes 1 and 2. About 1/3 of the isolates were pathogenic. All of these pathogenic strains belonged to biotype 1 (Bouzar et al., 1993b). It is often difficult to recover virulent *A. tumefaciens* from galls. In some cases this appears to be due to loss of virulence of bacteria growing with host plants. Belanger et al. (1995) found that when virulent strains isolated from apple were reintroduced onto to axenic apple plants, most of the bacteria recovered were avirulent. This was due to alterations in the pTi *vir* genes. The mutant strains grew faster in the presence of the plant than their virulent parents did and thus came to dominate the bacterial population.

Opines are thought to provide nutrition for *A. tumefaciens* and *A. rhizogenes* located near the transformed plant cells (Dessaux et al., 1993; Guyon et al., 1993). In at least some cases, opines can be transported from their site of synthesis to the rest of the plant and may be found in root exudates. Thus the production of opines at the site of infection may well influence the composition of the rhizosphere community at distant sites (Savka et al., 1996). Utilization of opines is not limited to agrobacteria. Several isolates of soil pseudomonads and coryneform bacteria have been shown to be able to use opines as carbon and energy sources (Beaulieu et al., 1988; Tremblay et al., 1987).

A. vitis

The fate of the bacteria on grapes colonized with *A. vitis* has been followed for 2 years after planting. The bacteria were still present and virulent although the grapes did not have galls or other obvious symptoms of disease (Burr et al., 1995). When the maintenance of bacterial populations was compared in infested soils planted with oats and those planted with grapes, higher population levels were maintained in the presence of grapes (Bishop et al., 1988).

Noncultivated grapes (*Vitis* spp.) have been examined for the presence of *A. vitis*. The bacteria were detected in association with more than half the plants examined. Interestingly the bacterial isolates, which appeared to be diverse as judged by DNA fingerprinting, were largely nonpathogenic (Burr et al., 1999). *A. vitis* is also routinely found in healthy grapes where it can cause gall formation at sites of injury. The bacteria may be found in the phloem or in the tissue just below the bark. Higher bacterial populations are usually recovered from susceptible as compared to resistant cultivars. Freezing injury may facilitate the spread of the bacteria in the plant (Burr et al., 1999).

Disease

General

Infections of wound sites in dicotyledonous plants by agrobacteria lead to the development of crown gall tumors or hairy roots. These abnormal growths result from the transfer of DNA sequences (the T DNA) from the bacterial tumor-inducing (pTi) or root-inducing (pRi) plasmid to the host plant cell. The T DNA sequences become incorporated into plant chromosomes and are maintained and expressed in the plant cell. They code for enzymes involved in

the synthesis of the growth hormones, auxin and cytokinin. It is the overproduction of these hormones that results in the growth of a tumor.

A. tumefaciens

The steps identified in tumor formation by *A. tumefaciens* include bacterial chemotaxis to wound sites in plants (Loake et al., 1988; Ashby et al., 1987); an exchange of signals between the plant and the bacteria (Matthysse, 1994); initial bacterial attachment to the surface of plant cells (Matthysse, 1986); induction by phenolics (including acetosyringone) released from the wounded plant of bacterial *vir* genes encoded on the Ti plasmid (Stachel et al., 1985); the formation of a pilus encoded by the *virB* operon (Fullner et al., 1996); the transfer of the T DNA sequences from the bacterium to the plant cell mediated by *vir* gene products (and possibly the products of other genes; Klee et al., 1983); the integration of the T DNA into plant chromosomes (Chilton et al., 1977); and the expression of the T DNA in the plant cell, leading to increased auxin and cytokinin production, resulting in uncontrolled growth of the cell to form a crown gall tumor (Binns et al., 1988; Akiyoski et al., 1982; Figs. 15–19). Other genes expressed in the plant cell are included in the T DNA, most notably the genes encoding the opine biosynthetic enzymes (Tempe et al., 1984). The bacterial Ti plasmid contains the genes required for the ability to use these opines as carbon and nitrogen sources and thereby support bacterial growth. The benefit of tumor formation to the bacterium is thought to be explained by crown gall-opine production and the subsequent use of opines as substrates for bacterial growth.

Because a wound is required for the interaction of the bacteria with the host, the sites most often infected are the sites of graft junctions. Thus crown gall occurs most often on fruit trees, grapes, roses, and other plants that are routinely grafted. However, disease can be observed on plants that are not grafted. Agrobacteria are found in the soil and in the rhizosphere and easily infect wounds on the roots or at the base of the stem (the crown of the plant).

A. rhizogenes

Two other less well-known species of agrobacteria have a similar pathogenic mechanism. *A. rhizogenes* causes the formation of hairy roots on a wide variety of dicots. These roots are caused by the transfer of DNA from the bacterium to the host, which contains genes (*aux* and *rol*) that lead to the formation of ageotropic branched roots rather than tumors (White et al., 1985; Amselm et al., 1992). Aside from the difference in the T-DNA of the plasmid, this bacterium differs from *A. tumefaciens* in its ability to grow on various carbon sources and in its low tolerance to NaCl (Kerr et al., 1977b). These traits presumably reflect differences in the bacterial chromosomes. Insofar as is known, the mechanism of pathogenesis of *A. rhizogenes* is similar to that of *A. tumefaciens*. The Ri plasmid contains vir genes that are analogous to those of pTi, and the steps in DNA transfer described above for *A. tumefaciens* appear to be similar for *A. rhizogenes* (White et al., 1985).

A. vitis

Agrobacterium vitis causes the formation of tumors on stems of grapes. On grape roots it causes necrotic lesions (Burr et al., 1987). This necrosis results in part from the enzyme polygalacturonase, which is secreted by the bacteria. Other agrobacteria appear to lack this enzyme (McGuire et al., 1991; Herlache et al., 1997). Although some strains of *A. vitis* have a broad host range in the laboratory, in nature *A. vitis* appears to be largely a pathogen of grapes. The bacteria are capable of invading the vascular system of the plant and multiplying in the xylem without any apparent symptoms; indeed, apparently most grape plants have *A. vitis* resident in the xylem (Burr et al., 1995). Unlike *A. tumefaciens*, these bacteria are able to use tartrate (which is found in grape xylem in higher concentrations than in most other plants) as a carbon source (Crouzet et al., 1995). When an infected grape stem is wounded, tumors develop at the wound site. The mechanism of DNA transfer appears to be similar to that of *A. tumefaciens*. The Ti plasmid of *A. vitis* carries *vir* genes which are similar to those of *A. tumefaciens* except that some limited host-range strains lack *virC*. The T DNA is also similar to that of *A. tumefaciens* except for the lack of cytokinin biosynthesis genes in some limited host-range strains (Bonnard et al., 1989; Otten et al., 1994; Canaday et al., 1992; Paulus et al., 1991; Otten et al., 1993). There is little information about the interaction of either *A. rhizogenes* or *A. vitis* with prospective hosts prior to the induction of *vir* genes and the initiation of T-DNA transfer.

Control of Disease Caused by Agrobacteria

Biocontrol of Crown Gall

Biological control of some strains of *A. tumefaciens* can be achieved by dipping the planting material in a suspension of *Agrobacterium* strain

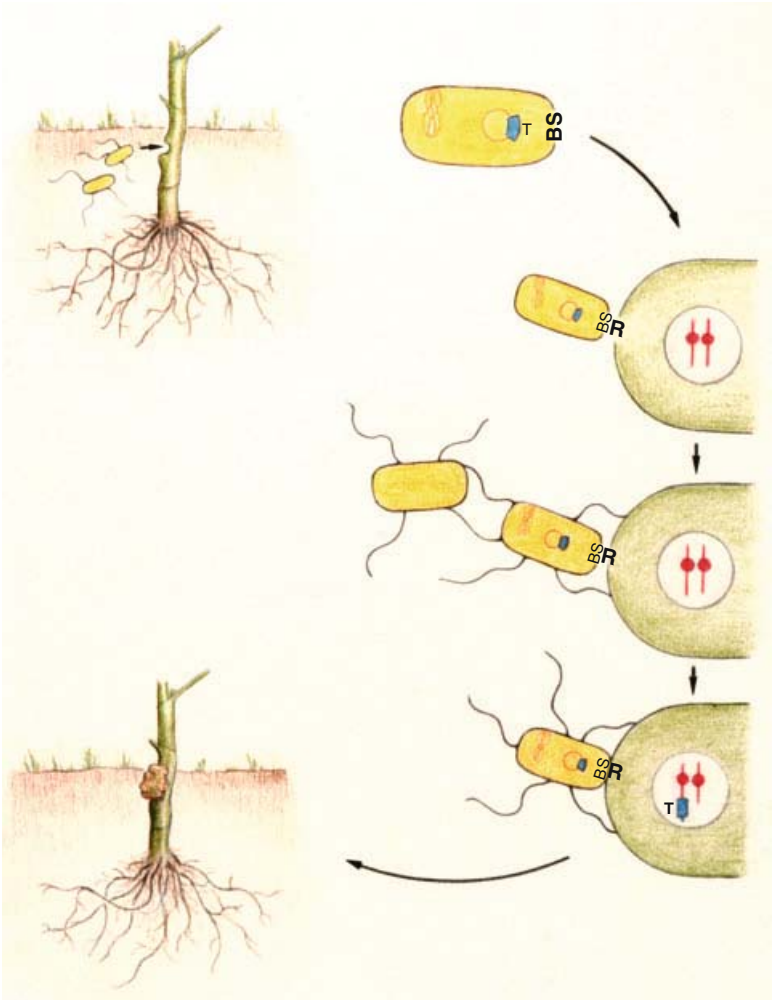

Fig. 15. Drawing showing the steps in the interaction of *A. tumefaciens* with a wounded plant leading to tumor formation. *A. tumefaciens* can be found in the upper layers of the soil. The bacteria are chemotactic to substances released from plant roots and wound sites. The bacteria (yellow) migrate to the wound site and bind to the surface of a plant cell (green). Substances from the plant induce bacterial cellulose synthesis, and the bacteria form aggregates on the plant surface held together with cellulose fibrils (only 2 bacteria are shown in the drawing for simplicity). The *vir* genes are induced and the bacteria transfer a piece of plasmid DNA, the T DNA (blue), to the host cell, where it becomes integrated into the host cell chromosomes. The expression of genes contained in the T DNA (which have eukaryotic promoters) leads to the overproduction of growth hormones in the plant cell and the resulting growth of a tumor. The tumor cells also produce opines which the bacteria use as a source of carbon and energy.

K84. These bacteria can also be applied to graft junctions during the grafting process. Strain K84 makes antibiotic-like compounds called agracins, which kill many strains of *A. tumefaciens*. A genetically engineered derivative of K84, K1026, is often used because it is unable to transfer resistance/immunity to agracins to the target pathogens. Strain K84 produces two agracins (K84 and K434). Agracin K84 only inhibits the growth of *Agrobacterium* strains carrying nopaline/agrocinopine type Ti plasmids. It is not effective against *A. vitis*. Agracin 434 is effective against biotype 2 strains. Strain K84 contains three plasmids: pAgK84 which encodes agracin K84 production, pAgK434 which encodes agracin K434 production and immunity to agracin K434, and pAtK84b which is a deleted pTi and carries nopaline catabolism and resistance to agracin K84. This last plasmid is self-transmissable (Clare et al., 1990). The structures and mechanisms of action of agracins K84 and K434 have been determined. There is some evidence that strain K84 may possess some biological control activity in addition to the production of the two agracins. However, currently this evidence is incomplete.

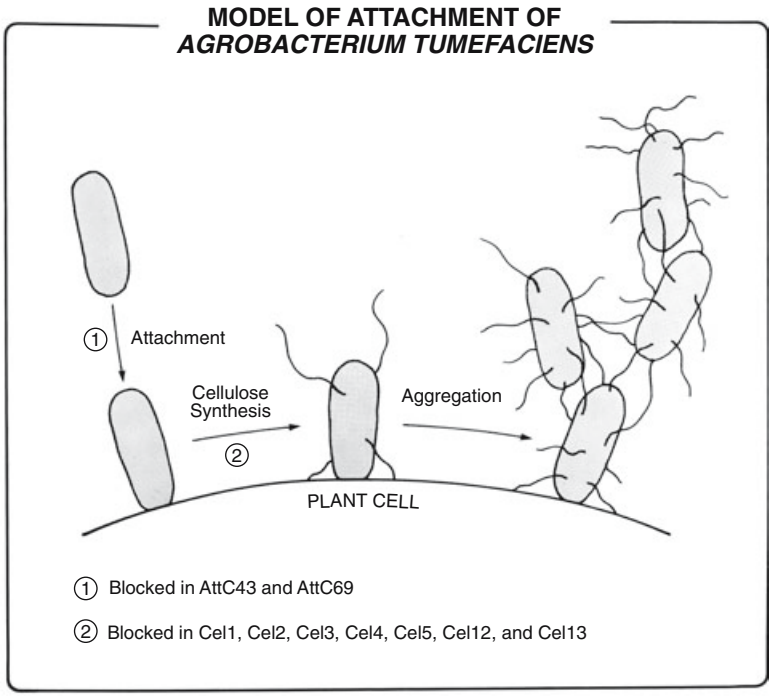

Fig. 16. Drawing showing the steps in bacterial aggregate formation on the surface of a plant cell. The bacteria are chemotactic to substances released by the plant cell. In response to substances released by the plant, the bacteria make and secrete a substance required for bacterial attachment to the plant surface. This step is blocked in *att* mutants, which can be complemented by conditioned medium. The bacteria then bind to the plant surface in a loose fashion and can be removed by shear forces such as water washing or vortexing of cultures. This step requires an acetylated capsular polysaccharide made by the bacteria. The bacteria elaborate cellulose fibrils. These fibrils bind the bacteria tightly to the plant surface. Shear forces can no longer remove the bacteria. The fibrils also trap other bacteria and these new bacteria are induced to form cellulose fibrils that in turn entrap additional bacteria, resulting in the formation of a large bacterial aggregate on the plant cell surface. Strong shear forces can remove the outer portions of these aggregates but the bacteria at the base of the aggregate are tightly bound to the host cell. Aggregate formation is blocked in *cel* mutants.

Fig. 17. Light micrograph showing *A. tumefaciens* bound to the surface of carrot cells. Note the presence of both individually attached bacteria and bacteria aggregates on the plant cell surface. From Matthysse (1987).

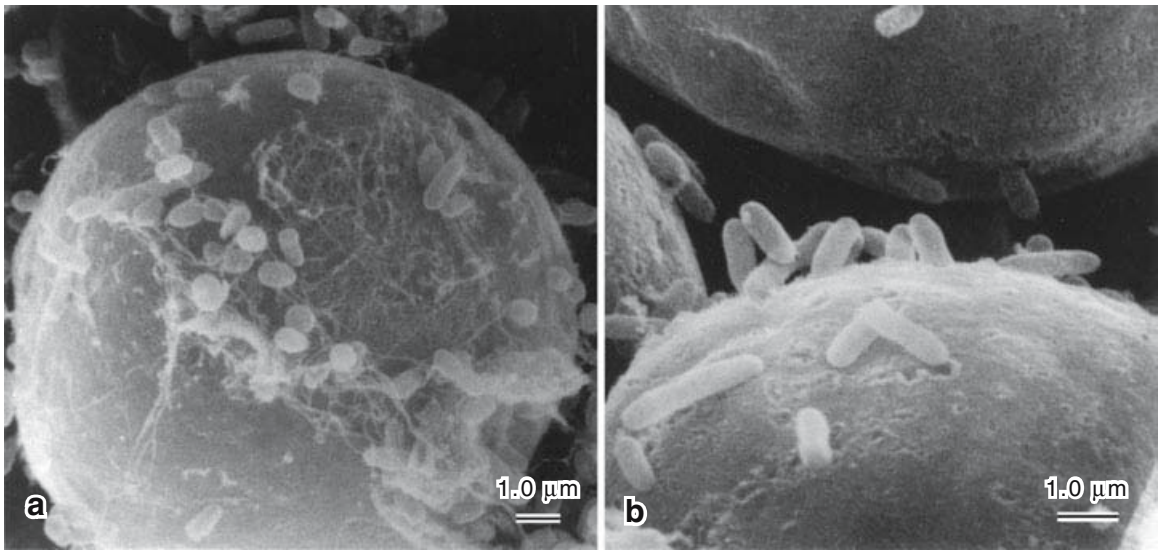

Fig. 18. Scanning electron micrographs showing *A. tumefaciens* bound to the surface of carrot cell protoplasts. A: wild type bacteria. The fibrils are composed of cellulose made by the bacteria. B: cellulose-minus bacteria. Note the absence of fibrils. The bacteria are still able to bind to the plant cells. From Matthysse (1983).

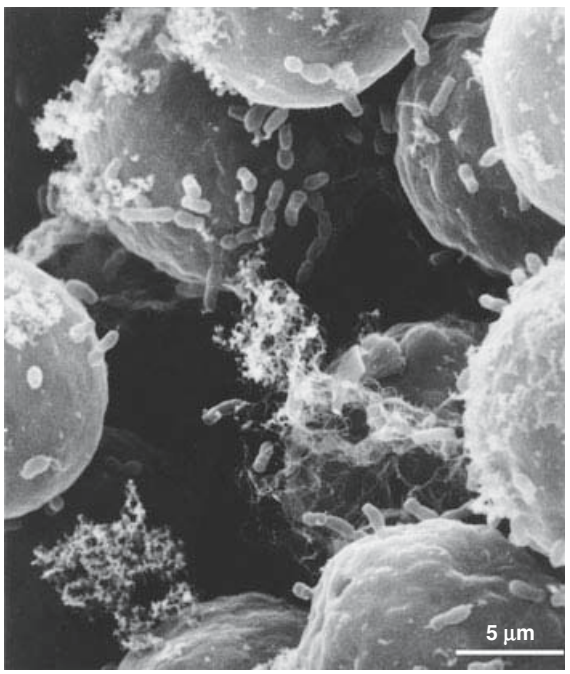

Fig. 19. Scanning electron micrograph showing *A. tumefaciens* on the surface of carrot cells. Both individually attached bacteria and bacterial aggregates held together by cellulose fibrils can be seen.

CONTROL OF *A. VITIS* Crown gall disease on grape has proven to be difficult to control. This is largely because of the persistence of the bacteria in plants that show no symptoms of disease. Management of the disease on grape combines the selection where possible of relatively resistant cultivars with cultivation practices designed to limit the growth of the bacteria (Burr et al., 1998). Cuttings also can be indexed for the presence of the bacteria by examining callus tissue formed at their base. Liquid can be forced through the vascular tissue and plated on semi-selective medium to detect *A. vitis*. In addition, PCR can be used to detect the presence of various bacterial virulence genes in DNA extracted from cuttings (see Identification). Propagation of vines from cultured shoot tips will often give rise to plants that are bacteria free.

Numbers of bacteria carried by grapevines can be reduced by submerging the vines in hot water prior to planting. However, this treatment does have the potential to injure the buds on the vine.

Biological control of *A. vitis* on grape is currently being studied. If *A. vitis* is found largely in the vascular tissue of asymptomatic grapes, then treatment of cuttings with external bacteria as biocontrol agents may fail to kill the internal bacteria. *A. vitis* is not susceptible to biocontrol by *A. radiobacter* K84 unlike *A. tumefaciens*. This may be due in part to the fact that the bacteria are not killed by the agracins produced by K84 and its derivatives (Burr et al., 1998).

Applications

Genetic Engineering

The ability of *A. tumefaciens* and *A. rhizogenes* to transfer genes to plant cells, where they are

stably integrated into the host chromosome(s) and expressed, has made these bacteria extremely useful in genetic engineering of plants. Transfer of T DNA to plants is not dependent on the sequences contained within it. Instead it is dependent on the border sequences which surround it. In addition to the border sequences, which must be located adjacent to the DNA to be transferred, other Ti plasmid and chromosomal genes are required. On the Ti plasmid these are the vir genes. The chromosomal genes required are numerous and not all of them are identified or characterized. Thus the general strategy used to transform plant cells is to clone the genes that are to be introduced along with a selectable marker, such as the *npt2* gene (which gives resistance to kanamycin and G418) or a hygromycin resistance gene, in a plasmid vector (which is a shuttle vector and will replicate in both *E. coli* [for ease of cloning] and agrobacteria). If it is important to be certain that the cloned genes are expressed only in the plant host, an intron can be included in the genes to prevent expression in the bacteria. Eukaryotic promoters and stop signals are placed before and after the gene(s) to be introduced. Once the plasmid carrying border sequences and the genes to be introduced into the plant has been constructed, it is transferred from *E. coli* into *A. tumefaciens* or *A. rhizogenes*. The *Agrobacterium* strain must contain the chromosomal genes required for virulence and a modified Ti plasmid that contains the *vir* region but has the border sequences and the T DNA deleted.

The resulting *Agrobacterium* strain is then used to infect plant tissue, often tissue culture cells or organs such as leaves or shoot meristems. The plant tissue and the bacteria are incubated together long enough for the cloned DNA to be transferred, expressed and integrated into host cell chromosomes (usually a few days). The bacteria are then killed with an antibiotic (such as cefotoxime) to which they are susceptible and the plant cells resistant, and the transformed plant material is treated to select for the marker contained in the transferred DNA. Success rates vary with the plant material used, the particular plasmid construct, the *Agrobacterium* strain, and the protocol employed. Some species of plants, notably legumes and many monocots including grasses, are more difficult to transform than are other plants such as tomatoes. This technique has been used commercially to construct many new lines of crop plants (Birch, 1997; van Wordragen et al., 1992).

CHAPTER 3.1.5

The Genus *Azospirillum*

ANTON HARTMANN AND JOSE IVO BALDANI

Historical Aspects

The growth of a spirillum-like bacterium in nitrogen deficient malate- or lactate-based media, which had been inoculated heavily with garden soil, was first observed by Beijerinck in 1922. In contrast to carbohydrate-based media, organic acid-based media supported growth of the spirillum without overgrowth by other nitrogen-fixing bacteria like *Azotobacter* and *Clostridium*. Beijerinck found that partially purified cultures of the spirillum exhibited increases in nitrogen at the expense of malate, whereas cultures lacking the spirillum failed to show such increases. In general, cells cultured in sugar media were plump, curved rods containing many lipoidal droplets which sometimes distorted the shape of the cells. On malate or lactate agar, the cells tended to be thinner and straighter, while in dilute bouillon they had a distinct spirillum shape with one or more helical turns. Because of the ease of cultivation on salts of organic acids, as well as the spirillum shape exhibited under certain conditions, Beijerinck considered the organism to be a member of the genus *Spirillum* and to be a bridging organism linking the genus *Spirillum* with the genus *Azotobacter*. He initially named the organism "*Azotobacter spirillum*," but later renamed it "*Spirillum lipoferum*" (Beijerinck, 1925). Later studies of *S. lipoferum* by Schröder (1932) also failed to demonstrate N_2 fixation by pure cultures, and the organism was forgotten for many years except for a few scattered reports. In 1963, Becking isolated an organism resembling *S. lipoferum* that showed incontestable nitrogenase activity (Becking, 1963). Ten years later, F. Favilli identified diazotrophs isolated from Italian soils as *Spirillum lipoferum* and showed their N_2-fixation capacity in pure culture, using a liquid medium containing small amounts of yeast extract (Döbereiner, 1990). The frequent isolation of this organism all over the world and especially from grass roots in the tropics must be attributed to the introduction by Johanna Döbereiner of N-free semisolid malate medium, in which bacterial growth can occur submerged at different depths (Döbereiner and Day, 1976a). This medium permits efficient enrichment of these bacteria because they can grow on molecular nitrogen (N_2) as sole N-source under microaerobic conditions. In a detailed taxonomic study, Tarrand et al. (1978) named these DNA homology group II bacteria "*Azospirillum lipoferum*" because this group seemed to correspond in more ways to Beijerinck's description of *S. lipoferum*, particularly with regard to growth with glucose or mannitol and to the formation of spirillum-shaped cells under certain conditions (Krieg and Döbereiner, 1984). Other species of the genus *Azospirillum* (e.g., *A. amazonense*, *A. irakense*, *A. halopraeferens* and *A. doebereinerae* and a diversity of other microaerobic diazotrophs) could be isolated subsequently from roots of diverse plants and from different (e.g., salt affected) soils using modified semisolid media (see below, Table 2). The scientific enthusiasm and competence of Dr. Johanna Döbereiner, who died in October 2000, have stimulated greatly basic and applied research on *Azospirillum* and the now known high diversity of other plant-associated microaerobic nitrogen-fixing bacteria (Hartmann et al., 2000). Detailed physiological, ecological and molecular genetic studies, mostly on *A. brasilense*, made *Azospirillum* one of the best studied rhizosphere bacteria.

Taxonomy Aspects

Azospirillum spp. are members of the α-subclass of Proteobacteria, which harbors a large number of plant-associated and symbiotic bacteria, such as *Rhizobium*, *Bradyrhizobium*, *Agrobacterium* or *Gluconacetobacter*. Using methods based on DNA and rRNA analyses, it became apparent in 1978 that the two *Azospirillum* species known at that time, *A. brasilense* and *A. lipoferum*, form a consistent DNA/DNA homology group within the RNA-superfamily IV (Tarrand et al., 1978; De Smedt et al., 1980). *Spirillum* spp., *Aquaspirillum* spp. and *Herbaspirillum* spp. could clearly be separated from the genus *Azospirillum* in the

following years by DNA-based molecular and physiological methods.

In a detailed 16S rDNA-based molecular phylogenetic study, Stoffels et al. (2001) demonstrated that the now known seven species of *Azospirillum* as well as *Skermanella* and *Rhodocista* form a cluster. *Azospirillum brasilense*, *A. lipoferum*, *A. doebereinerae*, *A. largimobile* and *A. halopraeferens* constitute one subcluster, while *A. irakense*, *A. amazonense* and *Rhodocista* form a second subcluster (Fig. 1). *Skermanella* is reported to form a third subcluster (Stoffels et al., 2001). The DNA G+C content for these species is in the range of 64–71 mol%. The 16S rDNA sequence similarity between the different species is in the range of 93.6–96.6% within one subcluster and 90.2–90.6% between the species members of the two subclusters. Accordingly, on the basis of different more or less conserved sequence stretches of the 16S rDNA, it was possible to create a set of oligonucletide probes with different degrees of specificity: from the whole cluster (probe AZO440a+b) to subcluster (AZOI-665) and individual species levels (Stoffels et al., 2001). For identification and in situ localization purposes, these probes can be applied in fluorescence in situ hybridization (FISH) of fixed bacterial cells. Since these probes were designed to identify different hierarchical levels, their application in a nested approach allows a very reliable identification (Fig. 2). *Azospirillum* spp. have also been investigated by 23S rDNA analysis (Kirchhof and Hartmann, 1992; Kirchhof et al., 1997b). These studies reported a comparable phylogenetic analysis of the genus *Azospirillum* with a set of oligonucletide probes, which could partially be used for whole cell hybridization but were more appropriate for filter hybridization. Since the data set of the 16S rDNAs is much bigger than that of the 23S rDNAs, the reliabilty of 16S rDNA-derived probes is better and can be reaffirmed or checked against ever-expanding databanks using, e.g., the ARB-software (Strunk and Ludwig, 1997). The 16S-rRNA-directed probes were also designed by Kabir et al. (1995), but at the present stage of knowledge, these probes have considerably limited specificity. They also cannot be used in FISH analysis. In addition to the phylogenetic analysis based on 16S ribosomal genes or diagnostic oligonucleotide probes (Stoffels et al., 2001), a number of other molecular taxonomic tools (e.g., random amplified polymorphic DNA [RAPD] markers [Fancelli et al. 1998] and restriction fragment length polymorphism [RFLP] analysis [Han and New, 1998]) have been used for the identification of *Azospirillum* spp. These approaches allow the rapid molecular identification at the species level. The RFLP-analysis of the whole genome with rarely cutting restriction enzymes followed by pulsed field gel electrophoresis can be used for strain specific identification (Gündisch et al., 1993). These and related studies have also shown that the 16S rDNA genes of *Azospirillum* spp. occur in multiple replicons (Gündisch et al., 1993; Caballero-Melado et al., 1999).

Habitats and Ecology of the Organisms

Azospirilla have a worldwide distribution and occur in large numbers (up to 10^7/g) in

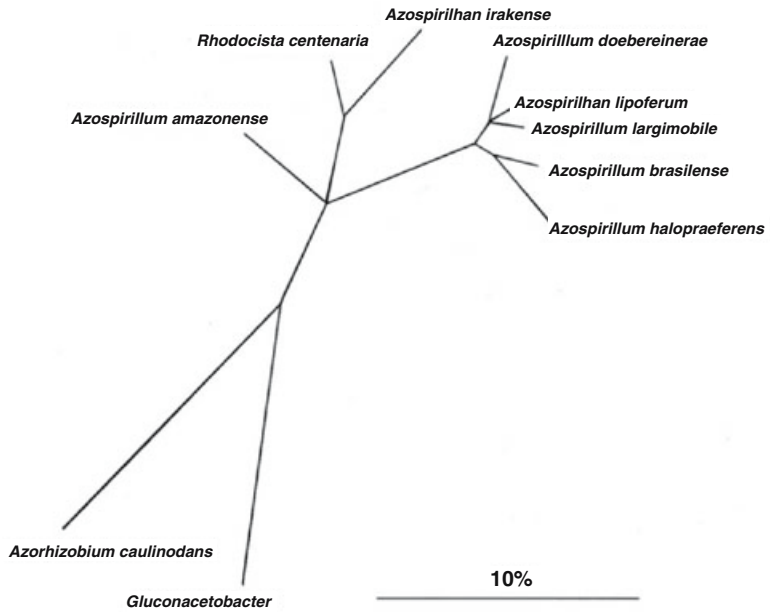

Fig. 1. 16S rDNA phylogenetic tree of *Azospirillum* (consensus tree). For the calculation of the phylogenetic tree, almost complete 16S rDNA sequences of the *Azospirillum*/*Rhodocista*-cluster and closely related members of the α-Proteobacteria were used. Only sequence positions that are represented in more than 50% of the members of the α-Proteobacteria were used for the calculation. The phylogenetic tree is based on "maximum likelihood" analysis, and the topology of the tree was checked with "maximum parsimony" and "distance matrix" analyses. A multiple bifurcation indicates that no exact relative branching order could be determined. From Eckert et al. (2001).

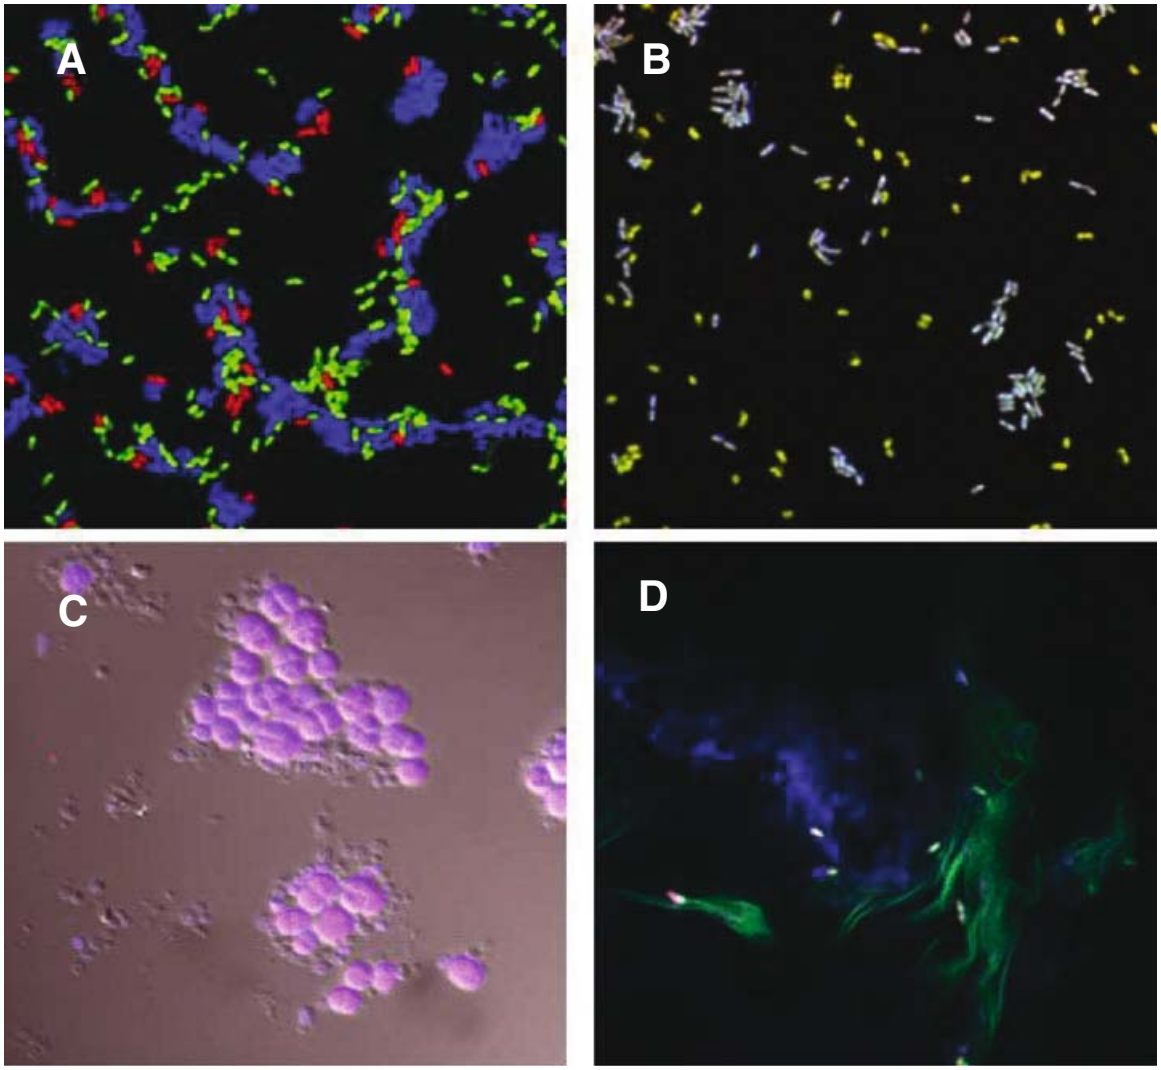

Fig. 2. Application of 16S rRNA-targeted fluorescence-labelled oligonucleotide probes. Multiple application of fluorescence in situ hybridization (FISH) and confocal laser scanning microscopy (CSLM) was used to identify *Azospirillum* species at the single cell level. A) Differentiation in an artificial mixture of *A. lipoferum* DSM 1691, *A. brasilense* DSM 1858 and *A. amazonense* DSM 2878 using the FISH technique. Cells of *A. brasilense* are stained blue by specific binding of the Cy5-labelled probe Abras1420; *A. lipoferum* cells are labelled red by specific binding of the Cy3-labelled probe Alila1113; and *A. amazonense* cells are stained green by specific binding of the FLUOS-labelled probe Aama1250. B) The "top to bottom" approach is a nested application of phylogenetic probes in whole cell identification of an environmental isolate. A mixture of the isolate GSF B3 (from banana roots) and *A. lipoferum* DSM 1841 was simultaneously hybridized with the nested probe set AZO440a+b-Cy3, specific for the *Azospirillum-Rhodocista-Skermanella*-cluster, AZOI-655-FLUOS, specific for the species cluster *A. lipoferum*, *A. brasilense*, *A. largimobile*, *A. doebereinerae* and *A. halopraeferens*, and the probe Abras1420-Cy5, specific for *A. brasilense*. Cells of the isolate GSF B3 are identified by all three probes as *A. brasilense*, resulting in a white staining of the cells, while the *A. lipoferum* cells appear yellow, since only two probes (AZO440a+b-Cy3 and AZOI-665-FLUOS) are bound. C) Whole cell identification of Skermanella parooensis cells with different morphological appearance. The paraformaldehyde-fixed culture was simultaneously hybridized with the Cy3-labelled probe Sparo84, specific for *S. parooensis*, and the Cy5-labelled probe AZO440a+b, specific for the *Azospirillum-Skermanella-Rhodocista*-cluster. The phase contrast image was superimposed with the two CSLM-panels by image analysis. The oligonucleotide probes allow the detection of both the unicellular and multicellular phases of growth. D) In situ detection of *A. brasilense* Cd at the root surface of an inoculated wheat seedling grown in a hydroponic system with quartz sand. A fixed root sample was hybridized with the FLUOS-labelled probe EUB338, the Cy3-labelled probe ALF1b and the Cy5-labelled probe AZO440a+b. *Azospirillum brasilense* cells are binding all three probes and yield a white image, while autofluorescent plant cell wall material appears green and blue. From Stoffels et al. (2001).

[b]Review.

rhizosphere soils and in association with the roots, stems and leaves of a large variety of different plants (Table 1). Both *Azospirillum brasilense* and *A. lipoferum* could be isolated from 30–90% of soil and rhizosphere samples collected all over the world (Döbereiner et al., 1976b).

In field-grown maize, azospirilla occur on the surface of roots, in the outer cortex, in the inner cortex and in the stele (Patriquin and Döbereiner, 1978; Döbereiner and Baldani, 1979). Infection of the inner cortex and stele occurs in the absence of a dense bacterial colonization or collapse of outlying tissues. Paraxylem vessels can be completely plugged with the bacteria. Infection occurs initially in root branches and spreads longitudinally into main roots. In monoaxenic cultures of pearl millet and guinea grass, azospirilla are found within the mucigel layer of roots and become firmly attached to root hairs. The bacteria enter the roots through lysed root hairs and void spaces created by epithelial desquamation and lateral root emergence (Umali-Garcia et al., 1980). Azospirilla have been observed in intercellular locations within the middle lamella of

root tissues and also intracellularly, sometimes in very large numbers (Patriquin et al., 1983).

The above observations of root colonization were mostly based on nonspecific staining techniques, and in situ identification has rarely been performed. However, these findings were confirmed for the *A. brasilense* strains Sp245 and Sp7 inoculated into wheat plants when their colonization patterns were evaluated using specific fluorescent oligonucleotide probes and confocal laser scanning microscopy (SCLM; Aßmus et al., 1995), strain-specific monoclonal antibodies (Schloter and Hartmann, 1998), or *nifH-gus* fusions (Van de Broek et al., 1993). There was a high predominance of *A. brasilense* in the root hair zone as compared with the root tips of wheat plants. *Azospirillum brasilense* strain Sp245 was repeatedly detected in the interior of root hairs, whereas *A. brasilense* strains Sp7 and Wa3—both isolated from rhizosphere soil—colonized predominantly the rhizoplane (Aßmus et al., 1995). Strain Sp245, already known to be a potential colonizer of the root interior (Baldani et al., 1986), could be found in intercellular spaces of the root parenchyma and inside cortex and parenchyma cells, with the point of emergence of lateral roots being the probable infection site (Aßmus et al., 1997). It has been observed that microcolonies are formed in the intercellular spaces (apoblast) of wheat roots inoculated with strain Sp245 but not with strains Sp7 and Wa3 (Schloter and Hartmann, 1998). However, the plant genotype may influence the extent of root colonization. Inoculation with a *gusA*-labelled derivative of strain Sp245 demonstrated that the bacteria initially concentrate in the root-hair zones and at sites of lateral root emergence. Its spread to the other parts of the root was dependent on the status of the nitrogen and carbon sources present in solution (Van de Broek et al., 1993). Although the process of association between *Azospirillum* and the host plant is still not completely resolved, a model has been suggested (Del Gallo and Fendrik, 1994; Fig. 3). In soil, the relevant properties of azospirilla, its behavior, and its relationship with soil microorganisms have recently been reviewed (Bashan, 1999).

Because of the ability of most strains of *Azospirillum* to colonize both the surface and in some cases the root interior including stems and leaves, these bacteria were grouped with the so-called "facultative endophytic" diazotrophs. This term was suggested to distinguish them from the

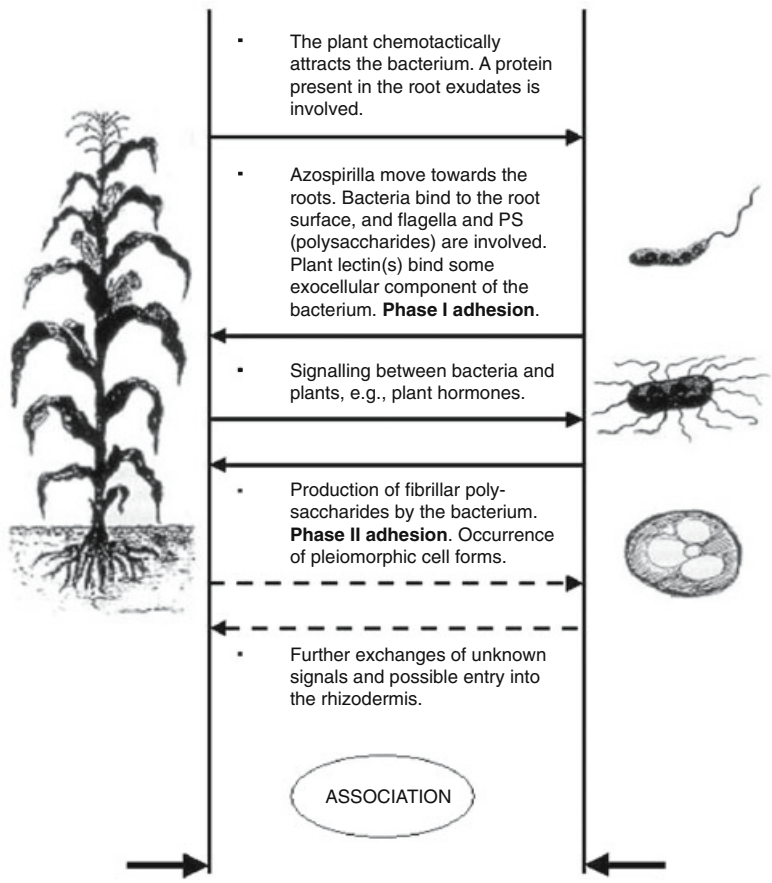

Fig. 3. Working model of the interaction of *Azospirillum* with plant roots. Modified from Del Gallo and Fendrik (1994).

"obligate endophytic" bacteria, which include *Gluconacetobacter diazotrophicus*, a bacterium found colonizing sugarcane plants endophytically (Döbereiner, 1992).

Evidence is accumulating that roots of maize, sorghum and *Phaseolus vulgaris* inoculated with *Azospirillum* have increased respiration rates (Okon et al., 1986; Sarig et al., 1992; Vedder-Weiss et al., 1999). Inoculated roots showed higher specific activities of housekeeping enzymes between the second and third week after inoculation (Fallik et al., 1988). Membrane proton efflux in wheat roots was also changed after inoculation, which might be coupled to the observed increased mineral uptake (Bashan et al., 1989). It seems that in the presence of *Azospirillum*, the hydrolysis of conjugated phytohormones and flavoids (e.g., by β-glucosidases) in the root tissue is stimulated, thus releasing these compounds in the active form (Volpin et al., 1996). Stimulation of root activities and development finally provides *Azospirillum* with enhanced possibilities for colonization and thereby increases its population in the rhizosphere (Vedder-Weiss et al., 1999; Dobbelaere et al., 2001).

Soon after its rediscovery in the mid 1970s, an application of *Azospirillum* as inoculant of crop plants had been suggested for the benefit of cereal and forage grasses, and the first trial of this application seemed very promising (Smith et al., 1984). *Azospirillum's* physiology, mode of association with the roots, and effects on crop plants were reviewed in the light of its potential agronomic application (Okon, 1982; Okon, 1985; Okon and Labandera-Gonzalez, 1994b). Although a substantial impact of nitrogen fixation due to the inoculation with *Azospirillum* was never proven, a consistent plant growth stimulatory effect was evident, leading to improved crop yields. Enhanced proliferation of the root system and root hair development as well as altered cell arrangements in the root cortex caused by *Azospirillum* inoculation was frequently demonstrated (Fallik et al., 1994). This root proliferation effect causes increased root surface activity, leading to enhanced specific uptake of mineral nutrients, microelements and water (Sarig et al., 1988).

Isolation Procedures

The isolation of *Azospirillum* spp. is based on the use of N-free semisolid media containing agar (1.75 g/liter). These microaerobically nitrogen-fixing (diazotrophic) bacteria are selectively enriched because they can grow with N_2 as nitrogen source. Because azospirilla do not harbor powerful oxygen-protective mechanisms for the oxygen-sensitive nitrogen-fixing system, they are unable to grow on N_2 as sole N-source in N-free agar plates or liquid media, as is the case for azotobacters or other strictly aerobic diazotrophs. Microaerobic diazotrophs are aerotactic, and as a result, the nitrogen-fixing population collects in zones of reduced oxygen concentration (Zhulin and Armitage, 1993). There, they form a thin pellicle or veil that moves upwards as it becomes thicker (Döbereiner and Pedrosa, 1987). Thus, the bacteria remain within the zone of an oxygen gradient where the respiration rate of the cells is in equilibrium with the oxygen diffusion rate. To permit this, the consistency of the medium must be perfectly correct so as to enable the bacteria to move through the medium on the one hand, while supporting the pellicle on the other. The agar concentration for such a semisolid medium actually has to vary with its pH, with the brand of the agar, or with the time of sterilization and must therefore be adjusted carefully for each medium formula. A medium with the proper consistency must be just thick enough not to flow upon gentle inclination of the test tube or vial. Two additional general characteristics of these media are important: the amount of medium in a vial, which should be large enough to make a layer at least as high as it is wide, and the addition of bromthymol blue indicator, which helps to make growth characteristics more readily apparent.

The composition of the various media used for the isolation of microaerobic diazotrophs is summarized in Table 2. Test tubes or 7- to 10-ml serum vials containing the semisolid media are inoculated with root or soil dilutions (10^{-5} to 10^{-7}) or directly with small root pieces or soil particles. After characteristic pellicles have formed, N_2 fixation is checked by acetylene reduction activity, and active cultures are transferred to new vials containing the same medium. As soon as a new pellicle is visible, the cultures are streaked out on agar plates containing the same medium with yeast extract (20 mg/liter) added. The small amount of yeast extract permits the growth of small colonies on the surface of plates. Characteristic individual colonies are then transferred again to N-free semisolid media, and those that grow well are streaked out on potato agar for final purification.

Isolation of *Azospirillum lipoferum*, *A. brasilense* and *A. doebereinerae*

These three species can all be isolated using the same semisolid medium (NFb or JNFb) and by exactly the same procedure (see above, Table 2). After 1–2 days of incubation at 35°C, very characteristic veil-like pellicles appear that grow into

Table 2. Four media used for the isolation and cultivation of *Azospirillum* spp.

dense, white, paper-like, undulated pellicles. These pellicles are just under the medium surface and are easily recognized within the blue medium (use of malic acid leads to a pH increase and a change in medium color). The bacteria should be checked microscopically in wet mounts, where quite characteristic forms and movements of the different species may be seen. *Azospirillum brasilense* cells are very motile, characteristically wiggling rods (0.6–1.7 μm in diameter and 2.1–3.8 μm in length) with poly-β-hydroxybutyrate (PHB) granules; *A. lipoferum* appears either as longer cells moving in a worm-like fashion or as nonmotile large polymorphic involution forms. Cells of *A. doebereinerae*, recently isolated from roots of the C4-plant *Miscanthus sinensis* (Eckert et al., 2001), are motile curved rods or S-shaped, 1.0–1.5 μm wide and 2.0–30 μm long. After growth overnight in liquid medium, cells are small and vibrioid, whereas after prolonged growth in semisolid Nfb medium the cells are very long and their movement is winding or snake-like. Colonies of *A. brasilense*, *A. lipoferum* or *A. doebereinerae* on Nfb agar are similar in appearance, being small, dense, and white or gray. On potato agar, they are first smooth and grayish, later becoming pinkish and structured.

Isolation of *A. amazonense*

Semisolid LGI medium (Table 2) is inoculated as described above and incubated 2–4 days. The medium turns yellow in enrichment cultures but remains greenish in pure cultures. Veil-like pellicles form, as with *A. brasilense*, but these grow into thick surface pellicles after a week. *Azospirillum amazonense* can use malate and starts to grow in Nfb medium, but, owing to its sensitivity to neutral and alkaline pH, the pellicle soon disintegrates and the bacteria die. Cells in LGI medium are very motile, helical or vibrioid, somewhat smaller than *A. brasilense* (0.8 × 2 μm), with very pronounced PHB granules. In media with combined N sources, the cells contain no or only very small PHB granules, and the cells are thinner. Colonies on LGI plates are small, dense and white; on potato agar, they are characteristically white and flat with elevated borders (saucers). In modified potato agar without malate, growth continues until luxuriant white, structured colonies are formed.

Isolation of *A. halopraeferens*

Semisolid NFb medium is modified by adding additional salts and $MgSO_4 \cdot 7H_2O$, $CaCl_2 \cdot 2H_2O$ and NaCl in higher concentrations to meet the moderate halophilic/halotolerant requirement of this species; in addition, the pH is elevated to 8.5 (Table 2). The medium is inoculated as described above and incubated at 41°C. The cells are very similar in appearance to *A. amazonense*. Isolation, as decribed by Reinhold et al. (1987), is best performed by suspending parts of the pellicle in modified Nfb medium, which is then used to seed

molten, cooled (45°C), soft, modified NFb (0.8% agar) medium; then, the medium is poured into Petri plates. Small, white colonies are visible within the agar after one week.

Isolation of *A. irakense*

Rhizosphere soil or roots of rice plants are crushed, suspended in sterile distilled water, diluted and inoculated into semisolid NFb medium. The intermediate purification steps follow basically those for *A. lipoferum*. The final purification is performed on the modified semisolid AAM medium, defined as follows (g/liter): K_2HPO_4, 2.0; KH_2PO_4, 6.0; $MgSO_4 \cdot 7H_2O$, 0.2; NaCl, 0.1; $CaCl_2 \cdot 2H_2O$, 0.026; $Na_2MoO_4 \cdot 2H_2O$, 0.002; $FeCl_3$, 0.01; NH_4Cl, 1.0; and distilled water, 1000 ml. For semisolid medium, 1.9 g of agar/liter is added and the NH_4Cl is omitted. For solid medium, 15 g of agar/liter is added. The carbon sources are sterilized separately (i.e., DL-sodium malate) or filter sterilized (i.e., sucrose) and added aseptically to the minimal medium to give a final concentration of 0.03 M. The AAM-medium also contains 4 ml/liter of a 1.64% solution of FeEDTA and the final pH is adjusted to 6.5. Subsurface pellicles are streaked out on the modified AAM agar plates. Colonies formed after 4 days are translucent, glistening, convex with a regular margin, and 1 mm diameter.

Isolation of *A. largimobile*

One drop of fresh lake water is spread onto the surface of lake water agar (LWA) plates, dried and incubated for up to 8 days at 28°C. Colonies grown on LWA for 72 h are 1–2 mm in diameter, colorless, translucent, low convex, round with an entire edge and smooth surface, and readily coalesce. These colonies, containing unicellular or multicellular forms, are further purified on LWA agar, where very active motile cells containing refractile granules appear 4–8 h after incubation. These motile cells have a striking resemblance to cells of *Beijerinckia* species. Although *A. largimobile* shows these peculiar characteristics of multicellular forms, strains of this species are able to grow and fix nitrogen in semisolid NFb medium and growth in many ways resembles that of *A. lipoferum*.

Cultivation of Azospirilla

For rapid multiplication, the *Azospirillum* spp. can be grown in liquid media (compositions given in Table 2 [omitting the agar]) to which a combined nitrogen source has been added (NH_4Cl [1 g/liter] or yeast extract [0.4 g/liter]). Alternatively, complex media such as nutrient broth (NB) or 1/2 DYGS medium (D,L-malate [1 g/liter], yeast extract [2 g/liter], glucose [1 g/liter], glutamate [1.5 g/liter], peptone [1.5 g/liter], $MgSO_4 \cdot 7H_2O$ [0.5 g/liter]; Rodrigues Neto et al., 1986) can be applied. In such media, with rapid stirring or shaking, cell concentrations of 10^8 per ml are reached after 24–48 h. To stabilize the pH at the desired value (Table 2) upon prolonged growth, the addition of 50 mM MOPS (3-[N-morpholino] propanesulfonic acid) buffer (pH 6.8) or MES (2-[N-morpholino] ethane-sulfonic acid) buffer (pH 6.0) is recommended. Alternatively, the phosphate buffer concentration can be increased, as in JNFb, but this may reduce the growth rate. Alternatively, the *Azospirillum* minimal medium of Okon et al. (1976), which also contains high phosphate levels, can be used.

The production of cell mass of nitrogen-fixing *Azospirillum* in liquid medium requires additional measures. Best results are obtained in fermentors where the pH is automatically controlled, and the dissolved pO_2 is maintained at 0.02–0.04 atm (Song et al., 1985; Hartmann and Hurek, 1988c). Nitrogenase activity (acetylene reduction activity, ARA) of such cultures can be checked by incubating in small vials where the gas-liquid interface and the pO_2 in the gas phase are adjusted to optimal pO_2 conducive to nitrogenase activity. N_2-dependent growth can also be obtained in Erlenmeyer or other flasks that are closed with perforable rubber stoppers and where the pO_2 in the gas phase is fixed by air injections according to the oxygen reading of an electrode; however, rapid mixing of the culture has to facilitate the diffusion of oxygen into the liquid phase. In such vials, the optimal pO_2 in the gas phase is difficult to define because it changes with the cell density, liquid/gas interface position, shaking rate, and culture volume. Depending on the species, cultures can be started at a pO_2 of 0.01–0.04 atm with slow shaking, but once logarithmic growth is achieved, such cultures can fix N_2 and grow under vigorous shaking at atmospheric pO_2 or even above (Volpon et al., 1981). An alternative for growing cells with derepressed nitrogenase is therefore to start such batch cultures with 10–20% inoculum or to add a starter dose of combined nitrogen in the range of 1 mM NH_4Cl or 50 mg/liter of yeast extract. This small amount of combined nitrogen is used up in the first phase of cultivation, after which efficient N_2-fixation is initiated in an actively respiring culture that removes excess oxygen to a level conducive for nitrogen fixation. Exact concentrations of such starter doses must be tested for each specific culture conditions. To ensure best conditions for nitrogenase activity, it is advisable to measure the dissolved oxygen concentrations in the culture liquid continously with an autoclavable Clark-

type oxygen electrode or a similar device and to adjust the dissolved oxygen accordingly to 0.2 kPa by adding small doses of air or oxygen manually or by using a regulated automatic device (Hartmann and Burris, 1987; Hartmann and Hurek, 1988c).

Preservation of Cultures

Routine preservation of *Azospirillum* spp. is possible on potato agar (Table 2) or well buffered NB-agar within tightly closed tubes or under mineral oil. Cells from a freshly grown culture are transferred with a wire into the depth of a small vial filled with nutrient agar. After incubation of about 2 days, sterile mineral oil is added in a layer of about 1 cm. *Azospirillum amazonense* must be stored on sucrose medium because an increase of pH over 6.5 kills the bacteria within a few days. Also, *A. lipoferum* is relatively sensitive to alkaline media. Storage of the cultures for many years at –80°C or in liquid N_2 is also possible after adding 50% glycerin or dimethylsulfoxide (DMSO) to an exponentially growing culture. The cells can also be preserved by lyophilization according to the following protocol (Döbereiner, 1995). The cultures are grown to late log-phase in the following medium: K_2HPO_4, 0.5 g; $MgSO_4 \cdot 7H_2O$, 0.2 g; NaCl, 0.1 g; K-DL-malate (for *A. brasilense*) or glucose (for *A. lipoferum*), 5 g; yeast extract, 0.4 g; and 1 liter of distilled water. The cells must then be collected by centrifugation and resuspended to a dense cell suspension with 10% sucrose solution containing 5% peptone. Then, 0.1 ml portions are transferred into lyophilization ampoules, which are frozen and lyophilized according to the procedures recommended for *Rhizobium* spp. (Vincent, 1970).

Identification

Azospirillum species as described by Krieg and Döbereiner (1984) are curved plump rods, 0.8–1.0 × 25 μm in size, with PHB granules, which in N_2-fixing cells can reach 50% of the cell dry weight (Okon et al., 1976). The cells are normally Gram negative but Gram variability has been observed in *A. brasilense* (Tarrand et al., 1978). Cells are motile with a single polar flagellum. Numerous lateral flagella of shorter length are formed in *A. lipoferum* and *A. brasilense* on soft nutrient agar where swarming is observed (Hall and Krieg, 1983).

Nonmotile cyst-like forms, or C-forms, occur in *A. lipoferum* and *A. brasilense* on nutrient-deficient media (Tarrand et al., 1978), and fructose favors their formation (Berg et al., 1979; Sadasivan and Neyra, 1985). In association with grass roots in monoxenic culture or in tissue cultures, the C forms have been suggested to serve for the protection of nitrogenase against O_2 damage (Berg et al., 1979; Umali-Garcia et al., 1980). C-forms are more resistant to desiccation than are vegetative cells, and therefore they were also suggested to be true cysts (Sadasivan and Neyra, 1985). Cyst-like cell forms of *A. brasilense* occurring in the rhizosphere of wheat were shown to bind fluorescently labeled rRNA-targeted oligonucleotide probes (Aßmus et al., 1995), and this binding indicates a high ribosome content and thus high physiological activity of these cell forms.

Azospirilla have a typically aerobic metabolism, with O_2 as the terminal electron acceptor. In *A. brasilense* and *A. lipoferum*, NO_3^- can replace O_2 in respiration, and under alkaline conditions N_2O and N_2 are formed (Stephan et al., 1984). Under these conditions, anaerobic growth and N_2 fixation have been shown to occur (Nelson and Knowles, 1978; Scott et al., 1979). Weak fermentative ability has been observed with *A. lipoferum* grown on glucose or fructose (Tarrand et al., 1978). The favored carbon substrates for all *Azospirillum* species are organic acids such as L-malate, succinate, pyruvate, and *trans*-aconitate. Fructose and galactose are also used by all species. The reason for the use of sucrose for isolation and cultivation of *A. amazonense* is its sensitivity to the alkaline pH caused by growth in media with salts of organic acids. The main differential characteristics of the *Azospirillum* species are summarized in Table 3.

Azospirillum spp. have been examined by DNA/DNA and RNA/DNA hybridization studies (Falk et al., 1986; Reinhold et al., 1987), which indicate that they are closely enough related to be included in one genus. The results of 16S rDNA sequence similarity studies confirm this conclusion (Xia et al., 1994; Eckert et al., 2001; Stoffels et al., 2001; Table 4). They demonstrate clearly that *A. amazonense* and *A. irakense* are in a separate subcluster together with *Rhodocista*.

Azospirillum lipoferum

Azospirillum lipoferum, Tarrand et al., 1978, syn. *Spirillum lipoferum* (Beijerinck, 1925) is the type species. Cells in young cultures and in sugar media are as described for the genus. The characteristic pleomorphism of this species is observed in organic acid-containing media, which turn alkaline following growth. The long spirilla or filaments, as well as large, deformed involution forms remain viable and the cell walls seem to remain unchanged. Colonies on potato agar become visible after 48 h and are small,

whitish, and smooth. After one week, the colonies turn light pink and become dry and wrinkled and are characteristically indented into the agar. This characteristic colony type occurs only when the medium becomes alkaline. When malate is replaced by a sugar substrate (glucose or fructose), large, white and gummy colonies are formed. Growth in liquid medium with a combined N source and heavy shaking results in rapid growth with extensive clumping of the cells. Microscopic examination of the clumps shows predominantly C-forms embedded within a polysaccharide matrix.

Azospirillum lipoferum can grow lithoautotrophically with H_2 (Pedrosa et al., 1982) owing to the presence of a hydrogenase (uptake hydrogenase) as well as its ability to form ribulose-1,5-bisphosphate carboxylase (Rubisco). Under these conditions, it can be considered as an aerobic, hydrogen-oxidizing bacterium. The type strain is strain ATCC 29707^T/DSM 1691^T (strain 59b of Tarrand et al., 1978), and additional reference strains are ATCC 29708 (strain RG20a), ATCC 29709 (strain SpBr17), and ATCC 29731 (strain SpRG6). Physiological characteristics useful for routine identification are the polymorphic cells in alkaline malate medium, the ability to use glucose, and a requirement for biotin. The species-specific 16S rRNA binding oligonucleotide probe Alila1113 together with the subcluster probe AZOI-665 (Stoffels et al., 2001) enables a fast and reliable identification of *A. lipoferum* by whole cell fluorescence in situ hybridization (FISH; Amann et al., 1995).

Azospirillum doebereinerae

Azospirillum doebereinerae is the most recently discovered *Azospirillum* species (Eckert et al., 2001). Until now, it has only been isolated from the C4-plants *Miscanthus sinensis* cv. *giganteus* and *M. sacchariflorus*, which are cultivated as "renewable energy" and fiber plants. *Azospirillum doebereinerae* is pleomorphic and forms

small (1.0–1.5 μm) vibrioid cells in neutral media, but long (2.0–30 μm) snake-like moving cells in alkaline semisolid NFb or JNFb media. It is very closely related to *A. lipoferum* and *A. largimobile*, but can be distinguished from these species by the inability to use *N*-acetylglucosamine and D-ribose (Table 3). Unlike *A. lipoferum*, *A. doebereinerae* is able to grow without biotin. The type strain is DSM 13131^T (strain GSF71^T) and the additional reference strain is DSM 13400^T (strain Ma4). Using the species-specific oligonucleotide probes Adoeb94 or Adoeb587 together with the subcluster probe AZOI-655, *A. doebereinerae* cells can rapidly and reliably be identified by FISH (Stoffels et al., 2001).

Azospirillum largimobile

Azospirillum largimobile is the former *Conglomeromonas largomobilis* subsp. *largomobilis* (Skerman et al., 1983) and was transferred to the genus *Azospirillum* as *Azospirillum largomobile* on the basis of the results of 16S rDNA similarity and DNA-DNA-hybridization (Dekhil et al., 1997). The name was subsequently corrected to *Azospirillum largimobile* by Sly and Stackebrandt (1999). It can be identified by its characteristic multicellular forms on lake water agar. In contrast to *A. lipoferum*, it has no biotin requirement (Table 3). The reference strain is ACM 2041^T. On the basis of 16S rDNA-directed oligonucleotide probes, *A. largimobile* cannot be distinguished from *A. lipoferum* by FISH, because it also binds the probe Alila1113 (Stoffels et al., 2001).

Azospirillum brasilense

Cells of *Azospirillum brasilense* (Tarrand et al., 1978) are, as described for the genus, indistinguishable from young cultures of *A. lipoferum* but remain very motile and vibrioid even in older alkaline cultures. All strains are Gram negative when cultured in nutrient broth, but they may become Gram variable on nutrient agar. Colonies on potato agar containing malate are indistinguishable from *A. lipoferum* but remain unchanged when malate is replaced by glucose because glucose is not used. This was shown to be due to an inability to transport glucose into the cell (Goebel and Krieg, 1984; Martinez-Drets et al., 1984) and not to the lack of glycolytic enzymes. Bright red mutants occur spontaneously, especially of the type strain Sp7. It was shown that the red pigments are carotenoids exerting some oxygen protective effect (Hartmann and Hurek, 1988c). The type strain is ATTC 29145^T/DSM1690^T (strain Sp7, isolated from grass rhizosphere soil in Rio de Janeiro), and other reference strains are ATCC 29710 (the red mutant Cd of Sp7) and ATCC 29711 (strain Sp35 isolated from grass roots in Rio de Janeiro). Routine identification can be made by the lack of growth on glucose and the presence of motile cells in old alkaline cultures. A rapid identification using the species-specific oligonucleotide probe Abras1420 together with AZOI-655 is possible. To optimize the specificity, the application of the unlabeled competitor probe Abras1420C is recommended (Stoffels et al., 2001).

Azospirillum halopraeferans

Azospirillum halopraeferans (Reinhold et al., 1987) has been found only in association with Kallar grass (*Leptochloa fusca*) in Pakistan and has not been isolated from inside roots or from any other plant. It shows a remarkable adaptation to the extremely arid environment of saline soils, having a pH optimum of 8.0 and a temperature optimum of 41°C even for N_2-dependent growth and a salt requirement of 0.25% NaCl. Cells are very similar in appearance to those of *A. amazonense* but can become wider in alkaline media (1.2 μm). They are motile by one polar flagellum, and cells move in a vibrioid or helical fashion; few cells are motile in very alkaline media. As with the other species, it is oxidase- and urease-positive and can assimilate and dissimilate NO_3^-, but anaerobic NO_3^--dependent growth has not yet been shown. The type strain is DSM 3675^T (strain Au4), and additional reference strains are LMG 7107 (strain Au2), LMG7109 (strain Au5), and LMG7112 (strain Au10). Routine differentiation from the other *Azospirillum* spp. is possible by its relatively high heat tolerance of nitrogenase activity and salt requirement. Additional differential characteristics are shown in Table 3. *Azospirillum halopraeferens* can be rapidly identified by FISH using the species-specific oligonucleotide probes Ahalo1115 or Ahalo1249 together with the cluster probe AZOI-655 (Stoffels et al., 2001).

Azospirillum amazonense

Cells of *Azospirillum amazonense* (Magalhães et al., 1983; Falk et al., 1985) are slightly smaller than those of the two first species (0.9 × 3–4 μm) and contain large PHB granules in N_2-grown cultures. Cells grown with combined nitrogen are much narrower in diameter and have no, or small, PHB granules. Only a single polar flagellum is observed, and there is no swarming on soft nutrient agar. In semisolid NFb medium with an initial pH of 6.8, growth starts with the veil-like pellicle, which however disintegrates once the pH rises above 7.0 (Magalhães et al., 1983). Good growth is observed in LGI medium con-

taining sucrose or glucose (where the pH does not increase). Typical for N_2-fixing cultures in semisolid LGI medium is the formation of a thick surface pellicle with the medium remaining green (pH between 6.0 and 6.5). The optimal pH for growth is between 5.8 and 6.8, and viability is lost rapidly in cultures which reach higher pH. Optimum temperature is the same as for the two first species, 36°C, and no growth occurs below 25 or above 39°C (Magalhães et al., 1983). Nitrate is assimilated but only slightly or not at all dissimilated (by a few strains only), and no denitrification or NO_3^--dependent anaerobic growth occurs. The type strain is DSM 2787^T (strain Y1); DSM 2789 (strain Y6) and DSM 2788 (strain Y2) are two additional reference strains. Additional characteristics are summarized in Table 3. Characteristics useful for routine identification are the white, flat colonies with elevated borders (about 5 mm in diameter) on potato agar containing malate and sucrose, good growth without acid production on sucrose, and the characteristically motile, smaller cell form with large PHB granules. The application of the species-specific oligonucleotide probe Aama1250 enables a reliable and fast identification using the FISH technique (Stoffels et al., 2001).

Azospirillum irakense

Azospirillum irakense, isolated from roots of rice plants (Khammas et al., 1989) but also from pond water (Winkelmann et al., 1996; K. Malik, unpublished observation), closely resembles *A. amazonense* in its physiological characteristics, especially because these two species are the only azospirilla that efficiently utilize sucrose (Table 3). In addition, Khammas and Kaiser (1991) demonstrated pectinolytic activity in *A. irakense* isolates. The type strain is DSM 11586^T (strain KBC1) and the additional reference strains are LMG 10655 (strain KAC5) and LMG 10655 (strain KAC5). *Azospirillum irakense* cells can be specifically identified using the phylogenetic oligonucleotide probes Airak1423 or Airak985 via the FISH technique (Stoffels et al., 2001).

Rhodocista centenaria and *Skermanella parooensis*

On the basis of 16S rDNA sequence similarity and DNA-DNA hybridization results, these two species fall in the same cluster as the *Azospirillum* spp. *Rhodocista centenaria* are nitrogen-fixing, thermotolerant anoxygenic cyst-forming phototrophic bacteria, which were originally named "*Rhodospirillum centenum*" (Favinger et al., 1989). They were reclassified as a separate photosynthetic bacterial genus (Kawasaki et al., 1992). The type strain is DSM 9894^T. However, *Rhodocista* is affiliated to the *Azospirillum* subcluster together with *A. amazonense* and *A. irakense* (Xia et al., 1994) and 16S rRNA from *Rhodocista* hybridizes with the cluster probe AZO440a+b (Stoffels et al., 2001). Using the 16S rRNA phylogenetic probe Rhodo654, *Rhodocista* can be rapidly and specifically identified with the FISH technique (Stoffels et al., 2001).

Skermanella parooensis (formerly *Conglomeromonas largomobilis* subsp. *parooensis*) is a non-nitrogen-fixing organism isolated from freshwater (Skerman et al., 1983; Dekhil et al., 1997). Only one isolate exists. Like in *A. largimobile*, growth of *Skermanella parooensis* occurs in unicellular and multicellular phases. Unicellular phase cells are rod-shaped with rounded or tapered ends, while multicellular conglomerates arise from single cells when they lose motility. They become optically refractile and reproduce by multiplanar centripedal septation. Under suitable conditions, conglomerates dissociate into single cells (Skerman et al., 1983; Dekhil et al., 1997). The type strain is *R. centenaria* ACM 2042^T. DNA from both cell forms gave hybridization signals with rRNA-directed fluorescently labeled specific oligonucleotide probe Sparo84 and the cluster probe AZO-440a+b (Stoffels et al., 2001). This clearly demonstrates that both types are active cell forms which belong to the *Azospirillum* cluster.

Physiology

Profound knowledge of the physiology of these microaerobic nitrogen-fixing bacteria plays an important role for their successful isolation from all over the world using simple semisolid N-free media (Table 2). Other microaerobic diazotrophs associated with plant roots comprise the α-subgroup Proteobacteria (*Gluconacetobacter diazotrophicus* [Gillis et al., 1989], *G. johannae* and *G. azotocaptans* [Fuentes-Ramirez et al., 2001]), as well as the β-subgroup Proteobacteria (*Herbaspirillum* with now three diazotrophic species [Kirchhof et al., 2001], *Azoarcus* spp. [Reinhold et al., 1993], and several diazotrophic *Burkholderia* spp. [Gillis et al., 1995; Estrada-De Los Santos et al., 2001; V. L. D. Baldani et al., submitted]). In the following paragraphs, selected physiological properties which have direct implications for the ecological performance and the application potential of *Azospirillum* are described. Diverse physiological aspects of *Azospirillum* were also reviewed by Hartmann and Zimmer (1994b) and Steenhoudt and Vanderleyden (2000).

Plant Root Colonization

In the rhizosphere, a gradient of exuded nutrients exists, stimulating microorganisms in the surrounding soil. Motility and chemotaxis enable the bacteria to move towards the roots, where they profit from the root exudates as carbon and energy sources. Survey of plant-inducible genes in *A. brasilense* grown in the presence and absence of plant root exudates identified an acidic 40-kDa protein, SbpA (Van Bastelaere et al., 1999). This protein, very similar to the ChvE-protein of *Agrobacterium tumefaciens*, is involved in the uptake of D-galactose and functions in the chemotaxis of *A. brasilense* towards several sugars (D-fucose, L-arabinose and D-galactose). Another important factor of directed movement of *Azospirillum* is oxygen gradients. This aerotactic behavior is necessary to guide the bacteria to optimal niches for microaerobic nitrogen fixation. The sensory system for spatial oxygen and redox gradients characterized in *A. brasilense* is unique (Grishanin et al., 1991; Zhulin et al., 1996).

Chemo- and aerotaxis need an efficient motility apparatus. *Azospirillum brasilense* genes required for the motility in liquid medium, on surfaces, and for general chemotaxis are located on the chromosome or on a 90-MDa plasmid (Onyeocha et al., 1990; Croes et al., 1991). All *Azospirillum* species possess plasmids of sizes from 4 MDa to over 300 MDa (Onyeocha et al., 1990). A 90-MDa plasmid has been commonly observed in *A. brasilense* and *A. lipoferum*. Deletion mutations in the 90-Mda plasmid (p90) of *A. brasilense* Sp7 enabled the identification of three loci involved in motility: Mot1, Mot2 and Mot3. While Mot1 and Mot2 are involved in the synthesis or functioning of lateral flagella, Mot3 deletion mutants lack both polar and lateral flagella. The use of these *A. brasilense* motility mutants in colonization assays directly demonstrated that bacterial chemotaxis was needed for the initiation of wheat root colonization at the root hair zone (Vande Broek et al., 1998). The structural gene encoding the flagellin of the lateral flagella (*laf1*) in *A. brasilense* Sp7 has been characterized (Moens et al., 1995a). Using a monospecific polyclonal antibody against the polar flagellum and a translational *laf1*::*gusA* fusion, it was demonstrated that blocking the rotation of the polar flagellum induces expression of the structural gene of the lateral flagellum (Moens et al., 1996). The structural protein of the polar flagellum, Fla1, is a glycoprotein that is suggested to act as a plant root surface adhesin (Moens et al., 1995b). The attachment of *Azospirillum* to plant roots has been shown in short-term in vitro binding assays as a biphasic process (Michiels et al., 1991). In a first step, the bacteria adsorb to the roots as single cells in a rapid, weak and reversible manner. The polar flagellum is involved in this step. The adsorption phase is followed by an anchoring phase in which bacterial aggregates form and are firmly and irreversibly anchored to the roots. Probably, the anchoring step is dependent on bacterial extracellular polysaccharide production (Del Gallo and Fendrik, 1994; Van de Broek and Vanderleyden, 1995; De Troch and Vanderleyden, 1996). Also fibrillar material has been reported in the anchoring of *Azospirillum* to the root surface (Umali-Garcia et al., 1980). Extracellular polysaccharide production has also been related to the process of flocculation of *Azospirillum* cells (Burdman et al., 1998). A spontaneous mutant of *A. brasilense* Sp7, impaired in surface polysaccharide production and flocculation, was altered in the colonization pattern of wheat roots as compared to the wildtype strain (Katupitiya et al., 1995). The regulatory gene *flcA* was demonstrated to control the production of capsular polysaccharides, flocculation, and colonization pattern of wheat roots (Pereg-Gerk et al., 1998). In addition, the *rpoN* gene, involved in the control of nitrate reduction, nitrogen fixation, and cell motility, also controls the colonization process of wheat roots by *A. brasilense* Sp7 (Pereg-Gerk et al., 1998). An interesting observation was made with a motile, laccase-negative strain (4B) and a nonmotile laccase-positive strain (4T) of *A. lipoferum*, isolated from the rhizosphere of rice (Alexandre et al., 1996). Upon inoculation of rice roots with *A. lipoferum* 4B, a two-step phenotypic transition was observed yielding spontaneously nonmotile laccase-positive variants under extremely low oxygen concentrations (Alexandre and Bally, 1999).

Wheat germ agglutinin (WGA) has been proposed as a signal molecule in the association of *Azospirillum* and wheat roots (Antonyuk et al., 1993). Nitrogen fixation, excretion of ammonium, and increase of indole-3-acetic acid (IAA) biosynthesis of *A. brasilense* strain Sp245 were found to be stimulated by WGA. A similar increase of nitrogen fixation in the presence of WGA has been demonstrated in *A. lipoferum* (Karpati et al., 1999). However, it remains unclear which structures of the cell surface of *A. brasilense* are responsible for WGA-binding. In addition, there are reports of lectin-like proteins on the cell wall of *Azospirillum* spp. that might be involved in the recognition and colonization of root surfaces (Castellanos et al., 1998). A major outer membrane protein of about 42 kDa has been identified in *A. brasilense*. It was proposed that under certain growth conditions, outer membrane proteins interact with exopolysaccharides (EPS), leading to aggregation and flocculation (Burdman et al., 1999).

In the search for *Azospirillum* genes relevant for interactions with plants, sequence homologies have been detected with the *A. tumefaciens chv* gene (Raina et al., 1995) and *Rhizobium meliloti nod* and *hsn* genes (Delledonne et al., 1990; Vielle and Elmerich, 1990). These genes are essential for attachment and tumor formation of plant cells or for nodule formation, respectively. The *A. brasilense chvB* gene could complement a *chvB* mutational defect in *A. tumefaciens* with respect to tumor formation. Therefore, the *chvB*-gene product of *A. brasilense* might also participate in root adsorption of *Azospirillum*. Interestingly, the *nodPQ* genes of *A. brasilense* are located on the 90-MDa plasmid, whereas the *nodG*-homologous gene is chromosomally located (Vielle and Elmerich, 1990; Vielle and Elmerich, 1992). However, the functions of these genes in the *Azospirillum*-plant interaction remain unclear.

Surface polysaccharide structures and the corresponding synthesis genes, which are also relevant for the surface interaction with plant roots, have been investigated via random Tn*5* mutagenesis and genetic complementation of *R. meliloti exo* mutants. *Azospirillum brasilense* produces cell bound capsular (CPS) as well as loosely attached extracellular (EPS) calcofluor-binding polysaccharides (Del Gallo et al., 1989; De Troch et al., 1992). Calcofluor-negative mutants lose the ability to anchor to wheat roots (Anc^-) but retain wildtype adsorption capacity (Ads^+), indicating that a surface polysaccahride is involved in anchoring (Michiels et al., 1991). Through complementation of *R. meliloti exoB* and *exoC* mutants, two *A. brasilense exoB* loci (*exoB1* and *exoB2*) and one *exoC* locus were isolated (Michiels et al., 1988). The *A. brasilense exoB* loci are functionally homologous to *R. meliloti exoB*, while the *A. brasilense exoC* locus could not complement for normal nodule formation. Interestingly, the *exoB1* and *exoC* genes are located at the p90 plasmid of *A. brasilense* Sp7.

Nitrogen Fixation

Azospirillum spp. can convert atmospheric nitrogen into ammonium under microaerobic conditions at low nitrogen levels through the action of the nitrogenase complex. Most of the genetic and biochemical work on nitrogen fixation by *Azospirillum* has been carried out with *A. brasilense*. An *A. brasilense nifHDK* operon, encoding both nitrogenase components, was first isolated on the basis of sequence similarity with the *Klebsiella pneumoniae nifHDK* genes (Quiviger et al., 1982). A number of additional *nif* and *fix* genes involved in processing of and electron transport to the nitrogenase complex, iron-molybdenum (FeMo) cofactor biosynthesis as well as regulation of nitrogen fixation are known (for review, see Steenhoudt and Vanderleyden, 2000). Except for the separately transcribed *nifA* and *nifB* genes, they all are located in the major 30-kb *nif* gene cluster on the chromosome (Liang et al., 1991). Only one report gives evidence of an alternative nitrogenase system in *A. brasilense* (Chakraborty and Samaddar, 1995).

Azospirillum fixes nitrogen only under microaerobic conditions. The optimum level of dissolved oxygen concentration is in the range of 0.2 kPa oxygen, but species- and strain-dependent differences exist in oxygen tolerance (Hartmann et al., 1985; Hartmann et al., 1988d). Mutants with increased carotenoid concentrations were shown to have slightly increased oxygen tolerance (Hartmann and Hurek, 1988c). A shift in dissolved oxygen concentration to 2.0 kPa caused an immediate inhibition (switch off) of nitrogenase activity, which can be recovered when the oxygen is shifted back to optimum levels. No covalent modification of nitrogenase reductase was found in this situation (Hartmann and Burris, 1987). Exposure of cells to higher oxygen levels caused an irreversible inhibition and destruction of the oxygen labile nitrogenase complex. A shift to anaerobic conditions also caused a switch-off in nitrogenase activity which was found to be accompanied by a covalent modification of the nitrogenase reductase in *A. brasilense* and *A. lipoferum* (Hartmann and Burris, 1987). The posttranscriptional regulation of nitrogen fixation is mediated through ADP-ribosylation of nitrogenase reductase (nifH-protein) in *A. brasilense* and *A. lipoferum*, but not in *A. amazonense* (Song et al., 1985; Hartmann et al., 1986). As was originally found in *Rhodospirillum rubrum*, the switch-off mechanism in *A. brasilense* and *A. lipoferum* consists of two enzymes: the dinitrogenase reductase ADP ribosyl-transferase (DraT) and the dinitrogenase reductase activating glycohydrolase (DraG; Fu et al., 1989b). In the presence of high ammonium or low oxygen concentrations, DraT catalyzes the transfer of an ADP-ribose of NAD to Arg 101 of one subunit of dinitrogenase reductase, whereby the covalently modified nitrogenase enzyme is inactivated. When ammonium concentrations are low (and/or oxygen is present), this inactivation is reversed by the action of DraG, which removes the ADP-ribosyl moiety (Zhang et al., 1992). DraT and DraG themselves are both subject to posttranslational control (Fu et al., 1990; Zhang et al., 1993). DraT is inactive under nitrogen-fixing conditions and is activated following a negative stimulus. DraG is active under nitrogen fixation conditions and is inactivated by a negative stimulus. *Azospirillum brasilense ntrBC* mutants escape nitro-

genase switch-off by ammonium. The primary effect of *ntrBC* mutations probably involves changes in DraG enzyme activity (Liang et al., 1992; Liang et al., 1993). It was shown that *draG* and *draT* are involved in the anaerobic and ammonium switch-off of nitrogenase activity and that these responses are regulated differently through the cellular nitrogen control (ntrB/C system; Zhang et al., 1994). Therefore, different environmental stimuli (NH_4^+, anaerobiosis) use independent signal transduction pathways to affect the reversible ADP-ribosylation system.

An alternative, noncovalent mechanism of posttranslational regulation of nitrogenase activity in response to ammonium, which exhibits slower and only partial inhibition of nitrogenase activity, has been demonstrated in *A. amazonense* that lacks the DraT/G-system and in mutant strains of *A. brasilense* harboring a nitrogenase reductase that cannot be ADP-ribosylated (Hartmann et al., 1986; Zhang et al., 1996). It is suggested that the regulation of electron flow to nitrogenase (Hochman et al., 1987) or other regulatory circuits involving respiratory components could be acting on the reversible switch-off at high oxygen conditions. Under nitrogen-fixing conditions, hydrogen metabolism is increased in *A. brasilense* (Chan et al., 1980). It has been demonstrated that hydrogen supports nitrogen fixation in carbon starved cultures of *Azospirillum* by an intracellular localized uptake hydrogenase (Fu and Knowles, 1988; Fu and Knowles, 1989a).

For general nitrogen regulatory control, NtrA and the transcriptional activator NifA are required in *Azospirillum* as they are in other Gram-negative nitrogen-fixing bacteria. Upstream of several *A. brasilense nif* genes, σ^{54}-type promotors and upstream activating sequences (UAS) typical for the binding of NifA have been found. In *A. brasilense*, the regulatory protein NifA is constitutively expressed, but the level of expression is reduced at conditions incompatible with nitrogen fixation (Liang et al., 1992). In addition, NtrC is required for optimal nitrogen fixation and maximal expression of *nifA* transcription. Since in *A. brasilense glnB* mutants (affecting regulatory P_{II}-protein) are *nif* minus, the general nitrogen regulatory cascade is also involved. Most interestingly, two distinct P_{II}-genes (P_{II} and P_Z), which are structurally similar but functionally different, were described in *A. brasilense* (de Zamaroczy et al., 1996; de Zamaroczy, 1998).

Ammonium Uptake and Assimilation

Under nitrogen-limiting conditions, *Azospirillum* express an ammonium-scavenging energy-dependent transport system, which takes up traces of NH_4^+ (Hartmann and Kleiner, 1982). Ammonium, which tends to leak out through the membrane by ammonia (NH_3) diffusion, is reutilized in this way. Recently, the *A. brasilense amtB* gene encoding this N-regulated ammonium transporter was characterized (Van Dommelen et al., 1998). Mutants in *amtB* are impaired both in $^{14}CH_3NH_4^+$ uptake and in growth at low ammonium concentrations. Since growth is not completely abolished in the *amtB* mutant at low ammonium concentration, the existence of a second NH_4^+-transport system was suggested (Van Dommelen et al., 1998). The *amtB* promotor region is characterized by a σ^{54} consensus sequence, and transcription requires the NtrBC two-component regulatory system (Milcamps et al., 1996). The second *A. brasilense* P_{II}-like protein (P_Z, encoded by *glnZ*) was shown to negatively regulate (methyl)ammonium uptake. Since P_Z is not required for NtrC-dependent regulation in *A. brasilense*, it is proposed that this protein is involved in modulating AmtB activity (de Zamaroczy, 1998). Aspects of nitrogen regulation in *Azospirillum* have recently been reviewed in more detail by Steenhoudt and Vanderleyden (2000).

Ammonium is assimilated through the glutamine synthetase/glutamate oxoglutarate aminotransferase (GS/GOGAT) pathway under nitrogen-limiting conditions. At high levels of ammonium or at ample supply of nitrogen through readily metabolizable amino acids, the glutamate dehydrogense (GDH) pathway is operating. Interestingly, NH_4^+ is excreted by *A. lipoferum* and *A. amazonense* when amino acids like glutamate or aspartate are used as sole carbon and nitrogen sources and acetylene reduction (nitrogen fixation) is operating at a reduced level (Hartmann et al., 1988d). In contrast, *A. brasilense* continues to fix nitrogen at high rates in the presence of high levels of external amino acids, and ammonium is not excreted (Hartmann et al., 1988d). Under nitrogen-limiting conditions, ammonium was never found to be released by *Azospirillum* wildtype cells under free-living (culture) conditions, if they still are supplied with a suitable carbon/energy source. Mutations in *glnA* (glutamine synthetase) and *amtB* (ammonium transporter) were reported to result in a less stringent regulation of nitrogen fixation by external ammonium levels, and these mutants release ammonium (Turbanti et al., 1988; Christiansen-Weniger, 1992). Inoculation of wheat plants with *amtB*-mutants resulted in an increased N-uptake by the plants as compared to the inoculation with the wildtype bacterium in 2,4-dichlorophenoxyacetic acid (2,4-D)-treated wheat plants in model experiments (Christiansen-Weniger et al., 1991; Sriskandara-

jah et al., 1993). In addition to assimilatory nitrogen metabolism, most azospirilla can denitrify under anaerobic conditions (Bothe et al., 1981). A possible role of nitrate reductase of *Azospirillum* in the nitrate assimilation of wheat plants was emphasized by Ferreira et al. (1987).

Production of Plant Growth Regulating Substances

The observed plant growth promotion by inoculation with *Azospirillum* can probably be explained in many cases by the action of plant growth regulatory substances produced by the bacterium. Three types of plant hormones can be detected in the supernatant of *Azospirillum* cultures: auxins (Tien et al., 1979; Lambrecht et al., 2000), and in smaller amounts, cytokinins and gibberellins (GA_3; Bottini et al., 1989). The application of an indolepyruvate decarboxylase (IpdC) mutant, producing only 10% of the indole acetic acid (IAA) level of the wildtype, strongly suggested that auxin production by *Azospirillum* plays a key role in the stimulation of plant root growth (Dobbelaere et al., 1999). GA_3 was found in an free acid form in roots of seedlings inoculated with *A. lipoferum* (Fulchieri et al., 1993). In plants with inhibited GA-biosynthesis, GA_3 could only be detected after these plants were inoculated with *Azospirillum* (Lucangeli and Bottini, 1997). Roots of *Azospirillum*-inoculated maize seedlings were found to have higher amounts of both free and bound IAA and indole-3-butyric acid (IBA) than control plants had (Fallik et al., 1989). Using a high-pressure liquid chromatography (HPLC) method with high separation power, a whole array of IAA-related compounds could be identified in *Azospirillum* cultures (Lebuhn and Hartmann, 1993; Lebuhn and Hartmann, 1994). It is not clear, however, whether the relative higher amounts of free IAA and GA_3 in root tissue of inoculated plants (i) are derived from substances directly excreted by *Azospirillum*, (ii) are due to changes in plant hormone metabolism caused by the bacteria, or (iii) are due to higher respiration rates of inoculated roots demanding more glycosidic residues from hydrolyzed hormonal conjugates, thus freeing IAA and GA_3.

After inoculation with *Azospirillum*, a stimulation of root growth is frequently observed with an optimum level of about 10^7 bacteria per plant (Okon and Labandera-Gonzalez, 1994b). The bacterial phytohormones probably provoke the detected changes in root morphology after inoculation. *Azospirillum* inoculated plants exhibit an enhanced root branching and surface area, which in turn can explain enhanced mineral uptake and water status of inoculated plants (Kapulnik et al., 1985; Sarig et al., 1988; Fallik et al., 1994). In certain *A. brasilense*-wheat associations, root hair branching and bacterial attachment were correlated with plant growth enhancement in model systems (Jain and Patriquin, 1984). The involvement of IAA in the interaction of *A. brasilense* and *Panicum miliaceum* roots has been emphasized by Harari et al. (1988). The diminished plant growth promotion effects after inoculation with *Azospirillum* mutants with reduced IAA production support the view that auxin-like substances could be key signals mediating the plant growth stimulation effect (Barbieri et al., 1986; Dobbelaere et al., 1999). The isolation of mutants that completely lack IAA biosynthesis has been unsuccessful so far because of the presence of multiple pathways leading to IAA. Tryptophan (Trp) is generally regarded as a precursor of IAA because the addition of this amino acid to cultures of *Azospirillum* results in higher IAA production (Hartmann et al., 1983). Three main pathways are known for the conversion of tryptophan into IAA: the indole-3-pyruvic acid (IPyA) pathway, the indole-3-acetamide (IAM) pathway, and the tryptamine (TAM) pathway (Costacurta and Vanderleyden, 1995). On the basis of ^{3}H-Trp and ^{3}H-IAM feeding experiments, the existence of an additional Trp-independent pathway was suggested; when no exogenous Trp was added, 90% of the IAA was formed in a Trp-independent process (Prinsen et al., 1993). Biosynthesis of IAA without tryptophan as precursor has been shown in plants, but this is unusal in bacteria (Wright et al., 1991).

The first pathway for the production of IAA starting from Trp involves the oxidative decarboxylation of Trp into IAM and the subsequent hydrolysis of IAM to obtain IAA. The genes encoding these enzymatic activities (Trp-2-monooxygenase [TMO] and indole-3-acetamide hydrolase) are cloned and sequenced in *A. tumefaciens* and *Pseudomonas syringae*. The occurrence of an IAM-dependent pathway for IAA biosynthesis in *Azospirillum* was proposed upon the detection of TMO activity in crude cell extracts from *A. brasilense* and the observation of partial homology of an *A. brasilense* genomic DNA fragment with the *iaaM* gene of *P. syringae* (Bar and Okon, 1993). The second Trp-dependent pathway operating in *A. brasilense* has been identified as the IPyA pathway, involving the transamination of Trp to yield IPyA, followed by a decarboxylation reaction to form indole-3-acetaldehyde. The subsequent oxidation reaction occurs spontaneously and yields IAA. The gene for the key enzyme in this pathway in *A. brasilense*, indole-3-pyruvate decarboxylase, has been isolated and sequenced (Costacurta et al., 1994). DNA hybridization experiments sug-

gested that the corresponding sequence is widespread in *A. brasilense*, *A. lipoferum* and *A. halopraeferens*, but absent in *A. irakense*. An *A. brasilense ipdC* knockout mutant was found to synthesize less than 10% of the level of the wild-type IAA production, indicating that IPyA decarboxylase is a key enzyme for IAA biosynthesis in this bacterium (Prinsen et al., 1993). Further physiological aspects of IAA-production in *A. brasilense* were studied by Iosipenko and Ignatov (1995). Interestingly, it was shown that the presence of auxins upregulates the indole-3-pyruvate decarboxylase gene in *A. brasilense* (Vande Broek et al., 1999). In *A. lipoferum*, Tn*5*-mutants affected in indole acetic acid biosynthesis are available (Abdel-Salam and Klingmüller, 1987).

Recently, it was demonstrated that *A. brasilense* transconjugant strains, expressing the 1-aminocyclopropane-1-carboxylic acid (ACC) deaminase gene, showed enhanced plant growth promotion in tomato and canola plants, but not in wheat (Holguin and Glick, 2001). ACC-deaminase cleaves the ethylene precursor 1-aminocyclopropane and thus can reduce too high levels of ethylene inhibitory for plant growth. The differential effect on plant species can be explained by different levels of sensitivity to ethylene. Modulating the concentration of the plant hormone ethylene has been proposed as a possible mechanism of plant growth promotion (Glick et al., 1998).

Osmotolerance

As soil bacteria and colonizers of the rhizosphere, azospirilla are subjected to manifold potential water stress situations. In saline soil, they have to cope with low osmotic potentials, and in drying soil, there are low matrix potentials—especially in the water-deleted rhizosphere—which may limit their activity and viability. From saline soil environments, bacteria with improved osmotolerance have been isolated, e.g., *Azospirillum halopraeferens* (Reinhold et al., 1987). To balance osmotic stress from the environment and to protect cellular functions, *Azospirillum* spp. can accumulate organic compounds, so-called "compatible solutes." In *Azospirillum* spp., trehalose, glycine betaine glutamate, and proline were characterized as compatible solutes (Hartmann, 1988a; Hartmann, 1988b; Hartmann et al., 1991). In general, the osmotolerance of *Azospirillum* spp. increases in the series *A. amazonense*, *A. lipoferum*, *A. brasilense* and *A. halopraeferens* (Hartmann, 1988a); the osmotolerance of *A. irakense* lies in between *A. brasilense* and *A. halopraeferens* (Khammas et al., 1989). *Azospirillum halopraeferens* is able to take up choline in a high affinity transport and to convert it into the potent osmoprotectant glycine betaine. It is known from some halotolerant plants that, e.g., choline is present in root exudates. In *A. brasilense* Sp7, a binding-protein-dependent, high affinity uptake of glycine betaine itself (K_m: 10 μM) was demonstrated. In *A. halopraeferens* and *A. brasilense*, glycine betaine stimulates growth and nitrogen fixation under salt stress (Hartmann, 1988b; Riou and Rudulier, 1990). In osmotolerant *Azospirillum* spp. like *A. brasilense*, *A. irakense* and *A. halopraeferens*, choline, glycine betaine, as well as, e.g., glutamate, aspartate or proline, are not or only weak sources of nitrogen or nitrogen and carbon (Hartmann et al., 1988b). Obviously, retarded utilization and degradation of osmoregulatory compounds is a prerequisite for using such compounds as osmolytes. Dehydroproline (DHP)-resistant bacteria with improved osmoregulatory properties could be isolated from *A. brasilense* Sp7 (Hartmann et al., 1992), as they could from enteric bacteria (Csonka and Hanson, 1991). The fact that DHP-resistant bacteria appear in some strains spontaneously at relatively high rates under selective conditions suggests an ecophysiological relevance of this trait (improved osmoregulation). Possibly, an insertion element associated transposition processes leading to chromosome rearrangements could be involved in this phenomenon, similar to the chromosome rearrangements demonstrated following the duplication of IS*50* associated with Tn*5* transposition in *A. brasilense* (Tripathi et al., 1998). Therefore, screening for improved osmoregulatory properties might be one way to improve the environmental fitness of inoculant strains for certain biotechnological applications (Hartmann, 1994a).

Siderophores

In aerobic environments, the availability of the essential micronutrient iron is limited by the extremely low solubility of ferric oxyhydroxy complexes, which have a dissociation constant as low as 10^{-38}. Most microorganisms excrete low molecular weight molecules (e.g., phenols and hydroxamates) with a very high binding affinity for ferric iron to sequester iron traces from environmental sources. A diversity of high affinity uptake systems for iron-loaded siderophores in microorganisms, plants and animals are well known to assimilate and store this solubilized iron (Römheld and Marschner, 1986; Braun et al., 1998). The presence of siderophores in soil and rhizosphere environments and the importance of siderophores for competitive growth of microorganisms (e.g., in the biocontrol of plant pathogens) are well known (Bossier et al., 1988).

Under iron-limiting conditions, *A. lipoferum* D-2 excretes the phenolate siderophores 2,3- and 3,5-dihydroxybenzoic acid conjugated with lysine and leucine as well as salicylic acid (Saxena et al., 1986). In *A. brasilense* RG, 2,3-dihydroxybenzoic acid conjugated with ornithine and serine, the so-called "spirillobactins," were characterized (Bachhawat and Ghosh, 1987b). Fe(III)-spirillobactin is taken up via a high affinity uptake process (K_M: 0.23 μM), which involves a specific outer membrane receptor (Bachhawat and Ghosh, 1987a). Since four outer membrane proteins with molecular weights between 72 and 87 kDa are induced under iron-limiting conditions, several structurally different siderophores could be recognized. Indeed, it has been shown for *A. brasilense* Sp245 that the fungal siderophores ferrichrome, ferrichrysine, and coprogen as well as the main siderophore of *Streptomyces* spp., ferrioxamine B, can be utilized as iron uptake carriers (Hartmann, 1988b). This property varies much among different environmental isolates and species: in *A. amazonense* Y1 and *A. lipoferum* SpBr17, no iron acquisition from external siderophores was observed, and in *A. brasilense* Sp7, iron acquisition was only slight. The siderophore iron uptake of *A. brasilense* Sp6 was studied more recently in molecular genetic terms and the *lon* gene was found to be involved in the iron uptake of *A. brasilense* (Mori et al., 1992; Mori et al., 1996).

Under severe iron-limiting conditions, spontaneous mutants were isolated, which could readily use coprogen and ferrichrysin as siderophores (Hartmann et al., 1992). For *A. halopraeferens* Au4, isolated from sodic alkaline soils which exert most severe iron-limiting conditions, the artificial iron scavenger dipyridyl was not inhibitory at all, while many *A. brasilense*, *A. lipoferum* and *A. amazonense* strains were inhibited to various degrees (Hartmann, 1988b). This could be explained by the medium range iron affinity of phenolate siderophores of the spirillobactin-type. Interestingly, it was recently demonstrated that *A. irakense* strains can hydrolyze and grow on ferrioxamine (Winkelmann et al., 1999). Moreover, the isolate *A. irakense* ASP-1 has been obtained from a sweet water pond through the ability to utilize ferrioxamines as carbon source.

Applications

All species of the *Azospirillum* cluster except *A. largimobile*, *Skermanella parooensis* and *Rhodocista centenaria* were shown to associate with a diversity of plants. Several authors using different methodological approaches proved that the colonization of plant roots by *Azospirillum* provokes structural and physiological changes in the root system. In some combinations of *Azospirillum* strains and plant cultivars, also endophytic colonization of the root was observed, although this seems to occur infrequently (Schloter and Hartmann, 1998). Efficient N_2-fixation and liberation and transfer of part of the nitrogen fixed by the bacterium to the plant have so far not been unequivocally shown for azospirilla colonizing the roots of healthy plants. Some increase of nitrogen fixation (acetylene reduction) was observed in so-called "para-nodules" induced by 2,4-dichlorophenoxyacetic acid (2,4-D) in wheat or when *A. brasilense* mutants with enhanced nitrogenase activity or ammonium release were used (Christiansen-Weniger et al., 1991; Pereg-Gerk et al., 2000). Mutants with improved environmental fitness, e.g., towards improved osmotolerance or iron acquisition, could be selected for some *A. brasilense* strains (Hartmann et al., 1992; Hartmann, 1994a). *Azospirillum* can contribute some nitrogen in cellulose-decomposing mixed cultures with *Cellulomonas gelida* (Halsall and Gibson, 1985a) or through the ability of straw decomposition by some specific N_2-fixing *Azospirillum* sp. isolates (Halsall et al., 1985b). Strains with improved competitiveness and sustained performance should be obtained through screening and selection procedures for superior rhizosphere fitness when agronomic application is envisaged. It has been shown that considerable differences exist in these properties in different strains of, e.g., *A. brasilense* (Hartmann, 1988b). Among *A. brasilense* isolates from Mexico, strains with elevated production of siderophore- and bacteriocin-like substances have been characterized by Tapia-Hernandez et al. (1990) as candidates for field inoculation trials. Furthermore, genetic improvement of *Azospirillum* inoculants tailored on the basis of the indepth knowledge of the physiology and regulation of key processes in *Azospirillum*, especially *A. brasilense*, seems to be a quite reasonable approach (Steenhoudt and Vanderleyden, 2000).

Under field conditions, detailed observations with various quantification methods clearly show that certain cultivars of sugar cane (Urquiaga et al., 1992), forage grass (Boddey and Victoria, 1986a), and *Pennisetum* (V. M. Reis, personal communication) derive as much as 30–60% of the plant N from atmospheric N_2, and thus nitrogen fixation by the associated diazotrophic population must occur. Because of the natural diversity of endophytic or epiphytic diazotrophs known to exist in these plants, the bacteria and sites in which nitrogen fixation and transfer of fixed nitrogen occur are not yet clear. The contribution of *Azospirillum* spp. within this plant-

associated bacterial community to this symbiotic process is still unknown. Responses of different plants, such as *Sorghum* and *Pennisetum*, to the inoculation by *Azospirillum brasilense* have been shown (Smith et al., 1984). However, the results of thorough field experiments with *Azospirillum* inoculants demonstrated an increase of uptake and assimilation of soil nitrogen and other plant nutrients rather than nitrogen fixation (Kapulnik et al., 1982; Lin et al., 1983; Boddey et al., 1986b). This was confirmed with a nitrate reductase-negative mutant of strain Sp245, which had no effect (Baldani et al., 1987). Wheat inoculated with two *A. brasilense* strains Sp245 and Sp107 repeatedly showed increased plant growth and N-uptake. Additionally, these strains were both isolated from surface-sterilized roots and shown to be established within roots of field-grown wheat upon inoculation (Baldani et al., 1986; Baldani et al., 1987). Statistically significant increases in plant dry-matter and/or N-yield have been shown in various cereals inoculated with *Azospirillum* strains (mostly *A. brasilense* Sp7 or Cd; Kapulnik et al., 1982; Baldani et al., 1986; Okon and Labandera-Gonzalez, 1994b; Dobbelaere et al., 2001).

An explanation for the observed increased nutrient uptake (of nitrate, potassium, phosphate and microelements) after *Azospirillum* inoculation in greenhouse and field experiments is the stimulation of root development (Fages, 1994). The proliferation of root hairs is enhanced and the cell arrangement in the outer layers of the root cortex, as observed in cross sections of inoculated plants, is changed (Fallik et al., 1994). The hydraulic conductivity of inoculated roots was increased (Sarig et al., 1992), and in plants subjected to osmotic stress, leaf senescence was delayed in inoculated plants, indicating an improved water uptake (Sarig et al., 1990). In field experiments, inoculated sorghum plants repeatedly showed higher leaf water potential, lower canopy temperature, and greater stomatal conductance and transpiration (Sarig et al., 1988). Moreover, inoculated compared to non-inoculated sorghum extracted more soil moisture (on the order of 15%) and from deeper soil layers (Fallik et al., 1994). In wheat, inoculation with *Azospirillum* improved coleoptile growth in seedlings grown in darkness under osmotic and salt stress (Alvarez et al., 1996). Effects on cell wall elasticity and/or apoplastic water status were evident (Creus et al., 1997). The production of plant growth-promoting substances such as auxins, gibberellins and cytokinins by the bacteria seems to be at least partially responsible for these effects (Dobbelaere et al., 1999). Therefore, it is very important to apply the optimum inoculum dose. For example in maize, seeds are coated with a peat-based inoculum at a final concentration of 10^7–10^8 colony forming units (CFU) per seed.

Field experiments involving *Azospirillum* inoculation during the 1990s were carried out in many countries including Belgium, France, Israel, Mexico, Uruguay, Argentina and South Africa (Dobbelaere et al., 2001). In Belgium, a combination of field experimentation and commercial application was carried out by Lipha-Lyon (France) and the Department of Applied Plant Sciences, Katholieke Universiteit, Leuven. Winter wheat as well as grain maize was inoculated with either *A. brasilense* Sp245 or *A. irakense* KBC1 in Tiegem, Belgium. Since Belgian soils are often very well or even overfertilized, leading to an excess of N in soil and groundwater, the increased N-uptake by cereals would help to reduce the amount of fertilizer used or even lost. An early effect of inoculation on root development and plant growth was observed. For winter wheat, a significant increase in plant dry weight of 62 and 46% above the control was evident upon inoculation with *A. brasilense* Sp245 and *A. irakense* KBC1, respectively. This corresponded to a 34% and 33% increase in the number of shoots and an early stimulation of root development (31% and 12%) after inoculation with Sp245 and KBC1, respectively (Dobbelaere et al., 2001). These effects occurred on plots without any additional nitrogen fertilizer at early and intermediate sampling dates, and in fertilized plots ($60\ kg \cdot N \cdot ha^{-1}$), they almost disappeared without producing significantly higher final yields. Similar effects especially on the nitric N-uptake by the plants were observed when the commercial inoculum AZOGREEN-m (Liphatech, France), which is a peat-based inoculum containing the strain *A. lipoferum* CRT1, was used on grain maize *Zea mays*; the inoculated plants took up more N than the control plants owing to the larger root system. In Mexico, extensive field inoculation trials of maize, wheat, barley, and sorghum with *Azospirillum* were conducted with significant yield increases (ranging from 20–70%; Caballero-Mellado et al., 1993). In a recent collaboration of the Ministry of Agriculture Research Institute (INIFAP) and the University of Cuernavaca, Mexico, an area of 450.000 ha of maize and 150.000 ha of sorghum, wheat and barley was inoculated with a mixture of local, prescreened *A. brasilense* strains, using sterilized peat as carrier containing a minimum of 5×10^8 viable cells $\cdot\ g^{-1}$ (Dobbelaere et al., 2001). By evaluating various cultivars of the crops and 171 sites all over Mexico with diverse soil and climatic conditions, the robustness of inoculation results was tested. The results showed consistent increases of on average 26%. Stimulation in fields with low N-levels was as much as 20–95%, while that in fields with high

N-level was only 0–19%, irrespective of the location and the inoculated crop (Dobbelaere et al., 2001).

An interesting area of application is the co-inoculation of legumes with *Rhizobium* and *Azospirillum*, which reportedly increases biomass parameters, nitrogen-content and yield (Burdman et al., 1998). These positive effects may be attributed to early and increased nodulation, enhanced N_2-fixation rates, and a general improvement of root development. Nodulation may be enhanced because a greater number of epidermal cells differentiate under the influence of *Azospirillum* into root hairs susceptible to rhizobium infection (Burdman et al., 1998). Nodulation may also be stimulated by an increased secretion of flavonoids that are involved in the activation of the nodulation genes in *Rhizobium* under the influence of co-inoculated *Azospirillum* (Burdman et al., 1996; Volpin et al., 1996).

Acknowledgment. We dedicate this chapter to Dr. Johanna Döbereiner, who died in October 2000 in Rio de Janeiro, in honor of her outstanding contributions and discoveries relating to *Azospirillum* and other rhizosphere diazotrophic bacteria.

CHAPTER 3.1.6

The Genus *Herbaspirillum*

MICHAEL SCHMID, JOSE IVO BALDANI AND ANTON HARTMANN

Historical Aspects

Owing to its cell form, growth behavior and habitat within grass roots, the first isolates of the later defined genus *Herbaspirillum* were initially thought to be a new *Azospirillum* species (Baldani et al., 1984). However, RNA-RNA hybridization experiments showed no close relatedness with *Azospirillum* spp. or *Aquaspirillum itersonii* (Falk et al., 1986). The first species of the newly defined genus *Herbaspirillum*, *Herbaspirillum seropedicae* (Baldani et al., 1986), was named after the location of the EMBRAPA National Center for Agrobiology (CNPAB) in Seropedica, Rio de Janeiro, Brazil. The genus *Herbaspirillum* was extended with [*Pseudomonas*] *rubrisubalbicans*, causative agent of "mottled strip disease" in some susceptible sugar-cane varieties, because DNA-rDNA and DNA-DNA reassociation hybridization studies showed a high degree of DNA similarity (Gillis et al., 1990; Baldani et al., 1992). Additional physiological and biochemical features, including the ability to fix nitrogen, confirmed the reclassification as *Herbaspirillum rubrisubalbicans* (Baldani et al., 1996). A group of clinical isolates (EF group 1) had to be included in the genus *Herbaspirillum* as "species 3" because of its molecular and overall physiological relatedness. However, members of *Herbaspirillum* species 3 do not exhibit nitrogen-fixing ability. More recently, several new species of *Herbaspirillum* were isolated from diverse plants like *Miscanthus sinensis* and *Pennisetum purpureum* (*H. frisingense*; Kirchhof et al., 2001) and nodules of *Phaseolus* (*H. lusitanum*; Valverde et al., 2003). On the basis of molecular relatedness, a group of bacteria having the ability to efficiently degrade chlorophenols was also included in the genus *Herbaspirillum* as *Herbaspirillum chlorophenolicum* (Im et al., 2004). Although most of the bacteria in the genus *Herbaspirillum* are N_2-fixing bacteria colonizing diverse plants endophytically (Döbereiner, 1992; Döbereiner et al., 1993), clinical and environmental isolates belong to this genus, too. This resembles the situation in other species of the Betaproteobacteria, where plant-associated or even symbiotic diazotrophs, opportunistic pathogens, and potent degraders of pollutants belong to the same genera like *Burkholderia* (Coenye and Vandamme, 2003), *Ralstonia* (Chen et al., 2001) and *Azoarcus* (Reinhold-Hurek and Hurek, 2000).

Taxonomy Aspects

Herbaspirillum spp. are members of the Betaproteobacteria which include many plant-associated bacteria such as the above-mentioned genera—*Azoarcus*, *Burkholderia* or *Ralstonia*. According to results based on DNA or RNA analyses, the genus *Herbaspirillum* belongs to the RNA superfamiliy III (De Smedt et al., 1980). DNA and RNA similarity studies clearly separate *Herbaspirillum* spp. from other betaproteobacterial genera and demonstrate a very high genomic DNA similarity in each of the *Herbaspirillum* spp.

Using the 16S-rDNA-based molecular phylogenetic approach the now known five species of *Herbaspirillum* form a close cluster within the Betaproteobacteria. The phylogenetic tree (Fig. 1) illustrates the position of the *Herbaspirillum* spp. and its closest relatives in the Betaproteobacteria. The tree was constructed by a maximum likelihood analysis, and the topology was confirmed by using a distance and maximum parsimony analysis. The 16S rDNA sequence similarity values within the genus *Herbaspirillum* are 98.5–99.4% and were clearly distinct from those of the next nearest relatives, i.e., the *Ultramicrobacterium* strains D-6 and ND5 (Iizuka et al., 1998) with 95.8–97.3% sequence similarity as well as *Janthinobacterium lividum* and *Oxalobacter formigens* with 95.4–96.2% and 94.6–95.4% (Sievers et al., 1998) sequence similarity, respectively. Within the different *Herbaspirillum* species, the 16S rDNA sequence similarities are very high. For example, *Herbaspirillum frisingense*, comprising isolates from different fiber plant tissues from Germany and Brazil, forms a tight cluster with 16S rRNA similarities of 98.9–99.4% (Kirchhof et al., 2001). Compared to the

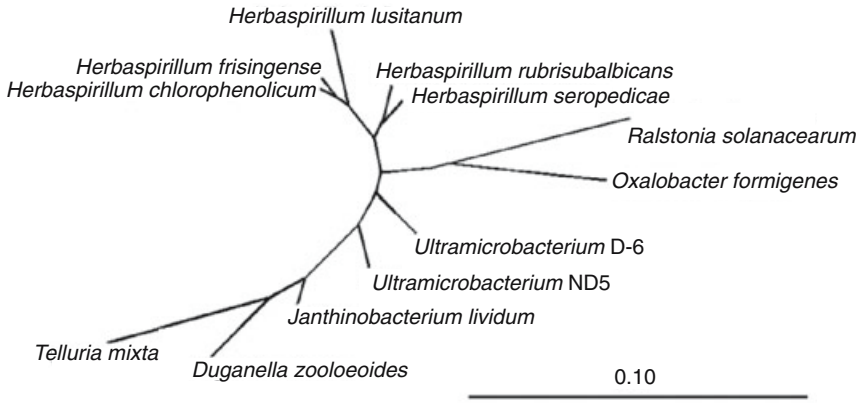

Fig. 1. 16S rDNA phylogenetic tree of *Herbaspirillum* (consensus tree). For the calculation of the phylogenetic tree, almost complete 16S rDNA sequences of the validly named *Herbaspirillum* spp. and most closely related members of the Betaproteobacteria were used. Only sequence positions which are represented in more than 50% of the members of the shown Betaproteobacteria were used for the calculation. The phylogenetic tree is based on "maximum likelihood" analysis and the topology of the tree was checked with "maximum parsimony" and "distance matrix" analyses.

Table 1. 16S rRNA-targeted oligonucleotide probes for fluorescence in situ hybridization (FISH-analysis) of *Herbaspirillum* spp.

Hfris 445	TCCAGAACCGTTTCTTCC	445–462	*H. frisingense*	50

From Kirchhof et al. 2001.

type strain of *Herbaspirillum seropedicae* (LMG 6513^T), *H. frisingense* strains have 16S rDNA sequence similarities of 98.7–99.1%. The high 16S rDNA similarity of 98.5–99.4% within the genus *Herbaspirillum* does not conclusively imply the differentiation of distinct species (Stackebrandt and Goebel, 1994). However, genomic DNA-DNA hybridization clearly allowed the differentiation, because the percentage of chromosomal DNA reassociation was 11% and 34% between *H. seropedicae* LMG 6513^T, *H. frisingense* [DSM13128]^T and *H. rubrisubalbicans* [LMG 2286]^T, respectively. Within the different species, the DNA-DNA hybridization values are 60–100% and the overall DNA G+C content (mol%) is 61–65% in all *Herbaspirillum* spp.

On the basis of the complete 16S rDNA sequences and the use of ARB-software for sequence analysis (Ludwig et al., 2004), it was possible to create a set of phylogenetic oligonucleotide probes on the genus and the species level (Hartmann et al., 2000; Kirchhof et al., 2001; M. Schmid and M. Rothballer, unpublished observation; Table 1). Using these probes, *H. seropedicae*, *H. rubrisubalbicans*, *H. frisingense* and *H. lusitanum* cells can easily be identified using the fluorescence in situ hybridization (FISH) technique (Amann et al., 1990; Wagner et al., 2003). In addition, 23S rDNA-directed oligonucleotide probes HS and HR complementary to a highly variable stretch of helix (position 55 to 59) of the 23S rRNA of *H. serpedicae* and *H. rubrisubalbicans* were developed (Kirchhof et al., 1997b). These probes were used for radioactive or nonradioactive filter hybridization in the identification of newly obtained isolates (Kirchhof et al., 1997a) but are not suitable for FISH analysis. They cannot be used, e.g., for specific differentiation between *H. rubrisubalbicans* and *H. frisingense*.

Polymerase chain reaction (PCR)-fingerprinting can be applied for the differentiation of DNA at the level of strains (Rademaker and De Bruijn, 1997). The clonal diversity of a variety of *Herbaspirillum* isolates was analyzed with different randomly amplified polymorphic DNA (RAPD) primers (Soares-Ramos et al., 2003) and primers directed to sequences derived from eukaryotic LINEs (long interspersed nuclear elements) conserved in all cells (Smida et al., 1996; Kirchhof et al., 2001; Valverde et al., 2003). The separation power was higher than the one obtained or achievable by amplified rDNA

restriction analysis (ARDRA) using four endonucleases *Alu*I, *Hae*III, *Hinf*I and *Rsa*I (Cruz et al., 2001). When different *Herbaspirillum* species were compared, RAPD- and LINE-analysis-derived banding patterns confirmed the different species, and it became additionally apparent that isolates of the same species (e.g., *H. frisingense*), originating from different plants, exhibit a different, although related, genomic fingerprint (Kirchhof et al., 2001). Isolates from roots, stems and leaves of banana formed a separate group (Soares-Ramos et al., 2003) which may even represent a new species. These findings indicate that the genetic diversity of plant-associated bacterial strains can be correlated with their plant origin (McArthur et al., 1988), reflecting a possible coevolution of plant endophytic bacteria with their hosts.

Habitats and Ecology

The origin of bacteria of the genus *Herbaspirillum* was mostly plant material, and the isolated strains showed the ability to fix nitrogen. In many cases, plant-associated *Herbaspirillum* spp. were found in apoplastic (Olivares et al., 1997; Elbeltagy et al., 2001) or intracellular locations (James et al., 1997; Olivares et al., 1997). When associated with plants, either as an asymptomatic bacterium or as a causal agent of mild disease, *Herbaspirillum* species have been found in species of the family Gramineae, like rice, wild rice (*Oryza officinalis*), *Sorghum bicolor*, *Miscanthus sinensis*, and *Pennisetum purpureum* (Baldani et al., 1996; Elbeltagy et al., 2000; Kirchhof et al., 2001). They are also associated with dicotyledoneous plants and could be isolated from root nodules of the legume *Phaseolus vulgaris* (Valverde et al., 2003) and roots as well as stems of different cultivars of banana (*Musa* spp.) and pineapple (*Ananas comosus* (L.) Merril; Weber et al., 1999; Weber et al., 2001; Cruz et al., 2001).

Some strains of *H. rubrisubalbicans* are mild pathogens of some susceptible sugar-cane varieties causing "mottled stripe disease"; they occur mainly in crops highly fertilized with nitrogen. However, all commercially used sugar-cane varieties in Brazil are resistant to this disease and *H. rubrisubalbicans* and *H. seropedicae* did not produce any characteristic symptoms when artificially inoculated into leaves by injection (Olivares et al., 1997). In addition, strains of *H. seropedicae* and *H. rubrisubalbicans* cause "red stripe disease" in *Pennisetum purpureum* as well as in *Sorghum bicolor* although symptoms are very mild in *Sorghum* leaves inoculated artificially (Pimentel et al., 1991; Olivares et al., 1997). No symptoms were observed in maize plants inoculated with *H. seropedicae* and *H. rubrisubalbicans*. In addition, no visible pathologic symptoms were apparent when *H. frisingense* was inoculated to *Miscanthus sinensis* seedlings (Eckert, 2003). In a survey to characterize the rhizobial community in nodules of *Phaseolus vulgaris*, isolates of a novel *Herbaspirillum* species, *H. lusitanum* ([LMG21710])^{T}, were obtained recently (Valverde et al., 2003). These bacteria were demonstrated to be infectious to *P. vulgaris* roots under axenic conditions, confirming the endophytic character of *H. lusitanum*.

In contrast to these plant associated *Herbaspirillum* spp., bacterial isolates (EF-group 1; Falsen, 1996) from different clinical specimens were grouped as *Herbaspirillum* sp. 3 (Gillis et al., 1991). Finally, an isolate from a 4-chlorophenol contaminated soil sediment was validly named "*H. chlorophenolicum* ([CPW301])^{T}" ([KCTC12096]^{T}; Im et al., 2004). This isolate was originally named "*Comamonas testosteroni*", collected from a stream near an industrial region in Cheongju, Korea, and selectively enriched using 4-chlorophenol as the sole carbon and energy source (Bae et al., 1996).

The majority of *H. seropedicae* and *H. rubrisubalbicans* isolates has been found in plants of tropical areas in numbers varying from 102 to 107 cells per g of fresh plant tissue (Table 2). Strains of *H. seropedicae* were first isolated from washed and surface sterilized roots of maize, sorghum and rice grown in two different soils in Rio de Janeiro State as well as from maize plants grown in a Cerrado soil in Brasilia, DF, Brazil (Baldani et al., 1986). Only a few isolates were obtained from rhizosphere soil (Baldani et al., 1986). Since *H. seropedicae* could not survive well in soil (Olivares et al. 1996), small root pieces could have been present in the rhizosphere soil used by Baldani et al. (1986).

Herbaspirillum seropedicae is a plant-endophytic bacterium (James and Olivares, 1998; James et al., 2002) infecting and colonizing tissues of rice roots mostly in the intercellular space, the apoblast. Using electron microscope analysis, *H. rubrisubalbican*s was localized in the intercellular space of the xylem and in the substomatal cavities of a mottled stripe susceptible sugar-cane variety, where the bacteria are restricted to microcolonies encapsulated within membranes of plant cell origin (Olivares et al., 1997). *Herbaspirillum seropedicae* and *H. rubrisubalbicans* were localized in the xylem in sugar-cane roots (Olivares et al., 1997) and *H. frisingense* in intercellular spaces of the root cortex and the root vascular tissue of *Miscanthus sinensis* roots (Eckert, 2003).

Isolation Procedures

Isolations of the nitrogen-fixing species *Herbaspirillum seropedicae*, *H. rubrisubalbicans* and *H. frisingense* take advantage of their ability to fix nitrogen under microaerobic conditions, as in the case of other microaerobic nitrogen-fixing bacteria like *Azospirillum* and *Gluconacetobacter* (Döbereiner, 1990). Serial dilutions of macerated root, stem or leave samples are inoculated into serum vials with nitrogen-free semisolid (1.75 g of agar/liter) NFb or JNFb medium (Table 3) and incubated at 32°C for one week (Döbereiner, 1995). In vials which exhibit a fine white pellicle, cells are examined under the microscope for the presence of small curved rods (0.6–0.7 × 4–6 μm). Following a transfer to fresh JNFb semisolid medium and incubation for 24–48 h, cultures are streaked out on solid JNFb medium containing 20 mg of yeast extract per liter and three times the bromothymol blue concentration of the JNFb medium. *Herbaspirillum seropedicae* and *H. rubrisubalbicans* form small moist white colonies with a green or dark blue center, in contrast to white colonies of *Azospirillum lipoferum* and *A. brasilense*. In the case of *H. frisingense*, the colored center of the colonies is not as highly marked as in the typical colonies of *H. seropedicae* and *H. rubrisubalbicans*. For final purification, single colonies are transferred to JNFb semisolid medium and cells from the typical pellicle are streaked onto moist BMS agar plates. Moist, smooth and small brownish colonies develop in the case of *H. seropedicae* and *H. rubrisubalbicans* (Baldani et al., 2003).

The original isolation of *H. lusitanum* (Valverde et al., 2003) was performed according to Vincent (1970) using YMA agar (Bergersen, 1961), because it was intended to isolate *Rhizobia*. On these plates, the colonies of *H. lusitanum* were mucoid, circular convex, white, slightly translucent, and usually 1–2 mm in diameter after two days at 28°C.

Herbaspirillum chlorophenolicum (Im et al., 2004), formerly *Comamonas testosteroni*, was isolated from a contaminated soil sediment near a stream in an industrial region of Korea (Bae et al., 1996) using 4-chlorophenol as the sole carbon and energy source.

Preservation of Cultures

Strains can be preserved in glycerol at –20°C or –80°C by mixing equal volumes of sterilized glycerol and washed, resuspended cells from a 48-h old culture grown in liquid JNFb medium (containing 20 mg of yeast extract and 5 mM ammonium chloride or sodium glutamate). Strains can also be kept lyophilized for many years. Cells grown on slant JNFb medium with D-glucose instead of malic acid for 48–72 h at 30°C are suspended in 2 ml of a 10% sucrose solution and

5% peptone in 100 ml water. Aliquots are distributed into lyophilization ampoules and lyophilized.

Stock cultures can also be maintained on JNFb or BMS agar under a layer of sterilized mineral oil in tubes tightly sealed with rubber caps. Under these conditions, *H. seropedicae* remains viable at room temperature for at least 12 years (Baldani et al., 2003).

Identification

Cells of *Herbaspirillum* spp. exhibit Gram-negative staining. As originally described by Baldani et al. (1986) and Baldani et al. (1996), they generally have a vibroid cell shape, but they are, depending on the growth conditions, spirillum-shaped with a diameter of approximately 0.6–0.7 μm. Cell length depends on the culture medium and varies between 1.5 μm and 5.0 μm. They are very motile, using one to three flagella at one or both poles (Baldani et al., 2003).

The organisms have a strictly respiratory type of metabolism and sugars are oxidized but not fermented. With the exception of *Herbaspirillum* sp. 3 and *H. chlorophenolicum*, herbaspirilla are able to fix atmospheric N_2 under microaerobic conditions. They are oxidase and urease positive, but the catalase is variable or weak. The favored carbon sources are salts of organic acids like malate, pyruvate, succinate and fumarate both for NH_4^+ or N_2-dependent growth. Other carbon sources like glycerol, mannitol, D-glucose and sorbitol are also catabolized. However, sucrose cannot be utilized. Phenotypic characteristics which separate the five validly named *Herbaspirillum* spp. are summarized in Table 4. As shown by Valverde et al. (2003), *Herbaspirillum* spp. also exhibit a unique antibiotic resistance pattern which may also be used for differentiation.

The optimal temperature is 30–34°C and optimal pH, 5.3–8.0. The colonies on JNFb agar plates containing bromothymol blue are smooth and white with blue or green centers after one week of incubation.

Herbaspirillum seropedicae, *H. rubrisubalbicans* and *H. frisingense* can rapidly be identified using 16S rRNA-directed oligonucleotide probes and the fluorescence *in situ* hybridization (FISH) technique (Kirchhof et al., 2001; Table 1; Fig. 1).

Physiology

Herbaspirillum spp. are microaerophilic nitrogen-fixing bacteria except the mostly clinical *Herbaspirillum* species 3 and the very recently renamed species *H. chlorophenolicum* (Im et al., 2004). The diazotrophic herbaspirilla form a pellicle below the surface in nitrogen-free semisolid agar because of their microaerobic characteristic. They cannot grow or fix nitrogen in liquid N-free medium under air. However, nitrogenase activity can be detected under air when grown in liquid JNFb medium supplemented with L-glutamate and L-glutamine but not with L-serine, L-alanine or ammonium chloride when the nitrogen source is exhausted from the medium (Klassen et al., 1997). This is in contrast to some species of the genus *Azospirillum*, which can grow and fix nitrogen simultaneously, e.g., on glutamate as sole carbon and nitrogen source (Hartmann et al., 1988). Other nitrogen sources such as L-histidine, L-lysine, L-arginine or the amines methylammonium chloride, tetramethylammonium chloride, and ethylenediamine chloride do not support growth or nitrogen fixation by *H. seropedicae* (Klassen et al., 1997). *Herbaspirillum seropedicae* can assimilate or dissimilate nitrate to nitrite under oxygen limitation, but no nitrate-dependent anaerobic growth or visible gas production from nitrate is observed. However, small amounts of nitrous oxide (N_2O) are detected in the presence of 10% acetylene. Most strains of *H. rubrisubalbicans* also reduce nitrate to nitrite, but denitrification has not been observed. *Herbaspirillum chlorophenolicum* is not able to reduce nitrate to nitrite.

Compounds that can serve diazotrophic *Herbaspirillum* spp. as sole carbon and energy sources for N_2-dependent growth include malate, succinate, citrate, α-ketoglutarate, fumarate, pyruvate, *trans*-aconitate as well as mannitol, glycerol, sorbitol, glucose, galactose, and L-arabinose. *N*-Acetylglucosamine is used as sole carbon source for N_2-dependent growth by *H. seropedicae*, *H. frisingense* and *H. lusitanum* but not by *H. rubrisubalbicans*. In contrast, *meso*-erythritol is only used by *H. rubrisubalbicans* when the mannitol component of YMA medium is replaced by this carbon source and a nitrogen source like ammonium chloride is present in the medium.

Herbaspirillum seropedicae is the most intensively studied *Herbaspirillum* species. Since *H. seropedicae* is a diazotrophic plant growth promoting bacterium with potential for application as "green fertilizer," the studies focus on the nitrogen metabolism, especially the molecular organization and regulation of nitrogen fixation and ammonium assimilation genes and activities. The structural organization and regulation of the nitrogen fixation genes are well known (Machado et al., 1996; Klassen et al., 1999; Pedrosa et al., 2001). Nitrogen fixation in this organism occurs under microaerobic conditions and is tightly regulated by nitrogen compounds both at the level of synthesis and activity. In addition, ammonium causes a rapid and reversible switch-off of nitrogenase activity in *H. seropedicae*, as it does in *Azospirillum brasilense* and *A. lipoferum* (Hartmann et al., 1986; Fu and Burris, 1989). The central regulator of nitrogen control is the NifA protein, the *nif*-specific transcriptional activator in response to the levels of fixed nitrogen and oxygen (Souza et al., 1999). In addition, the general nitrogen control of the cell is regulated by NtrC, which also controls the expression of the *glnA* gene coding for glutamine synthetase, the key enzyme of the high affinity ammonium assimilation pathway (Persuhn et al., 2000; Souza et al., 2000). In contrast to the gamma-proteobacteria *Klebsiella pneumoniae* and *Azotobacter vinelandii*, where the NifL protein forms an inactive complex with the NifA protein in the presence of high levels of ammonium and oxygen, the NifA-protein is directly inactivated in response to increased levels of nitrogen and oxygen in *H. seropedicae* and the alpha-proteobacterium *Azospirillum brasilense* (Souza et al., 1991; Arsène et al., 1996). Although the mechanism of NifA activity control differs in these two groups of bacteria, the signaling pathways leading to the ammonium response have similarities. In strains of *A. brasilense* and *H. seropedicae*, which do not contain NifL, the P_{II} protein—the product of the *glnB* gene—is necessary for the ammonium control of NifA activity (Benelli et al., 1997). The signaling pathway for control of NifA activity by oxygen in rhizobia (*A. brasilense* and *H. seropedicae*) is probably sensed directly by their type of NifA protein (Monteiro et al., 1999). It has been suggested that the oxygen sensitivity of these NifA proteins involves a cysteine motif located at the end of the central domain and a linker region for the C-terminal domain, which resembles an iron-sulfur cluster-binding motif (Fischer et al., 1988). It has recently been demontrated that an alternative iron containing signal transducer for oxygen sensitivity of the NifA activity in *H. seropedicae* involves the Fnr protein, a general transcriptional regulator for the switch from aerobic to anaerobic metabolism

responsive to molecular oxygen (Monteiro et al., 2003). NifA expression is controlled by the general nitrogen regulation Ntr system which, in turn, is controlled by the state of the *glnB* product, the P_{II} protein. In *H. seropedicae*, the *glnA*, *glnB* and *ntrBC* genes have been identified (Benelli et al., 1997), suggesting that an Ntr/P_{II}-dependent signal transducer cascade senses the nitrogen levels in this organism, as it does in *A. brasilense*. A second P_{II}-like protein, called "GlnK" like in enteric bacteria, has been characterized in *H. seropedicae* (Benelli et al., 2002); it is regulated by uridylylation (Benelli et al., 2001).

Using gfp-reporter constructs, the in situ expression of the *nifH*-gene was recently demonstrated in *H. seropedicae* Z67 during the endophytic colonization of different gramineous plants (Roncato-Maccari et al., 2002). Similar results of *in situ nifH*-activity were obtained with *Azoarcus* sp. BH72 colonizing rice roots endophytically (Reinhold-Hurek and Hurek, 1998).

Application

Owing to their ability to fix nitrogen and to produce phytohormones (Bastián et al., 1998; Lambrecht et al., 2000), the diazotrophic *Herbaspirillum* spp. have the potential of plant growth promotion and associative nitrogen fixation (Baldani et al., 1995; Boddey et al., 1995; James, 2000). *Herbaspirillum* spp. are aggressive colonizers of the root interior, establishing themselves not only in the cortex and vascular tissues of roots but also systemically in the whole plant. Using axenic systems of different plants, a significant stimulation of root development due to inoculation by *H. seropedicae* (Baldani et al., 1993) and *H. frisingense* (Eckert, 2003) was demonstrated. Up to now only *Herbaspirillum seropedicae* strains have been applied in field experiments. Pereira et al. (1988) and Baldani et al. (2000) showed significant yield increases of sorghum and rice when inoculated with *H. seropedicae*. Increases of dry weight and grain yield were also observed in rice plants inoculated with several strains of *H. seropedicae* (Döbereiner and Baldani, 1998). Certain aluminum (Al)-tolerant rice varieties were stimulated in growth and nitrogen accumulation because of inoculation with *Herbaspirillum seropedicae* (Gyaneshwar et al., 2002). *Herbaspirillum*-inoculated Al-tolerant varieties (e.g., cv. Moroberekan) showed significantly more $^{15}N_2$ incorporation and higher N-contents than did the Al-sensitive variety IR45. Al-tolerant varieties secrete larger amounts of C in their root exudates, and bacteria colonizing the roots of cv. Moroberekan strongly expressed gusA- and NifH-proteins. Since *Herbaspirillum* spp. are frequently occurring in agricultural soils in the tropics and subtropics, the inoculation effect is sometimes difficult to assess because of the lack of a clear negative control. It is also possible that *Herbaspirillum* spp. are distributed and introduced through the seeds or plant stocks in the field.

Acknowledgment. This chapter is dedicated to the late Dr. Johanna Döbereiner. Her enthusiasm for plant associated nitrogen-fixing bacteria led to the original discovery of *Herbaspirillum* and many other diazotrophs at the EMBRAPA Center for Agrobiological Research in Seropedica, Rio de Janeiro, Brazil.

CHAPTER 3.1.7

The Genus *Beijerinckia*

JAN HENDRIK BECKING

Analysis of rRNA cistrons of *Beijerinckia* species (De Smedt et al., 1980) and rRNA cistron similarities as observed in DNA-rRNA hybridization experiments (De Vos et al., 1985) has demonstrated that the genus *Beijerinckia* is not phylogenetically related to the family of Azotobacteraceae (genera *Azotobacter* and *Azomonas*), but that it belongs to the alpha subclass of the purple bacteria (Stackebrandt et al., 1988) or the fourth rRNA superfamily of De Ley (De Smedt et al., 1980). Its closest relatives appear to be *Xanthomonas autotrophicus*, *Mycobacterium flavum*, a number of *Pseudomonas* species (*P. azotocolligans* and *P. diminuta*), and some authentic rhodopseudomonads. Furthermore, within the same subclasses as *Beijerinckia* are also found the genera *Azospirillum*, *Agrobacterium*, *Rhizobium*, *Acetobacter*, *Gluconobacter*, and *Zymomonas*.

Representatives of the genus *Beijerinckia* are characterized as nonsymbiotic (i.e., free-living), aerobic, chemoheterorophic bacteria with the ability to fix atmospheric nitrogen. They can be distinguished from other nitrogen-fixing bacteria by cell morphology and some physiological characteristics. Members of this genus have typical rod-shaped cells with round ends containing polar lipoid bodies. Moreover, *Beijerinckia* species show great acid tolerance, being able to grow and fix dinitrogen at pH 3.0–4.0. On agar media (nitrogen-free, glucose mineral agar), they usually produce highly raised colonies of very tenacious and elastic slime, and on liquid media they turn the whole medium viscous (see Fig. 3). For more detailed characteristics see the section on "Identification" in this Chapter and Becking (1974a).

The genus is named for M.W. Beijerinck (1851–1931), a famous Dutch microbiologist.

Habitats

Beijerinckia was originally isolated from a Malaysian quartzite soil (pH 4.5) by Altson (1936), from a Dacca, Bangladesh, soil (pH 4.9), from a soil of Insein, Burma (pH 5.2), by Starkey and De (1939; type species description). Later it was found to be widely distributed in the more acidic soils of mainly tropical regions. Although it is found primarily in acid soils, it can also be isolated from neutral and slightly alkaline tropical soils using an acid (pH 5.0) enrichment medium. *Beijerinckia* is a relatively slow grower and, using neutral or alkaline enrichment media, it cannot compete against the faster growing *Azotobacter* species. In the tropics, it is mainly present in eluvial, lateritic soils and normally absent in illuvial soils (Becking, 1961a, 1961b, 1974b; Kluyver and Becking, 1955). It is, however, also found sporadically outside the tropics.

In a large soil survey covering 392 soils of worldwide distribution, *Beijerinckia* was found in some temperate and subtropical soils of Europe (Yugoslavia), South Africa, continental Asia (India), China (Hong Kong, Kwantung), and Japan (Tokyo, Nikko National Park, etc.) (Becking, 1959, 1961a). Other authors mention its isolation from other nontropical soils, i.e., from an acidic volcanic ash soil of Sendai, Tohoku District, Japan (lat. 38°N) (Suto, 1954, 1957); from some Indian nontropical soils (up to lat. 27–30°N) (Barooah and Sen, 1959); in some subtropical and nontropical soils in Australia (lat. 15–43°S) (Tchan, 1953; Thompson, 1968); and in two soils of Egypt (Kharga Oasis, lat. 25°N) (Vančura et al., 1965). In addition, it was isolated from some Pacific Northwest soils in North America (Snake River Plain, Idaho, USA; lat. 44°N), from soil of the Squamish Bay Area, British Columbia, Canada (lat. 50°N) by Anderson (1966), and from a Montalto stony loam (pH 6.0) of Rockton, not far from the Delaware River in New Jersey, USA (lat. 40°N), by R. L. Starkey (personal communication, 1974). Also, Jordan and McNicol (1978) reported the isolation of *Beijerinckia* from a permanently cold, high Arctic soil (Devon Island, Northwest Territories; lat. 75°N).

In addition to some South African soils (Becking, 1959, 1961a) *Beijerinckia* was observed to be widely distributed in the more tropical soils of the African continent. Evidence of its ubiquitous occurrence was obtained in soils of Zimbabwe (Meiklejohn, 1968), Ivory Coast (Kauffmann and Toussaint, 1951a, 1951b) Sierra Leone, Nigeria, Ethiopia, Uganda, Kenya, Tanzania, and Congo/Zaire (Becking, 1961a). *Beijerinckia* was also found in many soil samples of the South American continent and neighboring islands: Trinidad Islands, Surinam, Venezuela, Bolivia, and Brazil (Becking, 1961a). Large surveys that

This chapter was taken unchanged from the second edition.

include many soils of different types from various tropical and nontropical regions of worldwide distribution are given by Becking (1961a) and for the Australian continent by Thompson (1968). The latter author surveyed tropical, subtropical, and nontropical Australian soils for *Beijerinckia* species (Thompson and Sherman, 1979) and 46% of 155 soils of Queensland and northern New South Wales (26°40′–30°30′ S) were *Beijerinckia* positive but only 10% of 10 soils of southern New South Wales (34°70′ S) were positive, indicating again a tropical preference of *Beijerinckia*. Seven soils of South Australia (34°91′ S) and 12 soils of Tasmania (40°70′–43°40′ S) did not contain *Beijerinckia*, but of 12 soils examined from Victoria (37°60′–38°40′ S), 16.7% contained *Beijerinckia*. *Beijerinckia* occurred in the above-mentioned soil samples in the pH range 4.5–6.9, but most frequently in samples from pH 5.0–6.4. In a certain type of grumusol (Oakes and Thorp, 1950), which exhibits gilgai microrelief by topographic variation in mounds and shelfs, in 15 randomly selected samples at each site, only the shelf soils contained *Beijerinckia* (33% of the soils) and none of the mound soils contained it. The shelf soils had a pH of 6.3 and the mound soils were of pH 7.7.

Döbereiner and Alvahydo (1959) and Döbereiner (1961) noted increased numbers of *Beijerinckia* in rhizosphere soils of sugarcane cultivated under irrigated conditions compared to normal soil. Ruinen (1956, 1961) found *Beijerinckia* as a regular component of the phyllosphere of tropical plants.

Diem et al. (1978) have used the fluorescent antibody technique to study the behavior of a *Beijerinckia* isolate in the rhizosphere and seed region (spermosphere) of rice seedlings. Also in rice, Karkhanis and Tikhe (1980) and Karkhanis (1987) reported not only its presence in the rhizosphere, but also its intracortical occurrence within the rice root. The latter observation, however, needs confirmation.

Isolation

The most selective method for the isolation of *Beijerinckia* is the use of an acid nitrogen-free enrichment medium (Becking, 1961a; Derx, 1950a, 1950b). *Beijerinckia* is acid-resistant; therefore, the use of such a medium eliminates the growth of other microbes, especially the faster growing *Azotobacter* species.

General Enrichment Methods

Enrichment Medium for *Beijerinckia* (Becking, 1961a; Derx, 1950a, 1950b)

Distilled water	1 liter
Glucose	20.0 g
KH_2PO_4	1.0 g
$MgSO_4 \cdot 7H_2O$	0.5 g

Adjust to pH 5.0.

Trace elements such as iron are provided by the soil used as an inoculum. The medium is poured in thin layers (2–3 mm) into petri dishes to allow good access of oxygen and to inhibit the development of anaerobic, butyric acid bacteria (such as the nitrogen-fixing *Clostridium pasteurianum)* and facultative dinitrogen-fixing anaerobes. Approximately 0.5 g of soil per petri dish is used as inoculum. The enrichment cultures are incubated at 30°C. After 2 or more weeks, these enrichment cultures are examined microscopically for the presence of the characteristic *Beijerinckia* cells (i.e., blunt rods with two lipoid bodies, one at each end of the cell; Figs. 1 and 2). In an advanced stage of development, the entire enrichment medium changes into a viscous mass (Fig. 3). When positive on the basis of microscopic examination, the enrichment culture is

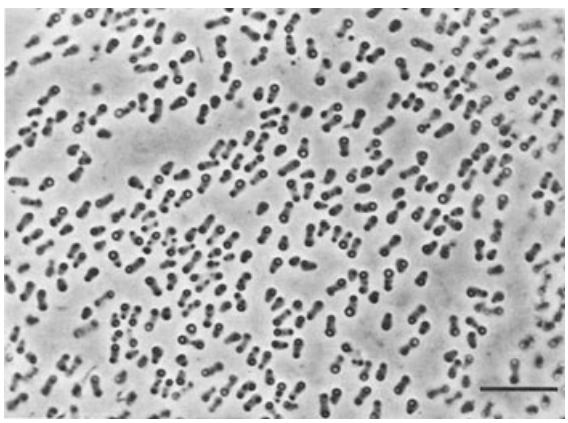

Fig. 1. *Beijerinckia indica* cells cultured in nitrogen-free glucose mineral agar (pH 5.0). The typical appearance of the cells and their intracellular polar lipoid bodies is illustrated. Living preparation, phase contrast microscopy. Bar = 10 µm.

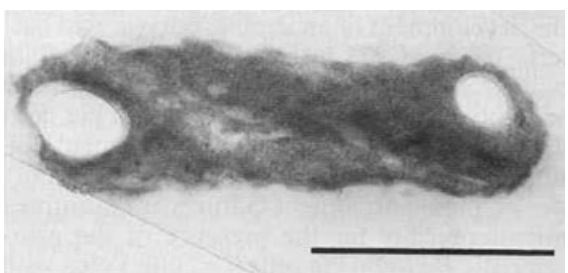

Fig. 2. *Beijerinckia indica* cell. Electron micrograph of a thin section showing the two polar lipoid bodies, which are surrounded by a membrane. Bar = 1 µm.

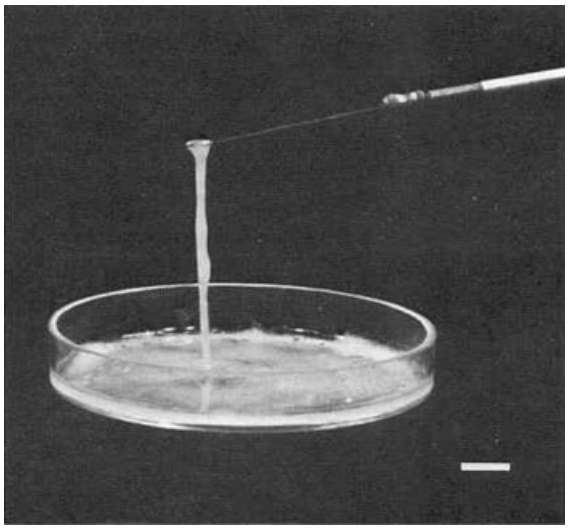

Fig. 3. Enrichment culture of *Beijerinckia*. The medium was inoculated with tropical soil. It demonstrates the highly viscous consistency of the medium after 3 weeks. Bar = 1 cm.

plated on the following nitrogen-free, mineral agar medium:

Isolation Medium for *Beijerinckia*

Distilled water	1 liter
Glucose	20.0 g
K_2HPO_4	0.8 g
KH_2PO_4	0.2 g
$MgSO_4 \cdot 7H_2O$	0.5 g
$FeCl_3 \cdot 6H_2O$	0.025 g (or 0.05 g)
$Na_2MoO_4 \cdot 2H_2O$	0.005 g
$CaCl_2$	0.05 g

Calcium may also be omitted; see "Cultivation." Adjust to pH 6.9.

Although an acid agar medium can be used for isolation, it is not recommended. After heat sterilization, such media tend to be soft or semisolid due to hydrolysis of the agar, and therefore the surface is difficult to inoculate with a needle.

Isolation from water sources (e.g., irrigation water of wet rice fields) is also possible, but the inoculum size should be large (10 ml or more/100 ml medium) because of the sparseness of this organism. More profitably, the sample is diluted with an equal volume of double-strength liquid enrichment medium (see above), and the pH of the medium is adjusted to 5.0 or lower. The medium is then dispensed into petri dishes in thin layers as described above.

For isolation from phyllosphere habitats, the same liquid enrichment medium (pH 5.0) can be used; the detached leaves are partially submerged in shallow layers of medium in petri dishes. On agar media, *Beijerinckia* develops characteristic, highly raised, glistening colonies of very elastic and tough slime (Fig. 4). For further purification, the same medium at neutral or alkaline pH is used with the addition of $CaCO_3$ (1 or 2% wt/vol) instead of $CaCl_2$. At alkaline pH, the slime is less tenacious and easier to dis-

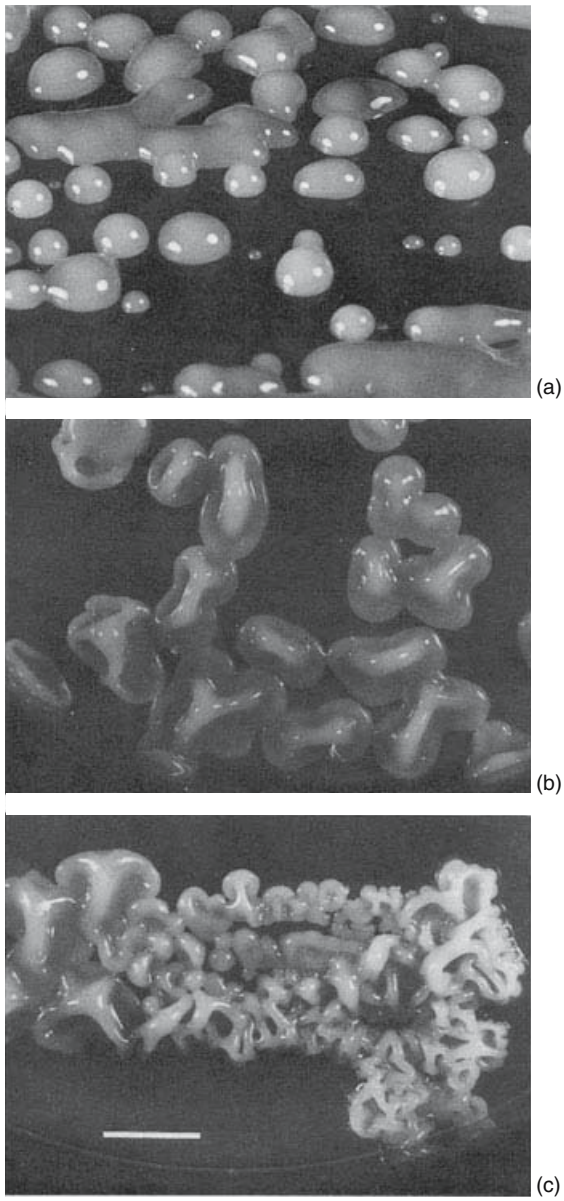

Fig. 4. (a) Typical colonies of *Beijerinckia indica* on nitrogen-free glucose mineral agar. The colonies are highly raised and have a very tough, elastic slime. In young cultures these colonies are colorless and transparent. (b) Typical colonies of an older culture of *Beijerinckia indica* on nitrogen-free glucose mineral agar. The colony turns opaque and its surface becomes plicated. (c) Typical colony of an aged culture of *Beijerinckia indica* on nitrogen-free glucose mineral agar. The colonies increase greatly in size due to copious slime production. The colonies become massive and opaque, with a plicated surface. In this stage they often become light reddish, pink, or cinnamon in color, especially on neutral or alkaline media. Bar = 1.0 cm.

solve in sterile tap water or in medium for the dilution series to obtain single-cell isolates.

When isolated, the *Beijerinckia* strains must be checked for purity by plating on plain peptone or broth agar. In contrast to *Azotobacter* and *Azomonas* species, *Beijerinckia* produces no growth on these substrates and contaminants are readily visible because they produce luxuriant development on these media.

Species-Specific Enrichment Procedures

So far, no species-specific isolation procedures are known for the five *Beijerinckia* species described. All strains obtained were random isolates from soil following the *Beijerinckia* general enrichment procedure, although the soil type may influence the occurrence of strains of certain species (see later). The isolated strains were generally only later assigned to the species level.

The use of various carbon compounds in the enrichment media offers no possibilities for species selection, because the utilization of these compounds is very variable within each species (see Tables 4.79 and 4.80, p. 318 in Becking, 1984). However, certain carbon sources might be used to increase the chance of obtaining certain species. For instance, citrate as sole source of carbon is used by 40% of the *Beijerinckia indica* strains and not by any of the other *Beijerinckia* species. Also, formate can be used for the specific enrichment of *Beijerinckia mobilis*, because it is weakly utilized by 70% of the *B. mobilis* strains, but not by the strains of any of the other species. In addition, propanol is utilized by all *B. mobilis* strains and only by 50% of the *B. indica* strains and not by *B. fluminensis* and *B. derxii*. Further, there is also a slight preference on the part of *B. mobilis* to utilize aromatic compounds (e.g., benzoate) compared to other *Beijerinckia* species. In this respect, it shows some resemblance to some representatives of the genus *Azobacter.*

The selection of the various species from plates obtained from the enrichment cultures is done primarily on the basis of colony morphology and chromogenesis (see "Identification" and "Species Differentiation," this chapter).

Cultivation

For routine maintenance or subculture, a nitrogen-free, glucose mineral agar medium of the following composition (g/liter of distilled water) can be used: Glucose, 20.0; K_2HPO_4, 0.8; KH_2PO_4, 0.2; $MgSO_4 \cdot 7H_2O$, 0.5; $FeCl_3 \cdot 6H_2O$, 0.025 or 0.05; $NaMoO_4 \cdot 2H_2O$, 0.005; $CaCl_2$, 0.05; and agar, 15.0. The pH is adjusted to 6.9. The $CaCl_2$ may be omitted to obtain a calcium-free medium.

Also a medium of similar composition, but with $CaCl_2$ replaced by $CaCO_3$ (10–20 g/liter), can be employed. As noted elsewhere (see "Physiological and Biochemical Properties" in this Chapter) *Beijerinckia* species do not require calcium for growth and $CaCO_3$ sometimes prolonged the lag phase of growth. However, sometimes, a more alkaline medium (containing $CaCO_3$) is preferred, especially for the isolation of the organism in pure culture, since on this medium, the polysaccharide slime is usually less tenacious and sticky and therefore easier to transfer with an inoculation needle.

The preferential growth temperature for *Beijerinckia* species is 25°–30°C; the growth range is from 10°–35°C.

Preservation of Cultures

Beijerinckia strains are usually lyophilized in skim milk or dextran-sodium glutaminate solution on filter paper and stored in the dark at room temperature.

Storage has also been achieved on the usual agar media in tubes plugged with sterile rubber seals with storage in the dark at room temperature (Antheunisse, 1972, 1973); after 10 years, 33% of the cultures retained viability. In the author's (J. H. Becking) laboratory, *Beijerinckia* cultures are stored under a seal of sterile liquid paraffin or mineral oil. Usually a nitrogen-free glucose mineral agar (see "Cultivation" in this Chapter) is employed for this purpose. Such cultures generally survive for at least 3–5 years.

Strains may also be preserved indefinitely in liquid nitrogen. At the Type Culture Collection in Delft, The Netherlands, dimethyl sulfoxide (10% vol/vol) is added to the liquid cultures in or at the end of log phase, and the cultures are frozen as rapidly as possible in liquid nitrogen. For recovery, the vials are thawed rapidly in a water bath at 37°C.

For routine use, cultures can also be kept in a refrigerator at –4°C for several months. Experiments have shown that cells are resistant to freezing, and no reduction of viability occurs when stored for 3–4 months at –4°C (Becking, 1961a).

Identification

Morphological and physiological properties are both important for the identification of *Beijerinckia* from other aerobic N_2 fixers. First, they can be distinguished from these by their high acid tolerance, which allows them to grow and to fix nitrogen in nitrogen-free media of pH 4.0 or 5.0 (sometimes, even pH 3.0). They are further

characterized by the failure to form a pellicle on the surface of liquid media and by their ability to make a liquid medium viscous by polysaccharide slime production. Moreover, on solid nitrogen-free media (nitrogen-free, glucose mineral agar) they produce characteristic, large, glistening, slimy colonies with a tough, tenacious, sometimes elastic slime (Fig. 4a). Because of this slime, it is often difficult to subculture portions of a colony for purification. The slime is semi-transparent in liquid media but more opaque on solid media. Often the surface of the colony becomes strongly plicated (Fig. 4b and c). On aging, the colonies sometimes develop a brick-red (*B. indica*) or amber-brown to mahogany-brown (*B. mobilis*) color. One species, *B. derxii*, excretes into the medium a water-soluble, green, fluorescent pigment.

Beijerinckia cells can be distinguished from those of *Azotobacter* and Azomonas species by their generally smaller size; by their rather unique rod form, sometimes with a somewhat pear- or dumbbell-shaped appearance, with rounded ends; and by the characteristic presence of a highly refractile lipoid body at each pole (Figs. 1 and 2).

Unlike *Azotobacter* and *Azomonas* species and many other nitrogen-fixing bacteria, *Beijerinckia* strains do not grow on plain peptone agar. For this reason, plating on peptone agar can be used for a purity test of *Beijerinckia* isolates. Many strains of *Beijerinckia* utilize nitrate poorly or not at all. In this respect, they differ from strains of *Azotobacter* species.

Although both *Beijerinckia* and *Derxia* produce slimy colonies on agar and viscosity in liquid media, *Beijerinckia* strains can be distinguished by 1) a failure to produce dark brown or mahogany-brown pigmented colonies (except some strains of *B. mobilis*, in which the color tends to be more amber brown); 2) cells containing bipolar lipoid bodies rather than numerous lipoid bodies throughout the whole cell, as in *Derxia*; 3) failure to form a pellicle at the surface of liquid media; and 4) a positive catalase reaction of the cells (negative in *Derxia*).

In routine screening by microscopic examination of colonies on agar plates, the characteristic appearance of the *Beijerinckia* cell is conclusive for its identification. *Beijerinckia* cells are unicellular, but sometimes appear to be bicellular due to cross-wall formation in the middle of the longitudinal direction of the cell (Figs. 5 and 6). Under certain conditions, *B. mobilis* strains showed coccoid cells without terminal lipoid bodies, especially on aging (Fig. 7). In average, *Beijerinckia* cells measure 1.7–4.5 μm in length and about 0.5–1.5 μm in diameter. Rarely, misshapen cells occur, of dimensions 3.0 × 5.0–6.0 μm, which are, in addition, occasionally branched or forked. The large, very prominent lipoid bodies at each end of the cell consist of poly-β-hydroxybutyrate as determined by chemical analysis (Becking, 1974b) and X-ray diffraction analysis (Fig. 8). The lipoid bodies are

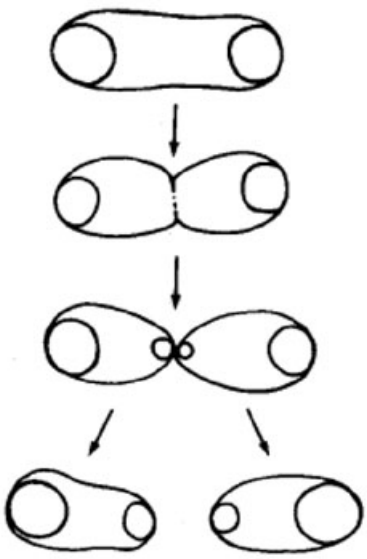

Fig. 5. Diagram of the life cycle of a *Beijerinckia* cell. A dividing cell forms a cross-wall in the middle of the longitudinal axis of the cell. In actively dividing cultures, intermediate stages can often be seen.

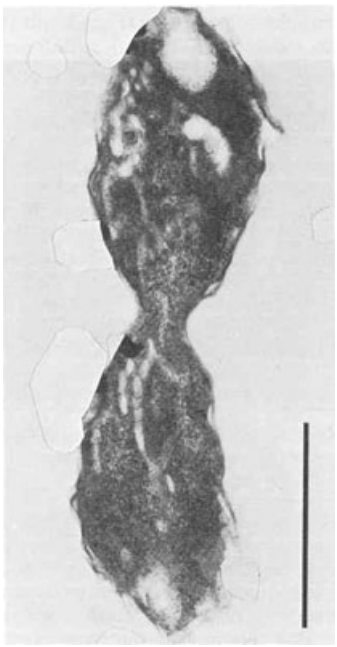

Fig. 6. Electron micrograph of a *Beijerinckia* cell in the process of division. The constriction in the middle of the cell is clearly visible and the two terminal lipoid bodies of the original cell can also be seen. Bar = 1 μm.

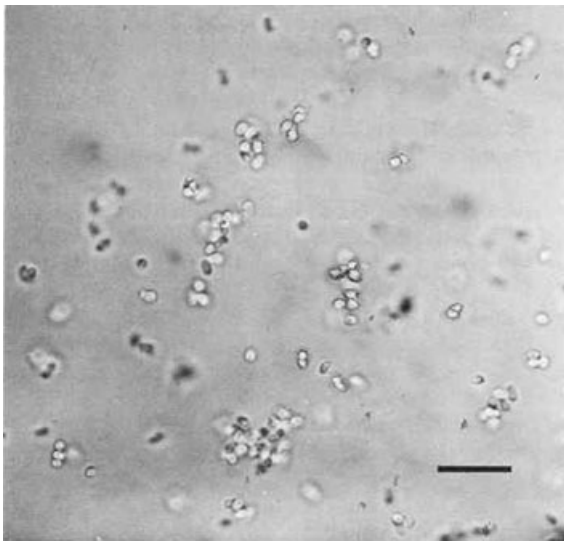

Fig. 7. *Beijerinckia mobilis* cells from an aged culture. The individual cells often lack the characteristic polar lipoid bodies and are more rounded in form, resembling certain *Azotobacter* species. Bar = 10 µm.

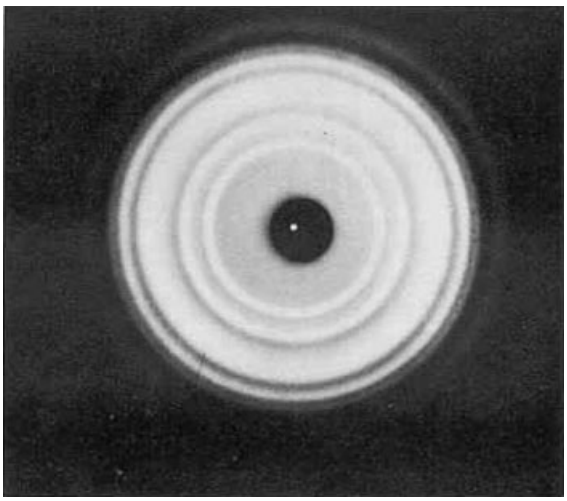

Fig. 8. X-ray diffraction diagram of crystalline poly-β-hydroxybutyrate powder obtained from *Beijerinckia*.

usually terminal in the cell, but sometimes, especially in *B. mobilis* strains, more than two lipoid globules per cell may occur (Fig. 9).

Cysts (enclosing one cell) and capsules (enclosing several cells) occur in some *Beijerinckia* species (*B. mobilis* and *B. fluminensis*, Figs. 10 and 11). The cells are Gram-negative. *Beijerinckia* species are motile by peritrichous flagella with the exception of some strains of *B. indica* (subsp. *lacticogenes*), but the flagellar arrangement has only been studied in a few strains (Hofer, 1944; Thompson and Skerman, 1979). Microscopic examination indicates that

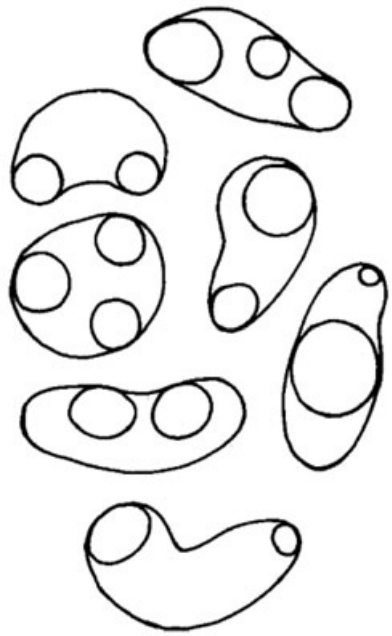

Fig. 9. Line drawing of *Beijerinckia mobilis* cells. Such misshapen cells may appear upon aging. The deformed cells show round, dumbbell, pear-shaped, or curved forms; sometimes even branched and forked forms may occur. Often, more than two lipoid bodies per cell may be present.

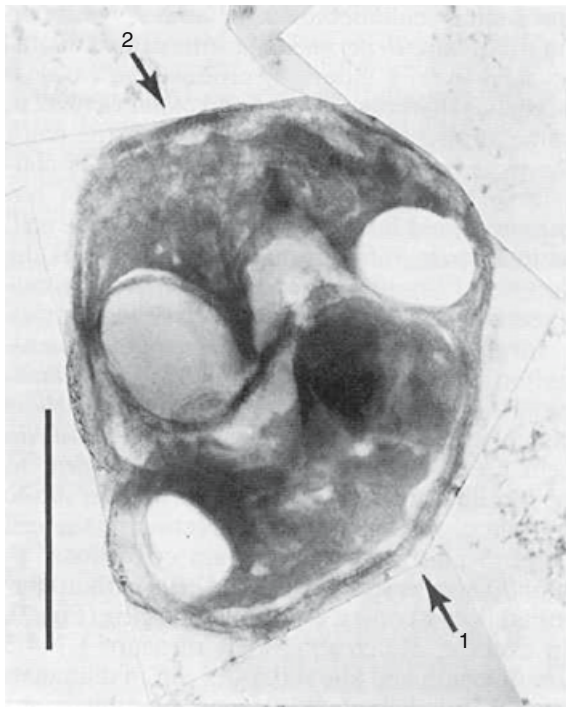

Fig. 10. Electron micrograph of a capsule of *Beijerinckia mobilis* containing two cells (see arrows 1 and 2). The terminal lipoid bodies of each cell and also the distinct capsular wall (see arrow 1) are visible. Bar = 1 µm.

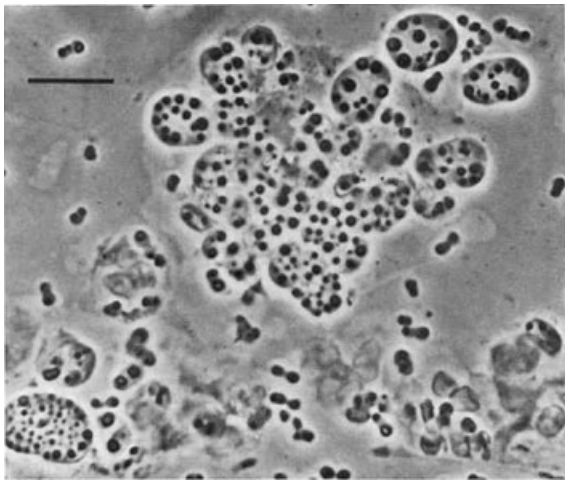

Fig. 11. *Beijerinckia fluminensis* cultured in nitrogen-free glucose mineral agar (pH 5.0), showing distinct capsule formation. The capsules enclose a large number of individual cells. Living preparation, phase contrast microscopy. Bar = 10 µm.

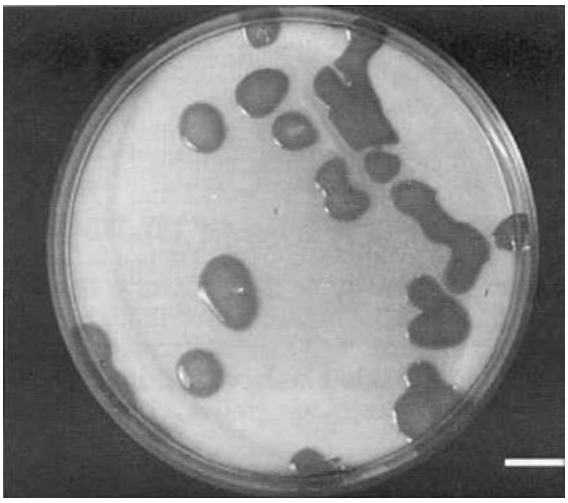

Fig. 12. Colonies of *Beijerinckia mobilis* on nitrogen-free glucose mineral agar containing $CaCO_3$. On alkaline media this species forms opaque, relatively flat *Azotobacter*-like colonies with a characteristic amber-brown pigment. The slime is less sticky than that of the other *Beijerinckia* species. Bar = 1 cm.

the flagella tend to originate in one-half of the often-dumbbell-shaped cells. The wave pattern is normal or curly, the wavelength has an average value of about 1.1–1.3 µm, and the amplitude is 0.26–0.35 µm. The amplitude of the waves in *B. fluminensis* and *B. derxii* strains is usually somewhat larger (up to 0.35 µm) than that in strains of *B. indica* (0.26 µm) (Thompson and Skerman, 1979). The GC content of the DNA of *Beijerinckia* species ranges from 54.7–60.7 mol% (T_m).

On nitrogen-free, glucose mineral agar (see "Cultivation" in this Chapter), colonies of *Beijerinckia* species exhibit various species-specific features in colony morphology and chromogenesis. For instance, *B. mobilis* colonies are flatter than those of *B. indica* and produce an uniform reddish brown or amber-brown colour on aging (Figs. 12 and 13). These colonies can readily be distinguished from those of *Azotobacter chroococcum* by their more reddish-brown color; *A. chroococcum* colonies are blackish brown. Moreover, in *B. indica* the slime is tenacious and difficult to remove, but in *B. mobilis* and *B. fluminensis* (Fig. 14) the slime is of more granular consistency, resembling that of *Azotobacter* or *Azomonas* species, and therefore is easier to remove. More details on colonial characteristics and pigmentation can be found under the individual species descriptions below. Thus colony characteristics can be used for rapid screening of isolates from plates obtained from enrichment cultures, prior to more precise identification by means of additional differential characteristics (see "Species Differentiation" in this Chapter).

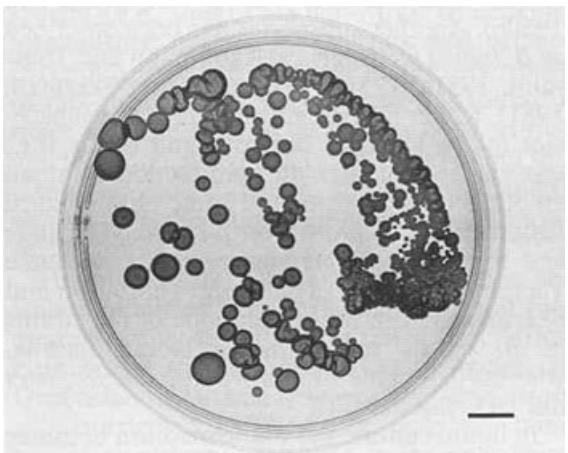

Fig. 13. Colonies of *Beijerinckia mobilis* on a nitrogen-free glucose mineral agar containing $CaCl_2$. On this transparent medium, the species forms only small raised colonies with a typical amber-brown color on aging. Bar = 1 cm.

Species Differentiation

Beijerinckia indica

Cells are straight or slightly curved rods, 1.6–3.0 µm in length and 0.5–1.2 µm wide. Lipoid bodies persist in aged cultures. No resting stages occur; cyst or ascococcus formation is never observed. Type description: (Starkey and De, 1939) Derx (1950a). The species *Azotobacter acida* Roy (1958), *Beijerinckia acida* (Roy)

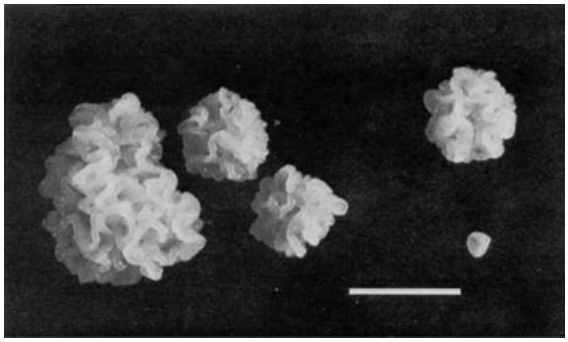

Fig. 14. Typical colonies of *Beijerinckia fluminensis* on nitrogen-free glucose mineral agar. This species forms rather small, raised colonies with a highly plicated surface. In this species the slime has a granular consistency. Bar = 0.5 cm.

Petersen (1959), and *Beijerinckia congensis* Hilger (1965) are regarded as synonymous with *Beijerinckia indica*.

This species produces highly raised colonies (Fig. 4), which on alkaline media on aging are colored brick red, cinnamon, or buff. In some strains, color production is very slow or even totally absent (i.e., *B. indica* var. *alba Derx*, 1950b). Another subspecies has been described as *B. indica lacticogenes* (Kauffmann and Tousaint, 1951a, 1951b; Thompson and Skerman, 1981), which is distinguished from the subspecies *indica* by more butyrous and brittle (i.e., less elastic) colonies, the production of small amounts of lactic acid, and some physiological features such as growth on *p*-hydroxybenzoate and the ability to metabolize protocatechuate via the *ortho*-cleavage pathway (Thompson and Skerman, 1979). Moreover, none of the strains of *B. indica* subsp. *indica* lacked flagella, whereas half of the strains of subsp. *lacticogenes* did lack flagella.

In liquid culture, the whole medium becomes viscous. On aging, color is produced but is less prominent than on agar.

Growth occurs between pH 3.0 and 10.0 (optimum rather broad, from pH 4.0–10.0; see Becking, 1961a, 1974b). Temperature range for growth is 10–35°C, with no growth at 37°C (Becking, 1961a).

Growth on and utilization of nitrate is poor, and N_2 is fixed in preference to utilization of nitrate in the medium (Becking, 1962). Weak growth occurs on malt agar, but no growth occurs in plain broth or on peptone agar.

The GC content is 54.7–58.5 mol% (T_m) (De Ley and Park, 1966; De Smedt et al., 1980).

It is the most common species, and it has been isolated from soils of all continents in tropical regions and sometimes also outside the tropics. It is particularly widely distributed in acid tropical soils.

Beijerinckia mobilis

Cells are straight, curved, or pear-shaped rods, 1.6–3.0 μm in length and 0.6–1.0 μm wide. Sometimes misshapen or forked cells occur. Ascococcus-like clusters of cells are often visible in older cultures. The typical polar lipoid bodies may disappear in aging cells, and the cells are then more rounded and resemble *Azotobacter* cells (Fig. 7). Motility is conspicuous. Type description: Derx (1950b).

This species has flatter colonies; on aging, they produce (also on relatively acid media) an amber-brown pigment (Figs. 12 and 13). Since its slime is neither elastic nor sticky, liquid media do not become viscous. There is a tendency to form a pellicle at the surface. Grows between pH 3.0 and 10.0. Optimum growth and N_2 fixation occur at pH 4.0–5.0 and decrease sharply at the more alkaline values (Becking, 1961a). Temperature range for growth is 10–35°C; no growth occurs at 37°C.

All strains tested grew well on nitrate or ammonium salts as the nitrogen source (in contrast to *B. indica*). Weak growth or no growth occurs on urea, glycine, glutamate, or tyrosine. All strains grow on leucine and casein agar. Moderate growth occurs on malt agar.

The GC content is 57.3 mol% (T_m) (De Smedt et al., 1980). This species was mainly isolated from very acid (pH mostly 4.0–4.5) tropical soils as well as in Southeast Asia, Africa, and South America. In agreement with these environmental conditions, physiological experiments showed optimum nitrogen fixation at pH 3.9; at pH 5.0, there is a sharp decline in growth and dinitrogen fixation (Becking, 1961a). Thus, soil pH is probably selective for its occurrence, and it might be possible to enrich this species selectively using more acid enrichment media (pH 4.0–4.5). It is particularly common in Indonesian (Javanese) soils.

Beijerinckia fluminensis

Cells are straight or slightly curved rods, 3.0–3.5 μm in length and 1.0–1.5 μm wide. Older cultures show characteristic large capsules enclosing 2–10 or more individual cells (Fig. 11). Division of the cells within the capsules has been observed. Motility is slow or absent, especially in older cells. Type description: Döbereiner and Ruschel 1958.

This species typically produces rather small, moderately raised colonies with irregular, rough surfaces (Fig. 14). The slime is not liquid, tenacious, or elastic, but more granular and stiff. Colonies are first opaque white, becoming, after 1–2 weeks on neutral and alkaline media, pinkish, reddish brown, or fulvous. Slime production

in liquid media is reduced as compared to that of *B. indica*. No pellicle or viscosity is produced, but a bluish-white turbidity of the whole medium is observed.

Growth occurs between pH 3.5 and 9.2. Temperature range for growth is 10–35°C (optimum is 26–33°C); no growth occurs at 37°C.

The GC content is 56.2 ± 1.8 mol% (T_m) (type strain) (De Ley and Park, 1966; De Smedt et al., 1980).

This species was originally isolated from a "Baixada Fluminensis" of pH 4.2–5.2 from the state of Rio de Janeiro, Brazil, and additionally from some other soils of Brazil (Döbereiner and Ruschel, 1958). It was also recovered from a large number of soils of Africa (including South Africa) and Southeast Asia (Indonesia) and from soils of India, Hong Kong, and China (Becking, 1961a).

Beijerinckia derxii

Cells are pear- or dumbbell-shaped, singly or occasionally in pairs, 1.3–2.1 µm in length and 1.8–2.9 µm wide. Sometimes larger or giant cells (3.3 µm–4.2 µm in length and 1.3–1.7 µm wide) may occur. Type description: Tchan (1957).

Agar colonies of this species are highly raised, slimy, and smooth. Colonies are at first semitransparent or opaque white, but after 2–3 weeks of incubation, a yellow-green fluorescent pigment is produced which diffuses from the colony into the medium. Pigment production is particularly prominent on iron-deficient media.

Two subspecies are recognized and also confirmed by the hierarchical classification of Thompson and Skerman (1979), i.e., a group containing the original type strain, *B. derxii* subsp. *derxii*, and a group of *B. derxii* subsp. *venezuelae*, originally described as *Beijerinckia venezuelae* (Materasssi et al., 1966).

The differences between the two groups are not markedly consistent. In general, strains of the subsp. *venezuelae* are characterized by the following: unable to utilize nitrate as sole source of N, nonmotile, not hydrolyzing glycogen, and growing over a slightly wider pH range (not more than 0.5 pH unit at each end of the range) and by differences in the utilization of several organic compounds as sole source of carbon (Thompson and Skerman, 1979).

In liquid culture, the whole medium turns uniformly turbid and viscous, but some strains produce less copious extracellular polysaccharides, resulting in only a turbidity, a flocculent bottom deposit, and show a slight tendency to pellicle formation.

The GC content is 59.1 mol% as examined in one strain (the type strain) (De Ley and Park, 1966).

B. derxii was originally isolated from Australian soil (Tchan, 1957); the soil pH was not specified. Later, the present author found it in several Asian and South American soils, mainly in the more alkaline ones (at least more alkaline than for the occurrence of the usual *Beijerinckia* species), e.g., soils of pH 6.5–7.0 (J. H. Becking, unpublished observations). Thus, soil pH apparently also has an influence on the occurrence of this species. This species also was found in more alkaline soils by Materassi et al. (1966) and by Florenzano et al. (1968), who found this green-pigment-producing species particularly abundant in the more alkaline Venezuelan soils (pH 6.8–8.3).

However, Meiklejohn (1954) mentioned one isolate obtained from an acid sandy soil (pH approximately 4.5) from Tanzania, East Africa, even before the type strain was described. In Queensland, Australia, where the type strain was isolated, J. P. Thompson (personal communication) mentioned that, in the undulating country of this region with alkaline soils of montmorillonite clay, *B. derxii* occurred preferentially in the soil of the shelves with a relatively more acidic reaction (pH 6.3–6.5), but rather alkaline for *Beijerinkia*, whereas in the more alkaline soil (pH 7.7) of the mounds (tops), *Beijerinckia* was entirely absent (see Thompson and Skerman, 1979, and "Habitats").

Physiological and Biochemical Properties

The efficiency of N_2 fixation in *Beijerinckia* strains is usually 10–13 mg N/g glucose consumed in a nitrogen-free medium containing 1 or 2% carbohydrate. In tests with 47 *B. indica* strains of various origins, it was observed that the efficiency of N_2 fixation was variable and related to the growth rate of the strains (J. H. Becking, unpublished observations). Of the strains tested, 21% were fast growers and poor N_2 fixers (6.0–9.9 mg N/g glucose consumed), 53% were moderate growers and moderate N_2 fixers (10.0–13.9 mg N/g glucose consumed), and 26% were slow growers and good N_2 fixers (14.0–16.9 mg N/g glucose consumed). The efficiency of N_2 fixation is also dependent on the age of the culture and on the carbohydrate concentration. Low carbohydrate levels tend to increase efficiency. In a study of some fast- and slow-growing strains of *B. indica*, the average amount of mg N fixed per g glucose consumed could be increased in the fast-growing strains from 10 to 20, and in the slow growing strains from 15 to 30, by decreasing the glucose level 10-fold (Becking, 1971, and J. H. Becking, unpublished observations).

Decreasing the partial pressure of O_2 below that of the normal air atmosphere also distinctly increases the N_2-fixing efficiency (Becking, 1971, 1978; Spiff and Odu, 1973).

The obligately aerobic character of their metabolism is also evident from the presence of cytochromes. Absorption peaks at 415–424 nm (Sorêt); 480 and 518 nm (β); 525–527, 551–556 nm (αc); and 604, 630 nm ($a_1aa_3a_2$) have been reported (Moss and Tchan, 1958). Therefore, the cells contain cytochrome *c* (γ_{max} 524 and 552 nm) and cytochrome *a* (γ_{max} 590 and 630 nm).

The mineral requirements of *Beijerinckia* species can generally be correlated with the mineral status of lateritic soils (Kluyver and Becking, 1955; Becking, 1961b, 1981). For example, such soils are rich in iron, and it is noteworthy that *Beijerinckia* species have a higher requirement for iron than do members of the Azobacteraceae, and also they are able to tolerate extremely high iron levels, even at low pH values (Becking, 1961a, 1961b). Thus, these organisms can be used as an indicator of the degree of "ferralitization" of these tropical soils (Dommergues, 1963). Ferralitization is the intense chemical weathering of soil, with the complete breakdown of all minerals except quartz, and the leaching of soluble salts and other exchangeable bases, usually producing an accumulation of iron and aluminum oxides.

Moreover, in agreement with the mineral status of lateritic soils and in contrast to *Azobacter* species, *Beijerinckia* does not require calcium for growth and dinitrogen fixation. Usually, $CaCO_3$ is even slightly inhibitory since it prolongs the lag phase of growth. The cause of this inhibition is unknown. It may be that a reduction of trace elements by precipitation and fixation by $CaCO_3$ during the heat-sterilization process are responsible. Media supplemented with 0.05% $CaCl_2{\cdot}2H_2O$ invariably showed good and relatively rapid growth.

Like most other N_2 fixers, *Beijerinckia* species require molybdenum for optimum growth and N_2 fixation. The molybdenum requirement in *Beijerinckia* species is variable, depending on the strain; for half-maximal growth under N_2-fixing conditions it ranges from 0.004–0.034 ppm Mo (0.4–3.5 μg Mo/100 ml). It is about 10–20 times higher than that in some *Azobacter vinelandii* strains and about two times higher than that in *Azomonas agilis,* whereas some strains of *A. chroococcum* have an equal to higher Mo requirement (Becking, 1962, 1974b). Moreover, unlike *Azobacter* species the molybdenum requirement cannot be replaced by vanadium (Becking, 1962, 1974b). Therefore, they probably do not possess an alternative vanadium-activated nitrogenase. Tests with nitrate-utilizing *Beijerinckia* strains showed that the Mo requirement of the nitrate system reductase is about 10 times lower than that of the nitrogenase system in the same strain (Becking, 1962, 1974b).

In alkaline nitrogen-free glucose mineral liquid media *Beijerinckia* strains decrease the pH of the medium to pH 4.0–5.0 by acid production. Analyses have shown that the acids produced are mainly acetic acid (Becking, 1961a) and a small amount of lactic acid (Kauffmann and Toussaint, 1951a, 1951b). In acid media (pH 4.0–5.0), no change of reaction occurred in spite of good growth, while in very acid media (pH 3.0) the pH of the medium is increased during growth by alkaline production.

In contrast to *Azotobacter,* many strains of *Beijerinckia* utilize nitrate poorly or not at all (Becking, 1962).

The polysaccharide slime of *Beijerinckia* species (Fig. 15) consists of glucose, galactose, mannose, glucuronic acid, and galacturonic acid, but no heptose. The main component (52% of the dry weight of the polysaccharide) is glucose (López and Becking, 1968).

The polar lipoid globules within the cell are poly-β-hydroxybutyrate (PHB), as shown biochemically, but also by elementary analysis (C, 52.5%; H, 7.5%; O, 37.8%) and by x-ray diffraction analysis (Becking, 1974b, and unpublished observations).

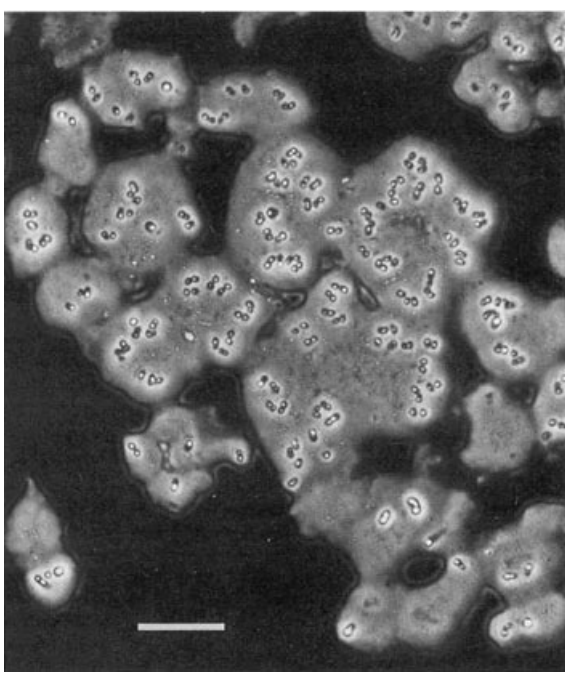

Fig. 15. Cells of *Beijerinckia indica* suspended in India ink, showing polysaccharide formation around the cells. Living preparation, phase contrast microscopy. Bar = 10 μm.

Applications

Although *Beijerinckia* was originally isolated from rice soils and tends to occur in larger numbers in the rhizosphere of rice plants, no evaluation has been made of the significance of this organism for rice culture. Its occurrence in these anaerobic water-logged rice soils is certainly not limited by oxygen supply, since rice plants have a continuous aerenchym system from the leaf and shoot to the roots, which transports air towards the root. In spite of the reduced status of the soil as evident by the black ferrous iron color of these iron-rich soils, along the rice roots a distinct layer of red ferric iron is observed (Becking, 1974b, 1978).

Increased densities of *Beijerinckia* have also been observed in sugar cane soils (Döbereiner and Alvahydo, 1959; Döbereiner, 1961) and a favorable effect of these populations on sugar cane growth was observed. Again, larger *Beijerinckia* numbers were found in the rhizosphere along the roots compared to plain soil (Döbereiner and Alvahydo, 1959). In greenhouse pot experiments, it was shown that sorghum (*Sorghum vulgare*) strongly stimulates the growth of *Beijerinckia* (Carneiro and Döbereiner, 1968).

CHAPTER 3.1.8

The Family Acetobacteraceae: The Genera *Acetobacter*, *Acidomonas*, *Asaia*, *Gluconacetobacter*, *Gluconobacter*, and *Kozakia*

KAREL KERSTERS, PUSPITA LISDIYANTI, KAZUO KOMAGATA AND JEAN SWINGS

Introduction and General Characteristics

Acetic acid bacteria comprise a widespread group of Gram-negative, obligately aerobic rods. They occur mainly in sugary, acidic and alcoholic habitats and have been studied extensively, since they can play a positive, neutral or detrimental role in foodstuffs and beverages. Some species of the Acetobacteraceae play a key role in the industrial manufacture of vinegar. The following genera belong to this family: *Acetobacter* (type genus), *Acidomonas*, *Asaia*, *Gluconacetobacter*, *Gluconobacter* and *Kozakia*. The names *Acetobacter* and *Gluconobacter* are known in literature since 1898 and 1935, respectively, whereas the other genus names were published after 1989.

All members of the Acetobacteraceae are obligately aerobic and their metabolism is strictly respiratory with oxygen as the terminal electron acceptor. A common feature of the acetic acid bacteria (with the exception of *Asaia*) is the aerobic oxidation of ethanol to acetic acid, with accumulation of the latter in the medium. After the complete oxidation of ethanol, strains of *Acetobacter*, *Gluconacetobacter* and *Acidomonas* oxidize acetic acid further to CO_2 and H_2O (overoxidation of ethanol), whereas oxidation of acetate is absent in *Gluconobacter* and weak in *Asaia* and *Kozakia*. Growth occurs in the presence of 0.35% acetic acid (except for *Asaia* strains), and gluconic acid is usually produced from glucose. The characteristic ubiquinone of *Acetobacter* is the Q-9 type, whereas all other acetic acid bacteria possess Q-10. Most acetic acid bacteria possess the $C_{18:1\omega7}$ straight-chain unsaturated acid as predominant fatty acid in their cell envelopes.

Phylogeny

Phylogenetically the six genera of the acetic acid bacteria (*Acetobacter*, *Acidomonas*, *Asaia*, *Gluconacetobacter*, *Gluconobacter* and *Kozakia*) belong to the Alphaproteobacteria. The simplified 16S rDNA dendrogram (Fig. 1) shows the phylogenetic position of the Acetobacteraceae among the major alphaproteobacterial families and groups. On the basis of DNA-rRNA hybridizations, Gillis and De Ley (1980) found that *Acetobacter* and *Gluconobacter* formed a separate branch in a rRNA superfamily which was later shown to belong to the alpha subclass of the Proteobacteria (Stackebrandt et al., 1988). The phylogenetic affiliations of *Acetobacter*, *Acidomonas*, *Asaia*, *Gluconobacter*, *Gluconacetobacter* and *Kozakia* species and related acidophilic taxa were studied on the basis of 5S rRNA (Bulygina et al., 1992) and 16S rRNA/rDNA sequences (Sievers et al., 1994a; Kishimoto et al., 1995; Sievers et al., 1995b; Yamada et al., 1997; Sokollek et al., 1998b; Franke et al., 1999; Lisdiyanti et al., 2000; Lisdiyanti et al., 2001; Lisdiyanti et al., 2002; Schüller et al., 2000; Yamada et al., 2000b; Katsura et al., 2001; Katsura et al., 2002; Cleenwerck et al., 2002; Yamashita et al., 2004; Yukphan et al., 2004b). Within the Alphaproteobacteria the six genera of the family Acetobacteraceae form a distinct line of descent together with the phylogenetic neighbors *Acidiphilium* and *Acidocella*, as well as with the species *Acidisphaera rubrifaciens*, *Rhodopila globiformis*, *Roseococcus thiosulfatophilus*, *Craurococcus roseus* and *Paracraurococcus ruber* (Sievers et al., 1994a; Yurkov et al., 1994; Saitoh et al., 1998; Hiraishi et al., 2000; Figs. 1 and 2). All the above-mentioned organisms are characterized by an acidophilic phenotype, with the exception of *Roseococcus thiosulfatophilus*. Several of these taxa, such as *Acidiphilium*, *Acidisphaera rubrifaciens*, *Rhodopila globiformis*, *Roseococcus thiosulfatophilus*, *Craurococcus roseus* and *Paracraurococcus ruber*, contain bacteriochlorophyll *a* and carotenoids and belong metabolically to the group of aerobic bacteriochlorophyll-containing bacteria.

The detailed phylogenetic relationships among the actual species of the acetic acid bac-

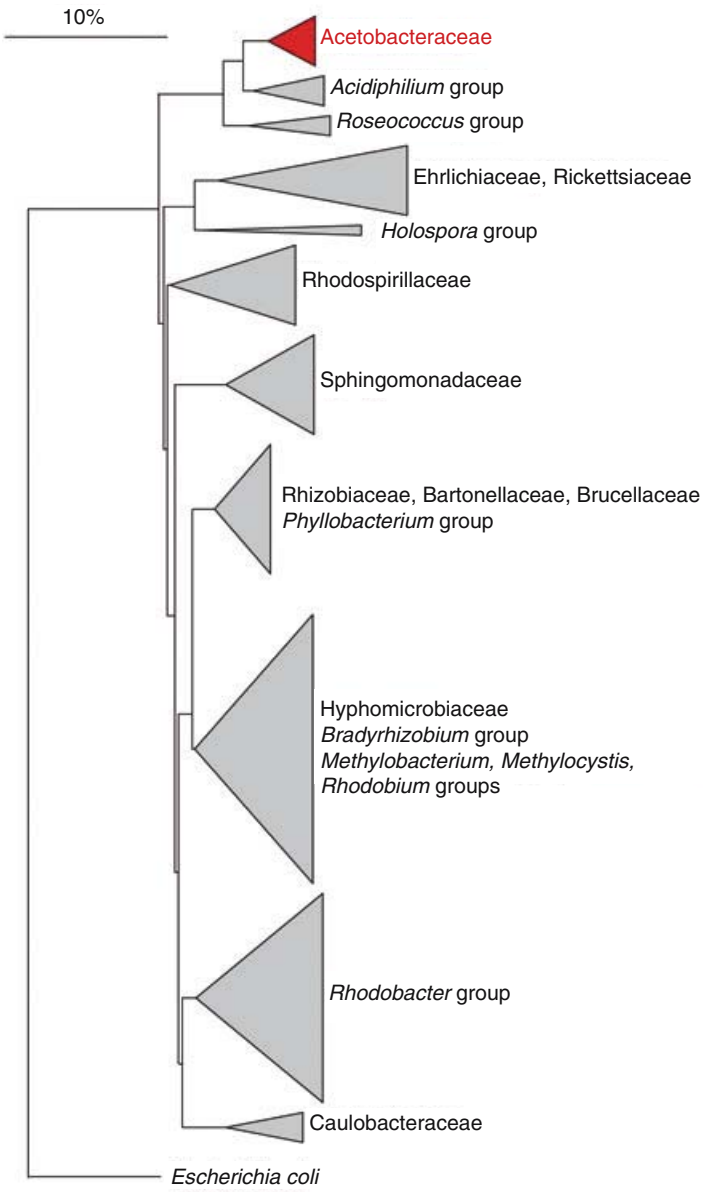

Fig. 1. Phylogenetic position of the Acetobacteraceae within the Alphaproteobacteria. The simplified neighbor-joining tree is based on the 16S rDNA sequences of the type strains of the type species of the alphaproteobacterial genera. The bar indicates 10% estimated sequence divergence. *Escherichia coli* was used as outgroup. The width of the triangles is proportional to the number of genera in the cluster. A more detailed phylogenetic tree of the Acetobacteraceae is represented in Fig. 2.

teria are shown in Fig. 2. Four major clusters can be recognized: one cluster containing all *Acetobacter* species; a second cluster with the *Gluconobacter* species; a third cluster grouping *Asaia* and *Kozakia*; and a fourth large cluster containing all *Gluconacetobacter* species, with a subcluster comprising *Ga. entanii*, *Ga. europaeus*, *Ga. hansenii*, *Ga. intermedius*, *Ga. oboediens*, and *Ga. xylinus* and a subcluster containing *Ga. azotocaptans*, *Ga. diazotrophicus*, *Ga. johannae*, *Ga. liquefaciens* (type species) and *Ga. sacchari*. *Acidomonas methanolica* (formerly *Acetobacter methanolicus*) forms a separate lineage among the acetic acid bacteria (Fig. 2): its 16S rDNA sequence similarity is less than 96.0% with all the other species of the Acetobacteraceae. Within the genus *Acetobacter*, the overall 16S rDNA sequence similarity values are above 95.5% and are less than 96.3% with those of other genera. Within the genera *Gluconobacter* and *Gluconacetobacter* the 16S rDNA sequence similarities are above 97.9% and 96.3%, respectively. *Gluconacetobacter europaeus*, *Ga. intermedius*, *Ga. oboediens* and *Ga. xylinus* are highly related as they share more than 99% sequence similarities (Fig. 2).

Taxonomy

Acetobacter and *Gluconobacter* have long constituted the core genera of the acetic acid bacteria (Asai, 1968; De Ley and Frateur, 1974a; De Ley and Frateur, 1974b; De Ley and Swings, 1984a; De Ley et al., 1984b; De Ley et al., 1984c; Swings,

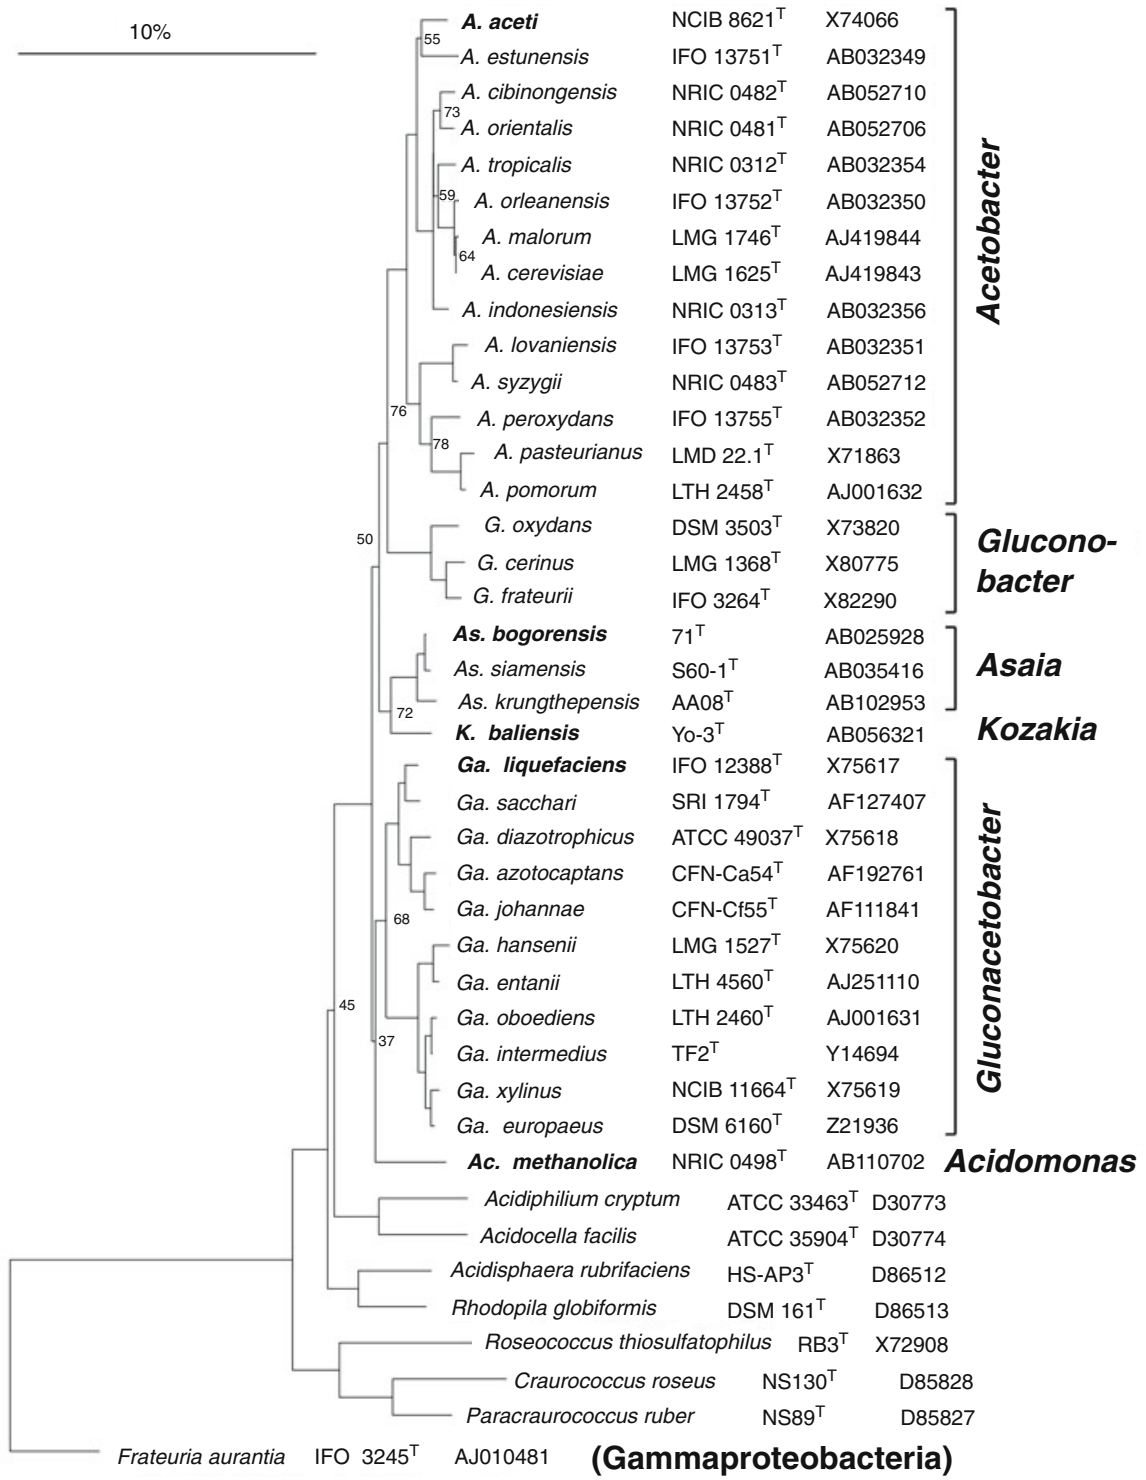

Fig. 2. Phylogenetic relationships of the Acetobacteraceae and some related taxa based on 16S rDNA sequences of the type strains (neighbor-joining method). Type species are in boldface; strain numbers and accession numbers are indicated. *Frateuria aurantia*, a member of the Gammaproteobacteria, shares phenotypic similarities with some acetic acid bacteria and was used as outgroup. The bar indicates 10% estimated sequence difference. Bootstrap values (derived from 1000 replications) greater than 80 are not shown. Abbreviations: *A.*, *Acetobacter*; *Ac.*, *Acidomonas*; *As.*, *Asaia*; *G.*, *Gluconobacter*; *Ga.*, *Gluconacetobacter*; and *K.*, *Kozakia*.

1992a). The generic designation "*Acetobacter*" was suggested in 1898 by Beijerinck (Beijerinck, 1898), whereas Asai (1935), studying for the first time oxidative bacteria living on various fruits, proposed the genus name *Gluconobacter* for those acetic acid bacteria displaying a limited ability to oxidize ethanol to acetic acid but a strong ability to oxidize glucose to gluconic acid. Bacteria belonging to *Gluconobacter* correspond to the "suboxydans" group of Frateur (1950). The status of the generic name *Gluconobacter* has been thoroughly discussed by De Ley and Frateur (1970). Various species and subspecies have been described in both genera, and taxonomic rearrangements have often been proposed. In his book on the acetic acid bacteria, Asai (1968) gives a detailed overview of the various classification systems for these bacteria. With the publication of the Approved Lists of Bacterial Names (Skerman et al., 1980), the genus *Acetobacter* was restricted to the following three species: *A. aceti* (with four subspecies), *A. pasteurianus* (five subspecies) and *A. peroxydans*, and the genus *Gluconobacter* contained one species (*G. oxydans*) with five subspecies.

The family name Acetobacteraceae was introduced in 1980 by Gillis and De Ley on the basis of results of DNA-rRNA hybridizations indicating that the peritrichously flagellated *Acetobacter* species were phylogenetically closely related to the polarly flagellated *Gluconobacter* species. A major change in the classification of the acetic acid bacteria was introduced when Yamada et al. proposed the genus *Gluconacetobacter* on the basis of partial sequence analysis of 16S rDNA and chemotaxonomic comparisons of ubiquinone systems (Yamada et al., 1997; Yamada et al., 1998). As a result, the following ubiquinone Q-10 containing *Acetobacter* species were transferred to the genus *Gluconacetobacter*: *A. diazotrophicus* (Gillis et al., 1989), *A. europaeus* (Sievers et al., 1992), *A. hansenii* (De Ley et al., 1984c), *A. liquefaciens* (Gosselé et al., 1983b) and *A. xylinus* (Yamada, 1983; Yamada et al., 1997; Yamada et al., 1998; Fig. 2).

Table 1 summarizes the current and part of the former classification (before 1998) of the acetic acid bacteria and includes the type strains and accession numbers of the 16S rDNA sequences of the validly published species names (situation June 2004). The facultative methylotrophic *Acetobacter methanolicus* (Uhlig et al., 1986) was transferred to the new genus *Acidomonas* (Urakami et al., 1989), a taxon occupying a separate position in the rDNA-dendrogram (Fig. 2). Yamada et al. (1999) and Lisdiyanti et al. studied a great number of acetic acid bacteria isolated from fruits, flowers and traditional fermented food collected in the tropical country Indonesia (Lisdiyanti et al., 2000; Lisdiyanti et al., 2001; Lisdiyanti et al., 2002; Lisdiyanti et al., 2003). These newly investigated biotopes led to the introduction of the two new genera *Asaia* (Yamada et al., 2000b; Katsura et al., 2001) and *Kozakia* (Lisdiyanti et al., 2002). In addition, since 1998, several novel species and new combinations were described in the genera *Acetobacter* and *Gluconacetobacter* (Table 1).

Table 2 summarizes the features which are useful for the differentiation of the six genera *Acetobacter*, *Acidomonas*, *Asaia*, *Gluconacetobacter*, *Gluconobacter* and *Kozakia*. Although identification at the genus level is relatively easy to make, differentiation and identification of the species are often more problematic. The identification methods, based on the phenotypic features of acetic acid bacteria (Swings et al., 1992b), are indeed time-consuming and not very accurate. In the last decade taxonomists increasingly used DNA-DNA hybridizations to reveal the genomic relationships and the species delineations among the acetic acid bacteria, particularly for the species of the genera *Acetobacter* (Sokollek et al., 1998b; Lisdiyanti et al., 2000; Lisdiyanti et al., 2001; Cleenwerck et al., 2002), *Asaia* (Yamada et al., 2000b; Katsura et al., 2001; Yukphan et al., 2004b), *Gluconacetobacter* (Franke et al., 1999; Schüller et al., 2000; Fuentes-Ramírez et al., 2001) and *Kozakia* (Lisdiyanti et al., 2002). The application of molecular methods based on the characterization of specific DNA segments (such as the 16S-23S rDNA internal transcribed spacer regions) will likely improve the speed and quality of the identification of acetic acid bacteria at the species level (Ruiz et al., 2000; Trček and Teuber, 2002; Yukphan et al., 2004a). Studies of new niches as well as the applications of rDNA-sequencing, DNA-DNA hybridizations and genomic fingerprinting techniques, together with phenotypic and chemotaxonomic characterizations, led in the past five years to an increase in the number of species and some nomenclatural rearrangements (Table 1).

Detailed descriptions of the various genera and species of the Acetobacteraceae can be found in the second edition of *Bergey's Manual of Systematic Bacteriology* (Sievers and Swings, 2005).

Habitats and Uses of Acetic Acid Bacteria

The following discussion will be focused not only on the classical niches of the acetic acid bacteria, i.e., beer and wine (where they occur as spoilers) or vinegar works (where they are the causative organisms), but also on lesser known niches. Since 1996, large numbers of acetic acid bacteria were isolated and characterized from a wide variety of habitats in Indonesia, Thailand and the Philippines (Yamada et al., 1999; Lisdiyanti

Abbreviations: [T], indicates type species of each genus; ATCC, American Type Culture Collection, Manassas, Virginia, USA; CFN, Centro de Investigación sobre Fijación de Nitrógeno, Universidad Nacional Autónoma de México, Cuernavaca, Mexico; DSM, Deutsche Sammlung von Mikroorganismen und Zellkulturen, Braunschweig, Germany; IFO, Institute for Fermentation, Osaka, Japan; IMET, National Collection of Microorganisms of the German Democratic Republic, Jena, Germany (see DSMZ); LMD, Laboratory of Microbiology, Technical University, Delft, the Netherlands; LMG, BCCM/LMG Bacteria Collection, Laboratorium voor Microbiologie, Universiteit Gent, Gent, Belgium; LTH, Institut für Lebensmitteltechnologie, Universität Hohenheim, Stuttgart, Germany; NCIB, National Collections of Industrial and Marine Bacteria Ltd., Aberdeen, Scotland, United Kingdom; NRIC, NODAI Research Institute Culture Collection, Tokyo University of Agriculture, Tokyo, Japan; and SRI, Sugar Research Institute, Mackay, Australia.

[a]Quotation marks indicate that the species name did not occur on the Approved Lists of Bacterial Names (Skerman et al., 1980).

[b]Strain numbers of the type strains correspond to the strains used for sequence determination of their 16S rDNA (last column).

[c]On the Approved Lists of Bacterial Names (Skerman et al., 1980) "*Acetobacter estunense*" and *Acetobacter lovaniensis* were listed as subspecies of *Acetobacter pasteurianus*: *A. pasteurianus* subsp. *estunensis* and *A. pasteurianus* subsp. *lovaniensis*, respectively.

[d]On the Approved Lists of Bacterial Names (Skerman et al., 1980) *Acetobacter orleanensis*, *Acetobacter liquefaciens* and *Acetobacter xylinus* were listed as subspecies of *Acetobacter aceti*: *A. aceti* subsp. *orleanensis*, *A. aceti* subsp. *liquefaciens* and *A. aceti* subsp. *xylinum*, respectively.

[e]The original spelling of the genus name *Gluconoacetobacter* (Yamada et al., 1997) was corrected to *Gluconacetobacter* at the occasion of its validation (Validation List no. 64, Int. J. Syst. Bacteriol., 48, pp. 327–328 [1998]).

[f]*Acetobacter xylinus* contains the following subspecies: *A. xylinus* subsp. *sucrofermentans* and *A. xylinus* subsp. *xylinus* (Toyosaki et al., 1995).

[g]*Gluconobacter asaii* (Mason and Claus, 1989) is a junior subjective synonym of *Gluconobacter cerinus* (Katsura et al., 2002).

[h]*Gluconobacter oxydans* contains the following subspecies: *G. oxydans* subsp. *industrius*, *G. oxydans* subsp. *melanogenes*, *G. oxydans* subsp. *oxydans*, *G. oxydans* subsp. *sphaericus*, and *G. oxydans* subsp. *suboxydans*.

[b]Contradictory reports were published for the growth on methanol by *A. pasteurianus*, *A. lovaniensis* and *A. pomorum* (Gosselé et al., 1983; Uhlig et al., 1986; Urakami et al., 1989; Sokollek et al., 1998b; Cleenwerck et al., 2002). (See text in the section *Acetobacter*.)

et al., 2000; Lisdiyanti et al., 2001; Lisdiyanti et al., 2002; Lisdiyanti et al., 2003; Seearunruangchai et al., 2004).

Grapes and Wine Starting in Pasteur's time, it was known that the acetification of wine was due to acetic acid bacteria (Vallery-Radot, 1924). The microbiologists at that time already knew that these bacteria could be isolated from the pellicle that forms on wine when it is exposed to air. They were also aware of the fact that the acetification requires oxygen (Wermischeff, 1893; Behrens, 1896; Fuhrmann, 1905). The high alcohol tolerance of acetic acid bacteria was already observed by Fuhrmann (1905), who isolated many acetic acid bacteria from wine must but was unable to isolate strains from either intact or injured grapes. Dupuy (1957) isolated *Acetobacter pasteurianus* (75% of the isolated strains) and *A. aceti* (19%) from wines in southern France. Acetic acid bacteria are present in about half of the samples of ripe grapes (Peynaud and Domercq, 1961), and they multiply on injured grapes. *Gluconobacter* occurs profusely on ripe grapes of the Bordeaux region (73% of all strains isolated), whereas *Acetobacter* and *Pseudomonas* constitute, respectively, only 12 and 15% of the isolates (Blackwood et al., 1969). *Gluconobacter* was present on intact and injured grapes but not during the fermentation. The ketogenesis by *Gluconobacter* strains on grapes leads to a higher requirement for SO_2 in the sulfitation process. These results apparently do not agree with the ones from Kahlon and Vyas (1972), who isolated *A. aceti*, *A. xylinum* and *A. pasteurianus* from grapes but no

Gluconobacter strains. The explanation is probably that they used an enrichment medium with ethanol, which favors the development of *Acetobacter*. Passmore and Carr (1975) isolated *Gluconobacter* but no *Acetobacter* strains from dried and mature grapes and vines. Ameyama (1975) isolated a strain of *G. oxydans* from grapes. In South Africa, Du Toit and Lambrechts (2002) reported *G. oxydans* as the dominating acetic acid bacteria in fresh grape must and *A. pasteurianus* and *Gluconacetobacter liquefaciens* during the fermentation process.

Sake The Japanese rice wine (sake) contains 14–24% ethanol (Prescott and Dunn, 1959). Rice starch is converted to fermentable sugar by the amylases of *Aspergillus oryzae*. Fermentation of this mixture yields sake. Takahashi (1907) studied several samples of altered "hyochi" sake (the term "hyochi" applies to sake altered after fermentation, clarification, and pasteurization). He isolated *Acetobacter pasteurianus* from samples that had the smell of acetic acid.

Palm Wine Palm wine is a typical tropical beverage, a product from the fermentation of sugary palm sap. Palm trees commonly used for this purpose are *Elaeis guineensis*, *Raphia vinifera*, *Cocos nucifera* and *Arenga pinnata*. Palm wines are popular beverages in Africa, South America, and the Far East.

To collect the sap, several tapping methods are practiced. One of them is to cut a hole at the base of the male flower bud, from which the juice oozes out. One tree may produce one to several liters of sap per day. Palm wine is a whitish, effervescent, acidic alcoholic beverage, the product of a mixed alcoholic, lactic acid, and acetic acid fermentation. As a first step, the sugar of the sap is fermented to ethanol within 8–12 h by *Zymomonas* and yeasts, thus creating a medium highly suitable for the development of acetic acid bacteria. A rather complex flora is present in palm wines (Swings and De Ley, 1977). During palm sap fermentation, the acetic acid bacteria appear after 2–3 days. Acetic acid bacteria utilizing glucose or sucrose or both may be present in earlier stages of the palm sap fermentation (Okafor, 1975). *Acetobacter* species were isolated from palm wines (Faparusi, 1973; Okafor, 1975) and from the immature spadix of the palm tree (Faparusi, 1973); *A. pasteurianus*, *A. lovaniensis*, *A. indonesiensis* and *A. tropicalis* from palm wine (Simonart and Laudelout, 1951; Lisdiyanti et al., 2003); and *Gluconacetobacter xylinus* from the leaflets of the palm tree and the surrounding air (Faparusi, 1973). *Gluconobacter oxydans* was found on the floret of the palm tree, in the tap hole, and in palm sap (Faparusi, 1973; Faparusi, 1974).

Tequila Greene and Breazeale (1952) described an *Acetobacter* infection in tequila that had developed cloudiness upon standing. The infection occurred during summer.

Fermentations of Cocoa Cocoa wine is made by fermentation of seeds of cocoa and is a popular drink in Nigeria (Bassir, 1968). The cocoa beans are ground and boiled in sugared water and allowed to cool to approximately 50°C before the inoculum is added. Its alcohol concentration (9.5–11.6% [w/v]) is significantly higher than that of palm wine (Bassir, 1968). *Acetobacter* and *Gluconobacter* strains have been isolated from cocoa wine (Bassir, 1968; Jones and Jones, 1984). Together with yeasts and lactic acid bacteria, the acetic acid bacteria contribute to the development of aroma and flavor as well as the necessary heat and acetic acid during the proper curing of the cocoa beans (Thompson et al., 1997). *Acetobacter* and *Gluconobacter* strains play a critical role during the aerobic phase of the natural fermentation of cocoa beans for the manufacture of chocolate (Schwan et al., 1995). To improve the reliability and quality of the cocoa fermentation process, Schwan (1998) successfully used a defined, mixed starter culture, including *A. aceti* and *G. oxydans*.

Cider In Europe, the word cider means apple wine. Acetic acid bacteria are associated with two bacterial cider disorders, i.e., the acetification of cider and "cider sickness." The acetification of cider (French: piqûre) by acetic acid bacteria, occurring previously in primitive cider manufacture, is almost completely ruled out in modern cider technology (Maugenet, 1962; Carr and Whiting, 1971). *Acetobacter* species are associated with another cider disorder known as "cider sickness" or as "framboisé" in France. This disorder of sweet ciders is characterized by: 1) an unpleasant odor and taste due to the formation of acetylaldehyde and 2) a milky colloidal precipitate that forms because the acetaldehyde combines with polyphenolic compounds (Guittonneau et al., 1939; Maugenet, 1962; Drilleau, 1977). Passmore and Carr (1975) extensively studied the acetic acid bacteria of the cider industry. The acetic acid bacteria involved in spoilage presumably hibernate in dried and injured apples, from which they spread to flowers in the spring. In September, they spread to the apples themselves. The apples for cider-making are shaken from the trees; most of them are bruised and become easily contaminated with a complex flora. As the pH range of the apple juice is 3.2–4.2 (Phillips et al., 1956), only acid-tolerant microorganisms such as *Zymomonas*, yeasts, lactic acid bacteria, and acetic acid bacteria can grow in the juice (Carr

and Whiting, 1971). The acetic acid bacteria presumably enter the cider factory with the damaged fruit: one week before the pressing season started, no acetic acid bacteria were found in apple silos, pressing equipment, or juice tanks, whereas two weeks later, several *Acetobacter* and *Gluconobacter* strains were isolated (Passmore and Carr, 1975). *Gluconobacter* was found mainly in the earlier stages of the cider-making process, which are rich in sugar, i.e., on the harvested apples, in the pressed pomace, and in the juice. Varieties of *Acetobacter aceti* and *A. pasteurianus* were found at every stage. Fernandez et al. (1994) observed a very similar composition of the bacterial flora during cider-making in the Basque country (Spain), and Maugenet (1962) isolated acetic acid bacteria from French cider samples and assigned them to the same two *Acetobacter* species.

Vinegar HISTORY OF VINEGAR. The word "vinegar" is derived from the French "vin" and "aigre" (in French: "vinaigre"), literally meaning "sour wine." Many interesting details about vinegar and its history can be found in the review article by Conner and Allgeier (1976). In the past, wine making and vinegar preparation were always linked. As early as 4000 B.C., vinegar was already mentioned in Babylonian writings, as a product of the date palm, the culture of which was highly developed (Nickol, 1979). Huber (1927) has given extensive details concerning the history of the role and the preparation of wines and vinegar in Babylon; "fruit honey," i.e., sugary syrups made from figs, apricots, grapes, and dates, was used in the kitchen and for the preparation of wine. After the process of wine-making was completed, the extracted dates together with their stones were used to make a drink composed of a sort of lemonade and vinegar. Vinegar was also a side product—mostly unwanted—of beer-brewing. Originally (4000–3000 B.C.), beer, wine and vinegar were homemade but later (3000–2000 B.C.) they were prepared in breweries. To obtain a higher alcohol content, the Babylonian and Assyrian breweries started mixing barley and dates. Raisin wine and raisin vinegar also became very popular in Babylon from approximately 1000 B.C. on.

In the Babylonian kitchen, it was quite common to add spices and herbs, such as tarragon, lavender, mint, celery, caper, and especially saffron, to vinegar, which was used as a seasoning agent together with salt, pepper, and sesame oil in salads of crude vegetables and as a dressing with lentils, beans, pears, or millet porridge. Because of the hot climate, the Babylonians also used vinegar as a pickling agent for fish, meat, vegetables (e.g., palm shoots, fennel, tarragon and anise), and fruits (e.g., melons, cucumbers, peaches, apricots, apples and pears). In antiquity, vinegar was the drink of the poor: the peasants, soldiers and travelers. Wine and beer were only drunk at home with meals and at festivities.

We are relatively well informed about the process of vinegar preparation in ancient Rome as well as vinegar's uses as a condiment and as a preservative and in medicine. Vinegar formation occurred spontaneously as a defect during wine manufacture. In the Greek settlements in Southern Italy, wine production and trade had become important from the eighth century B.C., and the Romans took over the Greek knowledge of vinegrowing and wine-making. In Rome, good cooking was an art for the rich, who eagerly accepted the Greek cooking heritage. One of the principal characteristics of the classical Latin taste was its preference for sweet-sour (honey-vinegar) combinations resembling those found in Chinese specialties (André 1961). Uncooked vegetables were eaten with a sort of French dressing ("vinaigrette"), the *acetaria* (Plinius, in André 1958). The following kinds of vinegar were known: *acetum piperatum*, vinegar containing pepper; *oxygarum*, made from vinegar, garum, and herbs; *oxymeli*, made by boiling vinegar, honey, water, and salt; and *oxysporium*, vinegar containing spices (André 1961). Plinius (in André 1958) recommended drinking vinegar to treat nausea, hiccupping, leprosy, freckles, ulcers, bites of dogs, and stings of scorpions, scolopendras, and other sting-possessing insects, but also by rectal injection to stop diarrhea.

Several natural sugar-containing juices or mashes that are first converted by fermentation to ethanol solutions can serve as raw materials for vinegar production. The vinegar is usually named after the original raw material, such as wine vinegar, cider vinegar or apple cider vinegar, malt vinegar, rice vinegar, etc. The latter type of vinegar is of course very common in Eastern countries.

The first commercial process for the production of vinegar used wooden casks in which, e.g., the wine was oxidized by the "mother of the vinegar," containing the acetic acid bacteria at the surface of the liquid. It was known as the "Orleans process" or "French method." In Japan, ancient techniques of vinegar making were probably introduced from China at the end of the fourth century, and the commercial production of vinegar started in the middle of the Edo period (1603–1867; Masai, 1980). The raw materials were rice, sake, and sake-cake, which is a by-product of the sake-production. Until the end of World War II, surface fermentation in wooden shallow tanks was the most common process used in Japan (Masai, 1980). The "German method" (or "quick process") was invented in Germany in the beginning of the nineteenth cen-

tury. Wine was added to the top of and allowed to trickle through a generator consisting of a tank packed with beechwood shavings. The acetic acid bacteria grow attached to the beechwood shavings and catalyze the oxidation of alcohol to acetic acid. Air is introduced through holes from the bottom of the tank. The latter generator method was only seldom used in Japan (Masai, 1980).

The development of scientific knowledge about vinegar and its formation is a reflection of the historical development of chemistry and microbiology. Milestones were: 1) the recognition of the alcoholic fermentation and vinegar formation as separate processes; 2) the role of oxygen in vinegar formation; 3) the determination of the chemical structure of acetic acid; and 4) the biological nature of vinegar production.

Kützing (1837) probably first suggested the biological nature of the acetification process. In France, Pasteur (1868) discovered that the cause of deterioration of wines was due to bacterial contamination during and after the yeast fermentation process, resulting in conversion of alcohol to acetic acid. He made also the observation that during vinegar manufacture similar bacteria, which he called "*Mycoderma aceti*," were responsible for production of the acetic acid by the oxidation of ethanol. Subsequently, Pasteur showed that partial sterilization or "Pasteurization" of wine at 55°C prevented the spoilage process.

VINEGAR PRODUCTION IN THE TWENTIETH CENTURY. In the twentieth century, the trickle vinegar generator was improved through mechanisms of forced aeration and temperature control, yielding 98% conversion of a 12% ethanol solution to acetic acid in 5 days. Hromatka and Ebner (1949) introduced the submerged reactor with an aeration system fixed at the bottom of the fermentor. This submerged process known as the "Frings acetator" has been used for many decades worldwide and allows a faster oxidation of ethanol. More details concerning vinegar production, including illustrations of the beechwood shavings generator and the Frings acetator, can be found in the chapter on Organic Acid and Solvent Production in Volume 1.

If one considers the interest that acetic acid bacteria inspired in many microbiologists, it is astonishing how little effect the available information about these bacteria has had on vinegar manufacture (Allgeier and Hildebrandt, 1960). This is particularly striking in regard to the application of the pure culture approach in the vinegar industry. Henneberg (1909) pointed out the enormous advantages of introducing pure cultures in vinegar manufacture: it would reduce the occurrence of vinegar eels, "Kahm" yeasts, and the unwanted contaminant *A. xylinum* (now named *Gluconacetobacter xylinus*). It would also permit the selection of suitable strains possessing the required technological and commercial qualities. Wiame and Lambion isolated several strains of acetic acid bacteria directly or after enrichment from acetators containing beechwood shavings (Wiame and Lambion, 1951a; Wiame and Lambion, 1951b). These organisms produced a satisfactory acetification under experimental conditions. Frateur and Simonart (1952) attempted to overcome the difficulties of isolating acetic acid bacteria from beechwood shavings by the use of "amphibian" cultures. They observed the appearance of extremely acid-resistant organisms, able to grow as dwarf colonies, which were identified as *A. pasteurianus* and *A. xylinum*. These species were also predominant in the normal flora. By examination of the plasmid profiles from the microfloras from both submerged and trickle vinegar fermentors it was concluded that only one strain was active in the former process, whereas a mixed-strain population was active in the latter (Sievers et al., 1989). The proof that the isolated strains were actually responsible for acetification could only be solved by the application of Koch's postulates. Shimwell (1954) isolated an *A. aceti* strain as a true working strain fulfilling Koch's third postulate. With this strain he produced up to 12% malt-, spirit-, or wine-vinegar of excellent quality at rates as fast as in the normal production process. Another strain, thought to be "the active one" in a quick vinegar process, was isolated from beechwood shavings by Wiame et al. (1959). It was characterized by a pronounced acidophily (its optimum pH was 3.1) and was appropriately named "*A. acidophilus*." Unfortunately, the original strains were lost (J. M. Wiame, personal communication).

Pure cultures are generally not used in the manufacture of vinegar. However, in the factory of the Finnish State Alcohol Monopoly, pure cultures of *A. pasteurianus* have been used to manufacture vinegar since 1945 (Suomalainen, 1961; Suomalainen et al., 1965), producing 10% acid in six days. No changes in the strain were observed over many years.

Turtura et al. (1973) isolated and identified more than 1000 strains of acetic acid bacteria from vinegars and soured pressed grapes; they found 56% of the isolates were strains of *A. pasteurianus*, 34% of *A. aceti*, and 10% of *Gluconacetobacter xylinus*. Passmore and Carr (1975) identified the following acetic acid bacteria in a cider-vinegar generator: *A. pasteurianus*, *A. aceti* and *Ga. xylinus*; they found no *Gluconobacter* strains. *Acetobacter pasteurianus* was also isolated from Japanese rice vinegar fermented by the traditional static method using

polished as well as unpolished rice (Nanda et al., 2001).

It may be surprising that even to the end of the twentieth century, the vinegar industry has mostly worked with acetic acid bacteria that were not properly characterized. The lack of defined and appropriate starter cultures is mainly due to problems associated with the isolation, cultivation and preservation of the acetic acid bacteria involved in high-acid vinegar production (Sievers and Teuber, 1995a). The availability of microbiologically defined starter preparations would, e.g., allow the accelerated start-up of the fermentation process or culture rotation as a method for controlling infections by bacteriophages (Sokollek and Hammes, 1997). Entani et al. (1985) developed a double layer agar technique using an acetic-acid-ethanol medium that allowed the cultivation of acetic acid bacteria capable of producing 10–15% acetic acid in commercial acetators. These improved techniques intensified studies on the bacterial flora in submerged high-acid vinegar fermentations, and the following new species isolated from high-acid vinegar plants have been described: *Acetobacter europaeus* (Sievers et al., 1992), *A. oboediens*, *A. pomorum* (Sokollek et al., 1988b) and *Gluconacetobacter entanii* (Schüller et al., 2000). The preservation methods for the handling of acetic acid bacteria outside the fermentation process were improved (Sokollek and Hammes, 1997) and applied for the cultivation and preservation of various isolates from industrial vinegar fermentations (Sokollek et al., 1998a).

Various aspects of the bacterial production of acetic acid are treated in detail in the chapter Organic Acid and Solvent Production in Volume 1.

Beer Acetic acid bacteria have been known as beer spoilers for many years. The acetification of beer was studied by the pioneers of microbiology, such as Pasteur, Hansen, Henneberg, and Beijerinck. In his book *Etudes sur la bière* Pasteur (1876) showed: 1) that beer sickness symptoms are always accompanied by the development of bacteria in wort or beer and 2) that the absence of "beer-sickness" symptoms coincides with the absence of bacteria. According to Pasteur (1876), "*Mycoderma aceti*" is involved in one of the seven forms of beer sickness, being characterized by an acetic smell and taste.

The infection of beer by acetic acid bacteria may lead to the formation of a film, cause turbidity, bring about a loss of alcohol accompanied by the formation of acetic acid, turn the beer ropy, and cause off-flavors and color changes (Vaughn, 1942; Shimwell, 1948). Infections due to acetic acid bacteria are reduced nowadays by modern sanitation practice, by the increased use of stainless steel, the use of single-strain yeast, and the controlled use of anaerobic conditions. The acetic acid bacteria can still cause problems in cask beer production (Ault, 1965; Rainbow, 1971). They are picked up at the end of the production process and will develop in the cask after air has entered to replace the beer drawn from it. The major beer-spoiling acetic acid bacteria are *Gluconacetobacter xylinus*, *Acetobacter pasteurianus*, and *Gluconobacter oxydans*. Acetobacters are part of the normal microbial flora in lambic beer (a Belgian beer obtained by spontaneous fermentation; Martens et al., 1991).

Fruits and Flowers Fruits, as sources of sugar and of ethanol, are excellent niches for acetic acid bacteria. Acetic acid bacteria have been found on apples, apricots, almonds, beets, bananas, coconuts, custard apples, figs, guavas, grapes, longans, loquats, mandarins, mangoes, oranges, papayas, passion fruit, pomegranates, pears, peaches, pineapples, plums, ponkans, persimmons, sapotas, star fruit, strawberries and tomatoes (Bhat and Rijsinghani, 1955; Asai, 1968; Kahlon and Vyas, 1972; Yamada et al., 1999; Lisdiyanti et al., 2000; Lisdiyanti et al., 2001; Lisdiyanti et al., 2003; Seearunruangchai et al., 2004). The presence of acetic acid bacteria on fruits can cause problems during the manufacture of cider, wine, etc. Most strains of the genus *Asaia* were isolated from tropical flowers collected in Thailand and Indonesia, such as the spider lily (*Crinum asiaticum*), orchid tree (*Bauhinia purpurea*), plumbago (*Plumbago auriculata*; Yamada et al., 2000b; Katsura et al., 2001) and *Heliconia* (Yukphan et al., 2004b). Some thermotolerant members of *Gluconobacter frateurii* were isolated from various kinds of fruits and flowers in Thailand and Japan (Moonmangmee et al., 2000).

Acetic acid bacteria can cause bacterial rot in pears and apples, which is characterized by different shades of browning and by tissue degradation. Allen and Ricker (1932) associated a bacterial rot of apples with infection by the apple maggot, *Rhagoletis pomonella*. They isolated *Acetobacter* strains both from decaying apple tissue and from the larvae and adults of the apple maggot. The authors also found that the occurrence of the rotting symptoms was correlated with an *Acetobacter* infection. Färber et al. (1957) isolated several *Acetobacter* and *Gluconobacter* strains and their typical endproducts of glucose and fructose metabolism (ketogluconic acids) from brown-rot on apples and identified them as a causal agents of bacterial rot. These publications remained almost unnoticed. Cole (1959) also studied bacterial brown rot of

apples and identified the causal agents as "*Pseudomonas melophthora*" and "*Pseudomonas pomi*." Dhanvantari et al. (1978) and Gillis and De Ley (1980) concluded that Cole's isolates belonged in *Acetobacter*. All pear and apple varieties were found to be susceptible to bacterial brown rot, but pears were more susceptible (Van Keer et al., 1981b). Bacterial brown rot could be induced by artificial inoculation, using an inoculum size as low as 100 cells. The optimal temperature for the development of rot symptoms was 25°C, but even at 4°C, rotting occurred (Vanden Abeele et al., 1980; Van Keer et al., 1981a; Van Keer et al., 1981b). *Gluconobacter* was also reported to be involved together with *Erwinia*, pseudomonads and fungi in the rapid colonization of apple wounds (Mercier and Wilson, 1994).

Soft Drinks Fruit juices and related beverages were introduced during the last two decades of the nineteenth century. A soft drink can be defined as a sugary solution at low pH, without free oxygen or growth factors, containing very little organic nitrogen. It is a very selective medium, allowing only the least exacting, acid-tolerant microorganisms to develop (Sand and Kolfschoten, 1970). In earlier microbiological examinations of fruit juices, the role of the acetic acid bacteria as spoiler-organisms was overlooked.

However, *Gluconobacter* is now considered to be a typical spoiler of soft drinks (Sand and Kolfschoten, 1970; Sand, 1971; Sand, 1976; Dittrich, 1972; Molitoris, 1973; Dachs, 1975; Dachs, 1976; Molitoris and Hubner, 1975; Fresenius et al., 1977–78; Cancalon and Parish, 1995). Lott and Carr (1964) identified *Gluconobacter* as the causative agent of a deleterious change in orange juice, characterized by a marked staleness of flavor. *Asaia* and *Gluconacetobacter sacchari* were reported as spoilage organisms in fruit-flavored bottled water (Moore et al., 2002a; Moore et al., 2002b).

Nata Nata is a white to creamy-yellow to pinkish, firm, gelatin-like substance formed through bacterial action on sugared fruit juices. "Nata de pina" and "nata de coco" are traditional dessert delicacies in the Philippines and other Southeast Asian countries (Villanueva, 1937; Alaban, 1962; Lapuz et al., 1967; Gallardo-De Jesus et al., 1973). Nata is considered as a healthy diet and became an important export product for the Philippines. Some confusion existed at first as to the chemical composition of nata and to the identity of the nata-producing organism. Its first students thought that nata was a dextran formed by a *Leuconostoc* species (Villanueva, 1937; Alaban, 1962). Today, it has been established that it is a form of cellulose produced by acetic acid bacteria belonging to *Gluconacetobacter* (Lapuz et al., 1967; Gallardo-De Jesus et al., 1973; Gosseléand Swings, 1985; Iguchi et al., 2000). More recently Bernardo et al. (1998) showed by 16S rDNA sequence analysis that the typical nata-producing strains are related to *Gluconacetobacter xylinus* and *Gluconacetobacter hansenii*. *Acetobacter pasteurianus*, *A. orleanensis*, *A. lovaniensis*, *G. oxydans* and *G. frateurii* were also found in the process of nata production (Lisdiyanti et al., 2003).

Pink Disease of Pineapple Fruit Acetic acid bacteria have been reported as causative agents of the pink disease of pineapple fruit (Buddenhagen and Dull, 1967; Rohrbach and Pfeiffer, 1976; Gosseléand Swings, 1986). However, various recent molecular studies indicate that the real causative organism is *Pantoea citrea*, a member of the Enterobacteriaceae (Cha et al., 1997; Pujol and Kado, 2000). The disease itself is recognizable by the appearance of a pinkish brown color after heating the fruit, although the fruit has an almost-normal appearance before the canning process.

Sugarcane and Coffee Plants Cavalcante and Döbereiner (1988) discovered a new nitrogen-fixing *Acetobacter* species in the stem and root of sugarcane in Brazil. Gillis et al. (1989) studied the isolates and proposed the new species *Acetobacter diazotrophicus*, which was later transferred to the genus *Gluconacetobacter* (Yamada et al., 1998; Table 1). This interesting endophytic bacterium represents a model system for the investigation of associations between monocots and diazotrophic bacteria (Muthukumarasamy et al., 2002b). *Gluconacetobacter sacchari* is closely related to *Ga. diazotrophicus* and was isolated in Australia from the leaf sheath of sugarcane as well as from the pink sugarcane mealy bug *Saccharicoccus sacchari*, living in the leaf sheath of sugarcane (Franke et al., 1999). *Gluconacetobacter sacchari* is not able to fix nitrogen. New species of nitrogen-fixing gluconacetobacters (*Ga. azotocaptans* and *Ga. johannae*) were isolated from the rhizosphere and the rhizoplane of coffee plants cultivated in Mexico (Fuentes-Ramírez et al., 2001; Table 1).

Bee Hives It is nearly impossible to determine the "normal" microflora of an insect because so many factors play a role in its composition. The honeybee, which visits many niches, undoubtedly comes into intimate contact with several pathogenic and nonpathogenic microorganisms. The digestive tracts of newborn worker honeybees are sterile. The microbial flora of the honeybee develops rapidly and appears largely to be the

result of chance. The bee first comes into contact with the microorganisms on their food and on the other bees of the hive. This means that the composition of the microbial flora will vary considerably depending on the food source of the bee colony. A considerable number of strains of bacteria, fungi, and actinomycetes have been isolated (Vecchi, 1959; Borchert, 1966; Batra et al., 1973). Nectar is transformed into honey by a complex process, beyond the scope of the present review; it is accompanied by a considerable loss of water. Ruiz-Argueso and Rodriguez-Navarro examined the microorganisms of ripening honey from an apiary in Madrid (Spain) surrounded by a flora of *Rosmarinus*, *Lavendula* and *Thymus* species (Ruiz-Argueso and Rodriguez-Navarro, 1973; Ruiz-Argueso and Rodriguez-Navarro, 1975). Two main groups of bacteria were identified: *Lactobacillus viridescens* and *Gluconobacter*. Occasionally, *Zymomonas mobilis* and several yeasts were also present. In natural honey, the number of bacteria decreases during the ripening process. An individual bee contains several hundred *Gluconobacter* cells, distributed equally between the intestine and the body surface. *Gluconobacter* was not isolated from larvae or from the sealed honey in the honeycomb. Lambert et al. (1981) isolated 56 *Gluconobacter* strains from honeybees in Belgium and characterized them by polyacrylamide gel electrophoresis of the soluble cell proteins. Not surprisingly, the sugar-loving and flower-associated gluconobacters occur on bees, which probably act as vectors in the dissemination of these and other bacteria.

Kombucha and "Tea Fungus" Kombucha is a slightly acidulous and effervescent beverage obtained by the fermentation of sugared black tea with a symbiotic culture of acetic acid bacteria and yeasts. The claimed health effects of kombucha have been discussed by Dufresne and Farnworth (2000) and Greenwalt et al. (2000). Several names have been given to the organisms responsible for the beverage obtained by acetic acid fermentation of tea infusions: kombucha, miracle fungus, fungus of charity, fungus of a long life, remedy for immortality, Ma Gu, Chinese or Japanese fungus, Hongo, Haipao, and Teekwasspilz (Dinslage and Ludorff, 1927; Kraft, 1959; Abadie, 1962). These names, often referring to a fungus, are confusing; in fact, what is meant is an association of a yeast with an acetic acid bacterium, forming a thick film on the surface of a tea infusion.

More than one thousand years ago the tea fungus was already used in Japan, China and India; and then in Russia, Poland and the Baltic States starting in about 1915; in the Balkans, Germany and Eastern Europe in about 1925; and in Spain, Italy, France and Switzerland in about 1955 (Kraft, 1959). The beverage is prepared from black tea to which sugar and the "tea fungus" are added. After approximately 3–5 days, the beverage is ready; it is slightly alcoholized, aromatic, acidic and refreshing. Hermann isolated *Gluconobacter oxydans* and *Acetobacter* (*Gluconacetobacter*) *xylinu*s from kombucha (Hermann, 1928a; Hermann, 1928b). *Acetobacter aceti*, *A. pasteurianus* and *A.* (*Ga.*) *intermedius* have also been identified in this beverage (Sievers et al., 1995c; Liu et al., 1996; Boesch et al., 1998), whereas the identified yeasts belong to the genera *Brettanomyces*, *Candida*, *Saccharomyces* and *Zygosaccharomyces* (Mayser et al., 1995; Liu et al., 1996). Abadie (1962) studied the relationship between the yeast *Candida mycoderma* and the *Acetobacter* cells as it occurs in the acetic fermentation of tea infusions. The bacteria are attached to the yeast cells and grow out to form a compact, granular, and gelatinous mass. The extracellular cellulose capsule is formed by the bacteria and incorporates the yeast cells. After about 20 days, the association is complete and well balanced. The author has also demonstrated that it was possible to constitute the association starting with pure cultures of yeast and acetic acid bacteria.

Flour At a moisture content of more than 13%, microbial growth can occur in flour, leading to acid fermentation, alcohol fermentation by yeasts, and acetic acid formation by acetic acid bacteria (Frazier, 1967). A strain of the species *Kozakia baliensis* (Lisdiyanti et al., 2002) was isolated from ragi, a starter used in Indonesia for the natural fermentation of rice flour.

Tanning Process The tanning process consists of the conversion of hides into leather by impregnation with either an infusion of tree bark, minerals, synthetic tannins, or other substitutes. Vegetable tanning liquors are characterized by an acetic acid "fermentation," which is preceded by a phase in which yeasts produce some ethanol from sugars. An extensive study of the acetic acid "fermentation" was made by Doelger (1936). *Acetobacter* may occasionally develop to a slimy pellicle at the surface of the liquor, and vinegar eels may thrive in it. This would suggest that the bacterium, besides its well-known acid tolerance, is also characterized by a pronounced tannin tolerance. Using mixtures of chestnut and oak bark extract (containing 25% tannin), the author noted the formation of acetic acid after 15 days of incubation.

Methanol Yeast Process Methylotrophic acetic acid bacteria were isolated from a septic methanol yeast process (Steudel et al., 1980) and from

sludge and described by Uhlig et al. (1986) as a new species, *Acetobacter methanolicus*, at present classified as *Acidomonas methanolica* (Urakami et al., 1989; Table 1).

The methanol-utilizing *Acidomonas methanolica* was reported in activated sludge from sewage treatment plants (Yamashita et al., 2004).

Fermented Meat Another unusual niche for acetic acid bacteria was described by Aries et al. (1982), who first isolated them from lactic-acid fermented meat used in the preparation of pet food. The isolates were further characterized as *Acetobacter pasteurianus* and *A. aceti* (Gosselé et al., 1984). The acetic acid bacteria alkalinize the meat by the dissimilation of lactic acid, thus allowing growth of pathogenic and toxigenic bacteria in a product where these bacteria had initially been inhibited by the low pH and by the lactic acid activity.

Isolation, Cultivation and Preservation A standard medium for the enrichment and isolation of acetic acid bacteria, with the exception of *Gluconacetobacter europaeus* and *Ga. entanii*, contains: yeast extract, 5.0 g; peptone, 3.0 g; D-glucose, 0.5 g; ethanol (99.8%), 15 ml; cycloheximide, 0.1 g; and distilled water, 1000 ml (Sievers and Swings, 2005). The following enrichment medium can also be recommended for most acetic acid bacteria except for isolates belonging to *Asaia*: yeast extract, 8.0 g; peptone, 15.0 g; D-glucose, 10.0 g; ethanol (99.8%), 5.0 ml; acetic acid, 3.0 ml; cycloheximide, 0.1 g; and distilled water, 1000 ml; final pH 3.5 (Lisdiyanti et al., 2003). Incubation is done at 30°C for 3–5 days and samples showing growth are then streaked on a $CaCO_3$-containing medium: yeast extract, 8.0 g; peptone, 5.0 g; D-glucose, 20.0 g; ethanol, 5.0 ml; $CaCO_3$, 3.0 g; agar, 15.0 g; and distilled water, 1000 ml. The acetic acid bacteria are selected as acid-producing strains that form clear zones around the colonies on the agar plates. Lisdiyanti et al. (2003) compared various media for the enrichment of acetic acid bacteria from Indonesian, Thai and Philippine sources. More specific methods for the isolation and cultivation of acetic acid bacteria are described in the sections of the individual genera.

Long-term preservation of strains of the Acetobacteraceae can be achieved by lyophilization or by storage in liquid nitrogen or by cryoconservation at –80°C using low-temperature refrigerators and appropriate cryoprotectants. Some of the acidophilic *Gluconacetobacter* strains require special precautions for their maintenance (see the section on Gluconacetobacter in this Chapter). Most acetic acid bacteria can be maintained at 4°C for several weeks on agar slants containing the appropriate medium (see sections on isolation and cultivation of the respective genera).

The Genus *Acetobacter* *Acetobacter* strains are easily differentiated from species of the genera *Gluconobacter*, *Gluconacetobacter*, *Acidomonas*, *Asaia* and *Kozakia* by their ability to oxidize acetate and lactate to CO_2 and H_2O and by having Q-9 as the major ubiquinone (Table 2). There are no exclusive phenotypic features to differentiate the 14 *Acetobacter* species. *Acetobacter aceti* (type species) and *A. pasteurianus* were mostly used in biochemical and genetic studies of *Acetobacter*.

Taxonomy In the eighth edition of *Bergey's Manual of Determinative Bacteriology* (De Ley and Frateur, 1974a), three species were recognized in the genus *Acetobacter*, basically referring to Frateur's classification system (Frateur, 1950): 1) *A. aceti* containing four subspecies (subsp. *aceti*, subsp. *orleanensis*, subsp. *xylinum*, and subsp. *liquefaciens*) and corresponding to Frateur's mesoxydans group; 2) *A. pasteurianus* encompassing five subspecies (subsp. *pasteurianus*, subsp. *lovaniensis*, subsp. *estunensis*, subsp. *ascendens* and subsp. *paradoxus*) and corresponding to Frateur's oxydans group with the exception of *A. paradoxus*; and 3) *A. peroxydans* corresponding to Frateur's peroxydans group. The names of these species and subspecies appeared on the Approved Lists of Bacterial Names (Skerman et al., 1980).

Gosselé et al. (1983), on the basis of numerical analyses of phenotypic features and protein profiles of more than 200 strains of acetic acid bacteria, rejected the subspecies concept in De Ley and Frateur's (1974a) classification and delineated four species in the genus *Acetobacter*: *A. aceti*, *A. hansenii*, *A. liquefaciens* and *A. pasteurianus*. These conclusive results appeared in *Bergey's Manual of Systematic Bacteriology* (De Ley et al., 1984c). However, Yamada (1983) revived *A. xylinus* as an independent species on the basis of its ubiquinone type. Subsequently, many new species were proposed in *Acetobacter*: "*Acetobacter polyoxogenes*" (Entani et al., 1985), *Acetobacter methanolicus* (Uhlig et al., 1986), *Acetobacter diazotrophicus* (Gillis et al., 1989), *Acetobacter europaeus* (Sievers et al., 1992), *Acetobacter pomorum* and *Acetobacter oboediens* (Sokollek et al., 1998b), and *Acetobacter intermedius* (Boesch et al., 1998). The establisment of the genus *Gluconacetobacter* (Yamada et al., 1997; Yamada et al., 1998) and the revival of the genus *Acidomonas* (Urakami et al., 1989) together with the transfer of *A. oboediens* and *A. intermedius* to the genus *Gluconacetobacter* (Yamada, 2000a) decreased the number of

Acetobacter species in 2000 to three: *A. aceti*, *A. pasteurianus* and *A. pomorum*.

On the basis of a polyphasic taxonomic study including DNA-DNA hybridizations, determination of ubiquinone composition and 16S rRNA gene analysis using strains freshly isolated from Indonesian sources together with strains from culture collections, Lisdiyanti et al. established five new species (*A. indonesiensis*, *A. tropicalis*, *A. orientalis*, *A. syzygii* and *A. cibinongensis*) and three new combinations (*A. estunensis*, *A. orleanensis* and *A. lovaniensis*) and revived *A. peroxydans* as a separate species in the genus (Lisdiyanti et al., 2000; Lisdiyanti et al., 2001). Cleenwerck et al. (2002) re-examined the classification of various *Acetobacter* strains, confirmed the entity of the new combinations and new species proposed by Lisdiyanti et al. (Lisdiyanti et al., 2000; Lisdiyanti et al., 2001), and additionally proposed two new species, namely *A. malorum* and *A. cereviseae*.

At present 14 species are recognized in the genus *Acetobacter* (Table 1; Fig. 2). *Acetobacter aceti* is the type species.

Habitats *Acetobacter* strains were isolated from vinegar, alcoholic beverages (such as sake, beer, wine, palm wine, cider, tequila, and cocoa wine), fermented foods (such as pickles, nata, and mash of alcoholic beverages), fruits (such as grapes, guava, sapodilla, starfruits, mangosteen, mango, banana, papaya, etc.), flowers (e.g., canna), and other materials (such as coconut juice, palm seed, and tofu; see the section Habitats and Uses of Acetic Acid Bacteria in this Chapter).

Isolation and Cultivation Basically, a medium containing glucose, ethanol and acetic acid is appropriate for the isolation of *Acetobacter* strains. Lisdiyanti et al. (2003) used an enrichment medium (glucose, 10.0 g; ethanol, 5.0 ml; acetic acid, 3.0 ml; peptone, 15.0 g; yeast extract, 8.0 g; cycloheximide, 0.1 g; and distilled water, 1000 ml) and described that more than 67% of the isolated acetic acid bacteria belonged to the genus *Acetobacter*.

Identification Features differentiating the genus *Acetobacter* from the other Acetobacteraceae are listed in Table 2. The sequence similarities of the 16S rDNA sequences of the *Acetobacter* type strains vary (97–99.5%). *Acetobacter aceti* is clearly distinguished from the other species by the formation of dihydroxyacetone from glycerol and the production of 2- and 5-ketogluconate from glucose, *A. pasteurianus* by its tolerance of ethanol, *A. peroxydans* by a negative catalase reaction and by its lack of acid formation from glucose, and *A. pomorum* by its requirement of acetic acid for growth. Differential characteristics of the 14 *Acetobacter* species are given in Table 3. At present DNA-DNA hybridization is recommended for the identification of *Acetobacter* strains at the species level.

Physiological and Biochemical Properties *Acetobacter* strains are motile by peritrichous flagella or nonmotile. They are obligately aerobic, oxidase negative, and oxidize ethanol to acetic acid. Acetate and lactate are oxidized to CO_2 and H_2O. Ethanol, glucose and glycerol are good carbon sources for growth. In liquid media *Acetobacter* strains develop usually rings or pellicles. They do not grow on Hoyer-Frateur medium (De Ley and Frateur, 1974a) or Frateur's modified Hoyer medium with glucose, ethanol or mannitol as a sole carbon source. They do not produce γ-pyrones from D-glucose or D-fructose and do not form 2, 5-diketogluconate from glucose (Table 2). Acids are formed from ethanol but not from sugar alcohols such as glycerol, sorbitol and mannitol.

Table 3. Differentiating features among the species of *Acetobacter*.[a]

[b]Nitrate reduction was tested in nitrate peptone according to Franke et al. (1999).

Data from Sokollek et al. (1998b), Lisdiyanti et al. (2000), Lisdiyanti et al. (2001), and Cleenwerck et al. (2002).

The oxidation of ethanol by *Acetobacter* strains is catalyzed by two cytoplasmic membrane-bound enzymes: ADH (alcohol dehydrogenase) and ALDH (aldehyde dehydrogenase). The ADH from *Acetobacter* was purified as a complex of several protein subunits; 72, 45 and 15 kDa in *A. aceti* (Inoue et al., 1989; Inoue et al., 1992; Matsushita et al., 1992b), and 78, 48 and 20 kDa in *A. pasteurianus* (Kondo et al., 1995). The larger subunit of the ADH possesses a heme *c* and a pyrroloquinoline quinone (PQQ) as cofactors and requires Ca^{+2} to be active, the second subunit is a cytochrome *c*, and the third and smallest subunit of the three-component ADH is considered to protect the catalytic subunit from proteolysis and to maintain the correct conformation of the ADH-complex for electron transport on the periplasmic surface (Kondo et al., 1995). For the breakdown of sugars, *Acetobacter* is equipped with the hexose monophosphate pathway and the tricarboxylic acid (TCA) cycle (Asai, 1968).

Contradictory data were reported concerning the growth on methanol or utilization of methanol by *A. pasteurianus*, *A. lovaniensis*, *A. pomorum* and *A. malorum* strains (Gosseléet al., 1983; Uhlig et al., 1986; Urakami et al., 1989; Sokollek et al., 1998b; Cleenwerck et al., 2002). Ambiguity about growth on methanol and utilization of methanol can be ascribed to unclear definitions of assimilation and utilization of methanol and growth on methanol. Differences in employed media may also contribute to contradictory reports concerning these features. Indeed, the yeast extract or peptone included in some media, together with impurities in the agar, can serve as carbon source for acetic acid bacteria, yielding false positive results for assimilation or utilization of methanol or both or false positive growth on methanol. We recommend that these characteristics should be tested on a defined medium, such as the yeast extract-omitted medium C of Yamashita et al. (2004), or by appropriate biochemical techniques.

Thermotolerant *Acetobacter* strains have been described and may find applications for the production of vinegar at higher temperatures (38–40°C; Lu et al., 1999; Adachi et al., 2003b). The DNA base composition of *Acetobacter* is 52–61 mol% G+C.

Genetics Genetic studies of *Acetobacter* are focused on the elucidation of the mechanism of acetic acid fermentation, resistance to acetic acid and ethanol, and other factors such as mutations associated with growth and environment (reviewed by Beppu, 1993). As a result of the development of host-vector systems (Fukaya et al., 1985a; Fukaya et al., 1990; Okumura et al., 1985; Okumura et al., 1988) and genetic transformation systems (Fukaya et al., 1985b; Fukaya et al., 1985c; Takemura et al., 1991), various genes of *Acetobacter* strains were cloned and characterized. In the context of the elucidation of the mechanism of acetic acid fermentation, the genes encoding the subunits of alcohol dehydrogenase (ADH) were cloned and characterized for *A. aceti* K6033 (Inoue et al., 1989; Inoue et al., 1990; Inoue et al., 1992), *A. aceti* 1023 (Fukaya et al., 1993b), *A. pasteurianus* NCI 1380 (Takemura et al., 1991; Takemura et al., 1993a) and *A. pasteurianus* NCI 1452 (Kondo et al., 1995). The ADH activity of *A. pasteurianus* is induced by ethanol (Takemura et al., 1993a).

For investigating the mechanisms of acetic acid and ethanol resistance, Fukaya et al. (1990) isolated acetic acid-sensitive mutants of *A. aceti* 1023 by chemical mutagenesis and cloned three genes (*aarA*, *aarB* and *aarC*) responsible for acetic acid resistance from the mutants. The *aarA* gene product is citrate synthase; the *aarC* gene product seems to be involved in acetate assimilation, and the function of *aarB* is still unknown (Fukaya et al., 1993a). Using the same mutagenesis method Takemura et al. (1993b) isolated an ethanol-resistant mutant strain of *A. pasteurianus* NCI 1380 and cloned a *his1* gene responsible for ethanol resistance. The *his1* gene encodes for a polypeptide displaying a significant homology with histidinol phosphate aminotransferase (HPAT) from *Escherichia coli* and other bacteria. However, the mutant still possesses almost the same HPAT activity as the parental strain. The mechanism of acetic acid and ethanol resistance remains still unclear and it was suggested that the energy generating system in the cell membrane may be linked to these mechanisms.

Quite often spontaneous mutations occur in *Acetobacter*. Ohmori et al. (1982) reported that a correlation exists between the loss of acetic acid resistance and ethanol oxidizing ability of *A. aceti* 1023. Kondo and Horinouchi (1997a) reported that insertion sequences (IS) integrated in the genome of *Acetobacter* are responsible for genetic instability leading to deficiencies in various physiological properties such as inactivation of ADH. *Acetobacter pasteurianus* strain NCI 1380 harbors five copies of IS*12528,* 10 copies of IS*1452* (Kondo and Horinouchi, 1997a), and 100 copies of IS*1380* (Takemura et al., 1991) with a total insertion element length of more than 6% of the nucleotide sequence of the genome (Kondo and Horinouchi, 1997a). Okamoto-Kainuma et al. (2002) cloned and characterized the *groESL* operon, believed to be associated with the resistance against various stress factors. The transcription of this operon in *A. aceti* IFO 3283 was induced by heat shock as well as by exposure to ethanol and acetic acid. Kashima et al. cloned and characterized the gene *est1*, coding

for the intracellular esterase which is involved in ethylacetate formation from ethanol and acetic acid (Kashima et al., 1999; Kashima et al., 2001). The transcription of this gene is induced by ethanol in *A. pasteurianus* and its regulation depends on the oxygen concentration.

Phosphatidylcholine, a major component of the membrane lipids, is found abundantly in cells of acetic acid bacteria. Hanada et al. (2001) cloned the *pmt* gene encoding phosphatidylethanolamine *N*-methyltransferase catalyzing the methylation of phosphatidylethanolamine to phosphatidylcholine in *A. aceti* and concluded that a correlation exists between phosphatidylcholine biosynthesis and acetic acid resistance.

Pathogenicity on Fruits *Acetobacter* strains can infect apples and pears and cause bacterial rot of these fruits, being characterized by browning and tissue degradation (see the section Habitats and Uses of Acetic Acid Bacteria in this Chapter). Bacterial rot of apples could be induced by artificial inoculation, using an inoculum size as low as 100 cells (Vanden Abeele et al., 1980; Van Keer et al., 1981a; Van Keer et al., 1981b).

Applications Several *Acetobacter* species (e.g., *A. aceti* and *A. pasteurianus*) were reported to be involved in the industrial production of vinegar (see the section Habitats and Uses of Acetic Acid Bacteria in this Chapter). More recently, various *Gluconacetobacter* species (e.g., *Ga. europaeus* and *Ga. entanii*) were isolated from vinegar production plants (see the section Gluconacetobacter in this Chapter). Vinegar has been used in the preservation of foods, in medicine as the first antibiotic known, as a common drink of slaves and soldiers in the Roman empire, and also as a cooking ingredient (see the section Habitats and Uses of Acetic Acid Bacteria in this Chapter and Organic Acid and Solvent Production in Volume 1).

Acetobacter peroxydans has been used as a biosensor for the determination of H_2O_2 by coupling immobilized living bacterial cells to an amperometric oxygen electrode (Rajasekar et al., 2000).

The Genus Acidomonas The facultatively methylotrophic *Acidomonas* strains share similar characteristics with other acetic acid bacteria such as growth at low pH and production of acetic acid and gluconic acid from ethanol and glucose, respectively. Utilization of methanol and a unique niche are characteristic for this genus.

Taxonomy The genus *Acidomonas* was validly established for Gram-negative, rod-shaped, acidophilic, facultatively methylotrophic bacteria by Urakami et al. (1989), incorporating *Acetobacter methanolicus* Uhlig et al. (1986). Sievers et al. (1994b) proposed a revival of *Acetobacter methanolicus*, but the separate phylogenetic position of the genus *Acidomonas* was justified by Yamada et al. (Yamada et al., 1997; Yamada et al., 2000b). Yamashita et al. (2004) emended the description of the genus *Acidomonas* on the basis of data using new strains isolated from activated sludge. The phylogenetic relationship of the genus *Acidomonas* as a member of the family Acetobacteraceae was reported by Bulygina et al. (1992) on the basis 5S rRNA sequencing and later confirmed by 16S rDNA sequencing (Sievers et al., 1994a; Sievers et al., 1994b; Yamada et al., 1997; Yamashita et al., 2004; Fig. 2). At present *Acidomonas methanolica* is the only species in this genus.

Habitats Currently 14 strains of *Ac. methanolica* are preserved in culture collections worldwide (Yamashita et al., 2004). Among the acetic acid bacteria, *Acidomonas* strains seem to occur in unique niches: sludge from sewage-treatment plants and a yeast fermentation process where methanol was the sole source of carbon and energy. They were not reported in fruits or plant material (Yamashita et al., 2004).

Isolation and Cultivation *Acidomonas* strains can be isolated by enrichment on medium C according to Yamashita et al. (2004). Medium C was described by Urakami et al. (1989) and its composition is as follows: methanol, 10 ml; yeast extract, 0.2 g; $(NH_4)_2SO_4$, 3.0 g; KH_2PO_4, 4.0 g; $MgSO_4 \cdot 7H_2O$, 0.2 g; $CaCl_2 \cdot 2H_2O$, 30 mg; $MnCl_2 \cdot 4H_2O$, 5.0 mg; $ZnSO_4 \cdot 7H_2O$, 5.0 mg; $CuSO_4 \cdot 5H_2O$, 0.5 mg; vitamin solution, 1.0 ml; and distilled water, 1000 ml. The vitamin solution contains: biotin, 2 mg; calcium pantothenate, 400 mg; pyridoxine·HCl, 400 mg; thiamine·HCl, 400 mg; *p*-aminobenzoic acid, 200 mg; folic acid, 2 mg; inositol, 2 mg; nicotinic acid, 400 mg; riboflavin, 200 mg; and distilled water, 1000 ml. Incubation is done at 30°C for 3–5 days in flasks with shaking. After enrichment, bacteria are streaked on agar plates containing medium C or PYMe medium. The composition of PYMe medium is: peptone, 5.0 g; yeast extract, 3.0 g; methanol, 10 ml, and distilled water, 1000 ml. The pH of both media is adjusted to 4.0 with HCl. Colonies are isolated, further purified on medium C, characterized and identified. *Acidomonas* strains can also be cultivated on PYM medium (peptone, 5.0 g; yeast extract, 3.0 g; malt extract, 3.0 g; glucose, 20.0 g; and distilled water, 1000 ml; pH 4.5) as described by Urakami et al. (1989).

Identification Features differentiating the genus *Acidomonas* from the other Acetobacteraceae are listed in Table 2. Phenotypically, *Acidomonas*

strains differ from other acetic acid bacteria in the utilization of methanol in medium C. Using Leifson's method *Acidomonas* strains oxidize acetate but do not (or weakly) oxidize lactate (Table 2). Further, *Acidomonas* strains are motile by a single polar flagellum (occasionally a polar tuft of flagella) or nonmotile, and their colonies on PYM agar medium are shiny, smooth, circular, convex, entire, beige to pink, and 1–3 mm in diameter after 5 days at 30°C. They grow at pH 3.0–8.0 and are therefore not acidophilic but acidotolerant. They grow at 30°C but not at 45°C. Acetic acid is produced from ethanol. Growth occurs in the presence of 0.35% acetic acid and 30% glucose. Yamashita et al. (2004) used 16S rDNA sequence analysis to assess the phylogenetic relationship between 14 strains of *Ac. methanolica* and reported that all strains formed a single cluster on the lineage of the Acetobacteraceae, clearly distant from the members of the genera *Acetobacter*, *Gluconobacter*, *Gluconacetobacter*, *Asaia* and *Kozakia* (Fig. 2).

Correct identification of *Acidomonas* isolates may require sequencing of 16S rDNA as well as DNA-DNA hybridizations.

Physiological and Biochemical Properties *Acidomonas* strains were once regarded as promosing bacteria for the production of single cell protein from methanol. Therefore, their growth on and oxidation of several carbon sources have been studied in detail.

Acidomonas strains utilize methanol, glycerol or glucose as a sole carbon source for energy and growth via a periplasmic oxido-reductase system and a cytoplasmic ribulose monophosphate pathway (Steudel et al., 1980). The strains have a methanol oxidase respiratory chain (similar to most methylotrophs) in addition to an ethanol oxidase respiratory chain functioning at acidic pH. However, the methanol oxidase system of *Acidomonas* is totally different from its ethanol oxidase system. Under methylotrophic conditions, the methanol oxidase respiratory chain operates by linking methanol dehydrogenase to cytochrome *co* via soluble cytochromes *c* (Chan and Anthony, 1991; Matsushita et al., 1992a). The methanol dehydrogenase of *Acidomonas* strains exhibits two different forms: type I has an $\alpha_2\beta_2$ conformation consisting of 62- and 8.5-kDa peptides, and type II exhibits an $\alpha_2\beta_2\gamma$ conformation with a γ-subunit of 32 kDa showing a high homology to MoxJ of the methylotrophic *Methylobacterium extorquens* (Matsushita et al., 1993). In *Acidomonas* strains grown on glycerol, the ethanol oxidase respiratory chain consists of alcohol dehydrogenase, ubiquinone-10, and cytochrome *bo* ubiquinol oxidase (Matsushita et al., 1992a). The alcohol dehydrogenase of the strains consists of three subunits and is repressed under methylotrophic conditions (Frebortova et al., 1997).

The structures of the capsular polysaccharide and O-side-chain of the lipopolysaccharide of three *Acidomonas* strains have been determined with the aid of bacteriophages specific for *Ac. methanolica* (Grimmecke et al., 1991; Grimmecke et al., 1994a; Grimmecke et al., 1994b).

Acidomonas strains produce only gluconic acid from glucose. Pantothenic acid is required for growth. *Acidomonas* strains assimilate ammoniacal nitrogen with D-glucose and other carbon sources when pantothenic acid is supplied to the defined media (Yamashita et al., 2004). Acid is produced from L-arabinose, D-xylose, D-ribose, D-galactose, D-mannose, D-glucose, glycerol, *n*-propanol, *n*-butanol, isobutanol, ethanol and methanol but not from L-rhamnose, D-fructose, sucrose, maltose, lactose, raffinose, trehalose, D-mannitol, inositol, D-sorbitol, dulcitol or soluble starch. Methanol, ethanol, D-glucose, glycerol, D-mannose and succinic acid are assimilated as a sole carbon source on defined medium (Yamashita et al., 2004).

The major ubiquinone is Q-10 (Urakami et al., 1989; Yamashita et al., 2004), and the major cellular fatty acid is C18:1 and the major hydroxy acids are 3-OH C16:0 and 2-OH C16:0 (Urakami et al., 1989). DNA base composition is 62–63 mol% (Yamashita et al., 2004).

Genetics Bacteriophage Acm1, virulent for the type strain of *Ac. methanolica*, was identified by Kiesel and Wunsche (1993). Auxotrophic mutants for homoserine and threonine were obtained from the type strain of *Ac. methanolica* by *N*-methyl-*N*′-nitro-*N*-nitrosoguanidine treatment (Follner and Babel, 1992). Heterologous genes have been expressed in *A. methanolica* (Follner et al., 1994).

Applications *Acidomonas methanolica* seems to supercede *Gluconobacter* for the industrial production of gluconic acid. A two-phase process has been developed in which *Ac. methanolica* cells are grown on methanol in phase one, and subsequently high glucose concentrations can rapidly be converted to pure gluconic acid during the production phase (Babel et al., 1991; Poehland et al., 1993). More details can be found in the chapter Organic Acid and Solvent Production in Volume 1.

The Genus Asaia Compared to the classical acetic acid bacteria *Asaia* strains have some unusual characteristics because they produce no or only limited amounts of acetic acid from ethanol, and their growth is completely inhibited by 0.35% acetic acid. *Asaia* strains were mostly isolated

from tropical flowers and prefer sugars for growth.

Taxonomy The genus *Asaia* was first described by Yamada et al. (2000). At present the following three species are recognized: *Asaia bogorensis* (type species), *Asaia krungthepensis* and *Asaia siamensis* (Table 1). This classification is based on phenotypic and chemotaxonomic features, as well as on data obtained from DNA-DNA hybridizations and 16S rDNA sequencing (Yamada et al., 2000b; Katsura et al., 2001; Yukphan et al., 2004b). *Kozakia baliensis* is a phylogenetic neighbor of the genus *Asaia* (Fig. 2).

Habitats *Asaia* strains were mostly isolated from flowers from tropical plants, such as the orchid tree (*Bauhinia purpurea*), plumbago (*Plumbago auriculata*), crown flower (*Calotropis gigantea*), spider lily (*Crinum asiaticum*), ixora (*Ixora chinensis*), lantana, heliconia, roses, etc. One strain of *As. bogorensis* (NRIC 0320) was isolated from "tape ketan" (an Indonesian traditional fermented food made from glutinous rice). In a batch of fruit-flavored bottled water, Moore et al. (2002a) detected through partial 16S rRNA gene sequencing an *Asaia* strain as a spoilage organism.

Isolation and Cultivation *Asaia* strains can be enriched in a medium containing D-sorbitol or dulcitol at pH 3.5 without the addition of acetic acid. The composition of the isolation medium is as follows (in g per liter distilled water): dulcitol or D-sorbitol, 20.0; peptone, 5.0; yeast extract, 3.0; and cycloheximide, 0.1; adjusted to pH 3.5 with HCl. Incubation is done at 30°C for 3–5 days in flasks with shaking (Lisdiyanti et al., 2003). Cultures showing growth are streaked on $CaCO_3$ agar plates containing (g per liter distilled water): D-glucose, 20.0; ethanol, 5.0; yeast extract, 8.0; $CaCO_3$, 7.0; and agar, 15.0. Colonies of *Asaia* strains are pinkish or yellowish, do no produce water-soluble brown pigments, and will dissolve the $CaCO_3$ around the colonies weakly. Such colonies are isolated and further purified.

Identification Features differentiating the genus *Asaia* from the other genera of the Acetobacteraceae are listed in Table 2. The three *Asaia* species form a very closely related cluster in the phylogenetic tree based on 16S rDNA sequences (16S rDNA sequence similarities between the three species are as high as 99.5–99.9%; Fig. 2). *Asaia* species can best be differentiated by DNA-DNA hybridizations.

Characteristic features of *Asaia* strains are as follows: good growth at pH 3.0 but no growth in a medium containing 0.35% acetic acid. They do not (or weakly) oxidize ethanol to acetic acid, they oxidize acetate or lactate weakly to CO_2 and H_2O, and they possess Q-10 as the major ubiquinone. These characteristics are useful for differentiation of this genus from members of the genera *Acetobacter*, *Acidomonas*, *Gluconacetobacter*, *Gluconobacter* and *Kozakia* (Table 2).

The three species of *Asaia* can be phenotypically differentiated by the acid production from dulcitol (Table 4). *Asaia krungthepensis* strains display weak growth on maltose, whereas the type strains of the two other *Asaia* species fail to grow on this substrate (Yukphan et al., 2004b; Table 4).

Physiological and Biochemical Properties *Asaia* strains produce gluconic acid, 2-ketogluconate and 5-ketogluconate but no 2,5-diketogluconate from D-glucose. They show vigorous growth on a vitamin-free Hoyer-Frateur medium containing D-glucose as sole carbon source but not when ethanol is supplied as a sole C-source. Therefore, they do not require any growth factors for growth on D-glucose as sole carbon source. Acid is produced from D-glucose, D-mannose, D-galactose, D-fructose, L-sorbose, D-xylose, L-arabinose, *meso*-erythritol, glycerol, melibiose and sucrose but not from lactose. The DNA base composition is 59–61 mol% G+C.

The Genus Gluconacetobacter *Gluconacetobacter* strains are nonmotile or motile by peritrichous flagella. They oxidize ethanol to acetic acid, which is generally overoxidized to CO_2 and H_2O. They possess ubiquinone of the Q-10 type as major quinone. Strains of *Ga. diazotrophicus* are good nitrogen fixers and live in association with plants, such as sugarcane. *Gluconacetobacter xylinus* strains produce thick cellulose pellicles in liquid media, and other species, such as *Ga. europaeus*, are involved in high-acid vinegar fermentations.

Taxonomy The genus *Gluconacetobacter* was created by Yamada et al. to accommodate the ubiquinone Q-10 containing *Acetobacter* species, such as *A. liquefaciens*, *A. diazotrophicus*, *A. europaeus*, *A. hansenii* and *A. xylinus* (Yamada

et al., 1997; Yamada et al., 1998), which in 16S rRNA sequence analysis clustered remotely from the core of the Q-9 containing *Acetobacter* species. Note that already in 1984 it was proposed to accommodate the acetate-oxidizing acetic acid bacteria containing ubiquinone Q-10 (*A. liquefaciens* and *A. xylinus*) in a new subgenus *Gluconoacetobacter* of the genus *Acetobacter* (Yamada and Kondo, 1984b). The (sub)generic name *Gluconoacetobacter* has been corrected to *Gluconacetobacter* (Yamada et al., 1998) in accordance with rule 61 of the International Code of Nomenclature of Bacteria. Later the *Acetobacter* species *A. intermedius* and *A. oboediens* were also transferred to *Gluconacetobacter* on the basis of their 16S rRNA gene sequences (Yamada, 2000a), and at present the genus *Gluconacetobacter* contains 11 species (Table 1; Fig. 2), with *Ga. liquefaciens* as the type species. The high degree of DNA-DNA hybridization between the type strains of *Ga. intermedius* and *Ga. oboediens* indicated that these two species might be synonymous (Sievers and Swings, 2005). Phenotypic and genotypic heterogeneity were reported among strains of *Ga. hansenii* (Gosselé et al., 1983; Navarro et al., 1999b).

Habitats *Gluconacetobacter* strains were isolated from various sources such as flowers and fruits, sugarcane tissues, the pink sugarcane mealy bug, the rhizosphere and rhizoplane of coffee plants, tea fungus (kombucha), nata de coco, and vinegar production units. Some of the working strains in vinegar acetators belong indeed to *Gluconacetobacter* (e.g., *Ga. europaeus*; Sievers et al., 1992). Gluconacetobacters can also cause infections in beverages and spirituous liquors (more details can be found in the section Habitats and Uses of Acetic Acid Bacteria in this Chapter).

Isolation, Cultivation and Preservation Most *Gluconacetobacter* species, such as *Ga. liquefaciens*, *Ga. azotocaptans*, *Ga. diazotrophicus*, *Ga. hansenii* and *Ga. johannae*, can be grown on a medium containing mannitol, yeast extract and peptone (MYP medium). The recommended growth media for the various *Gluconacetobacter* species are listed in Table 5. A special N-free acidic LGI medium (pH 4.5) has been used for the isolation of the N_2-fixing *Ga. diazotrophicus*, *Ga. azotocaptans* and *Ga. johannae* strains from their respective host plants (Cavalcante and Döbereiner, 1988; Fuentes-Ramírez et al., 1993; Fuentes-Ramírez et al., 2001).

Until 1985 the working strains in high-acidic vinegar fermentors (up to 17% acetic acid) could not be grown on the media commonly used for acetic acid bacteria, and the bacteriological composition of the "seed vinegar" of such acetators remained largely unknown. The lack of defined pure starter cultures is due to problems in isolation, cultivation and conservation of acetic acid bacteria involved in high-acid vinegar production (Sievers and Teuber, 1995a). This drawback was partly overcome by the invention of a special double layer technique introduced by Entani et al. (1985) for the isolation of the microflora from vinegar fermenters in Japan. The double-layered modified AE-medium (Table 5) provides a constant supply of ethanol and high humidity from the bottom to the top layer of the medium and supports the growth of bacterial colonies at the agar surface. The incubators should contain a relative humidity of 92–97%. The application of these isolation and cultivation techniques led to the description of new species such as *Ga. europaeus*, *Ga. entanii*, *Ga. oboediens*, etc. (Sievers et al., 1992; Boesch et al., 1998; Sokollek et al., 1998b; Schüller et al., 2000).

Special precautions should also be taken for the preservation of *Gluconacetobacter* strains isolated from high-acid acetators, such as *Ga. entanii* and *Ga. europaeus*: 20% malt extract appears to be an effective cryoprotectant (Sokollek and Hammes, 1997; Sokollek et al., 1998a; Schüller et al., 2000). Freshly grown cells are harvested by centrifugation at 0°C and resuspended in 2 ml of ice-cold 20% malt extract solution. This suspension is poured dropwise in liquid nitrogen. The frozen culture is then lyophilized and stored at –20°C (Schüller et al., 2000).

Identification Features differentiating the genus *Gluconacetobacter* from the other Acetobacteraceae are listed in Table 2. The similarities of the 16S rDNA sequences of the *Gluconacetobacter* type strains vary between 96.6% and 99.6%. Characteristics differentiating the 11 *Gluconacetobacter* species are compiled in Table 5. Some species can be differentiated by their differences in growth behavior on media with high concentrations of acetate or glucose. Correct identification may require sequencing of the 16S rDNA as well as DNA-DNA hybridizations. An oligonucleotide probe based on the 23S rDNA of *Ga. europaeus* seems to be a useful tool for the differentiation of *Ga. intermedius* from *Ga. europaeus* and *Ga. xylinus* (Boesch et al., 1998).

Physiological and Biochemical Properties Gluconacetobacters grow best on ethanol, glucose or acetate as carbon source. Acids are formed from ethanol, glucose and usually from fructose and glycerol. The overoxidation of acetate to CO_2 and H_2O depends upon the acetate concentration in the medium. Depending upon the species, the pH optimum for growth varies between 2.5 and 6.0. Two species (*Ga. europaeus* and *Ga. entanii*) require acetic acid for growth (Table 5). The respiratory chain of *Gluconacetobacter*

[b]DNAs from the type strains of *Ga. intermedius* and *Ga. oboediens* showed species-level similarity of 76% among each other (Sievers and Swings, 2005).
[c]The sum of acetic acid and ethanol concentrations has to exceed 6% (Schüller et al., 2000).
[d]Composition of media (in g per liter, except when indicated):
GYC-medium: D-glucose, 100.0; yeast extract, 10.0; $CaCO_3$, 20; and agar, 15.0.
MYP-medium: D-mannitol, 25.0; yeast extract, 5.0; peptone, 3.0; and agar, 15.0.
AE-medium (acetic acid and ethanol medium): D-glucose, 5.0; yeast extract, 2.0; peptone, 3.0; acetic acid, 40.0ml (filter-sterilized); ethanol, 30.0ml (filter-sterilized); agar, 5.0 (bottom layer); agar, 10 (top layer); and 930ml distilled water. Add the filter-sterilized ethanol and acetic acid aseptically to the sterile basal medium. Pour the bottom layer AE-agar into a Petri dish and allow to solidify. Overlay the bottom agar surface with a thin coating (5–10ml) of top layer AE-agar and allow to solidify. Carefully streak the plates and incubate at 30°C for 1–2 weeks at 92–96% relative humidity (use, e.g., closed containers such as plastic boxes; Entani et al., 1985; Sievers et al., 1992).
RAE-medium (reinforced AE-medium): D-glucose, 40.0; yeast extract, 10.0; peptone, 10.0; $Na_2HPO_4 \cdot 2H_2O$, 3.38; citric acid, 1.5; acetic acid, 10.0ml (filter-sterilized); ethanol, 20.0ml (filter-sterilized); agar, 5.0 (bottom layer); agar, 10 (top layer); and 970ml distilled water. Use the double-layered system as described for the AE-medium (Sokollek and Hammes, 1997; Schüller et al., 2000).
Data from Sievers et al. (1992), Boesch et al. (1998), Sokollek et al. (1998b), Franke et al. (1999), Navarro and Komagata (1999a), Fuentes-Ramírez et al. (2001), Schüller et al. (2000), and Sievers and Swings (2005).

contains cytochrome *c*, ubiquinne, and a terminal ubiquinol oxidase (Matsushita et al., 1994). A complete TCA cycle is present. The citrate synthase from *Ga. europaeus* has been purified and its activity appears to be activated by acetate, inhibited by ATP, and not affected by reduced nicotinamide adenine dinucleotide (NADH; Sievers et al., 1997). *Gluconacetobacter oboediens* grows in the presence of 30% glucose and accumulates high concentrations of gluconic acid (at least 130 g per liter; Sokollek et al., 1998b). The DNA base composition of *Gluconacetobacter* is 56–67 mol% G+C.

OXIDATION OF ETHANOL AND VINEGAR PRODUCTION. The alcohol and acetaldehyde dehydrogenases of *Ga. europaeus* (a species isolated from high-acid vinegar fermentors) have been investigated in detail (Thurner et al., 1997). The membrane-bound alcohol and aldehyde dehydrogenase complexes consist of two and three subunits, respectively. The larger subunit of the alcohol dehydrogenase contains heme *c* and a pyrroloquinoline quinone (PQQ) as cofactor, whereas the second subunit is cytochrome *c*. The aldehyde dehydrogenase complex is organized as an operon containing three consecutive open reading frames (ORFs) corresponding to proteins with molecular masses of 84, 49 and 17 kDa. Its larger catalytic subunit contains heme *b* and a molybdopterin instead of PQQ; the middle subunit is a cytochrome *c* with three heme-*c* binding sites, and the smallest subunit contains two [2Fe-2S] clusters (Thurner et al., 1997).

Gluconacetobacter europaeus strains display an absolute requirement of acetic acid for growth on ethanol, whereas *Ga. entanii* strains require ethanol as well as acetate and glucose for growth (Sievers et al., 1992; Schüller et al., 2000; Table 5). The latter microorganism grows only when the total concentration of ethanol and acetic acid exceeds 6% (Schüller et al., 2000; Table 5).

FORMATION OF CELLULOSE AND ACETAN BY *GLUCONACETOBACTER XYLINUS*. Bacterial cellulose is characterized by its chemical purity, distinguishing it from plant cellulose, which is usually associated with hemicellulose and lignin. Because of its high mechanical strength and its ultrafine reticulated structure, bacterial cellulose has found many applications in paper, textile and food industries, as well as in medicine and cosmetics. Studies on the biogenesis of bacterial cellulose have been pioneered by Hestrin (1947), Hestrin (1962), Colvin (1977), Colvin (1980) and their coworkers (Hestrin et al., 1947; Hestrin and Schramm, 1954). *Gluconacetobacter xylinus* strains (previously named *Acetobacter xylinum* or *A. xylinus*) have been intensively used as model organisms for basic and applied studies on the biochemistry and genetics of cellulose formation (for reviews, see Cannon and Anderson [1991], Ross et al. [1991], Brown and Saxena [2000], Bielecki et al. [2002], Römling [2002], and Brown [2004]). This research on *Ga. xylinus* contributed also significantly to the elucidation of the mechanisms of biogenesis of cellulose in plants. Various studies focus on cellulose formation by "*Ga. xylinus* subsp. *sucrofermentans*" (Toyosaki et al., 1995; Watanabe et al., 1998; Chao et al., 2001). Most *Ga. intermedius* strains and some *Ga. hansenii* and *Ga. europaeus* strains form also bacterial cellulose (Table 5).

In static cultures, *Ga. xylinus* synthesizes a thick cellulose mat (called a "pellicle") covering the surface of the growth medium, whereas round balls of cellulose are formed in shaken cultures. Mutants which do not produce cellulose can be formed spontaneously in cultures aerated by shaking or stirring. Cells of cellulose producing bacteria are entrapped in the polymer matrix, often supporting the population at the liquid-air interface (Williams and Cannon, 1989). This facilitates oxygen and nutrient supply, since the concentration of nutrients in the cellulose matrix is enhanced by its absorptive properties, in contrast to the surrounding aqueous environment (Jonas and Farah, 1998).

Although bacterial cellulose is chemically identical to plant cellulose, its macromolecular structure and properties differ from the latter. Linearly ordered pores along the longitudinal axis of *Ga. xylinus* cells secrete long β-1,4-glucan chains that aggregate to form subfibrils with a diameter of 1.5 nm. These subfibrils aggregate to microfibrils by crystallization with subsequent assembly to ribbons (average thickness of 3–4 nm and a width of 70–130 nm) in the surrounding medium (Zaar, 1977; Zaar, 1979; Bielecki et al., 2002). The width of plant cellulose fibers is two orders of magnitude larger. The ultrafine ribbons of bacterial cellulose reach a length of 1–10 μm and form a very dense reticulated structure, stabilized by extensive hydrogen bonding (Jonas and Farah, 1998). The key enzyme in cellulose synthesis by *Ga. xylinus* is the membrane-bound cellulose synthase (UDP-glucose:1,4-β-D-glucan 4-β-D-glucosyl transferase), which uses UDP-glucose as substrate. The complete pathway from glucose to cellulose consists of the following four enzymatic steps (Ross et al., 1991):

Glucose → glucose-6-phosphate → glucose-1-phosphate → UDP-glucose → cellulose

The cellulose synthase is activated by cyclic diguanylic acid (c-di-GMP) acting as an allosteric effector and stimulating the enzymatic reaction rate up to 200-fold (Ross et al., 1986; Ross et al., 1987; Weinhouse et al., 1997). This unique

cyclic oligonucleotide is synthesized and degraded by the enzymes diguanylate cyclase and a Ca^{+2}-sensitive phosphodiesterase A, respectively, which have regulatory effects on cellulose biosynthesis. The biochemistry of the allosteric regulation mechanism of the cellulose synthase in *Ga. xylinus* has been thoroughly investigated and reviewed by Ross et al. (1991).

Most *Ga. xylinus* and *Ga. intermedius* strains produce besides the water-insoluble cellulose also a water-soluble polysaccharide called "acetan," a heteropolymer containing glucose, mannose, glucuronic acid and rhamnose in a molar ratio of 4 : 1 : 1 : 1 (Couso et al., 1987). Acetan formation seems to influence the degree of polymerization and crystallinity of the cellulose fibrils (Watanabe et al., 1998). Various genes of the acetan biosynthetic pathway (UDP-glucose dehydrogenase, GDP-mannosyl transferase, etc.) have been identified and sequenced (Griffin et al., 1994; Griffin et al., 1996; Petroni and Ielpi, 1996; Griffin et al., 1997).

NITROGEN FIXATION BY *GLUCONACETOBACTER DIAZOTROPHICUS*. The hitherto described N_2-fixing and plant-associated acetic acid bacteria (*Ga. diazotrophicus*, *Ga. azotocaptans* and *Ga. johannae*) are phylogenetically highly related (Fig. 2) and belong to *Gluconacetobacter*. *Gluconacetobacter diazotrophicus* is an endophytic organism of sugarcane and a few other plants (Caballero-Mellado et al., 1995), whereas the two other species were isolated from the rhizosphere and rhizoplane of coffee plants (Fuentes-Ramírez et al., 2001). Although associated with sugarcane, *Ga. sacchari* does not fix nitrogen. The interactions between *Ga. diazotrophicus* and sugarcane are an interesting model system for the study of the association between an endophytic nitrogen-fixing prokaryote and a monocot. *Gluconacetobacter diazotrophicus* plays a major role in the supply of nitrogen to the plant (Boddey et al., 1991; Sevilla et al., 2001). The biochemistry and genetics of the N_2-fixation by *Ga. diazotrophicus* have been thoroughly studied (Sevilla and Kennedy, 2000; Perlova et al., 2003a; see also the section Genetics and Genomics in this Volume). *Gluconacetobacter diazotrophicus* can fix nitrogen in the presence of nitrates and at low pH-values (Stephan et al., 1991; Burris, 1994; Muthukumarasamy et al., 2002a). Sucrose concentrations of 10% have a positive effect on the nitrogenase activity, protecting the activity of the enzyme complex against inhibition by oxygen (Reis and Döbereiner, 1998). James and Olivares (1997) described the mechanisms of infection and colonization of sugarcane by *Ga. diazotrophicus*. Ureta and Nordlund (2002) provided evidence that besides increased respiration, a putative FeSII protein plays a crucial role in the protection of nitrogenase against oxygen.

Genetics and Genomics A genome sequencing project has been initiated for the type strain of *Ga. diazotrophicus*, the endophytic diazotroph of sugarcane (see http://www.riogene.lncc.br/ and http://www.riogene.lncc.br/). Its genome size is 2.7 Mb. The cluster of *nif*, *fix* and associated genes of *Ga. diazotrophicus* was sequenced and analyzed (Lee et al., 2000): it is 30.5 kb in size, encodes for 32 proteins and represents the largest assembly of contiguous *nif-fix* and associated genes so far characterized in any diazotrophic prokaryote. The overall arrangement of the genes resembles that of the *nif-fix* cluster in *Azospirillum lipoferum*, whereas the individual gene products are more similar to those in *Rhodobacter capsulatus* or in species of the Rhizobiaceae (Lee et al., 2000). The regulatory features of three genes encoding P(II)-like signal proteins have been investigated in relation to the control of nitrogen fixation in *Ga. diazotrophicus* (Perlova et al., 2003b).

In *Ga. xylinus*, the genes for cellulose synthesis are localized in an operon. Differences in numbers of ORFs exist among the strains (Wong et al., 1990; Nakai et al., 1998). In *Ga. xylinus* ATCC 53582, the *acs* operon is functional for the final steps of cellulose biosynthesis and consists of three genes: the *acsAB* gene codes for the 168-kDa cellulose synthase, the *acsC* gene codes for a 138-kDa pore-protein, and the third gene (*acsD*) codes for a small protein involved in the crystallization of the microfibrils (Saxena et al., 1994; Brown and Saxena, 2000). The genes coding for diguanylate cyclase and phosphodiesterase A (involved in the synthesis and breakdown of the specific nucleotide regulator c-di-GMP) are organized on three unlinked homologous operons (Tal et al., 1998).

Insertion elements have been reported in several *Gluconacetobacter* strains and are responsible, just as in other members of the Acetobacteraceae, for genetic instability. In two different strains of *Ga. xylinus*, the following IS-elements have been reported, causing the loss of cellulose and acetan synthesis: IS*1031* (930 bp) and IS*1032* (916 bp). The former is inserted 500 bp upstream of the operon for cellulose biosynthesis (Coucheron, 1991; Coucheron, 1993; Standal et al., 1994) and the latter is inserted in the gene for acetan synthesis (Iversen et al., 1994).

Plasmids have been isolated and characterized from a variety of *Gluconacetobacter* strains and genetic transformation systems and plasmid vectors for gluconacetobacters have been established (Valla et al., 1985; Valla et al., 1987; Blatny et al., 1997). Plasmid p21R1 (a RK2-derivative

carrying the gene for levansucrase) was introduced in *Ga. diazotrophicus*, increasing the levansucrase production by this genetically modified acetic acid bacterium (Hernandez et al., 1999). Electroporation systems developed for *Ga. xylinus*, when used with heterologous plasmids, yielded transformation frequencies of up to 10^5 transformants per µg of DNA (Hall et al., 1992). Plasmid pAH4 was characterized from a cellulose-producing *Gluconacetobacter* strain, and a shuttle vector system of both this strain and *E. coli* was constructed by connecting pAH4 and pUC18 (Tonouchi et al., 1994). Fukaya et al. (1989) introduced the aldehyde dehydrogenase gene from "*Acetobacter polyoxogenes*" into *Ga. xylinus*, enhancing the production of acetic acid by overexpression of the cloned gene. Shuttle vectors for cloning and expression of genes in *Ga. europaeus*, *Ga. intermedius* and *E. coli* were constructed by ligation of plasmid pJK2-1 from *Ga. europaeus* and pUC18 (Trček et al., 2000).

Applications Some of the *Gluconacetobacter* species are involved in industrial vinegar fermentations, particularly in high acid acetators (e.g., *Ga. europaeus* and *Ga. entanii*). Most of such *Gluconacetobacter* strains were isolated and described from vinegar factories in Europe. The biotechnological and industrial aspects of vinegar production by acetic acid bacteria are treated in detail in the chapter Organic Acid and Solvent Production in Volume 1.

The cellulose produced by *Ga. xylinus* displays unique properties, such as high crystallinity, high mechanical strength, and a highly pure and ultrafine fiber network structure. Although cost differences between the bacterial and plant polymer are currently prohibitive to extensive commercial usage, bacterial cellulose from *Ga. xylinus* has found medical application (as a wound healing skin substitute), industrial use (in acoustic membranes for audio equipment), and application as a high-quality paper additive, thickener, insulator material, food stabilizer as well as a dietary fiber and probiotic. Cellulose produced by *Ga. xylinus* is also one of the basic components of the traditional food nata de coco, which is popular in Asian countries (Bernardo et al., 1998; see the section Habitats and Uses of Acetic Acid Bacteria in this Chapter). Attempts were and are being made to improve the production of bacterial cellulose, both in surface culture and in submerged culture via strain improvement and production process development (De Wulf et al., 1996; Jonas and Farah, 1998; Vandamme et al., 1998; Bielecki et al., 2002).

The plant-associated and nitrogen-fixing gluconacetobacters (e.g., *Ga. diazotrophicus*) may find applications to enhance the crop yield of other monocotyledonous plants besides sugarcane. *Gluconacetobacter diazotrophicus* is also of interest for bulk production of gluconic acid, because it grows well in a simple mineral salts medium and oxidizes glucose at high rates in acid conditions (pH 3.5) and (unlike *G. oxydans*) in the presence of high concentrations of gluconic acid (Attwood et al., 1991; Organic Acid and Solvent Production in Volume 1).

The Genus Gluconobacter *Gluconobacter* strains are motile by polar flagella or nonmotile and oxidize ethanol to acetic acid. In contrast to the other members of the family, they do not oxidize acetate or lactate to CO_2 and H_2O. All strains produce 2-ketogluconic acid from D-glucose, and most strains form also 5-ketogluconic acid. *Gluconobacter* strains prefer sugar-enriched environments in contrast to most *Acetobacter* and *Gluconacetobacter* strains, which prefer to grow on alcohol-containing media. Gluconobacters generally produce acid during growth on several carbohydrates (Table 2) and show a pronounced and efficient ketogenesis from polyhydroxyalcohols via a single-step oxidation. The latter property finds numerous applications in industry.

Taxonomy Acetic acid bacteria from sugary environments, such as flowers and fruits, were studied for the first time in 1935 in Japan by Asai. These strains exhibited characteristics quite different from those of the usual acetic acid bacteria, and mainly on the basis of their capacity to oxidize ethanol and glucose, Asai (1935) proposed to divide the acetic acid bacteria into two separate genera, *Acetobacter* and *Gluconobacter*. Asai's 1935 paper, being written in Japanese, remained virtually unknown in the West. Studies on flagellation and oxidation of acetate and lactate led Leifson (1954) to propose the division of the acetic acid bacteria into the genera *Acetobacter* and *Acetomonas*. De Ley and Frateur (1970) discussed the classification and nomenclatural problems related to the genus *Gluconobacter* and pointed out that *Gluconobacter* Asai 1935, the "suboxydans group" of Frateur (1950), and *Acetomonas* Leifson 1954 are all to be referred to the genus *Gluconobacter*. In the eighth edition of *Bergey's Manual* (De Ley and Frateur, 1974b), the genus *Gluconobacter* was considered as a member of the family Pseudomonadaceae and was composed of a single species *G. oxydans* with four subspecies, which appeared on the Approved Lists of Bacterial Names (Skerman et al., 1980). In the subsequent edition of *Bergey's Manual*, *Gluconobacter* belongs together with *Acetobacter* to the family Acetobacteraceae (De Ley et al., 1984b), and De Ley and Swings (1984a) proposed to discontinue the use of subspecies names and retained a single species *G. oxydans*.

At present the following four species are recognized in *Gluconobacter*: *G. oxydans* (type species), *G. asaii*, *G. cerinus* and *G. frateurii* (Table 1). This classification is based on phenotypic and chemotaxonomic features, as well as on data obtained from DNA-DNA hybridizations and rDNA-sequencing (Yamada and Akita, 1984a; Yamada et al., 1984c; Micales et al., 1985; Mason and Claus, 1989; Sievers et al., 1995b; Yamada et al., 1999; Tanaka et al., 1999). Notably, particularly in the biochemical literature, the name *Gluconobacter suboxydans* is still used instead of *G. oxydans* (e.g., Adachi et al., 2001b; Adachi et al., 2003c). Recently, a polyphasic study indicated that *G. asaii* should be considered as a junior subjective synonym of *G. cerinus* (Katsura et al., 2002).

Habitats *Gluconobacter* strains were isolated from sugar-rich biotopes, such as fruits and flowers, honey bees, grapes and wine, palm sap, cocoa wine, cider, beer and soft drinks, where they can cause off-flavors, e.g., in orange juice (see the section Habitats and Uses of Acetic Acid Bacteria in this Chapter).

Isolation and Cultivation Enrichment of *Gluconobacter* strains present in flowers, fruits, soft drinks, etc. can be done using the following medium: D-glucose, 100 g; yeast extract, 5.0 g; peptone, 3.0 g; acetic acid, 1.0 ml; cycloheximide, 0.1 g, and distilled water, 1000 ml. Incubation is done at 28–30°C for 3–5 days in flasks with shaking. Cultures showing growth are plated on a $CaCO_3$-containing medium, where the colonies dissolve the $CaCO_3$ (Carr and Passmore, 1979). The composition of the medium for the $CaCO_3$-ethanol test is as follows (Sievers and Swings, 2005): glucose, 0.5 g; yeast extract, 5.0 g; peptone, 3 g; $CaCO_3$, 15.0 g; agar, 12.0 g; ethanol (99.8%), 15 ml (filter-sterilized and added after after sterilization to the basal medium), and distilled water, 1000 ml. The oxidation of ethanol to acetic acid causes a clear zone around the colonies. The overoxidation of acetic acid by strains of the genera *Acetobacter*, *Gluconacetobacter* and *Acidomonas* results in a reprecipitation of the $CaCO_3$, whereas *Gluconobacter* strains will dissolve the $CaCO_3$ without the reprecipation of $CaCO_3$. Such colonies are isolated, further purified on GYC medium, characterized and identified.

Gluconobacter strains can be grown at 28–30°C on GYC- or MYP medium at pH 6.0–6.8 (see footnote [d] of Table 5 for the composition of the media).

Identification Features differentiating the genus *Gluconobacter* from the other Acetobacteraceae are listed in Table 2. The *Gluconobacter* species form a coherent closely related cluster in the phylogenetic tree (Sievers et al., 1995b; Fig. 2): 16S rDNA sequence similarities vary between 97.0% and 98.8%.

Phenotypic features differentiating the three species *G. oxydans*, *G. frateurii* and *G. cerinus* are summarized in Table 6. Note that the validly described species *G. asaii* (Mason and Claus, 1989) was found to be a junior synonym of *G. cerinus* (Katsura et al., 2002). Correct identification of *Gluconobacter* isolates may require sequencing of 16S rDNA as well as DNA-DNA hybridizations but can also be done on the basis of sequence and restriction analysis of the 16S-23S rDNA internal transcribed spacer regions (Yukphan et al., 2004a). On superficial examination, *Gluconobacter* strains may resemble *Frateuria*, a genus phylogenetically belonging to the *Xanthomonas*-group of the Gammaproteobacteria (Swings et al., 1980; Swings, 1992a; Fig. 2). The polarly flagellated *Frateuria* does not overoxidize acetate but oxidizes lactate to CO_2 and water and is characterized by Q-8 as major ubiquinone.

Physiological and Biochemical Properties *Gluconobacter* cells catabolize D-glucose via the hexose monophosphate pathway. In contrast to *Acetobacter* and other genera of the Acetobacteraceae, gluconobacters are not able to overoxidize acetic acid to CO_2 and H_2O, because they do not possess a complete TCA cycle, lacking succinate dehydrogenase (Greenfield and Claus, 1972). The respiratory chain in *Gluconobacter* consists of cytochrome *c*, ubiquinone, and cytochrome *o*

Table 6. Differentiation of *Gluconobacter* species.[a]

Characteristic	1.	2.	3.[b]
Growth on *meso*-ribitol[c]	–	+	–[e]
Growth on L-arabitol[c]	–	+	–[e]

[d]Three transfers into nicotinate-free media are necessary to demonstrate nicotinate-dependence (Mason and Claus, 1989).

[e]One strain was described as positive (Mason and Claus, 1989); the type strain and most other strains are negative (Katsura et al., 2002).

[f]Data from Tanaka et al. (1999).

as terminal ubiquinol oxidase. *Gluconobacter* cells contain also a cyanide-insensitive alternative ubiquinol oxidase (Takeda et al., 1992; Matsushita et al., 1994).

As in most acetic acid bacteria, the membrane-linked alcohol and aldehyde dehydrogenase complexes of *Gluconobacter* are composed of several subunits (Matsushita et al., 1994; Kondo and Horinouchi, 1997c). The larger subunit of the alcohol dehydrogenase complex contains heme *c* and pyrroloquinoline quinone (PQQ) as cofactors.

An outstanding biochemical feature of *Gluconobacter* is its ability to incompletely oxidize a great variety of carbohydrates, alcohols and related compounds. These rapid and incomplete oxidations of carbon sources are exploited in various biotechnological processes (Gupta et al., 2001; Deppenmeier et al., 2002).

Sugars, alcohols, and polyols are oxidized via two alternative pathways. The dehydrogenases of the so-called "direct oxidative pathway" are localized on the cytoplasmic membrane and their active sites are oriented towards the periplasm. Oxidizable substrates pass through the outer membrane and are almost quantitatively transformed to oxidation products, which are released into the medium via the porins of the outer membrane. These membrane-bound dehydrogenases are coupled to the respiratory chain and are responsible for the rapid oxidation of various biotechnologically important substrates. For the second type of enzyme system, uptake of the substrates into the cytoplasm is required, where oxidation takes place by soluble nicotinamide dinucleotide phosphate ($NAD[P]^+$)-dependent dehydrogenases and the resulting intermediates are phosphorylated and further metabolized via the pentose phosphate pathway. These $NAD(P)^+$-dependent enzymes participate in the biosynthesis of precursors and are involved in the maintenance of the cells (Matsushita et al., 1994). Some of these soluble NAD(P)-dependent pentitol- and hexitol-dehydrogenases have been crystallized and characterized (Adachi et al., 1999a; Adachi et al., 1999b; Adachi et al., 2001a).

Various membrane-bound dehydrogenases have been identified and characterized (Deppenmeier et al., 2002). Dehydrogenases for glucose, alcohol, aldehyde, glycerol, sorbitol, D-arabitol, fructose and gluconate contain PQQ as prosthetic group, and some of these dehydrogenases are also equipped with heme *c*-containing subunits (Matsushita et al., 1994; Matsushita et al., 1999; Matsushita et al., 2003; Choi et al., 1995; Shinagawa et al., 1999; Adachi et al., 2001a; Adachi et al., 2001b). In addition, membrane-bound flavin-dependent dehydrogenases have been described oxidizing D-gluconate, 2-keto-D-gluconate and D-sorbitol (Matsushita et al., 1994). Most likely, *Gluconobacter* strains contain many more dehydrogenases than those presently described (see, e.g., Adachi et al. [2003a], Adachi et al. [2003b] and Hoshino et al. [2003]). Several *Gluconobacter* strains display, e.g., a strong quinate dehydrogenase activity (PQQ-linked), producing 3-dehydroquinate (Adachi et al., 2003b; Adachi et al., 2003c). During these incomplete oxidations, coupling of electron transfer and proton translocation is not very efficient, resulting in low growth rates and loss of energy via heat production (Matsushita et al., 1989). The isolation and characterization of thermotolerant *Gluconobacter* strains might be advantageous for industrial applications to reduce the costs of cooling during fermentation (Moonmangmee et al., 2000; Adachi et al., 2003b).

Gluconobacter cells oxidize polyols with different carbon chain lengths ranging from glycerol to heptitols and octitols to the corresponding ketoses according to the so-called "rule of Bertrand-Hudson," whereby polyols with a *cis*-arrangement of two secondary hydroxyl groups in D-configuration to the adjacent primary alcohol group (a D-*erythro* configuration) are oxidized regioselectively to the corresponding ketoses (Kersters et al., 1965; Kulhanek, 1984; Kulhanek, 1989). Moreover, cyclitols and chemically modified pentitols and hexitols (such as deoxy-, deoxyamino-, deoxyhalogen polyols) can also be oxidized incompletely.

Cleton-Jansen et al. (1991) showed that a one-point mutation in the gene coding for the PQQ-linked glucose dehydrogenase of a *G. oxydans* strain resulted in the replacement of histidine at position 787 by asparagine. This single amino acid substitution changed the substrate specificity of the glucose dehydrogenase, resulting in the conversion of maltose to maltobionic acid in addition to the oxidation of glucose.

Gluconobacter strains generally produce acid during growth on D-glucose, D-fructose, D-xylose, D-mannitol and maltose and tolerate up to 10% glucose. The best carbon sources for growth are D-glucose, D-mannitol and D-sorbitol. The formation of water-soluble brown pigments on glucose-containing media is correlated with the production of 2,5-diketogluconate and γ-pyrones from D-glucose.

The major ubiquinone of *Gluconobacter* strains is Q-10 and their DNA base composition is 54–63 mol% G+C.

Genetics and Genomics Mutation studies and DNA-recombinant analyses focus on the genes of the various dehydrogenases involved in the direct oxidative metabolism operative in *Gluconobacter* (Gupta et al., 1997; Saito et al., 1997; Saito et al., 1998; Miyazaki et al., 2002; Sugiyama

et al., 2003). The microbiological production of 2-keto-L-gulonic acid (a precursor of vitamin C production) has been improved by cloning the genes of L-sorbose dehydrogenase and L-sorbosone dehydrogenase from *G. oxydans* T-100 and introducing them via a shuttle vector in *G. oxydans* G624, a strain accumulating L-sorbose (Saito et al., 1997; Saito et al., 1998). Similarly, Shibata et al. were able to introduce the *Gluconobacter* genes for L-sorbose dehydrogenase and L-sorbosone dehydrogenase into a strain of *Pseudomonas putida* (Shibata et al., 2000a; Shibata et al., 2000b), and replacement of the native L-sorbosone dehydrogenase promotor by the *Escherichia coli* tufB promotor improved the productivity of 2-keto-L-gulonic acid considerably. Cloning of the cytoplasmic xylitol dehydrogenase of *G. oxydans* resulted in an improved production of *meso*-xylitol from D-arabitol (Sugiyama et al., 2003). Gupta et al. (1999) described a *G. oxydans* mutant deficient in gluconic acid dehydrogenase unable to produce 2,5-diketogluconic acid. Kondo and Horinouchi (1997b) detected and characterized an insertion sequence IS*12528* in mutants of *G. oxydans* with reduced alcohol dehydrogenase activity. Such transposable elements are likely responsible for genetic instability of *Gluconobacter* strains.

The sequence of the *Gluconobacter oxydans* genome (±3 Mb) is being determined in Germany (http://www.genomik.uni-goettingen.de). Some 3000 ORFs were found and all the genes necessary to encode the enzymes of the pentose phosphate pathway and the Entner-Doudoroff pathway are present, whereas the genes encoding phosphofructokinase and succinate dehydrogenase have not been detected on the *G. oxydans* chromosome, confirming that the Emden-Meyerhof pathway is not functional and the citric acid cycle is incomplete and functions only for the synthesis of biosynthetic precursors (Deppenmeier et al., 2002). The genome sequencing revealed that more than 80 ORFs encode putative dehydrogenases and oxidoreductases with unknown function. Among them are more than 20 alcohol and 30 sugar dehydrogenases, indicating that *G. oxydans* harbors genes for novel dehydrogenases which can be of interest for future biotechnological applications.

Two *G. oxydans* plasmids pAG5 and pGO128 (5648 bp and 4340 bp, respectively) were described and sequenced (accession nrs. [genbank AB086443] and [genbank AJ428837], respectively; Tonouchi et al., 2003; Sievers and Swings, 2005).

At least three DNA-phages have been isolated from *Gluconobacter*: phage A-1 (Schocher et al., 1979; Jucker and Ettlinger, 1981) and phages GW6210 and JW2040 (Robakis et al., 1985). Phage A-1 caused abnormalities in the oxidation of D-sorbitol to L-sorbose by *G. oxydans* (Schocher et al., 1979).

Applications The biotechnological applications of *Gluconobacter* strains are mainly based on their outstanding capacity to incompletely and rapidly oxidize a wide range of carbohydrates, alcohols and polyols, whereby the oxidation products (acids and ketones) are excreted nearly quantitatively into the medium. Using *Gluconobacter* cells offers the great advantage of regio- and stereoselective oxidation of the substrates, a process that would otherwise require complex protection group chemistry. Some aspects of these industrial applications are summarized in this section, and we refer the reader for more detailed information to the following reviews: Gupta et al. (2001), Macauley et al. (2001), Deppenmeier et al. (2002), and Hancock and Viola (2002).

PRODUCTION OF GLUCONATE AND KETOGLUCONATES. Gluconic acid, its lactone, salts and keto-forms have a wide range of applications in the food, pharmaceutical and chemical industries. The production of gluconic acid by *Gluconobacter* (and other microorganisms) is treated in detail in the chapter Organic Acid and Solvent Production in Volume 1. Gluconobacters can oxidize glucose and gluconic acid to ketogluconic acids (2-ketogluconic acid, 5-ketogluconic acid and 2,5-diketogluconic acid). 2-Ketogluconate and 5-ketogluconate are interesting precursors for isoascorbic acid synthesis and tartaric acid production, respectively (Klasen et al., 1992). 2,5-Diketogluconate can be converted to 2-keto-L-gulonic acid as a penultimate intermediate in the industrial production of vitamin C.

PRODUCTION OF L-SORBOSE AND VITAMIN C. *Gluconobacter* strains are used for the oxidative conversion of D-sorbitol to L-sorbose, which is an important intermediate in the production of L-ascorbic acid (vitamin C; estimated world production: approximately 100,000 tons per year; Macauley et al., 2001). Vitamin C is important for human and animal nutrition and is used as an antioxidant in the food industry. It is currently produced by the Reichstein-Grüssner process, involving a series of chemically based unit operations and a single biological oxidative step, where D-sorbitol is regioselectively oxidized to L-sorbose by a membrane-bound D-sorbitol dehydrogenase of *G. oxydans* (Fig. 3). D-Sorbitol is obtained by electrolytic or catalytic reduction of D-glucose.

The overall practical yield of the Reichstein process, with the recent advances in chemical engineering, is thought to be around 50% (Boudrant, 1990). The effects of crosslinking

Fig. 3. The Reichstein-Grüssner process for the production of L-ascorbic acid. The biological oxidation of D-sorbitol to L-sorbose (red arrow) is catalyzed by *G. oxydans*. The black arrows indicate nonbiological steps.

Fig. 4. The conversion of D-sorbitol to 2-keto-L-gulonic acid by *Gluconobacter*. Red arrows indicate transformations performed by three different dehydrogenases of *G. oxydans*. The black arrow is a nonbiological step to yield vitamin C.

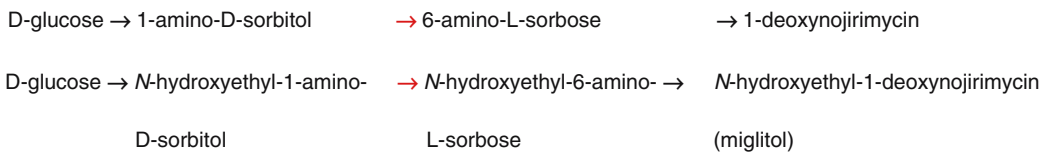

Fig. 5. Synthesis of 1-deoxynojirimycin and miglitol from D-glucose. Red arrows indicate the regioselective oxidation by a *G. oxydans* strain and the black arrows are nonbiological steps. The first step is a chemical reductive amination of D-glucose and the last step is a chemical stereoselective ring closure.

agents, such as glutaraldehyde and polyethyleneimine, on L-sorbose production by immobilized *G. oxydans* cells have been studied (Park et al., 1998). De Wulf et al. (2000) were able to obtain the theoretically maximal productivity of the biological oxidative step by using a *G. oxydans* mutant that was selected under conditions of substrate inhibition.

Several strategies including recombinant DNA-technologies are being developed to shift the synthesis of ascorbic acid from chemical procedures to purely bioconversion routes, where the synthesis of 2-keto-L-gulonic acid is a key intermediate (Deppenmeier et al., 2002). Some *Gluconobacter* strains convert D-sorbitol to 2-keto-L-gulonic acid via L-sorbosone. The 2-keto-L-gulonic acid can be converted nonbiologically to L-ascorbic acid (Hoshino et al., 1990; Saito et al., 1997; Fig. 4).

Overexpression of the L-sorbose dehydrogenase and the L-sorbosone dehydrogenase genes in *G. oxydans* results in improved yields of 2-keto-L-gulonic acid (Saito et al., 1997). In this respect the application of *Ketogulonicigenium* strains for the biological conversion of L-sorbose to 2-keto-L-gulonic acid may open new perspectives (Urbance et al., 2001). The latter genus belongs to the *Rhodobacter*-lineage of the Alphaproteobacteria (Fig. 1).

PRODUCTION OF DIHYDROXYACETONE AND ACETYLMETHYLCARBINOL. Dihydroxyacetone is used as a cosmetic tanning agent and as an intermediate for the synthesis of various organic chemicals and surfactants. The oxidation of glycerol to dihydroxyacetone by *G. oxydans* strains is catalyzed by a membrane-bound PQQ-dependent glycerol dehydrogenase (Claret et al., 1994) and can be optimized by using immobilized *G. oxydans* cells (Tkac et al., 2001). Similarly gluconobacters can be used to oxidize 2,3-butanediol to acetylmethylcarbinol.

SYNTHESIS OF 1-DEOXYNOJIRIMYCIN AND MIGLITOL. 1-Deoxynojirimycin and its N-substituted analog *N*-hydroxyethyl-1-deoxynojirimycin (miglitol) are strong inhibitors of α-glucosidases and are used for the treatment of non-insulin-dependent diabetes (Campbell et al., 2000). The industrial production of these compounds follows a combined biotechnological-chemical synthesis, whereby *G. oxydans* plays a key-role in the oxidation of 1-aminosorbitol derivatives (Deppenmeier et al., 2002; Fig. 5). As *Gluconobacter* cannot grow on aminopolyols, whole resting cells (grown on sorbitol) have to be used for this biotransformation process (Schedel, 2000).

GLUCONOBACTER AS BIOSENSOR. The cells and enzymes of *G. oxydans* find applications as biosensors for the estimation of the concentrations of various aldoses, polyalcohols, ethanol, glycerol, etc. (Lusta and Reshetilov, 1998; Tkac et al., 2000; Tkac et al., 2001; Macauley et al., 2001).

The Genus Kozakia During the isolation and identification of acetic acid bacteria from Indonesian sources, Lisdiyanti et al. (2002) detected a new cluster of acetic acid bacteria on the basis of 16S rRNA gene sequences. This new taxon, *Kozakia baliensis*, produces large amounts of mucous polysaccharides in a sucrose-containing medium. Genetic properties and applications of *Kozakia* strains have not yet been studied.

Taxonomy The genus *Kozakia* was first described by Lisdiyanti et al. (2002) as a new member of

the family Acetobacteraceae. At present it contains a single species, *Kozakia baliensis* (Table 1), and its classification is based on phenotypic and chemotaxonomic features, as well as data obtained from DNA-DNA hybridizations and 16S rDNA sequencing (Lisdiyanti et al., 2002). Its closest phylogenetic neighbor is the genus *Asaia* (Fig. 2).

Habitats Four strains of *Kozakia baliensis* were isolated in Indonesia and are presently available from culture collections: the type strain was isolated from palm brown sugar and three other strains originate from ragi (used as a starter for the preparation of fermented food).

Isolation and Cultivation *Kozakia baliensis* strains can be enriched on a medium containing: D-glucose, 10.0 g; ethanol, 5.0 ml; acetic acid, 3.0 ml; peptone, 15.0 g; yeast extract, 8.0 g; cycloheximide, 0.1 g; and distilled water, 1000 ml. The pH of the medium is adjusted to 3.5 with HCl. Incubation is done at 30°C for 3–5 days in flasks with shaking. Cultures showing growth are streaked on $CaCO_3$ agar plates containing: D-glucose, 20.0 g; ethanol, 5.0 ml; yeast extract, 8.0 g; $CaCO_3$, 7.0 g; agar, 15.0 g; and distilled water, 1000 ml. Colonies of *Kozakia baliensis* strains are slightly pinkish, mucous, do not produce water-soluble pigments, and dissolve the $CaCO_3$ around the colonies weakly.

Identification Phenotypically, the strains of *Kozakia baliensis* are similar to *Gluconacetobacter xylinus* because they oxidize acetate and lactate, have Q-10 as the major ubiquinone, and produce a large amount of levan-like mucous polysaccharides. The formation of levan by *Gluconacetobacter xylinus* has been reported by Tajima et al. (1997) and Kornmann et al. (2003). However, *Kozakia* strains are phylogenetically clearly distinct from the genus *Gluconacetobacter* (Fig. 2). The 16S rDNA sequence similarity between the type strain of *Kozakia baliensis* and the type strain of *Asaia bogorensis* is rather high (97.4%). *Kozakia baliensis* strains differ from *Asaia* strains in the production of acetic acid from ethanol, growth in the presence of 0.35% acetic acid, and absence of growth on 30% D-glucose (Table 2).

Physiological and Biochemical Properties *Kozakia* strains are nonmotile and produce levan-like mucous substance(s) on sucrose or D-fructose. They grow at pH 3.0 and 30°C, do not produce gelatinase, H_2S, indole or ammonia from L-arginine, and do not reduce nitrate. They oxidize acetate and lactate to carbon dioxide and water, but the activity is weak. They produce acetic acid from ethanol. Their growth is not inhibited by 0.35% acetic acid at pH 3.5. They grow on mannitol agar but not on glutamate agar and do not grow on 30% D-glucose. Ammoniacal nitrogen is not assimilated on glucose medium, mannitol medium, or ethanol medium without vitamins. The strains produce dihydroxyacetone from glycerol, produce γ-pyrones from D-fructose but not from D-glucose, and produce D-gluconate, 2-keto-D-gluconate and 5-keto-D-gluconate from D-glucose but not 2,5-diketo-D-gluconate. Acid is produced from L-arabinose, D-xylose, D-glucose, D-galactose, D-mannose, melibiose, raffinose, *meso*-erythritol, glycerol and ethanol but not from L-rhamnose, D-fructose, L-sorbose, lactose, D-mannitol, D-sorbitol or dulcitol. Acid production from D-arabinose and sucrose is variable depending on the strain. The major ubiquinone is Q-10 and the DNA base composition is 57 mol% G+C.

The Genera Saccharibacter *and* Swaminathania *Saccharibacter* (Jojima et al., 2004) and *Swaminathania* (Loganathan and Nair, 2004) are two new genera of acetic acid bacteria described and each containing one species. *Saccharibacter floricola* was isolated from pollen of Japanese flowers and is phylogenetically related to *Gluconobacter*. *Swaminathania salitolerans* strains were isolated from the rhizosphere, roots and stems of salt-tolerant wild rice and are able to fix nitrogen. *Swaminathania* is closely related to the genus *Asaia*.

CHAPTER 3.1.9

The Genus *Zymomonas*

HERMANN SAHM, STEPHANIE BRINGER-MEYER AND GEORG A. SPRENGER

Habitat

Zymomonas mobilis has been reported mainly from tropical and subtropical habitats, e.g., sugar-rich, plant saps from agave (Mexico; Lindner, 1928), sugar cane (Brazil and Fiji Islands; reviewed in Falcao de Morais et al., 1993), and palm wine from central Africa (Swings and De Ley, 1977). Other sources of this organism include fermenting sugarcane juice (Goncalves de Lima et al., 1970), fermenting cocoa beans (Ostovar and Keeney, 1973), and bees and ripening honey (Ruiz-Argueso and Rodriguez-Navarro, 1975). In Europe, *Z. mobilis* also appeared in spoiled beer and cider. One of the first written descriptions of "cider sickness" was presented by Lloyd (1903), in which he noted the presence of "sulphuretted hydrogen" in spoiled ciders. Barker and Hillier (1912) were the first to study cider sickness extensively and gave a description of the responsible bacterium. Cider sickness is recognized by frothing and abundant gas formation, a typical change in the aroma and flavor, reduction of sweetness, and development of a marked turbidity forming a heavy deposit. From the complex microflora of sick cider, Barker and Hillier isolated and purified a bacterium that caused the typical strong aroma and flavor in sterile cider upon reinfection; unfortunately, they did not give a Latin taxon to the new organism. In 1951, Millis isolated several bacteria from ciders and perries that resembled Barker's strains (Millis, 1951). It was Millis who demonstrated quite clearly that the cider sickness organism was a *Zymomonas*. Various strains formed approximately 1.9 mole of ethanol per 1 mole of glucose and about the same amount of CO_2. Furthermore, some H_2S, acetaldehyde and lactic acid could be detected. The optimal pH range for growth was 4.5 to 6.5 and the optimal temperature range was 25 to 31°C.

Pulque and Palm Wine

During his stay in Mexico in 1923 to 1924, Lindner studied the fermentation of agave sap to pulque, an alcoholic beverage containing approximately 4 to 6% ethanol (Lindner, 1928). Lindner discovered the causal organism of the fermentation, a bacterium which he called *Termobacterium mobile* (Lindner, 1931). Over the years this organism received many names. This very motile bacterium was able to ferment sucrose, fructose and glucose to ethanol and CO_2. Lindner suggested that these bacteria occur strictly in tropical regions, where they account for the alcoholic fermentations in palm wines, chica beer, etc., and where they are used for bread manufacture. *Zymomonas* strains are very well adapted to a great variety of plant juices in tropical areas around the world because in such environments sucrose, glucose, fructose, amino acids and growth factors are present. The bacterium is resistant to ethanol and grows at low pH values under anaerobic conditions. Kluyver and Hoppenbrouwers (1931) studied Lindner's isolate. Neither Lindner nor Kluyver and Hoppenbrouwers related the pulque bacteria to the cider sickness organisms described earlier by Barker and Hillier (1912).

Beer

Shimwell (1937) isolated a *Zymomonas* strain from beer, from the surface of brewery yards, and from the brushes of cask-washing machines. The cells were Gram-negative plump rods, 2 to 3 by 1 to 1.5 μm in young cultures and longer (without endospores) in old cultures. The organism was indifferent to hop antiseptic and capable of growing in a wide range of beers. Later, Ault (1965) recognized that *Zymomonas* is a serious contaminant in keg beers. These infections can occur because of anaerobiosis and presence of priming sugars. The bacteria produce a heavy turbidity, and the unpleasant odor of rotten apples is due to traces of acetaldehyde and H_2S. *Zymomonas* has not been reported in lager beers; the low temperature of the process, 8 to 12°C, is unfavorable for its growth.

Isolation

Several procedures are described in the literature for the isolation of *Zymomonas* strains

(Swings and De Ley, 1977). Barker and Hillier (1912) isolated the cider sickness organisms on beer wort gelatin as small colonies after 11 days incubation at 22°C. Swings (1974) described the isolation of *Zymomonas* from fresh palm wines in WL differential medium, which is designed for brewing and fermentation processes but contains a yeast and mold inhibitor (Difco). When the samples were streaked on the medium in Petri dishes and incubated at 30°C in the Gas Pak anaerobic system, colonies of 1 to 4 mm in diameter were obtained after 4 to 5 days. However, it was very important to use young wine, about 24-h old, because isolation from palm wines more than 48-h old was impossible; the viability of *Zymomonas* rapidly decreases in aged fermentation broths. Swings and De Ley (1977) described a selection medium containing 0.3% malt extract, 0.3% yeast extract, 2% glucose, 0.5% peptone and 0.002% cycloheximide. The medium is adjusted to pH 4.0, autoclaved, and then supplemented with ethanol to a final concentration of 3%.

For *Zymomonas* cultivation, Fein et al. (1983) described a defined medium consisting of (g per liter of distilled water): glucose, 20; KH_2PO_4, 3.5; $(NH_4)_2SO_4$, 2.0; $MgSO_4 \cdot 7\ H_2O$, 1.0; $FeSO_4 \cdot 7\ H_2O$, 0.01; and 2-[N-morpholino]ethanesulfonate (MES), 19.52. The medium is adjusted to pH 5.5 and autoclaved. Then, a sterile solution of biotin and Ca-pantothenate is added to final concentrations of 0.001 g/liter each. A complete medium was introduced by Bringer-Meyer et al. (1985; g per liter of distilled water): D-glucose, 20; yeast extract, 10; KH_2PO_4, 1.0; $(NH_4)_2SO_4$, 1.0; and $MgSO_4 \cdot 7\ H_2O$, 0.5.

Growth and Conservation Conditions

Zymomonas grows best between 25 and 30°C; 74% of the strains grow at 38°C, but rarely at 40°C (Swings and De Ley, 1977). Growth is slow at 15°C (Millis, 1951) and absent at 4°C. Members of the subspecies *pomaceae* do not grow at temperatures above 36°C; therefore a growth temperature test is a good method for distinguishing between the two subspecies.

Most *Zymomonas* strains are able to grow between pH 3.8 and 7.5. At pH 3.5, 40% of the strains develop, illustrating a good acid tolerance. This is not surprising because the natural niche of this organism is in acid palm wines, cider and beers at pH 4. We observed that death rapidly occurs in batch fermentation after all the sugar is fermented. The bacterial cells are kept alive on complex media at room temperature and transferred weekly. When lyophilized, the organism can be kept alive for several years.

Identification

In the 1970s, Swings and De Ley applied modern molecular biological techniques to compare approximately 40 different strains of *Zymomonas*. They concluded that all the strains of *Zymomonas* by then described belong to a single species, *Zymomonas mobilis*, with two subspecies: *Z. mobilis* subsp. *mobilis* (the organism isolated from pulque or palm wine and currently envisioned for industrial ethanol production) and *Z. mobilis* subsp. *pomaceae* (the organism responsible for beer and cider spoilage; Swings and De Ley, 1977). Growth at 36°C is the best phenotypic test to differentiate the subspecies *mobilis* from *pomaceae*; only the former grows.

Once *Zymomonas* has been isolated on an appropriate medium, its identification is a relatively simple matter. A listing of the phenotypic characteristics of *Zymomonas* is given in Table 1 (Montenecourt, 1985).

Inoculation of *Zymomonas* into media containing sugar will lead to growth and gas production only when glucose, fructose or possibly

Table 1. Phenotypic description of the genus *Zymomonas*.

1. Gram-negative rods, 2- to 6-µm length, 1- to 5-µm width
2. Either motile or nonmotile; motility can be easily lost; one to four lophotrichous flagella
3. Pleomorphic cell arrangement, rosettes, chains, filaments
4. Spores, capsules, intracellular storage compounds (lipids, glycogen and poly-β-hydroxybutyrate) absent
5. Catalase positive, oxidase negative
6. Anaerobic and microaeroduric
7. Ferments glucose and fructose producing ≥1.5 moles of ethanol and CO_2
8. Sucrose utilization inducible, may be accompanied by levan production
9. No other monosaccharides, disaccharides, polysaccharides or fatty acids metabolized
10. Contains pentacyclic triterpenoids (hopanoids), vaccenic acid, and sphingolipids in its cell membranes
11. Forms sorbitol and gluconic acid from sucrose or glucose fructose (presence of a periplasmic enzyme, glucose-fructose oxidoreductase)
12. G+C content, 47.5 to 49.5 mol %; genome size approximately 2,085 kb

Adapted from Montenecourt, 1985.

sucrose is present. The ratio (moles of ethanol produced to moles of glucose fermented) is at least 1.5, and only small amounts of lactic acid and traces of acetylmethylcarbinol (acetoin) are formed; thus, a pH indicator will not register any acidity. This feature makes *Zymomonas* a unique ethanol-producing bacterium, and as far as is known, no other bacteria behave in this manner. If a finer distinction is to be made, tests listed by Swings and De Ley (1977) may be applied. Recently, it was demonstrated that in comparison to other Gram-negative bacteria, *Zymomonas* strains contained a high level of cis-vaccenic acid (>60% of the total fatty acids; Tornabene et al., 1982). Furthermore, the lipopolysaccharide fraction from this organism is different from that of other Gram-negative species inasmuch as deoxyhexoses, pentoses, hexoses, aminopentose, uronic acid, phosphate and myristic acid are the principal constituents, whereas ketodeoxyoctulonic acid (KDO), heptoses or hydroxy fatty acids are not evident.

Main Features

Zymomonas mobilis is an aerotolerant, fermentative bacterium with a number of exceptional characteristics: over 95% of the glucose utilized by this organism is converted to an equimolar mixture of ethanol and CO_2, and only a small percentage (<3%) is incorporated into cell mass (Swings and De Ley, 1977). Catabolism of the only carbon sources, glucose and fructose, proceeds via the Entner-Doudoroff pathway and with a net production of a single mole of ATP per mole of glucose catabolized. *Zymomonas mobilis* lacks other pathways for glucose catabolism, is incapable of gluconeogenesis, and has an incomplete tricarboxylic acid cycle (Gibbs and De Moss, 1954; Dawes et al., 1970; Swings and De Ley, 1977). The presence of pyruvate decarboxylase and alcohol dehydrogenase enables the organism to perform a pure ethanol fermentation, i.e., to produce almost two moles of ethanol per mole of glucose. Because of its rapid growth, sugar catabolism (about 1 μmole glucose · min^{-1} · mg^{-1} cell protein; Arfman et al., 1992), and tolerance towards high concentrations of substrate (up to 30% glucose; Kluyver and Hoppenbrouwers, 1931; Swings and De Ley, 1977; Loos et al., 1994) and product (up to 13% ethanol w/v; Rogers et al., 1982), *Z. mobilis* ferments ethanol very efficiently. *Zymomonas*, *Rhizomonas* and *Sphingomonas* belong to the same subclass (α-4) of the Proteobacteria (White et al., 1993). These genera contain sphinganine lipids in their membranes (Tahara and Kawazu, 1994). The physiological properties and biotechnological aspects of *Z. mobilis* have been reviewed (Swings and De Ley, 1977; Rogers et al., 1982; Baratti and Bu'Lock, 1986; Buchholz et al., 1987; Bringer-Meyer and Sahm, 1988; Viikari, 1988; Ingram et al., 1989; Sahm et al., 1992; Conway, 1992; Johns et al., 1992; Sprenger, 1993a; Sprenger et al., 1993b; Doelle et al., 1993; Yanase and Kato, 1994; Sprenger, 1996; Gunasekaran and Raj, 1999; Sprenger and Swings, 2000).

Metabolism: From Sugar Uptake to Ethanol Formation

Carbohydrate Transport

Zymomonas mobilis utilizes only three carbon sources: sucrose, glucose and fructose. Sucrose needs no uptake system because it is cleaved extracellularly and its moieties (glucose and fructose) are subsequently taken up into the cells by facilitated diffusion through a common transport protein (glucose facilitator GLF; DiMarco and Romano, 1985; Snoep et al., 1994; Weisser et al., 1996; Parker et al., 1997). *Zymomonas mobilis* appears to be the only known bacterium that relies solely on such an uniport type for sugar uptake, i.e., equilibration of external and internal sugar concentrations. No phosphoenolpyruvate (PEP)-dependent sugar uptake system has been detected yet (DiMarco and Romano, 1985). The uniporter needs no metabolic energy but cannot accumulate substances. Subsequent phosphorylation steps, however, distract free hexoses from the equilibrium so that effective sugar uptake and metabolism are warranted. Apart of glucose and fructose, various other hexoses and pentoses are GLF substrates (DiMarco and Romano, 1985; Schoberth and de Graaf, 1993; Parker et al., 1995; Parker et al., 1997; Weisser et al., 1995; Weisser et al., 1996), but D-mannose and D-xylose are no-growth substrates for wild-type *Z. mobilis* (but see Metabolic Engineering). Glucose is the preferred substrate (K_m ~4 mM) over fructose or xylose (K_m ~40 mM each). The GLF transports its substrates at high V_{max} (up to 1 μmole of substrate · mg^{-1} of cell protein · min^{-1}), with D-xylose being the best substrate, followed by glucose and fructose (Weisser et al., 1996; Parker et al., 1997). Growth on fructose leads to an increase in the transcription of *glf*, and the increased GLF may compensate for the lower affinity with fructose (Zembrzuski et al., 1992).

Owing to high glucose and fructose transport rates, equilibration between external and internal sugar concentrations can be rapid and may contribute to osmotic adjustment (Struch et al., 1991). Although not a growth substrate for *Z. mobilis*, the compatible solute sorbitol accumulates (up to 1 M, intracellular concentration) and further improves growth of *Z. mobilis* in high-

sugar environments (Loos et al., 1994). The sorbitol transporter is dependent on the proton motive force (Loos et al., 1994). Ethanol diffusion across the cell membrane has been determined using nuclear magnetic resonance (^{13}C-NMR) techniques (Schoberth et al., 1996).

Glycolytic Flux and Regulation of Metabolism

The glycolytic enzymes of the Entner-Doudoroff pathway and the fermentative enzymes pyruvate decarboxylase and alcohol dehydrogenase of *Z. mobilis* represent over half of the organism's soluble protein (Algar and Scopes, 1985; Osman et al., 1987; An et al., 1991). These enzymes (see Table 2 for details and references) are considered to operate at or near substrate saturation and do not seem to be subject to major regulations, e.g., by allosteric control (Algar and Scopes, 1985). The overall catabolic activity of *Z. mobilis* leads to a nearly unlimited flow of carbon through the glycolytic pathway. Thus each minute, *Z. mobilis* consumes an amount of glucose equal to one-third of its mass (Snoep et al., 1996; Parker et al., 1997). Regulation of enzyme activity has been shown for glucokinase through an absolute demand for inorganic phosphate, and to a lesser degree, by feedback inhibition through glucose-6-phosphate (Scopes and Bannon, 1995). Fructokinase is inhibited by glucose (K_i of 0.14 mM; Scopes et al., 1985b). Pyruvate kinase, which is allosterically regulated in most other organisms, appears not to be subject to any allosteric activator (Steiner et al., 1998). Growth on fructose induces about twofold the transcription of genes for peripheral sugar metabolism which lead to the introduction of fructose into glycolysis (i.e., by fructose uptake via GLF, fructose phosphorylation by fructokinase FRK, and

isomerization to glucose-6-phosphate by phosphoglucose isomerase PGI; Scopes et al., 1985b; Hesman et al., 1991; Barnell et al., 1992; Zembrzuski et al., 1992).

Control on glycolytic flux is mainly exerted by glucose-6-phosphate dehydrogenase as shown by overexpression studies of several glycolytic enzymes of *Z. mobilis* (Snoep et al., 1995; Snoep et al., 1996). When overexpressing each of the first genes (*glf*, *zwf*, *edd*, *glk*) of the Entner-Doudoroff pathway (see Fig. 1), only recombinants with elevated glucose-6-phosphate dehydrogenase had a 10–13% higher glycolytic flux than that of the native organism, whereas increasing the expression of various other glycolytic operons caused a significant decrease in the glycolytic flux and growth rate. The latter was attributed to a protein burden effect (Snoep et al., 1995). Additional evidence for a major role of glucose-6-phosphate dehydrogenase in flux control was given by kinetic investigations which showed that the enzyme is allosterically inhibited by phosphoenolpyuvate (Scopes, 1997). Furthermore it was proposed that differences in transcript stability of the glycolytic enzymes of Z. mobilis represent a mechanism to balance the high levels of the ethanologenic enzymes (Meija et al., 1992). Hence, expression of glycolytic and

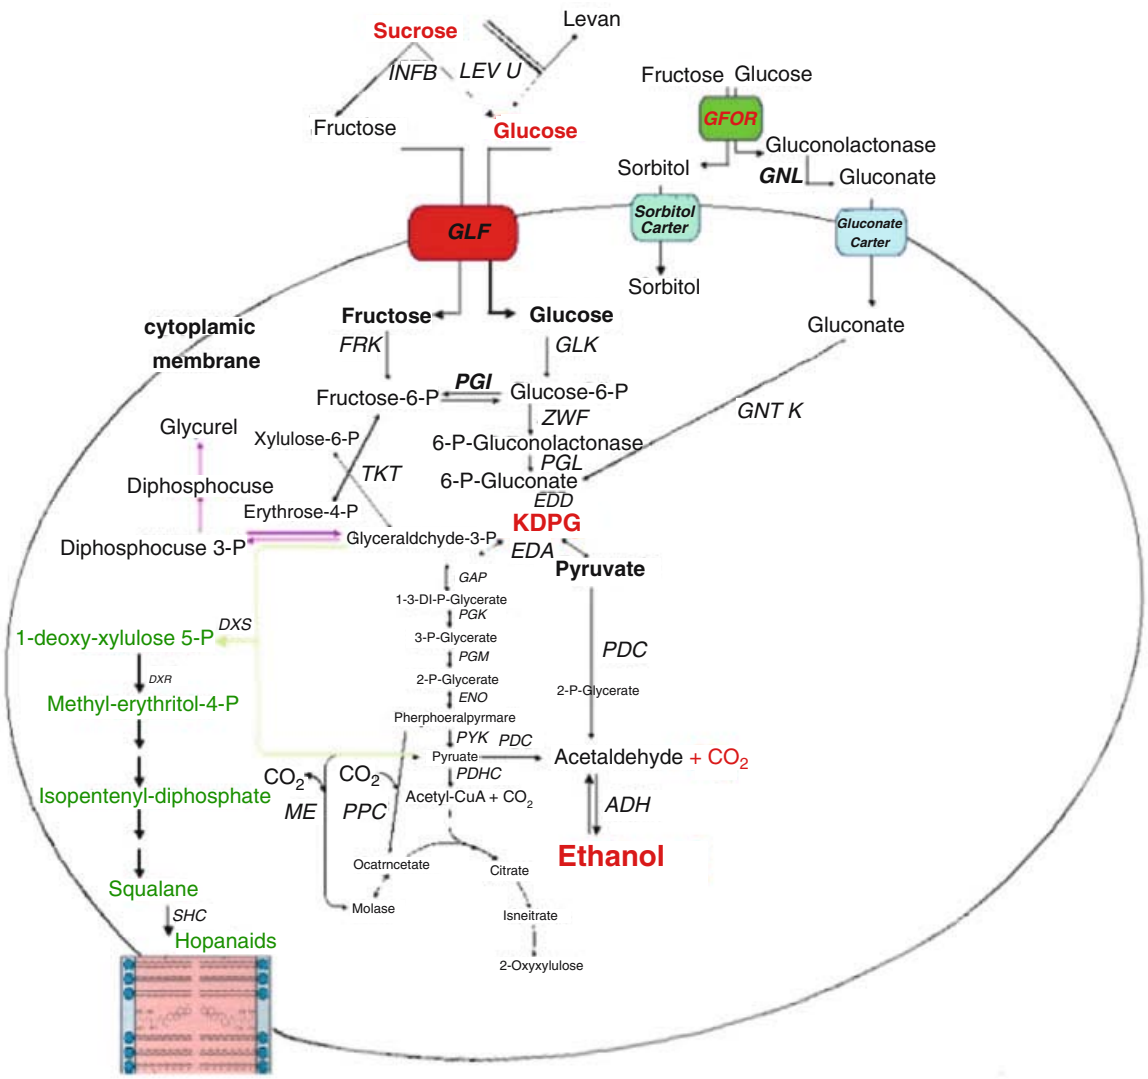

Fig. 1. Overview of main metabolic features in a schematic *Zymomonas mobilis* cell. Steps in carbohydrate metabolism (uptake and metabolism of sucrose, glucose, fructose, gluconate, sorbitol) are given together with anabolic reactions (incomplete tricarboxylic acid (TCA) pathway, formation of by-products, formation of hopanoids). Abbreviations: DXR = deoxyxylulose 5-phosphate reductoisomerase; DXS = 1-deoxy-xylulose 5-phosphate synthase; GNT K = gluconate kinase; ME = malic enzyme; PGL = phosphogluconolactonase; PPC = phosphoenol-pyruvate carboxylase; TKT = transketolase. For other abbreviations of enzymes see Table 2.

fermentative enzymes relies mainly on mRNA stability (the half-lives of transcripts for the glycolytic enzymes were in the range of 8–18 minutes; Meija et al., 1992). This relative mRNA stability may distinguish highly expressed glycolytic genes from biosynthetic genes. Differential expression of the *gap* and *pgk* genes, which form an operon, also has been attributed to differences in mRNA stability (Eddy et al., 1989).

When used in in vitro fermentations, the Entner-Doudoroff enzymes were remarkably resistant to ethanol inactivation and produced up to 16.5% (w/v) ethanol (Scopes and Griffiths-Smith, 1986). In living cells, 3-phosphoglycerate accumulated in the presence of 10% (w/v) ethanol, as detected by ^{31}P NMR spectroscopy. Enzyme assays confirmed that phosphoglycerate mutase and enolase were inhibited 31% and 40%, respectively, in the presence of 10% (w/v) ethanol in the test system (Strohhäcker et al., 1993).

A global regulatory protein (Grp) with high sequence similarity to the *Escherichia coli* global regulator Lrp has been discovered and can complement a glutamate-uptake mutant of *E. coli* (Peekhaus et al., 1995). The *grp* gene lies adjacent to an operon for a high-affinity glutamate carrier; its true function, however, remains to be elucidated (Peekhaus and Krämer, 1996).

Pyruvate Decarboxylase

Pyruvate decarboxylase (PDC, EC 4.1.1.1), a key enzyme in ethanol fermentation, catalyzes the conversion of pyruvate to acetaldehyde and carbon dioxide and depends on thiamine diphosphate and Mg(II) ions for its catalytic activity. Though PDC is widely distributed in fungi and higher plants, it is rare in prokaryotes and unknown in animals (Candy and Duggleby, 1998). In addition to being in *Z. mobilis* (Hoppner and Doelle, 1983; Bringer-Meyer et al., 1986; Neale et al., 1987; Diefenbach and Duggleby, 1991), bacterial PDCs have been found in *Sarcina ventriculi* (Stephenson and Dawes, 1971; Lowe and Zeikus, 1992), *Acetobacter* species (King and Cheldelin, 1954; De Ley and Schell, 1959), and *Erwinia amylovora* (Haq and Dawes, 1971; Haq, 1984). In *Z. mobilis*, PDC is one of the most abundant proteins, contributing 4–6% to the soluble cell protein content (Bringer-Meyer et al., 1986; An et al., 1991). The enzyme is a homotetramer with a subunit molecular mass of 60.79 kDa calculated from the DNA sequence (Neale et al., 1987; Conway et al., 1987b; Reynen et al., 1988). In contrast to genes in *Saccharomyces cerevisiae*, only one gene seems to code for PDC in *Z. mobilis* (Neale et al., 1987; König, 1998). *Zymomonas mobilis* PDC exhibits normal Michaelis-Menten kinetics with a K_m for pyruvate of 0.3–0.4 mM (Bringer-Meyer et al., 1986; Neale et al., 1987). This is exceptional because all other PDCs that have been characterized up to now are allosterically regulated by the substrate or other activator molecules such as pyruvamide (König, 1998). Recently, determination of the 3D crystal structure of the PDC from *Z. mobilis* revealed that the interface area between the dimers of the enzyme is much larger than in the yeast PDC. In addition, the dimers are more tightly packed in the PDC from *Z. mobilis*, thus preventing large rearrangements in the quarternary structure and locking the enzyme in an activated conformation (Dobritzsch et al., 1998). The critical amino acid residues involved in cofactor binding (Asp^{440}, Asn^{467}, Gly^{469}), substrate binding (Asp^{27}, His^{113}, His^{114}, Tyr^{290}, Thr^{388}, Glu^{473}) and catalysis (Glu^{473}) of the *Z. mobilis* PDC have been identified by site-directed mutagenesis (Sun et al., 1995; Pohl, 1997; Candy and Duggleby, 1998; Chang et al., 1999). A side reaction catalyzed by pyruvate decarboxylase is the carboligase activity, where the activated acetaldehyde bound to the thiamine diphosphate cofactor is condensed to a second aldehyde molecule (Bringer-Meyer and Sahm, 1988; Bornemann et al., 1995; Bruhn et al., 1995). This acyloin condensation reaction is used industrially for the production of phenylacetylcarbinol ([R]-1-hydroxy-1-phenylpropan-2-one), an intermediate in the synthesis of L-ephedrine. In *Z. mobilis* PDC, alanine replacement of the tryptophan (Trp^{392}) located near the active center enhanced the carboligase activity of the enzyme, increasing phenylacetylcarbinol formation by a factor of four (Bruhn et al., 1995).

Alcohol Dehydrogenase Isoenzymes

Zymomonas mobilis possesses two isoenzymes of fermentative alcohol dehydrogenase (ADH, EC 1.1.1.1): ADH I (a zinc-containing enzyme) and ADH II (an iron-containing enzyme; Wills et al., 1981; Hoppner and Doelle, 1983; Kinoshita et al., 1985; Neale et al., 1986). ADH activity is essential for the obligatory fermentative metabolism of *Z. mobilis*; therefore it is not surprising that the two ADH isoenzymes are abundant proteins in *Z. mobilis*, representing 2–5% of the soluble cell protein (Mackenzie et al., 1989). The ADH I, encoded by *adhA*, is a homotetramer with a subunit molecular mass of 36 kDa, and it contains one zinc atom per subunit (Wills et al., 1981; Neale et al., 1986; Keshav et al., 1990). The protein level of ADH I, which is more active at the early stages of growth, was found to decline in stationary-phase cells (Viikari, 1988; Keshav et al., 1990; An et al., 1991). The gene *adhB* encodes ADH II, also a homotetrameric enzyme with a subunit molecular mass of 40 kDa and one

iron atom per subunit. This enzyme catalyzes half the acetaldehyde reduction in *Z. mobilis* (Wills et al., 1981; Neale et al., 1986; Conway et al., 1987d). Under aerobic conditions, ADH I activity is fully conserved, but ADH II activity decays as the enzyme-bound Fe^{2+} atoms are oxidized (Tamarit et al., 1997). Whereas ADH I also oxidizes butanol, ADH II has almost no activity towards this substrate (Kinoshita et al., 1985; Neale et al., 1986). The enzyme has been found to transfer the pro-*R* hydrogen of NADH onto acetaldehyde (Glasfield and Brenner, 1989). Together with ADH IV of *Saccharomyces cerevisiae* and propanediol oxidoreductase of *E. coli*, ADH II of *Z. mobilis* forms a group of structurally related enzymes belonging to the iron-activated group III of dehydrogenases (Conway and Ingram, 1989; Reid and Fewson, 1994). These proteins share no homology with zinc-containing ADH enzymes (Cabriscol et al., 1994). The ADH II of *Z. mobilis*, identified as a major stress protein, was induced both by exposure to ethanol and by elevated temperature (Michel, 1993). The enzyme is expressed from tandem promoters which share partial sequence identity with the *E. coli* consensus sequence for heat shock proteins (An et al., 1991; Mackenzie et al., 1989). By a polymerase chain reaction (PCR)-mediated random mutagenesis, ADH II of *Z. mobilis* has been altered to produce more thermally stable variants. The same in vitro random mutagenesis technique enabled isolation of variant enzymes that had substrate specificities different from that of the wild-type enzyme, e.g., mutant enzymes active with butanol or with NADP (Rellos et al., 1997).

Ethanolic Fermentation

Zymomonas mobilis performs a highly productive ethanol fermentation and offers a number of advantages over the traditional yeast fermentation, i.e., higher sugar uptake and ethanol yield, lower biomass production, and oxygen independence (Rogers et al., 1982). Fermentations with *Z. mobilis* compared to those with yeast have a limited substrate range, which is restricted to glucose, fructose and sucrose (Swings and De Ley, 1977). Furthermore, the low salt tolerance of *Z. mobilis* poses problems for the fermentation of molasses, which usually have a high salt content (Montenecourt, 1985; Skotnicki et al., 1982). Nevertheless, it has been shown that glucose as well as unsterile hydrolyzed B-starch can be converted efficiently to ethanol in a continuous process employing a fluidized bed reactor (Bringer et al., 1984; Weuster-Botz, 1993a; Weuster-Botz et al., 1993b). In addition, processes for simultaneous saccharification and ethanol fermentation of starch or sugar cane have been developed (Kim and Rhee, 1993; Krishna et al., 1998). When glucose is fermented by nonaerated cultures, only insignificant amounts of by-products are formed. However, during growth of *Z. mobilis* in fructose-containing media the formation of acetoin, acetic acid, acetaldehyde, glycerol and dihydroxyacetone was more pronounced, and the cell yield was lower than when grown in glucose (Viikari, 1988; Johns et al., 1992; Horbach et al., 1994). Various genes encoding enzymes required for utilization of other carbon sources, e.g., starch, cellulose, raffinose, lactose, xylose or mannose, have been transferred into *Z. mobilis*; for details, the reader is referred to the chapter on metabolic engineering and to recent reviews (Doelle et al., 1993; Sprenger, 1993a; Gunasekaran and Raj, 1999). Another strategy for an efficient ethanol fermentation of such carbon sources is the transfer into *E. coli*, other enteric bacteria and also Gram-positive bacteria of the *Z. mobilis* genes *pdc* and *adhB* encoding pyruvate decarboxylase and alcohol dehydrogenase II, respectively (for a review see Ingram et al., 1998; Ingram et al., 1999).

During fermentation of sucrose by *Z. mobilis*, the formation of by-products such as levan and sorbitol decreases the ethanol yield (Viikari, 1988). Three types of transfructosylation occur in the presence of sucrose, resulting in the formation of free fructose, oligosaccharides and levan (Viikari, 1988). *Zymomonas mobilis* possesses three different sucrases: an intracellular sucrase (SacA or syn. InvA), an extracellular levansucrase (SacB or syn. LevU or syn. SucZE2), and an extracellular sucrase (SacC or syn. InvB or syn. SucZE3) (Kannan et al., 1997; Yanase et al., 1998; Song et al., 1999). Extracellular levansucrase and extracellular sucrase are involved in the sucrose metabolism of *Z. mobilis*, whereas the function of the intracellular sucrase is not understood (Kannan et al., 1997). The genes encoding for the extracellular levansucrase and sucrase are clustered on the chromosome (Gunasekaran et al., 1995), and the transcription of both genes was induced significantly when sucrose was added to the medium (Song et al., 1999). Extracellular levansucrase and sucrase do not carry an amino-terminal signal peptide usually found in proteins translocated across the cytoplasmic membrane (Gunasekaran et al., 1995; Kyono et al., 1995). In *E. coli* that carry the *Z. mobilis sucZE2* gene, a part of the expressed levansucrase was translocated across the inner membrane (Yanase et al., 1998), whereas the *Z. mobilis* gene for the extracellular sucrase expressed in *E. coli* did not lead to the enzyme's secretion (Kannan et al., 1995; Yanase et al., 1998). Levansucrase (EC 2.4.1.10) hydrolyses β-fructosides but not α-glucosides and catalyzes

levan formation from sucrose as well as from raffinose (Sangiliyandi et al., 1999). The optimum temperature for the polymerase activity (30°C) was lower than that for the hydrolase activity (50°C; Yanase et al., 1992; Sangiliyandi et al., 1999).

Sugar and Ethanol Tolerance

GLUCOSE-FRUCTOSE OXIDOREDUCTASE (GFOR) AND THE FORMATION OF SORBITOL The formation of sorbitol and gluconic acid from sucrose (or mixtures of glucose and fructose) by *Z. mobilis* has attracted much interest in the past, as yields of up to 90% for gluconic acid and up to 92% of sorbitol were reported for mixtures of glucose and fructose of up to 750 g/liter (Rehr et al., 1991; Silveira et al., 1999). A novel enzyme, glucose-fructose oxidoreductase (GFOR), with tightly bound NADP(H) as cofactor, has been detected (Zachariou and Scopes, 1986). The 3D crystal structure of the homotetramer GFOR enzyme has been elucidated recently (Kingston et al., 1996). So far, this enzyme is unique to *Zymomonas mobilis*, where it occurs in both subspecies, *mobilis* and *anaerobia* (Sprenger and Swings, 2000). The physiological function of this periplasmic enzyme (Loos et al., 1991; Aldrich et al., 1992) apparently lies in the formation of the compatible solute sorbitol. Sorbitol is accumulated in the cell (up to 1 M; Loos et al., 1994) and helps to counteract the detrimental effects of high sugar concentrations (Loos et al., 1994). A GFOR-deficient mutant, unable to form sorbitol (ACM3963; Kirk and Doelle, 1993), failed to grow in 1 M sucrose solutions, but after introduction of the wild-type *gfo* gene, it regained sorbitol forming ability and subsequently grew in high sucrose media (Wiegert et al., 1996). The periplasmic location of GFOR takes advantage of the concomitant presence of both substrates, glucose and fructose, at saturating concentrations (Sprenger, 1996), as the glucose facilitator prefers glucose over fructose (Weißer et al., 1995). The GFOR is formed as a preprotein with an unusually long N-terminal extension that serves as a signal sequence for the protein's export to the periplasm (Wiegert et al., 1996; Halbig et al., 1999). This signal sequence contains a so-called twin-arginine motif, which is a hallmark of a new class of Sec-independent protein export, the TAT or twin-arginine translocation in bacteria (Berks, 1996; Sargent et al., 1998; Berks et al., 2000). The TAT pathway transports folded proteins together with their redox cofactors to the bacterial periplasm.

HOPANOIDS IN *Z. MOBILIS*: MEDIATORS OF ETHANOL TOLERANCE AND FIRST INDICATORS OF THE EXISTENCE OF A NOVEL BIOSYNTHETIC PATHWAY FOR THE ISOPRENIC C_5 UNIT *Zymomonas mobilis* is capable of tolerating ethanol concentrations up to 13% (w/v). This ethanol tolerance is remarkably high and comparable to that of *Saccharomyces cerevisiae* (Rogers et al., 1982). The *Z. mobilis* cytoplasmic membrane contains a number of different hopanoids (Fig. 2): these membrane-stabilizing, pentacyclic

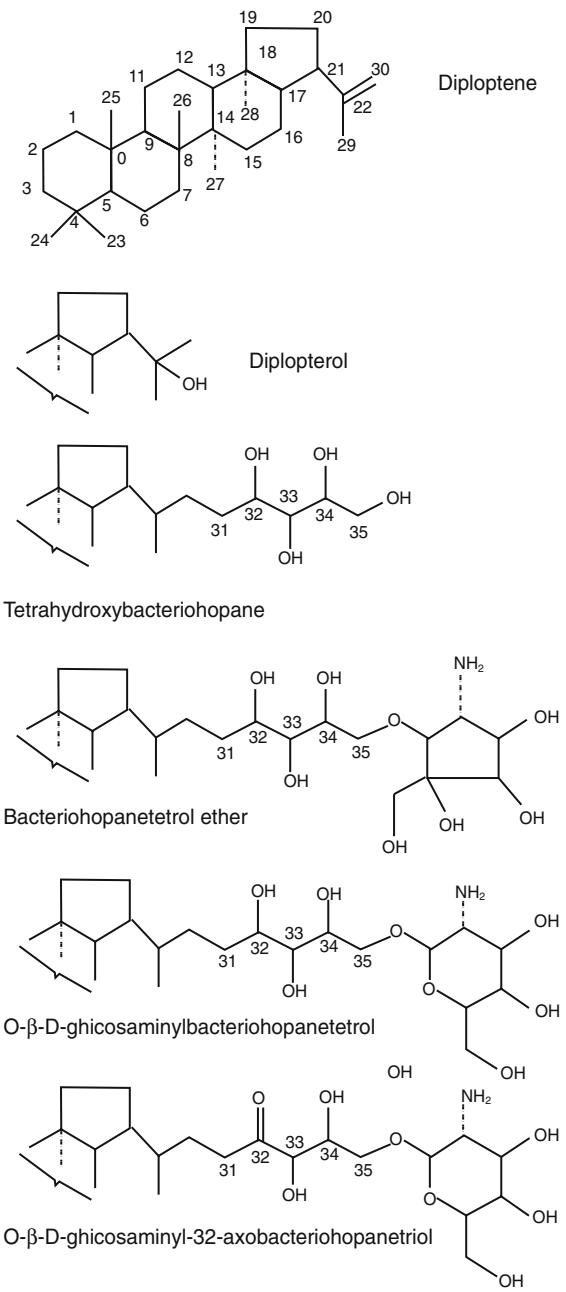

Fig. 2. Hopanoids from *Zymomonas mobilis*.

triterpenoids are present at concentrations of 30 mg/g cell dry weight (i.e., they contribute 40–50% to the organism's total lipid content; Hermans et al., 1991; Sahm et al., 1993; Moreau et al., 1997; Kannenberg and Poralla, 1999). Hopanoids play an important role in the ethanol tolerance of *Z. mobilis* by reinforcing the cytoplasmic membrane against the fluidizing effects of high concentrations of ethanol (Horbach et al., 1991; Sahm et al., 1993). Exposure to high levels of ethanol leads to an induction of several stress proteins (An et al., 1991) and their genes *adhB*, *dnaK*, and *groESL* (encoding for alcohol dehydrogenase II and the heat shock proteins DnaK, GroES and GroEL) have been cloned and characterized (Conway et al., 1987c; Michel, 1993; Barbosa et al., 1994). In continuous cultures at high ethanol concentrations and low dilution rates, sustained oscillations of biomass occur due to fluctuations of cell viability (Ghommidh et al., 1989; Vaija et al., 1993; Daugulis et al., 1997).

In vitro studies with cell-free extracts of *Z. mobilis* revealed that biosynthesis of the triterpenic moiety of the hopanoids proceeded from isopentenyl diphosphate via the intermediates farnesyl diphosphate and squalene (Shigeri et al., 1991); two enzymes involved in this part of isoprenoid biosynthesis in *Z. mobilis*, squalene synthase and squalene cyclase, were studied in detail and the corresponding genes were cloned and characterized (Reipen et al., 1995; Koukkou et al., 1996; Perzl et al., 1998).

However, the results of feeding studies with ^{13}C-labeled glucose and NMR spectroscopic analysis of the resulting labeling pattern of the triterpenoid moiety of the hopanoids clearly contradicted the classical mevalonate pathway for C_5 isoprenoid building-block isopentenyl diphosphate (IPP) biosynthesis (Flesch and Rohmer, 1989; Rohmer et al., 1989; Rohmer et al., 1993; Rohmer et al., 1996; Horbach et al., 1993; Sahm et al., 1993). Only recently was it evident that the unique characteristics of *Z. mobilis* could be of substantial help for the discovery of a novel, mevalonate-independent pathway for IPP biosynthesis, with glyceraldehyde-3-phosphate and pyruvate as precursors of isoprenic units (Rohmer et al., 1996). In this pathway, 1-deoxyxylulose 5-phosphate is formed as the first intermediate (Broers, 1994; Sprenger et al., 1997; Lois et al., 1998). Four further reactions of the pathway have been identified (Fig. 3; Takahashi et al., 1998; Rohdich et al., 1999; Lüttgen et al., 2000; Herz et al., 2000). The novel pathway is present in bacteria, green algae and the chloroplasts of higher plants (methylerythritol-4-phosphate pathway; Rohmer, 1999).

Special Features: Aerobic Metabolism, Pyruvate Dehydrogenase Multienzyme Complex

Aerobic Metabolism

Although strictly fermentative, *Z. mobilis* is an aerotolerant bacterium owing to the presence of a respiratory chain and the antioxidant enzymes catalase and superoxide dismutase (Belaich and Senez, 1965; Bringer et al., 1984; Pankova et al., 1985). However, at glucose concentrations >100 mM, oxygen inhibits growth due to an accumulation of acetaldehyde (Bringer et al., 1984; Pankova et al., 1985; Ishikawa et al., 1990). In the presence of oxygen, less NADH is available for the reduction of acetaldehyde to ethanol and therefore acetaldehyde accumulates to growth-inhibiting concentrations (Bringer et al., 1984; Pankova et al., 1985). Recently, continuous chemostat cultures of *Z. mobilis* growing aerobically with low glucose concentrations (<100 mM) exhibited a 2–2.5-fold increase in molar growth yields (Toh and Doelle, 1997; Zikmanis et al., 1997; Zikmanis et al., 1999). It was suggested that an inhibition of the proton pumping membrane ATPase by acetaldehyde in the presence of oxygen is the main cause for this increase. In this situation, membrane energization would be brought about by the respiratory activity (Toh and Doelle, 1997; Zikmanis et al., 1999).

The composition and function of the *Z. mobilis* electron transport chain is poorly understood, although the presence of a constitutive respiratory chain, containing cytochromes b, c and d, has been reported long ago (Belaich and Senez, 1965). Further studies have shown a structure with several membrane oxidoreductases and with branched electron pathways to oxygen. A hypothetical scheme is shown in Fig. 4. Cytoplasmic membrane vesicles oxidize NADH with a high specific rate, reaching 0.2-0.3 U · mg protein^{-1} (Bringer et al., 1984; Strohdeicher et al., 1990; Kalnenieks et al., 1995). Apart from the NADH oxidase, *Zymomonas* contains a membrane-linked NADPH oxidase with a similar activity (Bringer et al., 1984; Pankova et al., 1985). Two minor membrane oxidase activities have been reported: glucose oxidase, corresponding to a pyrroloquinoline quinone (PQQ)-containing glucose: ubiquinone oxidoreductase (Strohdeicher et al., 1988; Strohdeicher et al., 1990), and D-lactate oxidase (Kalnenieks et al., 1998). It has been demonstrated that electrons from both NADH and glucose are transported to oxygen via the quinone pool (Strohdeicher et al., 1990). Coenzyme Q_{10} (ubiquinone) has been found to

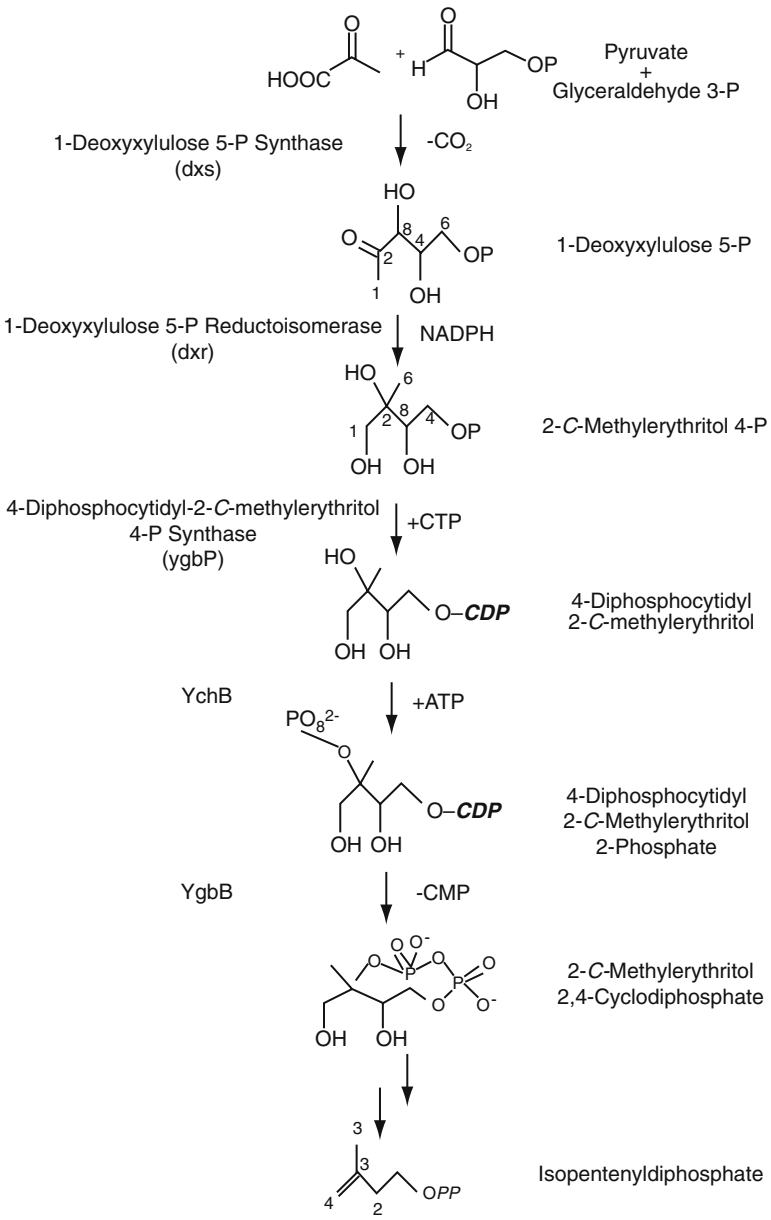

Fig. 3. The 2-methylerythritol 4-phosphate (MEP) pathway to isopentenyl diphosphate.

be the only quinone species in *Zymomonas* membranes (Strohdeicher et al., 1990).

Although aerobically growing cultures apparently do not produce extra ATP for biomass synthesis, oxidative phosphorylation can be measured in nongrowing cells and membrane vesicles (Kalnenieks et al., 1993). The energy coupling sites of the electron transport chain vary depending on the aeration of the culture. In the membranes of anaerobically cultivated cells, ATP synthesis is linked mainly to the site I (i.e., NADH dehydogenase I; Kalnenieks et al., 1995). On the other hand, for aerobically cultivated cells the buildup of membrane potential (Kim et al., 1995) and oxidative phosphorylation (Kalnenieks et al., 1996) takes place in the respiratory chain region downstream from site I. There are two kinetically distinguishable NADH oxidase activities in *Z. mobilis* membranes: one with a low K_m for NADH (around 7 μM) and another one with a higher K_m (around 60 mM; Kim et al., 1995; Kalnenieks et al., 1996). This points to the presence of two different membrane-bound NADH dehydrogenases, as was also found for other bacterial respiratory chains (e.g., for *E. coli*; Calhoun et al., 1993). It has been suggested that the NADH oxidase with the low K_m corresponds to the energy-coupling NADH: ubiquinone oxidoreductase of type I, and that the oxidase with the high Km represents the energy non-generating, type II NADH: ubiquinone oxidoreductase (Kalnenieks et al.,

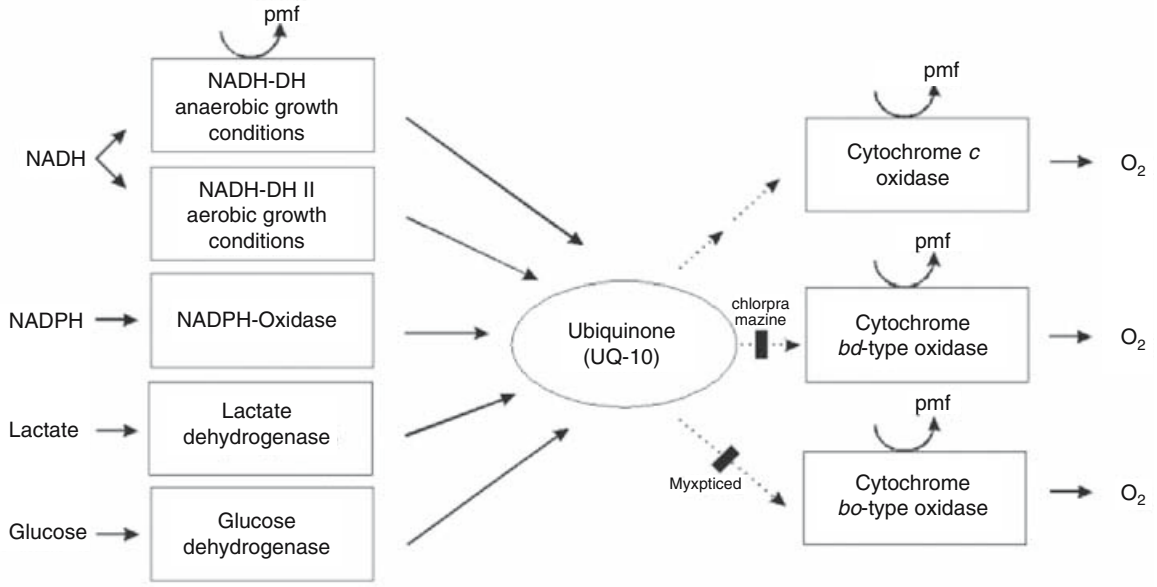

Fig. 4. Electron transport chain of *Zymomonas mobilis*; pmf, proton motive force.

1996). Spectral features of several types of cytochromes (b, c and d) have been observed in membrane preparations (Belaich and Senez, 1965; Pankova et al., 1985; Kalnenieks et al., 1998). In spite of high rates of respiration, the cytochrome content in *Z. mobilis* is comparatively low, being approx. 2–3 times lower than that in *E. coli* (Kalnenieks et al., 1998). From spectroscopic data it has been postulated that electrons, coming from the quinone pool, are distributed between three branches, terminated by 1) cytochrome *bd*, 2) a cytochrome *bo*-like component and 3) a cytochrome *a*-type terminal oxidase (Kalnenieks et al., 1998). At present it can be outlined that the respiratory chain of *Z. mobilis* is composed of several membrane oxidoreductases and of branched electron pathways to oxygen (Fig. 4). The presence of a respiratory chain in *Z. mobilis* supports the suggestion made by Swings and De Ley (1977) that this organism may have originated from aerobic ancestors.

Pyruvate Dehydrogenase Multienzyme Complex

In *Z. mobilis*, the formation of acetyl-CoA from pyruvate is catalyzed by a pyruvate dehydrogenase (PDH) complex (Bringer-Meyer and Sahm, 1993). The occurrence of this enzyme complex in *Z. mobilis* is surprising because anaerobically growing bacteria usually employ pyruvate formate lyase (EC 2.3.1.54) or pyruvate ferredoxin oxidoreductase (EC 1.2.7.1) for acetyl-CoA synthesis (Sawers and Watson, 1998; Chabriere et al., 1999). The formation of acetyl-CoA from pyruvate represents a main junction of catabolic and anabolic pathways. Up to 98% of the pyruvate is converted to the fermentation end products ethanol and CO_2, whereas only a small part of the pyruvate is oxidatively decarboxylated by the reaction of the PDH complex to acetyl coenzyme A, CO_2 and NADH (Sahm et al., 1992). Inasmuch as *Z. mobilis* lacks the 2-oxoglutarate dehydrogenase complex and other enzymes of the tricarboxylic acid cycle, the PDH complex plays an exclusively anabolic role in this organism (Bringer-Meyer and Sahm, 1993). Bacterial pyruvate dehydrogenase complexes are composed of multiple copies of three different enzymes: pyruvate dehydrogenase (E1p; EC 1.2.4.1), dihydrolipoamide transacetylase (E2p; EC 2.3.1.12) and lipoamide dehydrogenase (E3; EC 1.8.1.4; Reed and Hackert, 1990). In *Z. mobilis*, the PDH complex consists of four polypeptides, similar to the situation found in Gram-positive bacteria, with an E1α subunit of 38.6 kDa, an E1β subunit of 49.8 kDa, an E2 subunit of 48 kDa and an E3 subunit of 50 kDa. The E2 core of the complex is arranged to form a pentagonal dodecahedron, again resembling the quaternary structures of PDH complexes of Gram-positive bacteria and eukaryotes (Neveling et al., 1998a; Neveling et al., 1998b). The structural genes (*pdhA*αβ, *pdhB*, *lpd*) encoding the PDH complex of *Z. mobilis* are located in two distinct gene clusters, *pdhA*αβ and *pdhB*-orf2-*lpd* (Neveling et al., 1998b). Like the dihydrolipoamide acetyltransferases of *S. cerevisiae* and numerous other organisms, the product of the *pdhB* gene of *Z. mobilis* contains a single

lipoyl domain. In addition, the E1β subunit was found to contain an amino-terminal lipoyl domain, a property that is exceptional among PDH complexes (Neveling et al., 1999).

Genetics and Metabolic Engineering

Plasmids, Gene Transfer, Mutagenesis and Mutant Isolation

Most strains of *Z. mobilis*, including the type strains (ATCC10988 = ZM1; ATCC29191 = ZM6; ATCC31821 = CP4), contain several natural plasmids (in a size range from 1.6 kb to >40 kb; Rogers et al., 1982; Tonomura et al., 1982; Scordaki and Drainas, 1987). Plasmid profiling has been used to clarify uncertain strain status (Yablonsky et al., 1988; Degli-Innocenti et al., 1990). For the most part, the *Z. mobilis* plasmids remain cryptic, although some functions as antibiotic or heavy metal resistances have been assigned to them (Tonomura et al., 1982; Walia et al., 1984; Scordaki and Drainas, 1987; Ogale and Deobagkar, 1988). For genetic engineering, various broad host range plasmids (from several incompatibility groups), shuttle and/or expression vectors have been constructed (Byun et al., 1986; Brestic-Goachet et al., 1987; Conway et al., 1987a; Cho et al., 1989; Reynen et al., 1990)—some of them with inducible promoter features (e.g., *lacI*q/P*tac* vectors; Arfman et al., 1992; Reipen et al., 1995). Using plasmid R68.45, chromosome transfer between donor and recipient strains of *Z. mobilis* was reported (Skotnicki et al., 1982; Stokes et al., 1983). No bacteriophage has been reported for *Z. mobilis* yet. This, however, need not mean that no phages exist for *Zymomonas* but rather indicates the lack of in-depth investigations. A physical map of ZM4 strain has been constructed recently which allowed to estimate the genome size to about 2,085 kb (Kang and Kang, 1998) and the full genomic sequence of this strain is currently underway.

Mutant isolation and enrichment still poses remarkable problems (Sprenger et al., 1993b; Pencreac'h et al., 1996; Pappas et al., 1997) and up to now, no working method for gene disruption or even gene replacement has been reported, although an integrative shuttle vector has been reported recently (Delgado et al., 1995). Auxotrophic mutants have been won spontaneously, or after induction by UV light, by chemical mutagens (alkylating agents such as ethyl methane sulfonate [EMS] or nitrosoguanidine; Typas and Galani, 1992), or following transposon mutagenesis (Pappas et al., 1997). Mutants range from auxotrophs for amino acids or vitamins (Goodman et al., 1982; Eddy et al., 1988; Karunakaran and Gunasekaran, 1989; Pencreac'h et al., 1996; Estevez et al., 1997) to mutants with altered metabolic markers (fructose utilization; Bringer-Meyer et al., 1985; Suntinanalert et al., 1986; glucokinase; DiMarco and Romano, 1985; Aitabdelkader et al., 1996; alcohol dehydrogenases; Wecker and Zall; 1987; mannitol degradation; Buchholz et al., 1988; sorbitol formation; Kirk and Doelle, 1993). Furthermore, various strains with tolerance versus elevated temperatures (e.g., 42°C), molasses, salts or ethanol have been isolated as well as flocculent strains (see references in Ingram et al., 1989). Mutants resistant to allyl alcohol were found to be deficient in both alcohol dehydrogenases (Wecker and Zall, 1987; O'Mullan et al., 1995). These strong acetaldehyde-forming mutant strains grow and ferment poorly and are dependent on the presence of oxygen (Wecker and Zall, 1987).

Methods for introduction of foreign genes mainly rely on conjugation from *E. coli* donor cells (see references in Ingram et al., 1989; Sprenger, 1993a) or on electroporation (Okamoto and Nakamura, 1992; Lam et al., 1993; Liang et al., 1998), the latter at still low frequencies. Successful chemical transformation using spheroplasts (Yanase et al., 1986) or a chemical ($CaCl_2$) method with whole cells (Browne et al., 1984; Su and Goodman, 1987), yielding up to $1.8 \cdot 10^5$ transformants/μg of plasmid DNA, have been reported, but reproduction of these results has been difficult in other laboratories. *Zymomonas mobilis* is inherently resistant to nalidixic acid, which kills *E. coli* cells. In conjugations from *E. coli* donors to *Z. mobilis* recipients, nalidixic acid is therefore employed to discriminate against the donor cells (Uhlenbusch et al., 1991; Arfman et al., 1992). The other inherent antibiotic resistances limit the marker genes mainly to chloramphenicol and tetracycline. However, spontaneous resisters against both antibiotics also are found. The strain ZM6 (ATCC29191) and its derivatives are more sensitive to ampicillin than are the strains ZM1 (ATCC10988) and CP4; therefore replicons with Amp^R-genes may be utilized in ZM6 and its derivatives.

Metabolic Engineering

Nearly as soon as the paramount large-scale, ethanol-producing capabilities of *Z. mobilis* became widely known (Rogers et al., 1982), attempts to broaden the limited substrate and product range of *Z. mobilis* were started. Genetic and metabolic engineering of *Z. mobilis* have attracted many groups to study the unusual efficiency of sugar metabolism and ethanol produc-

tion and to improve the limited substrate and product range of the organism. Several reviews during the last years have dealt with these issues in depth and are recommended for further reading (Ingram et al., 1989; Conway, 1992; Johns et al., 1992; Sprenger, 1993a; Doelle et al., 1993; Sprenger et al., 1993b; Sprenger, 1996). Successful examples are summarized in Table 3. The main goals were to enlarge the substrate spectrum to the utilization of constituents of abundantly available and renewable carbon sources from wood and straw (e.g., hemicelluloses with D-xylose, L-arabinose and D-mannose as main monosaccharide constituents), whey (lactose), starch (maltose) and cellulose (cellobiose).

Many groups have worked especially on lactose as a carbon source, however, only with limited success. Main problems were that this disaccharide needs to be taken up by an energy-consuming step (proton-symporting lactose permease LacY), genes for galactose catabolism have to be co-introduced, and finally inhibitory by-products (such as galactonic acid or galactitol) may limit the growth and ethanol formation from lactose (literature reviewed in Sprenger, 1993a). More recently, catabolism of D-xylose, L-arabinose and D-mannose has been achieved with good ethanol yields (Feldmann et al., 1992; Zhang et al., 1995; Deanda et al., 1996; Weisser et al., 1996; de Graaf et al., 1999). Sugar uptake of D-xylose and D-mannose is gratuitous as the GLF transporter takes both sugars at good rates (Weisser et al., 1996; Parker et al., 1997). Introduction of a single phosphomannose-isomerase gene (*pmi*) from *E. coli* resulted in a mannose-positive phenotype of *Z. mobilis*, as another gratuitous reaction (involving fructokinase) took care of the mannose phosphorylation step (Weisser et al., 1996). Successful transfer of the plasmid-borne *pmi* gene could be monitored by growth of the *Z. mobilis* exconjugants on mannose as sole C-source; this can now be used as an alternative to the antibiotic-resistance markers, which are limited (Weisser et al., 1996). For D-xylose and L-arabinose catabolism, the peripheral enzymes have been introduced from various heterologous hosts into recombinant strains of *Z. mobilis* (Liu et al., 1988; Feldmann et al., 1992; Zhang et al., 1995; Deanda et al., 1996). After this was achieved it became evident that additional activities of the central pentose-phosphate metabolism are required (Feldmann et al., 1992; Zhang et al., 1995). Whereas transketolase is present at very low activity, transaldolase appears to be absent from *Z. mobilis* (Feldmann et al., 1992; Zhang et al., 1995). Introduction and expression of transketolase and transaldolase from *E. coli* were necessary to isolate xylose-positive clones of *Z. mobilis* (Zhang et al., 1995; de Graaf et al., 1999). In the same line, L-arabinose-fermenting clones have been isolated (Deanda et al., 1996). The path of ^{13}C-labeled xylose in recombinant *Z. mobilis* cells has recently been followed by NMR techniques (de Graaf et al., 1999; Kim et al., 2000).

To enlarge the product spectrum of *Z. mobilis*, an L-alanine dehydrogenase gene from *Bacillus sphaericus* has been introduced and was expressed from the strong *pdc* promoter. This led to a portion of pyruvate being diverted from the normal ethanologenic route to a fermentative L-alanine route. To reduce the overwhelming PDC activity, a thiamine-auxotroph strain was used which was then starved for thiamine in the

medium to reduce the activity of thiamine-diphosphate-requiring PDC. This resulted in a major rerouting of pyruvate to L-alanine (Table 3; Uhlenbusch et al., 1991). The strong isoprenoid-forming pathway of *Z. mobilis* was successfully altered into a carotenoid pathway by introduction of *crt* genes from *Erwinia* species (Table 3; Misawa et al., 1991).

CHAPTER 3.1.10

The Manganese-Oxidizing Bacteria

KENNETH H. NEALSON

The "manganese-oxidizing group" is a phylogenetically diverse assemblage, which is characterized by the ability to catalyze the oxidation of divalent, soluble Mn(II) to insoluble manganese oxides of the general formula MnO_x (where X is some number between 1 and 2). This results in the accumulation of conspicuous and easily detectable extracellular deposits of insoluble brown or black manganese oxides. Many different organisms have the ability to catalyze Mn oxidation, including a diverse array of bacteria, fungi, algae, and even eukaryotes (Ghiorse, 1984b). Among the prokaryotes, the ability to oxidize Mn is also quite widespread (Ehrlich, 1981; Ghiorse, 1984b, 1988; Marshall, 1979; Nealson, 1983); included are members of many phylogenetic and physiological groups: e.g., cyanobacteria, a diversity of heterotrophic rods and cocci, the sheathed (*Leptothrix*-like) and budding (*Hyphomicrobium*-like) bacteria, some purported autotrophic strains related to *Pseudomonas* species and the still-controversial *Metallogenium* group. The anaerobic lactobacilli, which utilize the Mn oxidation reaction as a protection against oxygen toxicity (Archibald and Fridovich, 1981, 1982) are not included, as they do not precipitate extracellular Mn oxides, but rather accumulate millimolar levels of protein-associated Mn in the cytoplasm. This chapter focuses on the process of Mn oxidation and also considers why so many bacteria have been identified as Mn oxidizers. It also offers suggestions that may help to clarify this complex area.

Since there is no evidence of any advantage that Mn oxidation confers on bacteria, one might well ask the reason for the widespread distribution of this trait. The answer may lie in the Mn oxidation reaction itself. Under the conditions characteristic of most of the environments in which microbes are abundant, Mn is a very active element. Some critical features of Mn chemistry are summarized in Fig. 1 and are also discussed in more detail elsewhere (Ghiorse, 1988; Mulder and Dienema, 1981; Nealson et al., 1988, 1989; Pankow and Morgan, 1981).

The oxidation of Mn(II) to Mn(IV) is thermodynamically favored under aerobic conditions, with a negative free energy of approximately 16 kcal/mol (Stumm and Morgan, 1981; Ehrlich, 1981; Nealson et al., 1988). However, the large activation energy of Mn(II) oxidation renders Mn(II) very stable in most aquatic environments (Stumm and Morgan, 1981). The activation energy barrier can be overcome by raising the pH (see Fig. 1) or by the addition of Mn-binding components, including Mn oxides themselves, which are excellent chelators of Mn(II) (Stumm and Morgan, 1981). The catalysis of Mn(II) oxidation by Mn oxides (autooxidation) makes it difficult to distinguish between chemically and microbially catalyzed Mn oxidation, especially in natural environments where organic chelators and Mn oxide particles may be abundant.

Mn is, therefore, an element whose distribution and chemical speciation is kinetically controlled, thus allowing for the intervention of microbes and microbial products into the system. Some of the ways in which microbes might oxidize Mn(II) are shown in Table 1. If the pH or Eh of the environment is raised, if oxidants are produced by cells, or if binding of Mn(II) occurs so as to lower the activation energy, Mn(II) oxidation can rapidly proceed. With this in mind, it is not surprising that so many different bacteria have been identified as Mn(II) oxidizers, since the mechanisms of Mn oxidation are quite diverse (Ghiorse, 1988; Nealson et al., 1988, 1989). A true understanding of the "Mn-oxidizing bacteria" will likely await the time when it is possible to identify those reactions that confer some advantage to the bacteria and to disregard those that occur simply because of the dynamic chemistry of Mn(II). With regard to this, some of the recent studies of the mechanism of Mn(II) oxidation by cells, which include the isolation of Mn(II)-binding proteins (both intra- and extracellular) and polysaccharides, are particularly encouraging (Ghiorse, 1988; Nealson et al., 1989).

Habitats

Manganese-oxidizing bacteria are ubiquitous; they can be isolated from nearly any habitat. It is the experience of many workers that habitats containing high levels of Mn and those in which Mn cycling is an active process tend to have high numbers of Mn-oxidizing bacteria. However, such correlations do not always hold (Gottfreund and Schweisfurth, 1983; Schuett and Ottow, 1977). Some examples of habitats from which abundant manganese oxidizers have been identified by morphology alone and/or isolation include: deep-sea manganese nodules (Ehrlich et al., 1972; Schuett and Ottow, 1977); hydrothermal vent plumes (Cowen et al., 1986); oxic/anoxic interfaces in fjords (Tebo et al., 1984); desert varnish (Hungate et al., 1987); manganese deposits in water pipes (Tyler and Marshall, 1967a, 1967b); manganese-rich surface films of shallow lakes (Ghiorse, 1984a), and freshwater lake sediments and ferromanganese deposits (Chapnick et al., 1982; Gregory and Staley, 1982; Kuznetsov, 1975; Maki et al., 1987).

A feature that is common to many of these habitats is a ready and continuous supply of

EXAMPLES OF COMPOUNDS FORMED	$MnCl_2$, $MnSO_4$, etc.	Mn_2O_3, MnOOH, etc.	MnO_2
GENERAL PROPERTIES	A. Forms soluble salts	A. Form insoluble oxides and oxyhydroxides, e.g., Manganates (MnO_X, 1 X 2)	
	B. Forms insoluble minerals 1. $MnCO_3$ 2. $MnPO_4$	B. Manganese oxides adsorb trace metals and radionuclides, e.g., Cd, Co, Cu, Ni, Mn	
	C. Biologically available 1. Required trace element 2. Specific transport systems 3. Toxic at high concentrations	C. Unavailable as trace nutrients 1. Nontoxic 2. Potential electron acceptor	

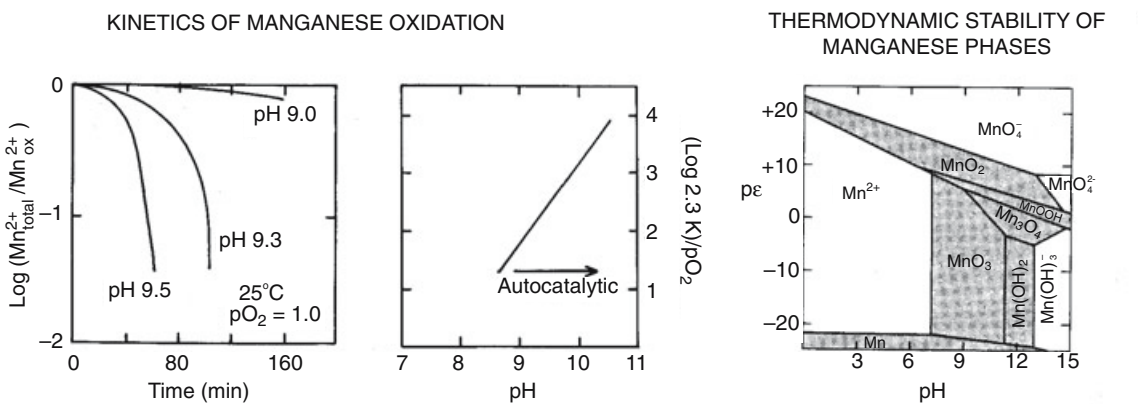

Fig. 1. Manganese chemistry and biochemistry. The top of the figure presents the major features of manganese cycling, including some of the well-known reactions leading to Mn(II) oxidation, the forms of Mn found in nature, and the general properties of these forms. The lower part of the figure shows the effect of pH on reaction kinetics and a thermodynamic phase-stability diagram for manganese (based on Stumm and Morgan, 1981).

Mn(II), which has been observed to typically occur in either of two ways (Fig. 2). The first (Fig. 2, part I) is in conjunction with oxic/anoxic interfaces. Under anaerobic conditions, Mn (III) and Mn(IV) can be rapidly reduced by a variety of indirect and direct mechanisms, such as excretion of organic or inorganic reductants, or by bacterial respiration (Nealson et al., 1989). This results in a solubilization of the Mn, which can then diffuse into the oxic zone, making an ideal natural enrichment condition for Mn(II)-oxidizing bacteria. Such interfaces are common in virtually all Mn-containing sediments and in stratified lakes and fjords.

Table 1. Possible mechanisms of Mn(II) oxidation by bacteria.

1. Indirect
   - A. Free radical or oxidant production
     - i. Hydrogen peroxide
     - ii. Superoxide
     - iii. Hydroxyl radical
   - B. Modification of redox environments
     - i. Oxygen production
     - ii. pH increase
       - a. CO_2 consumption
       - b. Acid consumption
       - c. Ammonia release
   - C. Production of Mn(II) chelators
     - i. Organic chelators
     - ii. Mn oxides
2. Direct
   - A. Mn-binding components
     - i. Proteins
     - ii. Glycocalyxes
     - iii. Cell wall components
   - B. Mn-oxidizing enzymes (oxidases)

Mn(II) is also continuously supplied by inputs of anoxic (reduced) water into aerobic environments (Fig. 2, part II). This occurs in deep-sea hydrothermal plumes in which chemically reduced Mn(II) is introduced into the deep sea and in ground water or hot spring inputs to oxic lakes, where chemically or biologically reduced Mn(II) is continuously introduced into lake waters.

In stratified aquatic environments (Fig. 2), microbial manganese oxidation can be a process of major biogeochemical importance. The freshly produced Mn oxides are returned as solid precipitates to the sediments or to anaerobic waters where they may be used for the anaerobic oxidation of other agents, including Fe(II), H_2S, and organic matter (see Nealson et al., 1989). Manganese is well suited for such a role, as it does not readily form insoluble sulfides and thus

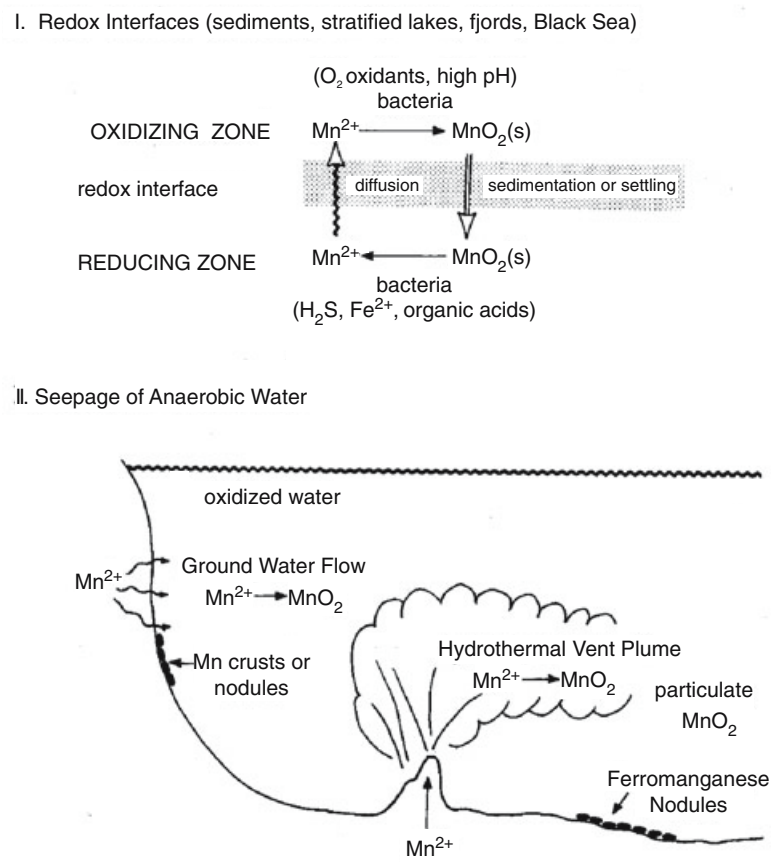

Fig. 2. Habitats of manganese-oxidizing bacteria: the two well-characterized general environments where one might expect to encounter natural enrichments of Mn-oxidizing bacteria.

remains in solution in marine anaerobic (sulfidic) zones (Stumm and Morgan, 1981).

While it has been known since the time of Beijerinck (1913) that pure cultures of bacteria catalyze Mn(II) oxidation, direct measurements of microbial Mn(II) oxidation in nature were, until a few years ago, very rare. In recent years, however, many research groups have utilized a variety of poisoned control experiments to implicate Mn(II)-oxidizing bacteria as the major catalysts of Mn(II) precipitation in many environments, including fjords, lakes, and sediments (see Ghiorse, 1988; Nealson et al., 1988). From these studies it can now be confidently stated that microbial Mn oxidation is a major biogeochemical process in freshwater, marine, estuarine, and soil habitats.

A detailed description of the sheathed bacteria (Mulder and Dienema, 1981) reveals that these organisms (*Leptothrix*-like) are found in abundance in the same environments as are other manganese oxidizers and that many of these bacteria are in fact characteristically encrusted with iron or manganese oxides. (See also The Sheathed Bacteria in the second edition)

Metallogenium

Perhaps the most controversial and enigmatic group of Mn oxidizers are those called *Metallogenium* (Zavarzin, 1981). These are Mn oxide-containing stellate structures of various morphologies that have been identified in environments throughout the world for many years (Emerson et al., 1989; Kuznetsov, 1975; Maki et al., 1987; Schweisfurth and Hehn, 1972; Zavarzin, 1968, 1981). The stellate morphotypes have been identified as organisms by some workers (Dubinina, 1970; Zavarzin, 1968, 1981) and disputed as such by others (Emerson et al., 1989; Maki et al., 1987; Schweisfurth, 1978; Schweisfurth and Hehn, 1972). The problem can best be demonstrated with the work of Maki et al. (1987), who identified abundant *Metallogenium* morphotypes in the deep, stratified waters of Lake Washington. These stellate precipitates contained no structural features of living cells and were not associated with the zone of rapid Mn precipitation in the lake. The conclusion reached was that they were not living particles, although it could not be proven that they did not have their origin as part of a living structure. There is thus little doubt that structures resembling *Metallogenium* exist, and they are abundant in many environments, especially in lake systems. However, there is little proof that *Metallogenium*-like structures are formed directly by, or associated with, any particular organism.

Emerson et al. (1989) reported that extracellular proteins and polysaccharides from a basidiomycetous fungus were capable of initiating the formation of *Metallogenium*-like structures in laboratory culture, and have suggested that similar extracellular catalyses occur in nature. While these studies do not prove that all *Metallogenium* structures are formed this way, they do provide a mechanism whereby such morphotypes can form without direct association with living cells. The *Metallogenium* question must be regarded as an open one, the answer to which might lead to new understanding of the relationship between Mn oxidizing organisms and the environmental chemistry of Mn.

Isolation and Enrichment of Mn-Oxidizing Bacteria

As discussed above, natural enrichments for Mn(II) oxidizers occur in environments in which manganese cycling is active, and in such habitats further enrichments may not be required. For example, Tyler and Marshall (1967a, 1967b) observed and isolated *Hyphomicrobium* species directly from ferromanganese deposits on hydroelectric pipes, and Ghiorse (1984a) observed and isolated *Leptothrix* species as the causative agent of manganese surface films in a shallow lake. In both these cases, large numbers of similar organisms were visible and closely associated with the manganese oxides; under such conditions it was easy to conclude that the organisms participated in the formation of the metal precipitates.

In other cases, while Mn(II)-oxidizing bacteria can be easily isolated, they are neither so abundant nor so obviously responsible for the observed precipitates. Furthermore, the isolation of Mn oxidizers indicates the "potential" for Mn oxidation rather than the "demonstration" of the direct involvement with precipitation of metals in nature. Since so many organisms are capable of Mn oxidation (and by so many different mechanisms), caution must be exercised in the interpretation of reports of high numbers of Mn oxidizers. Another important point is that the chemical methods used to identify Mn oxides (see below) are very sensitive, and it may well be that many organisms which are identified as Mn oxidizers in culture never accumulate such precipitates in nature.

Laboratory Enrichments

Reports of laboratory enrichments for Mn oxidizers are rare; perhaps because there is no known selective advantage for Mn oxidation, enrichments are not often attempted. Nealson (1978) reported long-term enrichments in which $MnCl_2$ was added to a variety of different marine sediment samples. After periods of

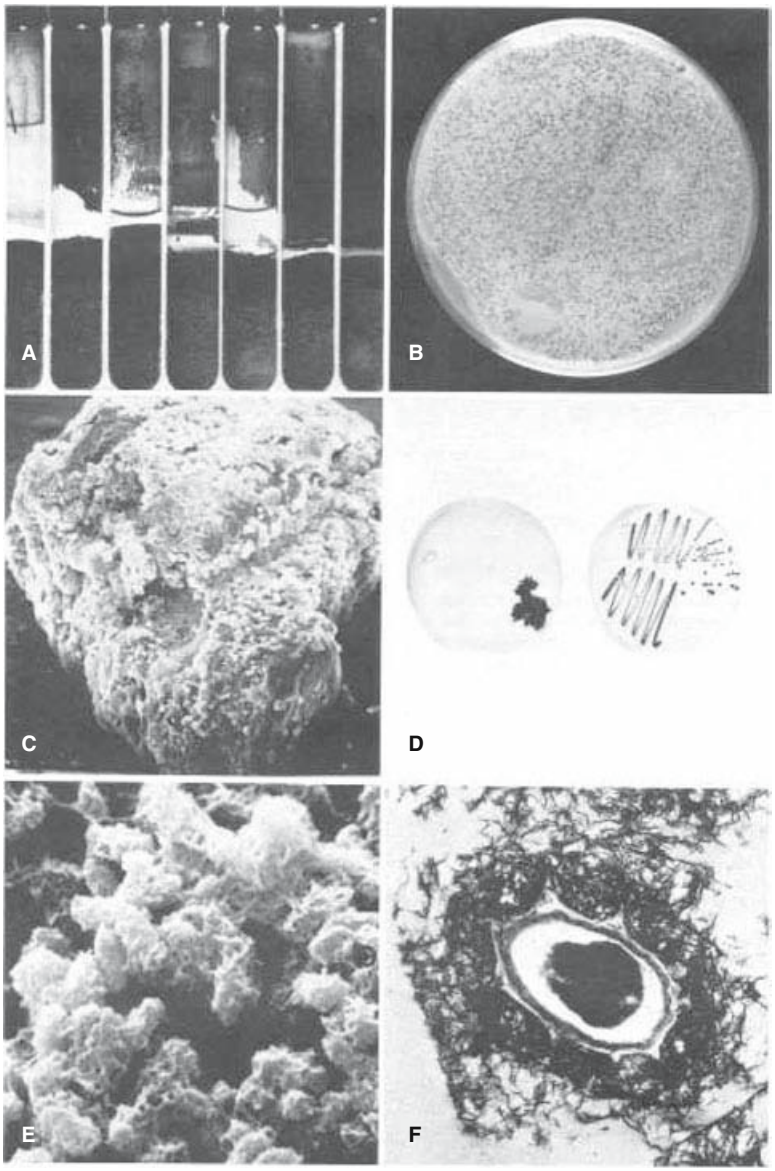

Fig. 3. Many faces of manganese-oxidizing bacteria. This figure shows six different views and size scales of Mn-oxidizing bacteria. (A) Black crusts and Mn-coated sand grains seen in enrichment culture tubes after several months of enrichment with 100 μM Mn(II). (B) Colonies resulting from plating of 0.1 ml of enrichment culture E-3—these colonies were stained with benzidinium HCl; the dark colonies are positive for Mn oxidation. (C) Scanning electron microscope (SEM) magnification of Mn-encrusted sand grain from enrichment culture. Mn coating appears to be bacterial in nature. (D) Left plate, outgrowth of Mn-oxidizing bacteria from sand grain placed on agar plate; right plate, pure culture isolate (called SG-1) from sand grain outgrowth; dark color of these colonies is due to Mn oxides precipitated around the cells. (E) High resolution SEM of pure culture of SG-1. (F) Transmission electron microscope (TEM) picture of thin section of spore of strain SG-1; crystalline material is Mn oxide.

enrichment of 3 months to 1 year, zones of Mn oxidation could be seen in nearly all enrichments, as Mn oxide films on tubes (Fig. 3A), as Mn-oxide-encrusted sand grains (Fig. 3A), or as zones of darkening in the sediment enrichments. Plating of these samples yielded very high numbers of morphologically and taxonomically similar bacteria (Fig. 3B; Nealson, 1978). These results suggest that there is a selective advantage for bacteria capable of Mn oxidation, and such approaches might be suggested as one method for finding those bacteria that should be properly placed in the "group" of true Mn-oxidizing bacteria (i.e., those that for one reason or another derive advantage from Mn oxidation).

Cultivation

Mn-oxidizing bacteria can be easily obtained in pure culture and grow well in liquid or solid media, so long as Mn(II) toxicity is avoided. As a guideline, some commonly used media are given below, but it may be equally helpful to discuss some of the general principles that need to be considered for growth of the Mn oxidizers.

Carbon Source Simple carbon sources (acetate, succinate, glycerol, etc.) are usually used for isolation of Mn oxidizers; for many of these organisms, Mn oxidation in culture occurs only after growth has slowed or ceased. Furthermore, some carbon sources will lower the pH of the

medium or repress Mn-oxidation ability (Nealson, 1978). Many of the media use very low levels of carbon, and in some media amino acids serve as the sole source of organic carbon. With newly isolated organisms, we routinely test several carbon sources for their ability to support growth and Mn oxidation.

pH Since the oxidation of Mn is strongly pH dependent (Fig. 1), it is important to control or at least monitor the pH of the medium. By the addition of a strong buffer near neutrality, one can avoid indirect Mn oxidation due to pH changes. We routinely add 10–100 mM Hepes buffer at a pH of 7.0–8.0 (see below).

Vitamins In general the Mn oxidizers are not fastidious organisms, although many workers routinely add a vitamin supplement (see below) or small amounts of yeast extract to the medium.

Mn Source The kind of Mn(II) salt used (e.g., acetate, carbonate, chloride, sulfate, etc.) appears to make little difference. It is, however, advisable to filter-sterilize the Mn(II) solution and to add it to the medium after autoclaving. Autoclaving can lead to partial oxidation and formation of Mn oxide particles which can then bind Mn(II) and catalyze its abiological oxidation.

Mn Concentration Mn(II) in the environment rarely exceeds 1–5 micromolar, and above 10 micromolar it can be toxic to bacteria (Chapnick et al., 1982). In rich media, such as the K medium given below, Mn can be added at relatively high (i.e., millimolar) concentrations without causing toxicity. However, as the medium become less rich and there are fewer organic compounds to chelate the Mn(II), the Mn concentration must be lowered to prevent growth inhibition. With newly isolated organisms, we routinely test for growth on media with both 10 and 100 micromolar Mn.

Continuous Culture One method for avoiding Mn toxicity involves the use of continuous cultures (chemostats). It is possible to begin experiments using a heterotrophic medium (with a carbon source like succinate or acetate) containing low levels (5–20 μM) of Mn(II). The Mn(II) concentration is monitored in the outflow of the chemostat, and when it has decreased to values of less than 1 μM, the Mn(II) concentration in the medium reservoir of the chemostat can then be slowly raised to 1 mM or more (Kepkay and Nealson, 1987). This allows studies of the relationship between the metabolism of the carbon source and Mn(II) at different concentration ratios. Continuous cultures could also be used for the isolation of organisms from environments where natural enrichments exist—this should enhance the possibility of finding Mn oxidizers in which the oxidation of Mn(II) yields biologically useful energy.

Autoclaving All the media listed below can be sterilized by autoclaving, but in those cases where solutions of metals or vitamins are involved, it is advisable to filter sterilize the stock solutions and add to the growth medium after sterilization. This avoids chemical precipitation and complexation with organics in the medium.

Representative Media for Mn Oxidizers

K Medium (Krumbein and Altmann, 1973)

This is a rich medium that supports the growth of a variety of different heterotrophic Mn oxidizers. The ingredients added per liter of seawater, freshwater, or distilled water are:

$FeSO_4 \cdot 7H_2O$ (may be omitted)	0.001 g
$MnSO_4 \cdot 4H_2O$ (or $MnCl_2$)	0.2 g
Peptone	2.0 g
Yeast extract	0.5 g
Hepes buffer (N-2-hydroxyethylpiperazine_ N′-2-ethanesulfonic acid, pH 7.5, added as 1M stock)	10 mM

Succinate Minimal Medium (after Kepkay and Nealson, 1987)

This is a basal medium for the study of Mn binding and metabolism, and it is made up with a distilled water (or artificial seawater) base. It contains in addition to the seawater or freshwater base:

NH_4Cl (KNO_3 used in some instances)	9.0 mM
K_2HPO_4	0.4 mM
$NaHCO_3$	2.0 mM
$FeSO_4$	5.0 μM
Hepes buffer (pH 7.8)	10 mM
Vitamin mix (solution #1 below)	10 ml
Sodium succinate (or other carbon source)	10 mM
$MnC1_2$ (concentration varied as needed)	10 μM

PC Medium (Tyler and Marshall, 1967a)

This is a low-nutrient medium used for the isolation of Mn-oxidizing Hyphomicrobia species. It may be made with distilled water or with water from the environment under study. It contains per liter of basal liquid:

$MnSO_4 \cdot 4H_2O$	0.02 g
Yeast extract	0.05 g

PYGV Medium (Ghiorse and Hirsch, 1979)

This is another low-nutrient medium used for the isolation and study of slow-growing budding and sheathed bacteria (Pedomicrobium and Leptothrix). It may take several days or longer for colonies to become visible on this medium, but there is also little trouble with fast-growing heterotrophs that tend to outgrow the Mn oxidizers on richer media. The medium contains per liter of distilled water or of artificial seawater:

Peptone	0.25 g
Yeast extract	0.25 g
Glucose	0.25 g
Vitamin mixture (solution no. 1 below)	10 ml
Mineral salts (solution no. 2 below)	20 ml

Solution no. 1: Concentrated Vitamin Solution

> The following vitamins are added to 1 liter of double-distilled water with stirring, filter sterilized, and stored at 5°C in the dark: 2.0 mg biotin; 5.0 mg niacin; 5.0 mg thiamine ·HCl; 5.0 mg p-aminobenzoic acid; 5.0 mg Ca-pantothenate; 5.0 mg pyridoxin ·HCl; 0.1 mg cyanocobalamin; 5.0 mg riboflavin; and 2.0 mg folic acid.

Solution no. 2: Hutner and Cohen-Bazire's salts

> 10 mg nitrilo triacetate (NTA) is dissolved by neutralization with KOH in 900 ml distilled water. The following salts are then added: 3.34 g $CaCl_2 \cdot 2H_2O$; 99 mg $FeSO_4 \cdot 7H_2O$; 29.7 g $MgSO_4 \cdot 7H_2O$; 12.67 g $NaMoO_4 \cdot 2H_2O$; and 50 ml metal solution "44" (solution no. 3, below). The final volume is adjusted to 1 liter with distilled water, and the solution, which should be clear, is stored at 5°C.

Solution no. 3: Metal Salt Solution "44"

> The following salts are added singly to 1 liter of double-distilled water to which a few drops of H_2SO_4 have been added: 250 mg ethylenediaminetetraacetate (EDTA); 1,095 mg $ZnSO_4 \cdot 7H_2O$; 154 mg $MnSO_4 \cdot H_2O$; 20.3 mg $CoC1_2 \cdot 6H_2O$; 500 mg $FeSO_4 \cdot 7H_2O$; 39.2 mg $CuSO_4 \cdot 5H_2O$; and 17.7 mg $Na_2B_4O_7 \cdot 10H_2O$.

Identification

Mn-oxidizing bacteria are usually identified by detection of brown or black solid Mn oxides that are deposited around or near the cells. However, this property is not definitive. First, many bacteria produce other dark pigments, and second, several different crystalline forms of Mn oxides are possible, and these have different colors and consistencies. Furthermore, other metals, particularly iron (Ghiorse and Hirsch, 1979), are often deposited with Mn oxides, lending yet different colors and consistencies to the precipitates.

In order to circumvent these problems, two manganese-specific spot-test indicators are commonly used to qualitatively establish the occurrence of Mn oxides. The first, benzidinium hydrochloride (Feigl, 1958), gives a deep blue color in the presence of Mn oxides. The reagent is prepared by dissolving 5 g of benzidinium ·HCl in 35 ml of glacial acetic acid. This solution is then diluted to a final volume of 500 ml with distilled water and stored at 5°C until needed. Colonies can be directly tested for the presence of Mn oxides by flooding the plates with 10 ml of reagent. Colonies of Mn oxidizers are identified by a dark blue color (see Fig. 3B).

There are some disadvantages to the use of the benzidinium reagent: 1) the reaction is interfered with by iron oxides, which can give weak false positives; 2) the reagent is toxic and has carcinogenic properties; and 3) the reagent mixture is bactericidal, so that colonies must be replicated before they are tested for Mn oxidation. Because of the toxic nature of this compound, it is recommended that it *not* be used unless there are no alternatives.

A second method utilizes the reagent leukoberbelin blue (LBB) (Krumbein and Altmann, 1973), a redox indicator which upon interaction with Mn(III) or Mn(IV) is oxidized and changes from colorless to a blue form. Mn oxides are reduced during this reaction, so that treatment with LBB can be used to gently remove oxides from Mn-encrusted cells (Nealson and Tebo, 1980). The LBB reaction is less susceptible to interference by iron than is the benzidinium reaction, and because it is less bactericidal, it can be used directly on cells or colonies to indicate Mn oxidation during growth on solid medium (Krumbein and Altmann, 1973). The reagent is made as follows: 4.0 g of berbelin blue-I (N, N′-dimethylamino-*p*,*p*′-triphenylmethane-*o*′-sulfonic acid) is dissolved in 80 ml of boiled distilled water. Prior to distillation, the water is acidified with a few drops of concentrated phosphoric acid. Then 0.3 ml concentrated NH_4OH is added, and the final volume is adjusted to 100 ml. This stock solution, which should be slightly acidic, can be stored for up to one year at 5°C in the dark. The working solution for use as a spot test reagent, stable for only a few days, is made by diluting the stock solution 1/100 into a weak (1 mM) acetic acid solution.

Mn oxidation can be quantified by monitoring the disappearance of soluble Mn(II) from the growth medium, either colorimetrically via the formaldoxime method of Brewer and Spencer (1971) or by measurement via atomic absorption spectroscopy (AAS). Alternatively, the oxidized Mn can be measured by separation of the insoluble oxides on membrane filters, dissolution (reduction) of the Mn oxides, and measurement of the resulting soluble Mn(II). Dissolution can be accomplished by any of several methods: 1) treatment with strong acid (6 M HCl) for several days; 2) treatment with a mixture of 5 parts concentrated HNO_3 to 3 parts concentrated HCl in a teflon bomb for 3 hours at 105°C; 3) leaching for several hours with concentrated nitric acid containing 1% $(NH_2OH)Cl$ (hydroxylamine hydrochloride); or 4) leaching for concentrated nitric acid containing 3% (w/v) H_2O_2. The method of choice will depend on the nature of the precipitates being analyzed and the subsequent analyses to be performed. We routinely use a 1% (w/v) NH_2OH solution without the HCl because it is easy, rapid, and causes minimum interference during AAS analysis.

Mn(II)-oxidizing bacteria can also be identified microscopically. However, the following comments should be made with regard to potential pitfalls: In the cases of the budding or appendaged Mn oxidizers, it is often possible to observe cell structures within and protruding

from the Mn oxides (Ghiorse and Hirsch, 1979; Tyler and Marshall, 1967a, 1967b), but with other types the oxides must be removed before the causative bacteria can be identified. Treatment with LBB can be used to remove the Mn oxides while working with natural precipitates under the light microscope, thus revealing whether cells are associated with the oxides. Alternatively, the oxides can be sectioned and examined by transmission electron microscopy, which reveals intimate associations between the cells and their Mn oxide coatings (see Fig. 3) (Ghiorse, 1984a; Ghiorse and Hirsch, 1979; Nealson and Tebo, 1980). Because of the nature of Mn chemistry, cases may also arise in which bacteria associated with Mn oxide precipitates have nothing to do with manganese oxidation, so caution must be exercized in interpreting such microscopic results.

Perhaps the least-valuable method for identification involves scanning electron microscopy (see Fig. 3C, 3E, and Ghiorse, 1988). Cells coated with Mn oxides can not readily be identified as bacteria. On the other hand, bacteria that are clearly identifiable as Mn oxidizers may be recognizable because they are not coated with Mn oxides (Nealson and Tebo, 1980). Since SEM analysis involves fixation of the cells or natural material before viewing, such analyses, in the absence of confirming studies with either light or transmission electron microscopy, can lead to misinterpretation, especially when natural Mn precipitates are examined.

On the other hand, when pure cultures of Mn-oxidizing bacteria are available, SEM, especially when coupled with other spectral methods, such as Energy dispersive X-ray analysis (EDAX) (Nealson and Tebo, 1980) or laser microprobe mass spectral analysis (Ghiorse and Hirsch, 1979), can add valuable information and insights into the properties of the Mn-oxidizing organism under study.

Applications

Toxic levels of Mn can be a problem in municipal water supplies and public and private wells; this occurs during summer months when the oxygen level falls and reduction of Mn oxides occurs. Once the Mn has been reduced and solubilized, it tends to be quite stable, even in the presence of oxygen, and one potential use of Mn-oxidizing bacteria (or products that these bacteria produce) is to remove dissolved Mn(II) from such environments (Czekalla et al., 1985). Understanding the mechanisms whereby these bacteria catalyze Mn oxidation may provide chemical or biological methods for dealing with this problem on a seasonal or even a permanent basis. Fresh Mn oxides are also potent chelators of other metals, and they have been used for the removal of radium from water supplies (Moore and Reid, 1973); the addition of manganese bacteria may provide a superior method for forming such fresh oxides in situ for such uses.

Mn oxides are also excellent electron acceptors for anaerobic respiration (see Nealson et al., 1989), and the possible application of Mn-oxidizing bacteria and Mn to stimulate respiratory carbon mineralization in sedimentary environments (especially under controlled conditions) may be worth considering. These bacteria in effect offer a natural system for "pumping" (via precipitation and sedimentation of Mn oxides) electron acceptor equivalents into an anaerobic environment (see Fig. 2).

Controversy and Perspectives

It is appropriate to end this chapter with a discussion of some of the current controversies surrounding the Mn-oxidizing bacteria. Perhaps the major question involves the advantages, if any, of Mn(II) oxidation to the bacteria. The advantages of Mn(II) oxidation, which have been discussed by Ghiorse (1984b), can neither be proven or eliminated by the data now available. The first advantage is the use of Mn(II) as an energy source for chemolithotrophic growth. While there is sufficient energy in the oxidation of Mn(II) to MnO_2 (Ehrlich, 1976), indisputable proof of Mn chemolithotrophy has been difficult to obtain. Several recent reports, when taken together, suggest that a resolution to this question may be near. Kepkay and Nealson (1987) reported the occurrence of growth of a marine *Pseudomonas* sp. (S-36), both mixotrophically on succinate plus Mn(II) and autotrophically on Mn(II), in Mn-limited chemostats. In the latter case, bicarbonate was the sole carbon source for growth. Ultrastructural studies of the same organism, S-36 (Tebo, 1983), revealed internal membranes and structures resembling carboxysomes in cells which had been grown under conditions of manganese-limited growth and with bicarbonate as the carbon source. Under these conditions, the carboxysomes, which are believed to be the sites of CO_2 fixation, are consistent with (but are not proof of) an autotrophic mode of metabolism. Finally, Tebo and Haygood (1989) have recently reported the presence of the gene coding for the large subunit of ribulose-bisphosphate carboxylase in marine Mn-oxidizing bacteria. These organisms should be excellent candidates for future study as Mn chemolithotrophs.

Adams and Ghiorse (1985) reported that survival of *Leptothrix discophora* in stationary-

phase cultures was prolonged by the addition of Mn(II) to the medium, and Mn(II) may provide a significant advantage to bacteria in natural habitats.

Bromfield (1978) discussed the possibility that Mn(II) oxidation may provide a protective mechanism against otherwise toxic levels of Mn(II) that might accumulate in the environment. Such a function is also discussed by Ghiorse (1984b) and is consistent with the observation that large numbers of bacteria capable of Mn(II) oxidation are found in habitats where Mn can reach toxic levels.

It now seems clear that there may be one or more advantages that accrue to those bacteria which oxidize manganese. For instance, it seems likely that the question of Mn chemolithotrophy will be resolved in the near future, as several lines of evidence suggest that such organisms do exist. Resolution of this question will enhance our understanding of the importance of Mn oxidation to bacteria and vice versa and give a new appreciation to the ecophysiology of the Mn oxidizers.

Second it also seems likely that there are other advantages that accrue to organisms that can oxidize Mn(II), including both unknown metabolic advantages and protective advantages. The elucidation of these will also aid in the definition of the "group" of Mn-oxidizing bacteria.

As discussed above, a careful study of the *Metallogenium* group is needed in order to understand how, or whether, these structures are true organisms, if they really fit into the biogeochemical scheme of Mn, and if they should be classified with the Mn oxidizers as a group.

With the answers to the above questions in hand, it may be possible in the future to specify which bacterial types (physiological and ecological) should be properly placed into this "group."

CHAPTER 3.1.11

The Genus *Paracoccus*

DONOVAN P. KELLY, FREDERICK A. RAINEY AND ANN P. WOOD

Introduction

At the time that Henk van Verseveld and Adriaan Stouthamer (1991) described *Paracoccus* in the second edition of *The Prokaryotes*, only two species were recognized: the type species (*P. denitrificans*) and *P. halodenitrificans* (Kocur, 1984). Of those two, *Paracoccus halodenitrificans* was subsequently excluded because it was shown to be a member of the genus *Halomonas* in the γ-subclass of the Proteobacteria (Dobson and Franzmann, 1996; Miller et al., 1994; Ohara et al., 1990; Urakami et al., 1990). In the past decade, a number of new species of *Paracoccus* have been described and a major critical review of the diverse biotypes of *P. denitrificans* and similar organisms was undertaken, leading to a clearer definition of the type species. At the time of writing, a total of 14 species of *Paracoccus* have been proposed (Table 1). These include two well-studied species of facultatively chemolithoautotrophic sulfur bacteria, *Thiosphaera pantotropha* and *Thiobacillus versutus*, which have been reclassified as species of *P. pantotrophus* and *P. versutus*. *Thiosphaera pantotropha* strain GB17 was initially believed to be a strain of *P. denitrificans* (Ludwig et al., 1993), until it and several biotypes of *P. denitrificans* were reclassified as a separate species, *P. pantotrophus* (Rainey et al., 1999). *Paracoccus denitrificans* and *P. pantotrophus* have continued to be the focus of much study of the molecular biology, respiratory mechanisms, and regulation of carbon and nitrogen dissimilation in *Paracoccus*.

The treatment of *Paracoccus* in the edition second of *The Prokaryotes* (van Verseveld and Stouthamer, 1991) concentrated on *P. denitrificans*, and we refer the reader to that treatment, and other more recent studies of *P. denitrificans*, for in-depth information concerning the physiology and molecular biology of *P. denitrificans* (and in some cases *P. pantotrophus*). More relevant reviews include those by Stouthamer (1992), Stouthamer et al. (1997), Baker et al. (1998) and van Spanning et al. (2000).

History of the Type Species, *Paracoccus denitrificans*

The original isolate by Beijerinck and Minkman (1910) is still extant as the type strain of the genus (Goodhew et al., 1996; Rainey et al., 1999). It was originally named *Micrococcus denitrificans* and shown to grow anaerobically in pure culture in a bouillon medium supplemented with ammonium nitrate (10 g · liter^{-1}), reducing nitrate to dinitrogen (N_2) and nitrous oxide (N_2O) in approximately a 2 : 1 ratio (Beijerinck and Minkman, 1910). Subsequently many workers used derivatives of that strain and another isolated by Koster (Goodhew et al., 1996), and *Paracoccus denitrificans* became a model organism for the study of its cytochrome system and electron transport mechanisms, denitrification, methylotrophy, and various aspects of metabolic and molecular regulation. It became apparent that a number of seemingly distinct biotypes were in use in various laboratories, and the isolation of other species with similar properties (initially named *Thiobacillus versutus* and *Thiosphaera pantotropha*) helped lead to a questioning of the relatedness of these to *P. denitrificans* and between the biotypes of *P. denitrificans*.

As a consequence of studies of their cytochromes and the history of *P. denitrificans* cultures by Goodhew et al. (1996), of their chromosomes by Winterstein and Ludwig (1998), and of their 16S rRNA sequences and DNA:DNA hybridization among *P. denitrificans* strains (Rainey et al., 1999), it became clear that the physiologically similar strains described as *P. denitrificans* actually fell into two distinct groups that differed so significantly that they justified separation into distinct species. These were *P. denitrificans* and *P. pantotrophus* comb. nov (Rainey et al., 1999): the type strain of *P. denitrificans* is ATCC 17741^T (LMD 22.21; Beijerinck and Minkman, 1910; Ludwig et al., 1993). The type strain of *P. pantotrophus* is ATCC 35512^T (LMD 82.5), which is the original isolate of *Thiosphaera pantotropha* (Kuenen and

[b]*P. denitrificans* is the type species of the genus.

Robertson, 1989; Robertson and Kuenen, 1983). Culture collection strains that (by this work) are indicated to be identical to each of these type strains are listed in Table 2. Winterstein and Ludwig (1998) have shown that the genome of *P. denitrificans* ATCC 13453, DSM 413 and strain Pd 1222 consists of three chromosomes, whose DNA molecules are approximately 2.1, 1.1 and 0.64 Mb in size. In contrast, *P. denitrificans* DSM 65 and *Thiosphaera pantotropha* LMD 82.5 contain four large DNA species that were 2.2, 1.50, 1.71–1.77 and 0.5 Mb in size. This observation is wholly consistent with our confirmation of the first three species as *P. denitrificans* and the assignment of the last two to the new combination, *P. pantotrophus*.

While it has long been recognized that the strains of *P. denitrificans* comprised several biotypes within a supposedly heterogeneous species (Jordan et al., 1997; Van Verseveld and Stouthamer, 1991), our work and that of Goodhew et al. (1996) revealed a more significant factor underlying this heterogeneity. This is that the validity of reference strains held by different international culture collections as derivatives of the type strain ATCC 17741[T] is uncertain. The results show that at some stage some culture collection strains supposedly derived from *P. denitrificans* LMD 22.21 (the original isolate of Beijerinck and Minkman, 1910) and ATCC 17741[T] must have been replaced with other strains (i.e. of *P. pantotrophus*). It is clear that where comparison with a type strain is of crucial significance, as in defining a genotype or the identity of a strain with the type strain, reference to the authentic type strain held by the collection is essential. It is obviously highly desirable that cross-checking by culture collection curators of the authenticity of type strains and the authenticity of cultures reportedly derived from them is undertaken.

Classical Taxonomic and Physiological Characteristics of Species of the *Paracoccus* Genus

Morphologically, all the species are coccoid, between 0.4–0.9 μm in diameter, or coccobacilli, up to 2 μm in length, and occur as single cells, pairs or clusters. All are Gram-negative and most species are non-motile. All species grow aerobically on a wide range of organic substrates and some are capable of anaerobic growth with nitrate or nitrous oxide as the terminal oxidant, producing dinitrogen as the final product. None is known to be able to grow fermentatively. The optimum temperature for growth of all the species is in the range 25–37°C, and the pH for good

[a]Transfer was based on 16S rRNA gene sequence similarities and DNA-DNA hybridization (Rainey et al., 1999) and cytochrome *c* profiles (Goodhew et al., 1996).

[b]*Thio. pantotropha* strain GB17, as used by Ludwig et al. (1993).

[c]Formerly regarded as the type strain of *P. denitrificans*.

[d]A derivative of *P. denitrificans* DSM 413.

growth ranges between pH 6.5–8.5 for different species, except for *P. alcaliphilus* (which is moderately alkaliphilic with an optimum of pH 8–9 and grows at pH 9.5, but only weakly at pH 7.0; Urakami et al., 1989). All the species examined to date contain ubiquinone-10 as the respiratory quinone, as expected for members of the α-3 subclass of the Proteobacteria, with small amounts of ubiquinone-9 and ubiquinone-11 also being reported for some species. Typically the major fatty acids are 18:1 and 18:0 straight-chain acids, 19cyc, and 10:0(3-OH), 12:1(3-OH), and 14:0(3-OH) hydroxy-acids (Katayama et al., 1995; Lipski et al., 1998). Most, if not all, strains may accumulate poly-β-hydroxybutyrate under carbon-sufficient growth conditions and are generally catalase and oxidase positive. The mol% G+C content of the DNA of the species described to date ranges between 63–71 mol%. When the genus *Paracoccus* was created (Davis et al., 1969), its sole member was the *Micrococcus denitrificans* of Beijerinck and Minkman (1910), a distinguishing feature of which was autotrophic growth on carbon dioxide using hydrogen oxidation as the source of metabolic energy (Kornberg et al., 1960). This property is not universal among the 14 species now named. Indeed, a number of the characters commonly used to define the general features of the genus (Van Verseveld and Stouthamer, 1991; Van Spanning et al., 2000) derive from the properties exhibited by the most-studied strains of *P. denitrificans*, *P. pantotrophus* and *P. versutus* and do not apply to some of the more recently-described species. Thus, the ability to use the oxidation of hydrogen or inorganic sulfur compounds to support autotrophic growth, the ability to grow either autotrophically or methylotrophically on methanol or methylamine, or the ability to grow by anaerobic denitrification do not now appear to be exhibited by all the species and are thus not common taxonomically diagnostic features of all *Paracoccus* isolates (Table 3).

The chemolithoautotrophic growth on inorganic sulfur compounds (e.g. thiosulfate) of three species of *Paracoccus* has been studied in some detail: *P. versutus*, *P. pantotrophus* and *P. thiocyanatus*. The type species, *P. denitrificans*, is also defined as being able to grow on thiosulfate. This property is in need of further study, as the analyses of Goodhew et al. (1996) and Rainey et al. (1999) showed that numerous strains of *P. denitrificans* were in fact strains of *P. pantotrophus*, and most comprehensive work on thiosulfate oxidation has been carried out with *P. versutus* and *P. pantotrophus* strain GB17 (Kelly et al., 1997; Friedrich, 1998). The type strain of *P. denitrificans* was received from C.B. van Niel by Davis et al. (1969) and became ATCC 17741, which Davis et al. (1969) thought likely to be the same as strains ATCC 19367 and ATCC 13543. We showed that this was true (Rainey et al., 1999) and that these strains were all identical to the original Beijerinck isolate (LMD 22.21). However, some strains supposedly also derived from the van Niel strain (via the strain Stanier 381: DSM 65 and LMG 4218) were in fact *P. pantotrophus* (Goodhew et al., 1996; Rainey et al., 1999). Strains DSM 413 and Pd 1222 are also representatives of the type

[a]List of species (numbered in the same sequence as in Table 4): 1. *P. denitrificans*; 2. *P. alcaliphilus*; 3. *P. marcusii*; 4. *P. carotinifaciens*; 5. *P. aminophilus*; 6. *P. solventivorans*; 7. *P. alkenifer*; 8. *P. kocurii*; 9. *P. thiocyanatus*; 10. *P. aminovorans*; 11. *P. pantotrophus*; 12. *P. versutus*; 13. *P. methylutens*; 14. *P. kondratievae*.

strain, *P. denitrificans* LMD 22.21, having been derived through the "Morris strain" (Goodhew et al., 1996). In an early study, Friedrich and Mitrenga (1981) showed that strain Stanier 381 (= *P. pantotrophus*) oxidized and grew on thiosulfate, while the Morris strain (= *P. denitrificans*) did not. The original Beijerinck isolate of the type strain, LMD 22.21, was, however, shown to grow autotrophically on thiosulfate (Robertson and Kuenen, 1983), but no other studies of the use of inorganic sulfur compounds by authentic strains of *P. denitrificans* seem to have been published.

Growth of the type species, *P. denitrificans*, and of *P. versutus* and *P. kondratievae* on methanol or methylamine has been proved to be autotrophic, using the complete oxidation of the one-carbon compounds to carbon dioxide to provide metabolic energy and the fixation of carbon dioxide by the Calvin cycle for biosynthesis (Bamforth and Quayle, 1978; Van Verseveld and Stouthamer, 1978; Kelly et al., 1979; Kelly and Wood, 1982; Van Verseveld and Thauer, 1987; Doronina et al., 2001). The type strain of *P. pantotrophus* (formerly *Thiosphaera pantotropha*; Robertson and Kuenen, 1983) does not grow on methanol or methylamine, but spontaneous mutational events during prolonged incubation with methanol resulted in the appearance of a strain able to grow on methanol, using ribulose bisphosphate carboxylase to fix carbon dioxide (Egert et al., 1993). In contrast, three *Paracoccus* strains isolated by Jordan et al. (1995) and subsequently shown to be strains of *P. pantotrophus* (Jordan et al., 1997; Rainey et al., 1999) were capable of good growth on methanol without prior selective methods.

While a number of other *Paracoccus* species also grow on one-carbon compounds (Table 3) and some (*P. aminovorans*, *P. aminophilus* and *P. kocurii*) use some or all of mono-, di-, and tri-methylamines, trimethylamine-*N*-oxide, formamide, *N*-methylformamide, *N*,*N*-dimethylformamide, and formate as growth substrates, experiments proving that all these are also autotrophic have not been reported. This information is quite important to obtain, as the possibility of the occurrence of alternative assimilatory pathways for one-carbon compounds (such as the serine pathway) has not yet been excluded. The existence of such pathways in any of these species would have considerable taxonomic importance. Of relevance is the observation that significant activities of hydroxypyruvate reductase, a key enzyme of the serine pathway, were found in *P. versutus* grown on formaldehyde (Kelly and Wood, 1984) and in *P. methylutens* grown on methylamine or dichloromethane (Doronina et al., 1998), although the major pathway for carbon fixation was the Calvin cycle in both species.

Phylogenetic Relationships Between the 14 Named Species of *Paracoccus*

16S rRNA gene sequences are available for the type strains of all 14 species of the genus *Paracoccus* and a number of additional strains. Phylogenetic analyses have demonstrated that all the described species of the genus *Paracoccus* form a coherent cluster within the α-3 subclass of the Proteobacteria with the closest relatives being members of the genus *Rhodobacter* (Tsubokura et al., 1999). Comparison of the 16S rRNA gene sequences of the type strains of each of the 14 species of the genus *Paracoccus* described to date shows the 16S rRNA gene sequence similarities within the genus to be in the range 93.5 to 99.8% (Table 4). *P. methylutens* shows the lowest 16S rRNA gene sequence similarity (93.5 to 97.5%) to the other species of the genus while *P. carotinifaciens* and *P. marcusii* share 99.8% sequence similarity. The phylogenetic dendrogram shown in Fig. 1 demonstrates the relationships between the species of the genus *Paracoccus*. The majority of species are found to comprise distinct lineages with long branches not closely related to their next neighbor. The lack of close relationships between the species is also seen through the bootstrap values, which clearly indicate low confidence in most of the branching points within the dendrogram. With the exception of the relationships between (i) *P. marcusii* and *P. carotinifaciens*, (ii) *P. solventivorans* and *P. alkenifer*, and (iii) *P. pantotrophus*, *P. versutus* and *P. methylutens* no other branching points are well supported by the bootstrap analyses. Considering the overall structure of the phylogeny based on the 14 described species, the high degree of divergence between the majority of these species and the fact that some true species share high levels (<99.5%) of 16S rRNA gene sequence similarity, it is clear that there is room to add numerous new species to this genus based on sequence analyses before the phylogenetic structure becomes saturated. Because of the use of different methodologies in studies to determine the degree of DNA reassociation between *Paracoccus* species and strains it is difficult to make any correlation between 16S rRNA gene sequence similarity values and percentage DNA reassociation values. However, from the DNA reassociation data of Rainey et al. (1999), it is clear that strains sharing high 16S rRNA gene sequence similarities can still be distinct species. Hybridization between DNA from *P. pantotrophus* DSM 65 and *P. versutus* DSM 582 showed 54% reassociation while the 16S rRNA gene sequences from these two strains showed <99.0% similarity. This comparison indicates that 16S rRNA gene sequence data are useful in assigning new isolates to the *Paracoccus* genus, but that high similarity values between 16S rRNA sequences do not necessarily indicate species identity. Additional tests such as assessment of DNA-DNA hybridization are also required to establish identity at the species level.

The "ae2" editor (Maidak et al., 1996) was used to align the 16S rRNA gene sequences of *Paracoccus* spp. available from the public databases (accession numbers indicated in parentheses). The programs of the PHYLIP package including "dnadist" and "neighbor" were used for the phylogenetic analyses (Felsenstein, 1993). The tree topology was reanalyzed using 1,000 bootstrapped data sets and the programs "seqboot," dnadist and "consense" of the PHYLIP package (Felsenstein, 1993). Bootstrap values from the analyses of 1,000 data sets (expressed as percentages) are shown at the branching points. The 16S rRNA gene sequence of *Rhodobacter capsulatus* was used as an outgroup in the

Table 5. Sources from which species of *Paracoccus* have been isolated.

Species	Sources of isolates
P. denitrificans	Garden soil, arable soil, field soil, sewage sludge, meadow soil, horse manure, cow dung, canal and well mud, unspecified soils
P. pantotrophus	Denitrifying, sulfide-oxidizing effluent treatment pilot plant (Gist-Brocades, The Netherlands), *Quercus* tree soil (Kew Gardens, England)
P. marcusii	Orange-pigmented contaminant (presumed airborne) on a nutrient agar plate
P. thiocyanatus	Activated sludge enriched with thiocyanate (isolated by H. Murooka; Katayama-Fujimura et al., 1983)
P. solventivorans	Soil from 1-m depth at a defunct natural gas company
P. alkenifer	Biofilters treating waste gas from an animal rendering plant
P. carotinifaciens	Orange-pigmented isolate (on nutrient agar) from soils in the Kanagawa prefecture (Japan)
P. versutus	Mud (used in enrichment culture for *Thiobacillus denitrificans*; Taylor and Hoare, 1969; Taylor et al., 1971)
P. kocurii	Pilot activated sludge system used to treat waste water from a semiconductor manufacturing process
P. alcaliphilus	Not reported (Urakami et al., 1989)
P. aminophilus	Soil (Japan)
P. aminovorans	Soil (Japan)
P. methylutens	Groundwater
P. kondratievae	Maize rhizosphere

analyses. The scale bar represents 2.5 nucleotide substitutions per 100 nucleotides.

Ecological Aspects and Enrichment Culture for Isolation of the Species of *Paracoccus*

Earlier reviews of *Paracoccus* have been devoted almost exclusively to *P. denitrificans* and showed it to occur in many terrestrial situations (Van Verseveld and Stouthamer, 1991). The sources from which 13 of the 14 species discussed here were isolated are given in Table 5 and serve to illustrate the ubiquitous distribution of *Paracoccus* species in terrestrial environments. While the enrichment media used for the isolation of these species were diverse (Table 6), none of these could be regarded as exclusively selective for the species recovered, especially as two species were first obtained on nutrient agar, so it is concluded that there is an element of serendipity in the successful isolation of novel or existing species of *Paracoccus*. To date, no strains seem to have been reported from the marine environment, although the tolerance of 3% (w/v) NaCl by some species (*P. alkenifer* and *P. methylutens*) indicates they would survive in sea water.

All the species of *Paracoccus* can grow heterotrophically, with most species being able to use a very wide range of simple and complex organic substrates. Some species exhibit distinctive and potentially exploitable novel metabolic traits. For example, some species can grow in one or more of the following modes: as methylotrophs on one-carbon compounds, as autotrophs at the expense of oxidizing hydrogen or inorganic sulfur compounds, as autotrophs on thiocyanate or carbon disulfide, and as mixotrophs on compounds such as methylated sulfides (when both methylotrophic and chemolithotrophic energy mechanisms operate). The type species and some others are facultative denitrifiers. This metabolic diversity can enable enrichment culture to be directed towards the selection of specific metabolic types.

The procedures advocated for the enrichment culture of a number of *Paracoccus* species (Van Spanning et al., 2000) depend on selection either of the autotrophic/methylotrophic species in oxic media with hydrogen, methanol or methylamine

Table 6. Substrates used for the enrichment and isolation of the *Paracoccus* species listed in Table 5.

Species	Substrates used for the original pure culture isolations of the strains	References
P. denitrificans	Tartrate and nitrate, anaerobic with denitrification	Beijerinck and Minkman, 1910
P. pantotrophus	Mixotrophic, anaerobic chemostat with 10mM thiosulfate, 10mM acetate and 32mM nitrate	Robertson and Kuenen, 1983
	Aerobic batch enrichment with carbon disulfide	Jordan et al., 1995
P. marcusii	Nutrient agar, aerobic	Harker et al., 1998
P. thiocyanatus	Thiocyanate, autotrophic growth conditions, aerobic	Katayama et al., 1995
P. solventivorans	Acetone, aerobic	Siller et al., 1996
P. alkenifer	Not indicated	Lipski et al., 1992, 1998
P. carotinifaciens	Nutrient agar, aerobic	Tsubokura et al., 1999
P. versutus	Thiosulfate, aerobic organism	Taylor and Hoare, 1969 Taylor et al., 1971
P. kocurii	Tetramethylammonium chloride, with yeast extract, aerobic	Ohara et al., 1990
P. alcaliphilus	Not reported	Urakami et al., 1989
P. aminophilus	*N*,*N*-dimethylformamide, aerobic	Urakami et al., 1990
P. aminovorans	*N*,*N*-dimethylformamide, aerobic	Urakami et al., 1990
P. methylutens	Dichloromethane, aerobic	Doronina et al., 1998
P. kondratievae	Methanol	

(in the presence of carbon dioxide) or of denitrifying species under anoxic conditions with nitrate as the respiratory oxidant and organic compounds as carbon and energy sources. The former procedure could be applied to the enrichment of all species except *P. marcusii*, *P. thiocyanatus*, wild type *P. pantotrophus*, and possibly *P. carotinifaciens*. Growth coupled to heterotrophic denitrification is proved to be exhibited only by eight of the 14 species here described (Table 3). These include *P. thiocyanatus* and *P. pantotrophus*, thus providing a route for selection of these species. *P. marcusii* and *P. carotinifaciens* are incapable of denitrification and might not be enriched by either route.

The type culture isolated by Beijerinck (Beijerinck and Minkman, 1910) was obtained from an anaerobic culture provided with sodium potassium tartrate (Seignettesalz; Rochelle salt) and potassium nitrate (10 $g \cdot l^{-1}$ of each). Nitrous oxide (N_2O) is both an intermediate and a product of nitrate reduction by *P. denitrificans* and can be used as a sole respiratory oxidant by *P. versutus* (Wood and Kelly, 1983) and some other species (Van Spanning et al., 2000). Successful enrichment of some *Paracoccus* species can be achieved anoxically in liquid media supplied with tartrate or succinate and incubated under a nitrous oxide atmosphere, but such enrichments will obviously not be exclusively selective for *Paracoccus* species (Pichinoty et al., 1977a; Pichinoty et al., 1977b).

Growth of most mesophilic facultatively autotrophic hydrogen-oxidizing bacteria is slow or impossible under anaerobic denitrifying culture conditions (Van Verseveld and Stouthamer, 1991). Thus the ability of *P. denitrificans* to grow autotrophically using hydrogen oxidation coupled to nitrate reduction provides a means of enriching for this type of organism. Of the 14 species described, to date only four have been shown capable of both hydrogen oxidation and denitrification (although not necessarily at the same time: *P. denitrificans*, *P. thiocyanatus*, *P. pantotrophus*, *P. versutus*; Table 3), meaning that such a selective regime would select for a maximum of only four of the 14 *Paracoccus* species. Some species are also capable of good autotrophic growth on formate (Table 3), and of those, three are also denitrifiers (*P. denitrificans*, *P. versutus* and *P. kocurii*). Anaerobic enrichment with formate, carbon dioxide and nitrate (or nitrous oxide) could thus provide a selective route for the enrichment at least of *P. denitrificans* and *P. versutus* (Wood and Kelly, 1983). *P. denitrificans* is also capable of (slow) autotrophic growth on methanol under denitrifying conditions (Bamforth and Quayle, 1978), providing a further route for its selective isolation from environments also containing (strictly aerobic) facultative methylotrophs such as *Methylobacterium*.

A number of *Paracoccus* species can grow autotrophically using thiosulfate oxidation to provide energy, while at least some strains of *P. pantotrophus* can use carbon disulfide and methylated sulfur compounds (Jordan et al., 1997), and *P. thiocyanatus* can grow as an aerobic autotroph on thiocyanate (Katayama et al., 1995). These substrates have served to produce successful enrichment cultures from which novel species of *Paracoccus* have been isolated. Since such aerobic enrichment conditions are also elective for some autotrophic chemolithotrophs such as *Thiobacillus thioparus*, further screening to discriminate target species would be required: to date, no *Paracoccus* species have been found

which can use the oxidation of tetrathionate to support growth, whereas this compound is a substrate for most "thiobacilli" (Kelly et al., 2000).

Media for the Isolation and Culture of *Paracoccus* Species

It has been made clear in the preceding sections that media absolutely specific for the isolation of each of the Paracoccus species do not exist, as most strains are versatile heterotrophs with some sharing methylotrophic and lithotrophic properties with other unrelated genera. We give below the composition of some media which will enrich for and serve as growth media for *Paracoccus* species able to grow anaerobically with hydrogen and nitrate, or lithotrophically with thiosulfate, but which will also support growth of other hydrogen bacteria or chemolithotrophs. For routine isolation or culture media, the basal salts mineral media typically used in any microbiology laboratory are likely to be suitable for the growth of *Paracoccus* species on most substrates, subject to the provision of any required vitamin supplement (Table 7). Commercially available rich nutrient media will support the growth of all the known species for routine maintenance and cultivation. When a lithotrophic oxidation substrate such as thiosulfate is used, the principal technical problem is the acidification of the culture by the sulfuric acid produced as a product of oxidation. This acidification can be ameliorated in batch cultures without pH control by the use of strongly buffered media (e.g. that for *P. versutus* described below), subject to determining the tolerance of any given species to the relatively high concentrations of phosphate (or other buffer compounds) employed.

For Routine Culture on Chemoorganotrophic or Methylotrophic Substrates

We suggest a basal salts medium containing the following constituents ($g \cdot l^{-1}$):

K_2HPO_4, 3; KH_2PO_4, 2; NH_4Cl, 2; $MgSO_4 \cdot 7H_2O$, 0.2; sodium molybdate, 0.2; $FeSO_4 \cdot 7H_2O$, 0.2; with KNO_3, 5, for anaerobic cultivation. For autotrophic growth, $NaHCO_3$ ($1\ g \cdot liter^{-1}$) should be added. The molybdate and iron can be replaced with a suitable trace metal solution (e.g. one of those described below), and for strains whose potential vitamin requirement has not been tested, yeast extract ($0.1\ g \cdot l^{-1}$) or a vitamin mixture (see below) should also be added. Known requirements (e.g. thiamine) can typically be provided at $0.2\ mg \cdot l^{-1}$. Growth substrates can be added at the desired concentrations, such as 10–20 mM for sugars, organic acids (as their salts), alcohols, and other heterotrophic substrates and 10–50 mM for substrates such as formate, methanol, methylamines, or thiosulfate. Toxic substrates need testing initially at lower concentrations, such as 0.5–5 mM for dimethylsulfide, carbon disulfide, carbonyl sulfide, sodium sulfide, or formaldehyde and 5–30 mM for thiocyanate when tested as an autotrophic substrate.

The Molecular Hydrogen-Nitrate System (Vogt, 1965) for Isolation and Culture of *Paracoccus denitrificans* and Hydrogen-Oxidizing Species of *Paracoccus*

Three separate solutions are prepared, sterilized separately and mixed after cooling to prevent precipitation of phosphates:

Solution 1 ($g \cdot liter^{-1}$): $Na_2HPO_4 \cdot 12H_2O$, 9; KH_2PO_4, 1.5; NH_4Cl, 1; $MgSO_4 \cdot 7H_2O$, 0.2; KNO_3, 1; trace elements solution, 2 ml.

Solution 2 ($mg \cdot 100\ ml^{-1}$): Ferric ammonium citrate, 50; $CaCl_2 \cdot 2H_2O$, 100.

Solution 3 ($g \cdot 100\ ml^{-1}$): $NaHCO_3$, 5.

The trace elements solution, which is not sterilized prior to mixing with Solution 1, contains ($mg \cdot liter^{-1}$): $ZnSO_4 \cdot 7H_2O$, 100; $MnCl_2 \cdot 4H_2O$, 30; H_3BO_3, 300; $CoCl_2 \cdot 6H_2O$, 200; $CuCl \cdot 2H_2O$, 10; $NiCl_2 \cdot 6H_2O$, 20; $Na_2MoO_4 \cdot 2H_2O$, 30.

Solution 2 (10 ml) and solution 3 (10 ml) are added to solution 1 (1 liter). Erlenmeyer flasks containing 10 ml of the combined medium are incubated in an anaerobic jar filled with 85% H_2 and 15% CO_2 and shaken at 30°C. An appropri-

Table 7. Requirement for vitamin supplements exhibited by some species of *Paracoccus* for growth in minimal media.

Organism	Carbon substrate	Vitamin required
P. alcaliphilus	Methanol or glucose	Biotin
P. aminophilus	Various	Thiamine
P. aminovorans	Various	Thiamine
P. kocurii	Methylamines	Thiamine
P. methylutens	One-carbon compounds	B_{12} or yeast autolysate
P. thiocyanatus	Thiocyanate	Thiamine

ate oxygen absorbent may be included in the gas jar. Pure cultures may be maintained on the same medium supplemented with 1.7% (w/v) of a suitable agar.

Enrichment, Isolation and Maintenance Media for Thiosulfate-Oxidizing *Paracoccus* Species (e.g., *P. versutus* and *P. pantotrophus*; Kelly and Wood, 1998)

Four salt solutions are prepared:

Solution 1: (g ·liter $^{-1}$): $Na_2HPO_4 \cdot 2H_2O$, 39.5; KH_2PO_4, 7.5.

Solution 2: 4% (w/v) NH_4Cl.

Solution 3: 4% (w/v) $MgSO_4 \cdot 7H_2O$.

Solution 4: Trace metal solution (g · liter $^{-1}$): EDTA (disodium salt), 50; NaOH, 9; $ZnSO_4 \cdot 7H_2O$, 11; $CaCl_2$, 5; $MnCl_2 \cdot 6H_2O$, 2.5; $CoCl_2 \cdot 6H_2O$, 0.5; ammonium molybdate, 0.5; $FeSO_4 \cdot 7H_2O$, 5.0; $CuSO_4 \cdot 5H_2O$, 0.2. Adjust pH to 6.0 with 1 N NaOH and store, unsterilized, in a dark bottle.

Thiosulfate-agar Medium for Maintenance Slopes or Plates Solution 1, 200 ml; 4% NH_4Cl, 10 ml; 4% $MgSO_4 \cdot 7H_2O$, 2.5 ml; Solution T, 10 ml; 1 N NaOH, 11.5 ml; $Na_2S_2O_3 \cdot 5H_2O$, 5.0 g; agar, 15.0 g; phenol red (saturated solution), 10 ml. Initial pH should be 8.4.

Liquid Culture Medium This is prepared and sterilized in three parts to avoid precipitation of phosphates and any decomposition of growth substrates. The recipe given is for a final volume of 1 liter.

Part I (ml): 4% NH_4Cl, 20; 4% $MgSO_4 \cdot 7H_2O$, 2.5; solution T, 10; distilled water, 550.

Part II (ml): Solution 1, 200; 1 N NaOH, 10. Autoclave separately Parts I and II at 115°C for 10 min, then mix them when they are cool.

Part III (200 ml): An aqueous solution of the growth substrate, which may be thiosulfate (for growth of *P. versutus* and *P. pantotrophus*), carbon disulfide (for growth of *P. pantotrophus*), or other acidigenic substrate or any normal organic substrate.

The pH of this medium may be modified. Omitting the NaOH lowers the pH from 8.4 to 7.3, whereas intermediate pH values are obtained by adding intermediate volumes of NaOH or altering the ratios of the acid and basic phosphate salts employed (Kelly and Wood, 1998).

A number of *Paracoccus* species are known to require vitamins for successful enrichment and culture (Table 7). The following vitamin B mixture may be used generally and might be used to isolate marine species of *Paracoccus*, inasmuch as a vitamin requirement is common among marine bacteria.

Vitamin B mixture (mg ·liter $^{-1}$): thiamine-HCl, 10; nicotinic acid, 20; pyridoxine hydrochloride, 20; *p*-aminobenzoic acid, 10; riboflavin, 20; calcium pantothenate, 20; biotin, 1; cyanocobalamin, 0.5–1.0. Adjust pH to 7.0 by addition of 0.1 M NaOH.

Summary Descriptions of the Species of *Paracoccus*

For sources and original isolation conditions and principal properties of these species, see Tables 3, 4, 5 and 6.

Paracoccus alcaliphilus Type Strain JCM 7364^T

This organism is alkaliphilic and a facultative methanol- and methylamine-user. It grows at pH 7.0–9.5, but not below pH 6.5 or above pH 10. Colonies are white to pale-yellow; granules of poly-β-hydroxybutyric acid are accumulated in the cells. Grows on several hexoses, pentoses and sugar-alcohols but not on sucrose, maltose, lactose and trehalose or on formate, di- and trimethylamine. Nitrate is reduced only to nitrite and neither denitrification nor fermentative growth occurs. Ammonium, nitrate, urea and peptone are used as nitrogen sources. Its major fatty acids are 18:1 and 10:0(3-OH) and 14:0(3-OH). Its % G+C is 64–66.

Paracoccus alkenifer Type Strain DSM 11593^T

This strain will grow over the range pH 6.0–9.0. It denitrifies and will grow on solvents such as acetone, ethanol and methanol, some organic acids and asparagine, but not on carbohydrates or amines. Typical mono-unsaturated fatty acids are 14:1*cis* 7 and 20:1*cis*13, while 12:1*cis*5, 16:0 and 19:0 cyclo11-12 are absent. It also contains the hydroxy-fatty acids 10:0(3-OH) and 14:0(3-OH), of which the first predominates. Its mol% G+C was not reported (Lipski et al., 1998).

Paracoccus aminophilus Type Strain JCM 7686^T

This strain grows on methylamine and *N*,*N*-dimethylformamide, as well as di-and trimethylamine, trimethylamine-*N*-oxide, formamide, and N-methylformamide, but not on methanol or formate. It grows between pH 6.0–9.0 but not at pH 5 or 10, with an optimum of pH 6.5–8.0. It grows at 30°C, but not at 37°C.

Colonies on rich medium (peptone-yeast extract-glucose) are white-pale yellow. Granules of poly-β-hydroxybutyric acid are accumulated. Nitrate is reduced only to nitrite, and no fermentative growth is seen. It grows on various sugars, alcohols and organic acids but not on fructose, disaccharides, sugar-alcohols, citrate, ethanol or butanol. Ammonium and peptone, but not urea or nitrate, are used as nitrogen sources. The major fatty acid is straight-chain unsaturated 18:1 and its main hydroxy-fatty acids are 10:0(3-OH) and 14:0(3-OH). Its mol% G+C is 63.

Paracoccus aminovorans Type Strain JCM 7685^T

The properties of this organism are mainly as given for *P. aminophilus*, except that *P. aminovorans* can grow on fructose, sorbitol, mannose and mannitol, but not on xylose. It grows at both 30 and 37°C, but not at 42°C. Ammonium and peptone, but not urea or nitrate, are used as nitrogen sources. The major fatty acid is straight-chain unsaturated 18:1 and its main hydroxy-fatty acids are 10:0(3-OH) and 14:0(3-OH). Its mol% G+C is 67.

Paracoccus carotinifaciens Type Strain IFO 16121^T

This organism is an orange-pigmented, astaxanthin carotenoid-producing species, which may be a strain of *P. marcusii*. Colonies are orange to red. Growth occurs at 10–33°C, optimum at 28°C, with no growth at 37°C. It grows at pH 6.0–9.0, with an optimum at pH 6.5–7.5. Obligately aerobic. It grows on glucose, mannose, maltose, mannitol and the organic acids gluconate and malate, but not on arabinose, citrate and various other acids. No information on use of one-carbon substrates is available. Ammonium, but not nitrate, is used as a nitrogen source. Its major fatty acid is straight-chain unsaturated 18:1; the major hydroxy-fatty acid is 10:1(3-OH). Its mol% G+C is 67.

Paracoccus denitrificans Type Strain ATCC 17741^T, LMD 22.21^T, DSM 413^T

The type species of the genus, exhibiting metabolic versatility, with respiratory growth aerobically or with denitrification on many substrates, facultative methylotrophy and autotrophy on formate, hydrogen, thiosulfate, methanol, methylamine, and formaldehyde. It produces white or cream-colored colonies with no carotenoid pigments. It stores poly-β-hydroxybutyric acid as an intracellular carbon reserve and does not require vitamins or other organic growth factors. Its optimum temperature is 30–37°C and optimum pH is 7.5–8.0. Numerous sugars, organic acids, amino acids, and alcohols are used as sole energy and carbon sources for growth. These incude ribose, arabinose, glucose, fructose, trehalose, sucrose, mannose, acetate, propionate, malonate, tartrate, lactate, pyruvate, succinate, malate, citrate, gluconate, *p*-hydroxybenzoate, serine, proline, histidine, asparagine, glutamine, ethanol, propanol, butanol, glycerol and sorbitol. It apparently cannot use xylose, rhamnose, lactose, glycogen, cellulose, benzoate, *p*-aminobenzoate, phenol, arginine, threonine, tryptophan, ethanolamine, tetrathionate or thiocyanate for growth. Anaerobic growth can be supported by the respiratory reduction of nitrate, nitrite, or nitrous oxide, with dinitrogen as the end product; nitrous oxide can also be a product of nitrate reduction. Ammonium, nitrate, urea and glutamate are used as nitrogen sources. It is probably desirable for the growth substrate range of an authentic strain of *P. denitrificans* (e.g. ATCC 17741 or LMD 22.21) to be reassessed as it is uncertain how much of the literature data of this kind was actually obtained with strains of *P. denitrificans* rather than strains of *P. pantotrophus*. Its mol% G+C is 64–67.

Paracoccus kocurii Type Strain JCM 7684^T

This species grows on tetramethylammonium, methylamine, and di- and tri-methylamine, trimethylamine-*N*-oxide, and formate, but not on methanol. Optimum temperature is 25–30°C, with no growth at 20 or 40°C; optimum pH is 6.6–8.2, with no growth below pH 6.1 or above pH 8.8. It grows only a restricted range of other organic compounds, including lactate, acetate, pyruvate, propionate, and butyrate. Ammonium, but not nitrate or glutamate, is used as a nitrogen source. The major fatty acids are 18:1 and 19:0cyc; the major hydroxy-fatty acids are 10:0(3-OH) and 12:0(3-OH). Its mol% G+C is 71.

Paracoccus kondratievae, Proposed Type Strain VKM B-2222^{PT} (STRAIN GB^{PT})

The description of this species has been provided to us prior to publication (Doronina et al., 2001). This species is alkaliphilic and thermotolerant, growing at 30–50°C and pH 7.5–10.5 with optima at 38–42°C and pH 8.0–9.0. It grows aerobically as a facultative chemolithotroph with hydrogen or thiosulfate and as a methylotroph on methanol, methylamine or formaldehyde, assimilating carbon dioxide by the Calvin cycle. It grows anaerobically on methanol with nitrate, shows heterotrophic denitrification, and can ferment glucose. It grows on glucose, fructose, galactose,

ribose, arabinose, adonitol, dulcitol, glycerol, inositol, mannitol, sorbitol, ethanol, acetate, malate, α-ketoglutarate, succinate, fumarate, alanine, aspartate, glutamate, sarcosine, serine, *N*,*N*-dimethylglycine, and betaine. It does not grow on methane, dimethylamine, trimethylamine, chloromethane, dichloromethane, dimethylsulfoxide, lactose, xylose, rhamnose, raffinose, sucrose, trehalose, propionate, citrate, pyruvate, or tartrate. It does not require vitamins but showed growth stimulation by yeast extract (0.01% w/v). Ammonium, nitrate, urea, methylamine and amino acids are used as nitrogen sources for growth. Its major fatty acids are cyclopropane 19cyc and 16:0 and minor fatty acids are 18:0 and 18:1. Its major phospholipids are phosphatidylethanolamine, phosphatidylglycerol, cardiolipin and phosphatidylcholine. DNA-DNA hybridization showed 37–43% similarity of *P. kondratievae* to *P. denitrificans* and *P. methylutens* and 20–30% similarity to *P. alcaliphilus*, *P. alkenifer*, *P. aminophilus*, *P. aminovorans*, *P. marcusii*, *P. pantotrophus*, *P. solventivorans* and *P. thiocyanatus*. Its mol% G+C is 62.5.

Paracoccus marcusii Type Strain DSM 11574^T

This species produces bright-orange colonies caused by the presence of large amounts of carotenoids, including astaxanthin. It is an obligate aerobe and does not reduce nitrate to nitrite. It grows on glucose, fructose, galactose, mannose, arabinose, maltose, cellobiose, lactose, melibiose, sucrose, turanose, trehalose, gentiobiose, gluconate, glucuronate, galacturonic, glycerol, erythritol, mannitol, sorbitol, xylitol, inositol, adonitol, arabitol, propionate, *cis*-aconitate, citrate, lactate, malonate, succinate, formate, malate and alanine. It could not grow on methanol, methylamine, trimethylamine, dimethylformamide, thiosulfate, acetate, trimethylamine or a very wide range of other compounds. The major fatty acid is straight-chain unsaturated 18:1, with some 18:0 and 10:0. Its mol% G+C is 66. The description of this species was validly published in 1998 (Harker et al., 1998) and predated the description of the physiologically and morphologically similar *P. carontinifaciens* (Tsubokura et al., 1999). Subsequent comparison of the 16S rRNA sequences of the two strains showed that *P. carontinifaciens* and *P. marcusii* share 99.8% identity (Table 4), and the two species show only a few differences in growth substrates used. *P. carotinifaciens* was reported as motile by means of peritrichous flagella, whereas *P. marcusii* is reportedly non-motile. Whether or not these are distinct species, as is the case for *P. versutus* and *P. pantotrophus* (cf., Table 4), or are both strains of *P. marcusii* requires investigation, including the assessment of DNA-DNA hybridization between them.

Paracoccus methylutens Type Strain (DM 12) VKM B 2164^T

This species is a facultatively methylotrophic species able to grow on dichloromethane, methanol, methylamine, formate, but not formaldehyde, or di- or tri-methylamine. Nitrate is reduced to nitrite. It grows at 10–37°C, optimally at 25–30°C; pH range is 6.5–9.5 with an optimum at pH 7.0–8.0. Aerobic. It grows on a wide range of organic substrates including glucose, mannose, arabinose, maltose, ethanol, acetate, citrate and Krebs' cycle acids, and propionate, but not acetamide, rhamnose, raffinose or trehalose. Ammonium, nitrate, methylamine and urea are used as nitrogen sources. Its major fatty acid is 18:1w7. Its mol% G+C is 67.

Paracoccus pantotrophus Type Strain ATCC 35512^T, LMD 82.5^T

Coccoid shaped cells may exhibit pleomorphism on very rich media. It is very similar physiologically to both *P. denitrificans* and *P. versutus* but can be distinguished from them by its inability to use citrate and its ability to grow as an anaerobic autotroph by denitrification on sulfide or thiosulfate as sole energy substrate. It grows autotrophically on reduced sulfur compounds and hydrogen and mixotrophically and heterotrophically on a wide range of organic compounds, but the wild type will not grow on one-carbon substrates. Aerobic and anaerobic heterotrophic growth is supported by glucose, fructose, mannose, lactate, pyruvate, acetate, succinate, fumarate, gluconate, glutamate, proline, aspartate, alanine, histidine, leucine, isoleucine, acetone, propan-1,2-diol, and propan-2-ol, but not by arabinose, lactose, methyl acetate, methanol, methyl ethyl ketone, propylene oxide, oxalate or pimelate. It grew aerobically but not anaerobically on benzoate and only anaerobically on propionaldehyde. Ammonium, nitrate, urea and glutamate but not methylamine are used as nitrogen sources. Its mol% G+C is 66.

Paracoccus solventivorans Type Strain DSM 6637^T

This species grows aerobically or with denitrification on acetone, acetoacetate, 2-butanone, 2-propanol, fumarate, gluconate, ribose, pyruvate, and a number of other compounds. Optimum pH is 7.0–8.0 and optimum temperature is 30–37°C.

Ammonium is used as a nitrogen source; other nitrogen compounds are not reported. Characteristic fatty acids are 12:1*cis*5 and 20:1*cis*13. Its mol% G+C is 68.5–70.

Paracoccus thiocyanatus Type Strain IAM 12816^T

As far as is known, this organism is unique among the *Paracoccus* species in being a chemolithoautotroph able to grow aerobically on thiocyanate as its sole energy substrate; it also grows autotrophically on thiosulfate and sulfur. Optimal growth is at pH 7.5–8.5 in rich medium (range pH 6.5–9.5) and pH 7.0–8.0 in thiocyanate medium (range pH 6.0–8.5). Optimum temperature was 30–35°C (range 15–40°C). It grows on a wide range of sugars, alcohols, organic acids and amino acids, but not on citrate, benzoate, maltose, lactose, sucrose, malate and several others. Growth with denitrification occurred only on organic substrates. Ammonium and glutamate, but not nitrate, urea or aspartate, serve as nitrogen sources. It exhibits the fatty acid profile typical of the genus, with 18:1 and 19cyc and 10:0(3-OH). Its mol% G+C is 66.5–67.6.

Paracoccus versutus Type Strain ATCC 25364^T, DSM 5m82^T

This species grows as an autotroph, mixotroph and heterotroph on a very wide range of substrates. Aerobic autotrophic growth occurs on thiosulfate, sulfide, sulfur, methanol, methylamine, formate and formaldehyde, but not on tetrathionate or thiocyanate. It grows anaerobically with denitrification on organic substrates but not with reduced sulfur compounds. It grows on many sugars and organic acids, but not on lactose or cellobiose. It grows optimally at pH 7.5–8.0 in complex media (range pH 6.5–9.5) and optimally at initial pH 8.0–8.8 in thiosulfate medium without pH control; optimum pH is 7.8 on thiosulfate with pH control. Optimum temperature is 30–37°C (range 17–40°C). Ammonium, nitrate, glutamate and aspartate, but not urea, may serve as nitrogen sources. Its mol% G+C is 67–68.

Cytochromes and Electron Transport Systems in *Paracoccus* Species

P. denitrificans and those other species that have been studied in detail show complex electron transport systems both for aerobic respiration and for denitrification (Lu and Kelly, 1984a; Van Verseveld and Stouthamer, 1991; Stouthamer, 1992; Baker et al., 1998), and the respiratory system of *P. denitrificans* has long been regarded as a model for the mitochondrion (Stouthamer, 1992; Baker et al., 1998). A major difference from the mitochondrial system is the presence in *P. denitrificans* of alternative terminal oxidases (ba_3, cbb_3, and aa_3), depending on the oxygen tension in the oxidase environment. The bacteria also exhibit a diversity of branched pathways for electron transport, enabling growth under various conditions of oxygen availability from fully aerobic to anaerobic denitrification. For detailed analysis of the genetics and functioning of these complex systems the reader is referred to Baker et al. (1998). At least 17 *c*-type cytochromes have been identified in *Paracoccus* species (Baker et al., 1998), which are located both in the cytoplasmic membrane and in the periplasmic space depending on the nature of the substrate and the growth conditions, and include those which are components of terminal oxidases, the bc_1 complex and nitrate and nitric oxide reductases. Some *c*-type cytochromes involved in inorganic sulfur oxidation in *P. pantotrophus* and *P. versutus* are unusual in their large size, in their multiple subunits and in containing at least two redox centres, with widely different midpoint potentials (Kelly et al., 1997; Friedrich, 1998). The roles of these separate centres have not yet been fully explained (Lu and Kelly, 1984a; Kelly et al., 1997).

Recently the cytochromes c_{551} and $c_{552.5}$ essential for the thiosulfate-oxidizing system of *Paracoccus versutus* (see following section) have been examined using electron paramagnetic resonance (EPR) spectroscopy (J. K. Shergill, A. C. White, W-P. Lu, D. P. Kelly, A. P. Wood, C. Joannou and R. Cammack, in preparation). Cytochrome c_{551} was estimated to contain approximately six atoms of Fe per mole, and EPR showed the presence of a single type of low-spin heme, with $gz = 3.22$ and $gx \sim 1.17$. The EPR and optical absorption spectra were consistent with methionine-histidine coordination. It was concluded that cytochrome c_{551} is a hexamer of a protein containing heme *c*. Cytochrome $c_{552.5}$ showed a more complex EPR spectrum indicating at least four different types of low-spin hemes (heme-1, $gz = 2.401$, $gy = 2.245$, $gx = 1.914$; heme-2, $gz = 2.516$, $gy = 2.302$, $gx = 1.875$; heme-3, $gz = 2.583$, $gy = 2.395$, and $gx = 1.834$; and heme-4, $gz = 3.5$). These hemes responded differently to changes in pH, reduction by dithionite and the presence of ethylene glycol in the medium, and it was found that heme-2 and heme-3 were interconvertible. A small and variable amount of high-spin heme also was observed. These EPR studies indicated that the cytochrome $c_{552.5}$ of *P. versutus* contained more redox centers than the two centers identified by optical redox measure-

ments, making this cytochrome among the most complex yet characterized.

Sulfur Compound Oxidation by *Paracoccus* Species

The oxidation of thiosulfate, sulfide or thiocyanate supports the autotrophic growth of several species, but only *P. versutus* and *P. pantotrophus* GB17 have been studied in detail (Kelly, 1999):

$$S_2O_3^{2-} + 2O_2 + H_2O = 2SO_4^{2-} + 2H^+$$
$$[\Delta G^\circ = -738.7 kJ \cdot mol^{-1}]$$
$$HS^- + 2O_2 = SO_4^{2-} + H^+$$
$$[\Delta G^\circ = -732.6 kJ \cdot mol^{-1}]$$
$$SCN^- + 2O_2 + 2H_2O = SO_4^{2-} + CO_2 + NH_4^+$$
$$[\Delta G^\circ = -824.5 kJ \cdot mol^{-1}]$$

In these species, thiosulfate is oxidized by a multienzyme system located in the cytoplasm (Lu et al., 1985; Kelly, 1989; Kelly et al., 1997), the mechanism of which is summarized by Kelly et al. (1997), Baker et al. (1998) and Friedrich (1998). Considerable progress has also been made in identifying the genes in *P. pantotrophus* controlling expression of the enzymes of the thiosulfate-oxidizing system (Wodara et al., 1994; Friedrich, 1998).

Phylogenetically, *P. versutus* and *P. pantotrophus* are very similar, although DNA-DNA hybridization showed them to differ at the species level (Fig. 1; Table 4; Rainey et al., 1999). The mechanism and genetic basis of thiosulfate and sulfide oxidation have been studied in depth only in these two species (Lu, 1986; Lu and Kelly, 1983; Lu and Kelly, 1984a; Lu and Kelly, 1984b; Lu et al., 1984c; Lu et al., 1985; Kelly, 1985; Kelly, 1988; Chandra and Friedrich, 1986; Mittenhuber et al., 1991; Wodara et al., 1994; Wodara et al., 1997; Kelly et al., 1997; Friedrich, 1998). It is thus likely that the mechanism and control of inorganic sulfur oxidation are likely to be very similar, if not identical, in the two species, enabling a composite model to be derived from the available data. Such a model may be an oversimplification as differences in detail may exist between the two species (Friedrich, 1998), although these differences may be seen to be less profound as further work is done.

The enzymes and some of the cytochromes of the thiosulfate-oxidizing multienzyme system are located in the periplasm (Lu, 1986; Lu et al., 1985), and periplasmic targeting sequences are seen in at least some of the proteins of the system (Baker et al., 1998; Friedrich, 1998). Schemes interrelating the components and the proposed mechanism of the thiosulfate-oxidizing system are given by Kelly et al. (1997), Baker et al. (1998), and Friedrich (1998).

The cluster of genes involved in coding for the thiosulfate oxidizing system was initially dissected using Tn5-*mob* mutagenesis (Chandra and Friedrich, 1986; Mittenhuber et al., 1991; Friedrich, 1998). To date, a sequence of six genes coding for enzymes and cytochromes involved in thiosulfate and sulfide oxidation have been identified. Collectively these have been defined as the Sox character (ability to oxidize inorganic sulfur) in *Paracoccus* and are coded (in downstream sequence): *soxA* to *soxF* (Friedrich, 1998). The six genes comprise a minimum of 6.3 kb pairs in the *P. pantotrophus* chromosome (Friedrich, 1998), although their location in the genome is uncertain. One strain, deficient in thiosulfate oxidation, was shown to lack the 450 kbp megaplasmid (Chandra and Friedrich, 1986; Baker et al., 1998), and the Sox locus was studied using a mutant containing a full complement of megaplasmids/minichromosomes (Mittenhuber et al., 1991). The genes identified or inferred to date, together with their gene products and the probable biochemical functions of these proteins in the thiosulfate-oxidizing system, are summarized in Table 8.

Dissimilatory Nitrogen Metabolism in *Paracoccus*

Respiratory denitrification has been studied in detail in *P. pantotrophus* and *P. denitrificans* (Berks et al., 1995; Baker et al., 1998) and its genetic regulation has been comprehensively analyzed (Baker et al., 1998). Nitrate reduction to nitrite is catalyzed by two nitrate reductases: one is a membrane-bound enzyme induced in the presence of nitrate under conditions of oxygen limitation; the other is a constitutive periplasmic molybdopterin enzyme with both heme and non-heme iron sites. Nitrite is reduced to nitric oxide (NO) by a periplasmic nitrite reductase, which contains two hemes as prosthetic groups and receives electrons for nitrite reduction from cytochrome *c*550 and a copper-containing pseudoazurin. The hemes are a typical *c*-type and an unusual *d*1 heme. Nitric oxide is reduced to nitrous oxide (N_2O) by a nitric oxide reductase anchored on the periplasmic side of the cytoplasmic membrane. This enzyme contains one large and one small protein subunit, the former binding heme *b* and the latter, heme *c*. Nitrous oxide is reduced to dinitrogen by a periplasmic nitrous oxide reductase which contains two different copper centers.

Table 8. Genes and gene products of the periplasmic thiosulfate-oxidizing multienzyme system of *P. pantotrophus* and *P. versutus*.

Sox gene	Gene product	Properties of mature gene product	Proposed identity of the gene product proteins
soxA	Sox A	29-kDa diheme cytochrome	Electron transport from thiosulfate; possible 29kDa subunit of *P. versutus* cytochrome $c_{552.5}$ (56-kDa dimer)
soxB	Sox B: 60.5kDa (with 16 amino-acid leader peptide)	59-kDa mature protein	Enzyme B (60kDa) of *P. versutus*; oxidation of covalently bound thiosulfate to sulfate
soxC	Sox C: 47.5kDa (with 40 amino-acid signal peptide)	43.7-kDa mature protein	Sulfite:cytochrome *c* oxidoreductase, possibly essential for full activity of the thiosulfate-oxidizing multienzyme system
soxD	Sox D	40-kDa protein	Periplasmic diheme cytochrome *c*; possible 43-kDa subunit of *P. versutus* cytochrome c_{551} (260-kDa hexamer)
soxE	Sox E	26-kDa protein	Periplasmic diheme cytochrome *c*
soxF	Sox F	12-kDa protein	Putative flavocytochrome *c* (possible sulfide dehydrogenase)
"sox Y"	Sox Y	12-kDa peptide	Component of a heterodimer with Sox Y
"soxZ"	Sox Z	16-kDa peptide	Enzyme A (16kDa) of *P. versutus*; probable thiosulfate-binding protein

P. pantotrophus has been reported to be able to carry out denitrification also under aerobic conditions, as well as being able to nitrify under heterotrophic conditions (Robertson et al., 1988; Arts et al., 1995). Periplasmic nitrate reductase was present in such aerobically grown bacteria and was the initiator of nitrate reduction; nitric oxide and nitrous oxide reductases were also active under aerobic conditions (Bell and Ferguson, 1991). The concerted action of the processes of nitrification and denitrification was indicated by the production (by cell cultures) of ^{15}N-labeled dinitrogen and nitrous oxide from ^{15}N-ammonia as well as from ^{15}N-nitrite (Arts et al., 1995). The physiological and ecological significance of these processes is not yet fully understood.

Glucose Dissimilation by *Paracoccus* Species

While central metabolic pathways such as the Krebs' cycle probably occur in all species of *Paracoccus*, different species exhibit a diversity of mechanisms for the aerobic dissimilation of glucose. As well as the Krebs' cycle, Forget and Pichinoty (1965) showed both the Entner-Doudoroff and oxidative pentose phosphate (hexose monophosphate) pathways to operate in *Paracoccus* denitrificans, but a later report that the glycolytic pathway is absent from *P. denitrificans* is not applicable to all species of *Paracoccus* (Slabas and Whatley, 1977; Van Spanning et al., 2000). The most detailed studies of glucose metabolism were conducted with *P. versutus*, in which all three of the Embden-Meyerhof-Parnas, Entner-Doudoroff and pentose phosphate pathways can operate simultaneously in glucose-grown bacteria (Wood et al., 1977; Wood and Kelly, 1978; Wood and Kelly, 1979; Wood and Kelly, 1980). The ratios of these pathways vary according to growth conditions, and during growth on other hexoses, pentoses and disaccharides or on mixtures of glucose and maltose, the Embden-Meyerhof-Parnas pathway is completely repressed, and the Entner-Doudoroff pathway predominates (Wood and Kelly, 1979; Wood and Kelly, 1980; Smith et al., 1980).

Chromosomes and Plasmids in *Paracoccus* Species

Only a few species of *Paracoccus* have been studied with respect to their plasmid complement. The earliest detailed study showed plasmids in three strains described as *P. denitrificans* (Gerstenberg et al., 1982). One was the "Morris" strain which can be assumed to have been correctly described as *P. denitrificans* (Goodhew et al., 1996; Rainey et al., 1999) and contained one megaplasmid of molecular mass exceeding 300 MDa. Another was the "Stanier" strain, which subsequently appeared in culture collections as both ATCC 17741 and DSM 65 (Goodhew et al., 1996). It is now known that ATCC 17741 is the type strain of *P. denitrificans* but that DSM 65 is a strain of *P. pantotrophus* (Rainey et al., 1999). This means that it is uncertain whether the "Stanier" strain used by Gerstenberg et al., 1982) was *P. denitrificans* or

P. pantotrophus. It contained two plasmids of molecular masses around 50 MDa and >300 MDa (Gerstenberg et al., 1982). The "Vogt" strain (DSM 415) contained only one <300 MDa megaplasmid and may thus also be *P. denitrificans* (Gerstenberg et al., 1982). *P. denitrificans* DSM 413 and *P. versutus* were also shown to contain megaplasmids <500 kb (Wlodarczyk and Piechuka, 1995; Jordan et al., 1997). We conclude that the evidence currently available shows the type strain (and its derivatives) of *P. denitrificans* may contain megaplasmids of at least 450 kb in size, but it is uncertain if they can also contain smaller (100 kb) plasmids, as none were present in strains DSM 413 or the "Stanier" strain (Jordan et al., 1997; Rainey et al., 1999). In contrast, some strains of *P. pantotrophus* do contain 85–110 kb plasmids as well as megaplasmids of 450 kb, but one strain (DSM 11072) lacked the 100 kb plasmid (Jordan et al., 1997; Rainey et al., 1999).

The genomic structure of *P. denitrificans* and *P. pantotrophus* is complex in that several very large DNA molecules comprise the genome and are presumed to be chromosomal elements (Baker et al., 1998; Winterstein and Ludwig, 1998). The authentic *P. denitrificans* strains ATCC 13543, DSM 413 and Pd 1222 contain three chromosomal DNA molecules: I, 1.83 Mb; II, 1.16 Mb; and III, 0.67 Mb (Winterstein and Ludwig, 1998), of which at least molecules I and II are linear DNA. The distribution among these molecules of genes coding for respiratory oxidases, cytochrome *c*550, methanol oxidation and *S*-formylglutathione hydrolase appeared "random," indicating that the three replicons together comprise the genome and are probably replicated concurrently (Winterstein and Ludwig, 1998). Two strains of *P. pantotrophus* (LMD 82.5 and DSM 65) contain four DNA molecules: 2.2, 1.5, 0.71 or 0.77, and 0.5 Mb, of which the 0.71 Mb molecule was circular (Winterstein and Ludwig, 1998). In addition, the *P. pantotrophus* strains showed the expected plasmid of molecular size 97 kb (LMD 82.5) or 60 kb (DSM 65).

While at least the three large replicons in both *P. denitrificans* and *P. pantotrophus* are likely to represent the chromosomal DNA (with a genome size of around 4 Mb), the genetic importance of the megaplasmids or mini-chromosomes of <450 kb in *P. denitrificans*, *P. pantotrophus* and *P. versutus* is unknown, as is that of the 107 bp pTAV1 plasmid of *P. versutus* (Jagusztyn-Krynicka et al., 1990; Bartosik et al., 1995), although loss of the 450 kb plasmid from *P. pantotrophus* was possibly linked to loss of the ability to carry out thiosulfate oxidation (see section on sulfur compound oxidation in this Chapter; Chandra and Friedrich, 1986).

Biotechnological Potential of *Paracoccus* Species

In common with other facultative denitrifiers, *P. denitrificans* can contribute to the removal of nitrate from wastewaters, and *P. pantotrophus* was isolated from a desulfurizing and denitrifying effluent-treatment system (Robertson and Kuenen, 1983). Experimentally, long-term continuous denitrification was obtained using *P. denitrificans* immobilized with a polyelectrolyte complex (Kokufuta et al., 1987). *Paracoccus* species are probably important components of many wastewater treatment system communities, having been found in denitrifying sand filters and activated sludge systems (Ohara et al., 1990; Katayama et al., 1995; Neef et al., 1996). Others have been isolated from biofilters treating effluent gases and from contaminated soils (Siller et al., 1996; Lipski et al., 1998). The ability of different species to degrade unusual and potentially polluting compounds indicates their potential role in natural or contrived bioremediation systems. Target compounds include methanol, acetone, dichloromethane and other solvents, tetramethylammonium compounds, methylamines, substituted formamides, thiocyanate, sulfides, organic sulfur compounds such as carbon disulfide, carbonyl sulfide and methanethiol, all of which are waste products of diverse commercial processes. As yet, no controlled system inoculated with specific *Paracoccus* strains seems to have been used on a commercial scale.

Exploitation of *Paracoccus* species as potential sources of bio-products has also received little attention to date. A mixture of co-immobilized cells of *P. denitrificans* and Corynebacterium was shown to be effective for the continuous production of L-phenylalanine from acetamidocinnamic acid (Nishida et al., 1987), and the production of relatively large amounts of astaxanthin by *P. marcusii* and *P. carotinifaciens* might enable these species to be exploited for the production of such pigments (Harker et al., 1998; Tsubokura et al., 1999).

Acknowledgements. We are grateful to Dr. T. P. Tourova (Moscow) and Dr Y. A. Trotsenko (Pushchino) for providing us with the 16S rRNA gene sequences of *P. methylutens* and *P. kondratievae* and for letting us see their manuscript on *P. kondratievae* prior to publication and to Dr. I. P. McDonald (Warwick) for assistance during the drafting of this study. We thank Dr. R. J. M. van Spanning (Amsterdam) and Dr. S. C. Baker (Oxford) for showing us unpublished manuscript material.

CHAPTER 3.1.12

The Genus *Phenylobacterium*

JÜRGEN EBERSPÄCHER AND FRANZ LINGENS

The genus *Phenylobacterium* comprises a single species called *P. immobile*, which is remarkable for its extremely limited nutritional spectrum. All strains isolated and described hitherto grow optimally only on artificial compounds like chloridazon, antipyrin, and pyramidon (formulas in Fig. 1). Chloridazon, formerly called pyrazon, is the active ingredient of the herbicide Pyramin®, which is used for the control of broadleaf weeds in sugar beet and beet root cultures. The fact that the breakdown of this herbicide is a microbial process was demonstrated by studies with soil samples, including heat-sterilized soil (Drescher and Otto, 1969; Frank and Switzer, 1969). Engvild and Jensen (1969) described the isolation of bacteria capable of growth on chloridazon as sole source of carbon and energy. At the same time and independently, Fröhner et al. (1970) isolated chloridazon-degrading bacteria that proved to be similar to the organisms of Engvild and Jensen. Meanwhile, more than 20 different strains have been isolated that can grow on the herbicide chloridazon and also on the structurally related analgesics antipyrin and pyramidon. All of these xenobiotic-degrading bacteria show a high degree of similarity with respect to different properties, and they were grouped together in one single species, named *Phenylobacterium immobile* (Lingens et al., 1985).

P. immobile is not closely related to any other Gram-negative bacterium, as demonstrated by 16S rRNA investigations (Ludwig et al., 1984). It was found to be a member of subgroup alpha-2 of the alpha subclass of the proteobacteria, standing phylogenetically isolated in this group (proteobacteria were formerly named "purple bacteria and their nonphotosynthetic relatives"). Lipopolysaccharide analysis (Weisshaar and Lingens, 1983), serological studies (Dorfer et al., 1985), investigations on the polyamine pattern (Busse and Auling, 1988), and ubiquinone analysis (R. M. Kroppenstedt, J. Eberspächer, and F. Lingens, unpublished observations) have confirmed the results on the phylogenetic position of *P. immobile*.

Habitat

P. immobile seems to be a typical inhabitant of the upper aerobic part of the soil. Different strains have been isolated from soil samples originating from various locations all over the world. Attempts to demonstrate the breakdown of chloridazon in soil or in mud samples under anaerobic conditions failed. Although in one case, a slow degradation of chloridazon in river water was observed, efforts to isolate chloridazon-degrading bacteria from this specific water sample were without success. However, we cannot rule out the possibility that phenylobacteria occur also in aquatic habitats.

Isolation and Cultivation

The technique for the enrichment of *P. immobile* is based on selective pressure exerted on a microbial soil population. This technique leads to the isolation of bacteria that are able to utilize synthetic molecules not normally encountered in nature as sole carbon source. As a synthetic substrate for selective enrichment, chloridazon, antipyrin, or pyramidon can be applied.

Isolation Procedure

A convenient method for the isolation of *P. immobile* starts with sampling about 300 g of soil or compost. Air-dried soil or soil with very low humus content was found to be less satisfactory. The soil sample is mixed with 0.5 g of chloridazon, antipyrin, or pyramidon, and the preparation is incubated at 30°C or at room temperature in a flower pot and regularly moistened with water. Degradation of the xenobiotic compound is followed by thinlayer chromatography. From the excess water that drains from the flower pot, about 0.05 ml is applied to a thin layer plate coated with silica gel containing a fluorescent indicator with maximum sensitivity under UV radiation of 254 nm. Decomposition is complete when the spot of the xenobiotic compound is no longer detectable under UV light and a new spot corresponding to the dephenylated heterocyclic moiety of the xenobiotic appears, usually after one to several weeks, depending on the soil. Then a 5-g sample of the active soil is placed into an Erlenmeyer flask containing 50 ml of mineral salts medium (for composition, see recipe below) supplemented with the xenobiotic as carbon source at a concentration of 0.4%. This culture is

This chapter was taken unchanged from the second edition.

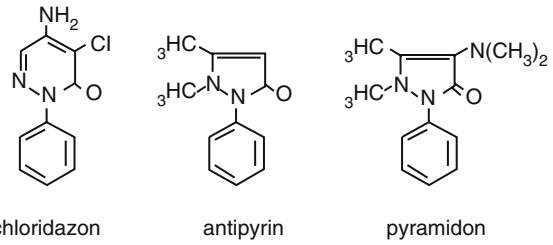

Fig. 1. The herbicide chloridazon and the structurally related analgesics antipyrin and pyramidon can be used for the enrichment of *P. immobile*. These xenobiotics are also the best growth substrates for the organism.

incubated on a rotary shaker at 30°C, and degradation is monitored by thin layer chromatography. When the decomposition of the xenobiotic is complete, 1 ml of the culture fluid is transferred into a new Erlenmeyer flask. After 5 to 10 transfers, a sample of the liquid culture is streaked onto agar plates containing the same medium. Single colonies, which normally appear after 1 to 3 weeks, are picked and again streaked onto agar. After 5 to 10 transfers, pure cultures can usually be obtained. In several cases, the isolation of a pure culture was more difficult than usual because *P. immobile* was closely associated with other nondegrading bacteria. In one case the other organism was identified as *Pseudomonas cepacia*.

Medium for *Phenylobacterium immobile*

Fröhner et al. (1970) found, for the first isolates of *P. immobile*, that vitamin B_{12} was an essential growth factor. This vitamin is thus routinely added to the mineral salts medium at 30 µg/liter. When grown on chloridazon or antipyrin *P. immobile* acidifies the culture fluid. Therefore a medium with reasonable buffer capacity was developed that due to the organism's osmotic sensitivity had to be kept at a low total salt concentration.

Medium for the Culture of *P. immobile*

The mineral salts medium has the following composition per 1 liter of deionized water:

$Na_2HPO_4 \cdot 12H_2O$	0.7 g
KH_2PO_4	0.3 g
$(NH_4)_2HPO_4$	0.7 g
$(NH_4)H_2PO_4$	0.3 g
$(NH_4)_2SO_4$	0.1 g
Trace element solution (see below)	1 ml
Vitamin B_{12} solution, 0.03 mg/ml	1 ml
$MgSO_4 \cdot 7H_2O$	0.25 g
$CaCl_2 \cdot 6H_2O$	0.05 g

To avoid precipitates the magnesium and calcium salts are each dissolved separately.

Trace element solution per 1 liter of deionized water:

$MnSO_4 \cdot 4H_2O$	400 mg
$ZnSO_4 \cdot 7H_2O$	400 mg
$FeCl_3 \cdot 6H_2O$	200 mg
$CuSO_4 \cdot 5H_2O$	40 mg
H_3BO_3	500 mg
$(NH_4)_6Mo_7O_{24} \cdot 4H_2O$	200 mg
KI	100 mg
Biotin	100 mg

As carbon source, chloridazon, antipyrin, or pyramidon is added at a concentration of 0.4 to 1 g per liter. The pH of the medium is 7.0.

Cultivation

Optimum growth and maximum cell yield are achieved when *P. immobile* is grown at 30°C in mineral salts medium with chloridazon or antipyrin at 0.4 to 1 g per liter. Under these conditions, a doubling time of 7 to 8 hours is observed, and, depending on the strain, a yield of about 0.4 to 1.0 g bacteria (wet weight) per liter of culture fluid is obtained.

Complex media used for routine cultivation in bacteriology with 10 to 20 g peptone per liter, or the same amount of yeast extract plus meat extract, do not support the growth of *P. immobile*. These bacteria were found to be osmotically sensitive, as demonstrated by NaCl addition to the chloridazon-mineral salts medium. At a NaCl concentration of 5 to 7 g per liter, considerable growth inhibition was observed with total inhibition at 10 g per liter. *P. immobile*, however, does grow on complex media with 0.5 to 2 g per liter peptone plus yeast extract, but growth is considerably slower than on antipyrin or chloridazon.

The strictly aerobic bacteria are cultivated on a rotary shaker, and in large-scale fermentations they are well aerated with 50 liter per min of air in a 100-liter-fermentor. For large-scale fermentation conducted with the type strain *P. immobile* strain E, a scale-up ratio of 1:10, starting with a 1-liter culture inoculated from an agar plate, was found to yield good results. In this case, a fermentation time of 24 h (from inoculation of the 100-liter fermentor to the late log phase) and a cell yield of 1 g per liter were obtained.

Growth on Agar Plates

Mineral salts medium with either 0.2% chloridazon or 0.1% antipyrin as carbon source and supplemented with 15 g agar per liter allows good growth of *P. immobile*. However, it takes at least 4 to 7 days until the first tiny colonies are visible on the agar even when the plate is inoculated with a large number of bacteria. After 2 to 3 weeks, the colonies reach a size of 1 to 2 mm in diameter. A concentration of 2 g chloridazon per liter leads to the precipitation of fine chloridazon

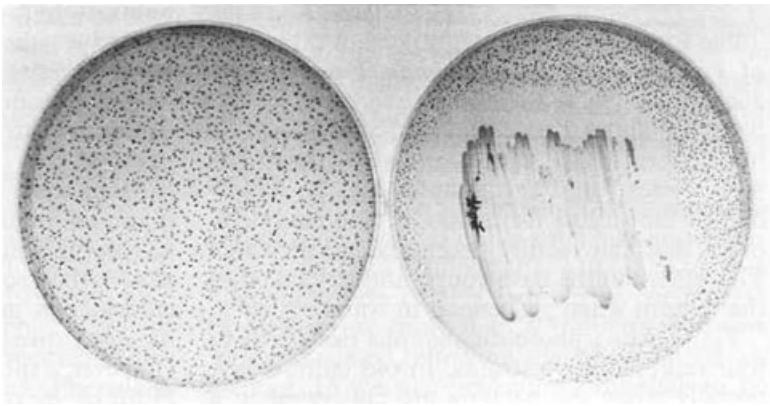

Fig. 2. Agar plates containing mineral salts medium with 2 g chloridazon per liter. On the plate at the right chloridazon crystals have been metabolized by *P. immobile*. The large crystal at the left margin of the bacterial smear is the dephenylated heterocyclic moiety of chloridazon, the main metabolite of chloridazon degradation.

crystals in the agar (Fig. 2). During growth on this agar, *P. immobile* removes the crystals by degradation, and as a result of bacterial growth, a clearance zone around the smear develops. In agar cultures of 4 weeks and older, new, and in most cases, relatively large crystals form within the bacterial smear. These crystals were identified as the dephenylated heterocyclic moiety of chloridazon, which is a dead-end metabolite of chloridazon degradation.

Purity of Cultures

Since none of the *P. immobile* strains grows on an ordinary complex medium, an inoculation of an agar plate containing the following medium is routinely used for testing purity:

Testing Medium

The complex medium contains per liter deionized water:

Nutrient broth (dehydrated)	10 g
Yeast extract	5 g
NaCl	5 g

Growth on this medium indicates contamination of the culture.

Preservation of Cultures

For short-term preservation, bacteria are regularly transferred on agar at intervals of 2 to 3 weeks. For long-term preservation, the bacteria suspended in skimmed milk are dropped onto silica gel grains and stored at 4°C. Good results were obtained with this method, when transfer is repeated every 2 to 3 years. However, even after a period of 10 years some of the strains were viable. Storage at –80°C of a concentrated bacterial suspension in fresh chloridazon-mineral salts medium supplemented with 15% glycerol also resulted in good viability after 2 years.

The following strains have been deposited in the Deutsche Sammlung für Mikroorganismen (DSM) and at the American Type Culture Collection (ATCC): strain E, type strain (DSM 1986, ATCC 35973); strain A_{12} (DSM 2115, ATCC 35972); strain J_1 (DSM 2116, ATCC 35974); strain K_2 (DSM 2117, ATCC 35975); strain N (DSM 2113, ATCC 35976); and strain Z_6 (DSM 2114, ATCC 35977). Two further strains have been deposited at the Czechoslovak Collection of Microorganisms (CCM): strain C_2 (CCM 3864) and strain R (CCM 3865).

Identification

The morphology and physiological properties of *P. immobile* are not especially remarkable (see Table 1). Nearly all biochemical tests are negative, and, with regard to this fact, *P. immobile* shows similarities with *Acinetobacter*. In fact, *Phenylobacterium immobile* was originally identified as an *Acinetobacter* species (Fröhner et al., 1970) but determination of the GC content clearly ruled out this identification.

The most distinguishing feature of *Phenylobacterium immobile* is its high nutritional specialization. This property is shared, although in a less pronounced way, by certain members of the pseudomonads, together with some morphological, physiological, and biochemical characteristics. The general definition of *Pseudomonas*, however, excludes nonmotile organisms, and all strains of *Phenylobacterium immobile* are nonmotile.

P. immobile is not closely related to any other Gramnegative eubacterium, as shown by partial sequence analysis of 16S rRNA from strain E (Ludwig et al., 1984). Phylogenetically, it was found to belong to subgroup alpha-2 of the proteobacteria (see "Phylogenetic Position" in this Chapter), with an isolated position in this group.

Table 1. Important characters for the identification of *Phenylobacterium immobile*.

Cells: Rods, coccal rods, or cocci; 0.7 to 1.0 by 1.0 to 2.0 µm; singly, in pairs or short chains; nonmotile; nonsporeforming; nonpigmented; no sheaths; no prosthecae.

Colonies: Develop slowly on chloridazon-mineral salts agar, small, colorless, circular, entire edges, convex; smooth or rough colonies possible.

Staining: Gram negative, not acid-fast, no capsule.

Physiology: Strictly aerobic, catalase positive, weakly oxidase positive; no growth at 4°C and 37°C, optimum growth at 28–30°C; no growth at pH 4 and 9, growth between pH 6.5 and 8, optimum pH 6.8–7.0; osmotically sensitive; vitamin B_{12} is a growth factor; NH_4^+ and NO_3^- used as N sources, no denitrification, no N_2 fixation.

Biochemical tests: Negative results in the indole reaction, methyl red, Voges-Proskauer, litmus milk, and urease test; no hydrolysis of gelatin, starch, agar, or esculin; weakly positive for H_2S from thiosulfate or cysteine; no acid or gas from 34 different sugars.

Carbon sources: Optimum growth on chloridazon, antipyrin, pyramidon, and L-phenylalanine (most strains after long lag phase only); no growth on simple carbon sources like sugars, alcohols, carboxylic acids (31 compounds tested), and amino acids (except phenylalanine and glutamate); poor growth on glutamate, pyruvate, fumarate, succinate, and malate; no growth on routine complex media unless medium is diluted (0.5 to 2 g peptone per liter).

GC content: 65–68.5 mol%.

Morphology

Table 1 summarizes some important properties of *Phenylobacterium immobile*. On chloridazon-mineral salts agar, after 2 to 3 weeks colonies are about 1 to 2 mm in diameter and do not adhere to the agar (see also "Growth on Agar Plates," and this chapter Fig. 2). Nearly half of the strains form smooth and shiny colonies that can readily be emulsified in water. The other strains have rough and dry colonies that clump when suspended in water.

Fig. 3 shows photomicrographs from cells of four representative strains. In old cultures, especially when the bacteria are cultivated in a medium that allows only poor growth, such as a dilute complex medium, pleomorphic forms, such as long rods, long chains of cells connected by small filaments, or club-shaped and elliptical forms, sometimes occur.

Gram staining, Ziehl-Neelsen staining, and capsule staining are negative, and electron microscopy of thin sections also reveals the typical Gram-negative cell wall pattern (Lingens et al., 1985). Strain K_2, which forms smooth colonies on agar, was treated with ruthenium red and electron microscopy of ultrathin sections revealed the presence of a microcapsule—or according to the definition of Costerton et al. (1981), a "flexible" capsule—surrounded by a slime layer of acid polysaccharides (Lingens et al., 1985). No microcapsule was detected in ruthenium-red-stained cells of strain E, which forms rough colonies on agar.

Physiological and Biochemical Characteristics

The osmotic sensitivity and nutritional specialization of *Phenylobacterium immobile* do not allow the use of routine media for biochemical characterization. Therefore, tests were performed in modified media (Lingens et al., 1985). The characteristics determined for all strains are shown in Table 1.

Utilization of Carbon Sources

All the different strains of *Phenylobacterium immobile* do not utilize all three xenobiotic substrates. Whereas chloridazon and antipyrin are well utilized by most strains, pyramidon is a growth substrate for only 7 of the 22 isolates. When pyramidon is added to media containing chloridazon or antipyrin, growth inhibition is observed among all of the isolates.

The pathway for the degradation of the three xenobiotics was elucidated by metabolic and enzymatic studies (Blecher et al., 1981; Eberspächer and Lingens, 1978; Miller et al., 1977; Sauber et al., 1977a; Sauber et al., 1977b). The pathway follows the well-known route for the oxidative dissimilation of aromatic compounds, and in the case of these xenobiotics only the aromatic nucleus is used as a carbon source, the heterocyclic moiety remaining unchanged.

More than 20 different heterocyclic or aromatic compounds that are structurally related to chloridazon or antipyrin were tested as possible carbon sources (Lingens et al., 1985). Most chloridazon analogs with altered heterocyclic moiety proved to be good growth substrates. However, a substitution at the aromatic nucleus, as for *o*-, *m*- or *p*-methylchloridazon, made the compound nondegradable by the organism. Of the aniline derivatives tested, N-methylacetanilide and N-methylformanilide were found to be poor growth substrates. Of 18 aromatic compounds that usually are utilized by various bacterial species, none

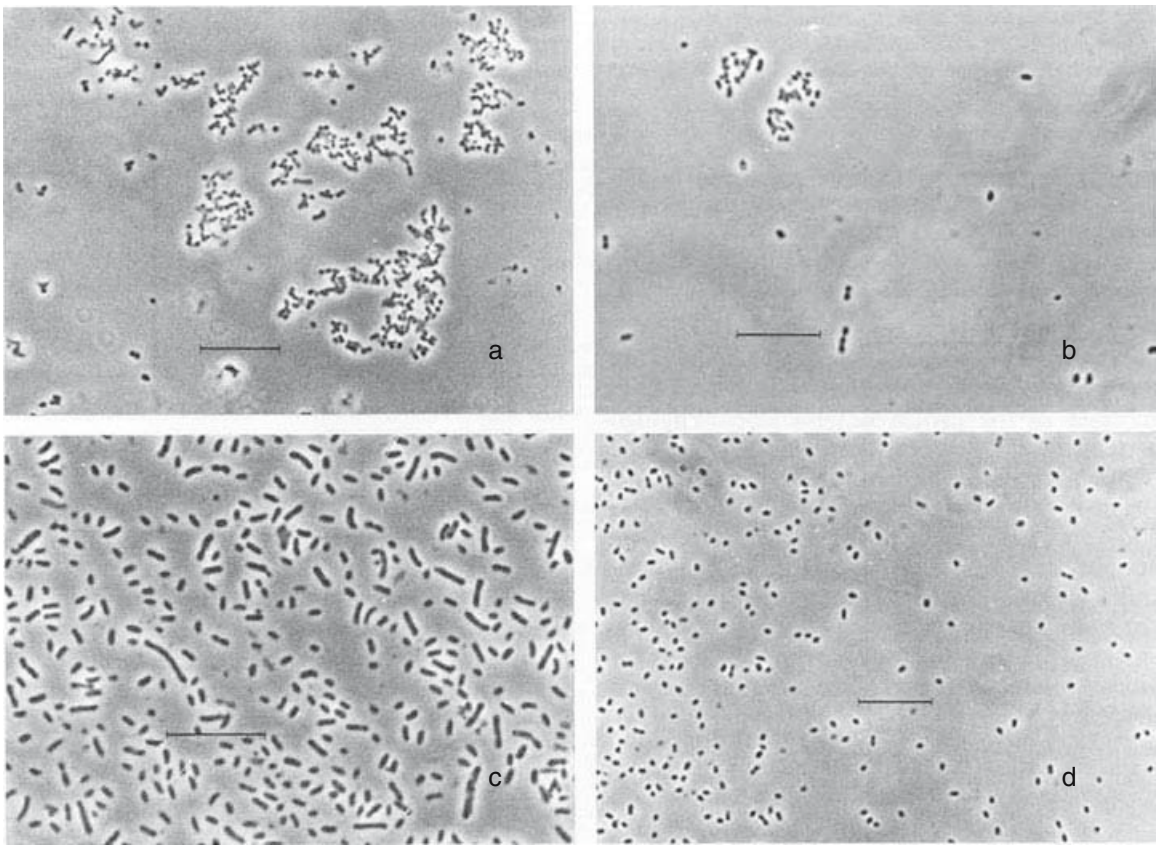

Fig. 3. Phase contrast photomicrographs of cells of *Phenylobacterium immobile*. (a) Strain A_{13}; (b) strain E, the type strain; (c) strain K_2; and (d) strain N. Bars = 10 µm.

supported growth of *Phenylobacterium immobile*. Among these compounds were benzene, toluene, phenol, catechol, benzaldehyde, benzoate, and a number of mono- and dihydroxylated benzoates.

One strain (strain N) was found to grow well on L-phenylalanine with a normal lag phase of 1 day. All other strains had lag phases of 2 to 3 weeks, but then they also grew well on phenylalanine. The long lag phases were only observed when the strains were transferred from chloridazon or antipyrin to phenylalanine for the first time, since after additional transfers the bacteria grew immediately. In liquid cultures during growth on mineral salts medium with phenylalanine, especially at higher concentrations (3 to 5 g per liter), a yellowish-green fluorescent pigment is produced. On chloridazon or antipyrin mineral salts media, a greenish-yellow nonfluorescent pigment is formed. Phenylalanine-induced cells also grow well on phenylpropionate, phenylpyruvate, and phenyllactate.

Nucleic Acid Data

GC content of the DNA of *P. immobile* was found to be between 65 and 66.5 mol%, although for one strain (C_2) a somewhat higher value of 68.5 mol% was determined. DNA hybridization tests revealed 100% homology of DNA preparations of four different strains with DNA of strain R. No homology was found using DNA from *Agrobacterium tumefaciens*, *Bacillus subtilis*, *Escherichia coli*, *Pseudomonas fluorescens*, or calf thymus.

Depending on the strain, between one and six different plasmids were found, which varied in size from 8 to 300 megadaltons (Kreis et al., 1981).

From the type strain, 16S rRNA was isolated, and oligonucleotides of hexamer size and larger were sequenced (Ludwig et al., 1984). With this oligonucleotide catalog, similarity coefficients (S_{AB} values) to more than 400 microorganisms were calculated, allowing the phylogenetic allocation of *Phenylobacterium immobile* to be determined (see "Phylogenetic Position" in this Chapter).

Lipopolysaccharide, Peptidoglycan, and Polyamine Pattern

The composition of the carbohydrate moiety and of the lipid A from the lipopolysaccharide of the

type strain has been described by Weisshaar and Lingens (1983). Remarkable is the presence of one mole of 2,3-diamino-2,3-dideoxy-D-glucose as a constituent of the lipid A backbone. This diaminosugar was only found in members of subgroup alpha-2 of the alpha subclass of the proteobacteria (see "Phylogenetic Position" in this Chapter), whereas the lipid A of most Gram-negative bacteria contains glucosamine.

The detection of ester-linked 3-hydroxy-5-*cis*-dodecanoic acid as a major substituent in the lipopolyaccharide is also remarkable (Bellmann and Lingens, 1985a). This unusual fatty acid, not found in nature before, was used to demonstrate the presence of *Phenylobacterium immobile* in soil samples (Bellmann and Lingens, 1985b).

The peptidoglycan composition of the type strain was identical to that of a normal Gram-negative bacterium (Lingens et al., 1985). The type strain was found to contain only sym-homospermidine as a polyamine component (Busse and Auling, 1988).

Toxicity

Bacteria of *P. immobile* are harmless when tested in rats and rabbits (Kaiser et al., 1981). Tests included oral administration, intracutaneous and intraperitoneal injections of the bacteria, and inhalation experiments.

Enzymes

The type strain was found to possess all of the enzymes of the citric acid cycle. Properties of citrate synthase, of rhodanese (Layh et al., 1982), of arogenate (pretyrosine) dehydrogenase (Keller et al., 1982), and of *meta*-cleaving chloridazon-catechol-dioxygenases (Schmitt et al., 1984) were studied in more detail, and the taxonomic significance of these enzymes has been discussed.

Serology

Agglutination and immunofluorescence tests revealed the serological uniformity of the different strains (Layh et al., 1983). Slight differences in immune reactions allowed a classification of the strains into 5 serological subgroups. No relationship was found between *Phenylobacterium immobile* and 40 representative Gram-negative bacteria, including *Acinetobacter calcoaceticus*, *Azospirillum brasiliense*, *Paracoccus denitrificans*, different *Pseudomonas* species, *Rhizobium* species, *Rhodomicrobium vannielii,* and *Rhodopseudomonas capsulata.* A slight but significant immunofluorescence reaction was observed with *Pseudomonas vesicularis*, *Gluconobacter oxydans*, *Aquaspirillum itersonii*, and *Rhodospirillum rubrum* (Dorfer et al., 1985). Crossed immunoelectrophoresis revealed a serological relationship between *Phenylobacterium immobile* and *Pseudomonas diminuta* (J. Dorfer, C. Löffler, J. Eberspächer, and F. Lingens, unpublished observations).

Phylogenetic Position

Partial sequence analysis of 16S rRNA has revealed the isolated phylogenetic position of *Phenylobacterium immobile* (Ludwig et al., 1984). The highest S_{AB} values (0.51) were found with *Pseudomonas diminuta* and *Rhizobium leguminosarum*. Similarity coefficients of this magnitude indicate a rather remote relationship that would not be detectable by DNA-DNA hybridization. A comparison of the 16S rRNA nucleotide catalogs showed that *Phenylobacterium* is a member of subgroup alpha-2 of the alpha subclass of the proteobacteria (in the nomenclature of Stackebrandt et al., 1988). These organisms have also been called the "subgroup alpha-2 of the alpha purple bacteria" (Woese, 1987) or the "subgroup Ib of the purple nonsulfur bacteria and their nonphotosynthetic relatives." Members of this group belong to the "4th rRNA superfamily," (de Vos and de Ley, 1983). S_{AB} values of 0.49 and 0.46 were found with *Rhodopseudomonas viridis*, *R. capsulata*, *R. sphaeroides*, *Rhodomicrobium vannielii*, and *Aquaspirillum itersonii*. For representatives of the other major groups of Gram-negative bacteria, including *Acinetobacter calcoaceticus* and the two phylogenetically defined clusters of the genus *Pseudomonas*, S_{AB} values of 0.23 to 0.32 were obtained, indicating a wide phylogenetic distance.

In accordance with this finding, weak serological reactions of *Phenylobacterium immobile* were found only with members of the alpha subclass of the proteobacteria (Dorfer et al., 1985) and not with any other Gram-negative bacteria.

Furthermore, the demonstration of 2,3-diamino-2,3-dideoxy-D-glucose as a lipid A constituent of *Phenylobacterium immobile* supports its relationship to subgroup alpha-2 of the proteobacteria. This unusual sugar was also detected in *Rhodopseudomonas viridis*, *R. palustris*, *R. sulfoviridis*, *Pseudomonas diminuta*, *P. vesicularis*, and *Nitrobacter winogradskyi*, which are all members of the same phylogenetic group (Weckesser and Mayer, 1987).

Busse and Auling (1988) have shown that polyamines may serve as a useful chemotaxonomic marker within the proteobacteria. They found that the species of the alpha-2 subgroup have sym-homospermidine as the dominant

component of the polyamine pattern. Consistent with its phylogenetic position, *Phenylobacterium immobile* contains sym-homospermidine exclusively.

Ubiquinones are also useful chemotaxonomic markers, and members of the alpha subgroup of the proteobacteria were shown to contain ubiquinone composed of 10 isoprenoid units. Strains E, J_1, and Z_6 of *P. immobile* contain a ubiquinone of the Q-10 type (R. M. Kroppenstedt, J. Eberspäher, and F. Lingens, unpublished observations).

CHAPTER 3.1.13

Methylobacterium

PETER N. GREEN

Introduction

The genus *Methylobacterium* is composed of a variety of pink-pigmented facultatively methylotrophic (PPFM) bacteria, which can grow on one-carbon compounds such as formate, formaldehyde and methanol as sole source of carbon and energy as well as on a wide range of multicarbon growth substrates. Most, but not all, strains can grow on nutrient agar and some can grow on methylated amines. Only one strain has been reported to utilize methane as sole carbon source.

Taxonomy

The first *Methylobacterium* strain to be described in the literature was isolated by Bassalik (1913) from earthworm contents and named *Bacillus extorquens*. Although they are common soil and environmental organisms, the PPFM bacteria were not isolated and studied extensively until the 1960s and 1970s, when interest in the study of the one-carbon assimilation pathways common to methylotrophic organisms and in the commercial applicability of these organisms first began.

Prior to 1960, the taxonomy of many of the isolates now assigned to *Methylobacterium* was still uncertain. Although regarded as Gram-negative, these organisms often stained Gram-variable. This Gram-variability, coupled with their morphological properties (mainly rods, which are occasionally branched and exhibit polar growth), has contributed to much of the confusion surrounding their checkered taxonomic history.

For example, Bhat and Barker (1948) assigned the *B. extorquens* isolate of Bassalik to the genus *Vibrio* as *V. extorquens*. Krasil'nikov (1959) and Bassalik et al. (1960) subsequently transferred the same species to *Pseudomonas* and *Flavobacterium*, respectively, before it temporarily came to rest, in the 8th edition of *Bergey's Manual of Determinative Bacteriology*, as *P. extorquens* incertae sedis (Doudoroff and Palleroni, 1974).

In a study of amine-utilizing bacteria, den Dooren de Jong (1927) described the pink, methylamine-utilizing species *Protaminobacter rubrum*, which De Vries and Derx (1953) later found to be very similar to organisms they had isolated from leaf nodules and leaf surfaces. On the grounds that all the organisms were Gram-negative, motile, branching rods, De Vries and Derx (1953) grouped *P. rubrum* with their isolates in the genus *Mycoplana* as *M. rubra*.

Peel and Quayle (1961), studying C-1 assimilatory pathways in methylotrophs, noted similarities between their own isolates, *Pseudomonas* AM1, and various other methylotrophic bacteria, including *V. extorquens*, *Protaminobacter ruber* (spelling amended, Breed et al., 1957) and *Pseudomonas methanica* isolated by Dworkin and Foster (1956). Peel and Quayle questioned the justification for classifying these organisms in different genera.

An early, but limited, taxonomic study by Stocks and McCleskey (1964) compared *V. extorquens*, *Protaminobacter ruber*, *Pseudomonas* AM1, and Harrington and Kallio's (1960) strain of *Pseudomonas methanica* with their own isolates and concluded that all were very similar and should be regarded as strains of *V. extorquens*, with the reservation that *Vibrio* might not prove to be the most suitable generic location.

In the more recent studies, Kouno and Ozaki (1975) isolated 59 different PPFM isolates from a variety of soil and water samples, and Austin et al. (1978) studied isolates from the phylloplane of *Lolium perenne*. In both these studies, there was agreement that the taxonomy of these organisms was obscure and needed further examination. Subsequently, Austin and Goodfellow (1979) concluded that their isolates were sufficiently different from *Protaminobacter ruber*, *Pseudomonas rhodos* (Heumann, 1962) and *P.* AM1 to merit placement in a new species, which they named *Pseudomonas mesophilica*.

Patt et al. (1974) isolated the first reported PPFM strain able to utilize methane and created

a new genus *Methylobacterium* to accommodate it. The new species *M. organophilum* was proposed for this single strain. Unfortunately, the genus description was based on the detailed examination of only one strain (*M. organophilum* xx), which has since lost its ability to utilize methane (R. S. Hanson, personal communication).

In a detailed taxonomic study, Green and Bousfield (1982) found *M. organophilum* strain xx to be phenotypically very similar to many of the strains of PPFM discussed previously, none of which could utilize methane. All of the 149 strains examined, using 140 biochemical, physiological, and morphological features, including *M. organophilum*, fell into either of two related (≥70% similarity) clusters, which were well separated from other facultative methylotrophs and nonmethylotrophic reference strains. As a result of this work, Green and Bousfield (1982) suggested that all the PPFM bacteria constituted a distinct taxon, which could be excluded from most of the genera to which they had previously been assigned. The genus *Methylobacterium* was chosen to accommodate this taxon (Green and Bousfield, 1981).

However, as the description of *Methylobacterium* (Patt et al., 1976) excluded organisms that could not utilize methane, an emended genus description was proposed (Green and Bousfield, 1983) that would allow the inclusion of all PPFM strains (whether they utilized methane or not), thus removing methane assimilation as an essential feature of the genus. At the same time, the description of *Methylobacterium* was more tightly circumscribed to prevent the genus from being used as a "dumping ground" for every facultative methane utilizer subsequently isolated, irrespective of its taxonomic relatedness to the PPFM bacteria.

As a result of this proposal the emended genus *Methylobacterium*, in addition to the type species *M. organophilum*, now contained three other validly named species: *Pseudomonas rhodos* (Heumann, 1962), renamed *M. rhodinum*; *Pseudomonas mesophilica* (Austin and Goodfellow, 1979), renamed *M. mesophilicum*; and *Pseudomonas radiora* (Ito and Iizuka, 1971), renamed *M. radiotolerans*.

Despite the overall similarities of the PPFM organisms and their recognition as a distinct taxon, there nevertheless remained doubts about the internal heterogeneity of the group (Green and Bousfield, 1983; Urakami and Komagata, 1981). This doubt was reinforced when subsequent work on representative strains of PPFM (Hood et al., 1987; Hood et al., 1988) involving DNA-DNA similarities and electrophoretic comparison of total soluble proteins revealed four major and several minor similarity (homology) groups. As a result, three new species of *Methylobacterium* were proposed (*M. rhodesianum*, *M. zatmanii* and *M. fujisawaense*) and several other probable centers of variation within the genus were recognized. Other workers have since described four new species. In 1993, Urakami et al. (1993) described a new species *Methylobacterium aminovorans*, which is involved in the biodegradation of tetramethylammonium hydroxide (TMAH) and *N*,*N*-dimethylformamide (DMF). In 1998, a strain that tolerates high (≥50 mM) thiocyanate and cyanate and is capable of utilizing these compounds as sole nitrogen source was isolated and described. This new species was named *Methylobacterium thiocyanatum* (Wood et al., 1998). The two most recently proposed species can grow on chlorinated methyl compounds as sole carbon and energy source. *M. chloromethanicum* (McDonald et al., 2001) and *M. dichloromethanicum* (Doronina et al., 2000) can utilise chloromethane (methyl chloride) and dichloromethane, respectively.

Two additional non-pink pigmented facultative methylotrophs claimed to be able to utilize methane as sole source of carbon and energy and to belong to the genus *Methylobacterium* ("*M. ethanolicum*" and "*M. hypolimneticum*"; see Lynch et al., 1980) have since been shown to be taxonomically unrelated to the PPFM (P. N. Green, unpublished observations).

Thus, twelve validated species of the genus *Methylobacterium* presently exist—the eleven discussed above plus *M. extorquens*, the type strain of which was recovered in one of the major DNA similarity (homology) groups and had already been described by Urakami and Komagata (1984) as *Protomonas extorquens*. As *Methylobacterium* was shown to have nomenclatural priority over *Protomonas* (Bousfield and Green, 1985), *P. extorquens* was subsequently transferred to the genus *Methylobacterium*.

Habitat

Members of the genus *Methylobacterium* are ubiquitous in nature and are thus found in a variety of habitats (Green and Bousfield, 1981; Green and Bousfield, 1983), including soil, dust, freshwater, lake sediments, leaf surfaces and nodules, rice grains, air, and hospital environments, and in various products and processes, e.g., as contaminants in pharmaceutical preparations such as face creams. As a common airborne organism, PPFM can occur in a wide variety of commercial processes where growth conditions are favorable, including various fermentation processes. Our identification service has also had isolates from pure water users such as silicon chip manufacturers.

The PPFM bacteria are strict aerobes and can be isolated from almost any freshwater environment where some dissolved oxygen exists; from tap water systems (Grfi and Bauer, 1973), where they produce pink ropy masses of growth; and from stratified lake systems (Hanson, 1980), where they occupy a special niche. The methane-oxidizing PPFM strains of *Methylobacterium organophilum* were isolated from the metalimnion of Lake Mendota, USA. Only in this stratified layer during the summer months, where methane was available in the presence of reduced oxygen tensions, did aerobic methane oxidation take place. Indeed, because of their ability to metabolize various breakdown products present in plant detritis such as methanol, methylamine, various other methylated compounds, and (in some cases) methane, the PPFM bacteria may play an important ecological role in the carbon cycle in nature. In addition, their ability to resist a certain degree of desiccation and to scavenge trace amounts of nitrogen and carbon (P. N. Green, unpublished observations) make them well suited for survival in stressful environments.

One such environment in which high numbers of PPFM bacteria are often found is roadside dust. Using selective media such as methanol salts agar (see Isolation), information has been obtained which suggests a correlation between levels of vehicular traffic and numbers of PPFM bacteria.

The association of *Methylobacterium* spp. with plants has been studied by various workers. In a numerical taxonomic study of phylloplane bacteria isolated from *Lolium perenne*, Austin and Goodfellow (1978) found pink chromogens (PPFM organisms) to be one of the major phenotypes isolated. Yoshimura (1982) found similar organisms in his study of pine-forest phylloplane bacteria and showed that their numbers varied quite dramatically with the seasons and with the accompanying environmental conditions.

After M. E. Rhodes-Roberts (personal communication) had isolated a PPFM strain (*Mycoplana rubra* NCIB 10409) from the sterilized leaf nodules of *Psychotria mucronata* and Corpe and Basile (1982) reported associations of similar organisms with lower plants, it became apparent that extra- and/or intracellular symbiotic or mutualistic associations may exist between plants and some strains of *Methylobacterium*. Although Corpe and Basile (1982) produced evidence to suggest that the PPFM bacteria present on mosses and liverworts may produce growth-stimulatory substances for these lower plants, there is presently no further evidence to support the theory of a symbiotic association. Also, radiotracer studies using $^{14}CO_2$ failed to demonstrate the uptake of labeled metabolites present in leaf exudates by a known *Methylobacterium* strain inoculated onto the surface of young *Vicia faba* plants (P. N. Green, unpublished observations). Thus, there remains the possibility that populations of PPFM attached to dust or soil particles are deposited on plant surfaces by the wind, and their numbers on leaf surfaces merely reflect the population size in the surrounding environment or as dictated by climatic conditions.

Because they are common airborne organisms, *Methylobacterium* spp. are also found as occasional contaminants in a variety of systems: domestic water supplies (mentioned above), media chills (refrigerated rooms on cabinets in which bacteriological culture media is stored prior to use), pharmaceutical products, fermentation vessels (especially in association with other C-1 compound-utilizing bacteria), and hospital environments (Gilardi and Faur, 1984). In the last case, they may pose a threat as opportunistic pathogens to seriously ill patients.

Isolation and Cultivation

Because of the ability of *Methylobacterium* spp. to grow on methanol as sole carbon and energy source and because of their characteristic pigmentation, these organisms are relatively easy to isolate. The following methanol mineral salts (MMS) medium is a suitable selective medium for *Methylobacterium*.

Methanol Mineral Salts Medium

The following are added per liter:

K_2HPO_4	1.20 g
KH_2PO_4	0.62 g
$CaCl_2 \cdot 6H_2O$	0.05 g
$MgSO_4 \cdot 7H_2O$	0.20 g
NaCl	0.10 g
$FeCl_3 \cdot 6H_2O$	1.0 mg
$(NH_4)_2SO_4$	0.5 µg
$CuSO_4 \cdot 5H_2O$	5.0 µg
$MnSO_4 \cdot 5H_2O$	10.0 µg
$Na_2MoO_4 \cdot 5H_2O$	10.0 µg
H_3BO_3	10.0 µg
$ZnSO_4 \cdot 7H_2O$	70.0 µg
$CoCl_2 \cdot 6H_2O$	5.0 µg

The MMS medium is sterilized by autoclaving at 121°C for 20 min and cooled to 50°C. A filter-sterilized vitamin solution (Colby and Zatman, 1973) is added if required, along with 0.1–0.2% (v/v) sterile methanol. The pH of the medium is adjusted to pH 7.0. Solidified media (MMS agar) are prepared by the addition of 1.5–2% Oxoid (purified) agar before autoclaving. No PPFM strain isolated to date has been shown to require vitamins or other added growth factors.

Although *Methylobacterium* strains can grow between 5° and 37°C, all grow well at 30°C, and

thus 25–30°C can be used for all isolation and subsequent growth experiments. These organisms are fairly slow growers, often taking 2–3 days at 30°C to produce clearly visible colonies or confluent growth and often taking more than 7 days for colonies to reach their maximum size of 1–3 mm in diameter. Growth is sometimes more luxuriant, with a deeper pigmentation, on Glycerol-Peptone (GP) agar.

Glycerol-Peptone Agar

The following are added per liter:

Agar	15 g
Glycerol	10.0 g
Peptone (Difco)	10.0 g

The pH is adjusted to pH 7.0

Although this medium is useful for subculturing stocks of pure *Methylobacterium* spp., it is less suitable for enrichment than the MMS medium, as other rapidly growing heterotrophs present in the sample can overgrow the PPFM bacteria. Certain antibiotics (see Identification) can also be considered for use in selective media, as can individual carbon sources for use in isolating specific groups or species of *Methylobacterium*. A summary of the properties of various species and isolates is given in Table 1.

If MMS agar is used as a selective medium, the vast majority of the pink colonies that reach diameters of more than 1 mm will be strains of PPFM organisms. Pink methylotrophic yeasts are not uncommon, but bacterial pink methylotrophs other than *Methylobacterium* species are rare.

Growth of PPFM organisms in liquid media is almost always characterized by a surface ring and/or thin pellicle, indicative of their aerobic nature.

When attempting to isolate PPFM strains from leaf surfaces, a leaf impression technique, using one of the above media, is recommended. Homogenization of whole leaves or embedding leaves in molten agar are alternatives, although they are not as successful as the impression technique.

Table 1. Substrate[a] utilized as sole carbon source to differentiate strains of *Methylobacterium*.

Symbols: +, utilized as substrate; –, not utilized; V, variable result; and nd, no data.

Abbreviations: TMAH, tetramethylammonium hydroxide; DMF, *N*,*N*-dimethylformamide.

[a]Owing to the slow growth of some strains on certain substrates, carbon utilization tests were read after 14 days of incubation at 30°C (Green and Bousfield, 1982). Doubtful results were checked by twice subculturing in liquid medium.

[b]Most strains which utilize sebacate can also utilize pimelate, suberate, azelate and adipate.

[c]Nutrient agar e.g. Oxoid cm55.

[d]Taken from Wood et al. (1998).

[e]Tested for glutamate only.

[f]Taken from McDonald et al. (2001).

[g]Taken from Doronina et al. (2000).

If fungal contamination of samples from particular habitats is a problem when attempting to isolate strains of PPFM, 20 μg/ml of cycloheximide can be added to the medium.

Isolation and cultivation of PPFM bacteria involving single carbon susbstrates should be carried out on an appropriate salts basal medium (e.g. MMS where the methanol is replaced by the test substrate). For most substrates a final concentration of 0.1% is satisfactory. (For those strains utilising dichloromethane, see Doronina et al. 2000. Gaseous compounds methane and chloromethane are usually provided as head space gases in the proportions 50 : 50 methane : air and 2 : 98 chloromethane : air.)

Identification

All *Methylobacterium* strains are rods (0.8–1.0 × 1.0–8.0 mm), which occur singly or occasionally in rosettes (Patt et al., 1974; Heumann, 1962). They are often branched or pleomorphic, especially in older stationary-phase cultures (Fig. 1a). There is some evidence to suggest that they exhibit polar growth or a budding morphology (L. B. Perry, unpublished observations). All strains are motile by a single polar, subpolar or lateral flagellum, although some strains are not vigorously motile. Cells often contain large sudanophilic inclusions (poly-β-hydroxybutyrate) and sometimes also volutin granules (Fig. 1b). They are Gram-negative, although many strains stain as Gram-variable. Representative strains have a multilayered cell wall structure and the type of citrate synthase (Green and Bousfield, 1982) characteristic of Gram-negative bacteria. Most strains grow slowly and some not at all on nutrient agar. After 7 days of incubation at 30°C, colonies on GP agar are 1 to 3 mm in diameter and pale pink to bright orange-red, whereas colonies on MMS agar are a more uniform pale pink. The pigment is nondiffusible, is nonfluorescent, and probably is a carotenoid (Downs and Harrison, 1974; Ito and Iizuko, 1971). In static liquid media, most strains form a pink surface ring and/or pellicle.

All strains are strict aerobes and are catalase and oxidase (often weakly) positive. They are chemoorganotrophs and facultative methylotrophs, capable of growth on a variety of C-1 compounds. All grow on formaldehyde (often at micromolar concentrations), formate, and methanol; some grow on methylated amines. Only one species (*M. organophilum*) is reported to have utilized methane as sole carbon and energy source, but the ability has since been lost by the type (and only) strain. This organism's ability to assimilate methane was thought to be plasmid borne and easily lost if cultures were not maintained on an inorganic medium in a methane atmosphere (R. S. Hanson, personal communication). Representative PPFM strains have been reported to assimilate C-1 compounds via the

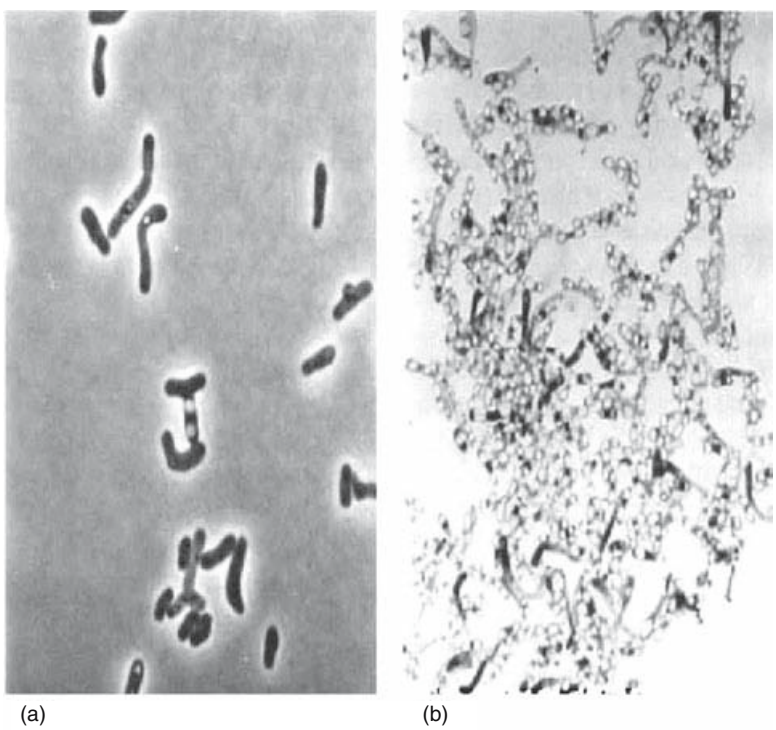

Fig. 1.

isocitrate lyase deficient (icl^-)$^-$serine pathway (Bellion and Spain, 1976; Quayle, 1972) and to have a complete tricarboxylic acid cycle when they are grown on complex organic substrates. The serine pathway is the major route for assimilating 1-carbon compounds such as methanol and methylated amines in *Methylobacterium* spp. Carbon is assimilated into the cell via formaldehyde and is incorporated via an icl^- variant of the pathway described by Quayle.

The optimum growth temperature for all *Methylobacterium* strains is in the range 25 to 30°C. Some strains will grow at 15°C or less, and some will at or above 37°C. Although growth is optimal around neutrality, some strains can grow at pH 4 and some at pH 10. Growth factors are not required by any strain although calcium pantothenate (Urakami et al., 1993) has been shown to stimulate the growth of some strains, and most strains do not degrade or hydrolyze casein, starch, gelatin, cellulose, lecithin or DNA. Urease is produced by all strains, and some strains have weak lipolytic activity. The enzymes β-galactosidase, L-ornithine decarboxylase, L-lysine decarboxylase and L-arginine dihydrolase are not produced. Indole (except for *M. thiocyanatum*) and hydrogen sulfide (H_2S) are also not produced. The methyl red and Voges-Proskauer tests are negative, although some strains reduce nitrate to nitrite.

Most strains are sensitive to the chemotherapeutic agents kanamycin, gentamycin, albamycin T, streptomycin, framycetin and especially the tetracyclines, whereas most are resistant to cephalothin, nalidixic acid, penicillin, bacitracin, carbenicillin, colistin sulfate, polymyxin B and nitrofurantoin.

Species within the genus *Methylobacterium* are differentiated mainly by the pattern of compounds they utilize as sole carbon and energy source (see Table 1). However, care should be taken to standardize such tests because they are notoriously difficult to duplicate between laboratories. All carbon utilization tests shown in Table 1 were carried out as described by Green and Bousfield (1982), who used faintly turbid suspensions of cells (which had been thrice washed in sterile saline) to inoculate media. All tests were read only after 14 days of incubation at 30°C, and growth was compared to a negative control containing no added carbon source. This long incubation time was necessary to allow for slow growth on certain compounds. Doubtful results should always be checked by twice subculturing in liquid media.

The following compounds were used by most (≥95%) strains of *Methylobacterium*: glycerol, malonate, succinate, fumarate, α-ketoglutarate, DL-lactate, DL-malate, acetate, pyruvate, propylene glycol, ethanol, methanol and formate. Some strains (see Green and Bousfield, 1982, and Table 1) can also utilize L-arabinose, D-xylose, D-fucose, D-glucose, D-galactose, D-fructose, L-aspartate, L-glutamate, adipate, sebacate, D-tartrate, citrate, citraconate, saccharate, monomethylamine, trimethylamine, trimethylamine-*N*-oxide, ethanolamine, butylamine, dimethylglycine, betaine, tetramethylammonium chloride, *N*-N-dimethylformamide, chloromethane and dichloromethane. None of strains appear to use any of the disaccharides or sugar alcohols examined (Green and Bousfield, 1982) (except for glycerol) or any of the following as sole carbon and energy source: propionate, DL-arginine, L-valine, glycine, geraniol, tryptamine, histamine, putrescine, *m*-hydroxybenzoate, testosterone, sarcosine, phenol, thiourea, tetramethylurea, hexane or benzene. Ammonia, nitrate and urea can serve as nitrogen sources. *Methylobacterium thiocyanatum* can utilize cyanate and thiocyanate as sole source of nitrogen for growth (Wood et al., 1998).

The fatty acid composition of PPFM cells is comprised largely (around 70–90%) of $C_{18:1}$ mono-unsaturated straight-chain acids, and the major isoprenoid quinone components are ubiquinones with 10 isoprene units (Urakami and Komagata, 1979; Urakami and Komagata, 1986). Representative strains have been shown to contain 3-hydroxy $C_{14:0}$ as the principal hydroxy fatty acid (Urakami and Komagata, 1987; Urakami et al., 1993), in addition to small amounts of $C_{16:1}$ and $C_{19:0}$ cyclopropane acids. Similarly, representative strains were shown to contain large amounts of cardiolipin (diphosphatidylglycerol), phosphatidylethanolamine and phosphatidylcholine, and a small amount of phosphatidylglycerol in their phospholipids (Urakami et al., 1993) and to contain bacterial hopanoids or sterols (Urakami and Komagat, 1986; Knani et al., 1994). The DNA base composition is 68.0–72.4 mol% G+C (Hood et al., 1987; Urakami et al., 1993).

DNA-DNA similarity studies (Hood et al., 1987) and electrophoretic comparison of total soluble proteins (Hood et al., 1987; Urakami et al., 1993) from representative strains have demonstrated the existence of a number of similarity (homology) groups within the genus *Methylobacterium*, several of which have been subsequently proposed as new species (Green and Bousfield, 1988; Urakami et al., 1993; Wood et al., 1998), which can be distinguished phenotypically (see Table 1). Genotypic studies (Wilfrum et al., 1986; Tsuji et al., 1990; Bratina et al., 1992) have confirmed that strains belonging to the genus *Methylobacterium* belong to a single, if somewhat heterogeneous, taxon that is clearly distinguished from other methylotrophic and non-methylotrophic genera.

Sato (1978), Sato and Shimizu (1979), and Nishimura et al. (1981) have shown that strains of *Methylobacterium* can form bacteriochlorophyll *a* under specific cultural conditions, thus suggesting a common link in their ancestry with the phototrophs.

Recent DNA-rRNA similarity studies by Dreyfus et al. (1988) have placed *Methylobacterium* in the rRNA superfamily IV of De Ley (1978), along with other members of the *Agrobacterium-Rhizobium* complex.

Preservation

All members of the genus *Methylobacterium* survive freeze drying or lyophilization. These organisms can also be cryopreserved in their liquid growth medium supplemented with a suitable cryoprotectant (e.g., 10–15% [v/v] glycerol).

Applications

Although *Methylobacterium* strains have potential for the production of single-cell protein from methanol, their bioconversion ratios (cell mass formed: substrate consumed) are inferior to those of other methylotrophs. Thus, no immediate future is seen for these organisms in this capacity. However, PPFM strains have been used in fermentation processes for the manufacture of various coenzymes (coenzyme Q_{10}); amino acids (L-lysine, L-tyrosine, L-phenylalanine and L-glutamic acid); and vitamins (vitamin B_{12}) and as a source of poly-β-hydroxybutyrate (Stirling and Dalton, 1985; Hou, 1984). Their carotenoid pigment, which has been tested as a colorant in the food industry, may also have commercial applications.

The ease with which PPFM strains can be isolated from environmental samples and their (albeit tentative) link with vehicular emissions suggest possible uses for these organisms as environmental pollution indicators. In particular, the ability of some strains to grow in the presence of particulate exhaust material (soot) is interesting. The evidence that a number of these organisms can grow on some of the polycyclic aromatic hydrocarbons and long-chain aliphatic hydrocarbons contained in exhaust emissions (P. N. Green, unpublished observations) suggests a possible role for these bacteria as biological monitors of vehicular pollution.

In addition, several PPFM strains (Ito and Iizuka, 1971) have exhibited resistance to gamma-ray irradiation 10 to 40 times higher than that tolerated by several other Gram-negative bacteria examined and in a similar resistance range to that tolerated by *Deinococcus (Micrococcus) radiodurans* under certain test conditions. This resistance, coupled with their easily identifiable pigmented colonies, may make some PPFM strains suitable candidates for irradiation-quality-control monitoring in the food and packaging industries.

The ability of *M. thiocyanatum* (and probably other *Methylobacterium* strains) to tolerate and degrade relatively high (≥50 mM) levels of cyanate and thiocyanate may have uses in the bioremediation of thiocyanate wastes from various manufacturing processes. Similarly, a use for relevant species in the biological treatment of industrial effluents (e.g. dicloromethane in wastewaters) remains a possibility awaiting further study.

CHAPTER 3.1.14

The Methanotrophs—The Families Methylococcaceae and Methylocystaceae

JOHN BOWMAN

Introduction

Methanotrophs are a group of bacteria possessing a highly specialized metabolism restricted to the utilization of methane and methanol and are a subset of the methylotrophs, bacteria and archaea able to utilize C1 compounds. Methanotrophs are by definition obligately methylotrophic and do not have the ability to grow on organic compounds possessing carbon-carbon bonds. Besides methane, the only other substrate generally utilized by methanotrophs for growth is methanol; however, a few strains can utilize methylamine and a narrow selection of other C1 compounds. Methanotrophs are an integral part of the natural ecosystem, consuming much of the methane that is biogenically (through methanogenesis) and non-biogenically (e.g., from hydrocarbon seeps, natural gas fields and coal mines) derived. This interception of methane helps maintain a balance of atmospheric methane. Methanotrophs can utilize methane as they possess an enzyme called methane monooxygenase (MMO) which occurs, depending on the methanotroph species, either in a particulate (membrane-bound) or soluble (cytoplasmic) form. In a process referred to as dissimilatory methane oxidation, MMO oxidizes methane to methanol and then methanol is further oxidized to formaldehyde, which methanotrophs use for cellular carbon. Excess formaldehyde is oxidized to CO_2 via formate. The pathway also provides cells with reducing equivalents and drives electron transport for generation of ATP. The MMO is a powerful catalyzer of oxidation reactions and has been found able to oxidize a wide range of carbon compounds. This has given methanotrophs a significant biotechnological potential that has been harnessed in applications including bioremediation and industrial processes.

There are two major groups of methanotrophs, Type I and II. Type I methanotrophs are split into two more groups (Type I and Type X). The biology of Type I and Type II methanotrophs differs in phylogeny, chemotaxonomy, internal ultrastructure, carbon assimilation pathways, and certain other biochemical aspects. The differences are summarized in Table 1. The Type I methanotrophs are housed within the family Methylococcaceae which has six genera: *Methylococcus* (the type genus), *Methylocaldum*, *Methylomonas*, *Methylobacter*, *Methylomicrobium* and *Methylosphaera*. The first two genera are also referred to as Type X methanotrophs, and this group is distinguished by certain physiological, biochemical and phylogenetic characteristics. The Type II methanotrophs are grouped in a family called the Methylocystaceae with *Methylocystis* (type genus) and *Methylosinus* as the member genera.

The taxonomy of the methanotrophs, which started with limited descriptions of several species groups, has undergone a series of developments (Whittenbury et al., 1970b). These studies were integral in advancing our understanding of methanotrophs. The subsequent usage of a systematic polyphasic approach (Murray et al., 1990) has resolved methanotrophic intra- and intergeneric relationships (Bowman et al., 1993b; Bowman et al., 1995). However it is clear the inherent biological and physiological diversity of methanotrophs remains untapped, as they appear to be ubiquitous in many environments. With the exploration of novel habitats using increasingly more sophisticated molecular techniques, the isolation of novel methanotrophs is inevitable. Thus, understanding of the role and ecology of methanotrophs and their intrinsic biology is still a highly active research area.

Phylogeny

The use of 16S ribosomal RNA-based phylogenetic analysis (Bratina et al., 1992; Brusseau et al., 1994; Bowman et al., 1995) has helped to resolve many nomenclatural problems which previously affected methanotrophs (Whittenbury and Krieg, 1984). On the basis of 16S rRNA sequence data, Type I methanotrophs belong in the gamma subdivision of the Proteobacteria; however, in most phylogenetic trees based on available sequences, the Family Methylococcaceae is made up of two separate groups (Figure

Table 1. Characteristics of methanotroph types.

Characteristics	Type I Methanotrophs	Type X Methanotrophs	Type II Methanotrophs
Family	*Methylococcaceae*		*Methylocystaceae*
Member genera	*Methylosphaera* *Methylobacter* *Methylomicrobium* *Methylomonas*	*Methylococcus* *Methylocaldum*	*Methylosinus* *Methylocystis*
Resting stages	*Azotobacter*-type cysts (or none)	*Azotobacter*-type cysts	Exospores or lipoidal cysts
Intracytoplasmic membranes	Type I	Type I	Type II
Soluble methane monooxygenase[b]	–[a]	–	+
Carbon assimilation pathway	RuMP	RuMP	Serine
Benson-Calvin cycle enzymes	–	+	–
Major fatty acid carbon chain length	16	16	18
Major quinone	Q-8 or MQ-8	MQ-8	Q-10
Mol% G+C (T_m)	43–60	56–65	60–67
Phylogenetic group (*Proteobacteria*)	Gamma	Gamma	Alpha

[a]Symbols: +, 90% or more of strains are positive; and –, 90% or more of strains are negative. RuMP pathway, ribulose monophosphate pathway.
[b]Absent in most Type I methanotrophs but is present in some strains of *Methylococcus* and *Methylomonas*.

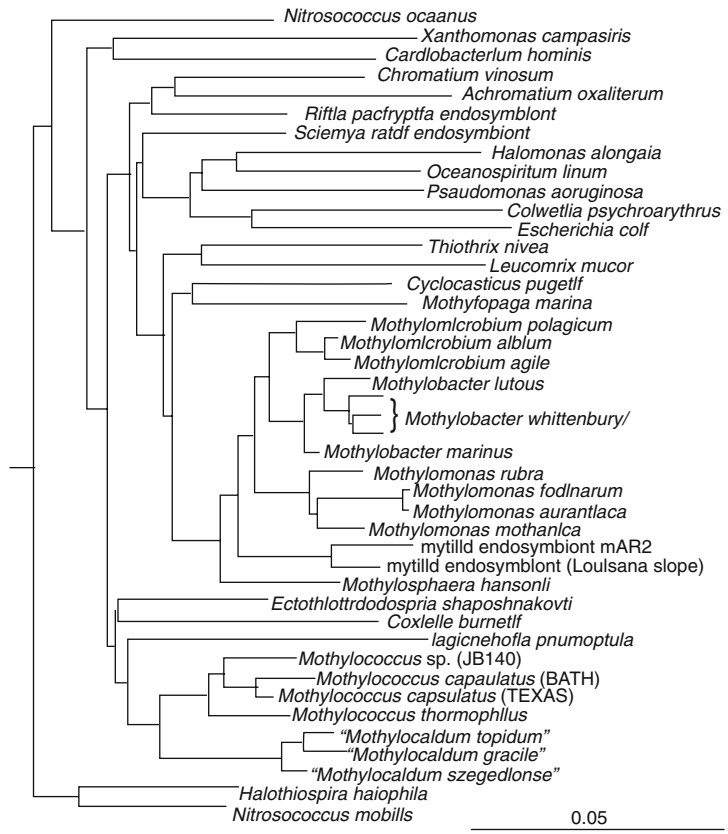

Fig. 1.

1). The first cluster includes the "Type X" methanotrophs—thermotolerant and thermophilic methanotrophs of the genera *Methylococcus* and *Methylocaldum*. This group deeply branches within the gamma subdivision, with the Ectothiorhodospiraceae, Chromatiaceae and Legionellaceae being amongst the closest relatives. The clade is separate from the remaining Type I methanotrophs, with evolutionary distances equal to other interposing genera. The second cluster contains mesophilic and psychrophilic type I methanotrophs, including the genera *Methylomonas*, *Methylobacter*, *Methylomicrobium* and *Methylosphaera*, as well as methanotrophic mytilid endosymbionts. This cluster is most closely related to *Methylophaga*

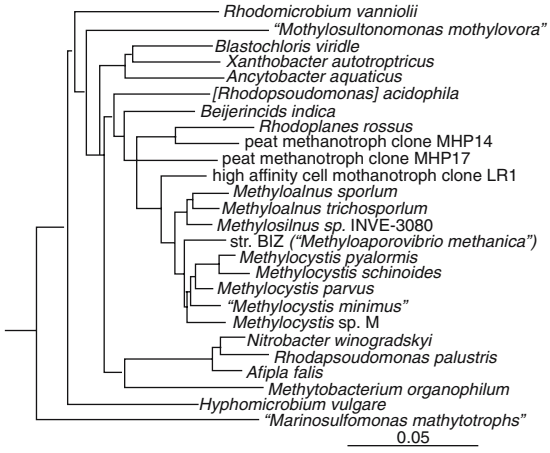

Fig. 2.

and *Cycloclasticus* and various chemoautotrophic endosymbionts.

Phylogenetic analysis based on 16S rRNA assigns *Methylocystis* and *Methylosinus* to the alpha subdivision of the Proteobacteria (Bratina et al., 1992; Brusseau et al., 1994). Owing to the close relationship, *Methylocystis* spp. is not clearly delineated from *Methylosinus* spp. (Figure 2). The Type II methanotrophs are more distantly related to an assemblage of facultatively methylotrophic, nitrogen-fixing and phototrophic bacteria including *Azorhizobium*, *Xanthobacter*, *Ancylobacter*, *Blastochloris*, *Rhodoplanes*, and *Beijerinckia*.

Taxonomy

Family Methylococcaceae

GENUS METHYLOCOCCUS AND GENUS METHYLOCALDUM Both *Methylococcus* and *Methylocaldum* represent the Type X methanotrophs, a subset of Type I methanotrophs with a thermotolerant or thermophilic growth tendency. The type species of *Methylococcus* is *Methylococcus capsulatus*, which was originally described by Foster and Davis (1966) and included strains isolated from sewage sludge. Subsequent numerical taxonomic analyses suggested several of the methanotrophic species groups of Whittenbury et al. (1970b) were related to *Methylococcus*, and new *Methylococcus* species descriptions were later published (Romanovskaya et al., 1978) including the species *Methylococcus bovis*, *Methylococcus chroococcus*, *Methylococcus luteus*, *Methylococcus vinelandii* and *Methylococcus whittenburyi* ("*Methylobacter capsulatus*"). However, later investigations using immunological analysis, protein electrophoresis, fatty acid analysis and genomic characteristics (Andreev and Galchenko, 1978; Galchenko and Nesterov, 1981; Bezrukova et al., 1983; Meyer et al., 1986, Bowman et al., 1991a; Bowman et al., 1991b) clearly demonstrated the genus was made up of two groups. This nomenclatural problem was resolved when only *Methylococcus capsulatus* and *Methylococcus thermophilus* were retained in *Methylococcus* with the description of *Methylococcus* appropriately emended to reflect the change (Bowman et al., 1993b). The other species were transferred to the genus *Methylobacter*, the original name coined for them by Whittenbury et al. (1970b). Other species have been described and include "*Methylococcus fulvus*" (Malashenko et al., 1972), which appears to be a synonym of *Methylobacter luteus* (Romanovskaya et al., 1978), whereas the single strain of the species "*Methylococcus mobilis*" (Hazeu et al., 1980) unfortunately has been lost.

Moderately thermophilic methanotrophs were recently described by Bodrossy et al. (1997) as the genus *Methylocaldum*. This group includes the species *Methylocaldum szegediense* (the type species), *Methylocaldum tepidum* and *Methylocaldum gracile*. The latter species was renamed from "*Methylomonas gracilis*" NCIMB 11128. Bodrossy et al. (1997) noted phenotypic similarity between *Methylococcus thermophilus* and *Methylocaldum* spp., though they appear to be phylogenetically distinct (evolutionary distance ~0.08). However, high levels of DNA:DNA hybridization have been recorded between *Methylococcus thermophilus* IMV-2Yu and *Methylocaldum gracile* NCIMB 11912 (Bowman et al., 1993b). As 16S rRNA sequences for these strains are quite divergent, the 16S rRNA sequence of *Methylococcus thermophilus* needs to be verified.

GENUS *METHYLOMONAS* The type species of the genus *Methylomonas* is *Methylomonas methanica*. The genus was first described officially by Whittenbury and Krieg (1984); however, this species has been known for quite some time as it was first isolated by Soehngen (1906), who named it "*Bacillus methanica*," making it the first recorded methanotroph. Orla-Jenson (1909) subsequently renamed it "*Methanomonas methanica*." Morphologically similar pink-pigmented strains were isolated also from methane:air enrichments of aquatic plants and other freshwater habits and were referred to as "*Pseudomonas methanica*" (Dworkin and Foster, 1956; Leadbetter and Foster, 1958). The name *Methylomonas methanica* was eventually coined by Whittenbury et al. (1970) for isolates very similiar to "*Pseudomonas methanica*," which they enriched from freshwater sediment.

Finally, the species was formally described by Romanovskaya et al. (1978), who at the same time described "*Methylomonas rubra*." Other pink-red pigmented groups of *Methylomonas* described by Whittenbury et al. (1970b) were regarded as variants of *Methylomonas methanica*. However DNA:DNA hybridization and phenotypic studies also suggested "*Methylomonas rubra*" was simply a synonym of *Methylomonas methanica* (Bowman et al., 1990). Additional species with a bright orange pigment isolated from coal-mine drainage water (*Methylomonas fodinarum*) and from sewage sludge and marshy soils (*Methylomonas aurantiaca*) also have been described (Bowman et al., 1990).

During the 1970s, with interest in biotechnology (particularly, the production of single-cell protein) expanding (Anthony, 1982; Hou, 1984), many methylotrophic bacteria were isolated which were grouped in the genus *Methylomonas*. Most of these species were able to utilize methanol and methylamine but not methane. In addition, practically all of these species were clearly misclassified, often lacking formal descriptions. Admittedly at that time, formal taxonomic arrangements were not available for the classification of methylotrophic bacteria. Thankfully most of these nomenclatural problems have now been resolved. Several invalid *Methylomonas* spp. are now recognized as belonging to *Methylobacillus glycogenes* (Urakami and Komagata, 1986b), including "*Methylomonas (Methanomonas) methylovora*" (Kuono et al., 1973), "*Methylomonas methanolica*," "*Methylomonas espexii*," "*Methylomonas methanocatalesslica*," and "*Methylomonas methanofructolica*" (Urakami and Komagata, 1986a). "*Methylomonas clara*" (Faust et al., 1977) has been shown to belong to *Methylophilus methylotrophus* (Jenkins et al., 1987).

A variety of methanotrophs were also grouped in *Methylomonas*, including "*Methylomonas methaninitrificans*" (Davis et al., 1964) and "*Methylomonas methanooxidans*" (Brown and Strawinski, 1958), both of which probably belong to the genus *Methylosinus* (Whittenbury et al., 1970a; Whittenbury et al., 1970b). The species "*Methylomonas margaritae*" (Takeda et al., 1974) and "*Methylomonas flagellata*" (Morinaga et al., 1976) possess traits very similar to those of *Methylomicrobium agile*; however, neither species has extant cultures. The marine species *Methylomonas pelagica* (Sieburth et al., 1987) was initially transferred to the genus *Methylobacter* (Bowman et al., 1993b) and then to the genus *Methylomicrobium* (Bowman et al., 1995).

GENUS *METHYLOBACTER* The representative type species of *Methylobacter* is *Methylobacter luteus*. The genus *Methylobacter* was formed following the emendation of the genus *Methylococcus* (Bowman et al., 1993b), and *Methylobacter* species are equivalent to the similarly named group first coined by Whittenbury et al. (1970b). Two species, *Methylococcus vinelandii* and *Methylococcus chroococcus*, have been shown by DNA:DNA hybridization to be synonyms of *Methylobacter whittenburyi*, while *Methylococcus bovis* is a synonym of *Methylobacter luteus*. Polyphasic taxonomic analyses have further refined the genus; species that cannot form cysts and have different fatty acid profiles were moved into the genus *Methylomicrobium* (Bowman et al., 1995) [RG1]. Recently two species "*Methylobacter psychrophilus*" (Omelchenko et al., 1996) and "*Methylobacter alcaliphilus*" (Khmelenina et al., 1997) were proposed for classification as strains, having been isolated from tundra soil and soda lake habitats, respectively. The genus contains the following validly described species: *Methylobacter luteus*, *Methylobacter whittenburyi*, and *Methylobacter marinus*.

GENUS *METHYLOMICROBIUM* The type species of *Methylomicrobium* is *Methylomicrobium agile* and it includes motile methanotrophs unable to form cysts. This genus was formed after polyphasic taxonomic analyses suggested that a number of *Methylobacter* species possessed sufficiently different traits (i.e., lack of encystment, more rod-like morphology, different fatty acid profile) to warrant the creation of a new genus (Bowman et al., 1995). The genus currently contains two terrestrial species, *Methylomicrobium agile* and *Methylomicrobium album*, and one marine species, *Methylomicrobium pelagicum,* previously called *Methylomonas pelagica* (Sieburth et al., 1987).

GENUS *METHYLOSPHAERA* A psychrophilic nonmotile, non-cyst-forming species from Antarctic lakes was found to form a distinct genus in the Methylococcaceae and is called *Methylosphaera hansonii* (Bowman et al., 1997).

Family Methylocystaceae

GENUS *METHYLOCYSTIS* The type species of the genus *Methylocystis* is *Methylocystis parvus*. The name *Methylocystis* was originally created by Whittenbury et al. (1970b); however, the actual description was published by Romanovskaya et al. (1978). Only *Methylocystis parvus* and "*Methylocystis minimus*" were included in the genus at the time, and several other species including "*Methylocystis methanolicus*," *Methylocystis echinoides* (Galchenko et al., 1977),"*Methylocystis pyreformis*," "*Methylocystis fuscus*" (Galchenko, 1977), and *"Methylocystis fistulosa"*

(Meyer, 1977) were ignored owing to lack of data, lack of a type strain and/or to the possibility that some were mixed cultures. The genus was not included in the Approved Lists of Bacterial Names (Skerman et al., 1980) but was subsequently revived and re-described in 1993 (Bowman et al., 1993b) and now includes *Methylocystis parvus* and the spinate, *Methylocystis echinoides*. Studies using protein electrophoresis (Galchenko and Nesterov, 1981) and immunotyping (Bezrukova et al., 1983) still suggest the diversity in *Methylocystis* is greater than what is currently recognized. Strains designated *Methylocystis echinoides* by Galchenko et al. (1977) were very similar to the strain IC 493S/5 (IMET 10491) of Haubold (1978) according to protein electrophoretic patterns (Galchenko and Nesterov, 1981). The strain IMET 10491 thus subsequently became the type strain of *Methylocystis echinoides* (Bowman et al., 1993b). "*Methylocystis minimus*" IMET 10519 (Whittenbury et al., 1970b; Romanovskaya et al., 1978) has been shown to be a synonym of *Methylocystis parvus* (Bowman et al., 1993b). Strain A of "*Methylovibrio soehngenii*" (Hazeu and Steenis, 1970) is probably just another strain of *Methylocystis parvus* (Anthony, 1982).

GENUS *METHYLOSINUS* The type species of the genus *Methylosinus* is *Methylosinus trichosporium*. As in the case of *Methylocystis*, the name *Methylosinus* was first coined by Whittenbury et al. (1970b) but was not published with a description until Romanovskaya et al. (1978) described the genus and two species, *Methylosinus trichosporium* and *Methylosinus sporium*. The genus was not included in the Approved Lists of Bacterial Names (Skerman et al., 1980) but was subsequently revived in 1993 (Bowman et al., 1993b). A variety of microorganisms have been confused with *Methylosinus* species including "*Blastobacter henrici*," which was misidentified as *Methylosinus trichosporium* (Trotsenko et al., 1989). "*Methylovibrio soehngenii*" strain B (Hazeu and Steenis, 1970) appeared to have a morphology identical to that of *Methylosinus sporium* (Anthony, 1982). Based on morphology, nitrogen-fixing methanotrophic strains designated "*Methylomonas methaninitrificans*" (Davis et al., 1964) and "*Methylomonas methanooxidans*" (Brown and Strawinski, 1958) are probably synonyms of *Methylosinus trichosporium* and *Methylosinus sporium*, respectively (Whittenbury and Krieg, 1984). Based on morphology and 16S rRNA sequences, "*Methylosporovibrio methanica*" strain 81Z (Tsuji et al., 1990) also appears to be equivalent to *Methylosinus sporium*. *Methylosinus*-like strains possessing a brilliant-red prodigiosin-like pigment (Strauss and Berger, 1983) also appear to belong to *Methylosinus sporium*.

Habitats

Methane is the next most important greenhouse gas after CO_2 and is the most abundant organic gas in the atmosphere. Methanotrophs' greatest significance is that they are the largest global methane sink and, as a result, are ubiquitous in nature. The largest and most active populations occur in environments with a stable gas exchange, in which both oxygen and methane are readily and continually available (Oremland and Cuthbertson, 1992; Reeburgh et al., 1993). Research indicates methanotrophs make up a high proportion of the total bacterial biomass in many freshwater aquatic environments, mostly within surface sediments (Boon et al., 1996; Ross et al., 1997). However their predominance in marine ecosystems is relatively unknown. Within these ecosystems methanotrophs represent a part of the basal trophic level and their carbon accumulates in the food web. Biogenic methane derived from methanogenesis is highly ^{13}C-depleted, and stable isotopic analyses indicate that carbon from methanotrophs reflects this. Measurement of ^{13}C isotope also suggests that a considerable proportion of carbon found in aquatic life at different trophic levels can be directly attributable to methanotrophic bacteria (Boschker et al., 1998). In other words, lower trophic levels such as zooplankton graze on methanotrophs and accumulate methanotroph carbon which is naturally ^{13}C-depleted, and as the zooplankton are consumed by higher life forms, this carbon can be traced up the food chain. Most generalist studies on methanotrophs in natural samples have measured methane oxidation rates as a very rough measure of population size and relative activity, however. Studies show in situ methane oxidation rates are affected by numerous biological and physical factors and are reviewed in some detail by Hanson and Hanson (1996).

Habitats in which methanotrophs are common include rice paddies; muddy soils of swamps and marshes; river, pond and lake surface sediments; meadow and deciduous forest soils; activated sewage sludge; some peat bogs; coal mine surfaces and drainage waters. Methanotrophs have in general not been isolated from "extreme" environments such as hypersaline lakes, hot springs and hydrothermal vents, even though some methanogenic archaea are able to grow in these habitats (e.g., *Methanopyrus*). For example, a study of a hypersaline mat environment failed to detect any methanotrophic activity (Conrad et al., 1995). However, methanotrophs have been isolated from Antarctic lakes, soda

lakes and tundra soils (Omelchenko et al., 1996; Khmelenina et al., 1997; Bowman et al., 1997) and thus some species possess psychrophilic and pH-based adaptations. In addition, methanotrophs (mostly of Type II) have been isolated from masonry of old buildings (Kussmaul et al., 1998).

Indirect immunofluoresence studies suggest Type I methanotrophs are common in surface sediments, the water column of various fresh and brackish water environments, and swampy soils (Reed and Dugan, 1978; Saralov et al., 1984; Ambramochkina et al., 1987; Malashenko et al., 1987; Galchenko et al., 1988; Galchenko, 1994). In addition 16S rRNA oligonucleotide signature probes (Brusseau et al., 1994) and isolation studies have demonstrated methanotrophs are associated with the roots and stems of aquatic macrophytes (Hanson et al., 1993; King, 1994; Calhoun and King, 1998). *Methylomonas* and *Methylococcus* spp. are found in significant populations in subtropical muds and swampy soils and in activated sludge (Bowman, 1992). *Methylococcus* and *Methylocaldum* strains have been isolated within and adjacent to thermal areas including thermal muds and springs which have temperatures up to 70°C or so (Malashenko et al., 1975a; Malashenko et al., 1975b; Bodrossy et al., 1997). The species "*Methylobacter psychrophilus*" was isolated from swampy tundra soils (Omelchenko et al., 1996), suggesting populations of methanotrophs in similar high latitude environments could be quite significant. In general little information exists on cold-adapted methane cyclers including both methanotrophs and methanogens. One place where such information does exist is Ace Lake in Eastern Antarctica, a marine-salinity meromictic water body in which methanogenesis occurs in the bottom water column and sediments (Franzmann et al., 1997). The lake supports a population of *Methylosphaera hansonii*, which concentrates in the oxycline of the lake (Bowman et al., 1997). It is possible this organism also may be common in surface sediments of the polar marine environments. Immunofluorescence studies suggest *Methylomicrobium pelagicum* is common in the upper mixing layers of temperate oceanic areas but is much less populous in estuarine waters (Sieburth et al., 1993). Conversely, *Methylobacter marinus* can be isolated from estuarine waters (Lidstrom, 1988). Various Type I methanotroph strains, intolerant to agar media (Lees et al., 1991), have been isolated from seawater off the coast of Britain.

Methylocystis and *Methylosinus* species have been isolated from a variety of soil and freshwater sediment habitats. *Methylosinus* strains tend to be isolated more regularly than *Methylocystis*, possibly because exospore formation makes them hardier. Indirect immunofluorescence studies suggest *Methylocystis* and *Methylosinus* can reach high populations in surface sediments of various freshwater and brackish water bodies (Reed and Dugan, 1978; Ambramochkina et al., 1987; Malashenko et al., 1987; Galchenko et al., 1988; Galchenko, 1994). *Methylosinus* has been found to dominate the culturable methanotroph population of groundwater (Bowman et al., 1993a) and rice paddy soils (Saralov and Babnazarov, 1982). Several strains of Type II methanotrophs have been isolated and detected on the root systems of the various aquatic macrophytes (Calhoun and King, 1998) and have been detected by gene probe methods in blanket peat bogs (McDonald et al., 1996).

Detection Direct plating procedures suggest methanotrophs are only a small proportion of the total viable microbial population in most samples. However direct plating methods are not very ideal for estimating methanotroph populations because of the poor transfer onto agar surfaces (usually less than 10% of cells survive subculture steps) and often rapid overgrowth by contaminating bacteria and fungi. Plating also is not aided by the intolerance to agar found in several methanotrophic strains from marine ecosystems. Most-probable-number counting based on liquid media, though generally labor- and materially intensive, gives a clearer indication of population levels (Bender and Conrad, 1994; Bowman et al., 1997; Escoffier et al., 1997) with the added advantage that methanotrophs can be isolated more easily from the highest dilutions.

Indirect immunofluorescence and ELISA techiques have been used extensively by research groups to detect specific species of methanotrophs, and the method appears useful in gaining a generalized concept of the distribution of methanotrophs (see above; Brigmon et al., 1998).

An alternative approach to detect methanotrophs involves use of specific phospholipid fatty acid (PLFA) biomarkers. For example, the PLFAs 16:1ω8c and 18:1ω8c (Nichols et al., 1985; Bowman et al., 1991a; Guckert et al., 1991) are very useful signatures for the detection and quantification of Type I and Type II methanotrophs, respectively, in environmental samples (Nichols et al., 1987; Sundh et al., 1995; Guezzenec and Fiali-Medioni, 1996; Boon et al., 1996). These fatty acids are practically methanotroph-specific. The detection of signature fatty acids relies on the confirmation of the double-bond geometry and isomeric state using gas chromatography-mass spectrometry. The quantity of the fatty acid also can be used to determine indirectly the biomass of methanotrophs in a given sample. However, a potential limitation

of this method is lack of sensitivity, as methanotroph populations in question must be relatively high (usually >1% of the total population) for lipid biomarkers to be reliably detectable. In addition, some methanotrophs, such as the species of *Methylococcus* and *Methylocaldum*, lack distinctive fatty acid biomarkers.

Nucleic acid oligonucleotide probe methods have been developed to detect methanotrophs in natural samples and have the advantage of detecting methanotrophs that have so far been resistant to cultivation, for example methanotrophic endosymbionts (Distel and Cavanaugh, 1994). Oligonucleotide probes have been developed from 16S rRNA sequences and shown to be specific for Type I and Type II methanotrophs (Brusseau et al., 1994). The method has been used for example to detect methanotrophs closely associated with aquatic plants such as duckweed (Hanson et al., 1993), freshwater lake water and sediment (Boon et al., 1996), peat (Dedysh et al., 1998; Edwards et al., 1998) and soil (Dunfield et al., 1999). A limitation of this method is that it depends on available sequence data and may underestimate populations that are present. To get around this problem gene probes based on methylotrophic functional genes have been developed also (Murrell et al., 1998). These include probes based on conserved genes of MMO and methanol dehydrogenase (McDonald and Murrell, 1997a; McDonald and Murrell, 1997b), which are known to be present in all methanotrophs and methylotrophs. Detection of these genes by PCR amplification has been useful in observing the distribution of methanotrophs in various environments including populations which so far have not been cultivated. For example methanotrophs detected in peat (McDonald et al., 1996) and seawater samples (Holmes et al., 1995b; Holmes et al., 1996) appear to belong to novel phylogenetic lineages distinct from other known methanotrophs. Finally more generalized molecular approaches for examining microbial communities can be applied to methanotroph studies. Jensen et al. (1998) utilized the DGGE (denaturing gradient gel electrophoresis) procedure to compare methane enrichments of agricultural soil and discovered that a number of novel groups of Type II methanotrophs were present. Also using DGGE, Dunfield et al. (1995) found a Type II methanotroph possessing a high affinity for methane and capable of oxidizing atmospheric methane (Bender and Conrad, 1992).

Endosymbionts Methanotrophic endosymbionts coexist with sulfur-oxidizing chemoautotrophic endosymbionts (Childress et al., 1986; Cavanaugh et al., 1987; Fisher et al., 1993) in a variety of unusual invertebrate communities associated with hydrocarbon seeps on the Pacific and Atlantic Ocean floor. Invertebrate hosts include deep-sea mytilid mussels (family Mytlidae; Childress et al., 1986) and the pogonophoran tubeworm *Siboglinum poseidoni* (Schmalijohann and Fluegel, 1987). Also cold water reefs of algae-free coral found in waters north of Norway, also associated with hydrocarbon seeps, are thought to use methane as a major nutrient and thus presumably contain methanotroph symbionts substituting for the algae (Hovland and Judd, 1988). That invertebrates can exist primarily on methane as a carbon source is shown by stable carbon isotope analyses (Southward et al., 1981; Cavanaugh, 1993). Methanotrophs growing in the gills of mytilids have been identified as Type I methanotrophs by the presence of key enzymes of the ribulose monophosphate pathway (RuMP), fatty acids, and hydrocarbons and by 16S rRNA oligonucleotide probes (Distel and Cavanaugh, 1994; Jahnke et al., 1995). Phylogenetic analyses indicate mytilid symbionts form a distinct lineage within the Methylococcaceae (Distel and Cavanaugh, 1994; Figure 1); however, cultivation of methanotroph symbionts has been unsuccessful to date. For more specific information consult the section of *The Prokaryotes* called "Symbiotic Associations between Prokaryotes and Animals" in Marine Chemesynthetic Symbioses in Volume 1.

Isolation and Cultivation

Media, Enrichment and Cultivation Methanotrophs can be enriched, isolated and cultivated in a mineral medium containing an inorganic nitrogen source and high purity methane in the headspace. The nitrate mineral salts (NMS) medium as described by Whittenbury et al. (1970a) is used with only minor modification of the mineral constituents. Nitrate salts are the usual nitrogen source for methanotroph cultivation; however, a low concentration of ammonia salts (<10 mM) can be substituted or used in combination with nitrates. High levels of ammonia are inhibitory to methanotrophs as it competitively inhibits MMO. Adding low levels of copper ensures good growth of all methanotrophs, as the membrane-bound form of MMO (see Physiology section) is a copper-containing enzyme. However, if copper is removed from the medium the isolation of methanotrophs able to form soluble MMO can be enhanced. Phosphates are also necessary for the growth of methanotrophs and in general media require 10–100 mM.

Unless otherwise specified, methanotrophs are always grown under methane. A small amount of sample is added to a liquid NMS medium (see below) in serum vials or in cotton-wool-stoppered flasks placed within air-tight contain-

ers. Agar plates can be incubated easily in containers, such as most desiccators and anaerobic jars, with an inlet tap or valve. An attached pressure gauge can be used if accurate methane additions are needed. Methane can then be added directly to vials and containers by first removing a portion of the headspace. The best methane : air ratio to use is equivocal but should be in a range of 1 : 10 to 1 : 1, as no dramatic difference in growth rates or yields occurs with the different ratios. Methane should be of high purity as natural gas could contain acetylene, which is a suicide substrate of MMO and will prevent growth even at very low concentrations. Static incubation proceeds at an appropriate incubation temperature. Most known species of methanotrophs, including those of *Methylocystis*, *Methylosinus*, *Methylomonas*, *Methylobacter* and *Methylomicrobium*, should be enriched and cultivated at 25–30°C. "*Methylobacter psychrophilus*" and *Methylosphaera hansonii* are psychrophiles, and their enrichment and cultivation should proceed at 2–10°C. In the case of the thermotolerant methanotrophs (*Methylococcus* and *Methylocaldum*), incubation should proceed at about 40–45°C, and depending on the source material, higher temperatures may be required. Enrichments take several days to several weeks, while pure cultures of most methanotrophs will form distinct colonies within 3–5 days. Some slow-growing species, such as *Methylosphaera hansonii*, may take up to 2 weeks to develop visible growth. Growth from the enrichments can then be directly plated onto mineral salts agar plates, which are then incubated under 1:1 methane:air or transferred to fresh liquid media for serial dilution. If samples contain large numbers of methanotrophs, turbidity in the enrichments will develop fairly rapidly (within 3–7 days) and static cultures often can develop a well-defined pellicle of growth, especially if *Methylomonas* species are enriched. For enrichments that rapidily develop turbidity, plating cultures early to achieve maximal biodiversity (if desired) is prudent, owing to the eventual domination of the culture by a single genotype. Unfortunately early plating does not make purification any easier. Pretreatment of samples can aid in the isolation of *Methylosinus* strains as they can be selected by exploiting the inherent heat- and desiccation resistance of their exospores. Soils and other samples should therefore be air-dried first and then heated to 80–85°C for 10–15 min before addition to enrichment media.

Methanotrophs also can be grown on methanol; however, this compound can often be toxic to methanotrophs due to accumulation of formaldehyde (see the Physiology section). Reliable growth on methanol can be achieved by incubating plates or liquid cultures in a sealed vessel containing a methanol-soaked tissue. The volatilized methanol is sufficient for growth. Alternatively, low levels of methanol can be used, though growth may be somewhat limited. Methanotrophs can be "trained" to tolerate higher levels of methanol by gradually building up the level of methanol (starting at 0.025% or so), with some strains able to tolerate levels as high as 5% (v/v). Specific strains of methanotrophs within a restricted number of species may use other C1 compounds (formate, methylamine, dimethylamine and formamide) for growth (see the Identification section).

Nitrate Mineral Salts Medium (NMS medium):

$MgSO_4 \cdot 7H_2O$	1 g
KNO_3	1 g
$Na_2HPO_4 \cdot 12H_2O$	0.717 g
KH_2PO_4	0.272 g
$CaCl_2 \cdot 6H_2O$	0.2 g
Ferric ammonium EDTA	5 mg
Trace element solution	1 ml

Trace Element Solution:

Disodium EDTA	0.5 g
$FeSO_4 \cdot 7H_2O$	0.2 g
H_3BO_3	0.03 g
$CoCl_2 \cdot 6H_2O$	0.02 g
$CuSO_4 \cdot 5H_2O$	0.03 g
$ZnSO_4 \cdot 7H_2O$	0.01 g
$MnCl_2 \cdot 4H_2O$	3 mg
$Na_2MoO_4 \cdot 2H_2O$	3 mg
$NiCl_2 \cdot 6H_2O$	2 mg

Preparation of trace element solution: Add components to distilled water and bring volume to 1 liter. Mix thoroughly. Neutralize pH with KOH.

Preparation of medium: Add components to 1 liter of distilled water (see below) and mix thoroughly. Adjust pH to 6.8 and distribute to culture vessels. If solid media are desired, add agar (Noble agar or agarose may also be used as well) to a concentration of 1.25 to 1.5% (w/v) and boil gently to dissolve the agar. Autoclave at 15 psi pressure (121°C) for 15 min to sterilize.

Artificial Sea Salts:

NaCl	24.32 g
$MgCl_2$	5.143 g
Na_2SO_4	4.06 g
$CaCl_2$	1.14 g
KCl	0.69 g
$NaHCO_3$	0.2 g
KBr	0.1 g
H_3BO_4	0.027 g
$Sr(NO_3)_2$	0.026 g
NaF	0.003 g
Na_2SiO_3	0.002 g
$FePO_4$	0.002 g
NH_4NO_3	0.002 g

Preparation of artificial sea salts solution: Add all components to 1 liter of distilled water and dissolve thoroughly. A slight precipitation of calcium salts may be encountered but will not affect its use in media.

Media modifications: For growth of marine methanotrophs (such as *Methylomicrobium pelagicum* and *Methylosphaera hansoni*), the medium is prepared with sea salts (artificial or natural seawater) instead of distilled water, and pH is adjusted to about 7.5. A few methanotrophs prefer "brackish" media rather than seawater media including "*Methylobacter alkaliphilus*" for which the NMS medium is amended with 2% NaCl and the pH is adjusted to 9.0. The growth of *Methylobacter marinus* requires preparation of NMS medium with tap water and emendation with 1–2% NaCl and, after autoclaving, addition of 1 ml of vitamin solution. Oddly this species will not grow in media prepared with distilled water, even with added NaCl and vitamins.

Vitamin Solution:

Pyridoxine · HCl	10 mg
Calcium pantothenate	5 mg
Nicotinamide	5 mg
Nicotinic acid	5 mg
Riboflavin	5 mg
Thiamine · HCl	5 mg
Biotin	2 mg
Folic acid	2 mg

Preparation of vitamin solution: Dissolve components in 1 liter of distilled water and then filter (0.45-µm or 0.22-µm) sterilize the solution. For long-term storage, the solution should be refrigerated and shielded from light.

Other growth substrates: If methanol is desired it should be added only after the liquid medium has cooled to about room temperature. Agar media should be cooled to about 50°C before addition of methanol. The methanol should be filter-sterilized before use.

About 0.1% (w/v or v/v) formate, formamide methylamine, dimethylamine, trimethylamine, or trimethylamine N-oxide should be added as needed before autoclaving.

Purification One of the most problematic areas of methanotroph study is obtaining pure cultures. In practically all situations methanotroph enrichments are heavily contaminated by non-methanotrophic (often methylotrophic) bacteria, which can easily overgrow and/or predate cultures. That is, predatory bacteria consume the methanotrophic bacteria, thus hampering isolation.

Because methanotrophs are relatively slow growers and plates are incubated in high humidity, fungal contamination is frequent unless containers are thoroughly cleaned with ethanol before each use. Combinations of fungicides such as cycloheximide and nystatin added to the medium are usually quite effective in reducing this problem. Cycloheximide and a suspension of nystatin can be added in a minimal amount of methanol (up to 0.25 ml per liter) to yield final concentrations of 200 U and 100 µg per ml of media, respectively. One approach to obtain pure cultures of methanotrophs is to use a plate microscope to observe colonies at an early stage of development (within 1–3 days). Colonies well separated from others can be picked with a sterile needle or loop and transferred to a clear section of the plate—well away from other developing microcolonies. Several colonies may have to be transferred in this way to obtain one successfully growing colony. It is necessary to make sure that the agar plates are fairly dry and excess liquid enrichment is not transferred onto the plate. This helps restrict the spreading of oligotrophic gliding bacteria and hyphomicrobia, both of which are a particular nuisance as they can rapidly overgrow the methanotroph colonies.

An alternative, rarely employed, straightforward approach to the isolation of methanotrophs utilizes NMS agar media containing a small amount of yeast extract (0.025% w/v) and methanol (0.025% v/v) (Malashenko et al., 1975) with incubation under a methane:air atmosphere. The enrichment cultures are serially diluted onto the media to the point of extinction. The yeast extract and methanol allow contaminants to reach larger colony sizes without affecting the growth of methanotrophs; indeed methanotroph growth may be considerably stimulated. Thus, methanotroph and contaminating bacterial colonies are more clearly visible. Single colonies on the spread plates are then transferred to liquid media. A number of passages from liquid media to spread plates and back to liquid media may be necessary. Several methanotrophs grow poorly or do not grow on agar. In some cases, highly purified agars, such as agar noble, used at lower concentrations may improve growth. Alternatively, silica gel may be used (Galchenko et al., 1975; Galchenko et al., 1977); however, preparation is often difficult and time consuming. For direct purification of these strains, a useful approach involves serially diluting in NMS liquid media in 96-well plastic titer trays (Bowman et al., 1997; Escoffier et al., 1997) as is done in most-probable-number counting experiments. Several strains can be purified in the same tray simultaneously. After sufficient incubation, the wells with the highest dilutions showing growth are examined microscopically. A number of separate transfers and dilutions may be required to obtain morphologically homogeneous cultures.

Some simple checks are necessary to assure the purity of methanotroph cultures. The checks include incubating methanotrophs on NMS agar or in liquid NMS media without methane; no growth should occur. In addition, strains should be plated in a complex organic medium such as nutrient agar (Oxoid or Difco) or R2A agar (Oxoid) and incubated with and without methane; again no growth should occur.

Identification

This section includes fairly detailed information on the morphology, ecophysiology, nutrition,

genotype and chemotaxonomy of methanotrophs (subdivided on the basis of family and genus) and can be used as a guide for identification. The information (unless otherwise indicated) comes from Bowman et al. (1993b). More specific information on metabolism and on physiologically related attributes, such as intracytoplasmic membranes and resting stages, can be found in the Physiology section. Characteristics differentiating the genera of the Methylococcaceae, e.g., Methylococcaceae and the Methylocystaceae, are summarized in Table 2 and Table 3, respectively.

Family Methylococcaceae *Genus Methylococcus* Cells of *Methylococcus capsulatus* are usually spherical and lack flagella. The cell envelope of *Methylococcus* species is typical for Gram-negative bacteria and cells are covered by an exopolysaccharide capsule (Whittenbury et al., 1970a) which often causes cells to clump. Single-bodied spherical cysts similar to those observed in *Azotobacter chroococcum*, but comparatively simpler and less defined in structure, are formed by *Methylococcus capsulatus* and *Methylococcus thermophilus* usually in the stationary growth phase (Whittenbury et al., 1970a; Malashenko et al., 1975b). *Methylococcus* strains also contain granules of poly-β-hydroxybutyrate, which contribute to changes in cell refractility. Cells also may contain polyphosphate (volutin) inclusions. Colonies on NMS agar are circular, convex, and smooth with an entire, even edge and have an off-white to pale tan pigment. *Methylococcus* spp. are thermotolerant or moderately thermophilic with optimal growth temperatures of 40–50°C, with no strains so far found that grow higher than 65°C or below about 25°C. No growth factors are required and the strains are non-halophilic. Some *Methylococcus capsulatus* strains can utilize methylamine, formate and/or formamide as sole carbon and energy sources. However, *Methylococcus thermophilus* strains, the type strain of *Methylococcus capsulatus* ATCC 19069 (strain "Texas"), and the more heavily studied strain ATCC 33009 (strain "Bath") cannot utilize any of these compounds. No carbon-carbon-bonded compounds can be used for growth. Nitrogen sources are usually provided in the form of a nitrate or ammonium salt, though *Methylococcus* strains can use yeast extract, casamino acids and amino acids. In addition, *Methylococcus capsulatus* and most strains of *Methylococcus thermophilus* can fix atmospheric nitrogen using an oxygen-sensitive nitrogenase (Murrell and Dalton, 1983b; Zhivotchenko et al., 1995).

The G+C content of the DNA of *Methylococcus capsulatus* ATCC 19069 has been found (62.5 mol%) using the buoyant density procedure. Analysis of several other strains using the thermal denaturation method found a range of 62 to 65 mol% (T_m). *Methylococcus thermophilus* strains have 59 to 61 mol% G+C (T_m), with the type strain IMV-2Yu possessing 59.1 (T_m; Table 3).

The major fatty acids in *Methylococcus* species have been found to be $16{:}0^{16{:}0}$.

Fatty acid nomenclature: A fatty acid structure can be described as follows. The first digit indicates the number of carbon atoms in the fatty acid. Following the colon, the number indicates the number of double bonds present. Following this a symbol and digit indicate the position of the double bond from the methyl end of the fatty acid and is used to designate bonds from the carboxyl end. Suffixes including "c" and "t" indicate the isomeric form of the fatty acid, with "c" indicating a cis isomer and "t" a trans isomer. Prefixes may also be present to indicate structural modifications of the fatty acid. For example, "i" indicates iso-branching, "a" anteiso-branching, and "cy" that the terminal three methyl units have been cyclized. The prefix "x-OH" indicates the fatty acid is hydoxylated at the x carbon position. Thus, 16:1ω7c is a cis isomer with 16 carbon atoms and a single double bond positioned next to the 7th carbon from the methyl end (for fatty acid nomenclature see footnote). The high levels of 16:0 distinguish this species from psychrophilic and mesophilic Type I methanotrophs. The neutral lipid fraction of *Methylococcus capsulatus* is unusual for a prokaryote, containing squalene, methylated sterols and hopanoids (Bird et al., 1971; Neunlist and Rohmer, 1985). The unusual distribution of cyclic triterpenes and cyclopropane fatty acids (which increase with growth under reduced oxygen tension) are believed to improve the stability of outer- and intracytoplasmic membranes (Jahnke and Nichols, 1986; Jahnke et al., 1992). The major respiratory coenzyme Q in *Methylococcus capsulatus* and *Methylococcus thermophilus* is 18-methylene-ubiquinone-8 (MQ-8; Collins and Green, 1985). Detailed analysis of hydroxy fatty acids from the outer membrane lipopolysaccharide in various *Methylococcus* strains (Bowman et al., 1991a) revealed the major components are 3-OH 10:0, 3-OH 12:0, 3-OH 14:0, and 3-OH 16:0.

Genus Methylocaldum Strains of *Methylocaldum* (Bodrossy et al., 1997) appear as motile, rod-like to coccoidal cells, 0.5–1.2 μm wide and 1.0–1.8 μm long. In logarithmic phase, cells usually appear as short rods; however, in stationary phase, they are quite pleomorphic. Usually, spherical cells are present which possess *Azotobacter*-type cysts typical of other group I methanotrophs such as *Methylococcus*. Cysts

formed may or may not be heat resistant (able to tolerate 80°C for 20 min). In addition, thinner rods may be present in older cultures of *Methylocaldum gracile*. Cells are arranged singly, in pairs and, in the case of *Methylocaldum szegediense* and *Methylocaldum gracile*, in chains. All strains have typical Gram-negative cell walls and some strains may have extensive capsular material, in particular, strains of *Methylocaldum szegediense*. Colonies on NMS agar are circular, convex, smooth or rough, with an entire even edge, often have a cartilaginous consistency, and are pigmented tan to dark brown. At early stages of isolation a diffusible brown pigment is exuded into the agar media; however, this property is lost after repeated subculture.

Methylocaldum strains are obligately methanotrophic, growing best on methane as a sole carbon and energy source. Growth on methanol has not been obtained possibly because cells have a high level of sensitivity to formaldehyde. No growth occurs on other C1 compounds nor any compounds with carbon-carbon bonds. *Methylocaldum* strains can use either nitrate or ammonia as nitrogen sources; however, nitrogen fixation has been found to be absent. The genus includes strains that are mesophilic to thermophilic. *Methylocaldum gracile* and *Methylocaldum tepidum* can grow as low as 20°C and 30°C, respectively, and grow to a maximal temperature of 47°C, with an optimum of about 42°C. *Methylocaldum szegediense* can grow between 37 to 62°C, with an optimal growth temperature of 55°C. In other respects strains are neutrophilic and non-halophilic.

Methylocaldum strains possess mol% G+C values ranging from 56.5 to 57.2. Information on the chemotaxonomic properties is only available for *Methylocaldum gracile*, which overall appears to be similar to *Methylococcus*. The fatty acid profile is dominated by 16:0, 16:1ω7c and, depending on growth conditions, cy17:0. Also, the primary lipoquinone of this species has been found to be 18-methyleneubiquinone-8 (MQ-8; Collins and Green, 1985).

Genus Methylomonas The cells of *Methylomonas* species are regular-shaped rods, which are either straight or slightly curved, and they are also occasionally branched. Cells occur singly, in pairs, and sometimes as chains. All species are motile by a single unsheathed polar flagellum. They possess standard Gram-negative cell walls, well-defined slime capsules, and standard type I intracytoplasmic membranes. Cells contain simple single-bodied cysts similar to but better defined than cysts typically observed in *Azotobacter* and similar to those observed in *Methylococcus* species. In both species, cysts do not confer either desiccation or heat resistance. On NMS agar, colonies are circular, convex, and smooth, possess an entire edge and a creamy consistency and are pigmented either bright pink or orange. The colonies of *Methylomonas aurantiaca* have a more mucoid consistency and often segregate into rough-textured, cartilaginous variants.

Methylomonas spp. are obligate methanotrophs with sole carbon and energy sources restricted to methane and methanol; however, some *Methylomonas aurantiaca* strains also can utilize methylamine and more rarely dimethylamine. Other C_1 compounds that have been tested but are not utilized include formate, trimethylamine and trimethylamine N-oxide. Useable nitrogen sources include nitrate, ammonia, yeast extract, casamino acids, and various amino acids; however, the addition of complex nutrient sources such as yeast extract generally does not lead to growth stimulation and can be growth inhibitory at concentrations over 0.25% (w/v). Most *Methylomonas* strains can form a urease and use urea as a nitrogen source. *Methylomonas fodinarum* and *Methylomonas aurantiaca* are also able to fix atmospheric nitrogen by an oxygen-sensitive nitrogenase, while nitrogenase activity has only been detected in a few *Methylomonas methanica* strains. All *Methylomonas* species have a mesophilic and non-halophilic ecophysiology and grow between 10 and 42°C without the need for growth factors. *Methylomonas fodinarum* strains have temperature optima of about 25–30°C, while *Methylomonas methanica* and *Methylomonas aurantiaca* have temperature optima slightly higher, ranging from 30–35°C. The growth pH range is from 5.5 to 8.5 and best growth occurs at approximately pH 7.0.

The mol% G+C of the DNA of *Methylomonas* ranges from 50 to 59 (T_m). Fatty acid profiles of *Methylomonas* species have been found very similar, with 16:1ω8c, 14:0, 16:1ω7c and 16:1ω5t being the most abundant components. The relatively high levels of 14:0 and 16:1ω8c distinguish *Methylomonas* species from those of *Methylobacter* and *Methylomicrobium*. The fatty acids 16:1ω8c and 16:1ω5t are unusual and, beyond some other Type I methanotrophs, are practically unknown in bacteria and thus make excellent environmental signatures (see Ecology section).

The hydroxy fatty acids from the outer membrane lipopolysaccharide have been analyzed in detail in *Methylomonas methanica*, *Methylomonas fodinarum* and *Methylomonas aurantiaca* (Bowman et al., 1991a). The major component hydroxy fatty acid detected was 3-OH 16:0. Smaller proportions of 3-OH 12:0, 3-OH i13:0, and 2-OH 14:0 were also present, the levels of which vary considerably between the species. The primary respiratory lipoquinone has been identified as MQ-8 (Collins and Green, 1985).

Genus Methylobacter The cells of *Methylobacter* species possess a characteristic elliptical rod-like morphology with a width of 0.8–1.5 μm and a length of 1.2–3.0 μm and occur mostly singly or in pairs; however, chain formation is prevalent in some strains in the late exponential growth phase. *Methylobacter luteus* is nonmotile, while *Methylobacter whittenburyi* strains usually are motile when first isolated but can spontaneously lose the ability after extensive subculture. Motility appears most pronounced in young cultures of *Methylobacter whittenburyi* and *Methylobacter marinus,* with older cultures often devoid of motile cells. Motility is conferred by a single polar flagellum. Cells are surrounded by capsular material detectable by India ink staining, and cell walls are typical of Gram-negative bacteria. *Methylobacter* species form well-defined Azotobacter-type cysts which may give cells a refractile appearance (Whittenbury et al., 1970a). Poly-β-hydroxybutyrate granules tend to form in early log-phase cultures. Colonies on NMS agar are circular, convex, smooth, have an entire edge and possess a creamy consistency. The colonies of *Methylobacter luteus* are pigmented yellow and some strains form a diffusible yellow pigment. Both *Methylobacter whittenburyi* and *Methylobacter marinus* colonies are tanner and slowly exude tan to brown pigments into the agar media.

Methylobacter strains are strictly aerobic obligate methanotrophs with carbon and energy substrates limited to methane and methanol; however, a few strains can also utilize methylamine. Methane appears to be oxidized only by particulate MMO. The presence of soluble MMO (see Physiology section) has not been demonstrated in *Methylobacter* strains so far (Stainthorpe et al., 1991; Stainthorpe et al., 1991; Murrell et al., 1998). *Methylobacter* can utilize nitrate and ammonia salts, yeast extract, casamino acids and various amino acids as nitrogen sources. High levels (>0.5% w/v) of complex organic compounds are inhibitory to their growth. Some strains, particularly those of *Methylobacter luteus*, can produce a urease, but none are known to fix atmospheric nitrogen. *Methylobacter* species are mostly mesophilic, with most strains growing between 15 and 40°C and optimally at about 30°C. However, "*Methylobacter psychrophilus*" (Omelchenko et al., 1996) isolated from tundra is psychrophilic with a growth optimum of about 10°C and growth in the range of 0–20°C. In addition, this species is able to form gas vesicles. Methylobacter species are by nature neutrophilic with the pH range for growth ranging from 5.5 to 9.0 and a pH optimum at about 7.0. An exception is *"Methylobacter alcaliphilus"* (Khmelenina et al., 1997), which was isolated from a soda lake (in the Tuva region of Eastern Siberia) and grows best between 9.0–9.5 and also grows optimally with NaCl levels of 2–4%. Neither *Methylobacter luteus* nor *Methylobacter luteus* strains require growth factors, and they are non-halophilic. The estuarine species *Methylobacter marinus* grows optimally with about 0.1 M NaCl in tap water or with half-strength seawater salts. Some strains of *Methylobacter marinus* require nicotinic acid for growth (Lidstrom, 1988).

The mol% G+C of *Methylobacter* DNA ranges from 46 to 55 (T_m). *Methylobacter* species have very similar fatty acid profiles, with 16:1ω7c predominating and accompanied by lower levels of 14:0, 16:1ω6c, 16:1ω5c, and 16:0. The lack of 16:1ω8c and the relatively low levels of 14:0 and 16:0 distinguish *Methylobacter* from other Type I methanotrophs. The major fatty acids of "*Methylobacter alcaliphilus*" are 16:0, i16:0 and cy16:0, which differs from that of the other *Methylobacter* species (Khmelenina et al., 1997). The fatty-acid and polar-lipid profiles of this species vary considerably when grown under different cultivation conditions including pH and salinity. The outer membrane lipopolysaccharide hydroxy fatty acids have been analyzed in detail in *Methylobacter luteus* and *Methylobacter whittenburyi* (Bowman et al., 1991a). The major components found in *Methylobacter luteus* are 3-OH 10:0 and 3-OH 16:0 plus smaller quantities of 2-OH 12:0, 3-OH 14:0 and 3-OH 15:0, while the major component of *Methylobacter whittenburyi* is 3-OH 16:0, which is almost the only hydroxy fatty acid present. *Methylobacter* spp. contain Q-8 as their major respiratory lipoquinone (Collins and Green, 1985).

Genus Methylomicrobium Cells of *Methylomicrobium* spp. appear as single or paired, regular short rods, 0.5–0.1.5 μm wide and 1.5–2.5 μm long. All species are actively motile, propelled by a single polar flagellum, possess a standard Gram-negative cell wall, and are surrounded by a thin slime capsule. Cells contain type I intracytoplasmic membranes typical of other Methylococcaceae; however, they lack the ability to form cysts. Most strains contain poly-β-hydroxybutyrate and polyphosphate granules. Cells are not

heat- or desiccation resistant and are somewhat sensitive to methane starvation, losing viability in only a few days when exposed to a methane-free atmosphere. Colonies on NMS agar are nonpigmented, circular, convex-flat, and smooth and possess a creamy consistency.

Methylomicrobium strains are strictly aerobic obligate methanotrophs with carbon and energy substrates limited to methane and methanol; however, some strains of *Methylomicrobium agile* can use methylamine, dimethylamine and trimethylamine. Upon isolation most *Methylomicrobium* strains can tolerate and grow quite well on methanol. Methane appears to be oxidized predominantly by a particulate MMO (see Physiology section). The presence of soluble MMO has not been demonstrated in *Methylomicrobium* strains so far. *Methylomicrobium* spp. can utilize nitrate and ammonia salts, yeast extract, casamino acids, and various amino acids as nitrogen sources, though high levels (>0.5% w/v) of complex organic compounds are inhibitory to growth. Urease and nitrigen fixation activity is absent. *Methylomicrobium* species are mesophilic, growing between 10 and 30°C. *Methylomicrobium agile* and *Methylomicrobium album* grow best at 25–30°C, while *Methylomicrobium pelagicum* grows optimally at about 20–25°C. The pH range for growth is 6.0 to 9.0, with optimal growth occurring at about pH 7.0. Neither *Methylomicrobium agile* nor *Methylomicrobium album* requires growth factors, and they are non-halophilic. The marine species *Methylomicrobium pelagicum* grows optimally in media containing either natural or artificial seawater (Sieburth et al., 1987).

The mol% G+C of the DNA of *Methylomicrobium* is relatively broad, ranging from 48 to 60 (T_m). Fatty acid profiles of *Methylomicrobium* species are quite similar and the most abundant components are 16:1ω5c, 16:1ω5t, 16:1ω8c, 16:1ω7c and 16:0 (Table 2). The low levels of 14:0 and abundance of 16:1ω5t and 16:1ω8c distinguish *Methylomicrobium* from *Methylobacter* and *Methylomonas* species. The high levels of the trans fatty acid 16:1ω5t are unusual and do not appear to be due to stressful cultivation conditions. The carbohydrate fraction of the outer membrane lipopolysaccharide in *Methylomicrobium album* includes D-glucose, L-fucose, and D-heptose (Sutherland and Kennedy, 1986). The hydroxy fatty acids from the lipopolysaccharide fraction *Methylomicrobium album* and *Methylomicrobium agile* (Bowman et al., 1991a) are predominantly 3-OH 16:0. The primary respiratory lipoquinone is Q-8, as in Methylobacter spp. (Collins and Green, 1985).

Genus Methylosphaera *Methylosphaera hansonii* strains appear as featureless spherical cells, which exhibit refractility by phase contrast microscopy. Though cells may show signs of uneven binary division, evidence for budding division is still lacking. *Methylosphaera* cells possess standard Gram-negative cell walls and type I ICM when grown under methane; however, cells lack flagella, cysts or other types of resting stages typically found in methanotrophic bacteria. Cells actively accumulate poly-β-hydroxybutyrate, while preliminary electron microscopic examination indicates the presence of gas vesicles (dimensions 0.05–0.1 μm by 0.2 μm; Bowman et al, 1997; Bowman, unpublished data). The species is intolerant to all forms of agar and so far has only been grown successfully in liquid seawater-NMS media.

Methylosphaera hansonii uses methane and methanol as sources of carbon and energy, and no other C_1 or carbon-carbon bonded compound supports growth. Methane monooxygenase activity appears to be restricted to the particulate (pMMO) form with no soluble (sMMO) activity detected by the naphthalene oxidation assay. *Methylosphaera* strains can utilize nitrate, ammonia and L-glutamine for nitrogen; however, yeast extract and casamino acids are less suitable, causing partial inhibition of growth when tested at 0.05–0.1% (w/v) and complete inhibition of growth at concentrations of 0.25–0.5% (w/v). Though strains of *Methylosphaera* cannot form a urease, they can fix atmospheric nitrogen. All strains are psychrophilic with optimum and maximum growth temperatures varying slightly between strains. Optimal growth occurs at 10–15°C, while no growth occurs at 25°C. A doubling time of 20–24 hours was determined for strains growing at or close to their optimum temperature. In NMS-seawater liquid media, growth occurs at pH 6.0–8.0 and a pH of approximately 7.5 is optimal for growth.

The DNA base composition values of *Methylosphaera hansonii* are the lowest among the known methanotrophs, ranging from 43 to 46 mol%. The type strain AM6 (ACAM 549) possesses a mol% G+C of 44.8. The major fatty acids of the genus include 16:1ω8c, 16:1ω7c and 16:1ω6c. The lack of 16:1ω5c and 16:1ω5t is useful in differentiating the species from other Type I methanotrophs.

FAMILY METHYLOCYSTACEAE *Genus Methylocystis Methylocystis* strains typically appear as small, nonmotile kidney bean-shaped or rod-shaped cells (0.8–1.0 μm long, 0.4–0.5 μm wide) which divide by binary division. Several light microscopic photographs of *Methylocystis parvus* can be found in the article by Whittenbury et al. (1970a, 1970b). Cells are in a well-defined polysaccharide capsule. In *Methylocystis parvus* strain OBBP (= ATCC 35066) the capsule is

made up of a viscous exopolysaccharide polymer consisting mainly of D-glucose and L-rhamnose (Hou et al., 1978). *Methylocystis echinoides* strains possess characteristic pericellular prosthecate appendages called spinae (Coombs et al., 1976; Easterbrook, 1989), which have a cylindrical shape, about 300 nm long and 40 nm in diameter, and up to 300 are found on each cell (Suzina and Fikhte, 1977). The rib spacing on the individual spinae has been estimated at 6 to 12 nm (Easterbrook, 1989). The function of the spinae is currently unknown. On NMS agar, *Methylocystis parvus* forms pale pink colonies with a circular shape, convex elevation, smooth creamy consistency, and an entire edge. By comparison *Methylocystis echinoides* grows poorly on agar-solidified media, only producing scant growth and forming white pinpoint colonies, and thus this species should be routinely cultured in NMS liquid.

Methylocystis strains are strict aerobic, obligate methanotrophs that can only use methane and methanol as sole carbon and energy sources and have generation times estimated to be about 4–5 hours when growing in methane (Whittenbury et al., 1970b; Takeda, 1988). *Methylocystis* strains can form catalase, cytochrome c oxidase, and can fix nitrogen using an oxygen-sensitive nitrogenase (Murrell and Dalton, 1983b; Takeda, 1988). *Methylocystis* strains are mesophilic and neutrophilic, with best growth obtained at 25–35°C and at pH ranges of 6.5–7.5. Strains will grow at 10–40°C, with poor to moderate growth occurring at 37°C, and at pH 6.0–9.0. All *Methylocystis* strains are non-halophilic and completely inhibited by 2–3% (w/v) NaCl.

The mol% G+C of the DNA of *Methylocystis parvus* ranges from 63 to 67 (T_m), while the values for *Methylocystis echinoides* are slightly lower, ranging from 61 to 62 (T_m).

Methylocystis species possess a fatty acid profile consisting of mainly 18:1ω8c, 18:1ω7c and 18:0, with smaller amounts of cyclopropane fatty acids (Table 3). The profile is very similar to that of *Methylosinus*, differing only in the greater abundance of 18:0 and lower level of 16:1ω7c. The fatty acid 18:1ω8c is an unusual feature found almost exclusively in the Methylocystaceae, as it is very rarely encountered in other prokaryotes. The major lipopolysaccharide-derived hydroxy fatty acids include 3-OH 14:0 and 3-OH 18:0. In addition, *Methylocystis* species also possess unusual ω-1 hydroxy fatty acids with carbon chain lengths of 26 and 28 (Skerratt et al., 1992) making up about 15% of the total hydroxy fatty acids. These hydroxy acids have been previously detected in freshwater sediments (Mendoza et al., 1987), and *Methylocystis* and *Methylosinus* represent the first recognized biological sources of these particular lipids. *Methylocystis* species contain a suite of polar lipids, which vary slightly between strains due possibly to cultivation conditions (Makula, 1978; Andreev and Galchenko, 1983; Andreev and Galchenko, 1983). Polar lipids are present and include: phosphatidylethanolamine, phosphatidylglycerol, diphosphatidylglycerol, phosphatidylmethylethanol-amine, phosphatidyl-N, N-dimethylethanolamine and lysophosphatidylglycerol. The major quinone (Collins and Green, 1985) of *Methylocystis* species is Q-8.

Genus Methylosinus Strains of *Methylosinus trichosporium* have a pear-shaped to rod-like morphology with a width of 0.5–1.5 μm and a length of 1.5–3 μm. By comparison, *Methylosinus sporium* strains are of similar size but have a vibrioidal morphology. When grown in liquid media, both species form rosettes consisting of 4–6 cells. Several photomicrographs of the morphology of *Methylosinus* species have been published by Whittenbury et al. (1970a, 1970b). In logarithmic phase, cells divide by standard binary division; however, when cultures enter the stationary growth phase, an increasing proportion of cells reproduce by budding-off exospores as either rosettes or individual cells. Once sporulated, the mother cell ceases to divide or bud, becomes granulated and eventually lyses. Sporulating cells produce an extensive capsule compared to vegetative cells (Whittenbury et al., 1970a) (see Physiology section for more details on exospores). *Methylosinus* strains produce poly-β-hydroxybutyrate as an internal carbon reserve (Weaver et al., 1975; Best and Higgins, 1981) and have standard Gram-negative cell walls. However unlike most other Gram-negative bacteria, *Methylosinus* strains are very resistant to lysis by detergents (such as sodium dodecyl sulfate) and to lytic bacteria (Starostina and Pashkova, 1993). Lysozyme pretreatment (1 mg/ml at 37°C, for 30–60 min) followed by addition of 2% sodium dodecyl sulfate can force cell lysis. Colonies on NMS agar are nonpigmented, circular, and convex and have a smooth creamy texture and even entire edge. Some strains of *Methylosinus sporium* may form a brilliant-red prodigiosin-like pigment.

Methylosinus strains are strictly aerobic and obligately methanotrophic, and the only carbon and energy sources supporting growth are methane and methanol. All strains produce catalase and cytochrome c oxidase. Nitrate and ammonia salts, amino acids, yeast extract and casamino acids can be used as sources of nitrogen (Warner et al., 1983; Toukdarian and Lidstrom, 1984b). In addition, *Methylosinus* spp. are capable of fixing atmospheric nitrogen using an oxygen-sensitive nitrogenase (Murrell and Dalton, 1983b) which appears to be similar to the *Methylocystis* spp. enzyme. *Methylosinus* strains are mesophilic and

neutrophilic and grow at 10–40°C and pH 5.5–9.0. Optimal growth occurs at about 30°C and at pH 6.5–7.0. Most strains will not grow or grow poorly in presence of more than 0.3M NaCl and no strains have been found to require growth factors.

The DNA of *Methylosinus* strains have mol% G+C values ranging from 62 to 67 (T_m). *Methylosinus trichosporium* strains possess values of 62–63 (T_m), while *M. sporium* strains have values of 65–67 (T_m). *Methylosinus* species possess phospholipid fatty acids consisting mainly of 18:1ω8c, 18:1ω7c and 16:1ω7c with smaller amounts of 18:0 and cyclopropane fatty acids. The profile is very similar to that of *Methylocystis* but differs only by having more 16:1ω7c and less 18:0. The major lipopolysaccharide-derived hydroxy fatty acids include 3-OH 14:0, 3-OH 16:0 and 3-OH 18:0 (Bowman et al., 1991a). In addition, about 15% of the total hydroxy fatty acids of *Methylosinus sporium* are unusual ω-1 hydroxy fatty acids with carbon chain lengths of 26 and 28 (Skerratt et al., 1992). The neutral sugar components of the LPS oligosaccharide core in *Methylosinus trichosporium* OB3b include mostly rhamnose, glucose and heptose (Sutherland and Kennedy, 1986). *Methylosinus* spp. contain a suite of phospholipids (Makula, 1978; Andreev and Galchenko, 1983) including phosphatidyldimethylethanolamine, phosphatidylglycerol, phosphatidylmethylethanolamine, phosphatidylcholine and lysophosphatidylglycerol. The major quinone of *Methylosinus* is Q-8 (Collins and Green, 1985).

Preservation

Viability of most methanotrophs on plates or in liquid cultures is lost in a week or so, when they are deprived of methane. This is particularly true for cystless methanotrophs such as species of *Methylomicrobium* and *Methylosphaera* and also *Methylomonas* spp., for unknown reasons. However when placed under a 1 : 1 methane : air atmosphere plate or slant cultures, methanotrophs can be stored for several months at 4°C. Takeda (1988) found the shelf-life of type II methanotrophs was enhanced to over 12 months if cultures were kept in a 100% nitrogen atmosphere. *Methylocystis* and *Methylosinus* strains are amenable to cryopreservation (using 20% v/v dimethylsulfoxide or 20–30% v/v glycerol as a cryoprotectant) and to freeze drying (using 20% w/v skim milk or 10% v/v horse serum as cryoprotectant). Most Type I methanotrophs unfortunately do not survive freezing well (Nesterov et al., 1986). Cryopreservation with 20–30% glycerol may be used in most cases; however, vials must be replaced quite regularly (once every 1–2 months), which limits this method's usefulness. Type I methanotrophs can be kept more successfully in liquid nitrogen; however, recoverability usually becomes problematic after 6 months.

Physiology and Genetics

Detailed aspects of the genetics of methanotrophs as well as the biochemistry of the oxidation of methanol (and other C1 compounds) are covered in the chapter "Aerobic Methylotrophic Prokaryotes" in Volume 2. This section details the major physiological characteristics of obligate methanotrophs.

Metabolism

Methanotrophs possess a strictly aerobic metabolism, which uses C1 compounds. Most methanotrophs are limited to methane and methanol as substrates; however, a few species can utilize other C1 compounds including formate and methylamine. In some strains, complex carbon sources can be used as a source of carbon by methanotrophs grown in the presence of methane. In some cases this results in significant growth stimulation (Whittenbury and Dalton, 1981).

Methanotrophic strains can grow over a wide range of oxygen concentrations (<0.5% to 60% v/v) and are not microaerophilic, as has been suggested in some previous studies. Only when oxygen levels drop below 0.5% does growth become limiting (Ren et al., 1997) and in some species, significant growth still takes place at <0.1% oxygen. The work of Takeda (1988) and more recent research (Roslev and King, 1994; Roslev and King, 1995) have shown methanotrophs can survive anoxia for several months (presumably due to resting cell formation) and can rapidly respond when methane and oxygen once again become available.

Resting Stages

Cyst Formation within the Methylococcaceae. Single- or multibodied spherical cysts, similar to those in *Azotobacter* species, develop in stationary growth phase cultures of *Methylobacter* and *Methylobacter*-like species (Whittenbury et al., 1970a; Malashenko et al., 1975b; Hazeu et al., 1980). Increased cyst formation is usually associated with increasing cell refractility and increased (tan) pigmentation of colonies. The cysts appear to confer some advantages to cells experiencing deprived conditions (such as lack of methane availability and drying), and thus the cysts are able to survive desiccation for several weeks. However the cysts do not confer heat resistance such as that provided by the exospores of *Methylosinus* species. In other Type I methanotrophs (*Methylomonas*, *Methylococcus* and *Methylocaldum* species), cyst formation is not as profuse as has been found in species of *Methylobacter* nor are cysts (appearing as single bodies) as well defined or as resistant to

dessication. Moreover, cysts contain glucan-type polysaccharides, which may act as an endogenous source of energy (Sutherland and MacKenzie, 1977). Cysts can be visualized by light microscopy by using a stain developed for Azotobacter- type cysts (Vela and Wyss, 1964).

Lipid Cysts of *Methylocystis.* In stationary growth phase, a proportion of *Methylocystis parvus* cells (but not its sister species *Methylocystis echinoides*) becomes refractile and more coccoid, eventually forming lipoidal cysts. These cysts are different from glucan-rich Type I methanotroph cysts by containing mostly poly-β-hydroxybutyrate and also possess a degree of desiccation resistance but no significant heat resistance.

Exospores of *Methylosinus.* As cultures enter the stationary growth phase, an increasing proportion of cells reproduce by budding-off exospore resting stages either when the cells are arranged in rosettes or by individual cells. When spores appear they are initially nonrefractile, Gram-negative, coccoidal bodies at the end of sporulating cells and as spores mature, they become increasing refractile and acid-fast. The malachite green spore stain (Doetsch, 1981) can be used to visualize mature spores. Thin sections show that exospores consist of an electron-dense outer coat (exosporium) surrounded by a cell wall derived from the parent cell. *Methylosinus trichosporium* exospores possess a capsular coat, attached to the exosporium but distinct from the parent cell's capsular layer (Reed et al., 1980). Within the exospore, there is a laminated inner coat and a poorly defined cortex (Reed et al., 1980; Dugan et al., 1982) lacking dipicolinic acid (a chemical present in the spores of Gram-positive bacteria) and no detectable respiratory activity. Exospores are resistant to desiccation, surviving 18 months of drying, and can also withstand heating at 85°C for 10 min and 10 min of ultrasonication.

Intracytoplasmic Membranes Methane oxidation usually takes place in methanotrophs within membrane systems referred to as intracytoplasmic membranes (ICM), which appear as a series of intracellular elaborate membrane folds that can be readily observed by electron microscopy. Intracytoplasmic membranes occur in two major ultrastructural forms. In Type I methanotrophs, ICM appear as a series of laminations or vesicular arrangements of the cytoplasmic membrane crossing the cell horizontally. In Type II methanotrophs, the ICM occur along the periphery of the cell wall and encloses a distinct lumen. Intracytoplasmic membranes are formed best when methanotrophs grow on methane, but ICM form to a lesser extent when methanotrophs grow on methanol (Best and Higgins, 1981). The amount of ICM increases in proportion to methane oxidation rates, acting to increase available surface area for the oxidation of methane. The affinity of methanotrophs to methane appears to vary with growth conditions, changing by greater than an order of magnitude (K_m 0.05→1 μM). The shifts in affinity are linked to the concentration of MMO within cells and changes in the relative levels of ICM (Dunfield et al., 1999). Methanotrophs in natural habitats experiencing low fluxes of methane are thus able to cope by maximizing methane-oxidizing efficiency. Methanotrophs experiencing oxygen limitation exhibit a reduction in ICM (Scott et al., 1981), while ICM synthesis is inhibited by removing copper from the medium (Prior and Dalton, 1985), which is linked to the concomitant repression in the synthesis of pMMO (see below).

Dissimilatory Methane Oxidation This pathway results in the oxidation of methane to CO_2 and is used by methanotrophs to generate energy and obtain carbon for biosynthesis. The first step of the pathway involves the oxidation of methane to methanol. Methanol is then oxidized to formaldehyde, the compound through which methanotrophs obtain the majority of their cellular carbon. A proportion of the formaldehyde is oxidized to formate and then to CO_2. In these latter steps, reducing power in the form of $NAD(P)H_2$ is generated and is used by methanotrophs to power electron transport and ATP synthesis. Only the first step of this pathway is dealt with in detail in this section, as the oxidation of methane to methanol is central to the growth of methanotrophs. The biochemistry and genetics of the remaining steps of the pathways are described in the chapter "Aerobic Methylotrophic Prokaryotes" in Volume 2.

Methane Monooxygenase (E.C.1.14.13.25) Methane monooxygenase (MMO) is the enzyme responsible for the oxidation of methane to methanol. It does this by incorporating a single atom of oxygen and the reaction has the following stoichiometry (Dworkin and Foster, 1956):

$$CH_4 + NAD(P)H_2 + O_2 \rightarrow CH_3OH + NAD(P^+) + H_2O$$

Particulate Methane Monooxygenase (pMMO). Two types of MMO have been found in methanotrophs; however, all methanotrophs possess pMMO—a copper-containing enzyme which is tightly bound within the ICM. Particulate MMO has an active site which includes copper and in the presence of copper limitation, pMMO synthesis is repressed, resulting in reduced growth yields on methane (unless the methanotroph possesses sMMO) and in

reduced ICM development. Previously it was found that the *amoA* gene, which codes for the active subunit of ammonia monooxygenase, hybridizes to methanotroph DNA (Semrau et al., 1995). Using *amoA* as a probe, the genes for pMMO were isolated and sequenced (Semrau et al., 1995) in three methanotrophs (*Methylococcus capsulatus*, *Methylomicrobium album* and *Methylosinus trichosporium)*. In each of these species pMMO contains two subunits, coded by *pmoA* and *pmoB* (45- and 27-kDa, respectively), which are present in duplicate gene copies in methanotrophs. The *pmoA* gene product has considerable amino acid sequence similarity to *amoA* product and the genes are believed evolutionarily related (Holmes et al., 1995a).

Soluble Methane Monooxygenase (sMMO) Some methanotrophs can form a soluble, membrane-free, form of MMO, sMMO. Soluble MMO is distributed irregularly amongst the methanotrophs and has been detected so far in most *Methylosinus* strains (Bowman et al., 1993a), some strains of *Methylocystis* (McDonald et al., 1997), *Methylococcus capsulatus* (i.e., strain ATCC 33009; Brusseau et al., 1990), and *Methylomonas methanica* (Koh et al., 1993). This enzyme has engendered considerable research interest owing to its enormous lack of substrate specificity. More than 250 known compounds of many different structural types (ranging from alkanes to heterocyclic compounds) can be oxidized by sMMO. This versatility has suggested a potential role for sMMO in bioremediation and industrial applications (see Applications section). Soluble MMO consists of three proteins including a non-heme hydroxylase, a ferredoxin-like reductase, and a regulatory coupling enzyme, with the separate proteins coded by a single gene cluster. The *mmo* operon has been characterized and sequenced in both *Methylococcus capsulatus* (Bath) (Stainthorpe et al., 1990) and *Methylosinus trichosporium* (OB3b) (Cardy et al., 1991). The hydroxylase component is a dimer of three separate subunits and has a non-heme di-iron active site (Nordlund et al., 1992). It is the unusual nature of this active site that is responsible for the potent oxidative nature of sMMO. The individual subunits are coded by *mmoX*, *mmoY* and *mmoZ*, respectively. The 3-dimensional structure of the non-heme hydroxylase enzyme has been resolved (Rosenzweig et al., 1993). The ferrodoxin-like reductase enzyme (coded by *mmoA* and *mmoC*) transfers electrons to the hydroxylase for the catalysis of methane oxidation. The coupling protein, coded by *mmoB*, links the reductase and the hydroxylase. It is thought this enzyme has a regulatory role, decoupling the hydroxylase and reductase possibly when formaldehyde reaches a critical level. Soluble MMO synthesis in methanotrophs is repressed in the presence of copper (at levels as low as 50 nM) with concurrent increased synthesis of pMMO, and thus it is thought sMMO may have evolved in conditions of copper limitation (Hanson and Hanson, 1996). Limitation in copper may arise from chelation, adsorption and complexation processes, especially with various organic compounds. Copper-limited environments such as groundwater are often dominated by sMMO-producing methanotrophs (Bowman et al., 1993a). When growing methanotrophs for the purpose of making sMMO, all glassware and media should be free of trace copper ions. Soluble MMO can be readily detected by the naphthalene oxidation assay (Brusseau et al., 1990; Graham et al., 1992), by gene probe (for example using regulatory gene, mmoB; Stainthorpe et al., 1991), or by PCR using specific primers (McDonald et al., 1995; Murrell et al., 1998). The genes for both pMMO and sMMO are genetically distinct (Martin and Murrell, 1995); however, they have a common copper-inducible regulatory pathway (Neilsen et al., 1997).

Carbon Assimilation Pathways Methanotrophs fix carbon in the form of formaldehyde, which is rapidly cycled owing to its high toxicity. Formaldehyde is fixed by two different pathways in methanotrophs: the ribulose monophosphate (RuMP) pathway used by Type I methanotrophs and the serine pathway used by Type II methanotrophs (Anthony, 1982; Hanson and Hanson, 1996). By assaying the key enzymes of these pathways, Type I and II methanotrophs may be distinguished. In the case of the RuMP pathway, the key enzyme is hexulose phosphate synthase, whereas in the serine pathway the key enzyme is hydroxypyruvate reductase. More details on these pathways can be found in the chapter "Aerobic Methylotrophic Prokaryotes" in Volume 2.

Nitrogen Metabolism Most methanotrophs assimilate ammonia and nitrate by the glutamine synthetase-glutamine 2-oxoglutarate aminotransferase system (Shishkina and Trotsenko, 1979; Murrell and Dalton, 1983a; Toukdarian and Lidstrom, 1984b). Methanotrophs also can assimilate nitrogen from amino acids and other complex mixtures such as yeast extract. In addition, many methanotrophs are able to fix atmospheric nitrogen and include all Type II methanotrophs and various members of the Type I methanotrophs, including *Methylomonas* spp., *Methylococcus capsulatus*, and *Methylosphaera hansonii*. In most cases the nitrogenase formed is oxygen-sensitive (Murrell and Dalton, 1983b;

Takeda, 1988; Zhivotchenko et al., 1995), except for *Methylosphaera hansonii*, which appears to possess a more oxygen-tolerant enzyme (Bowman et al., 1997). In the case of methanotrophs with oxygen-sensitive nitrogenase, reducing the oxygen partial pressure in the headspace enhances growth on agar under nitrogen-free conditions; however, oxygen concentrations over 10% will abolish nitrogenase activity almost completely (Zhivotchenko et al., 1995). A number of homologs of *nifH* have been shown in strains such as *Methylomonas methanica*, which appeared unable to fix nitrogen in vitro (Oakley and Murrell, 1988). Southern blotting indicates the *nif* genes of various methanotrophs are homologous with each other and genes of *Klebsiella pneumoniae* (Toukdarian and Lidstrom, 1984a; Oakley and Murrell, 1988).

Applications

Methanotrophs have been considered as cheap sources of single-cell protein (Anthony, 1982) and poly-beta-hydroxybutyrate (a natural polymer; Hou, 1984; Wendlandt et al., 1998). However most biotechnologically directed studies of methanotrophs have focused on the capability of sMMO from *Methylosinus trichosporium* OB3b to co-oxidize a wide range of carbon substrates. The compounds oxidized are too many to list but include a wide range of aliphatic, heterocyclic and aromatic compounds (Burrow et al., 1984). Several studies have focused on the industrial applications of this biocatalytic ability, in particular in the production of epoxides for plastics manufacture (Hou, 1984), but the primary focus of research has been in the bioremediation field, and this aspect has been reviewed extensively (Sullivan et al., 1998). *Methylosinus trichosporium* OB3b and other strains forming sMMO can co-metabolize a range of chlorinated aliphatic compounds including major groundwater pollutants such as trichloroethylene, chloroform and tetrachloroethylene (Oldenhuis et al., 1989; Tsien et al., 1989; Castro et al., 1996; Hamamura et al., 1997; Moran and Hickey, 1997; Tartakovsky et al., 1998). However, the industrial application of methanotrophs has been hampered by their relatively slow growth and requirement for methane, a potentially explosive substrate which also competitively inhibits co-metabolic reactions. Another problem is that trace copper levels can suppress sMMO activity, thus eliminating or reducing transformation rates (Oldenhuis et al., 1989; Lontoh and Semrau, 1998). To overcome this, constitutive mutants lacking sMMO activity suppression [RG7] have been created by chemical mutagenesis and by marker exchange (Phelps et al., 1992; Fitch et al., 1993; Martin and Murrell, 1995; Tellez et al., 1998). These mutants have been shown to be able to co-metabolize trichloroethylene in the presence of high levels of copper. Some of these copper-tolerant mutants have been utilized in treatments of chlorinated aliphatic pollutants (Tschantz et al., 1995). In addition, the sMMO gene cluster has been successfully cloned into *Pseudomonas putida* F1, which is not only able to degrade trichloroethylene but can grow much faster and lacks the problem associated with methane competitive inhibition (Jahng and Wood, 1994; Jahng et al., 1996).

CHAPTER 3.1.15

The Genus *Xanthobacter*

JUERGEN WIEGEL

Introduction

Strains of *Xanthobacter autotrophicus*, the type species, were originally described as *Corynebacterium autotrophicum* (Baumgarten et al., 1974) and as "Gram-positive Knallgas bacteria." They became of interest when Gogotov and Schlegel (1974) found that a strain named "7c" could grow chemolithoautotrophically and use molecular nitrogen (N_2) as nitrogen source, a property otherwise not known to exist in other bacteria. Ooyama (1971) had, however, published on N_2-fixing chemolithoautotrophic new isolates from Japan, but his publication in a non-mainstream journal did not receive much attention and his strains were never formally described. However, on the basis of the described properties, these isolates were probably *Xanthobacter* strains. De Bont and Leijten (1976b) observed similar properties with their isolates from The Netherlands. This initiated the isolation of more than 50 strains (Wiegel and Schlegel, 1976) later recognized as members of the novel genus *Xanthobacter* (with the type species *X. autotrophicus*; Wiegel et al., 1978b) on the basis of numerical taxonomy, Gramnegative staining reaction, and Gram-type negative classification (Wiegel and Mayer, 1978a). (For a definition of the term "Gram type," see Wiegel [1981] and Wiegel and Quandt [1982b].) The second recognized *Xanthobacter* species was also reported previously as an N_2-fixing heterotroph, *Mycobacterium flavum* strain 301 (Biggins and Postgate, 1969), which was subsequently renamed as the type strain of *X. flavus* (Malik and Claus, 1979).

Presently the following species have been recognized and validly published (Euzéby, 2004): *Xanthobacter autotrophicus* (type species; Wiegel et al., 1978b), *X. flavus* (Malik and Claus, 1979), *X. agilis* (Jenni and Aragno, 1988), *X. tagetidis* (Padden et al., 1997), *X. aminoxidans* (Doronina and Trotsenko, 2003), and *X. viscosus* (Doronina and Trotsenko, 2003; Table 1). In addition, "*X. polyaromaticivorans*" (Hirano, 2004) and "*X. methylooxidans*" strain 32P (Doronina et al., 1996) have been published but not validated.

All validly published members of the genus *Xanthobacter* are yellow Gram staining reaction negative and Gram-type negative pleomorphic rods containing the water insoluble yellow zeaxanthin dirhamnoside. However, "*X. polyaromaticivorans*" is slightly pinkish orange, which (based on the absorption peak at 473 nm) is probably due to a zeaxanthin but with different (yet to be confirmed) terminal substitutions. Owing to high concentrations of polyphosphate granula (see below), some species and strains give the appearance of staining Gram-positive.

Xanthobacter belongs phylogenetically to the family Hyphomicrobiaceae in the class Alphaproteobacteria. The relationship to the genera *Aquabacter* and *Azorhizobium* is not clear at this time (see below). The genomic G+C content is 60–70 mol%. Cells are pleomorphic rods that can become highly irregular, multibranched or twisted (e.g., *X. tagetidis*). The degree of pleomorphism depends on the species and the substrates on which they are grown (Figs. 1–4).

All known strains of *Xanthobacter* can obtain energy from the reaction $2H_2 + O_2 \rightarrow 2H_2O$ and fix CO_2 for carbon sequestering. Therefore, they belong to the group called "hydrogen-oxidizers" or "Knallgas bacteria" (see The H_2-Metabolizing Prokaryotes in Volume 2). *Xanthobacter* species are generally also methylotrophic. They grow well organoheterotrophically under aerobic or microaerophilic conditions with acids, alcohols, and selectively with carbohydrates as energy and carbon source. Carbohydrate utilization varies but is frequently restricted to the utilization of not more than three of the following: fructose, galactose, mannose and sucrose; some do not use any hexoses and pentoses (e.g., *X. autotrophicus* strain 14g, all strains of *X. agilis* and "*X. polyaromaticivorans*"). The ability to utilize mannose depends on growth conditions and is not always reproducible in taxonomic tests. For most strains, glucose is not a preferred substrate, but many strains of the type species tested could be adapted to utilize glucose as growth substrate through extended incubation in glucose-containing medium; however, the ability to grow

Table 1. Differential characteristics of the species of the genus *Xanthobacter*.[a]

Characteristics	1.	2.	3.	4.	5.	6.	7.	8.
Cell morphology: pointed ends, twisted	–	–	–	+	+	+	+	–
Highly pleomorphic on nutrient broth agar + succinate (TCA-cycle intermediates)	+	+	–	+	nd	nd	nd	nd
Asymmetric cell division ("budding")	–	–	–	–	+	+	–	–
Excessive slime production	+	+	–	(+)	–[b]/+	+	+	(–)

[b]Slime production in glucose.

[c]Pale yellow indicating low concentration.

[d]Under some conditions, tumbling is observed using phase contrast microscopy, but when grown on propanol, cells are motile (strains 7C and 301).

[e]Strain 14p1 does not degrade various aromatic compounds.

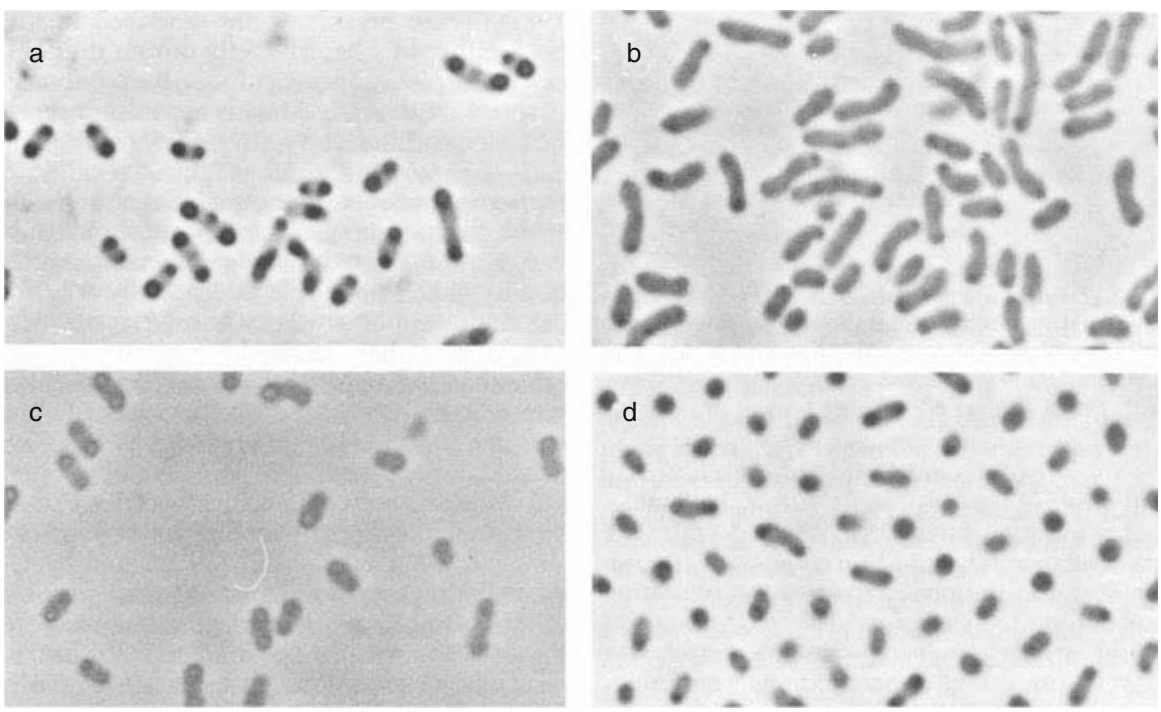

Fig. 1. Phase contrast photomicrographs of *X. autotrophicus*. Reference strain JW 33 a) to c) grown on various substrates in mineral medium plus 0.1% ammonium chloride. Growth conditions were: a) 0.5% fructose; b) autotrophically, 80% H_2 + 10% CO_2 + 10% O_2; and c) 0.2% propanol. d) Strain JW-KR-R10/47 isolated from rice roots, grown on rice roots in sterile sand and half-strength Hoagland's medium in the presence of nitrate. However, no significant changes where observed when grown under similar conditions but in the absence of nitrate. Phase contrast light microscopy. (All photos courtesy of K. Reding.)

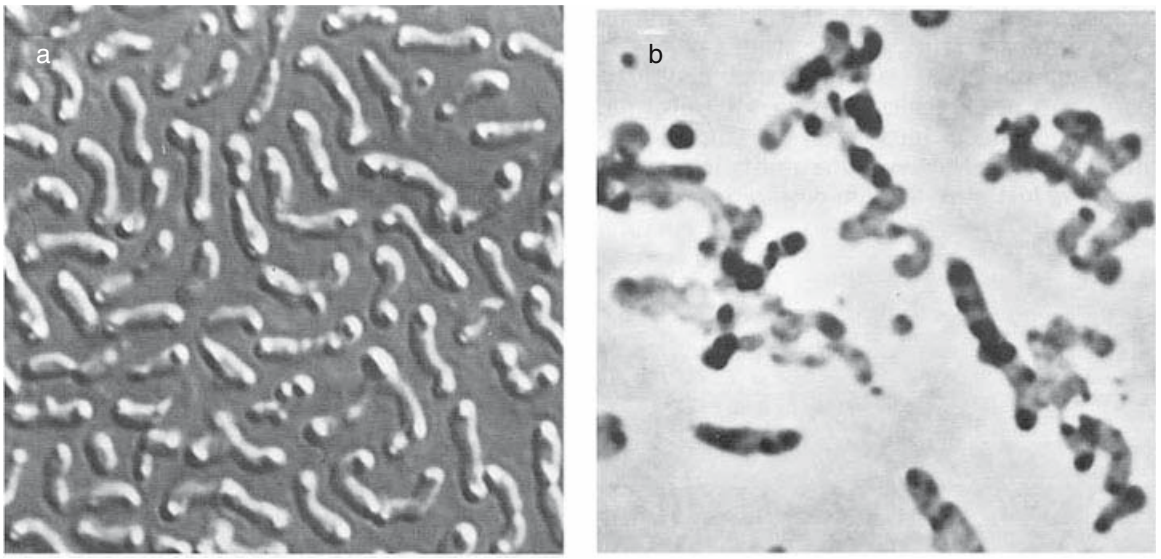

Fig. 2. *Xanthobacter autotrophicus* reference strain JW 33: a) grown on mineral salt medium plus 0.3% succinate, late exponential phase; b) grown on nutrient broth agar plates containing 0.3% succinate, 3- to 4-day-old colony. Nomarski technique. (Both photos courtesy of K. Reding.)

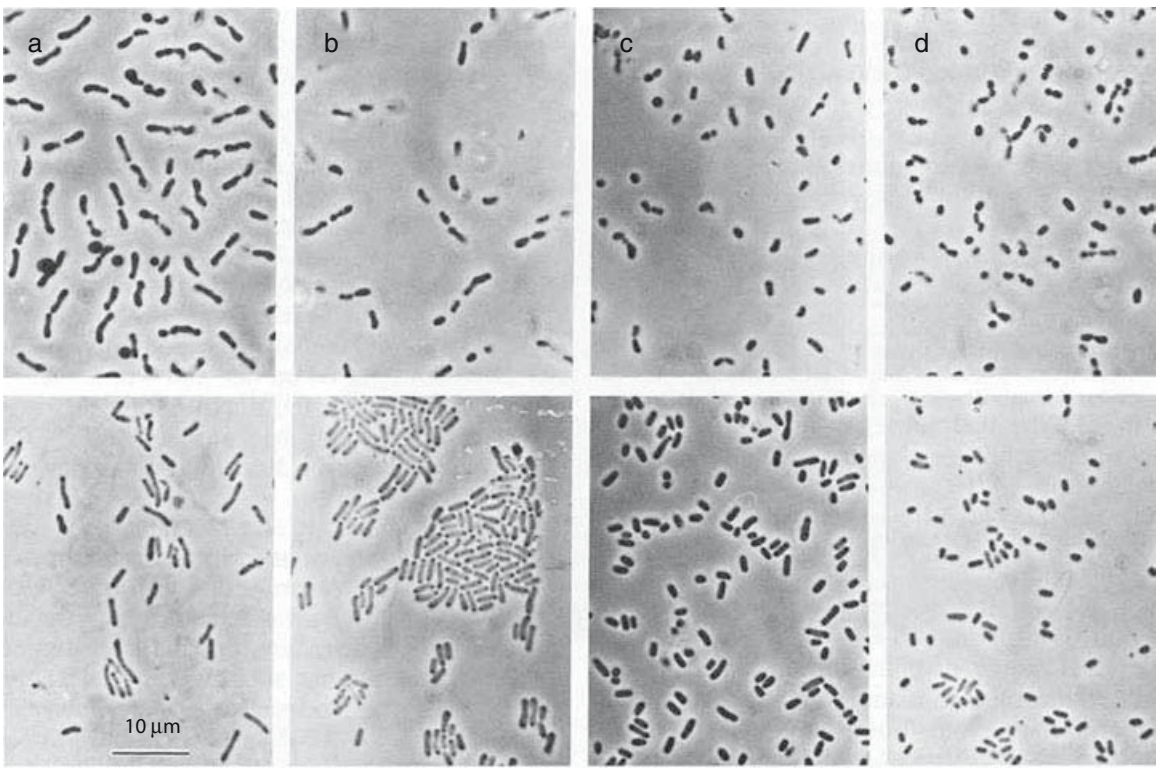

Fig. 3. Change in appearance of (top) *X. autotrophicus* reference strain JW 33 and (bottom) *X. agilis* type strain SA35 in the course of growth of a batch culture employing mineral medium plus 0.2% succinate at pH 7.0. The growth periods were: a) 24 h; b) 2 days; c) 4 days; and d) 8 days. (Photos courtesy of B. Jenni and M. Aragno.)

Fig. 4. (A) Scanning electron micrograph of *X. tagetidis*. Bar = 1 µm. (B) Transmission electron micrograph of a twisted cell and showing the insertion of flagella. Bar = 0.1 µm. (Courtesy of A. P. Wood; modified from Padden et al., 1997.)

on glucose is lost after a batch culture is grown in the absence of glucose. Several species and strains can utilize a variety of special substrates such as thiophenes (*X. tagetidis*; Padden et al., 1997) or polycyclic or heterocyclic aromatics (*X.* "*polyaromaticivorans*"; Hirano et al., 2004), on which they had been isolated.

All recognized *Xanthobacter* species can fix dinitrogen under chemoheterotrophic and chemolitho-autotrophic conditions (e.g., growing with H_2 plus O_2 or H_2 plus thiosulfate as energy source and with CO_2 as carbon source) but only at reduced oxygen tension and in the absence of organic nitrogen sources or ammonia. On the basis of their numbers, *Xanthobacter* should be regarded as an associative diazotroph (although entering roots to some extent, they do not form nodules like the symbiotic N_2-fixing bacteria). Historically, the special position of *Xanthobacter* among the chemolithoautotrophs and among the N_2-fixing aerobic microorganisms was due to their ability to fix N_2 while growing chemolithoautotrophically. At present, they share this property with other proteobacteria such as strains of *Hydrogenophaga pseudoflava* (synonym: *Pseudomonas pseudoflava*; Jenni et al., 1989; Willems et al., 1989), *Alcaligenes latus* (Malik et al., 1981b), *Azorhizobium* (K. Reding and J. Wiegel, unpublished observations), some strains of *Azospirillum lipoferum*, *Derxia gummosa*, *Bradyrhizobium japonicum* (synonym: *Rhizobium japonicum*), and possibly some others for which the N_2-fixation under chemolithoautotrophic growth has not been demonstrated unequivocally (Malik and Schlegel, 1981a). These organisms are described in the chapters dealing with hydrogen utilizers or the dinitrogen-fixing bacteria. However, if suitable conditions are provided, including the correct H_2 concentration and frequently a critical, low-O_2 partial pressure (below 5% [v/v] O_2 in the gas phase), it is possible that more diazotrophs may grow chemolithoautotrophically and may also fix N_2 under chemolithoautotrophic conditions. This is especially true for the strains known to grow with $H_2/CO_2/O_2$ or to have strong hydrogenase activity (other than the hydrogenase activity resulting from a side reaction of nitrogenase). Examples include strains of *Azotobacter*, *Derxia*, *Bradyrhizobium* and *Rhizobium* (Malik and Schlegel, 1981a) and *Azorhizobium* (R. Robson, personal communication).

Originally, one key taxonomic property for discriminating *Xanthobacter* from other yellow-pigmented bacteria, including diazotrophs, is the presence of the water-insoluble yellow pigment zeaxanthin dirhamnoside. However, for several of the newly described species, this property has not been tested unequivocally using a thin layer chromatographic assay (see below).

Xanthobacter strains can be enriched specifically and be isolated easily if certain conditions are applied: no other (or very limiting) sources of nitrogen other than N_2 or $H_2/CO_2/O_2/N_2$ (10 : 10 : 1 : 79) as gas phase providing an electron donor, a carbon source, electron acceptors, and nitrogen source, respectively, in liquid media; yellow colonies containing branched cells are selected from nutrient broth (with 1% [w/v] succinate) agar plates. Because of their metabolic diversity, *Xanthobacter* species are widespread. For this reason, and because there are some unusual strains which do not fit into the present scheme, it is expected that more species will be described beyond those presently known (Table 1). Note also that several strains described before the general use of 16S rRNA sequencing also appear to be *Xanthobacter* strains but have

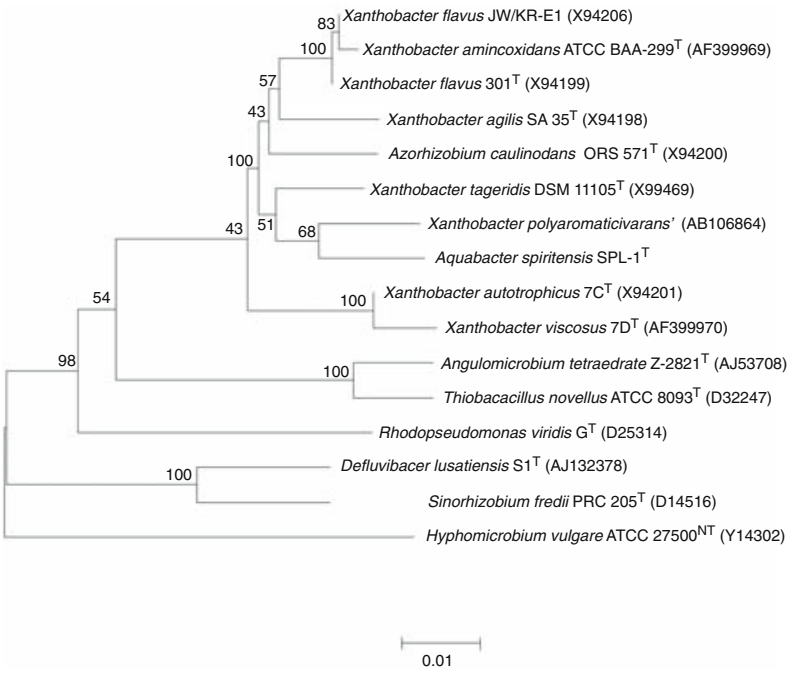

Fig. 5. 16S rRNA gene sequence-based phylogenetic tree for the *Xanthobacter-Aquabacter-Azorhizobium* clade using as outgroup *Hyphomicrobium vulgare*, which is the type genus and species for the family Hyphomicrobiaceae. We used the sequence of the falsely introduced "neotype strain" (http://www.bacterio.cict.fr.//h/hyphomicrobium.htm). (Courtesy of R. Onyenwoke.)

not yet been tested and thus are not validly described.

Phylogeny and Taxonomy

Phylogeny

The phylogenetic position of *Xanthobacter* based on 16S rRNA sequence analysis is as given in the *Bergey's Manual of Systematic Bacteriology*. According to the outline for *Bergey's Manual of Systematic Bacteriology*, the genus *Xanthobacter* (genus XX) belongs to the family Hyphomicrobiaceae, order Rhizobiales (order VI), class Alphaproteobacteria (class I), and phylum Proteobacteria (phylum BXII). Previously, *Xanthobacter* was described to belong to the *Rhodopseudomonas palustris* rRNA branch of the fourth rRNA superfamily of the Gram-type negative bacteria (De Smedt et al., 1980; Dreyfus et al., 1988).

All described species (in addition to the physiologically atypical type strain 7c and the reference strain JW 33) form a relatively narrow cluster around the type species *X. autotrophicus*. However, using phylogenetic trees constructed on the basis of 16S rRNA sequence comparisons, the type strains of *Aquabacter spiritensis* and *Azorhizobium caulinodans* appear intermingled with the otherwise well-defined genus cluster *Xanthobacter* (Dreyfus et al., 1988; Rainey and Wiegel, 1996; Fig. 5). *Aquabacter* and *Azorhizobium* (both single species genera) are presently recognized in the above-mentioned scheme as separate genera (V and VI) within the same family Hyphomicrobiaceae. Unfortunately, some of the key properties described in this chapter for the type species *X. autotrophicus* and all other recognized *Xanthobacter* species have not been tested or found for these two bacteria. Until this has been done and more isolates of this clade have been obtained and described, it is suggested to keep the separate genera names despite the 16S rRNA sequence similarity. Two nonvalidly published species of *Blastobacter* (genus IV of family VIMethylocystaceae) were recently renamed as *X. viscosus* and *X. aminooxidans*. The 16S rRNA sequence of the latter is more than 98% similar to those of *X. flavus* and *X. autotrophicus* strains (Fig. 5). However, the morphology and some of the physiological characteristics are different enough to retain a separate species, which is also supported by the low (below 50%) DNA-DNA hybridization data.

Taxonomy

Although most identifications of isolates are done via 16S rRNA sequence analysis, in a first traditional identification step, helpful diagnostic taxonomic properties are: 1) yellow, "fried egg" shaped colonies with various amounts of slime production when plated; 2) highly polymorphic, branched, twisted cell morphology while growing on nutrient broth agar containing succinate

(a tricarboxylic acid [TCA] cycle intermediate); 3) formation of the water insoluble zeaxanthin dirhamnoside, giving the colonies their characteristic yellow appearance (the yellow *Xanthobacter* colonies appear a little paler than the brilliant and darker yellow colonies of most Flavobacteria); 4) ability to grow chemolithoautotrophically; and 5) ability to fix dinitrogen under microaerophilic chemolithoautotrophic or organoheterotrophic conditions. Other characteristics are given in Table 1.

Azorhizobium, which appears to have a different habitat (stem nodulation) than that of *Xanthobacter* (free-living in soil and water as well as root-associated), exhibits acetylene reduction under chemolithoautotrophic growth conditions (K. Reding and J. Wiegel, unpublished observations). However, *Azorhizobium*, lacking the characteristic yellow *Xanthobacter* color, has not been tested for the presence of zeaxanthin dirhamnoside; colonies of *Azorhizobium* are cream-colored, which could be due to low amounts of zeaxanthin dirhamnoside or a difference in the zeaxanthin end group. Furthermore, colonies of *Azorhizobium* as well as of *Aquabacter* differ from *Xanthobacter* in lacking strong pleomorphism, having different colony morphology and physiological characteristics (such as being unable to utilize methanol and ethanol).

Note that many other features of *Xanthobacter* and of the high G+C-flavobacteria (as well as some flavobacteria sensu stricto and some *Cytophaga* spp.) are similar, including: 1) antibiotic sensitivity; 2) positive reaction for catalase, oxidase and phosphatase; 3) negative reaction for methyl red, gas from carbohydrates, and the Voges-Proskauer test; and 4) the presence of main ubiquinones Q_{10} and Q_8 (Urakami et al., 1995). However, a similar branching cell pattern is also seen with the yellow and non-yellow Gram-type positive *Corynebacterium* sensu stricto and other coryneform bacteria (Wiegel et al., 1978b), *Rhizobium* (Urban and Dazzo, 1982; Kaneshiro et al., 1983; Reding and Lepo, 1989), *Beijerinckia* (Thompson and Skerman, 1979; Vincent [1981] and literature cited therein), and *Azotobacter* (Löhnis and Smith, 1923). Succinate, which gives the strongest reaction for *Xanthobacter*, can be replaced by other acids from the TCA cycle (except malate for "*X. polyaromaticivorans*"). However, the motile species *X. agilis* exhibits only a slight pleomorphism, and only a few cells in a population show some branching after prolonged incubation. Thus, for definite identification of this species, demonstration of the presence of the pigment zeaxanthin dirhamnoside and acquisition of the 16S rDNA sequence are necessary (see below for the performance of the biochemical assay).

The frequently occurring larger amounts of polyphosphate granula (up to 15 mg per g dry weight of cells) can lead to the false impression of a Gram-positive staining reaction; however, experienced researchers will note that all *Xanthobacter* stain truly Gram negative when using a counterstain. Interestingly, polyphosphate-free cells of *X. autotrophicus* (only strains 7c and JW33 tested) could not be obtained by limiting phosphate concentrations in the media (Wiegel et al., 1978b).

Habitats

The known habitats of *Xanthobacter* reflect its physiological properties, especially its catabolic versatility. The sources for isolated strains include oil-contaminated soil and sludge from Japan (Ooyama, 1971; Hirano et al., 2004), marine sediments (Lidstrom-O'Connor et al., 1983), water and sediment samples from freshwater lakes (Aragno, 1975), soil of flooded rice fields, rhizosphere of wetland rice (Chistyakova, 1985; Oyaizu-Masuchi and Komagata, 1988; Reding et al., 1991a) and of marigold plants (Padden et al., 1997), street ditches and wet meadow soil and garden soil from Europe, South Africa, North America, and Asia (De Bont and Leijten, 1976b; Wiegel and Schlegel, 1976; Wiegel and Schlegel, 1984; Oyaizu-Masuchi and Komagata, 1988), sewage samples (Jenni and Aragno, 1987a; White et al., 1987; Doronina and Trotsenko [2003] and literature cited therein), and tree leaves (Samanta et al., 1986b). The author believes that *Xanthobacter* is ubiquitous in microaerophilic environments with decaying organic material or matter containing sufficient concentrations of H_2 and CO_2 and other products of anaerobic microbial activity, such as organic acids and alcohols. Thus, the metabolically versatile *Xanthobacter* species should be important in the microaerophilic interface between the anaerobic and aerobic zones. This is also indicated by their documented chemotaxis to aliphatic alcohols (Reding and Wiegel, 1993). Therefore, it is very likely that *Xanthobacter*, and possibly also other N_2-fixing Knallgas bacteria, can be found in habitats other than the ones mentioned above. So far, no thermophilic, psychrophilic, or halophilic strains have been isolated. Furthermore, it is not clear whether *Xanthobacter* contributes significantly as an associative azotroph to the nitrogen cycle in the environment including wetland rice or marigold flowers, even though in greenhouse experiments, *X. flavus* strains isolated from rice roots have been shown to increase growth rate and growth yields of rice plants. Despite the ease with which *Xanthobacter*, especially *X.*

autotrophicus and *X. flavus* strains, can be isolated from the many environments mentioned above, *Xanthobacter* 16S rRNA is not frequently detected by sequence studies of the various environments. This could be an artifact since *Xanthobacter* cells can sometimes be difficult to lyse, thus not releasing their 16S rRNA. The author is not surprised that *Xanthobacter* isolates are not that often found in studies that look for aerobic dinitrogen-fixing bacteria, since most strains are only azotrophic under conditions where the oxygen tension is low (below 2% [v/v] in the gas phase), and most of the studies use either anaerobic (negative E_h) or aerobic conditions but not microaerophilic conditions.

Enumeration Studies

Only a few specific enumerations for *Xanthobacter* have been carried out. De Bont and Leijten (1976b) reported most-probable-number (MPN) counts for yellow chemolithoautotrophic N_2-fixing bacteria (assumed to be *Xanthobacter*) of 35 and 1700 per ml of sample (water from a ditch) and 4.9–11 $\times$ 10^5 per g of wet weight of sediment. Reding et al. (1991b) found 500–20,000 colony-forming *Xanthobacter* cells per g dry weight of soil (excluding the rhizoplane and rhizosphere) from wetland rice fields and about 5×10^5 per g dry weight of washed, soil-free roots.

Interactions with Plants

Oyaizu-Masuchi and Komagata (1988) reported a detailed survey of N_2-fixing bacteria from roots of rice in Japan. They proposed that strains (which they called "group 2") were *X. autotrophicus* and found *Xanthobacter*-like strains (group 5; possibly a new genus). They employed not fully specified anaerobic conditions for the first enrichment step on plates. However, no enumeration or further detail on the microbe-plant interaction was given. Chistyakova (1985) found between 2.5×10^3 and 4.5×10^6 N_2-fixing methylotrophic bacteria per g of soil under rice. Some of these bacteria were identified as strains of *X. flavus* on the basis of morphological and physiological properties. Up to 25% of the nitrogen fixed by soil bacteria was incorporated into rice plants within three growing seasons. In one soil (takyr-like soils of Kasakh, Armenia) *Xanthobacter* made up 40–70% of the methanol-utilizing N_2-fixing population. Thus, Chistyakova and Kalininskaya (1984) and Chistyakova (1985) concluded that the methanol-utilizing N_2-fixing bacteria contribute significantly to N_2 balance in the soil of paddy rice. Reding et al. (1991b) demonstrated that strains close to *X. autotrophicus* and *X. flavus*, beside being present in the sediment of patty rice fields in Arkansas, United States, are more abundant (more than 10^5 cells per g dry weight of roots) in the rhizosphere of rice and were clearly associated with the roots. This was evident from enumerations of *Xanthobacter* after stepwise washings (for up to 10 min) of rice roots from the field and by electron microscopy of rice grown in sterile sand that had been inoculated with a *Xanthobacter* strain isolated previously from the rice roots (Fig. 6A). So far, no strains were isolated from inside of the roots. However, a plant-microbe interaction is indicated by the finding

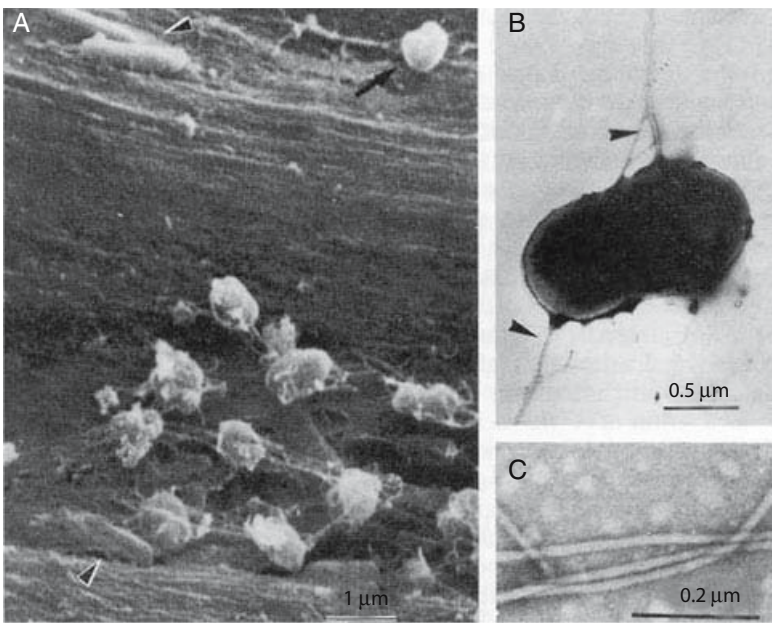

Fig. 6. A) Scanning electron micrograph of *Xanthobacter* strain JW-KR1 colonizing the surface of gnotobiotically (Hartel et al., 1990) grown rice. Notice the different shapes of the *Xanthobacter* cells, including typical rod-shaped cells (arrowhead), curled rods (long arrow), and coccoid cells. Electron micrograph (negative staining; 2% uranyl acetate) of: B) a flagellated cell of *X. flavus* type strain 301 grown on 0.1% propanol and C) flagella from *Xanthobacter* strain JW-KR1. The flagella are 13.7 nm in diameter. (All photos are courtesy of K. Reding.)

that a rice isolate, JW-KR1 of *Xanthobacter*, increased plant growth in both nitrogen-containing (15% greater top dry weight and 19% greater number of leaves per plant in comparison to the uninoculated control) and nitrogen-free plant growth medium (Reding et al., 1991a). Therefore, *Xanthobacter* can be classified as an associative diazotroph.

Samanta and Sen (1986a) reported that *X. flavus*, as well as other N_2-fixing microorganisms, contributed nitrogen to the plants through the leaves (doubling the nitrogen contents of the plants) when sprayed on rice and wheat plants. They suggested that the microbes use leaf wax components and leaf leachates to produce the energy required for N_2-fixation (Samanta et al., 1986b).

The possible role of *Xanthobacter* as a contributor of fixed N_2, a growth factor stimulant of the rice plants (as either a water or sediment organism), and an associative N_2 fixer (through either the phyllosphere or even stem nodules if in the future *Azorhizobium* is incorporated into the genus *Xanthobacter*) needs to be studied further. These studies should examine: 1) the role of the slime produced by *Xanthobacter* in its adherence to the rhizosphere and phyllosphere (an involvement of slime in adherence processes was shown for various anaerobic organisms; Brook, 1986); 2) the possible role of the polyglutamine polymer produced under high-nitrogen conditions (e.g., directly after fertilization); and 3) the role of plant growth stimulant formation by root and leaf-associated *Xanthobacter* cells. We have detected in cultures of *X. flavus* KR2 formation of indoleacetic acid when grown in medium containing tryptophan (Reding, 1991a; H. K. Reding and J. Wiegel, unpublished results).

So far, no *Xanthobacter*-like strains have been associated with any plant disease. However, the work of Kawai et al. (1989) indicates the possibility that because of the properties of the slime produced, *Xanthobacter* could indirectly mediate plant diseases by fostering the adherence of pathogenic microorganisms to plant cells.

Isolation

Selective Enrichments

CHEMOLITHOAUTOTROPHIC ENRICHMENT CULTURES. Inoculation could be done with soil, upper layers of marine or freshwater sediments, lake water, rice or marigold plant (*Tagetes*; yielding mainly *X. tagetidis* strains) roots or their washings, or samples of wet and decaying organic material (such as rotten leaves in ditches). A simple and proven method to isolate *X. autotrophicus* and *X. flavus* strains is as follows, but this procedure can be modified to isolate other species and strains with different properties and substrate specificity:

Incubate with shaking 1–2.5 g of material from freshwater lakes, rivers, or ditches or soil from wet meadows (rice fields) in 25–100 ml of 10 mM phosphate buffer (pH 7.0) and in an atmosphere of 5–10% air, 10% CO_2, 10% H_2, and 70–75% N_2 in the headspace. To supply the enrichment with the gas atmosphere, place the 100- or the 250-ml Erlenmeyer flasks containing the enrichment in an anaerobic jar (or any type of desiccator), evacuate it with the help of an aspirator, and then fill the jar with the above-mentioned gas mixture using a three-way valve. To obtain the required ratio of the gases, insert a manometer in the combined gas lines feeding the desiccator (for details, see The H_2-Metabolizing Prokaryotes in Volume 2). Exchange gas after 5, 8 and 10 days; after 12–14 days, transfer the culture to new medium (1–5% inoculum) and incubate the same way for 7 more days. The subculturing is repeated after another 5–7 days. The culture should have a slimy consistency and a yellowish, egg yolk color. Use this enrichment for further purification as described below.

DIRECT PLATING (FILTER METHOD) OF AQUEOUS SAMPLES. Another method involves direct plating using the filter method and incubation under chemolithoautotrophic growth conditions in the absence of ammonium salts. This method is especially recommended for the isolation of strains from water columns and for slower growing strains, such as strains of *X. agilis*. In liquid enrichments, strains of *X. agilis* tend to be overgrown by strains of *X. autotrophicus* and *X. flavus*. The following description of the filter method is adapted from that of Aragno and Schlegel (1981):

Filter 10 ml to 1 liter (depending on the filter size and source of the sample) of water through sterile 45- or 90-mm membrane filters with 0.2-µm pore diameter. To remove ammonium salts, low-molecular-weight organic nitrogen sources, and soluble carbon sources present in the samples, wash the membrane filters with 10–20 ml of 0.9% (w/v) saline solution to minimize the growth of oligocarbophilic and non-N_2-fixing organisms. Place the membrane filters on well-dried agar plates made with ammonium-free mineral medium solidified with 1.2% agar. Incubate the plates under an atmosphere of 80% N_2, 10% H_2, and 10% CO_2 (lithoautotrophic conditions) as described above until no new colonies appear. To discriminate between oligotrophs and H_2-utilizers (hydrogenase-positive strains), remove filters from the agar plates and place on filter paper soaked with a freshly prepared solution of 0.1% triphenyltetrazolium chloride. After 10 min of incubation under air, incubate the filters for another 10 min under 100% H_2. Except for the colonies that become red during the first incubation under air (i.e., colonies that reduce the dye via other reactions such as utilizing endogenous substrate or impurities from the agar), the red colonies represent hydrogenase-positive cells. Since the staining procedure is not lethal, the colonies can be transferred to succinate-nutrient broth agar plates (see below) for further purification and identification.

VARIOUS HETEROTROPHIC ENRICHMENTS. Using special substrates (non-N_2-fixing), the liquid enrichment procedure

described above will yield *X. autotrophicus* and *X. flavus* strains with high probability (Wiegel and Schlegel, 1976). To obtain new *Xanthobacter* strains with properties not present in the strains isolated using the above methods, other isolation procedures need to be and have been employed. For example: 1) Malik and Schlegel (1980) used normal aerobic, N_2-fixing conditions and, in addition to various other organisms, isolated the less oxygen-sensitive *Xanthobacter* strain CB6. Nakamura et al. (1984) isolated *X. autotrophicus* strain Y38 on plates as an oxygen-insensitive segregant of *X. autotrophicus* strain N34. Strain Y38 can grow on autotrophic plates in the presence of 40% O_2, although more slowly than under 10% O_2 (Ooyama, 1971; Nakamura et al., 1985a; Nakamura et al., 1985b). However, more oxygen-tolerant strains and segregants must be isolated and further taxonomic studies carried out to see whether this is a general property. 2) Enrichment with methanol and an inoculum of marine origin (Lidstrom-O'Connor et al., 1983) yielded the somewhat atypical strain H4-14 (Lehmicke and Lidstrom, 1985; Weaver and Lidstrom, 1985) now recognized as a strain of *X. flavus* (Meijer et al., 1990c). 3) "*Xanthobacter polyaramaticivorans*" was isolated from sludge of crude oil tanks under microaerophilic to anoxic conditions using dibenzothiophene-supplemented carbon and sulfur-free mineral medium (Doronina et al., 1996). 4) *Xanthobacter tagetidis* was isolated from roots of *Tagetes* (marigold) plants using 2.5 mM thiophene-2-carboxylate or thiophene-2-acetate supplemented mineral media (pH 7.3). Aerobic conditions in batch or continuous culture inoculated with material from the *Tagetes* root system yielded cultures where more than 90% of the cultures were *Xanthobacter*-like cells (Padden et al., 1997). 5) *Xanthobacter* strain E5a, which contains an interesting esterase, was isolated from sewage sludge on ethyl sulfate (White et al., 1987). And finally, 6) other promising heterotrophic substrates include various methyl(alkyl)amines (J. Wiegel, unpublished observations), propanol, propane, propene, ethane and butene (other gaseous and volatile hydrocarbons should also be tested), yielding strains with industrially interesting properties (see below; Siebert, 1969; De Bont, 1976a; Van Ginkel et al., 1986b; Van Ginkel et al., 1987; Van den Tweel et al., 1986). Other unusual strains which cannot be affiliated unambiguously into the present species have been isolated as Knallgas bacteria: strains such as 23A, RH9, 14g (tentatively, *X. autotrophicus*; Wiegel et al., 1978b), MA2 (tentatively, *X. agilis*; Jenni et al., 1987b), and strain 25a (Meijer et al., 1990c), which is similar to *X. autotrophicus* but exhibits a biotin requirement in continuous culture and greater motility than the type strain 7c, reference strains (JW33 and *X. flavus* 301), and several isolates from rice roots (including strain JW-KR1).

Unfortunately, many of the above-mentioned special strains have not been included in recent taxonomic studies and thus may represent other species or require the emendation of the present species description.

Isolation of Pure Strains

Because of slime formation (especially by *X. autotrophicus* and *X. flavus* strains), the use of agar plates containing special substrates frequently does not yield axenic cultures. This is especially true of chemolithoautotrophic agar plates without ammonium or organic N sources. Frequently, other oligotrophic organisms grow as contaminants in the slimy colonies of *Xanthobacter*. The nitrogen-fixing conditions enhance the formation of copious amounts of slime, which tend to keep the cells clumped together. Therefore, frequently it is difficult to obtain colonies from single cells using the common methods of plating cell material taken from liquid cultures or with a loop from colonies on plates. To overcome these difficulties, the following procedure, which involves treatment with NaOH, is recommended:

Preparation of Single Cells and Solubilization of Slime

Dilute an aliquot of a culture or suspended colony 1 : 3 with sterile medium, and adjust to pH 10–11 by adding drops of sterile 2 N NaOH. Mix the cell suspension vigorously for at least 1 min (on a vortex-mixer or similar equipment) to solubilize the slime and generate a homogenous suspension of single cells. Pellet the cells by centrifugation (5 min at 5000 *g*) and resuspend in fresh medium (pH 7.0), or, preferably, plate the cells directly on succinate-containing nutrient agar plates. Diagnostically characteristic branched cells grow on this medium.

Nutrient Broth Succinate Medium

Nutrient broth (Difco or Oxoid)	5 g
Yeast extract (Difco)	4 g
NaCl	3 g
Sodium succinate	5 g
Agar	10 g
Distilled water	1 liter

Adjust the pH to 6.8–7.0.

Besides leading to a suspension of single cells, the alkaline treatment of primary enrichment cultures markedly reduces the viability of non-*Xanthobacter* cells, resulting in a ratio of close to one *Xanthobacter* cell per cell of another organ-

ism. *Xanthobacter* strains can be recognized by the characteristic yellow color of the colonies and microscopically (if grown on the succinate-nutrient broth medium) by their irregularly branched cells (Wiegel and Schlegel, 1976; Wiegel, 2004; Fig. 2). The method described above has proven to be a reliable, rapid means of isolating pure strains of *X. autotrophicus* and *X. flavus* from various sources.

Cultivation and Storage

Media

Most *Xanthobacter* strains can be grown on various mineral media. However, since a low ionic strength is favorable for most *Xanthobacter* strains, a 5–10 mM sodium-potassium phosphate buffer with a pH around 7.0 is suggested. Phosphate buffer is preferred since storage at 4–25°C on nutrient broth plates leads within 2 weeks to nonviable cells. The following basal medium can be used for autotrophic as well as heterotrophic growth (Wiegel and Schlegel, 1976):

Basic Mineral Medium

K_2HPO_4	1 g
KH_2PO_4	0.5 g
$NaHCO_3$	2 g
$MgCl_2 \cdot 6H_2O$	0.1 g
$CaCl_2 \cdot 2H_2O$	0.04 g
$FeSO_4 \cdot 5H_2O$	0.01 g
Trace element solution	1 ml
Distilled water to	1 liter

A recipe for the trace element solution is given in Ormerod et al. (1961). Similar recipes containing 0.1–1 μM nickel ion can also be used. The addition of 0.1 μM nickel sulfate to previously published media recipes containing no nickel enhances growth, since nickel is required for hydrogenase in all tested strains. However, nickel ion concentrations of 1 mM and above appear to be inhibitory. Addition of nickel is not required for heterotrophic growth except when urea is used as nitrogen source, since *Xanthobacter* urease is a nickel-containing enzyme (e.g., as shown for strain Y38; Nakamura et al., 1985a). Traces of nickel are frequent impurities of other ingredients, leading to a limited growth in the absence of added nickel ions. No vitamins or additions of yeast extract are required for most *Xanthobacter* isolates, except for *X. flavus* and some special strains mentioned above which need the addition of biotin. However, the addition of 10–100 mg of yeast extract per liter to the mineral medium can reduce or avoid an extended lag time for autotrophic growth (both under nitrogen-fixing and non-nitrogen-fixing conditions) or when switching from one type of substrate to another.

During isolation, a vitamin solution (any mixture containing biotin can be used) is added to avoid the exclusion of strains that require biotin as well as other vitamins. For *X. flavus* and for fast growth of other strains, 10 ml of Pfennig's vitamin solution is satisfactory (Pfennig, 1965). For chemolithoautotrophic growth, the air is exchanged with an autotrophic gas mixture: 10% CO_2, 10% O_2, and 80% H_2 (v/v) when ammonium salts are present or 10% CO_2, 5% air, 10% H_2, and 75% N_2 when N_2-fixation is sought in the absence of ammonium or any organic nitrogen source. For heterotrophic growth, various carbon sources are added: 0.5% sugars, 0.3% (v/v) alcohols (except butanol, 0.1–0.2%), or 0.4–0.8% organic acids. For growth under non-N_2-fixing conditions, 0.1% of ammonium chloride or sulfate is added; a concentration of ammonium salts above 0.15% is inhibitory for most strains. For nitrogen-fixing conditions under heterotrophic growth conditions, delete ammonium salts and any organic nitrogen source above trace concentration (e.g., 10 mg yeast extract per liter medium) and use N_2 gas with 2–5% (v/v) air as the gas phase.

Complex Medium

For characterization or isolation purposes, the use of a succinate-nutrient broth-agar medium as selective medium, which leads to the formation of the characteristic branched cells, is recommended. Most strains have their shortest doubling time (as low as 2 h) in this medium. The exact composition of this medium is not critical, and good results have been obtained with the nutrient broth-succinate medium described earlier as well as nutrient broth containing other substrates such as methanol or glutarate rather than succinate. However, neither the liquid nor the agar-solidified complex medium, especially when supplemented with organic acids, is recommended for storage of cultures beyond 10 days; many strains lose their viability during storage on this medium even at 4°C.

pH and Temperature Ranges

Detailed studies of pH and temperature ranges and optima have not been performed for the type strains of the type species or for most other strains of *X. autotrophicus* and *X. flavus*. Most of the strains tested grow at pH 5.0–8.5 (Wiegel et al., 1978b). Except for *X. agilis*, *X. aminoxidans* and *X. viscosus*, which grow between 5°C and 34°C, the other species grow at 37°C and above (Jenni et al., 1987b). *Xanthobacter autotrophicus* strain 14g, studied in more detail, has its pH optimum for growth at 6.8–7.2 and its temperature optimum around 30°C (Schneider et al., 1973). For strain *X. autotrophicus* GZ29, only

the pH optimum for acetylene reduction has been determined; it exhibits the highest activity at a slightly lower pH of 6.7–6.8 (Berndt et al., 1976). *Xanthobacter aminoxidans* will grow between 6.5 and 8.5 (optimum 7.2–7.9), whereas *X. viscosus* and *X. tagetidis* have an optimum of pH 6.8–7.2 and 7.6–7.8, respectively. *Xanthobacter tagetidis* grows at temperatures of up to 43°C (Padden et al., 1997).

Storage of Cultures

Xanthobacter cultures grown on chemolithoautotrophic agar slants can be stored 1.5 years at 4°C after sealing the tubes tightly with parafilm (H. G. Schlegel and J. Wiegel, unpublished observations). Also, liquid cultures grown under chemolithoautotrophic conditions (mineral medium supplemented with 0.02% [w/v] yeast extract) have been kept for more than 15 months at 4°C and, if glycerol was added (40–60% [v/v] final concentration), at –20°C and –75°C for more than 8 years. For long-term storage, cultures should be lyophilized in the presence of skim milk and honey (10%), as originally described by Malik (1975) or later improved by Malik (Malik, 1988; Malik, 1990). Using these methods, cultures have been preserved at the Deutsche Sammlung von Mikroorganismen und Zellkulturen (DSMZ)~~G~~erman Collection of Microorganisms and Cell Cultures~~an~~d the author's laboratory for more than 20 years without a drastic loss of viability.

Harvesting

The copious amounts of slime produced under many growth conditions can lead to difficulties in harvesting cells since the cells form a paste whether harvested by centrifugation or filtration. Except for *X. autotrophicus* and *X. flavus* cells grown in the presence of ammonium salts with propanol or butanol as carbon and energy source or under chemolithoautotrophic conditions, it is recommended that the pH be increased to about 10–11 or decreased to pH 4.5–4.8 before cells are collected by centrifugation. Otherwise, when no alkali treatment is possible, high-speed centrifugation (20,000–35,000 *g*) at 10–15°C is the method of choice to harvest the cells (at 0°C, the slime can become more viscous while being pelleted). Amicon hollow fiber cartridges (or less easily, the Pellicon Cassette System, Millipore) can be used to concentrate cultures. However, some of the slime is also concentrated so that, depending on the slime and the pH of the broth, only a minimal concentration of less than 1 : 5 can be obtained. For further concentration, an alkaline or acidic treatment for temporary solubilization of the slime must be employed.

Identification

Colony Morphology and Pigmentation

The morphological features of *Xanthobacter* can be used initially for identification. Colony morphology depends on the substrate and growth conditions. On most carbohydrates, the colonies of all three species are large (1–5 mm in diameter), smooth, convex, circular, filiform, opaque, and of a characteristic egg-yolk yellow color due to zeaxanthin dirhamnoside. The colonies become less yellow and less opaque as the amount of slime increases. Strains of *X. agilis* generally produce less slime than strains of the other species produce. A few strains have been isolated which grow as whitish colonies under autotrophic conditions because they produce not only small amounts of zeaxanthin dirhamnoside but also copious amounts of slime. The production of slime on nutrient broth agar plates frequently results in colonies resembling fried eggs. For the isolation of *Xanthobacter* strains, it is recommended that the color and colony morphology be compared with that of one or two authentic strains (e.g., the reference strain JW 33 = DSM 1618) grown on the same agar plates. A variety of other organisms produce yellow pigments. Flavobacteria produce the carotenoid pigment zeaxanthin, but not zeaxanthin dirhamnoside; thus the shade of yellow differs (greenish-yellow, sulfur-yellow, or yellow containing a slight pink or brown). Zeaxanthin dirhamnoside is water-insoluble, in contrast to the reddish/pinkish/brown pigment or to the yellow-green diffusing pigments (also exhibiting fluorescence) of *Beijerinckia* and *Derxia* (the other yellowish diazotroph which can be obtained using the enrichment procedures described). *Xanthobacter* colonies do not noticeably change color with age, although the yellow darkens with an increase in cell density, partly due to shrinkage of the slime as water is lost. The latter fact also makes it easy to distinguish *Xanthobacter* from *Derxia* colonies, which turn brown with age (Becking, 1981). The exception among *Xanthobacter* spp. is "*X. polyaromaticivorans*," which has an orange water insoluble pigment that is proposed to be a zeaxanthin on the basis of its absorption spectrum (i.e., peak at 473 nm instead of the normal peak of around 450 nm; Hirano et al., 2004).

Cell Morphology

SIZE. The morphology of *Xanthobacter* (especially strains of *X. autotrophicus* and *X. flavus*) changes with growth conditions and carbon source (Figs. 1–4). Cells grown under chemolithoautotrophic conditions or grown het-

erotrophically with sugars or organic acids are straight or slightly irregular rods (0.4–0.7 μm × 2–4 μm; Figs. 1a, 1b, and 3). Most strains grown on methanol and ethanol are similar in morphology to cells grown autotrophically; cells grown on agar plates containing propanol as the sole carbon source can be coccoid or short rods (0.8–2 μm long) with little slime formation, and cells grown on agar plates containing 0.1% butanol can be coccoid or up to 10-μm-long rods (Van Ginkel and De Bont, 1986a; Wiegel, 2004; Fig. 1c). In contrast to the carbon source, the nitrogen source does not have a pronounced effect on the morphology. Cells grown under N_2-fixation conditions tend to be slightly longer than those grown in the presence of ammonium salts or other organic nitrogen sources. Cells grown on complex medium with 0.2–0.3% succinate or in the presence of other TCA cycle intermediates are multibranched and vary greatly in size (3–10 μm; Fig. 2).

The highly irregular branching pattern of *Xanthobacter* cells on nutrient broth agar plates is a characteristic morphological feature as well as the zeaxanthin dirhamnoside pigment. The formation of highly irregular, branched cells separates *Xanthobacter* from yellow flavobacteria and the so-called "high G+C" (65–70 mol%) flavobacteria such as *Flavobacterium capsulatum*, which are not related to *Xanthobacter*.

Suspensions of chemolithoautotrophically grown cells and cells heterotrophically grown with sugars frequently contain cell aggregates like those (due to snapping-type division) typical of *Corynebacteria* and some *Arthrobacter* spp. However, the cell aggregates formed by *Xanthobacter* are due to slime and not to the one-sided rupture of the cell wall during the cell division process. *Xanthobacter viscosus* and *X. aminoxidans* have a different cell type. Their cells are also pleomorphic and exhibit under various growth conditions branching cells that divide asymmetrically via a process resembling budding. *Xanthobacter aminoxidans* cells can occur in a V-formation, and *X. tagetidis* cells usually occur in a twisted form (Fig. 4).

CELL INCLUSION BODIES. Under most growth conditions, for all *Xanthobacter* species typical, large polar inclusion bodies (black cell poles in phase contrast microscopy) filling the cell tip are found at one or both cell ends. The multibranched cells can have inclusion (polyphosphate or poly-β-hydroxybutyrate [PHB]) bodies at each branch tip. PHB can constitute up to 600 mg per g dry weight of cells (Wiegel, 2004). Lipid inclusion bodies at both cell ends are also characteristic of *Beijerinckia* (Becking [1981] and literature cited therein). Nevertheless, *Beijerinckia* can be easily distinguished from *Xanthobacter* species by differences in 16S rRNA sequence, pigmentation, acid tolerance (most *Beijerinckia* species can grow and fix nitrogen at pH 3–4), growth on nutrient broth (which is poor for *Beijerinckia*), and ability to fix N_2 under air, i.e., under normal oxygen concentrations (*Beijerinckia* has this capability).

FLAGELLATION. *Xanthobacter agilis* exhibits the greatest motility of all *Xanthobacter* species under all growth conditions. Using light microscopy, strains of *X. autotrophicus* and *X. flavus* usually do not appear to be motile, but when grown chemolithoautotrophically on sugars or under N_2-fixing conditions, motility greater than the Brownian movement can be observed occasionally. This is due to reduced peritrichous flagellation found on many strains of these two species (Reding et al., 1992; Reding and Wiegel, 1993; Fig. 6). The flagella have the Type 1 morphology (Aragno et al., 1977), are 14.2 μm in diameter and 9–14 μm long, and have a wavelength of 2.0–2.5 μm. However, the flagella are fragile and break easily during preparations for electron microscopy (Aragno et al., 1977). The extent of flagellation appears to depend on growth conditions, including substrate and growth stage. Strains of *X. autotrophicus* (including type strain 7c), *X. flavus* (including type strain 301), strain JW/KR2, and many isolates from rice roots are motile when grown on methanol, ethanol, isopropanol (0.3%), and butanol (0.1%)~~w~~hich includes the longer chain alcohols that chemotactically attract *Xanthobacter*—or on gluconate, glutamate and diglutamate (Reding, 1991a; Reding et al., 1992; K. Reding and J. Wiegel, unpublished results). Thus, in contrast to the findings in prior reports (Jenni et al., 1987b), the differentiation of *X. agilis* from other *Xanthobacter* species has to be based on its pronounced motility under chemolithoautotrophic growth conditions, its reduced pleomorphology, and differences in substrate utilization (Table 1). For the other species, whether cells are motile under some growth conditions remains unclear since motility was probably tested under heterotrophic growth conditions (though not specified) and not checked when cells were grown on other compounds including alcohols during substrate spectrum determinations.

CHEMOTAXIS. *Xanthobacter* exhibits a positive chemotaxis toward aliphatic alcohols such as isopropanol and butanol but not towards methanol, ethanol, sugars or organic acids (Reding, 1991a; Reding and Wiegel, 1993).

BIOCHEMICAL PROPERTIES USEFUL FOR IDENTIFICATION Though 16S rRNA sequence analysis has become the standard for identification of novel isolates, other properties are still useful for identification of unusual strains at the species level, since significant differences can

occur despite a high 16S rRNA similarity (case in point, *X. flavus* and *X. aminooxidans*).

GRAM-STAIN REACTION AND CELL WALL TYPE AND COMPOSITION. Interpreting the Gram stain for *Xanthobacter* is sometimes misleading, as is evident from the various previous assignments of strains~~no~~w identified as *Xanthobacter~~to~~* "Gram-positive" *Corynebacterium* and *Mycobacterium*. False reading of the Gram-stain was due to large inclusion bodies that appear as dark zones in the otherwise not well stained cells. As was unequivocally shown (Wiegel, 1981; Wiegel and Quandt, 1982b), *Xanthobacter* species are Gram-type negative organisms, as defined by the presence of lipopolysaccharide (LPS; Wiegel and Mayer, 1978a). The presence of LPS, although at lower concentrations than found with other typical Gram-type negative organisms, can be demonstrated specifically and rapidly with the lipopolysaccharide-polymyxin B test of Wiegel and Quandt (Wiegel and Quandt, 1982b; Fig. 7). The cell wall type is the *meso*-diaminopimelic acid direct type (tested for *X. autotrophicus* and *X. flavus*), typical for Gram-type negative bacteria. Teichoic and teichuronic acids are absent. The peptidoglycan content for the tested strains of *X. autotrophicus* (including reference strain JW 33) is 15–25%, and thus is intermediate between typical Gram-type positive and Gram-type negative cells. Micrographs of ultrathin sections for this and the other species reveal a multilayer cell wall similar to that of typical Gram-type negative organisms. This is also supported by the presence of a citrate synthase in *Xanthobacter* strains GZ29 and JW 33, typically found in Gram-type negative bacteria, which have molecular weights above 250,000 and are inhibited by reduced nicotinamide adenine dinucleotide (NADH; Weizman and Jones, 1975; Berndt et al., 1976). Presently, there are no detailed data on cell wall composition of the other *Xanthobacter* species available.

One special effect was observed for *X. autotrophicus* strains (not tested for other *Xanthobacter* spp.), in that under heterotrophic growth conditions polyglutamine can substitute for the peptidoglycan in the cell wall. Kandler et al. (1982) demonstrated that all 20 strains tested from *X. autotrophicus*, *X. flavus* and *X. agilis* form an extracellular α-polyglutaminyl polymer. This polymer is isolated in association with the cell wall but not the slime from cells growing heterotrophically in the presence of sufficient ammonium or organic nitrogen, and the polymer is not dissolved along with the slime when cells are subjected to alkaline treatment. Cells shifted to nitrogen-limiting conditions apparently re-utilize the polymer (J. Wiegel, unpublished observations). The only other organism known to produce this polymer is *Flexithrix* (Kandler et al., 1982).

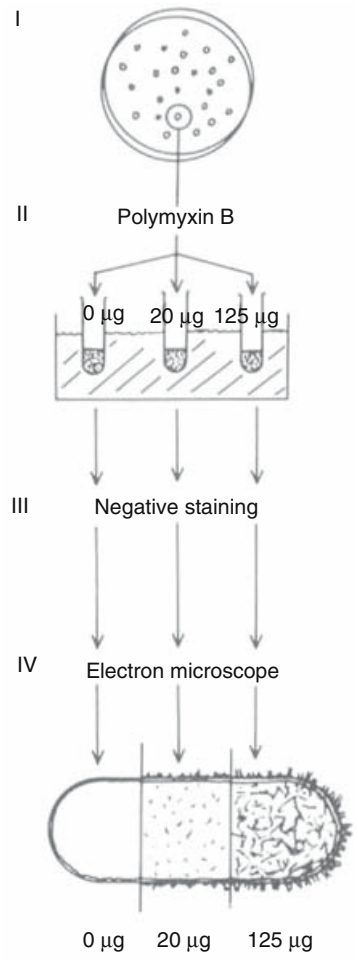

Fig. 7. Diagram for the LPS-polymyxin B test to determine the Gram type.

GLYCINE TREATMENT. The cell wall of *Xanthobacter* species (mainly observed with *X. autotrophicus* and *X. flavus*) can be difficult to break by French press or ultrasound disruption and the usual cell lysis procedure for DNA or cell wall analysis. Cells can be rendered easy to break and lyse by growing them for one to two doublings in the presence of glycine. The required concentration (0.1–0.4% [w/v] glycine) to be used varies with the strain. The glycine is added at the mid-to-late exponential growth phase, and then the cells are harvested after growth ceases within two doublings.

LPS-POLYMYXIN B TEST FOR THE PRESENCE OF LPS AND THE DETERMINATION OF THE GRAM-TYPE. The presence of LPS can be quickly determined by demonstrating specific bleb formation (representing LPS-polymyxin B complexes) in electron micrographs of negatively stained cells (Wiegel and Quandt, 1982b) as diagrammed in Fig. 7. The procedure is as follows:

Suspend cells, preferably grown on plates, in 1 ml of 10 mM Tris hydrochloride, pH 7.2. Incubate the cells for 5 min in the presence of 0 (control), 10 and 125 µg of polymyxin B per ml of cell suspension at 35°C. Fix the incubated cells directly to carbon-covered, copper grids and negatively stain them. In electron micrographs, Gram-type positive cells and the control cells (no polymyxin B treatment) have smooth cell walls, whereas Gram-type negative cells exhibit blebs of LPS-polymyxin B complex (for a detailed discussion of the method, see Wiegel and Quandt, 1982b).

Xanthobacter will exhibit only a few isolated blebs, in contrast to species of *Flavobacterium*, pseudomonads, or enterobacteria. Cells from an agar plate give cleaner preparations than washed cells grown in liquid cultures. This test is the most precise test for identifying the Gram type (Wiegel, 1981), since, in contrast to some other sensitive biochemical tests (e.g., the limulus lysate test for the presence of LPS), many individual cells are visually examined and this procedure avoids the error of recording a positive reaction due to a few contaminating dead LPS-containing cells. Presently most researchers use 16S rRNA sequence analysis to determine the phylogenetic position.

ANALYSIS FOR ZEAXANTHIN DIRHAMNOSIDE. As mentioned earlier, a specific biochemical check for *Xanthobacter* is to demonstrate the presence of zeaxanthin dirhamnoside, which is (on the basis of absorption spectra) otherwise found only in *Corynebacterium flavescens* and *Hydrogenophaga* species (Urakami et al., 1995). The following procedure is a modification of K. Schmidt's procedure, which is based on the one by Hertzberg et al. (Herzberg et al., 1976; K. Schmidt, personal communication).

Identify by thin layer chromatography after converting the pigment to the peracetylated form using the method described below. Exclude light and oxygen as much as possible during all the steps, since the carotenoid compounds are light and oxygen sensitive. Perform all steps under a black velvet cloth or in a room with low-level lighting. Furthermore, after freeze-drying the cells, keep all material in an atmosphere of N_2 or argon. Argon is heavier than air and thus can more easily replace the air in the reaction vessel.

Extract about 0.5–1 g of freeze-dried cells in a tightly stoppered separation funnel or bottle overnight with an argon-flushed 1 : 1 mixture of acetone and methanol. Remove the solvent and dry the residue over silica gel in a desiccator flushed with argon. After 12–18 h, dissolve the dry residue in 1 ml of water-free pyridine flushed with argon. To this solution, add 0.1 ml of acetic anhydride. Allow the mixture to react in the dark under argon at about 25°C for 20 h. Then add 2–3 ml of diethyl ether to stop the reaction, and add about 5 ml of argon-flushed, aqueous 3% NaCl solution to drive the acetylated product into the diethyl ether. Remove the pyridine quantitatively from the ether fraction by repeated washings with the argon-flushed aqueous NaCl solution. Evaporate the ether extract to dryness in a rotary evaporator; break the vacuum with argon. Then dry the sample further using an oil vacuum pump to remove traces of pyridine. If the sample needs to be stored, do so under argon in a desiccator kept in the dark. Dissolve the dry residue in about 100 µl of argon-flushed acetone. Use this solution immediately for thin layer chromatographic analysis on silica gel (e.g., no. 5721, Merck, Darmstadt, Germany, or a similar product) and an acetone-benzene ether (petro-ether; boiling point, 40–60°C) 3:7 (v/v) as solvent. R_F-values are around 0.8 for zeaxanthin, 0.63 for zeaxanthin monorhamnoside-peracetate, and 0.4 for zeaxanthin dirhamnoside-peracetate. Some minor other spots of breakdown products and intermediates of pigment synthesis are found. Use an authentic sample derived from a type strain (e.g., *X. autotrophicus* 7c or the reference strain JW 33) as a standard to ensure that the procedure was carried out correctly and to compensate for differences in specifications of solvents or silica gel plates. Spectral data (maxima) in acetone are: for the major (natural) *trans* form (428 nm), 453 and 480 nm; and for the minor form (at least partly derived as artifact 342 [425 nm]), 452 and 478 nm (Herzberg et al., 1976; K. Schmidt, personal communication).

OTHER PROPERTIES *Xanthobacter* strains are sensitive to various antibiotics, but the response depends on the method employed (e.g., liquid cultures or the use of Difco Dispense-O-Disk minifilters). With the latter method, *X. autotrophicus* and *X. flavus* were insensitive to ampicillin, chloramphenicol, erythromycin and penicillin. The four tested strains of *X. agilis* were sensitive to erythromycin but exhibited different responses with the other three antibiotics (Jenni et al., 1987b). In liquid culture, *X. autotrophicus* strains are usually sensitive to 100 µg/ml penicillin, novobiocin, and polymyxin B per ml of culture; they are resistant to 200 µg/ml erythromycin and bacitracin per ml of culture. The available data do not suggest antibiotic typing as a valid method for identification of *Xanthobacter*.

Several other indicative reactions give mixed results depending on the strains. For instance, only some strains can grow on violet red-bile medium (Oxoid), deoxycholate medium (Oxoid), tellurate agar (Difco), and mineral medium supplemented with crystal violet (red colonies; Wiegel, 2004). Also the effect of phosphoenolpyruvate on the easy-to-determine activity of glucose-6-phosphate dehydrogenase (Opitz and Schlegel, 1978) or the effect of the branched-chain amino acids on α-isopropylmalate synthase (Wiegel and Schlegel, 1977) can be used as a taxonomic test.

Xanthobacter autotrophicus strain 7c and CB2 grown at 37°C contain 8–13 µmol of putrescine and 16–22 µmol of *sym*-homospermidine per g dry weight of cells (Kneifel et al., 1986).

The distribution of the lipid fatty acids is presented in Table 2 as far as they have been analyzed. The main fatty acid (constituting up to 93% of the lipid) is the monounsaturated C-18:1 (*cis* and *trans*). In "*X. methylooxidans*" strain 32P (Doronina et al., 1996), the *cis*-vaccenic acid (C-

Data for 1.–3. from Henry Keith Reding. Ecological, physiological, and taxonomical studies of *Xanthobacter* strains isolated from the roots of wetland rice. Dissertation (1991): University of Georgia, Athens, GA (United States). Samples were prepared and analyzed by Microbial ID Inc. (Newark, DE).

Data for 4. from Padden et al. (1997), for 5. and 6. from Dorina and Trotsenko (2003), for 7. from Hirano et al. (2004), and for 8. from Doronina et al. (1996).

18:1-*cis* 11) is 55–75%. "*Xanthobacter polyaromaticivorans*" has a higher concentration of the saturated C-16:0. The main hydroxy fatty acid is the 3-OH C-16:0 acid.

Physiological Properties

Chemolithoautotrophy One of the characteristic properties of all strains of *Xanthobacter* spp. is the Knallgas reaction. All strains grow easily under chemolithoautotrophic conditions with doubling times from 3 to more than 12 h (Wiegel and Schlegel, 1976; Berndt et al., 1978). They differ in this respect from *Aquabacter* and *Azorhizobium*, which are intermingled with *Xanthobacter* species in the 16S rRNA sequence-based phylogenetic tree, but no chemolithoautotrophic growth has been demonstrated for these two. For detailed tests and methods of autotrophic growth, see The H_2-Metabolizing Prokaryotes in Volume 2. Thus far, none of the tested strains oxidize carbon monoxide to CO_2 or grow with carbon monoxide in either the presence or absence of H_2 (O. Meyer and J Wiegel, unpublished observations). However, H_2 can be replaced by thiosulfate to provide energy for CO_2 fixation (Friedrich and Mitrenga, 1981), and this has been observed in several strains of *X. autotrophicus* and *X. flavus* strain 301 by J. Wiegel (unpublished observations). When cells of *X. autotrophicus* type strain 7c were grown heterotrophically with high heterotrophic substrate concentrations and in the presence of an autotrophic gas mixture, no mixotrophy was observed; H_2 inhibited the induction of enzymes for heterotrophic growth in cells grown autotrophically and inhibited the utilization of sugars (fructose; Tunail and Schlegel, 1976). Using *X. flavus* strain H4-14 and *Xanthobacter* strain 25a in batch and continuous cultures, Meijer (1990a) could show that mixotrophy occurred when heterotrophic substrate concentrations were reduced or when pseudoheterotrophic substrates are used for growth. (Pseudoheterotrophic substrates such as methanol and formate [metabolized via oxidation to CO_2] are utilized at least partly via the autotrophic pathway.) Cells grown on acetate had no ribulose-1,5-biphosphate carboxylase (Rubisco) activity, and no activity was found when the gene was fused to the *lacZ* gene. However, at lower acetate concentrations, the addition of methanol or formate resulted in the induction of this enzyme and consequently utilization of both substrates, leading to additive growth yields. Thus, Rubisco is apparently regulated by repression caused by heterotrophic compounds and derepressed by autotrophic energy sources including the cryptic autotrophic substrate methanol (Opitz, 1977; Meijer, 1990a; Meijer et al., 1990b; Meijer et al., 1990c; Meijer et al., 1990d).

In *X. autotrophicus* strain 14g, H_2 exerts catabolite repression on the utilization of the organic

substrates gluconate, succinate and citrate in autotrophically grown cells, as well as in citrate grown cells. However, this was not observed in cells grown on gluconate or succinate. The uptake hydrogenase is inducible and its activity is increased up to 2500 µl of H_2 per mg of protein per h by incubation under autotrophic growth conditions with a gas mixture. In strain 14g, this occurs also in heterotrophic (succinate) grown cells in the presence of the organic substrate, although only to a lesser extent. In such induced cells both hydrogen and succinate are simultaneously utilized (mixotrophy). The gluconate-dehydratase, 6-phosphogluconate-dehydratase, and the Entner-Doudoroff enzyme system are induced in gluconate grown cells of strain 14g but not in autotrophically grown cells (Schneider et al., 1973).

Steinbüchel et al. (1983) have shown that anaerobically fermentative enzymes are induced in *X. autotrophicus* strains, and Berndt et al. (1978) reported the occurrence of anaerobic N_2 fixation by *Xanthobacter* strains. Oyaizu-Masuchi and Komagata (1988) used anaerobic conditions (with an unspecified technique) during enrichment. *Xanthobacter* strains are not killed during incubation under anaerobic conditions over several days, even when H_2S evolves (J. Wiegel, unpublished observations). However, *Xanthobacter* strains have not yet been shown to grow and multiply under strictly anaerobic conditions.

Rubisco, the key enzyme for autotrophic growth, is inducible but has been studied only to a small extent. *Xanthobacter* species fix CO_2 mainly via the ribulose-biphosphate pathway (Meijer et al., 1990b; Meijer et al., 1990c; Meijer et al., 1990d), but phosphoenolpyruvate carboxylase activity also has been demonstrated (Bowien and Schlegel, 1981). For *Xanthobacter flavus* strain H4-14, it has been shown that the genes encoding the key enzymes of the Calvin cycle are organized in two operons (Meijer, 1990a).

Ensign et al. (1998) have shown that the fixation of CO_2 plays an important role in the degradation of aliphatic epoxides and ketones by novel carboxylases (Ensign and Allen [2003] and literature cited therein).

The other key enzyme, hydrogenase, is membrane-bound and constitutive (in *Xanthobacter autotrophicus* type strain 7c, GZ29, and Y38) or inducible (in strain 14g). This enzyme cannot directly reduce NAD; no soluble hydrogenase has been found (Schneider et al., 1973; Tunail and Schlegel, 1974; Schneider and Schlegel, 1977; Berndt and Wölfle, 1979; Pinkwart et al., 1979; Schink and Schlegel, 1980; Nakamura et al., 1985a). Especially for strain Y38, it has been shown that nickel is required for hydrogenase activity; if nickel availability is restricted by adding metal-chelating agents, no hydrogenase activity is obtained. Addition of higher nickel concentrations restores autotrophic growth and hydrogenase activity. It is of taxonomic interest that the enzyme from *X. autotrophicus* strain GZ29 did not crossreact immunologically with the hydrogenase from *Alcaligenes eutrophus* H16 or with membrane extracts of *X. autotrophicus* strain 7c, 14g, and 12/60/x (Schink and Schlegel, 1980).

Heterotrophic Respiration Rates Using radiorespirometry on strain *Xanthobacter autotrophicus* 10/–/x, half maximal respiration rates were obtained with 0.26 mM fructose. With the addition of glucose at equimolar concentrations of fructose, no inhibition was observed. Glucose, used as sole carbon and energy source, leads only to low respiration rates, and increased concentrations were inhibitory (Opitz, 1977). When *X. autotrophicus* strain 19/–/x was plated on minimal medium containing glucose as carbon source, several colonies of glucose utilizing variants appeared after 2–6 weeks of incubation. In these cells, half maximal saturation for glucose respiration was 22 mM. Contrary to fructose, the glucose uptake seemed to be passive. Fructose, in contrast to sucrose, was respired in these cells without a lag phase (Opitz, 1977).

Methylotrophy (and Use of Other Alcohols) All strains of *Xanthobacter* species (except strain CB6 and two other strains out of over 60 tested strains of *X. autotrophicus* and *flavus*) can utilize methanol. Most strains also can grow on ethanol, *n*-propanol, *n*-butanol, 2-butanol and amyl alcohol (Wiegel et al., 1978b; Jenni et al., 1987b; K. Reding and J. Wiegel, unpublished observations). The longer alcohols have not been tested sufficiently as sole sources of carbon and energy.

Xanthobacter autotrophicus oxidizes methanol to CO_2 via a pyrrolo-quinoline quinone (PQQ)-containing methanol dehydrogenase that is stimulated by ammonium (Opitz, 1977; J. A. Duine, personal communication). Methanol utilization has been studied in detail in *X. flavus* strain H4-14 (Lehmicke and Lidstrom, 1985; Weaver and Lidstrom, 1985; Weaver and Lidstrom, 1987; Meijer, 1990a; Meijer et al., 1990c), in *Xanthobacter* strain 25a (Meijer, 1990a), in connection with the degradation of 2-chloroethanol in strain GJ10, which involves the PQQ-dependent methanol dehydrogenase (Janssen et al., 1987), and in "*X. methylooxidans*" (Doronina et al., 1996). Methanol is oxidized to CO_2 via methanol, formaldehyde, and formate (NAD) dehydrogenases, and carbon dioxide is then assimilated via the Calvin cycle, as in nearly all "Knallgas" (H_2/O_2/

CO_2-utilizing) bacteria. The mutant obtained by Weaver and Lidstrom (1987) indicated that the methanol dissimilation is regulated by a repressor mechanism. The PQQ-dependent methanol dehydrogenase was purified (Janssen et al., 1987). In *X. flavus*, the maximal induction of the *cbb* and *gap-pgk* operons (regulated by LysR-type regulator) encoding enzymes of the Calvin cycle occurs in the absence of multicarbon substrates and the presence of methanol, formate, hydrogen or thiosulfate. The operon is proposed to be regulated by the intracellular concentration of NADPH (Shively et al., 1998; Van Keulen et al., 2000; Van Keulen et al., 2003).

Nitrogen Fixation *Xanthobacter autotrophicus* fixes typically dinitrogen under heterotrophic growth conditions at rates of about 20–25 mg N per g sucrose; however, extreme values of up to 65 mg N per g have been found for cells from the early exponential growth phase (Wiegel and Schlegel, 1976). N_2-fixation under autotrophic growth conditions is the most important feature of *Xanthobacter*, but little work has been published in this respect. N_2 fixation was demonstrated unequivocally for several strains of *X. autotrophicus* using $^{15}N_2$ incorporation into cell protein (Wiegel and Schlegel, 1976). The biochemical studies on the enzyme and its relationship to oxygen have been restricted to *X. autotrophicus* strain GZ29 (Berndt et al., 1976; Berndt et al., 1978) and to *X. flavus* strain 301 (Biggins and Postgate, 1969; Biggins and Postgate, 1971). The nitrogenase in these two strains is similar to that in other aerobic diazotrophs. There is strong variation among the strains in respect to the optimal O_2 concentration for growth under N_2-fixing conditions (J. Wiegel, unpublished observations). In *X. flavus* 301 and *X. autotrophicus* GZ29, the response of the nitrogenase to exposure to air is quite different. The optimal partial pressures of O_2 for acetylene reduction are 5 and 2.5 kPa (whole cells) for strains *X. flavus* 301 and H4-14, respectively, compared to 0.36 kPa for *X. autotrophicus* strain GZ29 (Berndt et al., 1976; Murrell and Lidstrom, 1983). The nitrogenase activity in a cell-free extract of strain 301 decays exponentially with a half-life of about 5 min when stirred under an atmosphere of air. Growth of strain 301 in the presence of ammonium is not influenced by an oxygen partial pressure between 1 and 20 kPa, whereas strain GZ29 had a clear optimum around 15 kPa. This difference in the response to the oxygen partial pressure is even more pronounced for growth under N_2-fixing conditions. The O_2 optimum is around 10 kPa for strain 301 but only 1.5 kPa for strain GZ29.

Miller et al. (1988) demonstrated the presence of a strong vanadium uptake system in some *X. autotrophicus* strains. However, the presence of the alternative vanadium nitrogenase system could not yet be shown through substantial ethane production or through a substantial increase in growth above background when vanadium was added to molybdenum deprived medium (K. Reding and J. Wiegel, unpublished observation). Further research is needed to clarify this question.

Genetics Wilke (1980) described conjugational gene transfer in *X. autotrophicus* strain GZ29, obtaining a low-frequency recombination system with various isolated mutants. Several genes involved in carbon dioxide fixation and carbon metabolism were studied in strain H4-14 (Meijer, 1990a; Meijer et al., 1990b; Meijer et al., 1990c). The authors identified and sequenced the genes for the large (cfx1) and small (cfxS) subunit of Rubisco. Both genes are cotranscribed, and the cfxSL promotor appears to be similar to the *Rhodospirillum rubrum* cfxSL promotor. Downstream are the genes encoding for fructose-biphosphatase (cfxF) and phosphoribulokinase (cfxP). The sequence is similar to those from other sources (Meijer et al., 1990d).

Janssen et al. (1989) used the broad host-range cosmid vector pLAFR11 in a triparental mating system to prepare a gene bank of strain GJ10. Four clones containing genes involved in 1,2-dichloroethane metabolism by strain GJ10 were isolated, and consequently the gene for a haloalkane dehalogenase was cloned and sequenced. The cloned dehalogenase was expressed at a high level (up to 30% of the soluble intracellular protein) in *E. coli*, two strains of *Pseudomonas*, *P. oleovorans* TF41L, *X. autotrophicus* strains 7c, GZ29, XD, and in a halogenase-negative mutant of strain GJ10. The efficiency of conjugation with strong slime-producing strains (e.g, with strain 7c) was generally low (Wilke, 1980; Janssen et al., 1989). Interestingly, *Pseudomonas* strain GJ1 was able to degrade 1,2-dichloroethane after the genes for the dehalogenase were introduced. Also, vectors derived from *Xanthobacter* after introducing the broad-host-range plasmid IncP1 (a RK3 derivative) are suitable for gene cloning in *Xanthobacter* hosts. Whether the methods used by Janssen et al. (1989) provide general and efficient genetic systems for introducing genes into *Xanthobacter* species or cloning genes derived from various *Xanthobacter* species into various other organisms needs to be demonstrated.

Svaving et al. (1996) described an optimized electroporation procedure for *X. autotrophicus* GJ10 and some other strains with high transformation efficiencies (2×10^6 cells transformed per μg DNA). An efficient and useful transposon mutagenesis system (using hyperactive Tn*5*

transposase) has been recently developed and used for the genetic analysis of the pigment biosysnthesis in *X. autotrophicus* Py2 yielding frequencies of approximately 1×10^3 per recipient cell. Since this method worked also with other bacteria, it should work with most *Xanthobacter* strains (Larsen et al., 2002).

Applications Several strains of *Xanthobacter* are of interest for applied research and industrial applications. During the last few years the versatility of *Xanthobacter* strains has become evident. Some of these strains are deposited in nonaccessible deposits as patent strains or as nondisclosed industrial strains. It is anticipated that many novel strains (species) will emerge when further anthropogenic waste compounds are used as carbon and energy source in enrichments. A few strains with features of special interest for applications are described below.

Dehalogenation of Chlorinated Aliphatic and Chloroaromatic Compounds Strain *X. autotrophicus* GJ10 (Janssen et al., 1985) is able to utilize halogenated alkanes as its sole carbon and energy source. The utilization of 1,2-dichloroethane has been studied in detail because the United States Environmental Protection Agency's List of Hazardous Waste Compounds includes 1,2-dichloroethane, along with chloroethane and chloromethane. Strain GJ10 contains a novel haloalkane dehalogenase, which dehalogenates chlorinated, brominated, and iodinated one- to four-carbon *n*-alkanes (Keuning et al., 1985; Inguva and Shreve, 1999). The 36-kDa monomeric enzyme (the cloned gene appears to be a 310-amino acid polypeptide, corresponding to a molecular weight of 35,143; Rozeboom et al., 1988). Janssen et al. assume (Janssen et al., 1985; Janssen et al., 1987), based on physiological data and studies with a mutant, that 1,2-dichloroethane is dehalogenated to 2-chloroethanol in the cytoplasm; 2-chloroethanol, after being exported to the periplasm, is converted by a PQQ-containing 2-chloroethanol dehydrogenase (identified as a dehydrogenase) to chloroacetaldehyde (Bergeron et al., 1998); 2-chloroethanol can appear intermittently in the culture medium. The involvement of a cytoplasmic 2-chloroacetaldehyde dehydrogenase for further transformation to chloroacetate is indicated by the finding that the mutant lacking this enzyme was not able to grow on 1,2-dichloroethane. The final step is a chloroacetate dehalogenase reaction. The 1.7Å crystal structure of the L-2-haloacid dehalogenase (EC 3.8.1.2) is available on the web (http://www.rcsb.org/pdb/1qq7; Ridder et al., 1999). A comparison with other strains of *Xanthobacter* revealed that only the dehalogenases were unique to the 1,2-chloromethane utilizer, whereas the dehydrogenases are common enzymes with broad substrate specificity present in other alcohol-utilizing strains with similar specific activities. Spiess et al. (1995) published strain 14p1, which degrades readily 1,4 dichlorbenzene, whereas strain MAB2 (published as *Arthrobacter* sp.; Villarreal, 1991) degrades a variety of heteroaromatic compounds such as 2-chloracetanilides (2-chloro-*n*-ethylacetamide and propachlor). The substituted anilides are partly only converted to aniline, which is released into the medium. However in coculture with *Sphingomonas* sp. (DSM 7356), propachlor is totally degraded.

Ditzelmüller et al. (1989) isolated *Xanthobacter* strain CP, which could degrade 2,4-dichlorophenoxyacetic acid (2,4-D) with a growth rate of 0.13 per h and a growth yield of 0.1 g biomass per g of 2,4-D, as well as 2,4-dichlorophenoxybutyric acid, 4-chloro- and 2-methyl-4-chlorophenoxyacetic acid, and 4-chloro- and 2,4-dichlorophenol. However, activity for the required enzyme of the ortho-cleavage pathway, catechol 2,3-dioxygenase, could not be demonstrated in cell-free extract. The removal of 1,2-dichloroethane was shown on a laboratory scale using a packed-bed (immobilized microbes on porous diatomaceous earth) bioreactor that was continuously fed with contaminated groundwater from a site adjacent to a petrochemical facility (Friday and Portier, 1989). Feed concentrations of 160 and 230 mg/liter of ethylene dichloride were mineralized to less than 1 mg/liter employing a 12- and 18-h retention time, respectively (Portier and Friday, 1989). In another field study a similar 75-liter fermentor was tested, which was started with an adapted culture of strain GJ10; using a 20.5-h retention time and an approximate dissolved oxygen level of 2.5 mg/liter in the feed stream (leaving the aerator), 86% of 226 mg of ethylene dichloride per liter, 64.7% of 10.9 mg trichloroethylene per liter, and 57% of 2.5 mg tetrachloroethylene per liter were removed. After 42 days, in addition to *Xanthobacter*, four indigenous bacteria from the groundwater including *Comomonas acidovorans* had successfully acclimated to the reactor bed (Miller et al., 1990). Using oxygen gas for oxygenation, shorter retention times and minimization of stripping losses are achieved. Further scale-up for industrial use is under development (R. J. Portier and G. P. Miller, personal communication).

Aliphatic Alkane and Alkene Degradation and Epoxide Formation Adding 5% alkene in air to the gas headspace, Van Ginkel and De Bont (1986a) isolated six propene utilizers and one

butene utilizer (strain By2) from various soil and water samples. The alkenes were converted stereospecifically to the corresponding epoxides. The propene utilizers PY2 and PY10 were studied in more detail. The substrate utilization test indicated that the isolates are related closely to *X. autotrophicus*, although the type strain 7c and the reference strain JW 33 do not utilize either of the alkenes. None of the new isolates grew on alkanes, although alkane-utilizing *Xanthobacter* have been isolated previously on butane (Coty, 1967) and cyclohexane (Trower et al., 1985). DNA-DNA hybridization studies have not yet been published for these strains. The use of 1% alkene in air led only to the isolation of various strains belonging to *Mycobacterium* and *Nocardia*. These strains have a lower Km value for the alkene than do the *Xanthobacter* strains, but at higher concentrations, the *Xanthobacter* strains grow considerably faster. Thus, these strains of *Xanthobacter* can be enriched specifically using 5% alkenes as the sole carbon source. The conversion rates found were 65–70 nmol alkenes per min and mg of protein. The industrial interest is based on the high stereospecificity of the transformation. For example, strain PY10 utilizes ethene, propene, 1-butene, and 1,3-butadiene, but it contains two different 1,2-epoxyalkene-utilizing enzyme systems when grown on ethene or propene (Van Ginkel et al., 1986b). In addition, strain PY2 converts 3-chloro-1-propene to 1-chloro-2,3-epoxypropane with 80% as the S-enantiomer. Propene is converted to the R-1,2-epoxypropane and butene to R-1, 2-epoxybutane at 97% and 94%, respectively (Habets-Crützen et al., 1985). Weijers et al. (1988) used strain PY2 grown on propene for the chiral resolution of 2,3-epoxyalkanes. Since only the 2S-form is metabolized, a chiral resolution was obtained for *trans*-2,3-epoxybutane, *trans*-2,3-epoxypentane, and *cis*-2,3-epoxypentane. However, none of the *Xanthobacter* strains could be used for obtaining the enantiomers of 1,2-epoxyalkanes since all tested strains utilized both enantiomeric forms.

The group of Scott Ensign, using mainly strain Py2 over the last 10 years to work out the biochemistry of CO_2 fixation, aliphatic alkene degradation, epoxide formation, and degradation in *Xanthobacter*, has accumulated a wealth of data too numerous to report here in detail. The reader is referred to his excellent reviews on aliphatic epoxide carboxylation (Ensign and Allen, 2003) and on microbial metabolism of aliphatic alkenes (Ensign, 2001) as well as to his website (http://www. chem.usu.edu/~ensigns/index.htm) for updates on recent publications. Interestingly, the enzymes for aliphatic alkene and epoxide metabolism, which includes also the biosynthetic enzymes for the coenzyme M (2-mercaptoethanesulfonate), are apparently located on a linear megaplasmid (Krum and Ensign, 2001).

The finding that *Xanthobacter* contains coenzyme M was a great surprise since until then it was believed that coenzyme M was unique to methanogens. Subsequently, Ensign and his coworkers have elucidated at least some (5 catalytic activities) of coenzyme M in *Xanthobacter*, i.e., the involvement in the epoxyalkane degradation, including an epoxyalkane:CoM transferase (Zn-enzyme), a 2-ketopropyl-coenzyme M oxidoreductase and carboxylase, and a dehydrogenase (Allen et al., 1999; Krum et al., 2002; Nocek et al. [2002] and literature cited therein).

Magor et al. (1986) showed that the ability to utilize cyclohexane and its derivatives differs in different *Xanthobacter* species (*X. flavus* and *X. autotrophicus* type strains were not able to utilize cyclohexane, but *X. autotrophicus* could degrade cyclohexanol). However, on the basis of recent descriptions of new species and strains, the author believes it is more a property of strains than a discriminator between species per se. The degradation in the cyclohexane degrading strain (closely related to *X. autotrophicus*, but no final taxonomic position has been published) proceeded via cyclohexanol → cyclohexanone → ε-caprolactone → adipidic acid. The cyclohexanone monoxygenases in *X. autotrophicus* and the new strain differed significantly. The authors stated that there was no indication that the degrading strain contained plasmids. In light of the more recently found megaplasmid in strain Py2, the presence of a missed megaplasmid cannot be excluded at this time.

Degradation of Various Hazardous Waste Compounds *Xanthobacter* strain 124X can utilize 4-hydroxyphenylacetate, styrene oxide, and 2-phenylethanol (Van den Tweel et al., 1986; Hartmans et al., 1989). According to the authors, this organism can be used in biofilters to remove these compounds from industrial waste gases. In particular, the malodor of styrene, an important starting material for synthetic polymers and a possible cause of environmental problems, could be removed. A new degradation path was proposed for the metabolism of styrene oxide in strain 124X (Hartmans et al., 1989). Strain GJ10 (or mutants thereof) apparently has some potential for use in bioremediation processes of halocarbon-contaminated groundwaters.

The group of S. Ensign studied the biochemistry of acetone degradation, especially the inducible, ATP-dependent acetone carboxylase (Sluis and Ensign, 1997; Clark and Ensign, 1999; Sluis et al., 2002). Furthermore, Small et al. (1995) described a novel pathway for the degradation of epichlorohydrin by *Xanthobacter* strain Py2. *Xanthobacter tagetidis* (type strain Tag and

strain A2T2C) degrades thiophene-2-carboxylate, thiophene-2-acetate, pyrrole-2-carboxylate, furan-2-carboxylate, and dibenzothiophene while utilizing H_2, sulfide and thiosulfate, respectively, as energy and e-donor sources. The presence of glucose did not prevent the utilization of these substrates (Padden et al., 1997). *Xanthobacter autotrophicus* strain "J. Child, NCIB 11171" was isolated from oil contaminated soil and was shown to utilize a variety of alcohols such as ethylene glycol and propane-1,2-diol.

Applications for Slime Produced by Various *Xanthobacter* Strains Nearly all isolated strains of *X. autotrophicus* and *X. flavus* produce copious amounts of slime. Under chemolithoautotrophic growth conditions and with ammonium as the N source, strain 7c produces about 15–20% (w/w) of its biomass as slime, but grown with 2% fructose and ammonium, about 75–80% of the produced biomass was slime (Andreesen and Schlegel, 1974; Tunail and Schlegel, 1974). Generally, the highest slime production is under nitrogen-fixing conditions, and some strains can produce copious amounts of slime with almost no visible growth; upon cooling with ice, such a culture becomes a solid gel (J. Wiegel, unpublished observations). In this connection it should be mentioned that slime-free mutants have been isolated from *X. autotrophicus* strain 7c (Tunail and Schlegel, 1974) and from some of the alkene utilizers (Van Ginkel and De Bont, 1986a) using carbon-limiting chemostat cultures. We also isolated slime-less variants of the rice isolate JW/KR-1 during a greenhouse experiment when the strain was grown on root exudates from rice seedlings in sterilized sand without added carbon and nitrogen sources (K. Reding et al., unpublished observations).

Kern (1985) and Schubert et al. (Schubert et al., 1986; W. W. Schubert, personal communication) have shown that the slime is an excellent drag-reducing substance (68% reduction using a 1 : 10 dilution of a culture) for minimizing friction in turbulent flows in pipelines and water turbines. The properties of the slime favor its industrial application: apparently slime is resistant to microbial degradation (Andreesen and Schlegel, 1974) and has good shear stability.

Another suggested application of slime is as a viscosifier in oil fields. Wan et al. (1988) isolated a *Xanthobacter* strain producing slime with promising properties (e.g., excellent suspending ability, shear and thermal stability, high viscosity at low concentrations, and salt tolerance). The slime of this strain is composed of 25% glucuronic acid, 50% glucose, and 25% mannose. The largest amounts of slime were produced when this strain was grown using glucose as the carbon source and corn steep liquor as the nitrogen and mineral source. The concentration of both, as well as aeration and pH, played a major role in optimal slime production. In contrast to the new strain, the slime from strain 7c contains about 30% (mol/mol sugar) uronic acids, glucose, galactose, and mannose. The viscosity of this slime was not affected much by the presence of 0.5 M inorganic salts. A 0.4% (w/v) solution of the isolated slime had a viscosity 30 times greater than that of water (Andreesen and Schlegel, 1974).

Kawai et al. (1989) suggest that the slime from *Xanthobacter* could be used as an enhancer in gene recombination experiments of plants, especially when using *A. tumefaciens* as vector. This is based on their finding that the isolated slime (designated "PS-1") from the soil isolate *Xanthobacter* KB-3001 enhanced the attachment of and consequently the frequency of transformation by *Agrobacterium tumefaciens* in the agglutination test using a potato tuber disc assay to screen transformants and by measuring the attachment to tobacco protoplasts and cells. The partially purified (DEAE-cellulofine, AM column chromatography) slime has an apparent affinity for both the bacterial and the plant cells.

Transformations *Xanthobacter autotrophicus* strain 14g, isolated as a Knallgas bacterium, was shown to transform bicyclo [3.2.0]hept-2-3n-6-one and 7-endo propylbicyclo[3.2.0]hept-2-3n-6-one.

Cultures Deposited at Culture Collections For detailed description of the species, see the chapter "Genus *Xanthobacter*" by Wiegel (2004) in *Bergey's Manual of Systematic Bacteriology*, second edition, and in the cited original literature.

The following *Xanthobacter* strains are deposited in culture collections. The culture collections are: American Type Culture Collection (http://www.atcc.org/), Rockville, MD, United States; Deutsche Sammlung für Mikroorganismen (www.dsmz.de/species/gn202260.htm), Mascheroder Weg 1b, Braunschweig, Germany; Culture Collection Institute for Microbiology; (NEU), University Neuchatel, Switzerland; Culture Collection Fermentation Research Institute (FERM), Tsukuba Science City, Japan; and National Collection of Industrial Bacteria (www.ncimb.co.uk/), Torrey Research Station, Aberdeen, Scotland, United Kingdom. Other strains mentioned in this chapter can be obtained from the authors of the various publications, e.g., the author has an extensive collection of *X. autotrophicus*- and *X. flavus*-like strains.

Xanthobacter autotrophicus: Type species. Type strain 7c: DSM 432, ATCC 35674; NCIB 10809 slimeless mutant of 7c: DSM 2267; reference strain JW 33: DSM 1618; IFO 14758; strain GZ29: DSM 1393; strain 23A: DSM 685; strain 14g (oxidation of bicyclo[3.2.0]hept-2-3n-6-one and 7-endo propylbicyclo[320]hept-2-3n-6-one): DSM431, NCIB 10811; strain 19/–/x DSM 2009; strain GJ10 (degradation of chlorinated aliphatic compounds): ATCC 43050, DSM 3874; strain N34: FERM-P1098; strain Y38: FERM-P6724; strain T101: ATCC 700551; strain T102: TCCA 700552; and strain from J. Child (1,2-propandiol metabolism): NCIB 11171.

Xanthobacter flavus: Type strain 301: NCIB 10071, DSM 338, ATCC 35867; strain JW-KR-2 (associative N-fixation on rice roots): ATCC 51492; strain SA12: NEU 2003; strain SA14: NEU 2005; strain CB2: NEU 2151; strain CB5: NEU 2152; and strain 14p1 (1,4-dichlorobenzene utilization): DSM 10330.

Xanthobacter agilis: Type strain SA35: DSM 3770, NEU 2015, ATCC 43847, NCIB 12683; strain MA2: NEU 2038; strain MA37: ATCC 43848; and strain MA40: NEU 2069, ATCC 43849.

Xanthobacter tagetidis: Type strain TagT2C: DSM 11105, ATCC 7000314, NCIB 13547; and strain A2 (thiophenol utilizer): ATCC 700315.

Xanthobacter aminoxidans (basonym *Blastobacter*): Type strain 14a: VKM-B-2254, ATCC BAA-299, DSM 15009.

Xanthobacter spp.: Some of the strains are industrial strains whereas others are just isolates with no special features and which were isolated before 16S rRNA sequences were readily available. Strain CB2: DSM 14517; strain CB 5: DSM 14519; strain CB6: NEU 2153, DSM 14520; strain R-10: DSM 14521; strain MAB2 (degradation of propachlor): DSM 7325, ATCC 49876; strain Texaco NW-11 (patent involved strain for polysaccharide production): ATCC 53272, DSM 6448; and strain 124X (stryrene and toluene degrader): DSM 6696, ATCC 49450.

Acknowledgments. I thank all the colleagues who provided me with preprints, photos, and unpublished data to include in this chapter and K. Reding for providing most of the photographs. This chapter was written with the support of a Department of Energy (DOE) Grant (DE-FG02-01ER15260).

CHAPTER 3.1.16

The Genus *Brucella*

EDGARDO MORENO AND IGNACIO MORIYÓN

Members of the genus *Brucella* are pathogenic bacteria of humans and animals exceedingly well adapted to their host and not surviving for extended periods of time in open conditions. Although the classical definition of *Brucella* species describe these bacteria as facultative intracellular parasites, this definition does not honor their true nature which is better understood as a facultatively extracellular intracellular parasite. That means that the *Brucella* preferred niche is the intracellular environment of host cells. This environment sustains extensive replication, allowing bacterial expansion and the subsequent transmission to new host cells, frequently achieved through the heavily infected aborted fetus. In contrast to in other pathogenic bacteria, no classical virulence factors, such as exotoxins, cytolysins, capsules, fimbria, flagella, plasmids, lysogenic phages, resistant forms, antigenic variation, endotoxic lipopolysaccharide (LPS) or apoptotic inducers have been described in *Brucella* organisms. Instead, the true virulence elements of *Brucella* are those molecular determinants that allow them to invade, resist intracellular killing and reach their replicating niche in professional and non-professional phagocytes.

Brucella organisms are α-*Proteobacteria* phylogenetically closely related to plant pathogens and symbionts such as *Rhizobium*, *Agrobacterium* and *Wolbachia*, intracellular animal parasites such as *Bartonella* and *Rickettsia* and to opportunistic and free living bacteria like *Ochrobactrum* and *Caulobacter*. The demonstration of the phylogenetic closeness between the brucellae and other eukaryotic cell-associated bacteria, no matter whether they are of animal or plant origin, has had a profound impact in the way we envisage the virulence mechanisms of these bacteria. In course, this circumstance has resulted in new research strategies and biological interpretations that have greatly contributed to understand the biology and parasitism of *Brucella* organisms.

Phylogeny

Brucella species constitute a closely related monophyletic group with DNA-DNA reassociation values near 100% (Verger et al., 1985). Ribosomal cistron similarities and 16S RNA sequence comparisons demonstrate the phylogenetic position of *Brucella* species in the α-2 of the class Proteobacteria (De Ley et al., 1987; Moreno et al., 1990). The genus clusters with plant and animal pathogens, as well as with free-living heterotrophic and photosynthetic organisms of water and soil (Fig. 1). Phylogenetic analysis using GroEL heat shock proteins reveals similar branching dispersion to that obtained with ribosomal genes (Viale et al., 1994; Fig. 2). Comparison of lipid As, ubiquinones, membrane lipids, cyclic glucans and several cytoplasmic and membrane proteins also reveals close relationship of *Brucella* with other members of the α-2 Proteobacteria (Gupta, 1997; Moreno, 1992; Moreno et al., 1990; Velasco et al., 2000). On the basis of these genotypic and phenotypic characteristics, a model for explaining the evolution of *Brucella* parasitism from a common free-living ancestor has been proposed (Moreno, 1992; Moreno et al., 1990). This scheme has been upgraded and validated in successive works according to recent findings (Moreno, 1997; Moreno, 1998; Pizarro-Cerdá et al., 1999b; Sola-Landa et al., 1998; Velasco et al., 1998a; Velasco et al., 2000).

Ancestor-Descendent Relationships

The closest *Brucella* relatives are members of the genus *Ochrobactrum* (De Ley et al., 1987; Holmes et al., 1988; Lebhun et al., 2000; Velasco et al., 1998b). This genus contains five known species. *Ochrobactrum intermedium* is the most phylogenetically and taxonomically related to the *Brucella*, with 16S rDNA similarity values close to 97%. Both *Brucella* spp. and *O. intermedium* diverge from the same branch, outside of the other *Ochrobactrum* spp. (Fig. 1). In spite

Fig. 1. Phylogenetic tree showing the relationship among representative plant-associated, free-living, opportunistic and animal-associated α Proteobacteria of the subdivision. The genomic characteristics and the preferred host(s) for each bacterium are indicated in the table. The tree was constructed by the neighbor-joining method (Saitou and Nei, 1987) from Knuc values derived from 16S rRNA sequences available at the European Molecular Biology Laboratory (EMBL), GeneBank and DNA Databank of Japan (DDBJ) Nucleotide Sequence Database.[a] The presence of essential genes has not been confirmed.[b] These bacteria may behave as animal-opportunistic organisms.[c] Linear chromosome.[d] Non-curable essential replicon.[e] Plasmids have been detected in Caulobacter strains.[f] Lysogenic phages and recombination have been documented in *Wolbachia*. References for representative strains in the tree are as follows: *Agrobacterium* spp. (Allardet-Servent et al., 1988; Jumas-Bilak et al., 1998b; Goodner et al., 2001; Hulse et al., 1993; Southern, 1996; Yanagi and Yamasato, 1993); *R. galegae* (Huber and Selenskapobell, 1994; Jordan, 1984; Yanagi and Yamasato, 1993); *S. meliloti* (Galibert et al., 2001; Honeycutt et al., 1993; Kolsto, 1997; Yanagi and Yamasato, 1993); *M. loti* (Jordan, 1984; Kaneko et al., 2000; Yanagi and Yamasato, 1993); *P. myrisinacearum* (Jordan, 1984; Jumas-Bilak et al., 1998b; Lambert et al., 1990); *Bartonella* sp. (Birtles et al., 1995; Brenner et al., 1993; Dehio and Meyer, 1997; Jumas-Bilak et al., 1998b; Krueger et al., 1993; Maruyama et al., 2001; Maurin et al., 1994); *Brucella* spp. (Bricker et al., 2000; DelVecchio et al., 2002; Jahans et al., 1997; Jensen et al., 1999; Jumas-Bilak et al., 1998a; 1998b; Meyer, 1990; Michaux-charachon et al., 1993, 1997); *O. intermedium* (Holmes et al., 1998; Jumas-Bilak et al., 1998b; Lebhun et al., 2000; Velasco, 1996; 1998a; Yanagi and Yamasato, 1993); *Afipia felis* (Brenner et al., 1991; Fumarola et al., 1994); *Rhodobacter* spp. (Choudhary et al., 1995; Fonstein et al., 1992; Imhoff and Trüper, 1984; Jumas-Bilak et al., 1998b; Mackenzie et al., 1995; Nikolskaya et al., 1995; Suwanto and Kaplan 1992); *B. japonicum* (Jordan, 1984; Kündig et al., 1994; Masterson et al., 1985; Wong et al., 1994); *C. crescentus* (Nierman et al., 2001; Schoenlein and Ely, 1983); *R. prowaseki* (Andersson et al., 1998; Roux and Raoult, 1993; Weisburg et al., 1989); and *Wolbachia* sp. A. (Sun et al., 2001; Werren and Bartos, 2001). The *Brucella* marine strains possess two chromosomes with molecular weights similar to those of *B. abortus* (D. O'Callaghan, personal communication).

of the strong similarities between these two genera, their biological properties are strikingly different. While *Brucella* organisms are intracellular primary parasites, cycling from animal to animal, not requiring host predisposing conditions, *Ochrobactrum* organisms are opportunistic bacteria that cycle from soil-rhizoplane to immunocompromised humans.

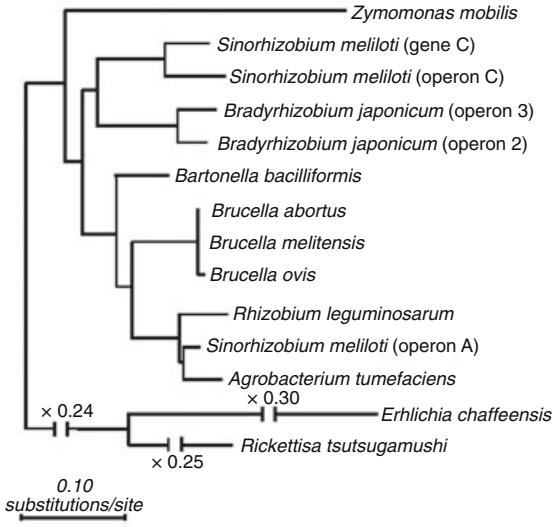

Fig. 2. Evolutionary relationships between α-2 Proteobacteria based on GroEL sequence comparisons. The tree was constructed by the neighbor-joining distance method (Saitou and Nei, 1987). *Escherichia coli* was used as an outgroup reference for rooting the tree. GroEL sequences were obtained from EMBL, GeneBank and DDBJ Nucleotide Sequence Database. Notice that the general topology of the tree agrees with that of (Fig. 1).

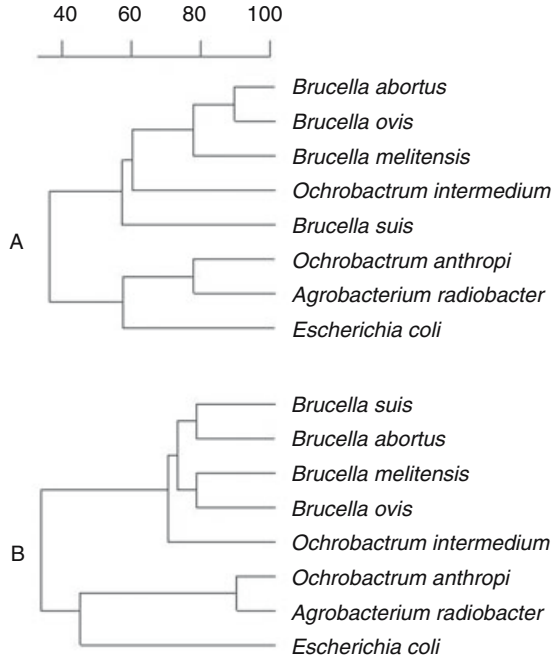

Fig. 3. Dendrograms derived from unweighted pair group average linkage of correlation for the corresponding banding patterns constructed by comparison of the whole cell protein antigens detected by Western blotting with antiserum against *O. intermedium* 3301 (A) and antiserum against *B. suis* 1330 (B). Notice that *O. intermedium* clusters together with *Brucella* species, in agreement with the phylogenetic tree constructed by 16S rRNA sequence comparison (Fig. 1). Modified from Velasco et al. (1998a), with permission.

Although *Brucella* demonstrate low DNA reassociation values with other members of the α-2 subdivision (20–30% for *Ochrobactrum*; Holmes et al., 1988), extensive immunochemical crossreaction between the proteins of *Brucella* and proteins of other α-2 Proteobacteria are evident (Cloeckaert et al., 1999; Velasco et al., 1998b). Dendrograms constructed on this basis reveal intermixing of *Ochrobactrum* and *Brucella* species and close relationship with members of the family Rhizobiaceae (Fig. 3). For this group of bacteria proteomic analysis seems to be a more reliable taxonomical tool than DNA hybridization (Cloeckaert et al., 1999; Velasco et al., 1998b).

Several of the characteristics present in *Brucella* and shared by various members of the α-2 subdivision are considered ancestral (Table 1). Among them are the RopA and RopB outer-membrane protein family, the long-chain fatty acids of the lipopolysaccharides (LPSs) and other membrane lipids, quinovosamine sugar in the LPS core (in smooth strains), the presence of phosphatidylcholine, ornithine-containing lipids and various lipoproteins, as well as the periplasmic cyclic glucans, catalase and superoxide dismutase (Sod), the inner membrane ubiquinones and various cytochrome types (Table 1). In metabolic activities, absence of a functional hexose diphosphate pathway, the oxygen and carbon dioxide requirements, a hexose monophosphate shunt, and the erythritol pathway seem to be ancestral features. The presence of two chromosomes is also considered to be ancestral, since several members of the α-2 subdivision, including *Ochrobactrum*, possess two chromosomes (Jumas-Bilak et al., 1998a; Fig. 1). The tendency of their members to associate with eukaryotic cells may be one of the most striking ancestral properties of the group (Dorsh et al., 1989; Moreno et al., 1990).

In addition to the metabolic and biochemical properties that distinguish the *Brucella* genus from other bacteria, there are some important derived characteristics (Tables 1–4). They include certain features affecting the cell surface, such as the presence of genes coding for *N*-formylperosamine polysaccharides and their expression in smooth strains, as well as the absence of capsules, flagella, pili and fimbriae (Table 1). Although genes coding for some of these structures have been identified in the *Brucella* genome, (DelVecchio et al., 2002), their expression in the *Brucella* surface has not been

revealed, in spite of several attempts to detect them (J. Gir6 et al., unpublished observations). Features that seem to have been derived independently in the *Brucella* lineage are the absence of a functional Entner-Doudoroff pathway, the more restricted metabolic alternatives, the absence of plasmids, the reduction of chromosome size and the reduction of G+C content with respect to the ancestor (Table 1; Fig. 1). Several of these properties are also present in various of the *Brucella* animal pathogen's close relatives (Moreno, 1992), but it is likely that they are the result of convergent evolution rather than of ancestral origin. The basis for this relies on the fact that *Brucella*, *Bartonella* and *Rickettsia* are intracellular parasites, which may have been exposed to equivalent evolutionary constraints within the intracellular environment of cells. For instance, reduction of chromosomal size, concomitant reduction of G+C content and the absence of plasmids (Fig. 1) probably emerged independently in these three genera. Similar to this may be the slow generation time displayed by intracellular bacteria. This characteristic, which correlates with the reduced number of *rrn* operons in the genomes of these organisms, may be the consequence of heterotrophic metabolism required for growth. This feature may have derived independently in several intracellular bacteria, such as *Mycobacterium*, *Rickettsia* and *Bradyrhizobium*, and therefore may be the result of coevolution rather than the consequence of an ancestor-descendent relationship (Moreno, 1998).

Brucella Speciation

A striking feature that distinguishes the *Brucella* genus is the clonal structure of its species as compared to the reticular arrangement of its soil-plant-associated bacterial relatives (Moreno, 1998; Yanagi and Yamasoto, 1993; Young and Wexler, 1988; Population Genetic Composition of the *Brucella* Species). This feature is probably the result of a founder effect during parasitism, and in fact, there are a considerable number of intracellular Proteobacteria with no recognized plasmids (species of *Brucella*, *Bartonella*, *Rickettsia* and *Anaplasma*), as well as some endosymbionts that must be considered clonal rather than reticulate bacteria (Fig. 1).

In *Brucella* species, restriction maps at insertion sequences and maps based on outer membrane proteins, fatty acids and numerical analysis generate dendrograms that are commensurate with the preference of *Brucella* species for their animal host (Fig. 2). On the one hand, the *Brucella* ancestor may have originated by a "brief" burst of change between 75 and 40 million years ago (Moreno, 1992; Ochman and Wilson, 1987), according to the mode of evolution proposed by punctuated equilibrium (Eldredge and Gould, 1972). On the other hand, dispersion of *Brucella* species and strains may be the result of more gradual genetic changes (i.e., point mutations, transpositions, recombinations, inversions and deletions) within the isolated environment of their host (Moreno, 1998). The fact that the *Brucella* genus stands as a clearly distinct assemblage among Proteobacteria, but at the same time constitutes a close monophyletic group of species, supports this path of evolution. Therefore, it is likely that speciation of intracellular pathogens and endosymbionts is commensurate with the evolutionary history of the bacterial host (Ochman and Wilson, 1987), since most of the environmental constraints that direct natural selection seem to be present in the host (Brunham et al., 1993; Laguerre et al., 1993). This also means that extinction of the natural host may cause extinction of the specific parasitic *Brucella* species or strain (Biological Attributes in the Context of *Brucella* Species Definition). In this respect, the evolutionary history of *Brucella* may reflect the outcome of a combination of these two modes of change, punctuated equilibrium followed by gradualism.

By comparing the various dendrograms (Fig. 4), it seems feasible to hypothesize that *B. abortus* and *B. melitensis* shared the same ancestor, and this ancestor probably shared a relationship with the common ancestor of the marine strains. Likewise, *B. canis* and *B. suis* shared a common ancestor. Indeed, the size of the two chromosomes of *B. canis* and biovars 2 and 4 of *B. suis* correspond; similarly, the size of the two chromosomes of *B. abortus* and *B. melitensis* also correspond, supporting the topologies of the trees. It has been hypothesized that *B. suis* is the closest species to the *Brucella* ancestor (Plommet, 1991). This postulate is sustained by several observations. For instance, *B. suis* is the most diverse brucellae in genomic structure (Number and Species Differences) and host preferences (Table 2), and because the species has a wider range of biochemical alternatives, its metabolic capability comes closest to prototrophy (Nutritional Requirements). Moreover, trees constructed on the basis of biochemical characteristics or protein crossreactivity, on which the heterotrophic *O. intermedium* is included as an outgroup, show that *B. suis* strains are the brucellae most closely related to *Ochrobactrum* (Fig. 3). If we accept that speciation in some clonal bacterial populations, with no horizontal transfer of genes, may be gradual and commensurate with time, then *B. suis* is the most diverse among the different *Brucella* species, and the most closely related to the heterotrophic ancestor.

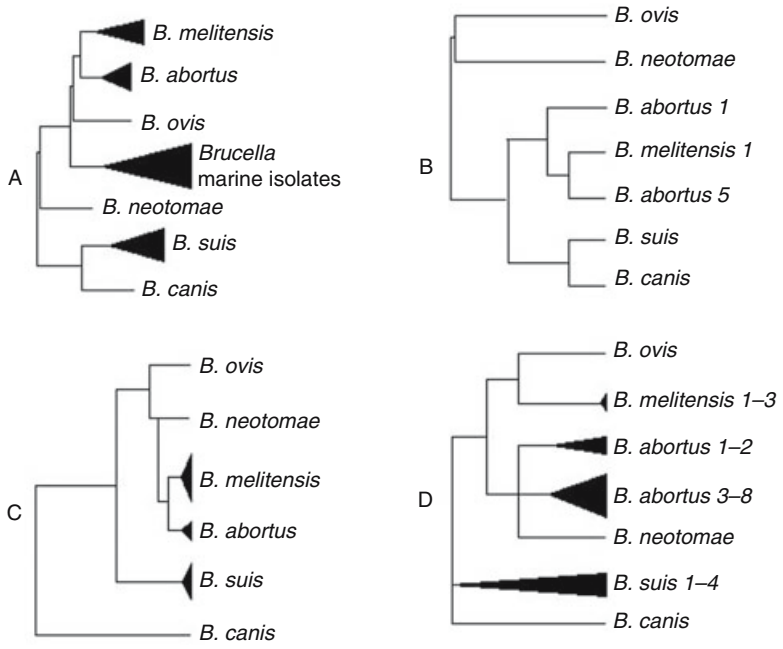

Fig. 4. Dispersion of *Brucella* species in dendrograms constructed by various methods. Modified dendrogram constructed on the basis of fingerprints with restriction endonucleases (A: Jensen et al., 1999); modified dendrogram constructed on the basis of sequence analysis of *omp*2 locus (B: Ficht et al., 1996); modified dendrogram constructed on the basis of fatty acid analysis (C: Tanaka et al., 1977); modified dendrogram constructed on the basis of numerical analysis (D: Gargani, 1977). Notice that although the species are resolved as independent units in the trees, the topology and the relative distances among the extant organisms in the different trees vary. The cones represent the dispersion of the various *Brucella* strains.

Genome Evolution

Brucella organisms are closely related to and phylogenetically entwined with heterotrophic bacteria that carry a single chromosome but have no plasmids and are associated with animal cells (Fig. 1). They are also entwined with opportunistic, plant-associated, chemoautotrophic and photosynthetic α Proteobacteria possessing one or more chromosomes and plasmids (Fig. 1). The genome organization and phylogenetic ancestor-descendent relationships between *Brucella* containing two chromosomes and *Brucella suis* biovar 3 harboring one single chromosome (*Brucella* Chromosomes) suggest that this biovar has undergone transition from two chromosomes to a single replicon (Moreno, 1987). The time at which this event took place can be estimated by comparing specific sequences from *B. suis* strains 1, 2 or 4 with two chromosomes with sequences in the chromosome of *B. suis* biovar 3 (Jumas-Bilak et al., 1998a). From phylogenetic analysis, it is likely that transition from two chromosomes to a single replicon in *B. suis* biovar 3 occurred after speciation. This is supported by the inclusion of *B. suis* biovar 3 within the same tree topology (Figs. 1 and 4) and by the maintenance of the biochemical characteristics and host preferences in relation to the other *B. suis* biovars (Tables 2 and 3). Therefore, the presence of one or more chromosomes within the same *Brucella* species seems to be the result of a contingency with no apparent consequences, as long as the essential information is correctly expressed.

The "local adaptation" hypothesis provides a framework for explaining the selective forces that generated phylogenetically related bacteria, some with larger and other with smaller genomes and some with plasmids and others without these genetic elements (Eberhard, 1990). This hypothesis states that "many of the characters that tend to occur on plasmids are adaptations to local variations in environmental conditions that occur only sporadically in time or space." In some instances, such as local adaptations to antibiotics, which are generally restricted to the immediate vicinity of antibiotic-producing organisms like fungi and actinomycetes in soil, "this kind of sporadic selection makes the maintenance of local adaptations more likely when genes are on plasmids than when they are on chromosomes." This circumstance also applies to the production of virulence factors, medical usage of antibiotics, heavy metal resistance, inactivation of poisons or degradation of unusual substrates, among others. Therefore, local variations in open environments, such as soil, water, manure, gut systems and the external surfaces of plants and animals, probably selected α Proteobacteria with extensive metabolic alternatives, broad genetic diversity, and more flexible and larger genomes with ability for horizontal gene flux. This would be the case for plant-associated *Rhizobium*, *Sinorhizobium*, *Agrobacterium*, *Phyllobacterium* and *Ochrobactrum* species. On the contrary, the constant and isolated animal cellular milieu selected heterotrophic *Brucella* species with smaller genomes, no plasmids, and a reduced genetic diversity as compared to their

[a]Adapted from Alton et al. (1988).
[b]Type strains can be obtained from ATCC (http://www.atcc.org/).
[c]Some isolates do not grow on dyes.
[d]Some isolates are resistant to fuchsin.
[e]Negative for most strains.
[f]*B. neotomae* grows on thionin at 10µg/ml.

plant-associated and phototrophic relatives, but similar to their animal pathogen relatives, such as *Bartonella*, *Rickettsia* and *Anaplasma* species. Therefore, it seems that the ancestral *Brucella* genome evolved through reduction of a larger genome of a chemoautotrophic free-living ancestor and became rich in adenine and thymidine, as compared to the genomes of its precursors (Moreno, 1998).

Under suitable circumstances of temperature and the presence of nutrients, *Brucella* organisms can survive in an open environment, but there is no evidence that they replicate to a significant extent in soil, water or manure under natural conditions (Corbel and Brinley-Morgan, 1984). Thus, *Brucella* species behave essentially as strict parasites and rely for their survival, reproduction and persistence in nature on transmission between animal hosts. This picture differs from that occurring in their plasmid-containing human opportunistic and plant-associated relatives, which shift from external to host environments (Alnor et al., 1994; Bouzar et al., 1993; Brenner et al., 1991; Hulse et al., 1993; Jordan, 1984). In their hosts, *Brucella* organisms do not confront adverse local conditions found in external surroundings, such as antibiotics, heavy metals, bacterial competition and rapid environmental changes. Since *Brucella* organisms only reproduce in their hosts, the advantage of plasmids carrying genes to cope with these conditions would be trivial. It could be argued that plasmids carrying genes (e.g., for adhesion/invasion and antiphagocytic proteins) necessary to deal with variable local conditions, such as the host immune response, would be maintained by positive selection (Eberhard, 1990). However, the *Brucella* lifestyle seems to favor the presence of these genes in chromosomes rather than in plasmids. On the one hand, the intracellular milieu protects the bacteria against intermittent variable defenses, such as antibodies and complement (Survival Outside Host Cells); on the other hand, *Brucella* evades the digestive mechanisms and attains control of the cell (Controlling the Host Cell). Since the cellular environment is relatively constant concerning temperature, acidity, oxygen tension, availability of substrates and presence of bactericidal molecules, the *Brucella* physiology must match that of their hosts, in that the bacteria must be able to salvage the metabolites they need (Life Within the Replicating Niche). Housekeeping genes must secure these delicate functions. Without the positive selection imposed by external or immune local forces, the plasmid-bearing bacteria would be at a slight disadvantage (in comparison with plasmid-free bacteria that would reproduce more rapidly). It is known that unpaired segregation and loss of plasmids

are likely to occur when plasmid carriage reduces bacterial fitness in the absence of selection for specific functions (Levin and Lenski, 1983). Accordingly, the periodic invasion by parasitic bacteria of higher fitness (arising from one or very few individuals without transmissible plasmids) would clonally expand. Transmission of the bacteria to a naïve host would generate a founder effect and the diversity of the "new parasite" would be restricted to chromosomal changes (Frank, 1994). Some of the genes involved in parasitism were, however, probably acquired by horizontal transference exclusively by the *Brucella* ancestor; among these are some genes coding for enzymes for the synthesis of the *O*-polysaccharide (Table 5; Acquisition of Ancestral Genes by Horizontal Transference).

The characteristics and genome sizes in the *Brucella* extant species suggest that a second smaller chromosome evolved from megaplasmids by the acquisition of housekeeping genes (i.e., RNA genes). For instance, the *Agrobacterium* arginase and ornithine cyclodeaminase genes, present in the virulence Ti plasmid, are necessary for inducing tumors in plants and display high similarity with homologous genes located in the same operon and in the same order in the smaller *Brucella* chromosome (Kim and Mayfield, 1997). Moreover, the *vir* genes necessary to build the type IV secretion apparatus in *Agrobacterium* and *Brucella* are located in the Ti megaplasmid of *Agrobacterium* and in the smaller chromosome of *Brucella*, respectively (O'Callaghan et al., 1999; Sánchez et al., 2001). The *Brucella vir* set of genes seems to be regulated in a similar fashion as the *vir* genes located in the plasmid of the *Agrobacterium* plant pathogen (O'Callaghan et al., 1999).

Derivation of Ancestral Preexisting Structures for Virulence

The fine adjustments between *Brucella* parasites and their host cells are the result of a prolonged and intimate association. The evolutionary process that has shaped *Brucella* parasites does not operate by inventing but rather by reinventing on the grounds of pre-existing structures that are constantly confronted with specific local conditions. For instance, the periplasmic domains (involved in environmental sensing) of the sensory proteins (ChvG, ExoS and BvrS) of the two-component, sensory-regulatory systems necessary for bacterial parasitism of *Agrobacterium*, *Sinorhizobium* and *Brucella* (The BvrR-BvrS System) show less similarity than do other protein domains, implying that they were derived for sensing different stimuli (Sola-Landa et al., 1998). Although it is remarkable that the two intracellular bacteria (*Sinorhizobium meliloti* and *B. abortus*) are more similar in this region than is the pericellular one (*Agrobacterium tumefaciens*), the *Sinorhizobium* system is involved in the production of succinoglycan (Cheng and Walker, 1998), whereas the *Brucella* Bvr system seems to be involved in the structural homeostasis of the outer-membrane (C. Guzmán-Verri et al., unpublished results).

The Vir systems of *Brucella* and *Agrobacterium*, although similar in many respects, function in different cellular environments (Fig. 5). In *Agrobacterium* this secretion system delivers Ti DNA and possibly some Vir proteins to govern the plant host cell (Christie and Covacci, 2000), whereas in *Brucella*, it is likely that the system transfers molecules inside phagosomes for controlling intracellular trafficking (Escaping from the Endocytic Pathway). Type IV secretion systems are probably derived from the basal body necessary to propel the flagellum. Although *Brucella* organisms possess genes for flagellin, the bacteria are nonmotile, stressing the notion that the system is derived directly from pre-existing secretion systems (GenBank accession number AFO19251).

The absence of cyclic glucan renders *Brucella*, *Agrobacterium* and *Rhizobium* incompetent to parasitize. The putative protein coded by the β (1–2) cyclic glucan synthetase *cgs* gene of *B. abortus* is highly similar to the NvdB protein of *S. meliloti* (Ugalde, 1999) and is capable of complementing that of *Agrobacterium* and *Sinorhizobium* for parasitism (and vice versa). Moreover, *Brucella cgs* restores mobility in these plant pathogens, suggesting that this protein has different functions depending upon the bacterial background where it is expressed. In *Brucella* organisms, the cyclic glucan is not osmoregulated (Briones et al., 1997) and captures cholesterol (I. Moriyón, unpublished observations), implying that its function may differ from that in *Agrobacterium* and *Rhizobium*. Among the proposed functions for Cgs, one is to serve as transporter for several components in the bacterial inner membrane (Ugalde, 1999).

Another important example of the adaptation of pre-existing structures designed for different purposes may be found in the characteristics of the outer-membranes, which are shared by various members of this group (Moreno, 1992; Moreno, 1998; Velasco et al., 2000). For instance, in spite of having almost identical lipid As and sharing many outer-membrane physical and chemical properties, *Ochrobactrum* is sensitive to bactericidal cationic peptides, whereas *Brucella* is highly resistant (Velasco et al., 2000). As in other α-2 Proteobacteria, the core oligosaccharide of *Ochrobactrum* (but not that of

[a]Where the gene has been identified.

[b]ID code in SWALL database.

[c]Step affected by mutation.

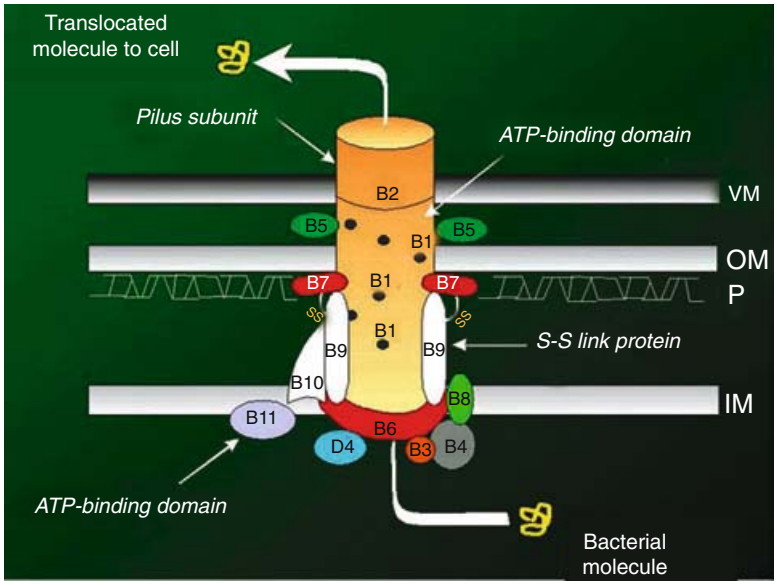

Fig. 5. Hypothetical model of a type-IV secretion system necessary for dispatching "virulent" proteins from the *Brucella* cell to the cytoplasm of the animal cell. Impairment of this system makes *Brucella* avirulent. Nonpolar *virB*$^{-10}$ mutant displays altered intracellular trafficking in epithelial cells (Fig. 36).

Brucella) possesses a negatively charged uronic acid residue that in all likelihood accounts for this different sensitivity (Response to Environmental Stress). Because the resistance to bactericidal cationic peptides is an essential property related to *Brucella* parasitism, the absence of uronic acids in *Brucella* LPS core is conspicuous and likely to be a key evolutionary variation linked to its adaptation as an intracellular pathogen (Fig. 6).

It has been determined recently that, in contrast to the LPS of free-living bacteria, the LPS of *Rhizobium* intracellular bacteroids become highly hydrophobic (Kannenberg and Carlson, 2001). It was suggested that the switch from hydrophilic to a predominantly hydrophobic LPS is the result of an adaptive response for changing environments. In the case of *Brucella*, the highly hydrophobic outer-membrane (Moriyón and Berman, 1982; Martínez de Tejada and Moriyón, 1993) seems to be well adapted to intracellular life (Moreno, 1992; Moreno, 1998; Velasco et al., 2000). This pattern offers a starting point on which the strong hydrophobicity of the lipid A of many α Proteobacteria is complemented in *Brucella* by modification of the LPS core and by the horizontal acquisition of *N*-formylperosamine genes for the synthesis of the hydrophobic *O*-polysaccharide and native hapten (NH)-polysaccharide (Godfroid et al., 1998; Velasco et al., 1996; Velasco et al., 1998a). The significance of this adaptive evolution of *Brucella* to its intracellular niche is stressed by carefully comparing the LPS of *Legionella* and *Brucella* (Fig. 7) since both intracellular pathogens have arrived from the extremes of different phylogenies to a very similar solution (Velasco et al., 1998b; Velasco et al., 2000; Zähringer et al., 1995; Acquisition of Ancestral Genes by Horizontal Transference).

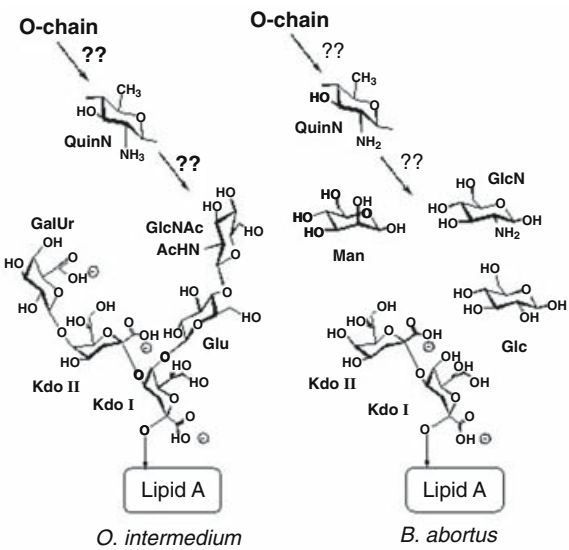

Fig. 6. Core oligosaccharides of the LPS of *O. intermedium* and *B. abortus*. The *O. intermedium* structure lacks heptose and phosphate also absent in *B. abortus* LPS. On the other hand, the *O. intermedium* carries anionic galacturonic acid that has not been detected in *B. abortus* or *B. melitensis*. The structure presented for *O. intermedium* LMG 3301 may represent only a partial structure, since sugar analysis of *Ochrobactrum* S-LPS suggests quinovosamine in the core and there is also evidence for an additional unknown sugar linked to glucuronic acid. Quinovosamine seems to be the sugar that links the core with the *O*-polysaccharide.

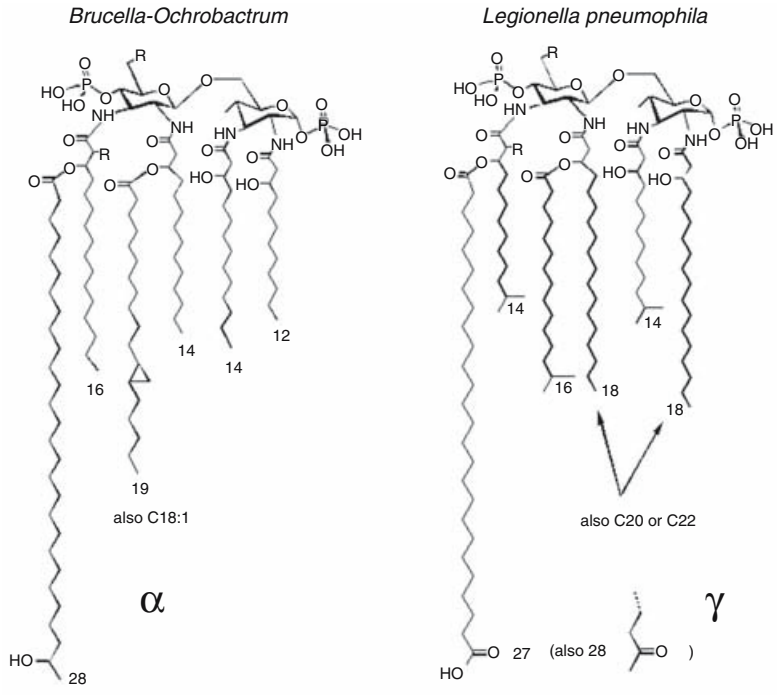

Fig. 7. Proposed structures of the lipids A of the *Brucella-Ochrobactrum* cluster and of *Legionella pneumophila*. The structures do not take into account heterogeneity due to different degrees of acylation or additional microheterogeneity due to variations in the type of acyl substitutions (based on the data of references Velasco et al., 2000; Zähringer et al., 1995). While *Brucella* and *Ochrobactrum* cluster within the α-2 subclass of Proteobacteria, *Legionella* belongs to the γ subclass. In spite of the far phylogenetic relationship between *Brucella* and *Legionella*, both intracellular parasites share a similar lipid A structure, likely to be the product of coevolution.

Acquisition of Ancestral Genes by Horizontal Transference

Local conditions may determine the plasticity and size of the genome during evolution (Population Genetic Composition of the *Brucella* Species) as well as the plasticity of the outer-membrane (Kannenberg et al., 2001; Moreno, 1997; Velasco et al., 2000). In contrast to other parasitic bacteria, most of the virulence genes identified in *Brucella* so far have been received vertically from a common ancestor, as revealed by the extensive amelioration of the sequences and by the fact that *Brucella* organisms do not possess plasmids (Genome Evolution; Genetic Exchange, Plasmids and Lysogenic Phages). One conspicuous exception may be the horizontal acquisition of the perosamine synthetase gene necessary for the synthesis of the *N*-formyl perosamine homopolymers (Godfroid et al., 1998), a gene which is also present in several pathogens, such as *Salmonella*, *Yersinia enterocolitica* and *Vibrio cholera* strains (Cherwonogrodzky et al., 1990; Table 6). This and other genes necessary to assemble the *O*-polysaccharide and NH polysaccharides were probably acquired exclusively by the *Brucella* ancestor, since none of the other members of the α-2 Proteobacteria seem to synthesize this sugar, not even the closest phylogenetic relative of *Brucella*, *Ochrobactrum* spp. (Velasco et al., 1998a; Velasco et al., 2000). The incorporation of *N*-formylperosamine polymers on the framework of a quinovosamine-containing core and lipid A basic structures (shared by many other α-2 Proteobacteria) was a crucial step for the development of the pathogenic properties of smooth *Brucella* (Inhibition of Lysosome-phagosome Function). Moreover, genes required for the synthesis of *O*-polysaccharides are present in the "natural rough" *B. ovis* and *B. canis* (Cloeckaert et al., 2000), suggesting that this was an ancestral character. Because dissociation from smooth to rough phenotype is a common event among brucellae (Colonies and Dissociation), it is likely that the loss of *O*-polysaccharide occurred separately during evolution of these two rough brucellae and not as an ancestor-descendent relationship. Changes that generated a low endotoxic core-lipid A structure, which also conferred resistance to bactericidal substances and proportioned the hydrophobic properties of the *Brucella* outer-membrane (Outer Membrane Versus Bactericidal Substances), must be added to the characteristics already described.

Taxonomy

The brucellae are included in a single genus placed in the α-2 subclass of the Proteobacteria (Population Genetic Composition of the *Brucella* Species). Through the years, classical *Brucella* taxonomists developed a classification system that established the six species (*B. melitensis*, *B. abortus*, *B. suis*, *B. neotomae*, *B.*

Table 6. Structures of the LPS *O*-polysaccharides of *Brucella abortus* and serologically crossreacting bacteria.[a]

Abbreviations: Rhap4*N*Fo, *N*-formyl-perosamine (pyranose); Rhap4*N*(3-deoxy-L-tetronic acid), *N*-3-deoxy-tetronyl-perosamine (pyranose); Glcp, glucopyranose; Galp*N*Ac, *N*-acetyl-galactosamine (pyranose); Rhap4*N*Ac, *N*-acetyl-perosamine (pyranose); and Fucp, fucopyranose.

[a]Structures are from Perry and Bundle (1990b). *Francisella tularensis* crossreacts with smooth *Brucella*, but its *O*-polysaccharide structure is not known.

[b]Although indistinguishable from the *O*-polysaccharide of *B. abortus* biotype 1, the reactivity with monoclonal antibodies suggests subtle chemical differences perhaps related to the degree of *N*-formylation.

[c]Other *V. cholerae* containing perosamine derivatives are Hakata (Rhap4*N*Ac), O76 and O144 (Rhap4*N*[2-hydroxypropionate]) and 1875 (Rhap4*N*[3-hydroxypropionate]). See Isshiki et al. (1995); Kondo et al. (1993, 1996); Sano et al. (1996).

[d]Only some serovars (such as *E. hermanni* NRCC 4262, 4279, 4298, 4299 and 4300; Perry and Bundle, 1990a).

[e]Only some serovars (such as *S. maltophila* 555 and 556 [CECT 112 and 113]).

ovis and *B. canis*) that are presently recognized by the Subcommittee on Taxonomy of *Brucella*. Main characters used in this classification are the host range and the cell surface features (Table 2). These six species are further subdivided into biovars (or biotypes) that have been useful in epidemiological studies. Although the system has proven to be useful in the past, revision is required in the light of recent discoveries. Several *Brucella* strains that do not fit into the classical species have been isolated from marine mammals and show internal diversity (Jahans et al., 1997). Depending upon whether marine strains are included as one species (*B. maris*) containing three biovars or as three different species, the genus may increase from 6 up to 9 species in the coming years (Jahans et al., 1997). This traditional view on the subdivision of the genus into species was challenged over a decade ago on the grounds that the high degree of DNA homology demonstrated in the DNA hybridization experiments conformed better with the definition of a single species of which the six classical species would not be but biovars (Verger et al., 1985). The view that the genus is divided into at least the six classical species is adopted in this chapter because the controversy arises from the use of different concepts of species, not all of which are valid or have a relevant biological value when applied to *Brucella*. This issue has been, and still is, a matter of confusion that has affected some important culture collections. This controversy is discussed in depth in the next sections (Population Genetic Composition of the *Brucella* Species; Defining the *Brucella* Species).

The Genus *Brucella*

The brucellae can be readily distinguished from other bacteria on the basis of the phenotypic and biochemical characteristics, host preferences, phylogenetic studies and serological analysis (Ficht et al., 1996; Moreno, 1998; Velasco et al., 1998b; Tables 1, 2, and 4). Comprehensive revisions of the genus based on traditional characteristics have been examined in several works (Alton et al., 1988; Corbel and Brinley-Morgan, 1984; Moyer and Hausler, 1992). The cellular and colonial characteristics (Identification), the nutritional and physicochemical requirements (Isolation), and the structural (Metabolism) and overall genetic (Genetics) properties are presented elsewhere in the chapter.

Although *Brucella* shares several features with other α-2 Proteobacteria, various idiosyncratic characters are remarkable (Table 1). All mem-

bers of the genus are primary parasites that do not require predisposing host factors. Host preference, predilection for reproductive tissues, affinity for fetal tissues and the induction of abortion and male epididymitis are some of the most marked biological features of the *Brucella* members (Pathology). Other distinctive biological characteristics of members of the genus are their ability to grow within the endoplasmic reticulum of infected cells (Replication Within the Endoplasmic Reticulum), the low endotoxicity of their LPS (Maintaining the Host Cell Alive), their strong resistance to the action of bactericidal cationic peptides (Outer Membrane Versus Bactericidal Substances), and the permeability of the outer-membrane to hydrophobic substances (Role of the Outer Membrane in Nutrient Uptake) (Freer et al., 1999; Freer et al., 1996; Martínez de Tejada and Moriyón, 1993; Martínez de Tejada et al., 1995; Velasco et al., 2000). In addition, many differential properties of *Brucella* are negative characters. For instance, all *Brucella* members are nonmotile, do not possess flagella, fimbriae, pili or capsules, are unable to ferment sugars or produce gas, and lack a functional glycolysis or an Entner-Doudoroff pathway. Exotoxins, hemolysins or proteolytic enzymes or resting forms have never been reported. Some of the negative distinctive features of *Brucella* concern the LPS: absence of heptose and uronic acids among the core sugars. Although shared with other intracellular parasites of the α Proteobacteria (Fig. 1), the absence of plasmids or lysogenic bacteriophages is one of the most distinctive characteristics of the genus.

Population Genetic Composition of the *Brucella* Species

A major problem in the definition of the *Brucella* species is to know whether these bacteria are clonal or reticulate evolutionary units (Moreno, 1997). In the first case, the inheritance is vertically transmitted as a result of binary fission and clonal expansion. In the second case, adaptive changes occurring within an individual can be horizontally transferred to many or all members of the group. A third alternative lies between these two possibilities (Fig. 8). Genetic drift and speciation in clonal bacteria will depend almost exclusively on mutation and internal genetic rearrangement processes, whereas speciation in reticulate bacteria will depend also on genetic exchanges.

In nonclonal reticulate bacteria, recombination may be a dominant force driving the divergence among the different members (Guttman and Dykhuizen, 1994). In general, recombination seems to take place more often between closely related bacteria than across species. The genetic relationships between closely related individuals could be regarded as tokogenetic (Moreno, 1997), in contrast to the phylogenetic links that interconnect the different species (Fig.

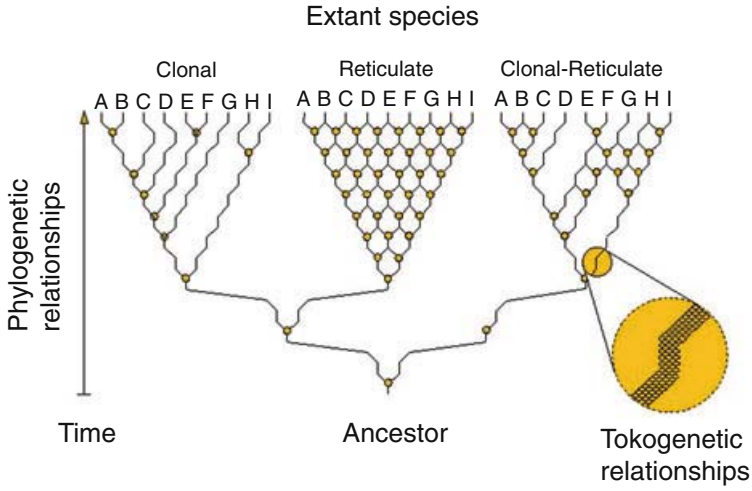

Fig. 8. Hypothetical phylogenetic trees and tokogenetic relationships among bacteria. Three different alternatives for generating bacterial species or strains (A-I) during evolution are presented. Speciation will depend on the probabilistic transmission and expansion of exogenous and endogenous genetic events as well as natural selection. Endogenous events such as mutation, internal recombination of genes and duplication or deletion of sequences are vertically transmitted and clonally expanded by the ancestor (O). Exogenous events include the horizontal acquisition or recombination of foreign bacteria sequences, plasmids and lysogenic phages (/\). Examples of clonal species are the *Brucella* spp., *Bartonella* spp., *Anaplasma* spp. and *Rickettsiae* spp.; examples of reticulate or clonal-reticulate bacteria are members of the Rhizobiaceae and Enterobacteriaceae families. Tokogenetic relationships have been documented in enterobacterial species (Guttman and Dykhuizen, 1994). Modified from Moreno (1997), with permission.

8). Tokogenetic recombinations are expected to homogenize the gene pool among the interacting organisms, thereby restricting the network structure of the species to a limited level. In comparison, recombination between different species (Amábile-Cuevas and Chicurel, 1992) results in genetic diversification promoting not only the expansion of the network structure of the species, but also favoring a fast and severe genetic drift, which may eventually cause speciation (Syvanen, 1994). A recombinational phenomenon between chromosomes and plasmids and between homologous sequences within chromosomes (Kim and Mayfield, 1997; Küdig et al., 1994; Lambert et al., 1990; Nikolskaya et al., 1995; Prakosh and Schilperoort, 1982; Rivilla and Downie, 1994; Schwedock and Long, 1994) may explain the difficulties in recognizing distinct genus and species among certain groups of α Proteobacteria, such as *Agrobacterium*, *Phyllobacterium*, *Rhizobium*, *Sinorhizobium*, *Bradhyrizobium* and *Rhodobacter* species (Laguerre et al., 1994; So et al., 1994).

In *Brucella*, like in other intracellular bacteria, recombination appears to be precluded or exceptional. The local conditions of intracellular parasites alternating from one host to another generate a founder effect in the population. Because the bacteria do not recombine, the expansion in the host must be considered of clonal origin. *Brucella*, therefore, must be contemplated within the context of clonality rather than a reticulate structure. Since clonality is maintained by the vertical transmission of genetic material, all evolutionary changes must be a result of mutational processes or autogenous rearrangement of genes mediated by insertion sequences, retrons, transposons or homologous recombinations (Ficht et al., 1996; Andersson and Andersson, 1997; Jumas-Bilak et al., 1998a; Jumas-Bilak et al., 1998b; Michaux-Charachon et al., 1997; Ouahrani et al., 1993; Sniegowski, 1997). These paths are comparatively limited in generating diversity, and accordingly, have generated a *Brucella* genus possessing a tight monophyletic clonal structure different from other members of the α-2 Proteobacteria. These concepts are relevant to understand not only because the problems posed by the species definition within the *Brucella* genus, but also because the strong tendency of the genus to maintain constant antibiotic susceptibility, antigenicity, cultural and serological properties, and genetic organization.

Defining the *Brucella* Species

Three different species concepts and one perception dominate in prokaryote classification: the phylogenetic species concept (Cracraft, 1983), the taxonomic species concept (Staley and Krieg, 1984), the biological species concept (Dobzhansky, 1937), and the microbiologists' perception (Pitt, 1994; Sneath, 1984a). The three concepts have strengths and weaknesses; each emphasizes different aspects of the evolutionary process and are within the boundaries of science. Because the taxonomic and phylogenetic concepts are based on numerical analysis (Sneath, 1984b; Williams et al., 1995; Woese, 1994), they are the most distinctly understood. The biological species concept may be the ultimate definition, but owing to the complexity involved in understanding the biology of a bacterial species, it has been relegated to last among the three scientific views (Krieg and Holt, 1984). The microbiologists' species perception is anthropocentric and nonscientific in nature. Nevertheless, it must be taken into account since sooner or later "a classification that is of little use to the microbiologist, no matter how fine a scheme or who devised it, will be ignored or significantly modified" (Staley and Krieg, 1984).

Speciation Concept Based on Phylogenetic Analysis A phylogenetic species is "the smallest diagnosable cluster of individual organisms within which there is a parental pattern of ancestry and descendence" (Cracraft, 1983). This concept has the advantage that species are defined as the terminal organism in a lineage that has an ancestor common to other terminal organisms, represented by the node joining their two branches, thus avoiding the meaningless classical ranked classification into kingdoms, phyla, classes, order and families. In the light of this definition, debates concerning bacterial ranks above the genus level are trivial and unimportant (O'Hara, 1994). A problem with this concept in defining *Brucella* species involves determining how monophily is to be recognized and how to distinguish gene phylogenies from pedigrees (Avise, 1990). The main question is which *Brucella* genes can better represent this genus and which of these genes best represent the dispersion into different species. *Brucella* phylogenies based on the sequences of conserved molecules, such as ribosomal RNAs and chaperone proteins, have greatly contributed to discerning the evolutionary relationships of *Brucella* with other organisms (Figs. 1 and 2). However, at the species level, a classification system based on these molecules does not have enough resolution for defining the different *Brucella* species as separate entities (Stackebrandt and Goebel, 1994). In this respect, it seems that phylogenies based in outer-membrane protein sequences and restriction maps seem to have better resolution at the *Brucella* species level (Allardet-Servent et al., 1988; Bricker et al., 2000; Ficht et al., 1996;

Higgins, 2000; Michaux-Charachon et al., 1997). The main problem is the absence of limits in the prediction of a terminal taxa: if one tries hard enough, sequence differences can be found to diagnose virtually any bacterial population. In spite of this, the phylogenetic approach based on outer-membrane protein sequences, restriction enzyme analysis or classical numerical analysis based on biochemical characteristics has clearly contributed to the discernment of what may be a natural system of classification, in agreement with the biological attributes displayed by the different *Brucella* species (Fig. 4). This approach has made us look more carefully at the common factors of *Brucella* belonging to the same branch, sometimes in spite of the diverse host preference or chromosomal structure displayed by sister brucellae, as is the case of *B. suis* biovars (Fig. 1).

Species Definition by the Polyphasic Approach The taxonomic species concept is a definition clearly linked to its method (see also Defining Taxonomic Ranks in Volume 1). The classical common procedures of *Brucella* classification are based on the analysis of phenotypic features, biochemical characteristics, genotypic similarities and immunochemical reactions. Taxonomical schemes have been then illustrated in the form of clades or dendrograms (Gargani, 1977; Moreno, 1992). The same procedures used to determine a species have been employed to further characterize the various *Brucella* species into biovars. The virtue of the polyphasic approach is that it allows high resolution at the terminal branches of dendrograms; its drawback is the inaccuracy in the earlier nodes of the branches (Moreno, 1997). This is due mainly to the fact that many characteristics displayed by the different brucellae (i.e., *B. canis* and *B. ovis* rough strains) may be the product of coevolution or parallel evolution. The combination of phylogenetic grouping based on sequence comparisons with taxonomic classification has been a very powerful method for approaching a practical definition of the *Brucella* species.

In spite of the advantages, the polyphasic approach possesses some drawbacks when coming to the interpretation of the *Brucella* DNA-DNA reassociation values. In other phylogenetically related genera, this interpretation is straightforward. For example, *Bartonella* members can be differentiated into at least 16 individual species according not only to different phenotypic, chemotypic and immunochemical criteria, but also by their DNA-DNA reassociation values (Birtles et al., 1995). The latter procedure has been pragmatically established as a "superior method" for the classification of species (Stackebrandt and Goebel, 1994). Owing that high DNA-DNA reassociation values among the different *Brucella* strains approach 100%, this has led to the proposal that the genus is constituted by one single species (*B. melitensis*) with several biovars (Verger et al., 1985). In spite of this, the different *Brucella* species may be resolved on the basis of DNA restriction patterns (Allardet-Servent et al., 1988; Bricker et al., 2000; Fekete et al., 1992a; Fekete et al., 1992b; Jensen et al., 1999; Tcherneva et al., 2000), phylogenetic analysis of idiosyncratic sequences (Ficht et al., 1996), as well as phenotypic, chemotypic and antigenic characteristics (Cloeckaert et al., 1999; Moreno, 1992; Velasco et al., 1998b). More important, *Brucella* species can be distinguished one from the other on the basis of their distinct biological behavior (Corbel, 1989; Meyer, 1990). Therefore, in the case of *Brucella* organisms, the DNA-DNA reassociation technique does not resolve as well as the observed phenotypic and biological characteristics between the different recognized classical species do (Meyer, 1990).

Biological Attributes in the Context of *Brucella* Species Definition In contrast to the numerical analyses used in the phylogenetic and taxonomic studies for the definition of bacterial species, the biological concept is based upon the identification of fundamental qualitative characteristics. In modern biological usage, species are defined as a particular group of organisms that retain their distinctness from other kinds in nature over a period of successive generations. *Brucella* "distinctness" refers to its biological characteristics, such as the basic comprehension of the life cycle (preferred habitat, potential habitat, preferred host, secondary hosts, vectors, reservoirs, interaction with other bacteria, commensalism, virulence and transmission), physiology (metabolism, generation time, optimal growth temperature, defense mechanisms, offensive mechanisms, repair systems and internal rearrangement of genes), and reproductive behavior (vertical versus horizontal inheritance). The bacterial species defined on the basis of qualitative biological characteristics is sometimes referred to as genospecies (Sneath, 1984b). Since in *Brucella* similar biological traits may occur owing to convergent or parallel evolution (i.e., roughness), the traditional biological species concept must be modified in favor of a more versatile notion.

Experience has demonstrated that biological characteristics by themselves are of little use in defining bacterial species (Weisburg et al., 1989). However, when phylogeny and taxonomy are considered, the biological properties shown by a bacterium contribute to resolving important uncertainties. For instance, brucellosis is a highly contagious bacterial disease of animals and humans. The six recognized species and the

marine strains display different affinities for mammals (Tables 2 and 7). *Brucella abortus* is a parasite of bovines, *Brucella melitensis* of goats and ovines, *B. suis* of swines, hares (biovar 2) and reindeer (biovar 4), *Brucella canis* of canines, *Brucella ovis* of male ovines, *Brucella neotomae* of wood rats, and the marine isolates parasites of dolphins, porpoises, whales and seals (Bricker et al., 2000; Corbel and Brinley-Morgan, 1984; Higgins, 2000; Jahans et al., 1997). Sporadically, *Brucella* organisms have been seen in the reproductive organs of ticks, fleas, lice and worms (Burgdorfer, 1967; Crespo-Leń, 1994; Meyer, 1977). It may be that some of the *Brucella* species use these animal parasites as sporadic vectors or reservoirs.

The known molecular and biochemical characteristics that distinguish the various *Brucella* species and strains, although important, do not explain the subtle and different biological behaviors among the species. Most *Brucella* are very aggressive pathogens that may infect other hosts; however, when this occurs, infection is often terminal and of minor epidemiological relevance. What makes the biological attributes of these microorganisms important in the context of the species definition is the fact that (under natural conditions) the different *Brucella* strains have the tendency to remain in their host animals, and cross infections only occur when the natural hosts are in close contact with a second mammal species. The most susceptible *Brucella* victim is the fetus of the preferred host (The Fetus, the Most Susceptible Host). However, the course of infection in the natural host (when nonpregnant) usually progresses without being noticed. After abortion, infection may recede and self-cure may proceed, and self-cure is the most frequent outcome in the natural host (Enright, 1990a) (Outcome of the Disease and Self Cure). On the one hand, abortion is an efficient condition that ensures dispersion of the bacteria (Infecting the Host); on the other hand, the immune response is a competent mechanism necessary to ensure the survival of the infected host (Control of the Infection). In general, *Brucella* species are well adapted to their natural hosts, reflecting the good equilibrium between both parties. It is important to point out that occurrence of live offspring from *Brucella*-infected mothers is relatively frequent (from 10–20% of cases) and that these animals could later in life abort or give live births (Fig. 9).

One of the important biological distinctions among *Brucella* is their virulence. For many years it has been known that *B. melitensis* is a "vicious bug" considered as one of the candidates for bacteriological warfare (*Brucella* as a Biological Weapon), whereas *B. neotomae* is a "nice bug" confined to desert wood rats (Corbel and Brinley-Morgan, 1984). This is not a matter

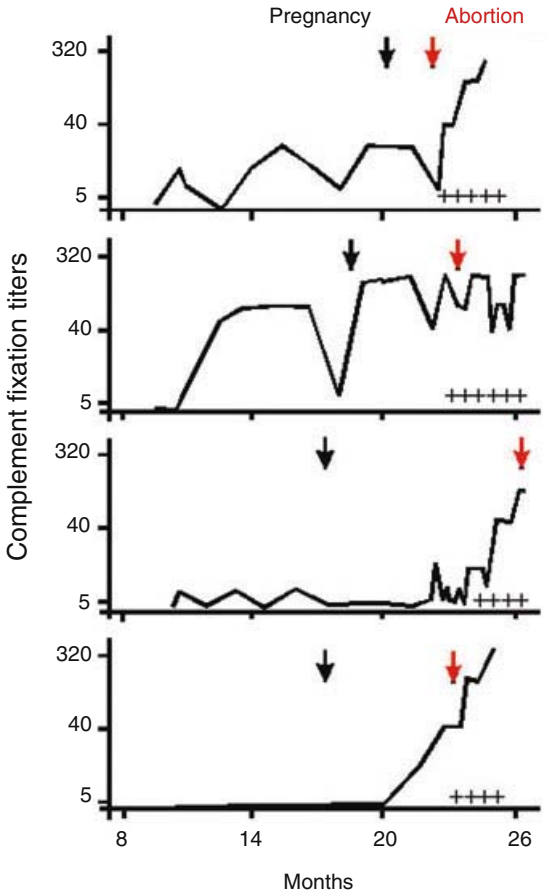

Fig. 9. Antibody responses of bovines born from *B. abortus* strain 554-infected mothers. The serological tests were performed in time before pregnancy, after pregnancy, during abortion and after abortion. After birth, calves were isolated with no possibility for secondary *Brucella* contamination. Then, insemination proceeded and abortion was recorded several months later. Bacteriological isolation was carried out after abortion. The *B. abortus* isolates corresponded to the same biovars isolated from the mothers. Notice that all calves at one time or during extended periods showed negative serological responses. One bovine demonstrated antibodies only after pregnancy. From Plommet (1977), with permission.

of semantics; in every single country, people responsible for control and eradication programs know the different pathological behavior and epidemiological circumstances that distinguish the various *Brucella* species. *Brucella neotomae* under certain conditions, however, displays virulence for mice (Gibby and Gibby, 1965). It is known that humans are more susceptible to *B. melitensis* than to *B. abortus* (Flores-Castro, 1979), whereas mice are more susceptible to *B. abortus* than to *B. melitensis* (Young et al., 1979). It has been determined that *B. melitensis* is more resistant than *B. abortus* to intracellular killing mediated by human neutrophils (Young et al., 1985), a fact that may explain the greater suscep-

tibility of humans to *B. melitensis* infections. Similarly, while rough *B. abortus* 2308 *per*A mutants incapable of generating *O*-chain or NH are readily killed by macrophages, rough *B. melitensis* 16M *per*A mutants are capable of replicating within these cells (Godfroid et al., 1998; E. Moreno et al., unpublished observations). The fact that the same gene mutation in each of these two species causes different biological behavior with respect to intracellular parasitism illustrates the importance in understanding the small but consistent genetic differences that distinguish the various *Brucella* species.

Although from the phylogenetic and taxonomical point of view *B. suis* strains form a closely related cluster, from the biological point of view the first three biovars are separated from biovars 4 and 5. While biovars 1, 2 and 3 have affinity for porcines, biovar 4 preferentially infects reindeer and biovar 5 infects wild rodents (Alton, 1990b; Table 2). In some cases, one biovar could have preference for two different hosts, as in *B. suis* biovar 2 that parasitizes swines and hares (Table 2). It is important to notice that the host preference is not related to chromosome number or size (Fig. 1). Therefore, the subtle genetic and biochemical differences that distinguish these *B. suis* biovars seem to be more relevant for host specificity than are the dramatic differences in the number of chromosomes. This further supports the hypothesis that the chromosome of *B. suis* biotype 3 is the result of the fusion of the two chromosomes with no major consequences for gene expression and competence of infection.

Regarding the *Brucella* marine strains, referred to as *Brucella* "maris" by some authors (Jahans et al., 1997), the cluster is composed of at least three subclusters, according to their biochemical, genetic and animal host preference (Bricker et al., 2000; Jensen et al., 1999; Tcherneva et al., 2000). Their exclusive isolation from marine mammals from diverse habitats suggests that, in spite of being widespread, marine strains do not normally infect terrestrial animals, including humans (Higgins, 2000). Because the transmission of terrestrial *Brucella* organisms mainly occurs by close contact between the infected hosts or tissues (Infecting the Host), the question arises as to how *Brucella* is transmitted under marine conditions. It has been found that filaria lungworms isolated from seals are infected with *Brucella*, suggesting a means of transmission among marine animals (Garner et al., 1997). Since some of these filaria worms cycle in fish, it is reasonable to propose that marine mammals eat fish containing lungworms infected with *Brucella*, and thereby fish become the source of *Brucella* infection for these mammals. If true, then this biological attribute would be characteristic of at least some marine *Brucella*, distinguishing them clearly from the remaining species.

Brucella ovis and (to a lesser extent) *B. canis* are not very aggressive pathogens for secondary hosts when compared to the smooth *Brucella* species, with the exception of *B. neotomae*, which seems to be the least virulent. At the surface level, *B. ovis* and *B. canis* are described as "natural rough" strains (Response to Environmental Stress; Outer Membrane Topology; Moreno et al., 1984a). In contrast to the rough mutants of *Brucella* derived from smooth strains, *B. ovis* and *B. canis* attach in lower numbers to cell surfaces and are more prone to intracellular destruction within lysosomes in epithelial and phagocytic cells (Freer et al., 1999; Pizarro-Cerdá, 1998a). In this respect, it seems that *B. ovis* and *B. canis*, although capable of invading and replicating within cells of their host's reproductive system, are not very efficient in invading cells in vitro (Fig. 21). The singular behavior of these "natural rough" *Brucella* may not only reflect an important biological difference with respect to smooth *Brucella*, but also reflect the restricted preferences of these bacteria for ovines and canines, along with their reduced virulence for other animal hosts, including humans (Corbel and Brinley-Morgan, 1984).

What makes the biological attributes of these microorganisms important in the context of the species definition is that under natural conditions the distinct biochemical, phenotypic, immunochemical and genomic characteristics that identify each of the different *Brucella* species have remained constant in space and time (Corbel, 1989; Meyer, 1990). Since the biological behavior of *Brucella* species does not depend on the presence of accessory genetic elements, it is feasible to consider the qualitative biological characteristics as a valid alternative for use in defining a scheme of *Brucella* species relationships.

At the molecular level, several differences among the various *Brucella* species and strains have been described (Bricker et al., 2000; Ficht et al., 1996; Jensen et al., 1999; Jumas-Bilak et al., 1995; Jumas-Bilak et al., 1998a; Michaux-Charachon et al., 1997; Ouahrani et al., 1993; Tcherneva et al., 2000). For instance, the absence of operons coding for putative proteins involved in the synthesis of polysaccharides and inversions in the genes coding for outer-membrane proteins in *B. abortus* strains are striking features that may be related to the different biological behavior of these brucellae with respect to other species (Vizcaíno et al., 1997; Vizcaino et al., 1999). The different distribution and number of insertion sequences that distinguish the various *Brucella* species may be an indicator not only of distinct gene locations around the two chromo-

somes, but also of the level of expression of these genes (Ouahrani et al., 1993). The absence of *O*-polysaccharide in *B. canis* and *B. ovis* species may be related to the reduced virulence of these species in relation to *B. melitensis*, *B. suis*, and *B. abortus*. The identification and characterization of these genetic and structural variations in relation to host preference and parasitism will help to define host preference and parasitism of the various *Brucella* species within a broader biological context.

Microbiologists' Perception of *Brucella* Species *Brucella* species are a closely related phylogenetic and taxonomic cluster with DNA-DNA reassociation values close to 100%, and on this basis, it has been proposed that *Brucella* is a monospecific genus (Verger et al., 1985). Even though this proposition may suggest a "superior rank" of classification (Stackebrandt and Goebel, 1994), this molecular technique fails to reveal the differences demonstrable in the biological behaviors of the different *Brucella* organisms. Although this is one of the reasons why this proposition has had little acceptance within the scientific community devoted to *Brucella* research (Meyer, 1990; Moreno, 1997), the ultimate judgment has come from veterinarians, microbiologists, physicians, epidemiologists and many other professionals who do not consider the new recommendation relevant for their purposes (Nielsen and Duncan, 1990b; Wong et al., 1992). Therefore, within this context, the name of the species and strains is not a matter of semantics. In every country, people responsible for *Brucella* control and eradication programs know the different pathological behavior and epidemiological circumstances that distinguish the various *Brucella* species. Talk of *B. abortus* is one thing, but the mention of *B. melitensis* is a very different matter. The name of the latter species would dispatch a general alarm among all public health units (Flores-Castro and Baer, 1979).

In modern times, very few scientists attempt to define species on the basis of a single or a few bacterial isolates. In general, the characterization of many distinct isolates is required before a serious committee in bacterial nomenclature would consider it appropriate to define a species as "new" (Graham et al., 1984). Nevertheless, this is not a straightforward subject. No one really knows how many *Brucella* isolates are necessary, and whether these isolates should be obtained during certain time periods from different niches, habitats, hosts, localities and so on. In this sense, the marine *Brucella* strains seem to fulfill the requirements for classification as a distinct cluster of separate species. The issue at this point is not whether the marine strains are different from the terrestrial brucellae, but rather what the differences are between them; that is, do the proposed *Brucella* "maris" comprise several species or only one species with several biovars? Similar questions may be raised with *B. suis* biovar 4 and 5 to which some investigators have delegated as different species owing to their preference for reindeer and wild rodents, respectively (Table 2). In this respect, it is likely that our human self-centered view of the world frequently makes us forget that the brucellae themselves are not as susceptible to systematics as we are.

Habitat

Traditionally, *Brucella* organisms have been defined as facultative intracellular pathogens, since they multiply in bacteriological media and also replicate within cells (Corbel and Brinley-Morgan, 1984). Their biology, however, seems to point in the opposite direction: *Brucella* organisms are pathogens whose ultimate goal is to propagate in their preferred niche, the cell (*Brucella* Traffics and Replicates Within Host Cells). In this sense the brucellae are better described as facultatively extracellular intracellular parasites (Moreno and Moriyón, 2002). With this perspective, it may well be that the most risky and uncomfortable environment for *Brucella* is the extracellular milieu from which these bacteria must escape to survive and persist as intracellular pathogens from one generation to another (Survival Outside Host Cells).

The *Brucella* species display host preference, although they may infect secondary hosts (Geographical Distribution). Under certain circumstances, *Brucella* can reproduce within fleas, lice, ticks and worms, which occasionally may serve as vectors for transmission to mammalian hosts. In temperate zones, *Brucella* could survive in soil, manure or water, depending upon the temperature. Normally in low temperatures (between 2–8°C), the bacteria live up to several weeks or even months, as long as enough organic material is available and the bacterium is protected from the sun's rays. When exposed to sun's rays in the open, *Brucella* organisms steadily die, a phenomenon that takes place more quickly when the bacteria are exposed to sun's rays above 18°C. At temperatures of 56°C or higher, *Brucella* organisms are quickly destroyed (Ray, 1977). Pasteurization (performed at 62°C for 30 min) of dairy products eliminates *Brucella* organisms and the risk of human contamination.

Isolation

All *Brucella* spp. are pathogens that are seldom obtained from sources other than human

patients and sick animals or their products, and their isolation is an essential part of the diagnostic procedures. Thus, the practical aspects of isolation are better understood in the context of the laboratory diagnosis of brucellosis, which includes the use of molecular methods in both humans (Direct Diagnosis of Human Brucellosis) and animals (Direct Diagnosis in Animal Brucellosis). Since they most often differ in feasibility, sample type, media, and criteria used in the evaluation of the results, the bacteriological diagnosis of human and animal brucellosis is described and discussed in two separate sections (Direct Diagnosis of Human Brucellosis; Direct Diagnosis in Animal Brucellosis). The present section deals only with the culture of *Brucella* in the microbiology laboratory.

Biosafety

Brucella has been classified as a group 3 microorganism and should be handled accordingly (*Brucella* as a Biological Weapon). Brucellosis is the most commonly reported laboratory infection, and although the infectious dose for humans is not known, it is likely that only very low numbers of bacteria (estimated at less than 10 cells) are enough to cause infection through the mucosae. Aerosols generated during homogenization of tissues, centrifugation, pouring or transferring of broths, shaking or stirring of tubes and flasks, inoculation of Petri dishes and other laboratory manipulations represent the highest risk. Biosafety level 2 practices can be used for activities involving clinical materials of human or animal origin, but all procedures likely to generate aerosols should be carried out in an appropriate biosafety cabinet. Biosafety level 3 containment practices and facilities are required for all manipulations involving large-scale culture and for experimental animal studies (http://www.hc-sc.gc.ca/hpb/lcdc/biosafty/msds/msds23e.html). Material safety data sheets can be obtained at (http://www.hc-sc.gc.ca/pphb-dgspsp/ols-bsl/index.html) and general laboratory precautions are described by Alton et al. (1988).

Culture

The brucellae are chemoheterotrophic bacteria that grow well in a variety of lifeless media and under relatively simple laboratory conditions, but for those biotypes and species that require CO_2 (Table 3).

Physicochemical Requirements and Atmosphere The temperature growth range of brucellae is 18–42°C, with variations that depend on the strain and medium. The optimal temperature is, however, between 34–37°C. The brucellae grow best at pH 6.6–7.4, and because they do not acidify the growth medium (a slight increase in pH is sometimes observed), buffering is not strictly necessary. The optimal osmotic pressure is reported to be somewhat lower (2–6 atmospheres) than that found in the usual culture media (about 7–8 atm; Gerhardt, 1958).

All *Brucella* spp. are strictly aerobic, but some *B. abortus* biovars, some *Brucella* isolates from marine mammals, and *B. ovis* only grow in atmospheres containing 5–10% CO_2 (Tables 3 and 7). This does not relate to a decreased pO_2 but to a specific requirement of CO_2 per se, and at least for the CO_2-dependent *B. abortus* strains, subculture frequently leads to selection of spontaneously occurring CO_2-independent mutants. Although the exact redox potential (E_h) and oxygen tension required for optimal growth are not known, the brucellae need vigorous aeration when grown in broth. For small-to-medium volumes, shaking is adequate, but for large volumes sparging and antifoaming agents are necessary. In this case, attention has to be paid to the antifoaming agents, since all brucellae are sensitive to many of these compounds. For laboratory fermentors with dissolved oxygen control, stirring and sparging conditions maintaining a 20–50% oxygen saturation at 37°C give good results (Rousseau et al.,1987). These and other conditions used in less sophisticated fermentors are summarized in Table 8.

Nutritional Requirements On primary isolation, most *Brucella* strains grow slowly or poorly in media devoid of blood, serum or tissue extracts. Accordingly, the brucellae are often described as fastidious, and in fact, reported doubling times in vitro (2.5–3.5 h) are longer than those of many pathogenic bacteria. However, careful analyses (Gerhardt, 1958; Plommet, 1991) show that at least the growth requirements of *B. suis*, *B. abortus* and *B. melitensis* are not excessive. Thus, the slow growth of brucellae upon primary isolation may reflect, in part, a lag phase required for adapting to an environment very different from the host, low efficiency in nutrient uptake, basic genetic features or other factors. Moreover, these bacteria are sensitive to low concentrations of inhibitors (such as fatty acids) present in some media (Huddleson, 1955) or resulting from heat sterilization (Gerhardt, 1958; Rousseau et al., 1987; Yantorno et al., 1978), and this explains the improvement of growth caused by agents with detoxifying action, such as charcoal, serum or agar itself (Robertson et al., 1977). Amino acid imbalance has also been suggested as a cause of reduced growth (Gerhardt, 1958). The variable growth rates observed

with different batches of commercial media and among manufacturers can be attributed to some of the above-summarized circumstances. An additional factor retarding growth detection on primary isolation is that brucellae may be present in only low numbers in some samples (Diagnosis).

In chemically defined media containing appropriate mineral salts (Gerhardt, 1958; Plommet, 1991; Table 9), *B. suis*, *B. abortus* and *B. melitensis* require nicotinic acid and thiamine for growth. Pantothenic acid is required by some strains and is only stimulatory for others, and biotin is stimulatory. But for some strains that require sulfur-containing amino acids, these three species can use ammonium sulfate and thiosulfate as nitrogen and sulfur sources and glucose as the sole carbon and energy source. Many *B. suis* strains can also use glutamate as the sole nitrogen and carbon source, and this ability is also displayed by some *B. melitensis* strains when grown in the presence of CO_2 but not by *B. abortus*, even though this species can actively oxidize this amino acid (Table 2). A combination of glutamate, lactate and glycerol seems also satisfactory as a carbon source. All these data show that most strains of these three species are endowed with prototrophic capacities for all organic constituents, with the exception of thiamine and nicotinic acid, and that *B. suis* is the closest to prototrophy. This last observation probably accounts for the fact that *B. suis* usually shows higher growth rates than those of *B. melitensis* or *B. abortus* and also for its comparatively greater variability in oxidative metabolic patterns (Table 2). On these bases, it has been suggested that *B. suis* may represent the metabolic type closest to that of the soil- or plant-associated α-2 Proteobacteria from which the brucellae probably evolved (Plommet, 1991). There are incomplete data or no nutritional studies performed with *B. canis*, *B. neotomae*, *B. ovis*, or the isolates from marine mammals.

The nutritional requirements of the brucellae are met by a variety of standard laboratory media (Tables 8 and 10). Most often these media contain a combination of peptones and glucose. Serum or blood supplements are not strictly required, although they would enhance the growth of some strains. *Brucella ovis* is an exception, since almost all strains will grow poorly or not at all in standard media that lack serum or blood. *Brucella abortus* biovar 2 also requires serum but only on primary isolation. As discussed above, this requirement may represent increased sensitivity to hydrophobic inhibitors rather than true

Table 8. Growth of *Brucella* in laboratory fermentors.

Medium	Sterilization	Growth conditions	Anti-foaming mixture[a]	Yield	Comments	References
3% Glucose, 1.5% enzymatic digest of casein,[b] 1.5% enzymatic digest of animal tissue,[c] 1% yeast extract, 0.9% NaH_2PO_4, 0.33% Na_2HPO_4	Filtration	Aeration increased progressively from 10 liters of air ·min $^{-1}$ at 400rpm to 14 liters of air ·min $^{-1}$ at 600rpm	0.0002% AF 60 silicone emulsion[d]	—	Mix the ingredients while boiling the water. The vessels and the antifoaming agent are sterilized before adding the medium (35min at 121°C). It is the standard USDA procedure for growing *B. abortus* 19 (vaccine strain).	Alton et al., 1988
2% Glucose, 2% fructose, 3.1% enzymatic digest of animal tissue,[c] 1% yeast extract, and 0.16% Na_2HPO_4	Heat 5min at 121°C followed by rapid cooling.[e]	Oxygen dissolved control set at 20–50% O_2 saturation	0.001–0.005% Silicone A-N-butyl acetate (1:3)[f]	2×10^{11} cfu ·ml $^{-1}$	All materials but the antifoaming mixture are sterilized together in the fermentor vessel. Tested with *B. abortus* 19 (vaccine strain) and 2308 and with *B. melitensis* 16M. Eight liters of medium in a 15-liter vessel.	Aragón et al., 1996

[a]The sensitivity to antifoaming agents may vary among strains, and it increases for rough mutants and at least for the rough species *B. ovis*.
[b]Bacto-casitone (Difco) or similar.
[c]Bacto-peptone (Difco) or similar.
[d]General Electric, Silicone Products Division, Waterford, New York. This product may be identical to Sigma antifoaming silicone A.
[e]Owing to the large volume of fermentor vessels, sterilization times have to be corrected for thermal inertia. The actual sterilization time at 121°C, plus the time the vessel is above 110° plus the cooling time must be equivalent to the standard sterilization conditions in autoclaves. Prolonged heat sterilization produces degradation compounds toxic for brucellae.

nutritional requirements. Synthetic or semisynthetic media have been reviewed by Gerhardt (1958) and Plommet (1991). This last author recommends a simple mineral salt-glucose-vitamin media for physiological studies, which can be prepared synthetically or semisynthetically with yeast extract (Table 9).

Selective Agents and Media The brucellae are inhibited by the hydrophobic dyes and surfactants used in media selective for classical Gram-negative bacteria, such as most enteric bacteria, pseudomonads and others (Permeability). Early formulations of *Brucella*-selective media that include crystal violet, ethyl violet or gentian violet are not satisfactory because some biovars and species are sensitive to these agents. On the other hand, the brucellae grow well in the presence of polymyxins (polymyxin B and colistin [polymyxin E]) at concentrations that are inhibitory for many Gram-negative bacteria (Lipopolysaccharide and Resistance to Outer-membrane Destabilizing Agents). Thus, selective and enrichment media have been designed that include these antibiotics plus others that, at the concentrations used, act preferentially on Gram-positive bacteria and fungi (Table 11). It has to be noted that present formulations of *Brucella*-selective media have only been tested extensively on *B. abortus*, *B. melitensis* and *B. ovis* and that, although unquestionably useful, they are inhibitory for some strains. Moreover, present formulations of selective media are not equivalent because of differences in antibiotic sensitivity (in particular, bacitracin and nalidixic acid) between *B. abortus* and *B. melitensis* (Marín et al., 1996). Although it is not known to what extent, these media are probably satisfactory for other *Brucella* species.

Identification

Identification of *Brucella* can be performed after isolation in pure culture by conventional bacteriological methods, including serological and phage typing, and also using Molecular Biology tools. The use of molecular probes to identify the presence of *Brucella* cells or their debris in blood, milk, tissues and other materials without prior isolation is discussed in the context of the diagnosis of human and animal brucellosis. Typing at biovar and strain level is necessary only for epidemiological studies and for the identification of the vaccine strains.

Cellular and Colonial Characteristics

These are important characteristics because the brucellae have a cell morphology, staining properties and colonial appearance on isolation media such that, along with the epidemiological evidence, enable experienced bacteriologists

Table 10. Standard media most commonly used to grow *Brucella*.

Common name	Basal medium	Commercial source[a]	Supplements	Comments
Tryptic soy broth (or agar)	1.5% enzymatic digest of casein, 0.5–0.3% enzymatic digest of soybean meal, 0.25% glucose, 0.25% K_2HPO_4, and 0.5% NaCl; (1.5–2.0% agar)	Trypticase soy broth (BBL); Trycase soy broth (bioMérieux); Bacto-tryptic soy broth (Difco); Tryptone soy (GIBCO); and Tryptone soy broth (Oxoid)	None or, depending on the purpose, one or several of the following: 2–5% filter-sterilized serum;[b] 0.2–0.5% yeast extract; 5–10% defibrinated blood.	General purpose media. Yeast extract is beneficial, in particular for *B. ovis*.
Blood broth (or agar) base	1.0% enzymatic digest of casein, 1.0% enzymatic digest of animal tissue, 0.1% glucose, 0.2% yeast extract, 0.5% NaCl, and 0.01% $NaHSO_4$; (1.5–2.0% agar)	*Brucella* broth (BBL); Bacto-*Brucella* broth (Difco); and *Brucella* medium base (Oxoid)[c]	None or, depending on the purpose, one or several of the following: 2–5% filter-sterilized serum;[b] 0.2% yeast extract; 5–10% defibrinated blood	General purpose media; it is equivalent to Albimi broth. Can be used to prepare selective media (**Table 11**)
Serum-dextrose agar	0.3–0.5% beef or meat extract, 1.0–0.5% enzymatic meat digest, 0.8–0.5% NaCl, and 1.5–2.0% agar	Nutrient agar (bioMérieux); and Bacto-nutrient agar (Difco)	One: 5% of a filter-sterilized mixture of 20% dextrose in serum	General purpose media; not identical but equivalent to BBL's and Oxoid's Nutrient agar. Can be used to prepare selective media (**Table 11**)
Glycerol-dextrose agar	0.3–0.5% beef or meat extract, 1.0–0.5% enzymatic meat digest, 5% serum, 1% glucose, 0.8–0.5% NaCl, and 1.5–2.0% agar	Bacto-nutrient agar (Difco)	One: 2% glycerol and 1% glucose (added independently from filter-sterilized stocks)	Recommended for dissociation testing
Glycerol-potato agar	20% potato infusion, 0.5% beef or meat extract, enzymatic meat digest, 1% glucose, 0.5% NaCl, and 1.5–2.0% agar	Bacto-Potato infusion agar (Difco)[d]	One: a 2% glycerol (added before autoclaving)	Propagation of smooth strains in Roux bottles for antigen or vaccine production
Modified Thayer-Martin's	1.5% enzymatic digest of protein, 0.1% corn starch, 0.4% K_2HPO_4, 0.1% KH_2PO_4, 0.5% NaCl, and 1% agar	Bacto-GC medium base (Difco); GC medium base (GIBCO); GC agar base (Oxoid); and GC agar base (BBL)	One of two: 0.7% blood (added to the molten medium equilibrated at 55–60°C) or 1% hemoglobin	Recommended for *B. ovis*. Can be used to prepare selective media (**Table 11**)

to perform an immediate presumptive identification.

Bacterial Cells The brucellae are coccobacilli or short rods of 0.5–0.7 by 0.6–1.5 μm, but at least some *B. suis* strains develop larger cells in rich media. They are arranged individually, less often in pairs or small groups. At least under standard growth conditions, all *Brucella* spp. are devoid of flagella or capsules. They are Gram-negative, and although not truly acid-fast, they are stained by the modified Ziehl-Neelsen method of Stamp (basic fuchsin staining followed by decolorization with diluted acetic acid; Fig. 10). All *Brucella* spp. but *B. ovis* are reported to be positive by the modified Köster's method (safranin-NaOH staining followed by decolorization with diluted sulfuric acid). For detailed staining protocols, consult Alton et al. (1988).

Colonies and Dissociation Colonies on translucid media are transparent, convex and have an entire edge. They are usually small (0.5–1.0 mm after 2–3 days of incubation of a fresh inoculum), but there are variations that depend on the medium and strain. When examined with obliquely reflected light, the colonies of the smooth species (Table 2) appear moist and glistening and somewhat bluish, whereas those of the rough species have a dry, granular aspect.

The smooth *Brucella* species often dissociate during growth to yield mixtures of typically smooth and rough colonies along with others of intermediate characteristics. The cell surface is responsible for the appearance of the colonies and dissociation is caused by spontaneous mutations leading to the synthesis of LPS lacking the *O*-polysaccharide (rough-LPS) (Response to Environmental Stress). Moreover, mucoid colonies derived from the smooth strains have been repeatedly described and can be distinguished by their slimy consistency, but the structural and genetic defects behind this phenotype are not known with certainty. The rough *B. canis* often produces mucoid colonies. The early literature contains descriptions of many environmental factors favoring dissociation, but the only ones clearly demonstrating effect are low oxygen and age of the culture (reviewed in Gerhardt, 1958). Dissociation is favored by anoxia and hence by growth in nonaerated broth or on humid solid media. Accumulation of rough mutants occurs late in the stationary phase of growth.

Since the smooth-LPS is a major surface antigen and a virulence factor, control of dissociation is essential in production of vaccines (Vaccines and Vaccination) and diagnostic antigens (Immunological Tests for Brucellosis). Specific and detailed control protocols are given in the manual *Techniques for the Brucellosis Laboratory* by Alton et al. (1988). Controls can be carried out by examination with obliquely reflected light but other tests requiring less experience may be more practical. Agglutination tests are particularly useful to test individual colonies. Smooth brucellae agglutinate only with sera of *O*-polysaccharide specificity, and semi-rough mutants can be detected by their simultaneous agglutination with sera of *O*-polysaccharide and rough-LPS specificities. A failure to agglutinate with sera of *O*-polysaccharide (LPS) specificity and a positive agglutination with anti-rough-LPS sera are characteristics of the rough mutants (and species). Moreover, the rough-type cells also agglutinate with neutral acriflavine at 1 : 1000. To examine cultures for dissociation, they can be plated out and plates briefly flooded with a 1 : 4 mixture of 10% crystal violet in ethanol and 1% ammonium oxalate in distilled water. By this method, and in opposition to the smooth-type colonies, the rough type colonies become stained (Fig. 11). Finally, smooth cultures sediment slowly in broth, whereas those of the rough mutants and rough species autoagglutinate rapidly. All these differential tests and properties reflect the profound alteration in outer-membrane topology (Outer Membrane Topology) caused by the defects in LPS.

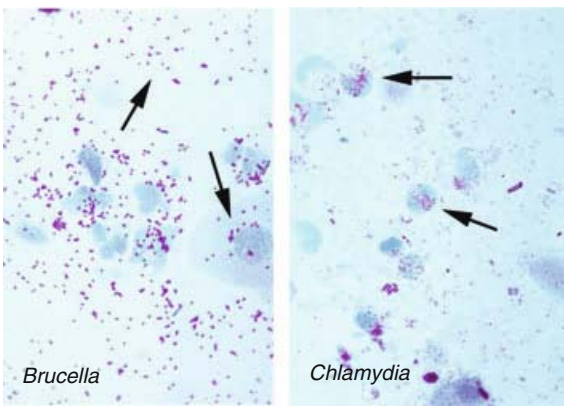

Fig. 10. *Brucella* staining by Stamp's method. The images show smears made with material taken from sheep abortions caused by *B. melitensis* or *Chlamydia* spp. Both parasites stain positive by the Stamp's method, but while *Chlamydia* bodies are mostly associated with cells and are of a very small size and of irregular appearance (due to the presence of both reticulate and elementary bodies), *Brucella* cells are larger and found everywhere. Courtesy of J. M. Blasco, SIA, DGA, Zaragoza, Spain.

Identification and Typing

Identification of brucellae at genus level is simple and can be achieved in most laboratories,

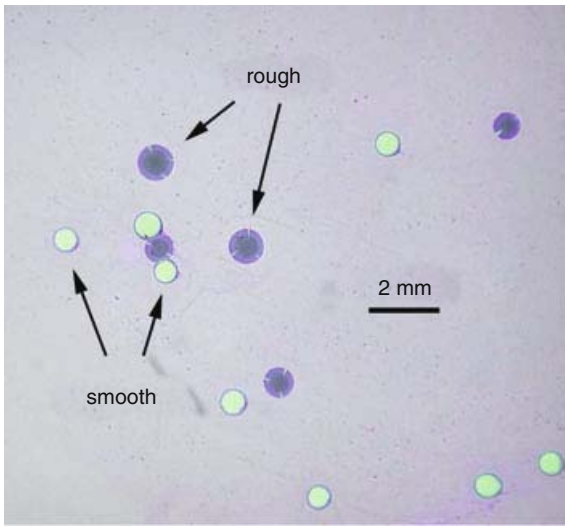

Fig. 11. Smooth and rough *Brucella* colonies demonstrated by the crystal violet method.

most conveniently by serological methods. Precise identification to species and biovar level is only possible in reference laboratories.

STANDARD TESTS Standard identification is based first on the morphological and staining characteristics of cells and colonies and on the growth requirements, including CO_2, and conditions of primary isolation (Isolation). Pure *Brucella* cultures are nonhemolytic. Catalase is positive and their metabolism is that of a strictly respiratory microorganism, although *B. neotomae* is reported to be able to show some fermentation from glucose. Since they are oxidative rather than fermentative microorganisms, they do not acidify the medium and are negative in tests that, like the methyl red and Voges-Proskauer tests, detect acidic metabolites or other fermentation products. With the exception of *B. ovis* and *B. neotomae*, all species are positive in the cytochrome *c*-oxidase test, and all but *B. ovis* are able to reduce nitrates to nitrites and have urease activity (Table 2). They do not produce indole from tryptophan and, depending on the strain and species, they have limited or no ability to use citrate as the sole carbon source.

Only few bacteria show serological crossreactivity with the *O*-polysaccharide of the *Brucella* smooth-LPS (Table 6), and they are easily differentiated on the basis of the standard bacteriological tests. Thus, slide agglutination tests with antisera of the appropriate specificity are very useful in the identification of *Brucella* and easily separate the rough from the smooth *Brucella* species. Those carrying a smooth-type LPS (Table 2) agglutinate with sera-containing antibodies to the *O*-polysaccharide but not with sera containing antibodies to the core-lipid A antibodies, owing to the topology of the outer-membrane of smooth cells (Outer Membrane Topology). The rough species and rough mutant strains agglutinate with sera of the latter but not of the former specificity. Sensitivity to the smooth- and rough-specific phages carries the same information (Table 13). Semi-rough strains or dissociated cultures agglutinate with both sorts of antibody and show intermediate sensitivities to the smooth- and rough-specific phages.

For species differentiation, cytochrome *c*-oxidase, urease and nitrate reduction tests are partially useful since, used along with the agglutination tests, they discriminate *B. ovis*, *B. canis* and *B. neotomae* but not *B. melitensis*, *B. abortus* and *B. suis*. Typing with the Tb phage discriminates these three species (Table 2). Further assessments to assign the isolates to biovars also confirm the species identification but require specific means and protocols (Alton et al., 1988). For identification to biovar level, the distribution of the A and M epitopes (Response to Environmental Stress), CO_2 requirements on primary isolation, H_2S production and growth on serum dextrose agar supplemented with thionin and fuchsin (and sometimes safranin) are used (Table 3), even though there are atypical strains in some of those tests. Metabolic oxidative profiles have an intermediate value: they discriminate species and, for *B. suis*, some groups of biovars (Table 2).

The *Brucella* isolates from marine mammals have not been assigned to species yet, and the number of isolates is too reduced to assess a possible distribution into biovars. So far, all isolates have smooth colonial morphology and are resistant to the rough specific RC phage. With one exception, they carry the A epitope and no intermediate A+M strains have been described. All grow on thionin and fuchsin at the standard (20 μg/ml) dye concentrations, show urease activity, and do not produce H_2S but vary in the CO_2 requirement for growth and sensitivity to the standard phages (Table 7).

MOLECULAR METHODS A number of probes have been used for the detection by polymerase chain reaction (PCR) of *Brucella* DNA in samples of human or animal origin (Bacteriological Culture for Humans; Molecular Tests for Humans). Identification at genus level is easily achieved under laboratory conditions by PCR with primers taken from a variety of available sequences, such as those of the 16S rRNA, heat shock proteins, outer-membrane proteins, insertion sequence IS*711* (also known as IS*6501*), and others (Table 4). Cross-identification or detec-

tion of phylogenetically related bacteria with some of the primers is a demonstrated possibility. In addition, gene polymorphism has been examined for the differentiation at species and biovar levels with partial success (Vizcaíno et al., 2000). To date, there is no established single molecular method that can fully replace the classical identification tests and biotyping scheme, even though species can be differentiated by some protocols, and markers specific for *B. melitensis*, *B. abortus*, *B. ovis* and *B. canis* and for some biotypes or groups of biotypes have been found (Table 4). This promising line of research will require further assessments of numbers of strains large enough to draw definite conclusions on the usefulness of particular protocols or methods.

Identification of Vaccine Strains *B. abortus* 19 (*B. abortus* US-19) can be differentiated from typical field isolates of *B. abortus* biovar 1 by its inhibition on media containing appropriate concentrations of thionin (2 µg/ml) and penicillin (5 IU/ml). Moreover, in opposition to typical *B. abortus* biovar 1 primary isolates, this vaccine strain does not require CO_2 for growth. Typical strain 19 is also inhibited by *i*-erythritol (1 mg/ml) because it carries a 702-bp deletion in the *ery* region (Sangari et al., 1994) causing a metabolic deficiency that probably leads to the toxic build-up of intermediate catabolites (Intermediary Metabolism). However, a few strain 19 isolates grow on *i*-erythritol (Alton et al., 1988) possibly because they carry compensatory mutations, and in this case, the phenotypic test fails. The deletion in the *ery* region can be directly examined by hybridization of *Eco*RI-digested DNA with appropriate *ery* probes (Sangari and Agüero, 1994a) or by PCR with primers taken either from the sequences at both sides of the deletion (Sangari et al., 1994) or from the 702-bp deletion plus the *ery* region conserved in strain 19 (Bricker and Halling, 1995).

B. melitensis strain Rev. 1 can be differentiated from typical field isolates of *B. melitensis* biovar 1 by its inability to grow on thionin and fuchsin (both at 20 µg/ml) or penicillin (5 IU/ml). Moreover, Rev. 1 is resistant to streptomycin at 2.5 µg/ml. (Rev. 1 is a revertant of a streptomycin-dependent mutant.) Molecular markers for this vaccine will certainly be developed, taking advantage of the expected mutation(s) in some of the ribosomal proteins involved in streptomycin resistance.

B. abortus RB51 is a rough strain that has been proposed as a live vaccine for cattle brucellosis. Because field strains infecting cattle are smooth, this strain can be easily differentiated from most field strains by the characteristics associated with the rough phenotype (Colonies and Dissociation). Resistance to rifampicin is also a characteristic of this strain. Moreover, strain RB51 carries two IS*711* elements in a specific locus, and this allows its differentiation from field isolates of *B. abortus* biovar 1, 2 and 4 (but not from the parental virulent strain *B. abortus* 2308; Ewalt and Bricker, 2000).

The Brucellaphages

Over twenty brucellaphages have been isolated from several natural sources, including the bacteria themselves, manure, fetuses, blood, milk and other materials from *Brucella*-infected animals. Although there is evidence compatible with the existence of a lysogenic state in some cases (Corbel and Thomas, 1980a), this has never been proven and all brucellaphages in use are lytic. The origin, species host range, and other basic features of the most significant brucellaphages are presented in Table 13, and data

Table 13. Characteristics of the main *Brucella* phages.[a]

Phage (group)[a]	Origin	Propagating strain	Host range lysis[b]		Other properties
			at RTD and 10^4 RTD	only at 10^4 RTD	
Tb (1)	Isolated from liquid manure of a cowshed in Tbilisi (Russia)	*B. abortus* 544[c] and S19[d]	*B. abortus*	*B. suis* and *B. neotomae*	Also known as TB; does not lyse rough mutants
Fi (2)	Isolated from a *B. abortus* culture collected in Firenze (Italy). Fi/13 is the type strain	*B. abortus* S19[d]	*B. abortus* and *B. neotomae*	*B. suis*	Also knonwn as Fz75/13; does not lyse rough mutants
Wb (3)	Isolated from a *B. suis* culture in Weybridge (England)	*B. abortus* S19[d], *B. suis* 1330[c]	*B. abortus*, *B. suis* and *B. neotomae*	Reported for some *B. melitensis* strains	Also knonwn as W; does not lyse rough mutants
Bk2 (4)	Obtained in Berkley (USA) by plating Bk0[e] on *B. melitensis* 16M[c]	*B. melitensis* Isfahan[f] and 16M[c]	*B. abortus*, *B. melitensis*, *B. suis* and *B. neotomae*	None reported	Does not lyse rough mutants; relative of Bk1
R/C (5)	Obtained from R/O[g] by serial propagation on *B. canis* Mex.51[h]	*B. canis* Mex.51[h] and RM 6/66[c]	*B. canis*, *B. ovis* and rough *B. abortus*	Reported for some rough *B. melitensis* mutant strains	Not active on smooth *brucellae*
R/M (5)	Obtained from R/C by serial propagation on *B. melitensis* 115	*B. melitensis* 115[i]	n.d.[j]	n.d.[j]	Reported to be more consistently lytic for rough *B. melitensis*
Iz (6)	Isolated from sheep and goat feces in Izatnagar (India)	*B. abortus* S19,[d] *B. melitensis* 16M[c], *B. melitensis* 115[i]	*B. abortus*, *B. melitensis*, *B. suis* and *B. neotomae*	Some *B. suis* strains	Lyses *B. melitensis*, *B. abortus* and *B. suis* rough mutants
Np (7)	Isolated from atypical *B. abortus* strains in Nepean (Canada)	*B. abortus* S19[d]	*B. abortus*	*B. neotomae*	Does not lyse rough mutants

[a]Phage stocks are maintained at the FAO/WHO Center for Brucellosis Reference and Research, OIE-Brucellosis Reference Laboratory Central Veterinary Laboratory, New Haw, Weybridge, Surrey KT15 3NB, England; some brucellaphages can be obtained from ATCC (http://www.atcc.org/). An exhaustive list of the brucellaphages is given in Ackerman et al. (1981).
[b]RTD is defined as the highest phage dilution producing confluent lysis on a lawn of the propagating strain. At 10^4 RTD, there is a "lysis from without" and no phage multiplication occurs.
[c]See Table 3.
[d]See 9.3.
[e]Bk0 was obtained by passage of Wb on *B. melitensis* Isfahan.
[f]A biotype 1 strain isolated in Isfahan (Iran).
[g]R/O was obtained from phage R by serial propagation on *B. ovis* 63/290; although it multiplies in some rough brucellas, some phages active on some smooth forms are produced. Phage R was obtained by simultaneous incubation of Wb, MC/75 and D with *B. abortus* 544 in the presence of *N*-methyl-*N'*-nitro-*N*-nitrosoguanidine; it is also unstable, and although it multiplies on some rough mutants, some phages are active on smooth *B. abortus*. Phages MC/75 and D are Tb derivatives obtained after storage at 4°C in toluene for 5 years and by propagation on *B. abortus* 544 in the presence of mitomycin, respectively.
[h]A strain isolated in México.
[i]*B. melitensis* 115 (also known as B115) is a goat isolate that showed the rough phenotype on the isolation plates and not as a result of subsequent dissociation.
[j]n.d., no data available.
From Corbel and Thomas (1980); Rigby (1990).

available on other brucellaphages can be found in the review of Ackermann et al. (1981).

The first brucellaphages isolated were fully active only on *B. abortus* or on *B. abortus*, *B. suis* and *B. neotomae*, and since they proved useful for *Brucella* identification, derivatives active on *B. melitensis* and rough *Brucella* species were obtained from them under laboratory conditions. A phage (Iz) active on both S and R brucellae was isolated in the eighties. The brucellaphages active on smooth brucellae are often named after the place where they were isolated or obtained, whereas those active on rough brucellae are named using the letter R followed by the initial letter of the species used to adapt the parental phage to multiply in rough brucellae. They are usually grouped by their *Brucella* host range, with numbers that reflect the order in which they were isolated or developed (Corbel and Thomas, 1980a; Rigby, 1990).

Structural Characteristics The brucellaphages are footed viruses with a 50–80 nm diameter isometric icosahedral head carrying double-stranded DNA and a 10–30 × 7–9 nm long tail (morphological group C1 of *Podoviridae*). Tail fibers are apparent in some preparations. All brucellaphages tested are serologically related, and where determined (Tb and a few others not listed in Table 13), the DNA has a molecular weight of about 25×10^6, with a G+C content of 45.3–46.7% (Ackermann et al., 1981). Restriction endonuclease (*Eco*RI, *Hind*III, *Pvu*II, *Ava*I and *Bg*II) analyses have not shown major differences among DNAs from phages Tb, Fz, Wb, R/C and Iz, but the DNA of phage Np shows some differences when digested with *Eco*RI and *Hind*III (Rigby, 1990).

Multiplication *Host Range* The brucellaphages fail to replicate in a large variety of Gram-negative bacteria tested, including *Yersinia enterocolitica* O:9, *Salmonella* group N, *Vibrio cholerae*, *Stenotrophomonas maltophilia* 555 and *Francisella tularensis*, all of which produce LPS *O*-polysaccharides with structural similarities to that of smooth brucellae (Table 6). To date, there is no report indicating that the brucellaphages are not specific for brucellae. Thus, variations in host range are limited to those existing within the genus (Table 13).

Receptors Adsorption kinetics are similarly slow in all brucellaphages tested, with K values ranging from 0.3×10^{-10} to 4.9×10^{-11} ml/min depending on phage and host. The molecular nature of the receptors is not known. Although the rough-specific brucellaphages are derived from smooth-specific ones, the Tb, Fi, Wb and Bk2 phages (active on smooth brucellae) are not absorbed efficiently by rough strains or species. As far as it is known, the major difference between the surface of rough and smooth *Brucella* lays on the structure of the LPS and the exposure of the outer-membrane proteins (Omps) (Outer Membrane Topologyz), and this suggests that the LPS *O*-polysaccharide should be part of the receptor of Tb, Fi, Wb and Bk2. However, *Y. enterocolitica* O:9, which has an LPS *O*-polysaccharide structurally very similar to that of *B. abortus*, does not absorb any of those phages (Corbel and Thomas, 1980a), and this is also true for other bacteria with structurally related *O*-polysaccharides (Table 6). Absorption of phages Tb, Fi, Wb and Bk2 by smooth *B. melitensis*, *B. abortus*, *B. suis* and *B. neotomae* roughly corresponds to their species host range (Table 13) and occurs regardless of the intraspecies variations in *O*-polysaccharide structure associated with the distributions of the A and M epitopes among the biotypes (Table 3). Taken together, all these observations show that the fine structure of the smooth LPS is not relevant and that, in addition to LPS, some other and hitherto undetermined surface feature in which *B. melitensis* differs from other smooth brucellae plays a role in the receptor activity. In *B. neotomae*, the receptor has been associated with a thermoresistant periodate- and protease sensitive protein-phospholipid-LPS complex (Corbel and Thomas, 1980a).

Latent Period and Burst Size These parameters have been estimated to be 30–140 min and 22–121, respectively, depending on phage and host (Ackermann et al., 1981). In comparative experiments carried out under the same conditions, the values were 60–150 min and 8–26 (Corbel and Thomas, 1980a).

Use in Typing Owing to their narrow host-range, the brucellaphages are useful in the identification of *Brucella* at the genus and, along with other tests, species (Table 2) levels. For this purpose, phages Tb and R/C are routinely used. The strains to be tested are inoculated onto plates of an appropriate medium, such as serum-dextrose agar (Table 10), so as to produce a lawn, spotted with phage suspensions at the appropriate concentrations, and incubated. Detailed protocols for the maintenance and titration of brucellaphages can be found in the following references: Alton et al. (1988); Corbel and Thomas (1980a).

Preservation

For short-term preservation, *Brucella* cultures can be kept at 4°C and transferred periodically (in sealed tubes, they usually last longer than 6 months) on slopes of an appropriate medium,

provided precautions to minimize the establishment of laboratory-favored mutants are taken. For the smooth-to-rough dissociation, these precautions include avoiding the use of media with excessive moisture, incubation times as short as possible, and unnecessary holding of cultures at room temperature. Even so, many strains tend to dissociate, and in this case, the rough mutants can be eliminated by inoculation into suitable laboratory animals and recovery of the strain from spleens a few weeks later.

For long-term preservation, freeze-drying is the method of choice, keeping in mind the hazards posed by the aerosols that can be created during this kind of manipulation. Stabilizers described for *Brucella* include water solutions of 5% bovine serum albumin, 7.5% saccharose, 1% monosodium glutamate, or 2.5% enzymatic digest of casein, 5.0% sucrose, 1% monosodium glutamate (Alton et al., 1988). It is advisable to keep the freeze-dried bacteria at 4°C. At least *B. abortus* and *B. melitensis* can be maintained in skim milk suspensions at –80°C for more than 5 years, but the method is not suitable for *B. ovis*. *Brucella* stored on potato infusion agar slopes directly at –80°C survives for more than 5 years without significant loss of viability.

Physiology

The brucellae are chemoorganotrophic microorganisms that are able to grow both on lifeless media and within host cells (Habitat). As discussed elsewhere in this chapter, this behavior is based on a complex set of properties, and among them, some have a structural basis (Metabolism). Presumably, these bacteria are able to adapt their metabolism to the changing conditions they encounter in the external and intracellular environments. However, little is known on this important aspect of the biology of *Brucella*, and this is explained by both the experimental limits inherent to the work with highly virulent microorganisms and, until recently, the paucity of suitable genetic tools.

Structure

The brucellae are Gram-negative bacteria (Extracellular Enzymes and Uptake) and, therefore, their cell envelopes have inner- and outer-membranes enclosing a periplasm (Intermediary Metabolism) that contains the peptidoglycan mesh and some periplasmic soluble components. Free lipids (phospholipids and neutral lipids) are structural elements of the outer-membrane and inner membranes. In addition, the outer-membrane (Fig. 20) contains LPS (Response to Environmental Stress) and several Omps, and the inner-membrane contains proteins involved in substrate transport and other metabolic processes. Our knowledge of the topology of this cell envelope is hampered by the lack of adequate methods to physically separate the outer-and inner-membranes. These methods often include a step in which the outer-membrane is destabilized to be rendered either susceptible to detergent action or permeable to lysozyme. However, *Brucella* shows a marked outer-membrane stability that prevents the application of such methods and is also the probable reason for the failure of classical protocols to preferentially extract soluble periplasmic components. Despite these problems, a combination of chemical, genetic and morphological approaches has yielded a substantial amount of information on the *Brucella* cell envelope.

Ultrastructure of the Cell Envelope

Electron microscopy of *Brucella* shows the classical structure of the Gram-negative cell envelope with an outer-membrane of 6.5–8.0 nm and a cytoplasmic membrane of similar thickness, both separated by a periplasmic space of variable dimensions, possibly depending on the section examined and the fixation procedure (De Petris, 1964; Dubray, 1972; Dubray, 1975). Differences between smooth and rough *Brucella* cells can be observed by using phosphotungstic acid (Dubray, 1976). Positively charged stains and polycationic ferritin derivatives densely stain the surface of rough *Brucella* (Weber et al., 1977), possibly revealing that the negatively charged groups of the inner core of the LPS become exposed in rough cells (Fig. 12). Intracytoplasmic membranous structures have been reported (De Petris, 1964; Dubray, 1972). With differences among strains and species, exponentially growing *Brucella* cells release significant amounts of outer-membrane fragments enriched in several Omps (Gamazo and Moriyón, 1987; Gamazo et al., 1989). Although a capsule-like material associated with smooth cells (Vysotskii et al., 1967; Vysotskii, 1968) or reacting with anti-smooth LPS antibodies (Oberti et al., 1982) has been reported, the nature of the material has not been clarified.

Comparative studies show that the layer corresponding to the peptidoglycan is both thicker (5 versus 2–3 nm) and in an interaction with the outer-membrane much tighter in *Brucella* than in *Escherichia coli* (Dubray, 1976). In addition, it has been noted that whereas heat inactivation of cells causes the *B. abortus* cytoplasmic membrane to collapse, the outer-membrane keeps its morphological appearance despite release of important amounts of LPS and other outer-membrane materials (Rubbi, 1991). These observations suggest that the outer-membrane-

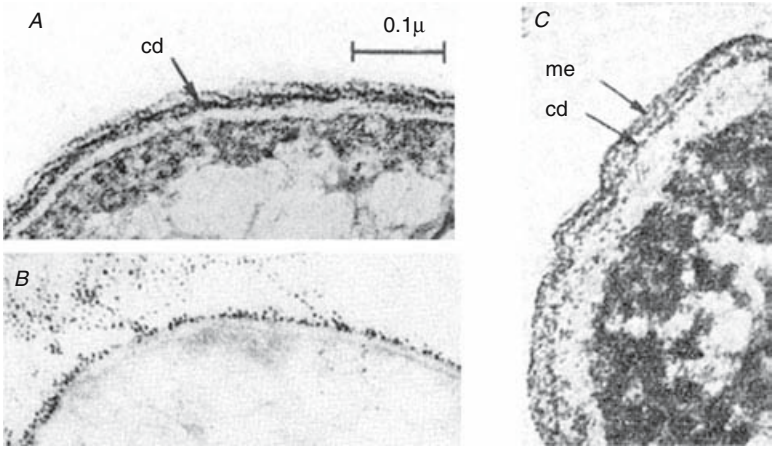

Fig. 12. Ultrastructure of *Brucella*. Thin sections of *B. abortus* 99 (A), *B. canis* (B), and *Escherichia coli* B (C) stained by the glutaraldehyde-uranyl acetate-lead citrate method (A and C) or with polycationic ferritin (B). Arrows mark the outer membrane (me) and the peptidoglycan layer (cd). Panel A adapted from Dubray (1975), panel B from Weber et al. (1977), and panel C from Dubray (1976), with permission.

peptidoglycan interaction could result in outer-membrane stiffness greater in *Brucella* than in other Gram-negative organisms. This could be related to the tight association of some Omps with the peptidoglycan (Sugar Catabolism and Tricarboxylic Acid Cycle).

Periplasmic Components

Peptidoglycan There is no detailed analysis of the structure of *Brucella* peptidoglycan or specific studies on its mechanism of synthesis. Based on qualitative analysis (Mardarowicz, 1966), the taxonomical position of the group, its sensitivity to muramidases and the action of antibiotics on *Brucella*, this peptidoglycan seems to be similar to that of most Gram-negative organisms. Although early studies reported quantitative and qualitative interspecies differences in peptidoglycan amino acid composition (Lacave and Roux, 1965), these data should be confirmed because *Brucella* peptidoglycan interacts with a variety of Omps difficult to remove (Omp-peptidoglycan Association). L-Forms devoid of peptidoglycan have been repeatedly observed and can be obtained with penicillin in vitro (Hatten et al., 1969) and from tissue cultures infected with *Brucella* (Elberg and Ralston, 1980; Hatten and Sulkin, 1966a; Hatten and Sulkin, 1966b) or isolated from infected animals treated (Schmitt-Slomska et al., 1981) or not treated (Corbel et al., 1980b) with antibiotics.

Soluble Components The *Brucella* periplasm contains comparatively large amounts of cyclic β-glucans (β-(1→2)-linked D-glucopyranose) made of 16 to 25 sugar units identical to some found in other members of the α-2 Proteobacteria (Moreno, 1992), such as *Agrobacterium*, *Rhizobium* and *Sinorhizobium* (Bohin, 2000). At least in these three bacteria, cyclic β-glucans synthesis is stimulated at low osmotic pressure, and it has been postulated that they take part in the regulation of the periplasmic colloid osmotic pressure. In *Brucella*, however, cyclic β-glucans synthesis is not osmoregulated (Iñ de Iannino et al., 2000), and they must accomplish a different function. Considering *Brucella* mutants defective in cyclic β-glucans are attenuated and show an altered intracellular trafficking, such function seems essential for full virulence (Escaping from the Endocytic Pathway) and may relate to the activity that closely related compounds, such as the methyl-cyclodextrins, has on animal cell membranes. Some authors have mistakenly equated these periplasmic glucans with polysaccharide B (see below) (Native Hapten Polysaccharides).

Two important detoxifying enzymes, a Cu^{++}/Zn^{++} superoxide dismutase (different from the cytosolic Mn^{++}-superoxide dismutase) and a catalase, have been identified in the periplasm of *B. abortus* (Kim et al., 2000; Stabel et al., 1994). Both enzymes protect against oxidative stress (Response to Environmental Stress), but their role in virulence is controversial (Neutralization of Oxygen and Nitrogen Intermediates). Other proteins identified in the periplasm include proteins BP26 (Immunological Diagnosis of Human Brucellosis Caused by Smooth *Brucella*; Rossetti et al., 1996) and P39, which are likely to be substrate-binding proteins involved in transport (De Fays et al., 1999).

The Free-Lipids The free lipids (i.e., the lipids that can be extracted with organic solvents from whole cells) include the overall cell envelope lipid composition and represent about 4.5% of the total cell dry weight. They have been the topic of an extensive review (Cherwonogrodzky et al., 1990) and their composition (Table 12) reflects the taxonomical position of *Brucella* (Fig. 4). There are interspecies differences in the

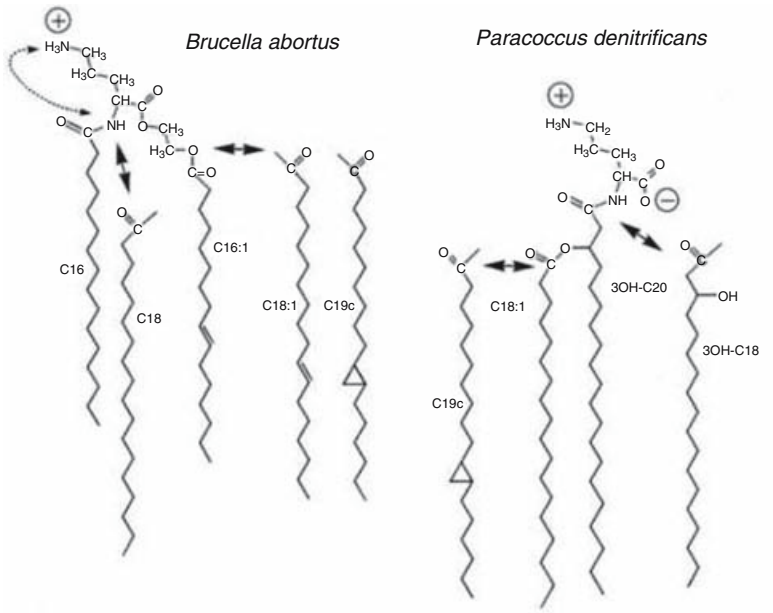

Fig. 13. Structures proposed for the ornithine-lipids of several Proteobacteria. Whereas *B. abortus* ornithine lipid carries an ester-linked acyl-ethyleneglycol (and is thus diacylated) and a positive net charge, other ornithine-lipids carry acyl-oxyacyl substitutions and are zwitterionic. Double arrows mark alternative acyl groups, and the dashed double arrow in the *B. abortus* ornithine-lipid marks an alternative acylation in the δ-amino group.

fatty acid profiles obtained by methanolysis of whole cells (Tanaka et al., 1977), and it is also known that the exact lipid composition depends on the medium and growth phase.

Phospholipids Although the precise lipid composition depends on growth medium and age of the culture, the major *Brucella* phospholipid is always phosphatidylcholine (Outer Membrane Topology) or its immediate biosynthetic precursors. Phosphatidylethanolamine is in close proportion to phosphatidylcholine, and cardiolipin and phosphatidylglycerol are also present in significant amounts. The dominant fatty acids are C16, usually at position C1 of glycerol, and C18:1 and C19 cyclopropane (lactobacillic acid), mostly at C2.

Neutral Lipids *Brucella* cells contain a substantial amount (over half of the total free lipids) of neutral lipids of which the ornithine lipids are particularly remarkable. These ornithine lipids differ from those described in other bacteria, are ester-linked to an acylated ethylene glycol residue (Figs. 13 and 14) and should carry a positive charge under most conditions (Outer Membrane Topology). Other neutral lipids described in *Brucella* include mono-, di- and triglycerides and other acyl-esters.

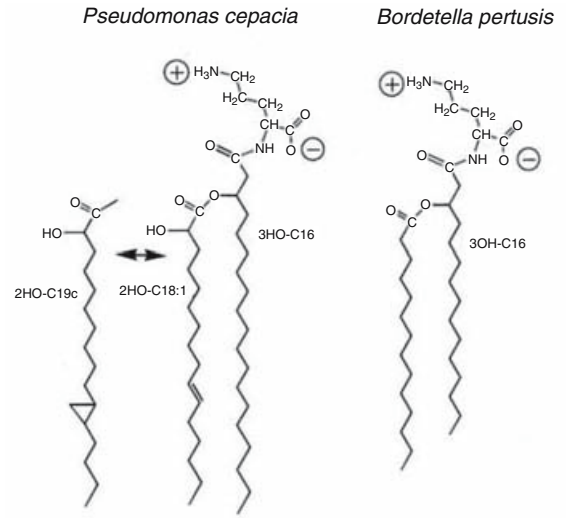

Fig. 14. Structures proposed for the ornithine-lipids of several Proteobacteria (second part). See first part in Fig. 13. Whereas *B. abortus* ornithine lipid carries an ester-linked acyl-ethyleneglycol (and is thus diacylated) and a positive net charge, other ornithine-lipids carry acyl-oxyacyl substitutions and are zwitterionic. Double arrows mark alternative acyl groups, and the dashed double arrow in the *B. abortus* ornithine-lipid marks an alternative acylation in the δ-amino group.

The Lipopolysaccharide *Brucella* is unique among Gram-negative bacteria in that some species have smooth-type LPS and others have naturally rough-type LPS (i.e., lipo-oligosaccharides; Table 2) different from the LPS of the rough mutants of the smooth types. The *Brucella* LPS have not been completely characterized. Presumably, the smooth- and rough-type LPS of *Brucella* have a closely similar lipid A structure and differ mostly in the saccharide moiety. *Brucella* LPS extracts are constituted by a

heterogeneous group of LPS molecules (Freer et al., 1995). This heterogeneity arises from the different length and different degree of acylation of the O polysaccharide, from the different acylation of the lipid A moiety and possibly from various substitutions of the core oligosaccharide.

Lipid A The structures proposed for the lipid A of *B. abortus* and *O. intermedium* (Velasco et al., 2000; Zähringer et al., 1995) are shown in Fig. 7. The more remarkable features are i) the 2,3-dideoxy, 2,3-diaminoglucose (diaminoglucose) rather than 2-deoxy, 2-aminoglucose (glucosamine) backbone found in classical lipid A, ii) the fact that all acyl substitutions on the disaccharide are in amide linkages (rather than in both amide and ester linkages), iii) and the long chain acyl substituents, which include not only C18:1 and C19 cyclopropane but also 27-OH-C28:0 and minor amounts of 29-OH-C30:0, 27-Keto-C 28:0, and 29-Keto-C30:0. It is remarkable that this structure shows a basic similarity with that of *Legionella pneumophila* (Fig. 7), a taxonomically distant bacterium that shares with *Brucella* the acid-fastness and the ability to multiply within host cells.

Core Oligosaccharide The qualitative composition of the *B. abortus* LPS core can be inferred from partial chemical analyses and some genetic evidence (Table 5) but the detailed structure is not known. Sugars present in the core oligosaccharide of the *Brucella* smooth-LPS are 3-deoxy-D-manno-octulosonic acid (Kdo), glucosamine, 2-amino, 2,6-dideoxy-D-glucose (quinovosamine), glucose and mannose (Velasco et al., 2000). Like the LPS of other members of the α-2 Proteobacteria, the LPS core oligosaccharide of *Brucella* lacks heptose and phosphates. It is interesting to compare this core oligosaccharide with that of *O. intermedium* (Fig. 6). The comparison shows that in *O. intermedium*, but not in *B. abortus*, LPS contains galacturonic acid, which would carry a negative charge under physiological conditions. Galacturonic or glucuronic acids are present in the LPS core of other α-2 Proteobacteria examined, and therefore its absence in *Brucella* is remarkable (Lipopolysaccharide and Resistance to Outer-membrane Destabilizing Agents; Outer Membrane Versus Bactericidal Substances). Two epitopes have been described in the core oligosaccharide of *B. abortus* R mutants: R1, which includes the outermost sugars, and R2, which includes Kdo and sugars immediate to it (Rojas et al., 1994; Fig. 15).

O-polysaccharide The *O*-polysaccharides are synthesized by the smooth but not by the rough *Brucella* species (Table 2). This structure is also missing in the surface of the rough mutants of the smooth species that appear spontaneously during culture dissociation (Colonies and Dissociation). They are homopolymers of 4,6 dideoxy-4-formamido-D-mannose (*N*-formylperosamine; Perry and Bundle, 1990b). Their basic structure is represented by the *O*-polysaccharides of *B. abortus* biovar 1 and *B. melitensis* biovar 1 in which *N*-formylperosamine is in exclusively α-(1→2) linkages or in repeating blocks of five sugar residues, four α-(1→2)-linked and one α-(1→3)-linked, respectively (Fig. 16). The bacteria that significantly crossreact with smooth brucellae at LPS level carry *O*-polysaccharides that contain perosamine (Table 6).

Like in other smooth-type LPS, the *O*-polysaccharides show molecular weight heterogeneity within a given strain, and there is heterogeneity in average length among strains. The average number of 96 sugar units has been estimated for the *O*-polysaccharide of *B. abortus* 1119-3. From the molecular weight estimated by gel permeation chromatography, a range of 25–92 and of 35–130 sugar units can be calculated for the *O*-polysaccharides of *B. abortus* 2308 and *B. melitensis* 16M, respectively. *N*-formylperosamine has just one free hydroxyl group, and this peculiarity makes these smooth-LPSs phenol-soluble in opposition to most smooth-LPSs that partition into water when extracted by the hot water-phenol protocol. However, *N*-formylperosamine polysaccharides have a dual character, since they are also readily soluble in water where they show a marked tendency to self-aggregate at low ionic strength (Aragón et al., 1996b).

The smooth-LPS is the major antigen of the cell surface of all smooth *Brucella* species, and its *O*-polysaccharide is the serologically immunodominant section. Smooth brucellae show strong interspecies serological crossreactivity. Studies with monoclonal antibodies show that biovar 1 of *B. abortus* and *B. melitensis* carry the A (abortus) and M (melitensis) epitopes, respectively, and that there is a common *Brucella* (C/B) epitope (Douglas and Palmer, 1988; Fig. 15). There are three combinations of these epitopes (A-C/B, M-C/B and A-M-C/B) distributed among the different biovars of smooth brucellae in a nonspecies-specific manner (Table 3). Similar studies show a second common epitope (C/Y) shared by all the smooth brucellae and by *Yersinia enterocolitica* O:9 whose *O*-polysaccharide is also a homopolymer of *N*-formylperosamine in a-(1→2) linkages (Table 6). Although conceptually useful, the A-M-C epitopic scheme is a simplification because there are antibodies that recognize more than one of those epitopes, although with different intensity (Weynants et al., 1997). Thus, in polyclonal antibody responses, such as those occurring

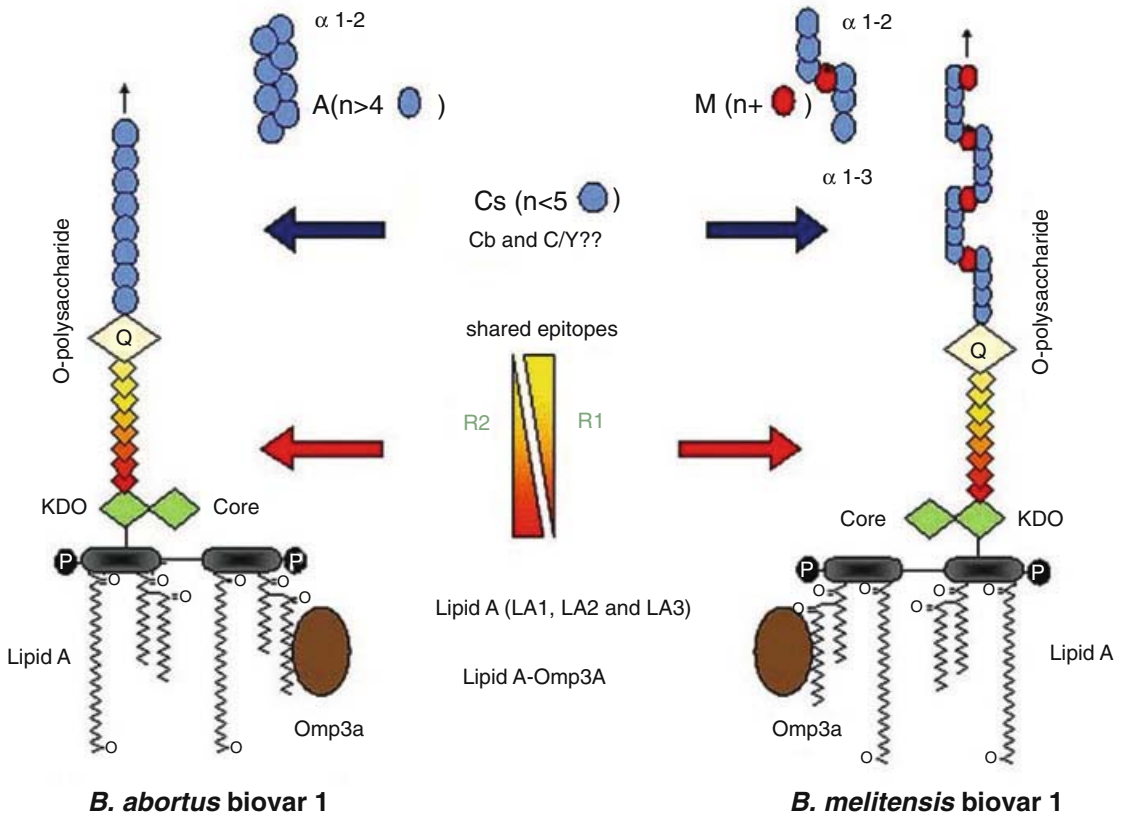

Fig. 15. Simplified epitopic structure of the smooth LPS of *B. abortus* and *B. melitensis*. Sugars in α (1-2) and α (1-3) linkages are represented in light blue or red, respectively. The *O*-polysaccharide A and M epitopes are specific of *B. abortus* (biovar 1) and *B. melitensis* (biovar 1), respectively. Shared epitopes are the *O*-polysaccharides C epitopes, the outer (R1) and inner (R2) core epitopes, the lipid A epitopes (LA1, LA2 and LA3) and some epitopes created by the interaction of the rough LPS with some Omps (possibly Omp3a [Omp25]). The beginning of the core (K do linked to the lipid A) is marked as a green diamond, while the end of the core (quinovosamine linked to the *O*-polysaccharide) is represented by a light yellow diamond (Q) structure.

during infection, the *Brucella O*-polysaccharides behave as structures made of overlapping epitopes, and this contributes to the intensity of the crossreactivity among smooth brucellae. These considerations are relevant to understand the serological diagnosis of brucellosis (Immunological Tests for Brucellosis).

The epitopic structure of the *O*-polysaccharide is explained by the relative frequency of α-(1→2) and α-(1→3) linkages. The α-(1→2) linkages relate to both the A and C epitope(s) and the α-(1→3) linkages to the M epitope, and intermediate biovars expressing both the A and M-type epitopes (such as *B. melitensis* biovar 3) and M-type *B. abortus* biovars have the expected proportions of α-(1→2)- and α-(1→3)-linked sugars. Indeed, the structural similarities between the A- and the M-type homopolymers also explain the concept of overlapping epitopes. On the other hand, the structural details accounting for the differences between the C/Y and C/B epitopes are not known. According to the ^{13}C-nuclear magnetic resonance analyses performed so far, the *O*-polysaccharides of *B. abortus* and *Y. enterocolitica* O:9 are indistinguishable, and this would leave no room for a C/B epitope carried by the *O*-polysaccharides of smooth-brucellae but not of *Y. enterocolitica* O:9. Since there is evidence that the smooth brucellae carry perosamine polysaccharides (Physiology of CO_2 Requirements) in which not all amino groups are formylated (M. Staaf et al., unpublished observations) a possibility is that differences in the degree of *N*-formylation not detectable by conventional ^{13}C-nuclear magnetic resonance methods account for the C/B and C/Y epitopes.

The Lipooligosaccharide of Rough Brucella Species *Brucella ovis* and *B. canis* carry lipooligosaccharides (naturally rough-LPS) in their outer-membranes rather than smooth-type LPS (Table 2). Our present knowledge of these rough LPSs is rather incomplete. *Brucella ovis* rough-LPS contains Kdo and up to 7 additional sugars, including glucose, mannose, glucosamine and

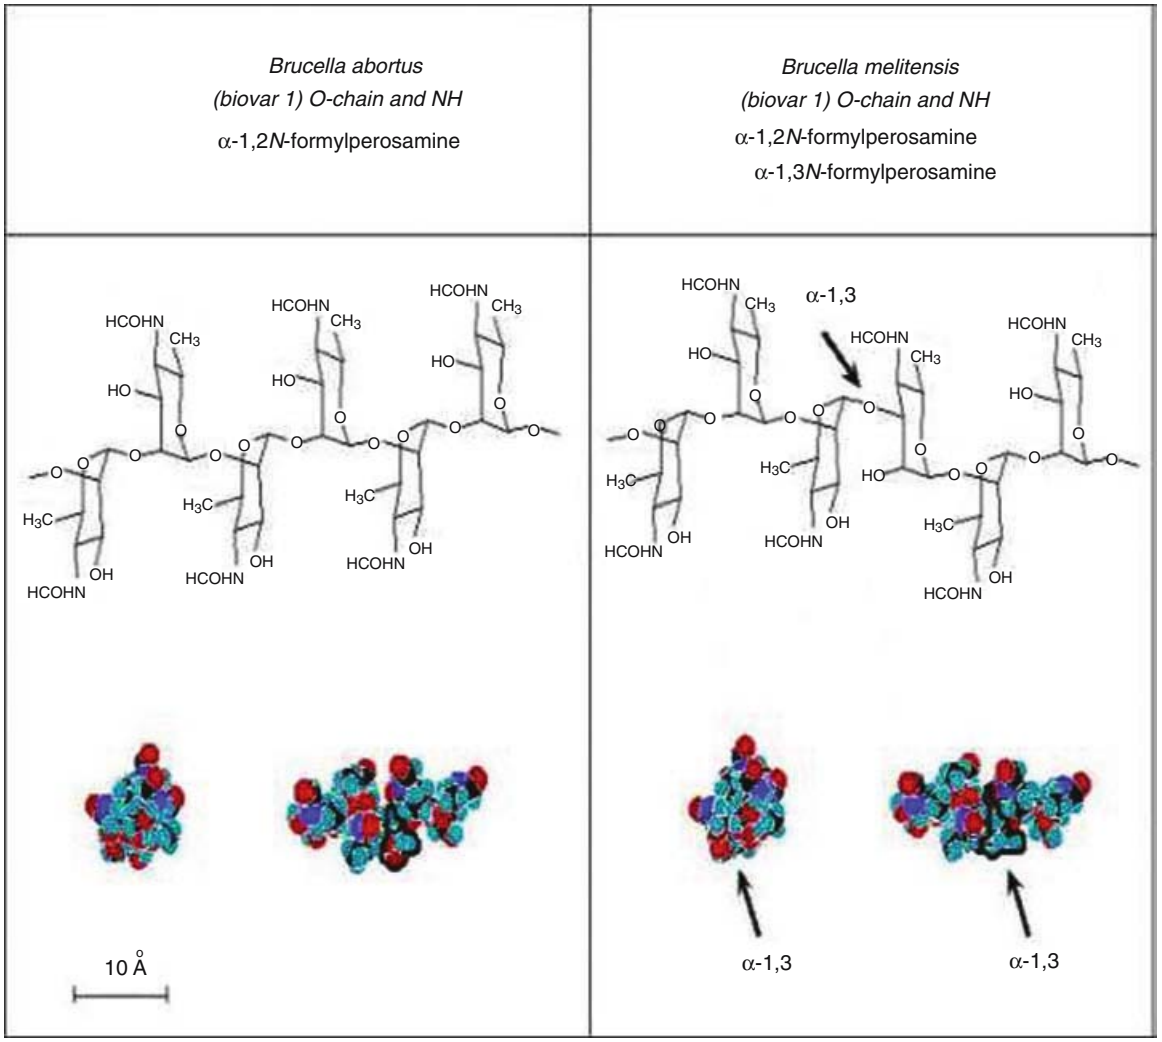

Fig. 16. Tridimensional and structural model of the *O*- and NH-polysaccharide molecules of *B. abortus* (biovar 1) and *B. melitensis* (biovar 1). Notice how the α 1,3 linkages interrupt each string of four α 1,2 linked *N*-formylperosamine residues in the *B. melitensis* homopolymer, unlike the continuity of the α 1,2 linkages observed in the *B. abortus* polysaccharides. Although formyl groups are substituents on most perosamine residues, the degree of formylation varies among the different homopolymer polysaccharides (*O*-chain > NH > Poly B).

unidentified sugars (Moreno et al., 1984a; Suárez et al., 1990). This short oligosaccharide stub bears the antigenic determinants of the *B. ovis* rough-LPS, which include epitopes shared with the LPS-core of smooth-*Brucella* species and *B. canis*, as well as *B. ovis*-specific epitopes (Díaz and Bosseray, 1973a; Moreno et al., 1984a). Likewise, *B. canis* rough-LPS seems to carry their own antigenic determinants (Carmichael, 1990). Although *B. ovis* and *B. canis* produce only rough-LPS, it is remarkable that they contain genes required for the synthesis of the *O*-polysaccharide (Table 5).

Genetics and Biosynthesis of Lipopolysaccharide Little is known on the biosynthesis of *Brucella* LPS. Indirect evidence shows that the three main pathways (lipid A, core and *O*-polysaccharide) used by the best studied Proteobacteria are as expected present in *Brucella*. Several genes involved in LPS biosynthesis have been identified, including those involved in the synthesis of perosamine and its formylation, polymerization and transport of the *O*-polysaccharide (Table 5). Six of these genes are most likely in a single operon. Interestingly, the G+C content of the open reading frames likely to be involved in *O*-polysaccharide synthesis is lower (44–49%) than that of the whole genome of *Brucella* (56–58% for *B. melitensis*; Godfroid et al., 2000). This suggests that these genes could have been acquired by horizontal transfer, and indeed, *O*-polysaccharides close to or identical to those of *Brucella* are found in some phyloge-

netically distant bacteria (Table 6). Since the genetic and ecological characteristics of the brucellae suggest that they presently have little opportunities for such exchanges (Genetic Exchange, Plasmids and Lysogenic Phages), acquisition of *O*-polysaccharide genes could have been an early event in the evolution of the genus (Acquisition of Ancestral Genes by Horizontal Transference). This is in keeping with the structural homogeneity of the *N*-formylperosamine homopolymers and with the presence in *B. ovis* and *B. canis* of genes involved in its synthesis (Cloeckaert et al., 2000).

LPS Biological Activities Lipid A is the structure directly involved in the endotoxin-related properties of LPS. Since the lipid A of *Brucella* has a structure that clearly departs from that of the classical enterobacterial-type lipid A, it is not surprising that its LPS shows lower biological activities (Table 14). In general, the lower endotoxicity of *Brucella* LPS is manifested as a marked reduction in toxicity linked to a reduced ability to stimulate susceptible host cells to release immune mediators. Indeed, *Brucella* LPS is from 200 to 2,000 times less active than *Salmonella* LPS (Fig. 17). *Brucella abortus* LPS activates the complement system poorly by the alternative pathway, and the *O*-polysaccharide has been shown to be involved in this phenomenon (Fig. 18). Both reduced endotoxicity and poor complement activation contribute to virulence (Opsonization and Complement Susceptibility). There is no evidence of interaction between the *O*-polysaccharide of *B. abortus* and collectins (mannose-binding protein and surfac-

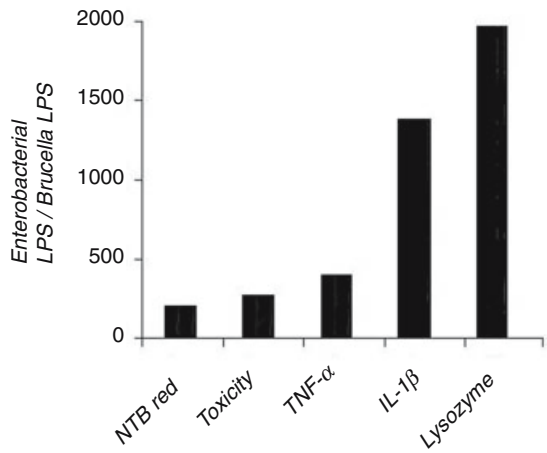

Fig. 17. Comparison of the biological activities of *Brucella* LPS with *S. typhimurium* and *E. coli* LPSs in phagocytic cells. The concentration of *Brucella* LPS at which the maximum biological effect is generated was recorded and compared with the concentration of *S. typhimurium* or *E. coli* for the same effect. Respiratory shunt in human polymorphonuclear leukocytes was measured as reduction of nitro-blue tetrazolium (*NTB-red*); maximum level of toxicity (*Toxicity*) reached with *B. abortus* LPS was less that 10% at 500 mg/ml $\times 10^6$ macrophages; TNFα production (*TNF-α*) in murine macrophages; IL-1β production (*IL-1β*) by murine macrophages; and lysozyme release (*Lysozyme*) by human polymorphonuclear leukocytes. Notice that *Brucella* LPS is from 200 to 2,000 times less potent than *Salmonella* or *Escherichia* LPSs. Adapted from Rasool et al. (1992); Goldstein et al. (1992).

tant proteins), although *B. abortus* has been shown to bind to human B cells and macrophages by a lectin-type mechanism (*Brucella* Bacterins and Lipopolysaccharide as Immunological Tools).

NATIVE HAPTEN POLYSACCHARIDES These are haptenic polysaccharides that can be demonstrated in extracts of smooth *Brucella* by immunoprecipitation with sera from *B. abortus*- or *B. melitensis*-infected animals in the presence of hypertonic buffers (Fig. 19). The *B. melitensis* 115 rough mutant is unable to produce smooth-LPS but also accumulates a similar compound (named "polysaccharide B") in the cell envelope and its phenotype is close to that of LPS *wzm* mutants (Table 5). Both NH and polysaccharide B are *N*-formylperosamine homopolymers with a frequency of α-(1→2) and α-(1→3) linkages similar to that of the *O*-polysaccharide (Fig. 16) of the strain from which they are isolated (Aragón et al., 1996b). However, in contrast to the *O*-polysaccharide of LPS, neither polysaccharide B nor NH is linked to core oligosaccharide sugars and both are partially (up to 50%) deformylated (M. Staaf et al., unpublished observations). This last feature is intriguing because polymerization of at least *B. melitensis* LPS *O*-polysaccharides is blocked by disruption of the gene coding for the putative formyltransferase (Godfroid et al., 2000; Table 5). NH and polysaccharide B may represent biosynthetic precursors of the *O*-polysaccharide of smooth-LPS, but NH also has been demonstrated in the outer-membrane fragments that are released spontaneously by growing *B. melitensis*. Thus, NH is in the outer-membrane as a structure that, although similar to the *O*-polysaccharides, is not linked to core-lipid A (Outer Membrane Topology). This type of polysaccharide was described long ago in several Gram-negative bacteria (Anacker et al., 1964) and it is known as their presence in the outer-membrane results from variations in the standard polymer-lipid A-core ligase reaction (Whitfield et al., 1997).

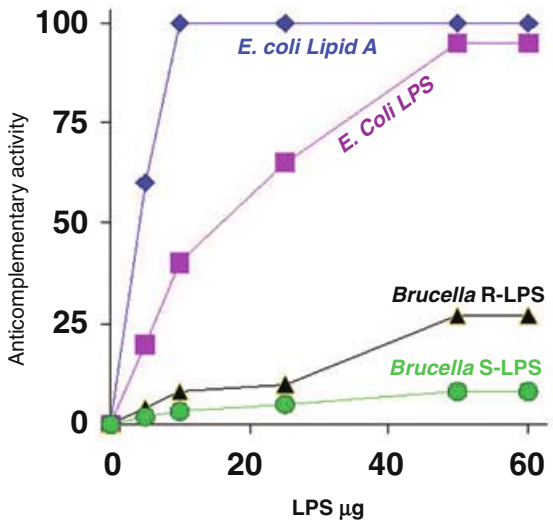

Fig. 18. Anticomplementary activity of LPS and lipid A. Increasing amounts of each preparation were incubated with guinea pig complement and percentage loss of hemolytic activity was measured. Notice that *B. abortus* smooth and rough LPSs exert low anticomplementary activity only at high concentrations of material, whereas *E. coli* lipid A and *Salmonella* LPS display a powerful anticomplementary activity. Adapted from Moreno et al. (1981), with permission.

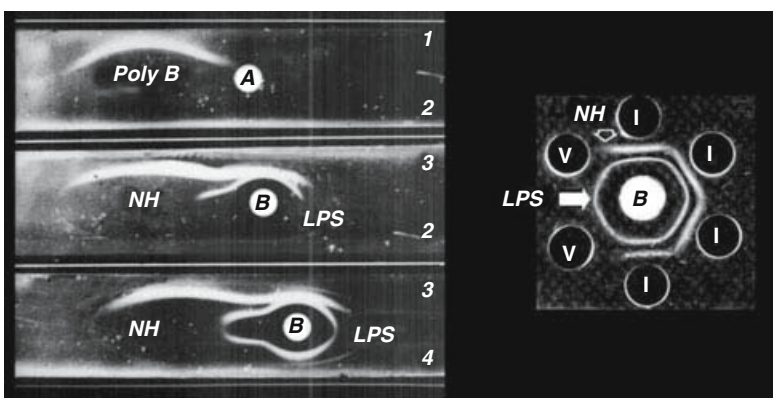

Fig. 19. Immunoprecipitation analysis of *Brucella* polysaccharides and lipopolysaccharides. Left panel: immunoelectrophoresis of rough *B. melitensis* 115 polysaccharide B (A); and *B. melitensis* extracts containing native hapten (NH) and smooth LPS (B). The troughs contained sera from infected cattle either plain (1 and 3) or absorbed with smooth *Brucella* cells (2) or polysaccharide B (4). Right panel: Double gel immunodiffusion of *B. melitensis* extracts containing NH and smooth LPS and sera from infected (I) or *B. abortus* strain 19 vaccinated (V) cattle. Notice that while infected bovines react with both LPS and NH, vaccinated animals only react against the LPS, with no traces of reaction against the NH.

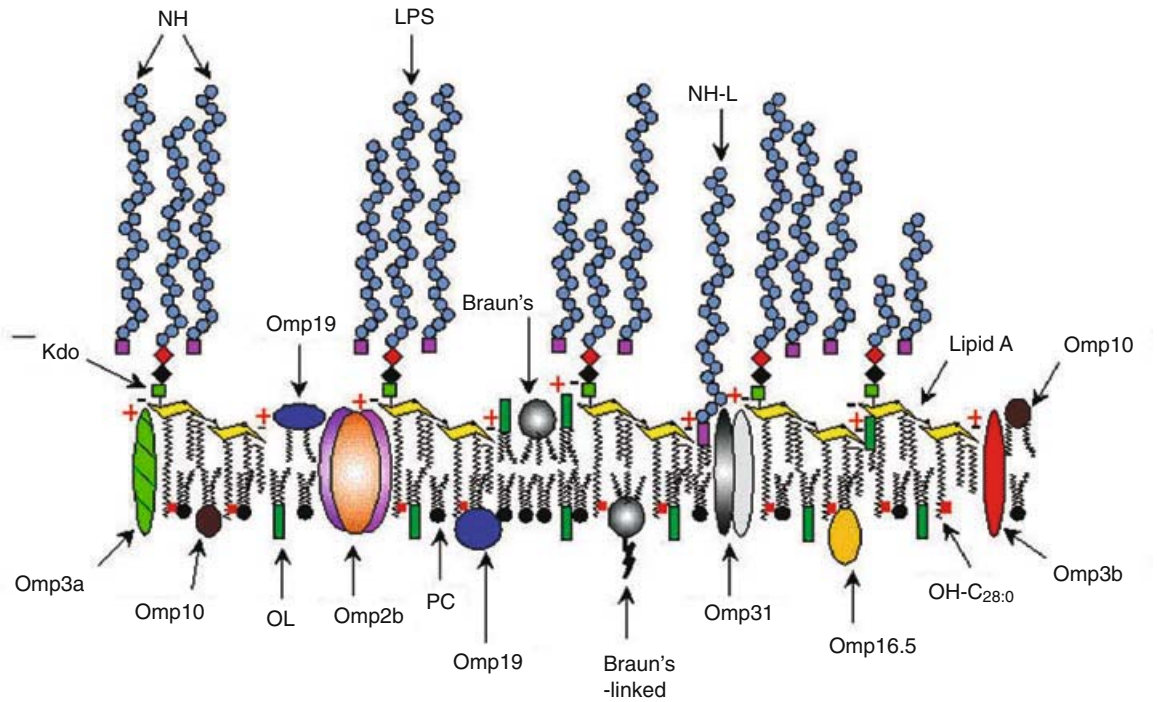

Fig. 20. A hypothetical model of the *Brucella* outer membrane. Omps are indicated by their mass in kDa, except for two group 3 proteins (Omp3a and Omp3b) with molecular weights of 26 kDa and 23 kDa, respectively. Lipoproteins have their acyl groups inserted in the bilayer. The lipid A diaminoglucose disaccharide backbone (represented by yellow trapezoids) is linked to fatty acids (black zigzag structures). The red squares in the bottom of the structure mark the hydroxyl groups of the LPS acyl chains that span the outer membrane. Purple squares mark the reducing ends of the NHs, an unknown sugar that in some cases may be linked to a lipid (NH-L). Braun's lipoprotein may be linked to peptidoglycan or free in the outer membrane. The polar heads of ornithine lipids (OL) are marked as green rectangles. Dark circles represent phospholipids, mainly phosphatidylcholine (PC). Notice that the NH of various sizes are intertwined with the *O*-polysaccharides of the LPS in the outer membrane, forming a dense layer. The negative charges of the LPS are neutralized by the positive charges of the ornithine lipids (OL) and cationic Omp such as Omp3b. Group 3 proteins (Omp3a [Omp25], Omp3b and Omp31) are strongly bound to LPS. Omp2b is a porin.

Outer Membrane Proteins The major Omps of *Brucella* were first identified by detergent extraction of cell envelopes and classified according to their apparent molecular weights as group 1 (94 or 88 kDa), group 2 (36–38 kDa), and group 3 (31–34 kDa and 25–27 kDa). Moreover, a lipoprotein linked to the peptidoglycan and three other lipoproteins have been identified in the cell envelope. Group 2 are porins and group 3 contains at least three unrelated proteins (Omp31, Omp3a or Omp25, and Omp3b), but the nature and role of group 1 remains to be elucidated (Fig. 20). Presently, little is known about the Omps of the *Brucella* isolated from marine mammals, and the data summarized in the following sections concern only the six classical species. Most information concerning the *Brucella* Omps has been reviewed by Cloeckaert et al. (1996b).

Porin Proteins The brucellae carry two related porin genes (*omp2a* and *omp2b*) with a high degree (>85%) of internal homology but with little homology to the genes of other porins described so far. This *omp2* locus is present in all *Brucella* species and is highly polymorphic at both *omp2a* and *omp2b*. This locus contains some species-specific sequences, specific markers for several of the classical biovars, and other sorts of intraspecific diversity (Fig. 4), including natural Omp2a-Omp2b chimeric proteins (Paquet et al., 2001). Thus, sequence analysis of the *omp2* genes has also taxonomical and phylogenetic implications (Table 4). Most of these variations are created by simple exchanges of conserved motifs between *omp2a* and *omp2b* and, in general, seem to have little impact on the antigenic variability of the proteins. The cognate proteins are predicted to be folded as a 16 stranded β-barrel, and most differences seem accumulated at the external loops (Paquet et al., 2001). At least Omp2b is in a trimeric state in the outer- membrane and behaves as a peptidoglycan-associated protein (Fig. 20). Obvi-

ously, *Brucella* porins span the outer-membrane and contribute to its permeability. In vitro, *B. abortus* only expresses Omp2a, and Omp2b may be expressed under other conditions. The pattern of expression in other *Brucella* species is not known.

Omp31 The *omp31* gene is present and expressed in all *Brucella* classical species but *B. abortus*, which carries a long 8-kb deletion encompassing this gene and others of unknown function (Vizcaíno et al., 1997). Gene *omp31* shows only little homology with *omp3a* (*omp25*) or *omp3b*, the other two groups of genes coding for a group 3 protein. Omp31 shows a tight interaction with LPS and is associated with peptidoglycan (Outer Membrane Topology). These features suggest that this protein plays a structural role, but if so, its absence from *B. abortus* suggests that it is not essential. Omp31 is able to form oligomers resistant to denaturation, and since this is a property characteristic of some porins, it has been suggested that it may play this role (Fig. 20).

Omp3a and Omp3b Family Two different groups of Omps, Omp3a (formerly Omp25) and Omp3b, are composed of 8 beta sheets and are related to RopA and RopB proteins of *Rhizobium* (Fig. 20). These two protein families have a molecular weight ranging from 26–23 kDa and each group displays from 5 to 8 spots in two dimensional gels (C. Guzmán-Verri et al., unpublished results). Several putative genes coding for these proteins have been identified in the *Brucella* genome, supporting the two-dimensional gel findings and supporting that they constitute a family of Omps with unknown functions. Similarly to Omp31, they show characteristically tight interaction with the LPS and are also associated with the peptidoglycan (Outer Membrane Topology). Omp3a is highly conserved in *Brucella* species and the only remarkable variation is a 36-bp deletion at the 3' end of the *B. ovis omp3a* gene that causes an antigenic shift in the Omp3a of this species. Although both families may play a structural role, this does not exclude additional functions in virulence, since at least in *B. abortus*, its expression in the outer-membrane seems to be regulated by the BvrR-BvrS system (Mechanisms of Entry to Host Cells).

Lipoproteins The *Brucella* cell envelope contains three proteins (Omp19, Omp16.5 and Omp10) with genetic features characteristic of bacterial lipoproteins and which have been shown to incorporate palmitic acid (Tibor et al., 1999). These lipoproteins are similar to the peptidoglycan-associated lipoproteins of other Gram-negative bacteria (Outer Membrane Topology) and crossreact with homologous proteins of other members of the α-2 Proteobacteria. An additional lipoprotein of overall characteristics similar to those of Braun's lipoprotein has been shown in *B. abortus*, *B. melitensis* and *B. ovis* (Gómez-Miguel and Moriyón, 1986), but the corresponding gene has not been identified (Fig. 20).

Outer Membrane Topology Like in other Gram-negative bacteria, the LPS is located in the outer leaflet of the outer-membrane anchored by its lipid moiety (Fig. 20). The very long fatty acids of the lipid A are likely to span the outer-membrane and to be anchored on the inner surface by the hydroxyl group close to the end of the acyl chain. The phosphate groups in lipid A and the Kdo carboxyl groups of the core may be associated with ornithine lipids, because the latter lipids appear as contaminants in LPS extracts and have a free amino group with a positive charge (Freer et al., 1996). With regard to the phospholipids, there is evidence that phosphatidylcholine is preferentially distributed in the outer-membrane (Gamazo and Moriyón, 1987), perhaps in its inner leaflet. In the smooth strains, the *O*-polysaccharide extends outwards, in association with the NH. This last molecule is maintained in the outer-membrane intertwined with the LPS *O*-polysaccharide or linked to a lipid other than lipid A (Rojas et al., 1994).

The presence or the absence of the *O*-polysaccharide profoundly modifies the topology of the surface of *Brucella* cells. First, it masks the ionic groups of the proteins and the core-lipid A LPS sections. Since the latter sections are dominant, mutants lacking the *O*-polysaccharide have a negatively charged surface at physiological pH, which contrasts with the very weak charge carried by smooth cells (Schurig et al., 1981; Weber et al., 1978). This difference is the basis of some tests used to distinguish smooth strains from their rough mutants (Cellular and Colonial Characteristics). Second, access to the anionic groups of the lipid A-core is sterically hindered in the smooth strains and this contributes to resistance to polycations (Properties of the Outer Membrane). Finally, there are differences in the surface exposure of Omps between the smooth *Brucella* species on the one hand and the rough mutants and *B. ovis* and *B. canis* on the other. In general, these differences are manifested as a comparatively reduced Omp accessibility to antibodies in the smooth strains. However, not all smooth strains are identical in this property, and the variations reflect at least in part different degrees of *O*-polysaccharide polymerization and also the total amount of smooth LPS produced. In some smooth strains studied in detail, Omp accessibility to antibodies is par-

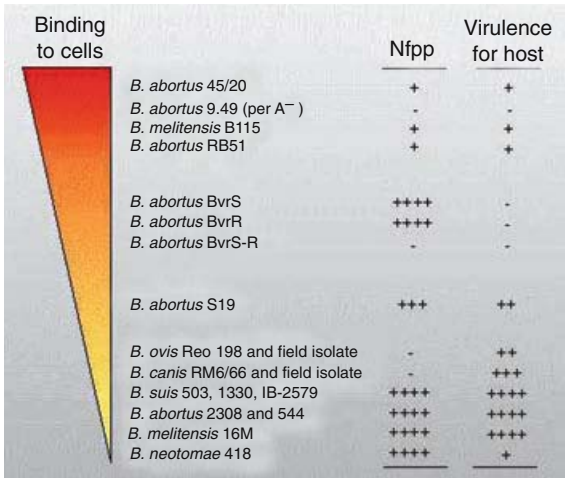

Fig. 21. Correlation among *Brucella* strains binding to epithelial cells, presence of *N*-formylperosamine polysaccharides (Nfpp) and virulence. Values are ranked from negative or absent (–), weak positive or present in low quantities r (+) to strong positive or present in large quantities (++++). The base of the triangle is compatible with the high number of bacteria binding to cells, whereas the apex of the triangle is compatible with the low number of brucellae binding to cells. Notice the absence of correlation between presence of Detilleux et al. (1990a, b); Freer et al. (1999); and Pizarro-Cerdá (1998).

alleled by an increase in both sensitivity to the R/C (rough-specific) *Brucella* phages (The Brucellaphages) and exposure of LPS core-lipid A epitopes. However, not all rough mutant strains are identical in Omp antibody accessibility, and differences between *B. ovis* and *B. canis* also have been observed (Bowden et al., 1995). Interestingly, these differences correlate well with the differences observed between the "natural rough" and rough mutants in the attachment and invasion of cells (Fig. 21).

Several Omps behave as peptidoglycan-associated proteins. If molecular weight, surface exposure and association with the peptidoglycan are used as criteria, porins, Omp31 and Omp3a are membrane-spanning proteins. The topology of Omp19, Omp16.5 and Omp10 proteins is probably more complex. They are accessible to antibodies on the surface of rough strains, and although according to the predicted amino acid sequence are hydrophilic, they also carry a lipid moiety and are extracted with detergents. Their similarities with the peptidoglycan-associated lipoproteins of other Proteobacteria suggest that they could be in the periplasmic space and play a role in the interaction of the outer-membrane with the peptidoglycan but they should also be anchored on the cell surface. The Braun's lipoprotein of *Brucella* seems to be covalently attached to the peptidoglycan but it also has been reported to be surface exposed, perhaps as a free form (Fig. 20).

Properties of the Outer Membrane Some simple observations, such as the inability to grow in media containing hydrophobic dyes, the ability to grow on selective media containing polymyxin B (Table 11), and the acid-fastness when stained by Stamp's method (Fig. 10) (Cellular and Colonial Characteristics), show that the brucellae have cell envelopes with a characteristic set of properties, some of which reflect, in all likelihood, an adaptation to intracellular parasitism (Outer Membrane Versus Bactericidal Substances).

Permeability Nutrients or precursors must passively cross the outer-membrane before they are taken up by the periplasmic and membrane proteins engaged in transport and translocation through the cytoplasmic membrane. Some early observations on the oxidation of glutamate by resting cells suggest that there is a link between outer-membrane permeability and virulence (Oxidation of Amino Acids). This could occur as a result of subtle differences in outer-membrane topology indirectly causing alterations in the pathways described (The Hydrophilic Pathway). There are two possible pathways for substrates to penetrate through Gram-negative outer-membranes and both are accessible in *Brucella* cells.

The Hydrophilic Pathway Some small hydrophilic molecules penetrate the outer-membrane of *Brucella* through Omp2 porins (Douglas et al., 1984). In classical functional assays, porins of *B. abortus*, *B. melitensis* and *B. canis* show an apparent internal diameter of about 1.2 nm, comparable to that of the OmpF porin of *E. coli*. At least for *B. abortus*, this result should correspond to Omp2b, since Omp2a is not expressed in vitro. However, cloned *B. abortus* Omp2a increases the outer-membrane permeability of *E. coli* to maltodextrins, and in planar bilayers, Omp2a forms monomeric pores smaller than those of Omp2b (the latter shows channel activity in trimeric state) (Marquis and Ficht, 1993). Although only three species and a few representative strains have been examined, there are small differences in the selectivity of porins purified from cell envelopes in functional assays according to which *B. melitensis* porin could have the smallest internal diameter and *B. canis* the largest, with *B. abortus* showing intermediate diameters (Douglas et al., 1984). Since thionin (a dye used in *Brucella* biotyping) has an exceptionally low hydrophobicity among dyes and its size is compatible with that of the *Brucella* porin channel, it has been suggested that differences in thionin

sensitivity of *B. melitensis* and *B. abortus* (Table 3) relate to different functional properties of the porins (Douglas et al., 1984). Recent comparative analyses suggest functional differences between Omp2a and Omp2b, the former being more efficient in allowing sugar diffusion (Paquet et al., 2001).

The Hydrophobic Pathway The antibiotic and dye sensitivity patterns and the direct assessment of permeability with hydrophobic probes show that the outer-membrane of *Brucella* is readily permeable to hydrophobic compounds (Martínez de Tejada and Moriyón, 1993; Fig. 22). The same evidence suggests that this permeability is more marked in *B. ovis* than in *B. abortus* and *B. melitensis* (Freer et al., 1999), but comparative studies with a representative number of strains have not been performed. The well-known variations in sensitivity to the large hydrophobic dye basic fuchsin (Table 3) also suggest species and biovar differences in this pathway, which could reflect subtle outer-membrane structural or topological differences. This pathway also accounts for the effect of sexual hormones on *Brucella* cell envelopes and metabolic rates (Meyer, 1976) and for the inability of *Brucella* to grow on media designed for bacteria that, like *Escherichia*, *Salmonella*, *Pseudomonas* and many others, have efficient outer-membrane barriers to hydrophobic permeants. In *Brucella*, permeability to hydrophobic compounds is linked to the LPS structure (Freer et al., 1996), and comparative studies with *Ochrobactrum* suggest that the absence of negatively charged groups and counterions at core level (Fig. 6) plays an important role in the inability to establish an effective barrier (Velasco et al., 2000).

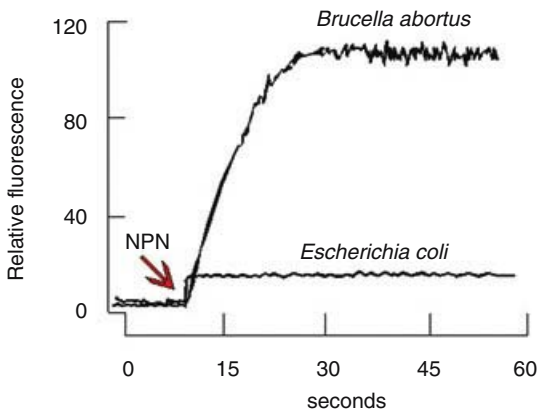

Fig. 22. Outer membrane permeability to the hydrophobic probe *N*-phenyl-1-naphthylamine (NPN). The arrow marks the time at which the bacteria were exposed to NPN and partition of the probe into the cell envelope (detected as a fluorescence increase) begins. Notice the increased uptake and permeability for the hydrophobic NPN probe by *Brucella* in comparison with the strong resistance to NPN penetration by *E. coli* cells. For details see Martinez-de-Tejada and Moriyón (1993).

Outer Membrane Stability It is a common observation that, as compared to *E. coli*, the brucellae are resistant to physical disintegration. Likewise, detergent extraction of *Brucella* cell envelope components needs conditions harsher than those used in many Gram-negative bacteria (reviewed in Moriyón and López-Goñi, 1998). Finally, *Brucella* cell envelopes are not destabilized by EDTA or polycationic microbicidal peptides and proteins that have a strong action on the majority of Gram-negative bacteria examined (Freer et al., 1996). At least in part, these observations are accounted for by the structure of the *Brucella* cell envelope.

Omp-peptidoglycan Association Electron microscopy shows that the peptidoglycan of *Brucella* is in an interaction with the outer-membrane much tighter than that observed in *Escherichia coli* (Fig. 12). Moreover, in some extraction procedures, Omps appear associated with the peptidoglycan. Although there are conflicting views on the precise structural meaning of this association (Moriyón and López-Goñi 1998), it could provide the *Brucella* cell envelope with additional stability.

Lipid Composition As compared to *Escherichia*, *Salmonella* and *Pseudomonas*, *Brucella* contains free lipids that carry longer acyl chains suggestive of a stronger hydrophobicity (Table 12). Moreover, phosphatidylcholine, which is the major phospholipid, has structural properties different from those of phosphatidylethanolamine (the major phospholipid in many other Gram-negative organisms), and at least in vitro, it forms more stable bilayers. Long acyl chains are also a characteristic of the *Brucella* lipid A (Fig. 7), and the overall hydrophobic effect could be reinforced by the topology of the very long fatty acids (Outer Membrane Topology). These features are present in other members of the α-2 Proteobacteria with which the brucellae share the property of the acid-fastness when stained by the modified Stamp's method (Fig. 10).

Lipopolysaccharide and Resistance to Outer-membrane Destabilizing Agents The reduced presence of anionic groups in the LPS core oligosaccharide and its strong hydrophobic anchorage (Fig. 20) are the main reasons for the marked resistance of *Brucella* to polymyxins (Fig. 23) and other polycationic peptides (Freer et al., 1996; Velasco et al., 2000; Fig. 24; Outer Membrane Versus Bactericidal Substances). Moreover,

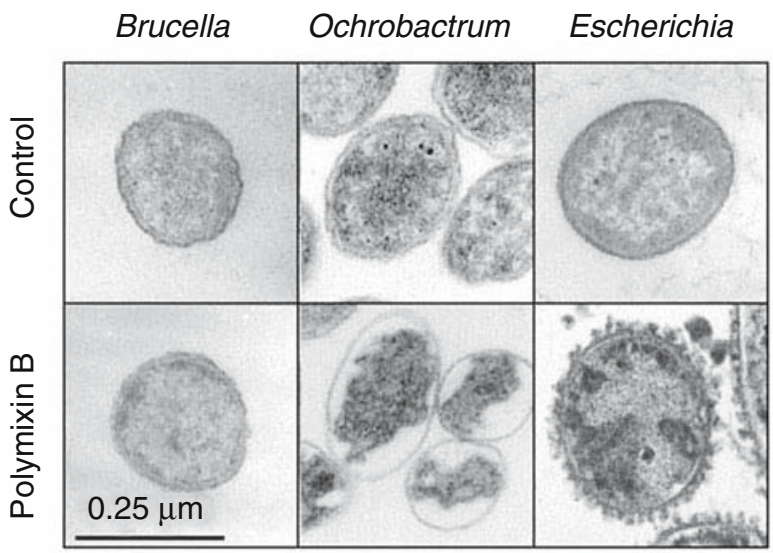

Fig. 23. Bactericidal activity of polymyxin B against *B. abortus*, *O. intermedium* and *E. coli*. Notice the characteristic outer membrane blebbing caused by polymyxin B in *E. coli* but not in *B. abortus* or *O. intermedium*. *Brucella abortus* treated with polymyxin B looks intact and not significantly different from the control. On the contrary, *E. coli* and *O. intermedium* are killed by polymyxin B. Although the outer membrane is morphologically unharmed, self-promoted uptake of polymyxin B in *O. intermedium* is inferred from the extensive damage to the cytoplasmic membrane and from the subsequent cytoplasm coagulation. From Velasco et al. (2000), with permission.

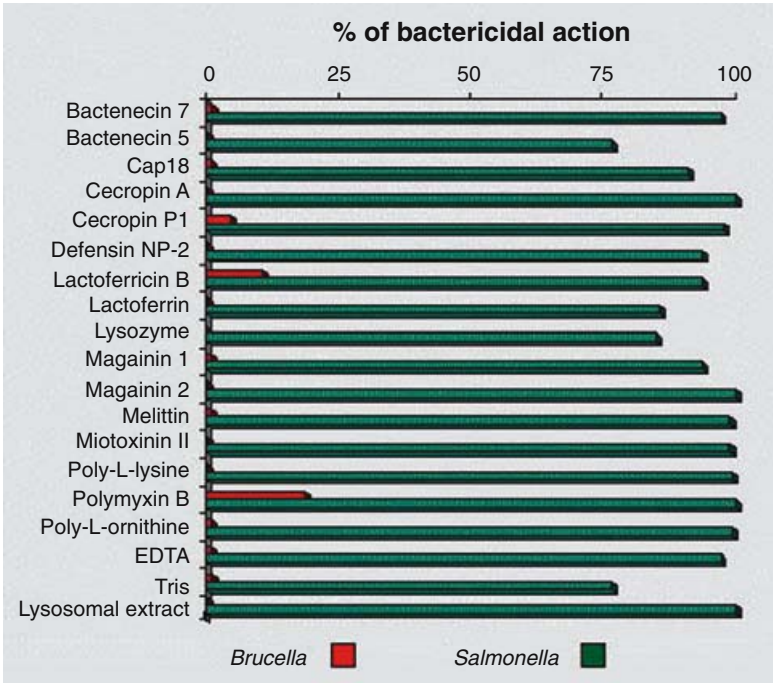

Fig. 24. Bactericidal activity of various cationic peptides and microbicidal substances against *B. abortus* and *S. typhimurium*. Concentrations used were the minimal quantity of bactericidal substance required to reduce the *Salmonella* colony-forming units (CFUs) not less than 75% in more than 99% of the controls. Incubation and number of organisms tested were the same for both bacteria: Notice the high resistance of *Brucella* to bactericidal substances in comparison to *Salmonella*. Adapted from Martínez de Tejada et al., 1995; Freer et al., 1996 and Páramo et al., 1998.

ornithine lipids could also shield the negatively charged groups of Kdo and lipid A (Outer Membrane Topology), which are the initial targets of these agents (Fig. 20). In many Gram-negative organisms, such negatively charged groups are bridged by divalent cations that play an essential role in outer-membrane stability. However, the resistance of *Brucella* to divalent cation chelators shows no significant structural role for this effect, and it can be postulated that their absence is compensated by the stronger hydrophobic anchorage of the LPS (Velasco et al., 2000).

Metabolism

This section summarizes what is known about the uptake of nutrients (Extracellular Enzymes and Uptake), intermediary metabolism (Intermediary Metabolism), and energy-yielding processes (ATP Synthesis and Respiratory Chain) of *Brucella* and its response to environmental stress (Response to Environmental Stress). Recently, the results of a large genomic sequence survey carried out in *B. abortus* (http://www.iib.unsam.edu.ar/genomelab/brucella/

index.html) (Sánchez et al., 2001) and the complete sequences of the genomes in *B. melitensis* strain 16M (http://www.genome.scranton.edu/Brucella/) (DelVecchio et al., 2002) and *B. suis* (www.tigr.org/) (Paulsen et al., 2002) have been made available to researchers. As our knowledge of the *Brucella* genome expands, it is expected that many details of its physiology will be revealed and become accessible to experimental testing. Although reference to some of the sequence data will also be made, the reader has to keep in mind the problems associated with the interpretation of this still incomplete information.

Extracellular Enzymes and Uptake The brucellae are devoid of extracellular hydrolytic enzymes acting on proteins, nucleic acids or polysaccharides. Accordingly, these bacteria depend exclusively on low molecular weight nutrients, such as sugars, amino acids or oligopeptides, etc., that are already present in the growth medium and that, depending on their hydrophobicity, cross the outer-membrane either through the porins or directly through the bilayer; both possibilities exist in *Brucella* (Permeability). The periplasmic space of many Gram-negative bacteria contains binding proteins that act coordinately with some cytoplasmic membrane transport systems. Attempts to isolate binding proteins from *Brucella* have been unsuccessful, which has been attributed to a tighter interaction of these proteins with the cell than those reported for other bacteria (Rest and Robertson, 1974), probably reflecting its outer-membrane properties (Lipopolysaccharide and Resistance to Outer-membrane Destabilizing Agents). However, the *Brucella* genome contains genes whose products have characteristics suggestive of the periplasmic binding proteins involved in transport of oligopeptides, dipeptides and amino acids (Sánchez et al., 2001). In one case (protein P39), the genetic evidence has been complemented by modeling studies that also suggest a periplasmic binding role (De Fays et al., 1999) (Auxotrophic and Cell Cycle Genes During Intracellular Life).

Sequences corresponding to aquaporins, mechanosensitive channels, transporters for the uptake of osmoprotectants, and probable ion-specific channels are also present. *B. melitensis* contains an ORF that is similar to the aquaporin of *B. abortus* (Rodriguez et al., 2000). There are genes coding for three putative ABC transporters for osmoprotectants, but not for members of the betaine/carnitine/choline transporter (DelVecchio et al., 2002).

Uptake of Organic Nutrients The transport of glucose has been examined in *B. abortus* (Rest and Robertson, 1974) and the functional studies show the absence of a phosphotransferase (phosphoenolpyruvate-dependent) system and the presence of a proton-coupled uptake. The system is equally active in cells grown in the presence of fructose, galactose, erythritol and glucose, and seems therefore constitutive. Galactose acts as a competitive inhibitor for the uptake of glucose (Rest and Robertson, 1974) and complementation studies performed in *E. coli* with the *B. abortus* gene show that both sugars are transported by the same transmembrane protein (Essenberg et al., 1997). The putative glucose-galactose transport protein belongs to the proton-coupled transporters of the major facilitator superfamily, and a genomic sequence survey suggests ABC-type transporters active on sugars (D-fructose, D-mannose, melibiose, sucrose, trehalose, maltose, xylose, and sorbitol in *B. melitensis*), amino acids and oligopeptides (Sánchez et al., 2001; DelVecchio et al., 2002). The genomic analysis (*B. melitensis*) shows no erythritol-specific transporters (see below) such as those found in *Rhizobium*, but both glycerol and erythritol could be taken up by several putative polyol ABC transporters. A homologue to the gene coding for the multiple sugar-binding proteins of *Agrobacterium* and *Azospirillum* is present in at least *B. melitensis*. Also worth mentioning is that the *bacA* gene, which encodes a putative cytoplasmic membrane transport protein, is critical for virulence (LeVier et al., 2000).

Uptake of Inorganic Nutrients Some aspects of the iron uptake systems of *Brucella* have been investigated. In early studies on the effect of iron availability, it was observed that *Brucella* releases large amounts of the monocatechol 2,3-dihydroxybenzoate but not hydroxamate-type siderophores, and 2,3-dihydroxybenzoate and other simple monocatechols were observed to promote Fe uptake by an energy-dependent mechanism (López-Goñi et al., 1992). Since monocatechols have much less affinity for iron than complex catechols (such as enterobactin or agrobactin) have, their role as siderophores is not obvious (for a possible different role of 2,3, dihydroxybenzoate, see Iron Chelation and Bactericidal Action). More recently, a *B. abortus* transposon mutant has been described that is unable to grow on iron restricted medium albeit it releases 2,3-dihydroxybenzoate (González-Carreró et al., 2002). This mutant fails to release a minor catechol which, in cross-feeding experiments, has the ability to promote growth of the mutant under Fe limiting conditions. The mutated gene shows homology with genes (*entC*) involved in the synthesis of complex catechols by other bacteria, including vibriobactin and enter-

obactin (González-Carreróet al., 2002). However, enterobactin fails to promote growth of *B. abortus* and, interestingly, neither agrobactin nor rhizobactin mediate Fe uptake by *B. abortus* (López-Goñet al., 1992). These data show that *B. abortus* produces a complex catechol siderophore (brucebactin) of unknown structure which is different from some of the catechols produced by related bacteria. A puzzling observation is that the release of catechols is not accompanied by the expression of new outer-membrane proteins that could act as siderophore receptors (López-Goñet al., 1992). However, because 2,3, dihydroxybenzoate and related compounds are moderately hydrophobic, direct penetration of siderophore chelates by the hydrophobic pathway could explain this observation. Once in the cytoplasmic compartment, iron has to be stored in such a way that the generation of free oxygen radicals, including the very toxic hydroxyl radical, is prevented, and a bacterioferritin gene with a high similarity to the corresponding *E. coli* gene has been characterized in *B. melitensis* (Denoel et al., 1995) (Iron Chelation and Bactericidal Action).

Recently, some aspects of the high affinity system of nickel (Ni) uptake have been elucidated in *B. suis* (Jubier-Maurin et al., 2001). The *nik* gene cluster of *B. suis* closely resembles that of the corresponding *E. coli* operon, and although the regulatory gene (*nikR*) is found in a different position and orientation, both systems can complement the heterologous deficiency. This system is activated by low oxygen tension and metal ion deficiency and repressed when Ni is in excess. As expected (the enzyme contains Ni), its impairment leads to a severe reduction in urease activity (The Urea Cycle and Urease Activity). Finally, sequences compatible with systems involved in Mg^{++}, Zn^{++}, NO_3^- and SO_4^{2-} transport have been identified in genomic surveys.

Efflux Systems Genomic surveys (DelVecchio et al., 2002) show the presence of genes putatively coding for members of the cation diffusion facilitator (CDF) family and P-type ATPases involved in heavy metal efflux. Moreover, there are homologues of ABC transporters involved in drug efflux and of multidrug-resistance proteins and acriflavine-resistance and quaternary ammonium resistance systems. A TolC homologue (a common outer membrane component of several of these efflux pumps) is also present.

Intermediary Metabolism

Sugar Catabolism and Tricarboxylic Acid Cycle At least *B. melitensis* (strain 16M) carries genes predicted to code for the enzymes of all pathways of central carbohydrate metabolism but those of the glycogen cycle. This includes genes for the pentose phosphate enzymes as well as for the complete Entner-Doudoroff pathway but this is in apparent conflict with the results of functional studies (DelVecchio et al., 2002). The pathways of glucose catabolism have been studied in *B. abortus* (strains 19 and 2308), *B. melitensis* (strain 16M) and *B. suis* (strain 1330) using glucose radiolabeled at positions C1, C2, C3, C4 and C6 in a complex medium (Robertson and McCullough, 1968a). The kinetics of $^{14}CO_2$ release in dependence of the labeled position is C1 > C2 > C3 > C4 > C6, and this is compatible with either the operation of the hexose monophosphate pathway by itself or the hexose monophosphate plus the Entner-Doudoroff pathways working simultaneously, in both cases in conjunction with pyruvate oxidation through the tricarboxylic acid cycle. However, analysis of pyruvate from arsenite-poisoned cells or of alanine as the major product derived from pyruvate shows that glucose C1, C2 or C3 does not contribute significantly to the labeling of these two molecules. This implies that a C3–C4 cleavage does not occur significantly in the degradation of glucose and therefore that neither the Entner-Doudoroff pathway nor the hexose diphosphate pathway is active in *Brucella*. Differences between the $^{14}CO_2$ release pattern of *B. suis* and the other species tested have been noted (Robertson and McCullough, 1968a) and attributed to a higher activity of the reactions leading from glyceraldehyde-3-phosphate to pyruvate. In cell-free studies with *B. abortus* 19, it has been observed that fructose 1,6-diphosphate is oxidized very slowly, that fructose diphosphate aldolase activity is very low and that, although phospho-2-keto-3-deoxygluconate aldolase activity is detected, there is no phosphogluconate dehydratase activity (Robertson and McCullough, 1968b). Consistent with the genomic studies, the cell-free studies also show the major enzymatic activities of the pentose cycle when they are tested during anaerobic dissimilation of ribose-5-phosphate. All these findings support the existence of an operative pathway in which glucose is phosphorylated (the glucokinase gene has been characterized; Essenberg, 1995) and oxidized first to gluconate-6-phosphate. Gluconate is then oxidized in the pentose cycle to yield 3 moles of CO_2 plus 1 mole of glyceraldehyde-3-phosphate, and the latter is channeled into the tricarboxylic acid cycle via pyruvate (Fig. 25). So far, the oxidative pentose phosphate cycle as the major glucose catabolic pathway has been described in only a few bacteria.

Glycerol is efficiently used by brucellae, and the genes that encode glycerol kinase and glycerol-3 phosphate dehydrogenase have been

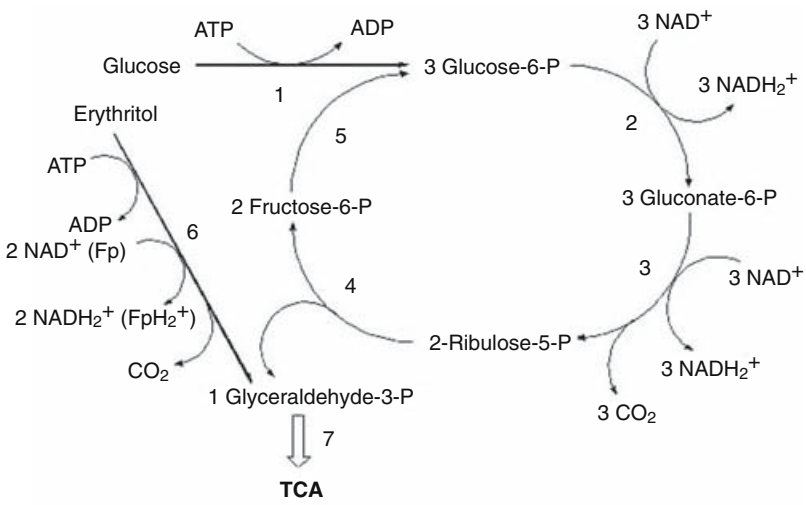

Fig. 25. Glucose and erythritol catabolism in *B. abortus*. 1) glucokinase; 2) glucose-6-phosphate dehydrogenase; 3) gluconate-6-phosphate dehydrogenase; 4) transaldolase and transketolase interconversions; 5) glucose-phosphate isomerase; 6) erythritol pathway (see Fig. 26 and 27); and 7) terminal reactions of the glycolytic pathway and pyruvate dehydrogenase leading to the tricarboxylic acid (TCA) cycle.

identified in, at least, B. melitensis (DelVecchio et al., 2002). Also, early studies on the ability to grow on McCullough and Dick minimal medium (Table 9) with sucrose, glucose, galactose, mannose, fructose, threalose, xylose, arabinose and erythritol as the sole energy and carbon sources showed that all these compounds supported the growth of the four *B. suis* strains tested, that the growth of four *B. melitensis* strains showed variable results in arabinose, mannose, sucrose and threalose, and that none of the four *B. abortus* strains grew on arabinose, mannose, sucrose and threalose (McCullough and Beal, 1951). Because McCullough and Dick medium does not furnish the minimal requirements of the less prototrophic *Brucella* species (Nutritional Requirements), absence of growth in these experiments has to be interpreted with care. Nevertheless, the results suggest that at least *B. suis* has both transport and enzymatic abilities to channel all those compounds into the tricarboxylic acid cycle, and several putative sugar kinases can be identified in genomic surveys (Sánchez et al., 2001; DelVecchio et al., 2002). Similar speculations can be made on the meaning of the oxidative metabolic patterns established for the classical species and biotypes of *Brucella* (Table 2), taking always into account that the differences may also reflect differences in uptake and not necessarily in catabolic abilities.

The tricarboxylic acid cycle has been demonstrated in *B. abortus* 19 by using pyruvate- and acetate-^{14}C (Robertson and McCullough, 1968a) and also in other *B. abortus* strains in enzymatic studies (Altenbern and Housewright, 1953; Marr et al., 1953). Evidence for the functioning of several steps of the cycle has also been provided by studies on the oxidative dissimilation of amino acids by *B. abortus*. These data are consistent with those of the genomic analyses which also show genes putatively coding for the enzymes required for anaplerotic reactions (NAD-dependent malate dehydrogenase [malic enzyme], phosphoenolpyruvate carboxykinase and pyruvate carboxylase). In addition, there is a pyruvate phosphate dikinase, which converts pyruvate to phosphoenolpyruvate (Oxidation of Amino Acids).

Erythritol The early studies described in the section Sugar Catabolism and Tricarboxylic Acid Cycle showed that erythritol is able to support the growth of all *B. abortus*, *B. suis* and *B. melitensis* strains (McCullough and Beal, 1951) and this has been confirmed repeatedly. Other characteristics also make the metabolism of this compound by *Brucella* particularly interesting: growth with erythritol occurs earlier than with other substrates, and at least in *B. abortus*, erythritol is used preferentially over glucose in complex media (Anderson and Smith, 1965). These observations, and the presence of erythritol in the placenta of ungulates, led to the controversy on the possible relationship(s) between erythritol metabolism and virulence and viscerotropism in *Brucella*.

The metabolic pathway of erythritol was elucidated in *B. abortus* B19 (British strain 19) (Sperry and Robertson, 1975). *Meso*-erythritol is oxidized through five steps that involve a kinase, three dehydrogenases and a decarboxylase to CO_2 and dihydroxyacetone-phosphate, which is then converted to pyruvic acid through the final steps of glycolysis (Figs. 25 and 26). Two dehydrogenases are membrane bound and require NAD, but the third (3-keto-L-erythrose-4-phosphate dehydrogenase) is coupled directly to the electron transport chain. The pathway is different from that described in other bacteria that either transform erythritol in L-erythrulose

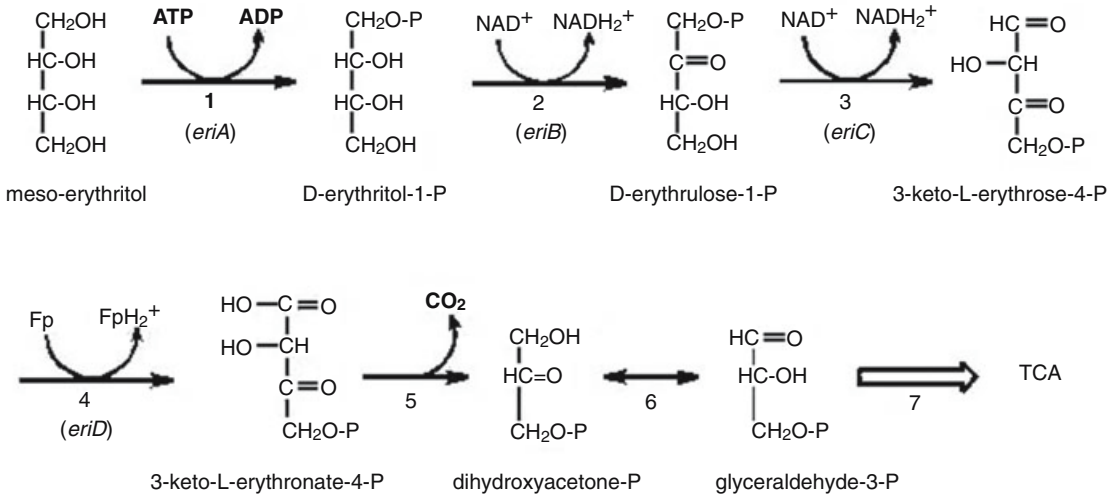

Fig. 26. The erythritol pathway in *B. abortus*. 1) erythritol kinase; 2) erythritol-1-phosphate dehydrogenase; 3) erythrulose-1-phosphate dehydrogenase; 4) 3-keto-erythrose-4-phosphate dehydrogenase; 5) 3-keto-erythronate-4-phosphate decarboxylase; 6) phosphotriose isomerase; and 7) terminal reactions of the glycolytic pathway and pyruvate dehydrogenase leading to the tricarboxylic acid (TCA) cycle. Putative genes are indicated in parenthesis.

by means of a dehydrogenase (*Acetobacter suboxydans* and *Alcaligenes faecalis*) or split L-erythrulose-1-phosphate directly into formaldehyde plus dihydroxyacetone-phosphate (*Propionibacterium pentosaceum*). However, it has to be noted that the ability to use erythritol is also present in many bacteria of the α-2 subgroup of the Proteobacteria including strains of *Rhizobium tropicii*, *Rhizobium loti*, *Sinorhizobium meliloti*, *Sinorhizobium fredii*, *Agrobacterium* biovar 2 and all known species of the genus *Ochrobactrum* (De Lajudie et al., 1994; Lebhun et al., 2000). None of these bacteria are primarily associated with animals, and although the erythritol pathway has not been elucidated in them, it should not be different from that of *Brucella*. Therefore, it seems likely that the erythritol pathway of *Brucella* has not resulted from the adaptation to pathogenicity in ruminants, but represents an ancestral metabolic pathway for the α-2 Proteobacteria (Genome Evolution).

In the study of over 100 strains of *B. abortus*, it was noted that erythritol not only did not promote growth of strain US19, but actually inhibited it (Jones et al., 1965). The US19, the current *B. abortus* 19 vaccine, and the B19, the British 19, are possibly related but whereas the former is unable to grow on erythritol which is, in fact, toxic for it, the latter catabolizes erythritol (Identification of Vaccine Strains). This peculiarity of the vaccine was explained in the course of the studies on erythritol metabolism. It was found that *B. abortus* US19 lacks D-erythrulose-1-phosphate dehydrogenase activity and has a 20% reduced 3-keto-erythrose-4-phosphate dehydrogenase activity (Sperry and Robertson, 1975). Presumably the build-up of intermediary metabolites becomes toxic for strain 19 and prevents growth when erythritol is present. This defect can be traced to a 702-bp deletion in the *ery* region of strain 19 (Sangari et al., 1994b) (Identification and Typing). This region is known to contain at least four genes of which presumably *eryA* codes for the erythritol kinase, *eryB* for the erythritol-1-phosphate dehydrogenase, *eryC* for the erythrulose-1-phosphate dehydrogenase and *eryD* for a regulator of *ery* expression (Sangari et al., 2000). The 702-bp deletion in strain 19 affects both *eryC* and *eryD*, thus creating the described phenotype. In contrast, B19 carries no deletion (Sangari, 1993), and "revertants" of US19 for which erythritol is not toxic probably carry compensatory mutations elsewhere in the chromosome.

Erythritol analogues have been studied for their in vitro and in vivo anti-*Brucella* activity. Fluoro-mesyl and bromo-derivatives of erythritol and threitol inhibit the growth of *B. abortus*, *B. melitensis* and *B. suis* in vitro and in bovine phagocytes (typical concentrations causing a 50% inhibition of *B. abortus* range from 5 µg/ml [for 1,2-3,4-dianhydro-DL-threitol] to 100 µg/ml [for 1,4-dimesylerythritol]). The therapeutic value of the analogues in *B. abortus*-infected guinea pigs is, however, very limited (Smith et al., 1965).

It has been shown that primers taken from the *ery* region amplify DNA of the expected size from *B. ovis* and *B. canis* (Sangari, 1993). These species do not or poorly oxidize erythritol (Table

2), but this substrate is not toxic for them. Thus, their characteristics are different from those of *B. abortus* US19. There is a need for comparative studies to understand these differences.

Oxidation of Amino Acids In a study of the ability of *B. abortus* 19 to grow on amino acids and related compounds, it was found that only glutamate, asparagine and histidine were used as the sole nitrogen source (Gerhardt et al., 1950b), and that the rate of oxygen uptake with glutamate was considerably greater than with any of the other substrates (Gerhardt et al., 1950a). It was also found that a simple medium containing glutamate as the nitrogen, carbon and energy source, plus accessory factors, supported growth (Table 9). The data obtained in subsequent metabolic studies (Marr et al., 1953) are consistent with a very active pathway through which glutamate is converted first to ketoglutarate and then metabolized in the tricarboxylic acid cycle to yield energy and reduced coenzymes plus intermediary metabolites for biosynthesis, including pyruvate. Oxidation of glutamate was also shown to be coupled to the urea cycle (The Urea Cycle and Urease Activity). Interest in the metabolism of glutamate was spurred by the observation that, at least in *B. abortus* and *B. suis*, its oxidative rate was lower in strains of high virulence than in strains of low virulence (Wilson and Dasinger, 1960). However, cell free studies showed no differences in the pathway of glutamate oxidation or in enzymatic activity associated with virulence, and it was concluded that unequal rates of permeability (Properties of the Outer Membrane) to the substrate could account for the observations (Dasinger and Wilson, 1962).

The Urea Cycle and Urease Activity *Brucella abortus* and *B. melitensis* resting cells slowly metabolize glutamate with transient accumulation of arginine, ornithine and citrulline as metabolites, and at least in *B. abortus*, aspartate is also metabolized to ornithine (Cameron et al., 1952). Moreover, arginase activity (direct conversion of arginine into ornithine) exists in *B. abortus*, *B. melitensis* and *B. suis* (Cameron et al., 1952; Cameron et al., 1954). This enzymatic activity is considered the landmark of the urea cycle, and therefore, these results strongly suggest that at least these three *Brucella* species should have this metabolic cycle. The linkage with the metabolism of glutamate shown by the preceding observations could occur through the tricarboxylic acid cycle plus an aspartic-glutamic transaminase, since this enzymatic activity has been shown in at least *B. abortus* (Altenbern and Housewright, 1951). Moreover, *Brucella* contains ornithine lipids (Figs. 13 and 14) in the cell envelope and the cycle should furnish this amino acid for acylation and further modification.

All classical *Brucella* smooth species, *B. canis* and some *B. ovis* strains (Corbel and Hendry, 1985) show a characteristic urease activity as do the *Brucella* marine isolates, and the enzyme is located in the cytoplasmic fraction (Brun and Descous, 1984). It has been proposed that urease is available in *Brucella* because of the occurrence of the urea as an intracellular metabolite (Cameron et al., 1952). Removal of urea would be necessary when the bacteria are growing with amino acids as the main source of carbon and energy. The role of urease in virulence is discussed elsewhere in the chapter (Metabolism), and these aspects of the metabolism of *Brucella* are summarized in Fig. 27.

Physiology of CO_2 Requirements The biochemical basis of the CO_2-dependence of some *Brucella* species and biotypes is not known. CO_2 cannot be replaced by cell extracts, complex nutrients, tricarboxylic acid cycle intermediates, purines or pyrimidines, and the major products of CO_2 assimilation in complex media are in the protein fraction as alanine and glycine and in the nucleic acid fraction as pyrimidines (Newton et al., 1954b; Newton and Wilson, 1954a). In keep-

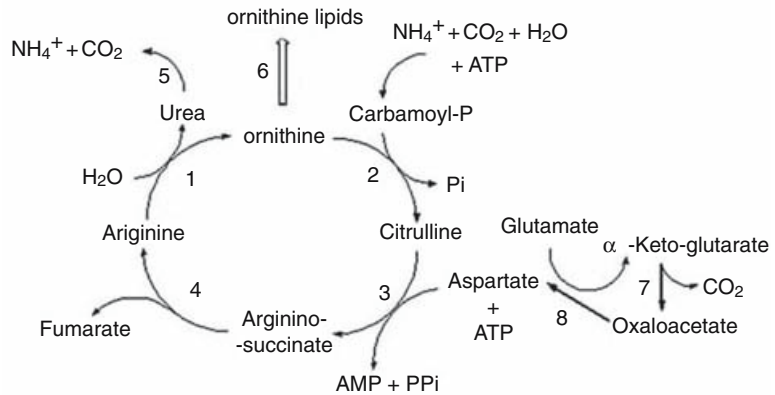

Fig. 27. The urea cycle and associated reactions in *B. abortus*. 1) arginase; 2) ornithine transcarbamoylase; 3) argininosuccinate synthetase; 4) argininosuccinase; 5) urease; 6) synthesis of membrane ornithine lipids; 7) tricarboxylic acid cycle reactions; and 8) glutamate-aspartate transaminase.

ing with the strong respiratory activity of the *Brucella* (Physicochemical Requirements and Atmosphere), these observations demonstrate that CO_2 is not required to reduce oxygen tension, but rather that it is needed as a nutrient per se. In bacteria, CO_2 is used in the synthesis of purines, pyrimidines, carbamoyl-phosphate and fatty acids. In some cases studied (Burns et al., 1995), the CO_2 requirement is due at least in part to the high *Km* of one of the carboxylases involved. The rate of appearance of CO_2-independent phenotypes in the CO_2-dependent strains has been estimated in approximately 3×10^{-10} per cell division (Marr and Wilson, 1950). Therefore, if this *Brucella* phenotype is dependent on the affinity of carboxylases for CO_2, few of them are involved. This is consistent with the observation that a CO_2-dependent strain and its CO_2-independent derivative did not differ in the distribution of fixed $^{14}CO_2$ and showed the same basic nutritional requirements (Newton et al., 1954a; Newton and Wilson, 1954b).

ATP Synthesis and Respiratory Chain Because glucose is mostly oxidized by the hexose monophosphate pathway, the substrate-level phosphorylation contribution to ATP synthesis should be minimal (provided glyceraldehyde 3-phosphate is only an intermediary to the tricarboxylic acid cycle), and *Brucella* should obtain ATP from glucose or erythritol (and presumably other sugars) mostly by coupling coenzyme oxidation to the electron transport system (Rest and Robertson, 1975). In functional studies performed with the envelope fraction of *B. abortus* 19, $NADH_2^+$ dehydrogenase activity and also other primary dehydrogenases using L-lactate and succinate as substrates were observed by spectral analyses and polarographic determination of oxygen consumption. $NADH_2^+$ dehydrogenase and succinate dehydrogenase have also been demonstrated in the characterization of the cell envelope fraction of other *B. abortus* strains and in *B. melitensis* (Moriyón and Berman, 1982). Moreover, at least in *B. abortus*, oxidation of erythritol 1-phosphate is also directly coupled to the electron transport chain (Rest and Robertson, 1975) through the 3-keto-l-erythrose 4-phosphate dehydrogenase (Sperry and Robertson, 1975; Fig. 26). Analysis of the free lipid fraction of *B. melitensis* and *B. abortus* (Thiele and Schwinn, 1969; 1973) shows the characteristic e^-/H^+ transporter ubiquinone Q_{10}, and the polarographic data obtained with B. abortus 19 (Rest and Robertson, 1975) are consistent with the location of the primary dehydrogenases early in the respiratory chain. The spectrophotometrical analyses also provided evidence for the presence of flavoproteins and several cytochromes which were different in exponentially growing bacteria from those in the late exponential phase of growth, suggesting the ability to adapt the terminal elements of the electron transfer to different oxygen tensions (Rest and Robertson, 1975).

According to the predictions of the gemomic analysis, in *B. melitensis* a terminal cytochrome o ubiquinol oxidase acts under normal oxygen concentration and a cytochrome cbb3 oxidase acts under low oxygen concentration. During microaerobic conditions, *B. melitensis* can use the cytochrome bd quinol oxidase for electron transfer to oxygen from the membrane quinone pool. Complete sets of genes for all of the subunits for complex I (NADH-quinone oxidoreductase), complex II (succinate dehydrogenase), and complex III (ubiquinol-cytochrome c reductase) and for the soluble electron-transporting cytochromes c2 and c552 have also been identified as well as those of several primary dehydrogenases (D- and L-lactate dehydrogenases, flavoprotein-quinone oxidoreductase, glycerol-3-phosphate dehydrogenase [$NAD(P)^+$], and malate:quinone oxidoreductase). These enzymes supply electrons and protons for the aerobic respiratory chain and oxidative phosphorylation pathways. Genes coding for H^+-coupled ATP synthase, NAD(P) trans-hydrogenase, and Na^+/H^+ and K^+/H^+ antiporters are present and the cognate proteins should be involved in oxidative phosphorylation and the proton gradient maintenance.

Nitrate-nitrite reduction is observed in all *Brucella* classical species but *B. ovis*. Nitrate reductase activity was detected in the course of the above-described studies on the characterization of the electron transport system of *B. abortus* 19 (Rest and Robertson, 1975). Moreover, in the studies on the catabolism of erythritol, it was shown that nitrate was almost as effective as oxygen in stimulating the breakdown of erythritol, whereas nitrite and hydroxylamine had no effect (Sperry and Robertson, 1975). Apparently, *B. abortus* (and possibly the rest of the *Brucella* species reducing nitrate to nitrite in a dissimilative way) has a terminal nitrate reductase coupled to the electron transport chain via flavoproteins and cytochromes and this is consistent with the genomic analyses. At least in *B. melitensis*, the respiratory nitrate reductase complex consists of four subunits encoded by a single operon (DelVecchio et al., 2002).

Response to Environmental Stress Aerobic organisms are endowed with enzymes that detoxify the reactive by-products of oxygen, which are generated mostly during the operation of the respiratory chain. Two types of superoxide dismutase (Sod) have been found in *Brucella abortus*, a cytosolic Mn^{++}-Sod and a Cu^{++}/Zn^{++}-Sod

(Bricker et al., 1990) located in the periplasmic space (Stabel et al., 1994). By Western-blotting with antisera to the homologous *E. coli* protein, the periplasmic Sod has been demonstrated in all *Brucella* species and biovars tested except in *B. neotomae* and *B. suis* biovar 2 (Bricker et al., 1990). Moreover, catalase activity can be demonstrated in all *Brucella* species in the standard H_2O_2 assay, and according to manometric studies performed with *B. abortus*, *B. melitensis* and *B. suis*, the latter species displays the strongest catalase activity, which is also slightly higher in *B. melitensis* than in *B. abortus* (Huddleson and Stahl, 1943). A periplasmic catalase has been purified and cloned from *Brucella abortus* and characterized as a tetrameric protein (MW of the monomer 55,000) lacking a typical N-terminal export signal sequence (Sha et al., 1994).

The periplasmic location of catalase and Cu^{++}/Zn^{++}-Sod suggests that they protect the cell from external sources of oxidative damage (Stabel et al., 1994), such as those generated by phagocytes upon ingestion of bacteria (Neutralization of Oxygen and Nitrogen Intermediates). In fact, the periplasmic catalase behaves as an oxidative stress protein, and exposure of *B. abortus* cells to sublethal concentrations of H_2O_2 increases both their resistance and the expression of the enzyme. Although the magnitude of the increase is lower, oxidative stress also increases expression of the periplasmic Cu^{++}/Zn^{++}-Sod (Table 15). Because Sod activity leads to the production of H_2O_2, this different level of response is consistent with the respective roles of these enzymes in protecting the cell from oxidative damage (Kim et al., 2000).

Homologues to the *htrA*, *groEL* and *dnaK* genes have been identified in *Brucella*, and the latter has been cloned and shown to express a functionally active product in a thermosensitive *E. coli dnaK* mutant (Cellier et al., 1992; Elzer et al., 1994; Lin et al., 1992; Roop et al., 1994; Tatum et al, 1994). As expected, the synthesis of the two cytoplasmic molecular chaperones (GroEL and DnaK) and the periplasmic protease HtrA is stimulated under heat stress (42°C), and impaired growth has been shown for an *htrA*-defective mutant under these conditions. Moreover, an increased expression of these three genes is also observed in acidified media (Table 15).

In addition to the above-described proteins, heat, oxidative, acid and nutritional stresses cause an increase in the synthesis of over 100 proteins, among which many are not expressed under normal conditions. Conversely, many proteins expressed in normal media become repressed under these conditions. A small fraction of these proteins has been identified by proteomic methods (Table 15), and some elicit antibodies in naturally infected animals, demonstrative of their expression in the host. It is noteworthy that the profile of proteins induced and repressed when *B. abortus* grows in cultured macrophages does not correspond to a simple sum of the proteins observed under stress conditions in vitro (Lin and Ficht, 1995; Rafie-Kolpin et al., 1996).

Genetics

The *Brucella* Genome

The genome of a bacterium includes the chromosome plus any extrachromosomal DNA, such as prophages and plasmids carrying nonessential genes useful only under some environmental conditions. Bacterial chromosomes can be linear and bacteria can have more than just a single chromosome (Kolst, 1999). Interestingly, of the bacteria currently known to have a large part of their essential genes in replicons outside the larger chromosome (i.e., to have one or more additional chromosomes of different size), many belong, like *Brucella*, to the α Proteobacteria (Jumas-Bilak, 1998b; Kolst, 1999; Moreno, 1998). Moreover, some members of the α Proteobacteria are known to have a linear chromosome in addition to the major circular one (Jumas-Bilak et al., 1998b) and many also have plasmids (Moreno, 1998). In this taxonomic context, the brucellae are characterized by the presence of two or, in *B. suis* biovar 3, one circular chromosome and by the absence of plasmids (Fig. 1). The results of *B. melitensis* genomic sequence (DelVecchio et al., 2002), a survey carried out in *B. abortus* (Sánchez et al., 2001) and the genome sequence of *B. suis* (Paulsen et al., 2002) represent a wealth of genetic details yet to be evaluated. The general genetic characteristics of the *Brucella* genome are summarized here, and their evolutive and taxonomical meaning is discussed elsewhere in the chapter (Biosafety).

Brucella Chromosomes

Number and Species Differences The distribution of some essential genes (ribosomal *rrn* and genes coding for heat shock proteins), combined with pulse-field gel electrophoresis, shows that the reference strains of all *B. melitensis* and *B. abortus* biovars, *B. suis* biovar 1, *B. ovis*, *B. canis*, and *B. neotomae* carry two circular chromosomes of about 2.1 and 1.15 Mb (Michaux-Charachon et al., 1993; Jumas-Bilak, 1998a; Jumas-Bilak, 1998b), and the reference strains of *B. suis* biovar 2 and biovar 4 also have two circular chromosomes but of 1.85 and 1.15 Mb (Jumas-Bilak, 1998a). On the other hand, the reference strain of *B. suis* biovar 3 has a single

Table 15. Some proteins of *Brucella* that are regulated by heat, oxidative and pH stress.

[a]Where appropriate the % identity, bacteria, and/or ID in SWALL protein database is included in parentheses.

circular chromosome of 3.10 Mb (Jumas-Bilak, 1998a; Fig. 1). *Brucella* marine strains also possess two chromosomes close to the size of *B. abortus* (D. O'Callaghan, personal communication). For the species carrying the 2.1- plus 1.15-Mb chromosomes, the physical maps demonstrate a high conservation of restriction sites, although with differences due to small insertions and deletions of 1 to 32 Kb (Michaux-Charachon et al., 1997), accounting for the species-specific restriction patterns (Table 4). On the other hand, there are major chromosomal rearrangements affecting the 1.85- and 1.15-Mb chromosomes of *B. suis* biovar 2 and biovar 4, since sequences of the 2.1 Mb chromosome of *B. suis* biovar 1 are found in the 1.15 Mb chromosome of these biotypes and also in the single chromosome of *B. suis* biovar 3. Similar to what occurs in other bacteria, these differences in chromosome size and number can be explained by rearrangements caused by homologous recombination at the redundant *rrn* loci (Jumas-Bilak, 1998a) or insertion sequences (reviewed by Moreno, 1998). Taking into account the great homogeneity of the genus *Brucella* (Ancestor-descendent Relationships), the variations observed in *B. suis* are remarkable. For hypotheses on the origin of the two chromosomes, see Genome Evolution.

Size and Percentage of Guanine Plus Cytosine The data summarized in Table 1 (Number and Species Differences) show that the size of the genome varies between the 3.25 Mb of most *Brucella* spp. and the 3.0 Mb of *B. suis* biovar 3. This is significantly less than the 5.29 Mb (2.70 and 1.90 Mb chromosomes, plus two 0.59- and 0.10-Mb plasmids) of the genome of the closest known relative of *Brucella*, the genus *Ochrobactrum*, and the differences are due to both the smaller size of the chromosomes and the absence of plasmids in *Brucella*. Similar or even larger differences in genome size exist with other taxonomic neighbors, such as *Agrobacterium*, *Rhizobium*, *Phyllobacterium* and *Bradyrhizobium*, and the average G+C content of *Brucella* spp. (57%) is somewhat lower than that of these bacteria (Table 1). On the other hand, a relatively reduced genome size and a comparatively low G+C content are also characteristic of other pathogenic α Proteobacteria (Fig. 1) and probably relate to their adaptation to an intracellular or pericellular animal environment (Genome Evolution).

Methylation and Control of Chromosome Duplication and Cell Cycle It is not known how segregation of the genome is controlled in *Brucella* or in other bacteria carrying more than one chromosome. However, it is known that *Brucella* has genes whose products are involved in the control of the cell cycle. In bacteria, DNA methylation not only is involved in restriction-modification systems but also plays regulatory roles in the cell. The Dam methyl transferases of the γ Proteobacteria control the timing of initiation of chromosome duplication and the expression of some genes, including virulence genes, and are involved in methyl-directed DNA mismatch repair (Reisenauer et al., 1999). The counterpart of Dam in the α Proteobacteria seems to be CcrM (cell-cycle-regulated methyl transferase). This enzyme was originally described in *Caulobacter crescentus*, a bacterium that presents a morphologically defined cell cycle Caulobacter and of which synchronic cultures are relatively easy to obtain. The CcrM catalyzes the methylation of the adenine residue in GANTC sequences, and like Dam, uses *S*-adenosylmethionine as a donor and has no known cognate restriction enzymes. CcrM (but not Dam) is essential for cell viability and its activity is controlled during the cell cycle by tightly regulating the activation of *ccrM* expression (by the global regulator CtrA [see below] and quick constitutive degradation by Lon proteases). When *ccrM* is transcribed constitutively and the chromosomes are fully methylated, most *Caulobacter* cells abnormally increase the number of chromosomes from 1 or 2 to 3, and methylation seems to be particularly frequent in close proximity to DnaA boxes. On these bases, it has been postulated that CcrM plays a key role in the regulation of the chromosome replication (Reisenauer et al., 1999). *B. abortus* carries a CcrM homologue (78% similarity) that has been shown to be essential for viability, and when the number of *ccrM* copies is artificially increased over a given number, a dramatic effect in cell shape and a relaxation in the control of DNA are observed; cells appear highly branched and contain up to five genome equivalents (Robertson et al., 2000b). Moreover, *B. abortus* constructs overexpressing *ccrM* to levels not inducing aberrant morphologies or altered chromosome number still present reduced rates of intracellular multiplication (Robertson et al., 2000b). This indicates that other cell functions related to intracellular survival are likely to be regulated by CcrM. The attenuation of virulence caused by these alterations in CcrM is discussed elsewhere (Auxotrophic and Cell Cycle Genes During Intracellular Life).

Insertion Sequences (*IS*) and Other Genetic Elements All classical *Brucella* spp. examined carry a characteristic insertion sequence (IS*711* or IS*6501*) that is also present in the marine mammal *Brucella* isolates examined so far (Clavareau et al., 1998; Halling and Zehr, 1990;

Halling et al., 1993; Ouahrani et al., 1993). In addition, there are other IS elements scattered in the genome of those brucellae that have been sequenced (DelVecchio et al., 2002; Paulsen et al., 2002). The insertion sequence IS*711* is bound by two 20-bp imperfect inverted repeats, has a G+C content similar to that of the genome and is of 842–836 bp in length. It shows significant similarity (53.4%) with IS*427* of *A. tumefaciens*, suggesting a common ancestral sequence, and like some other IS, has overlapping open reading frames rather than one long open-reading-frame extending over the length of the element. A long open-reading-frame of 708-bp encodes a putative protein sharing sequence identity with the hypothetical protein 1 of *A. tumefaciens* and with a transposase of *Mycobacterium tuberculosis*. Characterization of the flanking sequences suggests that some IS*711* copies may have resulted from mechanisms other than transposition and also that there are hot spots for insertion. Two repeated palindromic DNA elements (Bru-RS1 and Bru-RS2) that are present in more than 35 copies in brucellae act as such insertion hot-spots (Halling and Bricker, 1994). The number of IS*711* copies per genome varies among *Brucella* species: there are 20–35 copies in *B. ovis* and 5–15 copies in other species. The copies present in a given strain may have minor differences in nucleotide sequence, and variations in position and number among species and biotypes result in genetic polymorphism (Table 4). At least in one case, the position of IS*711* causes phenotypically demonstrated differences in protein expression between *B. ovis* and the other classical *Brucella* species (Halling and Zehr, 1990), suggesting that this insertion sequence is a significant source of natural genetic variation in *Brucella* (Genome Evolution). This hypothesis is also supported by the fact that the rough phenotype of *B. abortus* RB51 is due to the spontaneous insertion of IS*711* in the *wboA* LPS gene (*B- abortus* RB51). The movement and transposition of this IS may be one of the sources for gradual microevolution, generating strains and eventually new species (Genome Evolution).

Regulation of Gene Expression

The few examples of known regulatory systems of *Brucella* that have been partially characterized are briefly discussed here.

THE BVRR-BVRS SYSTEM This is a two-component regulatory system. The sensor protein kinase BvrS is homologous to sensor proteins of the histidine protein kinase family, and the response regulator BvrR shows significant similarity to response regulators of the OmpR subfamily. The BvrS protein bears the characteristics of an intrinsic cytoplasmic membrane protein with a periplasmic domain that, in all likelihood, carries the region sensing an unidentified environmental stimulus. This protein crossreacts with ExoS sensor protein of *Rhizobium meliloti* (C. Guzmán-Verri et al., unpublished observations). Thus, it is presumed that, under some environmental circumstances, BvrS catalyzes its own phosphorylation and then transfers the phosphoryl group to BvrR, which, in turn, coordinately activates or represses the expression of genes that, although not identified as of yet, have been demonstrated to be essential for virulence and intracellular multiplication (Sola-Landa et al., 1998; Mechanisms of Entry to Host Cells). Dysfunction of the BvrS-BvrR system is known to alter the outer-membrane permeability, the expression of several Omp3 proteins (among the most conspicuous Omp3a [Omp25] and Omp3b) (Outer Membrane Proteins), and the pattern of lipid A acylation (C. Guzmán-Verri et al., unpublished results), but the underlying genetic mechanisms are yet to be unraveled (Fig. 28; The *Brucella* Genome).

An important feature of the BvrS-BvrR system is that it is highly conserved in other pericellular pathogens or endosymbionts of the α-2 Proteobacteria; it is homologous to the ChvI-

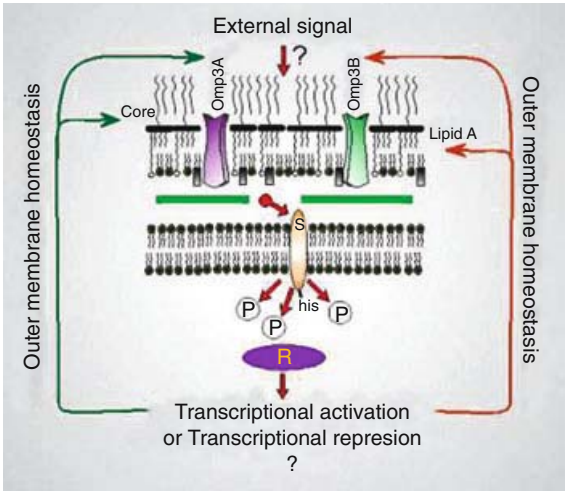

Fig. 28. Hypothetical model of the BvrS-BvrR regulatory system. Accordingly, an external unknown signal stimulates the sensor region of the BvrS protein, translocating the signal to a histidine kinase domain, which in turn promotes its own phosphorylation to phosphorylate the BvrR regulatory protein. The phosphorylated BvrR protein induces or represses transcription of genes not yet identified. By this system, the structure of the lipid A and the expression of Omp3a (Omp25) and Omp3b as well as the presence of other proteins at the *Brucella* outer membrane are regulated. The consequence of mutating either of these two genes in *Brucella* is an altered sensitivity to cationic peptides and hindrance to the cell invasion and intracellular replication.

ChvG (response regulator and sensor histidine protein kinase) of *A. tumefaciens* and to the ExoS of *R. meliloti* (Derivation of Ancestral Preexisting Structures for Virulence) as well as to genes found in *Bartonella* spp.

THE FEUP-FEUQ SYSTEM A response regulator sequence with 96% similarity to *R. leguminosarum* FeuP has been identified in *Brucella*. In *R. leguminosarum*, the FeuP is part of a two-component sensory regulatory system (FeuPQ) operating as described for the BvrS-BvrR system and known to take part in the regulation of iron uptake. Its precise role in *Brucella* remains to be determined (Dorrell et al., 1998).

THE NTRBC SYSTEM This is also a two-component sensory-regulatory system, with a sensor histidine-kinase protein (NtrB) and a regulatory transcriptional activator (NtrC) that has been identified in *B. melitensis* and *B. suis* (Dorrell et al., 1999). NtrC is a member of a family of bacterial proteins that enhance transcription of promoters recognized by the RNA polymerase carrying the alternative σ^{54} factor. The NtrCB system is involved in the regulation of the metabolism of nitrogen in several bacteria. When the NtrC element becomes growth-limiting, the genes necessary to use a variety of nitrogen sources become activated by NtrC. Consistent with this, *B. suis* NtrC mutants have increased metabolic activity in the presence of L-asparagine and L-alanine and decreased activity in the presence of other amino acids, such as glutamic, arginine, and lysine, and several sugars (Dorrell et al., 1999).

THE CTRA REGULATOR The CtrA regulator is a member of the response regulator family whose members, upon phosphorylation by a kinase, act as gene transcription activators. *Brucella abortus* carries a *C. crescentus* CtrA homologue (80% similarity) and the purified *C. crescentus* protein recognizes sequences upstream of the transcription starting site of the *Brucella ccrM* promoter, further stressing the similarity of the two methylating systems (Robertson et al., 2000b). By indirectly controlling the level of DNA methylation, CtrA should also be involved in the regulation of *Brucella* genes other than *ccrM*, but the kinase acting on CtrA has not been identified.

Genetic Exchange, Plasmids and Lysogenic Phages

No naturally occurring system for genetic exchange has ever been demonstrated for any *Brucella* spp. Moreover, the weight of the evidence shows that, in contrast to their phylogenetic neighbors, the brucellae do not harbor plasmids. They have not been found in an extensive search carried out with over 600 *Brucella* strains by a variety of methods (Meyer, 1990) and have never been occasionally observed. Likewise, no firm evidence has ever been provided on the existence of lysogenic phages (The Brucellaphages). Undoubtedly, these genetic characteristics relate to the peculiar intracellular habitat and to the genetic homogeneity of the group (Derivation of Ancestral Preexisting Structures for Virulence), and in all likelihood, the absence of plasmids is one factor contributing to the stability of the antibiotic sensitivity pattern of *Brucella* (Treatment). On the other hand, even with the limited information examined so far, there is evidence for gene acquisition by horizontal transfer. This is at least the case of the genes of the *wbk* region of *B. melitensis* 16M (the *gmd*, *perA*, *wxm*, *wzt*, *wbkA*, *wbkB* and *wbkC* LPS biosynthetic genes [Table 5]), the G+C content of which (44–49 mol%) significantly differs from that of the whole genome (57%) and suggests a shared origin with LPS genes of bacteria showing structurally related *O*-polysaccharides (Table 6; Acquisition of Ancestral Genes by Horizontal Transference).

Epidemiology

Brucella is the causative agent of brucellosis, undulant fever, contagious abortion and Malta fever, all names that describe an important malady of animals and humans. When affecting domestic animals, primarily bovines, caprines, ovines, and swines, the disease acquires a great economical importance. If the bacterium is transmitted from animals to humans, then an important zoonosis is established and public health interest arises, mainly due to the fact that the disease causes disability and requires long and expensive treatment (Treatment).

Since the time the bacterium "*Micrococcus melitensis*" (*Brucella melitensis*) was recognized more that 100 years ago in Malta as the causative agent of brucellosis, the epidemiology of this disease has received much attention. Many of the investigations carried out for already more than ten decades have been crucial for the control and eradication of brucellosis in several parts of the world. However, brucellosis remains as a relevant disease of domestic animals and as an important zoonosis, mainly in low-income countries (Geographical Distribution). Furthermore, brucellosis is an important infection of various wild life animals and a threat if some of the strains are utilized as biological weapons. In this respect, much controversy has come out in how to control and eradicate *Brucella* from these nat-

ural reservoirs and how to neutralize the bacterium if used in a confrontation (*Brucella* as a Biological Weapon). Because of these, the epidemiology and vaccination of brucellosis still capture the attention of many investigators in both developed and low-income countries (Vaccines and Vaccination). For extensive reviews in the epidemiology of animal brucellosis, the publications of Crawford and Hidalgo (1977) and Nielsen and Duncan (1990b) are recommended. For a comprehensive analysis on human brucellosis, the reviews of Spink (1956) and Flores-Castro and Baer (1979) are recommended.

Geographical Distribution

Although *Brucella* organisms infect a broad range of animals, the bacterial species and strains have strong tendency to remain in their preferred hosts (Biological Attributes in the Context of *Brucella* Species Definition). When infecting a secondary host (i.e., *B. melitensis* in cows), the removal of the source of infection (i.e., *B. melitensis*-infected goats) results in the disappearance of the bacteria from the secondary host population (Crawford and Hidalgo, 1977; Nielsen and Duncan, 1990b). In this respect, *Brucella* species and biovars follow the geographical distribution of their natural hosts and not the secondary or the accidental hosts, such as wild animals, humans or horses (Fig. 29). Since in many cases where domestic animals reside borders wildlife habitats, wild animals frequently become infected after contact with domestic livestock or their products, such as fetuses or infected tissues (Crespo-León, 1994). In wild animal accidental hosts (i.e., coyotes), the disease is limited to the infected individual;

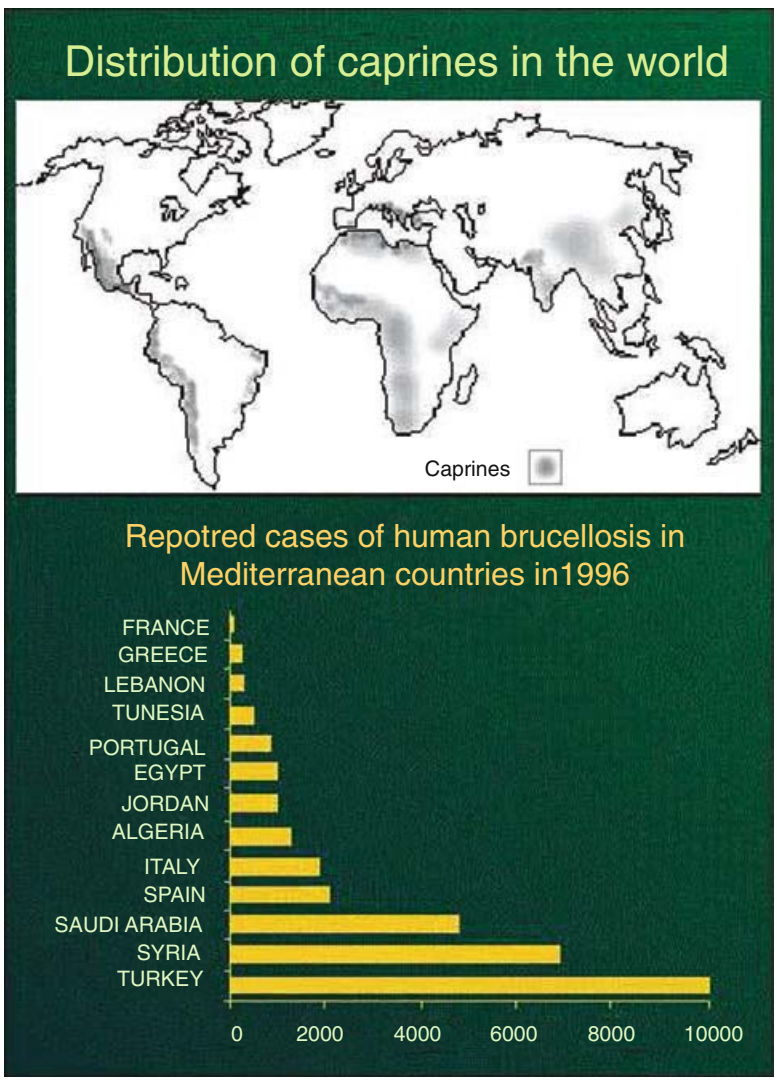

Fig. 29. Geographic distribution of domestic caprines in the world, and human brucellosis in Mediterranean countries for the year 1996. Human and animal brucellosis caused by *B. melitensis* follows the distribution of goats, the natural host for this bacterium. From the United Nations Food and Agriculture Organization/World Health Organization/International Office of Epizootic, Animal Health Year Books.

however, when wild ungulates are involved (i.e., bison), the bacteria may remain for prolonged periods in the population. In this last case, the wild animals may be considered reservoirs of the disease (Davis, 1990; Hayes, 1977). Then, a double hazard occurs: one for wildlife and the other for the domestic animals. Consequently, a conflict between environmentalists and producers arises (McCorquodale and DiGiacomo, 1985). This pattern is more critical in developing countries, mainly in Africa and Asia, since there are not efficient procedures for the control and eradication of *Brucella* in wild animal populations.

Bovine, ovine, caprine and swine brucellosis has also been eradicated from domestic livestock in Canada, Central Europe, Scandinavian countries, Japan and in the northern and central regions of the United States (Crawford et al., 1990; Crespo-Leń, 1994; Plommet, 1992). In Australia and New Zealand, the prevalence of smooth *Brucella* pathogens in bovine, porcine, ovine and caprine herds is close to zero. Although at a low prevalence, *B. ovis* remains in ovine herds in some of those countries with extensive wool production (Crespo-Leń, 1994). In Southeast Asia, bovine and caprine brucellosis is not common, although porcine brucellosis shows a relatively higher prevalence. Bovine, caprine and swine brucellosis also has been eradicated in Uruguay and in some regions of Argentina and Chile. However, ovine and caprine brucellosis caused by *B. ovis* and *B. melitensis* remains in some isolated herds in the latter two countries. In some of the "brucellosis-free" countries and regions, *B. abortus* biovar 1, *B. canis*, *B. suis* biovars 2 and 4 and *B. neotomae* prevail in wildlife hosts, mainly in bison, dogs, wild boars, reindeer and wood rats, respectively, animals native to these countries. In addition, marine *Brucella* strains infect seals, dolphins, porpoises and whales that live in the ocean limits and coasts of many of these "brucellosis-free" countries. In this sense, it could be said that with a few exceptions, *Brucella* pathogens are found worldwide (Jahans et al., 1997).

Brucellosis caused by *B. melitensis* is endemic in Mexico and the principal cause of recurrent infections in caprine and ovine herds as well as the main zoonosis (Crespo-Leń, 1994). In this North American country, *B. melitensis* is also a significant cause of bovine brucellosis due to the breeding of bovines close to goats and sheep. *Brucella abortus*, *B. suis* and *B. canis* are also prevalent as the main cause of brucellosis in bovines, swines and canines, respectively, in populations where goats are excluded. *Brucella suis* may be the second cause of occupational zoonosis in Mexico. In Central America, *B. abortus* (biovar 1) is the leading cause of brucellosis in bovines. *Brucella melitensis* is less frequently found in these animals because of the fewer goats and sheep found in these countries (Crespo-Leń, 1994). *Brucella abortus* (biovar 1) is also the main cause of bovine brucellosis in most South American countries. Peru and Bolivia possess a large number of goats infected with *B. melitensis*, and the domestic livestock is the source of infection for American camelids (llamas and alpacas). *Brucella suis* has been sporadically reported in some areas of Brazil, Uruguay, Argentina and Central America; however, the prevalence is low because of the introduction of intensive management and short-term recycling of swines in these countries.

In the European Mediterranean countries, *B. melitensis* and *B. ovis* are more prevalent than other species of *Brucella* (Plommet, 1992). The northern regions of Portugal, Spain, and Italy, as well as Southern France, have strict control programs for eradication of *B. abortus* bovine brucellosis. In these countries, *B. suis* is detected sporadically and *B. canis* is not currently isolated and may have been eradicated. Among the Mediterranean countries in Europe, Turkey, Greece, Italy, Portugal and Spain have a higher incidence of brucellosis, which is largely caused by *B. melitensis*. In the Eastern European countries and countries of the former Soviet Union, mainly in the Balkanic areas, *B. abortus* and *B. suis* seem to be highly prevalent, although accurate numbers are not available. In some of these countries, in particular those located in the Southern Euroasiatic region in which caprine and ovine herds are maintained, *B. melitensis* remains an important cause of infection. *Brucella suis* biovar 4 is prevalent in reindeer and caribou living in the northern latitudes and are predominantly limited to Alaska, Canada and Siberia.

Brucella melitensis is endemic in the Middle East, Arab countries, Indian Peninsula and southern Asia, mainly due to the population of caprines in these regions. *Brucella abortus* is also present in most of these countries and seems to be more prevalent in Central and Northern Asia (Crespo-Leń, 1994). In these countries, *B. suis* seems to be sporadic, possibly owing to the fact that the population of swines remains small because of religious practices. *Brucella suis* biovar 3 is prevalent in Southeast Asia, the Pacific Islands, Singapore, the Philippines and southern China, and Taiwan, whereas biovar 1 is more frequently found in Indonesia. Although it is known that the major pathogenic *Brucella* species are present in Africa, their prevalence and exact distribution are not known (FAO/WHO, 1986). The prevalence of *B. melitensis* in Africa seems to coincide with the distribution of the large number of caprines existing in many countries of this continent. *Brucella abortus* has been detected in bovine herds and in African wildlife, mainly in

ungulates; however, other mammals, such as elephants, giraffes and camels, have been infected, mainly as a result of contact with domestic livestock. *Brucella suis* also has been detected in feral swines in several African countries.

Although *B. canis* has been detected in widely separated areas, such as Mexico, Madagascar and Japan, the prevalence and exact distribution in the world are not known. It is likely that *B. canis* attains high prevalence in countries possessing a large population of dogs, mainly in developing countries where most dogs freely roam around urban and suburban areas (Carmichael, 1990).

Infecting the Host

It is generally accepted that the most frequent route of infection is through the digestive tract. In goats and probably in other animals as well, the ingested bacteria are engulfed and transferred to the submucosa by intestinal M cells (*Brucella* Invades Healthy Hosts), but the ability to penetrate through the oral and pharyngeal mucosa has also been documented (Enright, 1990b). The conjunctival route seems to be an alternative path for natural infection in herds where intensive management of animals is a common practice (Plommet, 1977). The tissues of the aborted fetuses are massively contaminated with *Brucella* organisms (up to 10^{10} organisms per cm^3 of tissue or allantoic fluid) and therefore are the main source of infection for susceptible hosts. Vaginal secretions are also an important source of infection, mainly for those animals under intensive management and when conditions of close contact among animals prevail. The udder of infected cows, goats and ewes frequently harbors a large number of *Brucella* organisms and the milk is a frequent source of infection. Although calves have been estimated to be more resistant to brucellosis than are adult animals (Russell, 1977), they can be infected by ingesting milk from infected cows, mostly after abortion or parturition. A similar situation may occur with kids, lambs and piglets. In ungulates, the infection is normally acquired through the habit of licking and smelling the aborted products and other infected animals. The congenital route is of epidemiological relevance because animals born from infected mothers may remain latently infected and without symptoms or serological response until pregnancy (Plommet, 1977; Fig. 9). *Brucella* organisms are also transmitted by the venereal route. This channel is more important in swine, ovine and canine brucellosis. Artificial insemination of contaminated semen with *Brucella* organisms is a risk factor for iatrogenic transmission (Manthei et al., 1950).

Although it has been demonstrated that the bacteria can survive in water, soil and manure for limited periods of time and that transmission may occur by penetration of the bacteria through broken skin or by insect bites, these probably are more fortuitous than regular routes and are considered of minor epidemiological importance (Meyer, 1977). Rodents and carnivores do not play a relevant role in the direct transmission; however, they may be important in the indirect transmission of brucellosis. For instance, wild scavengers and dogs may spread contamination by carrying aborted fetuses from infected animals to various sites (Davis, 1990). Accidental hosts, such as humans and horses are frequently infected through the ingestion or inopportune contacts with contaminated raw tissues or milk. From the epidemiological point of view, these accidental hosts are irrelevant for the transmission of *Brucella* organisms. Very little is known regarding the transmission of *Brucella* among marine mammals. It is thought that newborns may acquire the bacteria congenitally or through milk from infected mothers. Nematodes of seals have been proposed to play a role in the transmission of *Brucella* in these animals (Garner et al., 1997).

Vaccines and Vaccination

Long experience has shown that vaccination is an essential tool in the eradication of animal brucellosis (Alton, 1977). Since humans contract the disease from animals and are themselves not a source of contagion, animal vaccination is also decisive in eradicating human brucellosis. Although attempts to vaccinate human beings with some of the living animal vaccines or with subcellular vaccines have been made, these practices have been abandoned. Access to the information on human vaccination with live vaccines is difficult to obtain, but it seems that where implemented, vaccination was discontinued because of the lack of attenuation of the vaccine and/or its noxious side effects. There is information on a subcellular vaccine based on the phenol-insoluble fraction of smooth *Brucella* (Bentejac et al., 1984), but its actual value in humans has never been rigorously tested, and it does not induce protection in suitable animal models (De Bolpe and Garcia-Carrillo, 1991). Although there is a growing interest in developing attenuated strains suitable for human vaccination, none has been tested except in laboratory animals (Crawford et al., 1996; Drazek et al., 1995; Hoover et al., 1999).

Protective immunity achieved by *Brucella* vaccines depends upon several factors, such as animal species, age, gender, administration route, and vaccine dose, type and challenge. Vaccination has been extensively used in cattle, sheep, and goats but not in other domestic

animals, either because the breeding conditions do not make it necessary, or because attempts have been discouraging. None of the existing vaccines against animal brucellosis induce lifelong 100% protection against the challenge encountered in heavily infected flocks, and the most effective vaccines interfere in the serological diagnosis of brucellosis. To solve these problems, subcellular vaccines, adjuvant formulations, and different vaccine strains have been investigated. Moreover, for the classical live vaccines (i.e., *B. abortus* strain 19 and *B. melitensis* strain Rev. 1), variations in the dose, route, age of the animals at vaccination and tests used in the serological follow-up have been studied. So far, only these live vaccines have clearly proven prophylactic efficacy in the natural hosts. The use of dead vaccines in adjuvant is generally considered much less effective, and little research on subcellular vaccines has progressed beyond the laboratory animal models (Blasco, 1990; Nicoletti, 1990a). Attenuated mutants derived from the identification of genes related to virulence (Vaccines and Vaccination; *Brucella* Virulence Mechanisms) have been rarely tested in the natural hosts and either the studies have not been continued (Cheville et al., 1993) or the results are inferior to those obtained with the classical vaccines (Elzer et al., 1998).

Animals are generally immunized with the vaccine strain homologous to the *Brucella* spp. for the corresponding host range (i.e., *B. melitensis* vaccines are used in sheep and goats and *B. abortus* in cattle). There have been attempts to use *B. abortus* strain 19 in small ruminants but the results have been less satisfactory than those obtained with the homologous vaccine. Although preliminary reports are encouraging (Garcia-Carrillo, 1980; Horwell and Van Drimmelen, 1971), *B. melitensis* Rev. 1 has not been used in cattle and its safety in this host is unknown.

B. melitensis Rev 1 Attenuated *B. melitensis* biotype 1 Rev. 1 (revision one) vaccine has been efficiently used for more that 40 years in the prevention of caprine and ovine brucellosis, including *B. ovis* infections (Blasco et al., 1984b; Blasco et al., 1987; Marín et al., 1999). Although it is not exempt of problems (Origin, Characteristics and Attenuation of Rev 1), vaccination of sheep with the standard dose by the conjunctival route is the most practical means to rapidly reduce the rate of *B. melitensis* infection in both sheep and humans (Garin-Bastuji et al., 1998). This smooth-strain vaccine displays some residual virulence inducing abortions and testicular problems when administrated to sexually mature caprines and ovines, and it is also capable of infecting humans (Crespo-León, 1994). Some female animals vaccinated with Rev. 1 may release the bacteria in milk for several weeks or months.

Origin, Characteristics and Attenuation of Rev 1 *B. melitensis* Rev. 1 is strain number 1 of a set of revertants obtained from a streptomycin-dependent strain by Elberg and his colleagues at the University of California in the mid-1950s (Alton and Elberg, 1967, 1981). This strain has a smooth phenotype (Response to Environmental Stress), but also has some traits that allow its differentiation from field strains (Identification of Vaccine Strains), an essential property in a live vaccine against brucellosis. Its rate of smooth-to-rough dissociation (with the ensuing over-attenuation) is relatively high and calls for strict vaccine quality control. Moreover, the biological properties of Rev. 1 seeds conserved in different laboratories seem to have shifted through the years, so that the bacteria in different commercial vaccines may vary in critical properties. There are demonstrated cases in which the particular vaccine used clearly lacked attenuation (Blasco, 1997), whereas in other cases the vaccine varied to the rough phenotype (E. Díaz-Aparicio, personal communication). Biological quality control procedures, which should be implemented at least for periodic seed stock control, have been developed to measure Rev. 1 residual virulence and immunogenicity (Bosseray, 1991; Grilló et al., 2000).

The original Rev. 1 strain is attenuated in mice and guinea pigs, where it develops an infection milder than that caused by virulent strains and elicits protective immunity. It is also attenuated in goats and sheep where it induces a generalized infection, which is practically eliminated from most animals by the fourth month post vaccination (Alton and Elberg, 1967, 1981). The cause(s) of the attenuation is not known but the dye sensitivity pattern suggests that at least some properties of the outer-membrane are altered. It is important to stress that, despite its attenuation in animals, Rev. 1 is clearly infectious for humans (Alton and Elberg, 1967, 1981) and resistant to streptomycin (Human Brucellosis). Although it is rarely excreted in sheep milk, goats are reported to excrete Rev. 1 more often and for longer times, thus posing a hazard for farmers (Alton, 1990a). Moreover, veterinarians applying the vaccine and workers restraining the animals during this process are also at risk.

Protection of Rev 1 The vaccine can be administered either subcutaneously or conjunctivally with no differences in the degree of protection obtained. In controlled experiments, it has been demonstrated that at the optimal (or standard) dose (about 10^9 colony forming units [CFUs]) Rev. 1 protects 70–85% of the sheep against a

challenge (about 10^8 CFU of a virulent *B. melitensis* strain) infecting 75–100% of unvaccinated controls (Blasco, 1997; Garin-Bastuji et al., 1998). Under field conditions, the immunity obtained in sheep and goats is satisfactory for eradication purposes when vaccination is combined with the removal of infected animals detected in the most specific serological tests (Alton, 1990a; Garin-Bastuji et al., 1998). Controlled studies in goats show that immunity induced by Rev. 1 vaccination may last longer than four years. In sheep, the experimental evidence shows a high level of immunity for at least two and a half years (Alton, 1990a). However, it is not known whether vaccination of young animals with the standard dose induces lifelong immunity. Obviously, adult vaccination would be desirable for eradication and in fact must be applied when programs start and prevalence is high (Garin-Bastuji et al., 1998), but this increases the side effects of vaccination. Also, Rev 1 is the best vaccine available against *B. ovis* ram epididymitis, and the conditions of use are the same as in ewes (Blasco, 1990; Marń et al., 1990).

Interference in the Serological Diagnosis and Other Side Effects of Rev 1 Because it is a smooth strain, Rev. 1 induces antibodies interfering in the smooth-LPS serological tests and this complicates the diagnosis (Immunological Diagnosis of Animal Brucellosis Caused by Smooth *Brucella*). The duration of this response depends on the age of the animals at vaccination. The duration is longer as they approach or reach sexual maturity. It is significantly more protracted when the subcutaneous route is used and, in this case, many animals show positive serological results for years. When using the best strategy (i.e., the conjunctival route and less than 6-month-old animals), the great majority of the animals become serologically negative in the most specific serological test in less than a year (Alton, 1990a; Fensterbank, 1987; Garin-Bastuji et al., 1998; Jiménez de Bagüs et al., 1989; Plommet and Fensterbank, 1984; Zundel et al., 1992).

Rev. 1 is very abortifacient and rates of vaccine-induced abortions can be as high as 80% if animals are vaccinated in the second to third month of pregnancy (Alton, 1990a; Alton and Elberg, 1967; Blasco, 1997; Garin-Bastuji et al., 1998). The risk of inducing abortions is substantially reduced but not eliminated when the conjunctival route of vaccination is used (Blasco, 1997; Jiménez de Bagüs et al., 1989; Zundel et al., 1992). Alternatively, the use of reduced doses (from 10^5 to 10^7 CFU) has been proposed but abortions are not totally avoided, and there is clear evidence that the immunity achieved is not adequate (Blasco, 1997).

B. ABORTUS STRAIN 19 *B. abortus* strain 19 vaccine has been extensively used in cattle. With a few exceptions, most of the successful control and eradication programs have been carried out with this strain. It is noteworthy that this vaccine was developed more than 70 years ago and that, although several alternative attenuated strains have been developed subsequently and studied, none has such a wide application as strain 19.

Origin, Characteristics and Attenuation of S19 Strain 19 is derived from the nineteenth stock culture made by Buck from a milk isolate in the early twenties. The culture was maintained at room temperature for over a year and this resulted in attenuation in the guinea pig. Strain 19 has a smooth phenotype (Response to Environmental Stress), and since occasionally it dissociates to yield rough mutants unsuitable for vaccination (Colonies and Dissociation), quality control of at least this property is necessary. It carries some traits that allow its typing and differentiation from field strains (Identification of Vaccine Strains), including inhibition by erythritol (Erythritol).

As compared to field isolates, strain 19 is also markedly attenuated in cattle and only induces a transient infection in heifers that is usually cleared in a few months and seldom lasts for more than a year (Nicoletti, 1990a). When used in adults, however, about 2% of the animals develop udder infections and shed the vaccine in the milk for several years. Although the precise reasons for the attenuation are not known, strain 19 clearly shows altered intracellular trafficking (Association with the Autophagic Machinery; Interleukins in Brucellosis). The deletion in the *eri* region carried by this vaccine and the alteration of outer-membrane properties suggested by its antibiotic and dye sensitivity pattern may be related to the loss of virulence. Although not as dangerous as *B. melitensis* Rev. 1, *B. abortus* strain 19 also has been a demonstrated cause of human infections (Meyer, 1985).

Protection of S19 In controlled experiments, 40–75% of heifers vaccinated subcutaneously with the standard dose (10^{11} CFU) are protected against conjunctival challenges infecting 100% (about 10^7 CFU) to 87% (about 10^6 CFU) of the unvaccinated controls (Nicoletti, 1990a), and the level of protection is no different when the conjunctival route is used (Nicoletti et al., 1978; Plommet and Fensterbank, 1984). Although these experiments also show that the immunity obtained can be overcome by a heavy challenge, it has been repeatedly shown under field conditions that strain 19 vaccination reduces the prevalence to very low levels and that eradication is possible when the vaccine is combined with the

removal of the reactors in serological tests of the adequate specificity (Immunological Diagnosis of Animal Brucellosis Caused by Smooth *Brucella*). Protection is reported to last for more than five pregnancies, and it is not clear whether revaccination increases immunity (Nicoletti, 1990a). A single dose has proved to be enough to achieve eradication in test and slaughter programs applied to herds varying from medium to small size. In these cases, the problems created by revaccination in the interpretation of the serological tests (Interference in the Serological Diagnosis and Other Side Effects of S19) would outweigh the potential benefits. On the other hand, revaccination may be necessary to control the disease in large herds, or under conditions in which obligatory slaughtering is not economically viable, as is the case in low income countries (Nicoletti, 1990a). This strategy is the most practical one in those cases where diagnosis is not routinely carried out as part of a control program and where abortion is causing the major losses. Revaccination in these cases slows the abortion rate and decreases the level of infection by lowering the bacterial inocula. From this perspective, revaccination must be considered an emergency strategy. Some experiments have shown that the best protection is obtained by subcutaneous vaccination of calves followed by a conjunctivally administered booster dose (Plommet and Fensterbank, 1984).

Interference in the Serological Diagnosis and Other Side Effects of S19 Although the level of protection induced by strain 19 is good, the presence of residual antibodies against the *O*-polysaccharide complicates the differentiation between vaccinated and infected individuals. To solve this problem, four major strategies have been proposed (Hidalgo et al., 1977): (1) to develop sensitive and specific serological tests capable of differentiating infected from vaccinated animals, (2) to limit vaccination to calves, (3) to reduce the vaccine dose, and (4) to administer the vaccine by the conjunctival route. Each strategy has its benefits and drawbacks.

Although the combination of serological tests under defined circumstances may achieve sensitivity and specificity close to 100% (Immunological Diagnosis of Human Brucellosis Caused by Smooth *Brucella*), the specificity and sensitivity of these assays considerably decrease under conditions in which infection of some vaccinated individuals occurs or when revaccination is used. Calf vaccination shortens the time lapse during which there are significant levels of antibodies against the *O*-polysaccharide, but the level of protection is lower than that obtained in adult animals (Nicoletti, 1977). The optimal age of calf vaccination is between 3 and 6 months, and under these conditions, most animals are negative in the most specific tests a year later. On the other hand, if vaccinated when they are 6 months to one year old, up to 20% of the animals may be serologically positive 18 months later (Nicoletti, 1990a; J. M. Blasco, personal communication). As discussed above, there are a number of situations that make vaccination of adults necessary but the vaccine persists in adults for a longer time than it does in calves and induces a more protracted serological response. Conjunctival vaccination (two doses of 5×10^9 CFU at a 4–6 month interval) dramatically reduces the serological response without compromising the level of immunity obtained (Nicoletti, 1977; Nicoletti et al., 1978; Plommet and Fensterbank, 1984), and reducing the subcutaneous dose (from 5×10^9 to 5×10^8 CFU) also reduces the serological response. In a large field study, no differences in prevalence rates were found between groups of animals that had received the standard or the reduced dose, and the usefulness of the latter has been confirmed in other studies (Nicoletti, 1990a). However, reduced doses have to be used with care and always considering the age of the animals and particular conditions of the herds as other studies have shown that both younger and old heifers are not adequately protected by strain 19 at a dose of 1×0^9 to 9×10^6 CFU (Huber et al., 1990).

B. abortus strain 19 is abortifacient when applied to pregnant cattle but the rate of abortions is relatively low (about 5%). As mentioned (Origin, Characteristics and Attenuation of S19), adults may develop udder infections and shed the vaccine in their milk.

B. suis Strain 2 An attenuated strain (strain 2 or S2) was obtained in China after serial transfer of a virulent *B. suis* biotype 1 strain on culture media for years. *Brucella suis* strain 2 is of smooth type, shows the same level of attenuation as strain 19 shows in guinea pigs, and does not revert to the virulent state after repeated passaging through guinea pigs, sheep, goats or boars. It is reported to protect cattle, goats, sheep and pigs when administered orally. Implementation of vaccination programs in semiarid grasslands where sheep and goat breeding is extensive is necessarily difficult. Since in these areas the only source of drinking water is from wells, *B. suis* strain 2 has been administered orally in the drinking water. By this route, the S2 vaccine has been widely used for prevention of animal brucellosis in China (Xin, 1986). Good results were also obtained with sheep in a trial in Libya (Mustafa and Abusowa, 1993). However, in controlled experiments performed in France (Verger et al., 1995) and Spain (Blasco et al., 1993b), *B. suis* strain 2 administered subcutaneously did not

protect sheep against a *B. melitensis* or a *B. ovis* challenge under conditions in which the standard *B. melitensis* Rev. 1 was effective. The different breeds employed, differences in the challenging strains used, the climatic and nutritional conditions and the difficulties in obtaining reliable data under field conditions may account for the discrepancies.

ROUGH VACCINES The use of rough vaccines has been proposed on the premise that protective immunity in bovine brucellosis is carried exclusively by cells and that the generation of antibodies against the *O*-polysaccharide is unnecessary and undesirable, since it complicates the differential diagnosis (Cunningham, 1977a).

B. abortus 45/20 A killed vaccine prepared with the rough strain 45/20 suspended in a water-in-mineral oil emulsion has been used in the past (Cunningham, 1977a). This vaccine was developed to overcome the disadvantages of the interference in the serological tests caused by strain 19, which limited its use to calves before the development of more specific serological tests and the demonstration of the usefulness of reduced doses and the conjunctival route in adult cattle. However, strain 45/20 was shown to revert to smooth pathogenic forms when injected into cattle, and this limited its use to a killed in adjuvant vaccine (Adams, 1990; Chukwu, 1985). Although vaccine 45/20 induces some protection in adults, calves of less than six months old may not be well protected (Nicoletti, 1990a). Also, some commercial 45/20 vaccines undoubtedly induced antibodies to the smooth-LPS (Díaz and Jones, 1973b), thus reducing the only advantage of this vaccine. In countries where the conditions were favorable (low prevalence and intensive breeding with good animal management practices), vaccine 45/20 was found to be useful in providing herd resistance (Roerink, 1969) but other experiences have been less favorable (Plenderleith, 1970; Ray, 1976).

B. abortus RB51 In recent years, a great deal of attention has been placed on the possibilities that *B. abortus* strain RB51 offers as a live vaccine (Schurig et al., 1991). Strain RB51 is a spontaneous rough mutant selected after repeated in vitro passage of *B. abortus* 2308 (United States Department of Agriculture challenge strain) in the presence of rifampin and penicillin (Schurig et al., 1991). Selection was performed using the crystal violet and acriflavine tests (Colonies and Dissociation) and a considerable effort has been dedicated to the genetic characterization of RB51. The RB51 strain carries an IS*711* spontaneously inserted in the *wboA* gene (Table 5), which is undoubtedly related to its phenotype and attenuation (Vemulapalli et al., 1999). However, *B. abortus* 2308 *wboA* mutants obtained by transposon mutagenesis are not equivalent to RB51, which shows that the latter strain carries additional and unknown defects (McQuiston et al., 1999). The strain is stable and, although it should show very little or no virulence in humans, there is little experience on this point. RB51 infections cannot be diagnosed in the standard serological test, as this vaccine lacks the O-polysaccharide (see Immunological Tests for Brucellosis), and it has to be stressed that it is resistant to rifampin (Treatment).

Being a rough strain, RB51, although it produces small quantities of *N*-formylperosamine polysaccharides (G. G. Schurig, personal communication), does not induce antibodies interfering in the smooth-LPS serological tests (Stevens et al., 1994b) even when used as a booster in adult animals vaccinated with strain 19 during calfhood (Uza et al., 2000).

This vaccine has been reported not to be abortifacient in cattle (Edmonds et al., 1999; Palmer et al., 1997; Uza et al., 2000). However, animals vaccinated at pregnancy excrete it in the milk (Uza et al., 2000) and full doses of RB51 (1×10^{11} CFU) administered intravenously induce severe placentitis and placental infection (Palmer et al., 1996). Moreover, recent evaluations of some field experiences have demonstrated high numbers of RB51 isolates in aborted cattle (Lopetegui, 1999). When using the reduced dose of this vaccine (1×10^{9} CFU), no abortions or placentitis lesions are produced in subcutaneously vaccinated cattle (Palmer et al., 1997). However, this reduced dose does not protect against *B. abortus* (Olsen, 2000).

The data on the level of protection afforded by RB51 in cattle are contradictory. In field studies carried out in Venezuela, it was concluded that RB51 was superior to strain 19 (both used at a dose of 5×10^{9} CFU) in protecting against the natural challenge existing in infected herds (Lord et al., 1998b). On the other hand, in a controlled experiment, RB51 protected 26 of 29 vaccinated animals and strain 19 protected 20 of 22 (both used at a dose of 10^{10} CFU), but only a moderate challenge was used in the experiment (12 of 20 nonvaccinated controls were infected) (Cheville et al., 1996b). More recently, the results of a study in which 3-month-old heifers were given RB51 at doses ranging from 10^{9} to 1.4×10^{11} have been presented (Olsen, 2000). Four of eight nonvaccinates, two of four 10^{9} CFU vaccinates, and two of fourteen 1.4×10^{11} CFU vaccinates aborted. In a separate study conducted with 6-month-old heifers, three of seven nonvaccinates and one of eighteen 10^{10} CFU vaccinates aborted. The author concluded that RB51 was efficacious in preventing abortion and fetal infec-

tions, but the data also show that the incidence of maternal infection with *Brucella* at necropsy did not differ among RB51 vaccinates and nonvaccinated controls (Olsen, 2000). Additional comparative experiments with strain 19 under controlled conditions are necessary to define the level of protection achieved with this vaccine in cattle, and it is still premature to draw conclusions on its ability to protect under field conditions. Up to now, RB51 vaccine seems to prevent brucellosis under conditions of low prevalence; however, under conditions of high prevalence, this vaccine has not been satisfactorily tested. Our own experience is that under field conditions, strain 19 performs better than RB51, at least in circumstances where high inocula of virulent *Brucella* organisms (high incidence in the herd) are likely to occur (E. Moreno et al., unpublished observations).

B. abortus RB51 does not seem useful in sheep. In a stringent experiment (100% of infection in unvaccinated controls), RB51 afforded no protection against *B. ovis* under conditions in which Rev. 1 fully protected 40% of the animals (Jiménez de Bagüés et al., 1995). Moreover, controlled evaluations against *B. melitensis* challenges are also unsatisfactory (el-Idrissi et al., 2001). There is also one study in pigs, although conducted under field conditions. In these animals, the vaccine was reported to induce 100% protection regardless of the dose (10^6 or 10^9), the number of injections (1 or 3) and the administration route (oral and intramuscular) (Lord et al., 1998a). Controlled experiments would be necessary for a further evaluation of the vaccine in pigs.

Control, Eradication and Prevention

Control and subsequent eradication of brucellosis can be consummated by the simple, costly and sometimes impractical procedure of totally eliminating the primary hosts from the designated area, with or without replacement of the population with clean animals. Although this method has been attempted by some, most countries that have achieved eradication of brucellosis from bovine, ovine and caprine herds have followed a stepwise strategy (Boyd, 1977; Flowers, 1977). The first initiative towards the control of brucellosis in a specific population usually consists of the serological examination of the animals (Immunological Tests for Brucellosis). Under circumstances where the animal population has not been vaccinated, a simple sensitive test (i.e., card or rose bengal) is enough for identification of the infected animals. However, when strain 19 vaccination is carried out, a combination of sensitive and highly specific assays (Immunological Diagnosis of Animal Brucellosis Caused by Smooth *Brucella*) for the differentiation of infected and vaccinated animals (i.e., complement fixation, radial immunodiffusion [RID], enzyme-linked immunoabsorbent assay [ELISA] or competitive ELISA) is required. The second initiative is the vaccination of the population at risk followed by removal and slaughtering of the serologically positive animals. During this phase, brucellosis-free farms and regions with or without vaccination could be declared. The final step is to stop vaccination. Constant serological surveys are necessary, mainly when potential foci of contamination are colliding with brucellosis-free areas. Only after several years of continuous surveillance, brucellosis may be considered eradicated from these nonvaccinated serologically negative herds. Up to now, only strain 19 and Rev. 1 vaccines have demonstrated to control and eradicate brucellosis under conditions where control programs have been implemented (Blasco, 1997; Nicoletti, 1990a).

One very important aspect in the prevention of brucellosis outbreaks is to limit and strictly control the import of animals from regions where brucellosis has not been eradicated. Similar to this is the introduction of susceptible hosts into areas where brucellosis may remain latent in the population. This is especially important in cases involving wildlife hosts, such as the introduction of bovines, goats or ovines in regions where bisons, reindeer and perhaps marine mammals remain as potential reservoirs of *Brucella* organisms.

Zoonosis

Human brucellosis is a highly contagious bacterial zoonosis, which follows the distribution of the natural animal hosts (Fig. 29). Removal of the infected hosts, therefore, eliminates the contagion risk. Human brucellosis is most frequently found in third world countries, mainly due to the high prevalence of *Brucella* infections in domestic herds and to the ingestion of unpasteurized dairy products. The disease in humans is also known as "undulant fever" or "Malta fever," since the first isolation of the causative bacterium was made in the Mediterranean island of Malta from spleens of British soldiers who became infected as a consequence of drinking contaminated caprine milk. The most common *Brucella* species infecting humans are *B. melitensis*, *B. abortus* and *B. suis*. Among these, *B. melitensis* and *B. suis* are the most aggressive species for humans. These bacteria cause a severe syndrome, which if not treated may lead to death. *B. canis* has been reported sporadically to infect humans. *B. ovis*, *B. neotomae* and the marine *Brucella* strains have not been detected in humans. The marine

strains may represent, however, an authentic hazard for human communities that hunt and gain subsistence from whales and seals, as well as for workers that are in close contact with marine mammals (Garner et al., 1997; Higgins, 2000).

Contamination of humans depends upon interaction with infected animals, their products, or their secretions. Because of the wide acceptance of pasteurization, brucellosis is regarded in many countries as an occupational disease of sporadic occurrence among livestock handlers, veterinarians, vaccinators, laboratory workers, and meat-processing and slaughter plant personnel. In many third world countries the consumption of raw milk and unpasteurized dairy products, such as butter, fresh cheese, cream or curd, as well as fresh raw viscera and blood is still an important source of infection. The infection of domestic animals, frequently accompanied by slaughtering, and the possibility of contamination of food products with *Brucella* add important restrictions to the marketing of foodstuffs. In consequence, incomes for many families are reduced.

The diagnosis of human brucellosis is well established (Antibody Detecting Tests in Infected Patients). It depends mainly on the detection of antibodies in the serum of patients against *Brucella* organisms by immunological techniques. The confirmation of infection is achieved by the isolation of the etiological agent in the blood of infected patients. Although pasteurization is the mandatory public health procedure, examination of foodstuffs, presumed to be the source of contagion, may occasionally be necessary. The demonstration of antibodies in milk is suggestive of herd infection and of the possible presence of *Brucella* spp. in dairy products, but it is not a specific method of diagnosis because revaccination or adult vaccination can cause secretion of antibodies in milk. Shedding of the vaccine strains by the immunized animals may also occur. Since vaccine strains are virulent for humans, their presence in dairy products constitutes a zoonotic risk. Isolation of *Brucella* organisms can be achieved from milk, but it is more difficult when processed dairy products are concerned, complicating matters even more. Culture on selective media follows the same procedures described for animal diagnosis by bacteriological culture (Molecular Tests for Humans; Molecular Tests for Animals). Molecular methods, such as PCR, may be useful and could be used to detect some of the vaccine strains (Molecular Tests for Humans; Molecular Tests for Animals), but there are few reported studies on their application to processed foodstuffs.

Disease

Brucellosis is a disease of the reticuloendothelial system, the reproductive organs and of the fetus, and then the pathological signs are perceptible accordingly (Pathology). In the primary host the main manifestation of the disease is abortion or epididymitis. In humans the syndrome is in extreme complex and could be evidenced in many forms, recurrent fever being one of the main manifestations. From a gross perspective, the pathobiology of brucellosis is in several respects similar to that of other intracellular bacteria; however, it possesses many idiosyncratic manifestations and a unique intracellular life cycle (Pathobiology). The infection is controlled by an efficient immune cellular response (Control of the Infection), although antibiotic therapy is mandatory in humans (Treatment). Diagnosis is mainly based in determining the immune response of the infected host and in the isolation of the bacteria from infected tissues and blood (Diagnosis).

Pathology

The pathology of brucellosis is complex and its study requires biosafety conditions (Biosafety) due to the fact that the bacteria are primary pathogens of animals (Brucellosis in the Host Animal) and humans (Brucellosis in Humans) and then are a risk for contamination. For comprehensive reviews on the pathology of brucellosis, the publications of Blasco (1990), Enright (1990a) and Spink (1956) are recommended.

The Disease Named Brucellosis

Considering the close phylogenetic relationship among the different members of the genus, it is not surprising that the pathologies induced by the various *Brucella* species in their host animals are very similar. Likewise, the gross physiopathological events that occur in accidental or experimental infections in secondary hosts, such as humans, mice and horses, have many things in common. Although some strains are more virulent than others, the different pathologies observed seem to be related more to idiosyncratic differences of the hosts than to individual virulence properties of the *Brucella* strains. This means that once *Brucella* organisms have gained access into the tissues, they proceed in a very similar manner. Control of the infection depends mostly on the confrontation between the host defenses, on one side, and the ability of *Brucella* to reproduce and gain access to various tissues without being destroyed, on the other (Control of the Infection).

Most of the pathobiological studies have been performed in experimental animals, such as mice

and guinea pigs, as well as with a variety of cell lines. In the natural hosts, studies have been conducted with bovines, caprines and ovines and with strains of *B. abortus*, *B. melitensis* and *B. suis*. Although the data are more limited, similar pathologies have been observed with the marine strains *B.* "*maris*," *B. canis* and *B. ovis* in their natural hosts. This last species, however, demonstrates preference for male ovine reproductive organs, with low pathogenicity for ewes (Blasco, 1990). Similar to *B. ovis*, the wood rat parasite *B. neotomae* seems to display low virulence, even though production of highly aggressive strains generating similar events to other *Brucella* species has been reported (Gibby and Gibby, 1965). Finally, the study of human brucellosis has contributed to the understanding of the pathology and pathobiology from various perspectives.

Brucellosis in the Host Animal In general terms, brucellosis can be viewed as a chronic infection, which in nontreated cases may cure or persist for life, mainly within cells of the reticuloendothelial system (Blasco, 1990; Enright, 1990b). The incubation period in the preferred animal host under natural conditions depends upon the *Brucella* strain, inoculum size, as well as upon host factors. In the natural host, incubation times range from two to five weeks, although longer periods are not exceptional. In the accidental host, the incubation period is more variable and generally longer than in the natural host animal, often lasting for several months. The onset of symptoms in the natural hosts normally courses with recurrent fever and enlarged lymph nodes, spleen and liver. Arthritis with gastrointestinal and nervous symptoms may be observed. Bacteremia normally coincides with the fever events. In the natural pregnant host, the infection frequently results in abortion in the last trimester of gestation and in contagion to other members of the herd. In males, invasion of the reproductive organs is frequently observed, facilitating venereal transmission and inducing partial or total sterility. Orchitis and epididymitis are two prevailing signs. In the immunocompromised host, invasion of many organs, including the central nervous system, may take place followed by death. Reproductive impairment in females may occur upon placental retention or for other causes; however, this event is exceptional rather than a common outcome in brucellosis.

The most frequent ports of *Brucella* entrance are the mucous membranes of the oral, respiratory and gastrointestinal tracts, as well as those membranes covering the conjunctiva, vagina and the prepuces (Enright, 1990b). Very likely bacterial penetration takes place through the epithelial cells lining the mucous membranes (*Brucella* Invades Healthy Hosts). At the site of lodgment, the organisms are ingested by resident phagocytic cells and then carried via the lymphatics to the regional lymph nodes. Once ingested, the bacteria travel to a specialized intracellular compartment where they multiply. Some of the bacteria and cells die during the confrontation, and the released *Brucella* debris stimulate a local immune response with the concomitant activation and proliferation of inflammatory and mononuclear cells (Anderson et al., 1986b; Anderson et al., 1986c; Cheville et al., 1992; Tobias, 1993). The result of this confrontation determines whether the infection is contained or transgresses to other organs. In the immunized host, the memory and activated cells of the immune system normally are capable of dominating the infection (Control of the Infection). If not, polymorphonuclear leukocytes and macrophages carrying the bacteria reach the blood, transporting the microorganisms to the reticuloendothelial system, mammary glands and reproductive organs (Enright, 1990b). The histopathological signs of the colonized lymph nodes are typical of infections by intracellular bacteria, demonstrating hyperplasia with mononuclear infiltration, local hemorrhage, presence of granulomas with histiocytes, epithelioid cells and gigantic Langerhans cells, edema and extramedullary hematopoiesis. Severe paracortical lymphocyte depletion, destruction of germinal centers and serofibrous lymphadenitis with effacement of lymph node architecture are observed during the first weeks of infection. In most cases, dead and alive intracellular bacteria can be detected in large numbers within phagocytic cells and in lesser proportion within lymphocytes (Fig. 30).

The Fetus, the Most Susceptible Host In pregnant animals, such as bovines, caprines, ovines, swine and very probably marine mammals, the bacteria reach the gravid uterus, infecting the cotyledons (Anderson et al., 1986b; Anderson et al., 1986c). Once installed in this site, the bacteria replicate within the endoplasmic reticulum of erythrophagocytic trophoblasts followed by extensive replication within chorioallantoic trophoblasts (Fig. 30). This action generates necrosis and subsequent ulceration of the chorioallantoic membrane with production of anti-inflammatory exudates composed of phagocytic cells and cellular debris (Fig. 31). At this point, *Brucella* can be observed within the uterine lumen and in the placental capillaries disseminating through the chorionic villi. As a consequence, placentomal and fetal infection with concomitant inflammation proceeds. Interestingly, *Brucella* organisms are not found within placentomal trophoblasts, cells of the

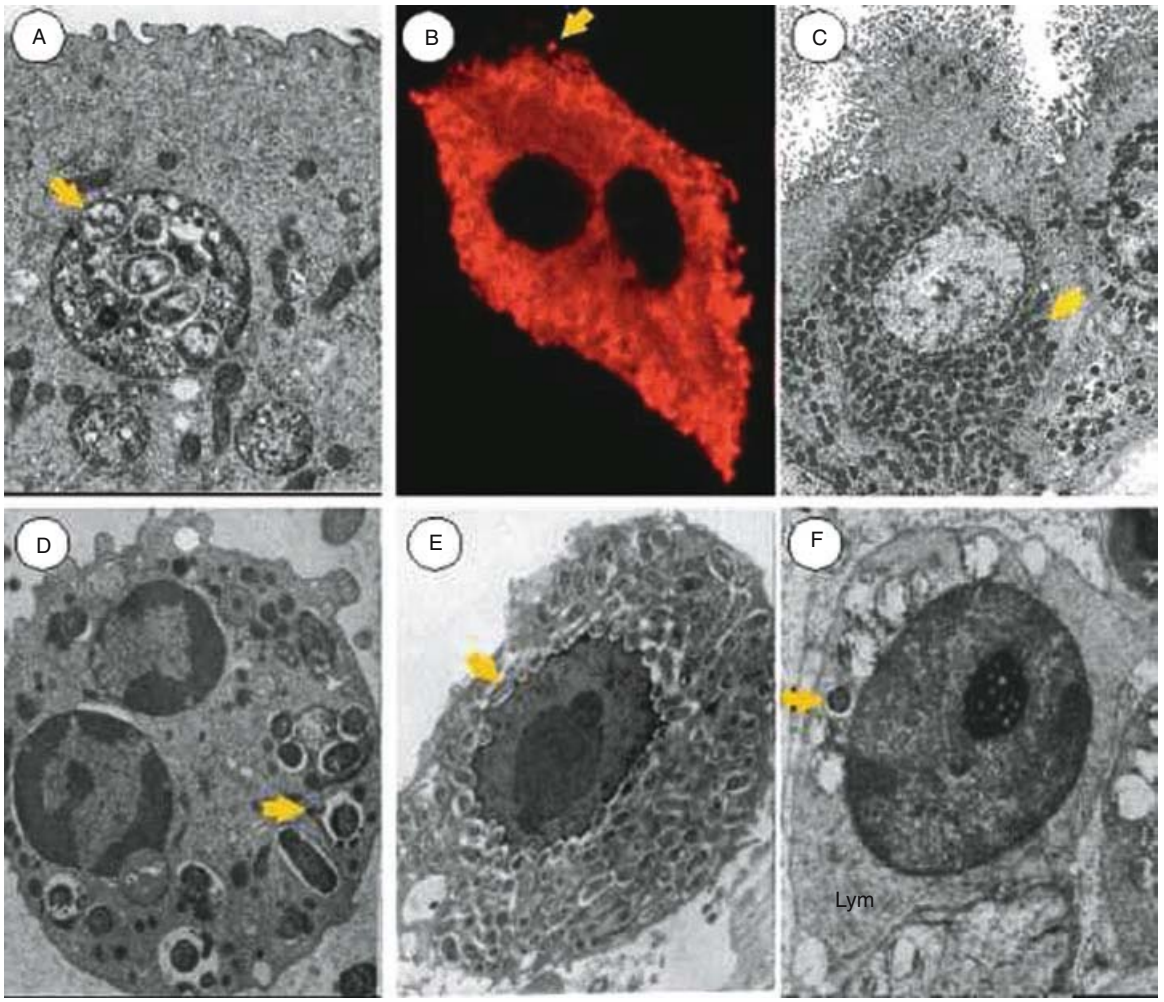

Fig. 30. Intracellular parasitism of *Brucella* in different host cells. Transit of *B. abortus* in caprine M (lymphoepithelial) cells (A); dividing HeLa cell with replicating *B. abortus* (in red) within the endoplasmic reticulum (ER) (immunofluorescence) (B); caprine trophoblast with replicating *Brucella* within the ER (C); human polymorphonuclear leukocyte with intracellular *B. abortus* in phagosomes and phagolysosomes (D); murine macrophage with replicating *B. abortus* within cisterna resembling endoplasmic reticulum (E); and caprine lymphocyte with intravacuolar *B. melitensis* (F). In (A), extracellular material was co-ingested with *Brucella* organisms. Notice in (B, C and E) that the cell nucleus is constrained but not invaded by the replicating brucellae. Notice in (B) that karyokinesis is not inhibited by the replicating brucellae. Notice in (D) that several azurophil granules fuse with phagosomes containing *Brucella*. In spite of the large number of intracellular bacteria the cells do not present signs of apoptosis or necrosis. The arrows indicate a single bacterium within a vacuolar compartment. Panel (A) is from Ackermann et al. (1988), panel (C) from Anderson et al. (1986b), panel (D) from Riley and Robertson (1984a), panel (E) from Jiang and Baldwin (1993b), and panel (F) from Cheville at al. (1996a), all with permission.

endometrium or syncytial epithelium (Fig. 32). Abortion without significant compromise and bacterial invasion of the endometrium or lamina propia are characteristic of this phase. Extensive necrosis promotes diffusion of *Brucella* into different adjacent tissues. Vasculitis with separation of the maternal epithelium promotes fetal death and abortion. Ulcerative endometritis and metritis may occur as a consequence of postparturient infections with opportunistic bacteria. From the clinical point of view, abortion due to brucellosis resembles other infectious diseases, although retention of placental tissues or endometritis seldom occurs in the natural hosts.

Following *Brucella* invasion and depending on the age of the fetus, leukocytosis with significant numbers of neutrophils develops. In ruminants, the infected fetuses demonstrate lymphoreticular hyperplasia of secondary lymphatic organs and extensive granulomatosus centers composed of macrophages, histiocytes, epithelioid cells, gigantic Langerhans cells, extramedullary hematopoiesis and a variable number of polymorphonuclear granulocytes. Liquefaction and

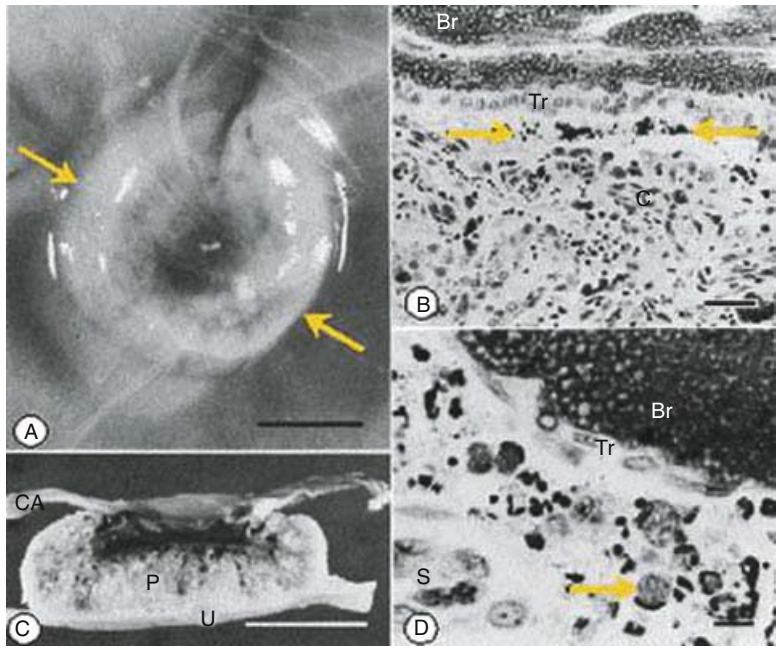

Fig. 31. Pathological examination of placentoma from a pregnant goat infected with *B. abortus*. A) Diffuse chorioallantoic edema (arrows) obscuring view of the placentoma in a goat given 10^9 *B. abortus* cells intravenously and necropsied on postinoculation day 19. White periplacentomal exudate is predominant (arrows). Bar = 1 cm. B) Multifocal abscesses and bacterial colonies of *B. abortus* in the placentoma are observed in the connective tissue of chorionic villi and rimmed by intact trophoblastic epithelium (tr). Exudate (arrows) separates maternal septa (s) and capillaries (c) from the bacteria-filled chorionic villus. Bar = 30 µm. C) Placentoma from a goat that was inoculated in a middle uterine artery with 10^9 *B. abortus* cells and euthanized while aborting on postinoculation day 14. Multiple abscesses and hemorrhages are present in placentomal cross-sections. Uterine wall (u), placentoma (p), chorionic membrane (ca). Bar = 1 cm. Multifocal abscesses and bacterial colonies of *B. abortus* are observed in the placentoma. D) Bacteria-filled phagocytes (arrow) and necrotic cell debris separating maternal septa (s) from trophoblast (tr). Brown-Hopps Gram stain. Bar = 20 µm. From Anderson et al. (1986a), with permission.

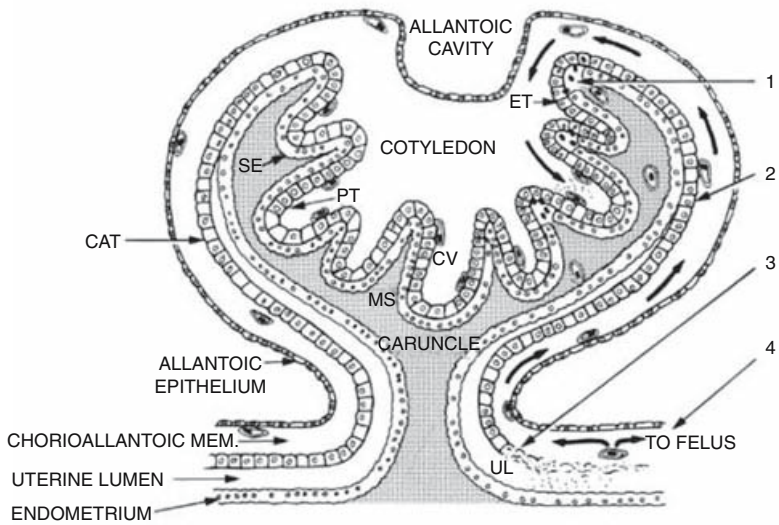

Fig. 32. Diagram summarizing the pathogenesis of placental and fetal infection in a caprine placentoma, as determined in this study. 1) *B. abortus* first seen in phagosomes of erythrophagocytic trophoblasts (ET). 2) Subsequently, *B. abortus* replicates in the rough endoplasmic reticulum of chorioallantoic trophoblasts (CAT). 3) After trophoblast infection, necrosis of chorioallantoic trophoblasts, spewing of *B. abortus* into the uterine lumen (UL), and ulceration of the chorioallantoic membrane occur. 4) Coincidentally, intravascular *B. abortus*, present in placental capillaries, spreads to chorionic villi (CV) and fetal viscera. *Brucella abortus* is not present in placentomal trophoblast (PT), maternal septa (MS), syncytial epithelium (SE), or endometrium. Erythrophagocytic, placentomal, and chorioallantoic trophoblasts form the continuous epithelial sheet that covers chorionic villi of the cotyledon and the chorioallantoic membrane. They are differentiated here, owing to differences in anatomic location, function, and role in *Brucella placentitis*. From Anderson et al. (1986b), with permission.

mineralization of the necrotic zones may occur. Commonly, these reactions are also observed in a variety of fetal organs, such as the liver, lungs and kidney. *Brucella* invasion of the central nervous system is a frequent outcome.

Male Infections In male ruminants, bilateral acute orchitis with extensive irreversible damage is a frequent event (Blasco, 1990; Enright, 1990b). After invasion and bacterial replication, the tunics become distended, and necrotic foci are evident within the testicular parenchyma, with hemorrhagic foci and purulent exudate. Focal necrotizing epididymitis and spermatic granulomas are frequently observed after the initial inflammatory reactions. Seminal vesiculitis and prostatitis are not uncommon. After these episodes caused by *Brucella* infection of the male reproductive tract, partial or total sterility remains as a consequence of the chronic infection. Perivascular edema and infiltration of mononuclear cells and polymorphonuclear leukocytes accompany the initial localization into the tubular tissue. Subsequently, the inflamed tubular epithelium develops papillary hyperplasia and local hydropic degeneration and intraepithelial cysts. Eventual destruction of the epithelium, either by bacteria or by inflammatory reaction, leads to extravasation of the spermatozoa. Complete blockage of the epididymis and testicular degeneration with fibrosis represent the outcome of the chronic infection. Damage of epidydimis and prostate epithelial cells acts as a trigger for the production of autoantibodies to spermatozoa, contributing to the general pathology observed in male organs and one of the mechanisms for causing sterility (Serikawa et al., 1984). *Brucella ovis* is an important cause of epididymitis in rams, and it is less frequently associated with abortions in ewes. Although female ovines are more resistant to the infection than males are, they are important sources of passive venereal transmission to the copulating males. The target organ of *B. ovis* is the epididymis and accessory sexual glands. The pathological signs caused in ram epididymis are similar to those described above.

Brucellosis in Humans Although many of the pathological signs of *Brucella* infection in the natural hosts are reproduced in humans, idiosyncratic differences are found (Spink, 1956; Young, 1983). The outcome of the disease in humans depends on host factors, inoculum size and the *Brucella* strain. In general terms, the most aggressive species for humans is *B. melitensis*, followed by *B. suis* and *B. abortus*, although this tendency is not strictly lined up. For instance, *B. abortus* biotype 5 and *B. suis* biotype 2 seem to harbor low pathogenicity for man. Limited infections have been described with *B. canis*. No human infections caused by *B. ovis*, *B. neotomae* or *B. maris* have been reported. However, human brucellosis caused by the marine strains has been barely explored, owing to the fact that these strains were recently described (Higgins, 2000; Jahans et al., 1997).

The evolution of brucellosis in humans has the tendency to be more dramatic than in the animal reservoir, with no pathognomonic signs or symptoms. The incubation period is highly variable, with the most common interval between one and three weeks. However, longer periods are not uncommon. After invasion of host tissues, the organism multiplies in regional lymph nodes draining the site of entry and gives rise to a bacteremia, which may vary from short duration to intermittent or prolonged times. Normally this event is accompanied by symptoms that resemble in some aspects a strong cold, with clinical features that include undulant fever, chills, weakness, malaise, sweating, headache, backache, muscle joint pain and anorexia. After this period, and following colonization of the reticuloendothelial system, more severe symptoms may arise which cause weight loss, nausea, cough, vomiting, diarrhea, epistaxis and rash. After this, lymphoadenopathy, hepatomegaly, splenomegaly, osteomyelitis, thrombosis and valvular endocarditis may arise. In many cases compromise of the central and autonomous nervous systems may appear as well as compromise of the urogenital organs. Abortion due to *Brucella* infections, with invasion of maternal and fetal tissues, has been reported in a limited number of cases. If nontreated, complications due to *Brucella* occur in about 10% of the cases. These generally involve suppurative abscesses in different organs and tissues. Mortality usually is less than 2%, mainly reduced by antibiotic therapy (Animal Brucellosis). Chronicity with sporadic appearance of symptoms may remain for years. Allergic hypersensitivity is a common consequence of human and animal brucellosis (Díaz and Oyeledum, 1977; Spink, 1956). This is especially important in laboratory workers or medical personnel who may be exposed to *Brucella* organisms or their products (antigens) on a routine basis.

Brucellosis in Experimental Animals In addition to the natural hosts, a number of experimental animal models have been tested including chick embryos, rabbits, rats, hamsters, gerbils, guinea pigs and mice (Garcia-Carrillo, 1990). For many years guinea pigs remained as the preferred model, mainly due to their high susceptibility to *Brucella* infections and the resemblance of the disease with humans and also because these animals were originally used for

isolating *Brucella* organisms from clinical samples. In the last 20 years, guinea pigs have been abandoned, and mice have been established as the preferred animal model. The reasons lay mainly in the economical feasibility of the mouse model, the extensive number of available defined strains, the amenability of mice to genetic manipulation, and the extensive knowledge of the immune system of this murine species. However, mice display a relatively strong innate resistance to brucellosis and may not be the more appropriate model for *Brucella* studies.

Brucellosis in Guinea Pigs In guinea pigs, as few as 50 intraperitoneal or intravenously injected *Brucella* colony forming units (CFU) are required to cause infections, with incubation periods that range from one to three weeks (Ne'eman and Jones, 1963). Although these rodents are susceptible to being infected by oral, conjunctival or respiratory routes, which are estimated to be the most common natural course of infection, safety has prevailed and intraperitoneal, subcutaneous and intramuscular routes are preferred. No major differences have been found between male and female or the various strains of guinea pigs. However, pregnancy seems to be a propensity factor for susceptibility to *Brucella* infection and is an experimental model to demonstrate vertical transmission and abortion. The initial stages of the infection are similar to those described for other animals, including humans (Moulton and Meyer, 1958; Sterba, 1984). After this initial outcome, splenomegaly, hepatomegaly and compromise of the lymphatic tissues are almost invariably observed. Acute and subacute inflammation occurs with exudation of fluids and accumulation of polymorphonuclear leukocytes. As the infection continues, typical granulomatous lesions with the presence of macrophages, histiocytes, epithelioid cells and giant cells surrounded by proliferating lymphocytes occur. In later stages of the infection, fibrosis is detected (Moulton and Meyer, 1958; Sterba, 1984). In males, compromise of urogenital organs can be observed. In pregnant females, compromise of placental and fetal tissue is evident. Although *Brucella* organisms have been detected in the semen and fluids of infected guinea pigs, no horizontal transmission has been demonstrated. After several weeks, the infected guinea pigs demonstrate strong delayed-type hypersensitivity reactions when tested with *Brucella* protein extracts.

Brucellosis in Mice It is estimated that, in general, mice are from 10^3 to 10^6 times more resistant than guinea pigs to *Brucella* infections (Taran and Rybasov, 1972). After intravenous inoculation, *Brucella* organisms are cleared by phagocytic cells of the reticuloendothelial system where the bacteria replicate (Cheers, 1984). In the case of intraperitoneal inoculation, *Brucella* organisms are rapidly cleared by resident phagocytic cells that transport the bacteria to the regional lymph nodes, spleen and liver. Normally during the first stages of the infection, lasting from one to two weeks, there are no manifestations of symptomatic acute brucellosis. However, depending on the size of the inoculum and virulence of the *Brucella* strain, a variable number of organisms are recovered from the spleen, liver and lymph nodes. Following this, replication of *Brucella* rapidly increases until a plateau is reached. This period commonly lasts a few days; then, the number of organisms declines until equilibrium has been established, corresponding to the development of the immune response. In spite of the fact that splenomegaly is maintained and the organisms may be isolated up to three months after the experimental infection, no severe pathological symptoms are developed. Histopathological studies during the replicating and steady phases reveal a focus of chronic inflammatory reactions in the spleen, lymph nodes and liver.

If large quantities of bacteria are inoculated ($>10^6$ per mouse), overloading the innate and immune capabilities, or immunocompromised (hormone- or mucine-treated or genetically immunodeficient) mice are used, granulomas and suppurative infections in different organs are observed, followed by death. In cases where low and moderate numbers of *Brucella* are administered, limited placental colonization and a few vertical bacterial transmissions to the newborn are observed (Bosseray, 1983; Bosseray, 1984). However, injection of large numbers of *Brucella* in pregnant mice results in preferential bacterial replication within placental giant trophoblasts and within the visceral yolk sac endoderm. Despite the anatomical differences in placentation between ruminant and rodent (epithelial versus hemochorial) placental damage, fetal infection and fetal death occurs (Tobias et al., 1993), but in contrast to what is observed in the natural hosts, pregnant mice are relatively more resistant to abortion and fetal death.

Outcome of the Disease and Self Cure In the natural host, the immune system generally gains control of the infection a few weeks after the appearance of the symptoms (Enright, 1990b; Nicoletti and Winter, 1990b). However, some bacteria may remain in reproductive organs, mammary gland, bones and joins for prolonged periods. Some of the primary infected hosts, therefore, may remain as healthy shedders and of epidemiological importance. In contrast, in the accidental hosts, the bacteria are dispersed

into different tissues, causing a severe disease with no shedding and in consequence of medical but not epidemiological importance (Alton, 1990a, 1990b; Spink, 1956). In nontreated accidental hosts, such as horses or humans, hepatic involvement in the form of acute diffuse hepatitis with focal necrosis, generation of granulomas, and the compromise of lymphatic organs is a common event of chronicity.

Both symptomatic and asymptomatic animals can transmit brucellosis, which means that many of the infected individuals shed the bacteria independently of being ill or healthy. After abortion, infection commonly recedes and self-cure proceeds, which is the most frequent outcome in the natural host (Enright, 1990a). Some bovines are naturally resistant to brucellosis, which is related to the ability of their macrophages to kill *Brucella* organisms intracellularly (Price et al., 1990; Templeton and Adams, 1990). Moreover, calves, kids and lambs may remain without clinical signs, in spite of drinking milk containing millions of *Brucella* secreted in the udder by their infected mothers. A low proportion of these infected animals at a young age may abort later in life; however, many remain infected but asymptomatic, demonstrating a good equilibrium between the *Brucella* invader and the host. Furthermore, several of the infected animals which acquired *Brucella* by vertical transmission, in addition to being asymptomatic, do not display positive serology (Fig. 9), suggesting anergic immune responses. Other individuals, mainly secondary hosts, may remain allergic for life after cured (Spink, 1956).

Pathobiology

After invasion of host tissues, *Brucella* binds and penetrates cells. Once inside, the bacterium is protected from extracellular microbicidal substances and the new life cycle begins. Intracellularly, *Brucella* traffics and replicates within vacuolar compartments, avoiding digestive mechanisms of cells by means of virulence factors that allow the bacterium to control its cellular environment for its own benefit. The complexity of these bacterial mechanisms and the cross-talk between the host cell on one side and the *Brucella* parasite on the other are just being unrevealed. Comprehensive reviews on these topics can be found elsewhere (Baldwin and Winter, 1994; Liautard et al., 1996; Pizarro-Cerdá et al., 1997; Pizarro-Cerdá et al., 1999b; Pizarro-Cerdá et al., 2000).

Brucella Invades Healthy Hosts It is known that some bacterial pathogens rapidly gain access to the internal host tissues by penetrating specialized epithelial cells. The penetration of invasive bacteria requires the interaction of specific receptors and ligands between the animal and bacterial cells that trigger the internalization and the transference of the pathogen inside the body (Van Nhieu and Sansonetti, 2000). The primary routes of *Brucella* infection are the cells of mucosal surfaces (Enright, 1990b). In goats, *B. abortus* laying in the ileum is ingested by M cells using a zipper-like mechanism but not by enterocytes (Ackermann et al., 1988; Fig. 33). In these phagocytic cells, the ingested bacterial organisms are located as single entities or in small clusters, within transient vacuoles that do not show signs of lysosomal fusion. The phagocytic vacuolar membrane does not associate with ribosomes, and some of the *Brucella*-containing compartments demonstrate coingested opaque material. The engulfed *Brucella* are eventually translocated by M cells to the gastrointestinal-associated lymphatic space, where they are taken up by macrophages and neutrophils (Ackermann et al., 1988; Fig. 33). The numbers of intracellular *Brucella* in M cells decrease with time after bacterial inoculation, indicating that microorganisms are steadily translocated. After penetrating mucosal layers, both virulent and vaccine *B. abortus* strain 19 strains induce an inflammatory response in the submucosa (Cheville et al., 1992).

It has been demonstrated that urease-negative *B. abortus* mutants are virulent when injected intraperitoneally in mice (Grillóet al., 1997). Wild type and urease-deficient mutants also show the same sensitivity to acid. However, when urease-deficient mutants are administered by the oral route, the numbers of bacteria recovered in the intestine or in the spleen are considerably lower than those of the wild-type strain. As in the case of Ureaplasma or *Helicobacter pylori*, in which urease plays a relevant role in the colonization of the host cells (Cover et al., 1991), it may be that in *Brucella* this enzyme also participates in modifying the immediate local acid environment (Salyers and Whitt, 1994; Sangari et al., 2000). This is an important aspect that must be taken into consideration because the intestine seems to be the most frequent route for invading the primary and secondary hosts through ingestion of milk and dairy products as well as through licking of the aborted fetus or contaminated secretions.

Survival Outside Host Cells *Brucella* are organisms whose ultimate goal is to propagate inside cells (Habitat). Therefore, when released to the extracellular lumen, these pathogens are deprived of their shelter and natural replicative niche and subjected to the attack of a variety of bactericidal substances present in the plasma and body fluids, against which they must defend. The blood, pulmonary secretion, tears, intestinal flu-

C) *Brucella* is found within macrophages (M) and neutrophils (PMN) and also between the base (arrows) of M cells from ileum cells (L) at two hr postinoculation. Abundant apical mitochondria are seen in the M cells (arrow head). From Ackermann et al. (1988), with permission.

ids, milk and colostrum contain substances that participate in protecting the body against bacterial invasion (Opsonization and Complement Susceptibility). In addition, *Brucella* discharged in the inflammation site is exposed to the local attack of molecules released by leukocytes, such as those present in the azurophilic and secondary granules. In general, it has been demonstrated that *Brucella* is capable of resisting the microbicidal action of soluble substances released by cells (Modulation of Neutrophil Function and Resistance of Bactericidal Secretions). Despite that, there is not a complete picture of how this is achieved. Various properties, mainly related to the structure and function of the *Brucella* outer-membrane, have been implicated in the resistance of *Brucella* to humoral substances (Properties of the Outer Membrane).

Opsonization and Complement Susceptibility
Work carried out mostly with *B. abortus*, *B. melitensis* and *B. suis* has identified several features of these bacteria which are relevant for parasitism (*Brucella* Virulence Mechanisms). It is becoming clear that some of these bacterial properties are modulated by the interaction between antibodies and complement with the *Brucella* cell surface molecules. Indeed, opsonized bacteria stimulate the oxidative burst and the intracellular killing mechanisms in a higher proportion than that in nonopsonized *Brucella* (Caron et al., 1994b; Harmon et al., 1987; Harmon et al., 1988; Jiang and Baldwin, 1993a; Jiang et al., 1993c; Kreutzer et al., 1979b; Young et al., 1985). The *O*-polysaccharide makes *B. abortus* more resistant to complement-mediated killing in the presence of *O*-polysaccharide-specific antibody (Corbeil et al., 1988). It is feasible to hypothesize that evasion of opsonization and complement lysis constitute adaptive survival mechanisms employed by *Brucella* organisms.

Animals infected with smooth *Brucella* characteristically generate a strong antibody response against smooth LPS and NH polysaccharides (Díaz-Aparicio et al., 1993; Marín et al., 1999; Fig. 19). The NHs are LPS-independent molecules intertwined with the *O*-polysaccharide in the outer-membrane (Aragón et al., 1996b; Fig. 20). Part of their function is to increase the density of O-type polysaccharides

on the cell surface, creating a protective layer that prevents the binding of antibodies and the interaction of lytic complement with the deeper structures of the outer-membrane (Aragón, 1996a; Fig. 20). It has been demonstrated that with the exception of core and lipid A determinants, all the other epitopes of smooth LPS are present in the NH (Aragón et al., 1996b; Moreno et al., 1987). Therefore, it is not surprising that practically all infected animals with smooth *Brucella* strains develop similar levels of antibodies to NH and to the *O*-polysaccharide of the LPS; however, a proportion of the same animals do not develop detectable antibodies against core or lipid A determinants (Fig. 34). Despite this, the reaction of these molecules differs regarding the antibody-mediated complement activation. In sharp contrast with smooth LPS, the antibodies bound to NH are poor consumers of complement component C3b (E. Moreno and I. Moriyón, unpublished observations). The failure of NH molecules to activate complement may be due to subtle differences in the degree of formylation between the smooth LPS *O*-polysaccharide and NH, rather than in the absence of core and lipid A, in the latter (M. Staaf et al., unpublished observations). Indeed, absorption assays performed to remove antibodies against core and lipid determinants showed that complement activation by smooth LPS could not be due to antibodies against these moieties.

Abundant surface C3b receptors promote phagocytosis in activated macrophages (Wright and Silverstein, 1983). Reduced C3b opsonization could help to avoid ingestion by those cells in which brucellae would have a reduced chance of survival. Although NH mostly binds immunoglobulin G (IgG; Díaz-Aparicio et al., 1993), and macrophages bear Fcγ receptors, reduced C3b opsonization could be important at the onset of the infection when the predominant antibodies are IgM. At this time, *Brucella* could penetrate phagocytes by interaction of the smooth LPS and NH with the mannose-fucose receptor without triggering the production of toxic oxygen derivatives, as has been pointed out before (Campbell et al., 1994). This opsonin-independent route of entry could represent a strategy suitable for an intracellular pathogen because *B. abortus* cells either nonopsonized or opsonized with nonimmune serum fail to induce a significant oxidative burst in bovine polymorphonuclear leukocytes (Canning et al., 1988).

Modulation of Neutrophil Function and Resistance of Bactericidal Secretions Although *Brucella* organisms are moderately resistant to acid (Teixeira-Gomes et al., 2000), they display a strong resistance to bactericidal proteins normally found in secretions, such as lysozyme, lactoferrin, lytic complement, chelating substances, proteolytic enzymes, phospholipase A2, defensins and defensin-like molecules, as well as to a variety of substances released by leukocytes during inflammation (Martínez de Tejada et al., 1995; Páramo et al., 1998; Riley and Robertson, 1984a). This resistance is related to the *Brucella* outer-membrane structure (mainly the LPS and

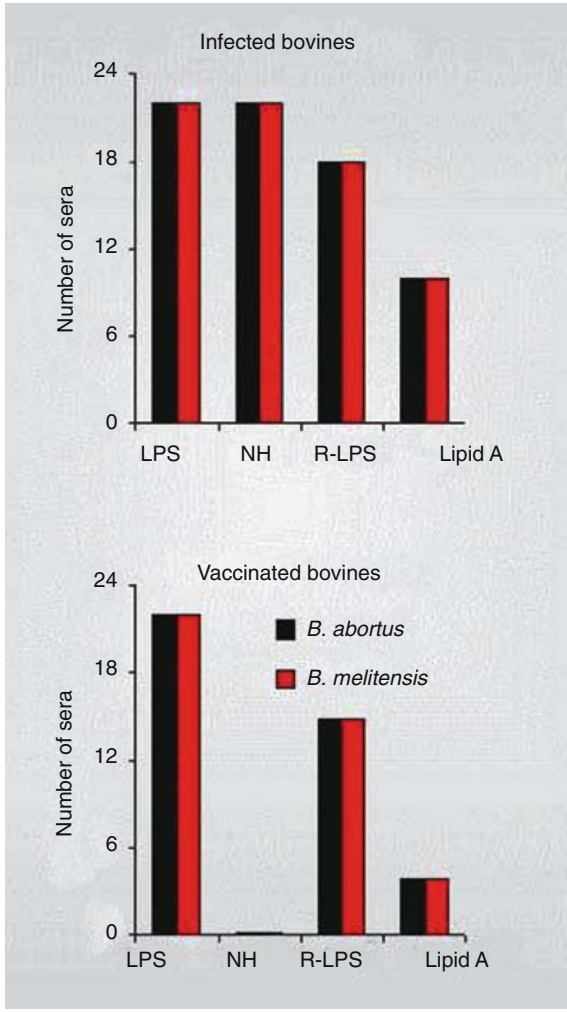

Fig. 34. ELISA and radial immunodiffusion (RID) representing the IgG reactivity of *B. abortus* S19 vaccinated or *B. abortus* (biotype 1) naturally infected cows against smooth LPSs, rough LPSs, NHs and lipid as from *B. abortus* (biovar 1) and *B. melitensis* (biovar 1). Independent of the antigen attached (*B. abortus* or *B. melitensis*) to the ELISA plate or the NH used in the RID analysis, results are the same for both types of antigens. ELISA optical density values for *B. abortus* and *B. melitensis* antigens did not vary more than 5% in three different runs. RID was qualitatively evaluated as positive or negative. Notice that vaccinated animals do not react against NH, while infected animals do. Compare to (Fig. 19). The relevant epitopes in these reactions are the overlapping common epitopes in both *B. abortus* and *B. melitensis* antigens.

polysaccharide molecules), which from the chemical and functional point of view constitutes an excellent shelter for resisting the assault of these bactericidal mediators (Kreutzer and Robertson, 1979a; Martínez de Tejada et al., 1995). In addition to this natural resistance, *Brucella* cells or extracts obtained from these organisms do not significantly induce the exocytosis of neutrophil granules (Canning et al., 1986; Kreutzer et al., 1979b), suggesting functional modulation of these cells. Indeed, *Brucella* LPS does not stimulate the degranulation, respiratory burst or lysozyme release from neutrophils (Rasool et al., 1992). Moreover, GMP- and adenine-containing *Brucella* extracts have been proposed to inhibit neutrophil degranulation (Canning et al., 1986). This last result, however, must be considered from the perspective that killed *Brucella* do not inhibit digestion by phagocytic cells.

Brucella Binds and Penetrates Host Cells

Very few clear-cut studies have addressed the question of the mechanisms by which *Brucella* binds to and penetrates cells. Similarly to other pathogens (for review, see Méresse et al., 1999; Pizarro-Cerdá et al., 1997; Pizarro-Cerdá et al., 2000), *Brucella* organisms may have developed specialized microbial structures to gain access to host cytoplasmic compartments. In nonprofessional phagocytic epithelial cells, *Brucella* may induce its own uptake, since certain mutant bacteria are poorly internalized by the inoculated monolayers (Sola-Landa et al., 1998). Compared to other intracellular Proteobacteria, such as *Salmonella*, *Shigella* or *Legionella*, surprisingly low numbers of virulent *Brucella* bind to the surface of naive professional and nonprofessional phagocytes (Pizarro-Cerdá et al., 1998b; Pizarro-Cerdá et al., 1998c; Sola-Landa et al., 1998). Despite this low attachment of virulent *Brucella*, their efficiency of penetration is close to 100%. As early as five minutes after infection, *B. abortus* is found within vacuoles of cells. Electron micrographs of *Brucella* penetrating cells have shown that phagocytosis can occur via a zipper mechanism (Ackermann et al., 1988; Pizarro-Cerdá et al., 1999a; Fig. 33) or alternatively by a slow process resembling capping with little cell membrane rearrangements (Guzmán-Verri et al., 2001).

Interaction with the Host Cell Membrane

Sequences coding for putative proteins similar to those necessary to build flagella have been identified in the *Brucella* genome (DelVecchio et al., 2002; Sánchez et al., 2001; O'Callaghan et al., 1999), but none of these structures have ever been observed in *Brucella* cells, precluding their participation as attachment molecules. Alternatively, the involvement of nonfibrillar adhesins remains open, since sequences compatible with these protein molecules have been discovered in *Brucella* (DelVecchio et al., 2002; Ugalde, 1999; http://www.genome.scranton.edu.WIT2; www.tigr.org).

Various studies have reported that nonvirulent smooth and rough *Brucella* mutants bind more readily and in larger amounts to the surface of professional and nonprofessional phagocytes than virulent strains do (Detilleux et al., 1990a; Detilleux et al., 1990b; Sola-Landa et al., 1998). However, there is not a strict direct correlation between the expression of *O*- and NH polysaccharides and binding to cells (Freer et al., 1999; Pizarro-Cerdá, 1998a). For instance, the virulent smooth *Brucella* and the "natural" rough *B. ovis* and *B. canis* (not expressing *O*-polysaccharide or NH) bind in very low number to HeLa cells. In contrast, the perosamine synthetase (perA) rough *B. abortus* mutants (not expressing *O*-polysaccharide or NH molecules) and the spontaneous rough *Brucella* mutants bind to these cells in much higher numbers than do smooth brucellae (Freer et al., 1999). Although difficult to interpret, the fact is that virulent *Brucella* cells have the tendency to attach in lower numbers to cultured epithelial cells than nonvirulent bacteria do (Fig. 21).

The host cytoplasmic membrane directly adjacent to rough *Brucella* mutants is frequently thicker than the cell membrane adjacent to smooth bacteria and occasionally forms coated-pits (Detilleux et al., 1990a). These observations, although interesting, may not reflect the real physiological interactions between virulent smooth organisms and their host cells, since coated-pits adjacent to smooth *Brucella* have not been seen during phagocytosis. In contrast, increased adherence displayed by many mutant *Brucella* seems to be the result of altered outer-membrane properties, which expose "new" sites for attaching in a nonphysiological manner (Allen et al., 1998; Corbeil et al., 1988; Detilleux et al., 1990a, 1990b; Freer et al., 1999). It is known that polysaccharide moieties in the outer-membrane hide hydrophobic and ionic charges on the surface of the bacteria (Fig. 20) that obstruct membrane domains capable of participating in the nonspecific interactions between *Brucella* and the host cells (Aragón et al., 1996b). In addition, the absence of surface *O*-polysaccharide and NH exposes core sugars to the external surface and gives more access to Omps, which may serve as ligand sites (Bowden et al., 1995; Cloeckaert et al., 1990).

Invasion of Professional Phagocytes

A scheme showing the binding, penetration and replication

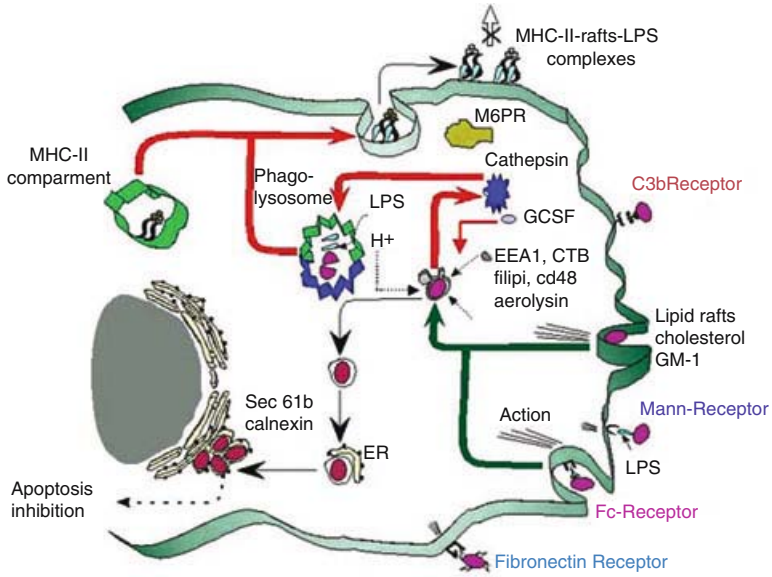

Fig. 35. Schematic model of *B. abortus* invasion and intracellular trafficking in macrophages. *Brucella* organisms bind to discrete sites via receptor molecules (FcR, C3bR, MannR, and fibronectin), some of which are unknown. *Brucella* penetrates by a zipper-like phagocytosis with moderate recruitment of actin filaments. The ingested bacterium initially follows its route (thick green arrows) to early phagocytic compartments (marked by EAA1) which may be acidified (H^+) by acquisition of specific proton pumps (dotted arrows). Granulocyte colony-stimulating factor (G-CSF) is involved in promoting fusions between endocytic vacuoles and phagosomes (dotted arrows). In macrophages, most of the brucellae are routed (thick red arrows) to fuse with lysosomes (marked by cathepsin D and LAMP1) generating phagolysosomes where they are destroyed, whereas only a few bacteria follow the route (black thin arrows) to their replicating niche inside the endoplasmic reticulum (marked by Sec61β) following the autophagocytic (marked by Sec61β and LAMP1) pathway. The released LPSs merge with MHC-II compartments and the complexes MHC-II-LPS are transported to the cell membrane, inhibiting antigen presentation (crossed white arrow). Inhibition of apoptosis is induced in both infected and noninfected phagocytic cells (broken arrow). Steps indicating endoplasmic reticulum recruitment and *Brucella* replication within the endoplasmic reticulum have been adapted from unpublished results from Jean Celli of the CIML-Marseille-Luminy, France.

cycle of smooth *Brucella* in macrophages is presented in Fig. 35. *Brucella* cells bind to and penetrate more efficiently professional than nonprofessional phagocytes. Still, the number of *Brucella* organisms associated to the former cells is comparatively much lower (from one to four logs) than the numbers observed with other intracellular Proteobacteria, such as *Salmonella*, *Shigella* or *Legionella*. There are differences in the binding and internalization of *Brucella* by phagocytic cells (Pizarro-Cerdá, 1998a). Concomitantly, opsonized *Brucella* cells attach and are more readily ingested by phagocytes than are nonopsonized cells. This phenomenon is more clearly observed with activated than with non-activated professional phagocytes (Arenas et al., 2000; Eze et al., 2000; Gross et al., 1998; Harmon et al., 1988; Young et al., 1985). As in the case of *Mycobacterium* (Schorey et al., 1997), it may be that highly opsonized *Brucella* (prozone effect) could take advantage of phagocytosis by Fc or complement receptors to invade cells expressing these receptors. However, opsonization seems to negatively affect the rate of survival and multiplication of *Brucella* within phagocytes, suggesting that Fc or complement receptor-mediated phagocytosis works in favor of the host cells rather than the bacteria (Caron et al., 1994b; Gross et al., 1998; Harmon et al., 1988; Harmon et al., 1989). *Brucella* LPS and NH do not activate the alternative complement pathway (Moreno et al., 1981; Hoffmann et al., 1984). Therefore, these polysaccharides do not serve as direct attachment of C3b on the bacterial surface. The fact that nonopsonized *Brucella* organisms bind, penetrate and reproduce in vivo and in vitro within phagocytes from nonimmunized animals (Campbell et al., 1994; Gross et al., 2000; Kuzumawati et al., 2000; Sola-Landa et al., 1998) indicates the existence of a receptor-ligand mechanism independent from the Fc and complement receptors.

The exclusion of membrane negatively charged groups on the site of *Brucella* attachment in macrophages, followed by zipper-like phagocytosis, suggests specific interactions between both types of cells (Gay et al., 1981). Lipid rafts rich in cholesterol, glycosylphosphati-

dylinositol and GM1 gangliosides seem to provide a port of for *Brucella* entry into murine macrophages under non-opsonic conditions (Naroeni and Porte, 2002; Watarai et al., 2002). *Brucella* organisms (either opsonized or nonopsonized) are rapidly internalized by murine macrophages and human monocytes after inducing recruitment of actin filaments without generating marked structural changes but a general membrane ruffling (Gay et al., 1981; Kuzumawati et al., 2000; Watarai et al., 2002). Penetration of *Brucella* into bovine mononuclear phagocytes is inhibited by bacterial cell envelopes, antibody against the α chain of the MAC-1 integrin (CD11b), *O*-polysaccharide and denatured IgG, no matter whether the cells originated from cattle naturally resistant or susceptible to brucellosis. In addition, fibronectin, mannan and antibodies against C3 also inhibit the penetration of nonopsonized bacteria to phagocytes from brucellosis-resistant cattle (Campbell et al., 1994). Since the *O*-polysaccharide of LPS and mannan inhibit the binding of *Brucella* to bovine macrophages, it is likely that lectin-like receptors on the surface of phagocytic cells participate in the *Brucella* uptake. This idea also is supported by the observation that the strong binding of *Brucella* onto murine B lymphocytes is inhibited by α-methyl mannosamine and LPS (Lee et al., 1983). In addition, it has been demonstrated that phagocytosis of *Brucella* by macrophages is accompanied by secretion of fibronectin, which is then detected inside the phagocytic vacuole (Gay et al., 1986). Since fibronectin also blocks the invasion by *Brucella*, it is likely that this fibrous matrix protein could participate in the binding and penetration of *Brucella* in macrophages. Moreover, the intravacuolar fibronectin contributes to the electron-dense material that is commonly seen surrounding the phagocytosed brucellae, suggesting that this protein is coingested with the bacteria (Gay et al., 1981; Gay et al., 1986).

Invasion of Non-Professional Phagocytes A model showing the penetration and intracellular cycle of *Brucella* within nonprofessional phagocytic HeLa cells is presented in Fig. 36. As expected, immune or native sera are not necessary for invasion of *Brucella* species into nonprofessional phagocytes (Anderson and Cheville, 1986a; Anderson and Cheville, 1986b; Anderson et al., 1986c; Detilleux et al., 1990a; Detilleux et al., 1990b; Pizarro-Cerdá et al., 1999b). In HeLa cells, *B. abortus* attaches to cellular extensions that are compatible with adhesion plaques and between cell-to-cell contacts and penetrates by a zipper-like mechanisms or by capping-like mechanisms with moderate rearrangement of the cell membrane (Guzmán-Verri et al., 2001). Some of these observations have been performed in HeLa cell monolayers previously intoxicated with *C. difficile* toxins B [TcdB] and BF [TcdBF] and then infected with *Brucella*. The TcdB-intoxicated cells retract their body, leaving cellular spikes attached to the substrate. In contrast, TcdBF induces cell rounding and retraction of cellular spikes from the substratum. *Brucella* organisms attach in normal numbers to the cellular spikes of TcdB-treated cells. On the contrary, in TcdBF-intoxicated cells, *Brucella* organisms bind only in reduced numbers, and when binding occurs, the bacteria locate on the cellular body. It has been proposed that α5β1 integrin mediates the adhesion of rough mutant *B. abortus* RB51 to bovine trophoblasts (Bress et al., 1996). However, this observation has not been reproduced in HeLa cells in spite of the highly adherent nature of mutant rough *Brucella* to cells and inert substrates (Pizarro-Cerdá, 1998a). Uptake of killed or alive *Brucella* by Vero cells is suppressed by inhibitors of energy metabolism (iodoacetate and dinitrophenol), inhibitors of receptor-mediated endocytosis (monodansylcadaverine, amantadine and methylamine) and by repressors of endosomal acidification (chloroquine, ammonium chloride and monensin). These drugs are capable of inhibiting penetration when added at the same time as the bacterial inoculum (8 h), but not when added after the inoculation period, suggesting that the infection process occurs via receptor molecules and requires energy input from the host cell (Detilleux et al., 1991).

The participation of the cytoskeleton, second messengers and GTPases in the internalization of *B. abortus* to HeLa cells has been recently investigated (Guzmán-Verri et al., 2001). Phalloidin staining has revealed a modest recruitment of actin filaments in the site of *Brucella* attachment. Inhibition of actin filaments by drugs (Detilleux et al., 1991; Pizarro-Cerdá, 1998a; Guzmán-Verri et al., 2001) or by different clostridial toxins (TcdB, TcdBF, TcdA, and TcsLT) functionally modifying the actin cytoskeleton through interaction with small GTPases of the Rho family hampers internalization but not binding to cells (Guzmán-Verri et al., 2001). Infection also is inhibited by chemicals and toxins that increase the levels of cyclic-AMP (dibutyl-cyclic-AMP and *Vibrio cholerae* enterotoxin), but it is stimulated by toxins and chemicals that increase the levels of cyclic-GMP (*Escherichia coli* enterotoxin A and dibutyl-cyclic-GMP). This suggests an inverse relationship between these two second-messengers during *Brucella* infection. Similarly, wortmanin (which inhibits the PIP3 kinase) considerably reduces the internalization of *Brucella* by HeLa cells, suggesting involvement of PIP3-kinase

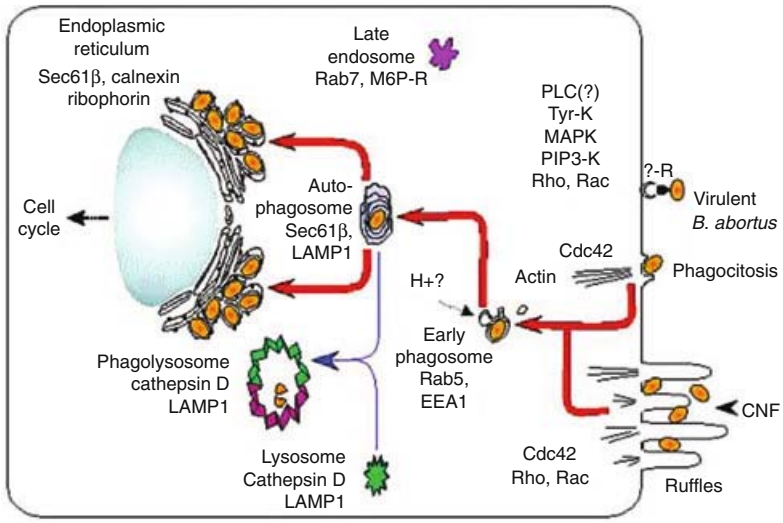

Fig. 36. Schematic model of *B. abortus* invasion and intracellular trafficking in epithelial HeLa cells. *Brucella* organisms bind to discrete sites of cells via unknown receptor molecules (???-R) and penetrate by a discrete phagocytosis with moderate recruitment of actin filaments, activation of small GTPases (Cdc42, Rac, and Rho), mainly Cdc42, and signals mediated by second messengers (Tyr-K, MAP-K, and PIP3-K). The ingested bacterium is initially routed (green arrows) to early phagocytic compartments (marked by Rab5 and EEA1) which may be acidified (H^+) by acquisition of specific proton pumps (dotted arrows). In HeLa cells most of the ingested virulent brucellae are routed (thick red arrows) to the endoplasmic reticulum by the autophagocytic route (marked by LAMP1 and Sec61β), whereas only a few bacteria are directed (thin black arrows) to phagolysosomes. Some mutants (BvrS/BvrR) are defective in penetration (crossed arrow), others cannot avoid fusion of early phagosomes with lysosomes (BvrS/BvrR, VirB1-VirB10, and *cgs*), whereas others transit from autophagosomes to phagolysosomes (S19) or from early phagosomes to the cell membrane (nonpolar VirB10; blue thick arrow). Signals for apoptosis inhibition may be released from the *Brucella* replicating niche.

phosphorylation during this process (Guzmán-Verri et al., 2001). Since the level of cyclic GMP usually increases when the inositol phospholipid pathway is activated, it is likely that binding of *Brucella* to cells also stimulates the generation of IP3 via phospholipase C activation. Other cellular kinases, such as tyrosine kinases and MAP kinases, seem to be required for physiological internalization to HeLa cells, since inhibition of these enzymes hampers bacterial penetration (Guzmán-Verri et al., 2001).

Brucella abortus attaches in larger numbers and is internalized more efficiently after intoxication of HeLa cells with the cytotoxic necrotizing factor (CNF), which deamidates the small GTPases Rho, Rac, and Cdc42 and induces ruffles and stress fiber formation (Guzmán-Verri et al., 2001). In these cells, *Brucella* organisms bind to the ruffles as well as to discrete sites and penetrate through these structures. Moreover, HeLa cells transfected with constitutive negative mutant plasmids expressing defective Rho, Rac and Cdc42 proteins are considerably less infected than control cells. On the contrary, the positive counterparts of these small GTPases expressed in HeLa cells stimulate binding and penetration of *Brucella*. Virulent *Brucella* selectively stimulates the generation of Cdc42 GTPase, reaching its maximum at 30 minutes after bacterial contact with cells. This property may be related to an Omp of group 3, more likely Omp3a (Omp25) and/or Omp3b. This is supported by the fact that the nonvirulent *B. abortus* BvrS mutant does not stimulate any of the GTPases, in spite of its binding to cells (Guzmán-Verri et al., 2001). Microtubule depolymerizing agents, such as nocodazole and colchicine, partially reduce the internalization but not the replication of *Brucella* in HeLa cells (Guzmán-Verri et al., 2001). This strategy for invading cells differs from those employed by other intracellular pathogens, such as *Salmonella* and *Shigella*. Despite the obvious differences between *Brucella* and *Listeria*, both types of pathogens seem to employ very similar strategies (Finlay and Cossart, 1997a).

Brucella Traffics and Replicates Within Host Cells

Brucella organisms have been found to survive and replicate within membrane-bound compartments of professional and non-professional phagocytes (Fig. 30). Despite the tropism of these pathogens for reproductive organs, the bacteria also localize within cells of various tissues at later stages of the infection (Enright, 1990b). In vivo, *B. abortus* has been

described within bovine, caprine and murine trophoblasts, in caprine lymphocytes, M cells, and chicken embryo fibroblasts, as well as in a number of professional phagocytes lining different tissues (Ackermann et al., 1988; Anderson and Cheville, 1986a; Anderson et al., 1986c; Anderson et al., 1986b; Cheville et al., 1992; Cheville et al., 1996a; Detilleux et al., 1988; Holland and Pickett, 1956; Richardson and Holt, 1964). In vitro, *B. abortus* has been described to replicate within vacuoles of hamster kidney cells (Hatten and Sulkin, 1966a; Hatten and Sulkin, 1966b), primary cultures of bovine adult and fetal cells (Richardson and Holt, 1964), and a number of epithelial cells and macrophages (Baldwin and Winter, 1994; Caron et al., 1994b; Detilleux et al., 1990a, 1990b; Liautard et al., 1996; Pizarro-Cerdá et al., 1998b; Pizarro-Cerdá et al., 1998c; Sola-Landa et al., 1998). Among the nonprofessional phagocytes, epithelial HeLa and fibroblastic Vero cell lines have been the most extensively used for studying *Brucella* replication and intracellular trafficking. Among professional phagocytes, murine J774, murine peritoneal macrophages, human monocytes, bovine mammary gland macrophages and human neutrophils have been the most widely used cells.

M cells, neutrophils, nonactivated macrophages from newly infected hosts, activated macrophages from immune animals and nonprofessional phagocytes all serve a different purpose during the course of *Brucella* infection. While the translocation of ingested *Brucella* organisms occurs through M cells, the first line of defense against *Brucella* invasion is secured by neutrophils, short-lived cells with a strong capacity to phagocytize (Ackermann et al., 1988). Although neutrophils are not the preferred niche for *Brucella* replication, some of these intracellular bacteria are capable of withstanding destruction inside these leukocytes (Kreutzer et al., 1979b; Young et al., 1985). In turn, this event may favor the spreading of the parasite from neutrophils to other tissues (Ackermann et al., 1988; Enright, 1990a). In the second line of defense are the macrophages, which, like neutrophils, can destroy an important proportion of the ingested *Brucella* but may also serve as substrate for *Brucella* replication as well as vehicles for transportation to other tissues. In the pregnant animal, *Brucella* invades the erythrophagocytic trophoblasts, which are the preferred replicating host cells and the site from which the bacteria spread to the fetus (Anderson et al., 1986b; Anderson et al., 1986c; Tobias et al., 1993). Generally, immune individuals are capable of controlling the infection via stimulation of the macrophagic system. Depending upon the animal species, the humoral response may serve as an important aid for phagocytosis and for conducting the intracellular route of the phagocytosed bacteria to destructive compartments.

Important findings revealing the interaction between *Brucella* parasites and their cells have been established. At the molecular level, the information is still incomplete and analysis of the bacterial factors and cellular receptors involved in the invasion process is necessary to understand the downstream steps observed during internalization and intracellular transit. Physical isolation and molecular examination of the different *Brucella*-containing compartments are necessary for the identification of the molecules that play a role in the original trafficking exhibited by this parasite.

Survival Within Polymorphonuclear Neutrophils Neutrophils are the primary line of defense during *Brucella* invasion. These cells are capable of ingesting and killing *Brucella* faster and more efficiently than other cells are (Kreutzer and Robertson, 1979a; Riley and Robertson, 1984a; Riley and Robertson, 1984b). After incubation with neutrophils, virulent *Brucella* organisms are steadily destroyed. From 50 to 80% of the ingested bacteria are killed within 2 to 5 hours (Riley and Robertson, 1984a). This microbicidal activity seems to be more efficiently performed when bacteria are opsonized (Canning et al., 1988; Young et al., 1985). Once ingested, the bacteria are found within vacuoles, some of which already demonstrate fusions with lysosome-like granules (Figs. 30 and 33). At later times, fusions of azurophilic granules increase in most but not all *Brucella*-containing vacuoles. These events proceed without extensive neutrophil degranulation (Riley and Robertson, 1984b). Exudates from lesions, milk and blood from infected animals demonstrate *Brucella* within resident neutrophils with no signs of replication (Ackermann et al., 1988; Tobias et al., 1993). It seems that some intracellular bacteria are capable of resisting for several hours or even for days the microbicidal assault displayed by neutrophils, which in time may release live bacteria on sites where they could invade more temperate host cells (Ackermann et al., 1988).

Life Within Non-professional Phagocytes The initial number of *Brucella* cells per infected epithelial Vero or HeLa cell is low, with one or two bacteria per cell (Detilleux et al., 1990a, 1990b; Pizarro-Cerdá et al., 1998c; Pizarro-Cerdá et al., 1998b; Fig. 21). Even if the bacterial inoculum is augmented in several logs, the rate of infection per cell remains low, suggesting that not all cells are permissive (Sola-Landa et al., 1998). Despite this, once the brucellae bind, the penetration efficiency is close to 100%. Immediately after phagocytosis, *Brucella* organisms localize within

single membrane compartments generally containing only one bacterium. During the first hours (1–5), no clear signs of intracellular bacterial replication are demonstrated, and the rate of cellular infection remains relatively constant for the next 5–8 hours. After 24–48 hours, the number of infected cells may decrease down to one half, depending on the concentration of antibiotic in the culture media, suggesting that at early stages phagosomes containing *Brucella* may converge with readily pinocytosed vacuoles from the constitutive endocytic route. The number of bacteria, estimated as CFU, increases several logs from the initial inoculum, indicating extensive bacterial replication within the cytoplasm of infected cells. Although many cells possess a large number of intracellular bacteria, the cell monolayers do not show signs of cytopathic effect and the individual cells remain attached to the matrix. A small proportion of cells contain a low number of *Brucella* (1–50) with no signs of bacterial degradation, while fewer of them demonstrate bacterial debris within phagolysosome-like compartments. The small number of bacteria within cells is not the result of new infections, since normally low concentrations of gentamycin (0.5 µg/ml) are capable of controlling extracellular bacteria (Pizarro-Cerdá et al., 1998c; Pizarro-Cerdá et al., 1998b). Alternatively, the low number of live bacteria within host cell vacuoles after 48 hours may be reminiscent of chronic infections in animals (C. Guzmán-Verri et al., unpublished observations). Multivesicular bodies compatible with autophagosomes are frequently present in infected cells but not in control monolayers.

The absolute increase in CFU is due to an expansion in the number of intracellular bacteria per parasitized cell rather than to an increase in the number of infected cells (Detilleux et al., 1990a, 1990b; Pizarro-Cerdá et al., 1998b; Pizarro-Cerdá et al., 1998c). Under the electron microscope, the cell cytoplasm is filled with *Brucella* within ribosome-lined cisternae, compatible with the endoplasmic reticulum (Detilleux et al., 1990a, 1990b). In the most heavily infected cells, bacteria also are seen within the perinuclear space. Although the nuclear membrane is constrained due to the large number of bacteria surrounding the nucleus, none of them invade the cell nucleus. These heavily parasitized cells do not show degeneration, do not look apoptotic or present signs of necrosis (Chaves-Olarte et al., 2002). Moreover, dividing cells with the cytoplasm packed with bacteria are frequently observed (Fig. 30). Nevertheless, beyond 48 hours cellular rupture proceeds as a consequence of *Brucella* overgrowth. The antibiotics in the tissue culture medium kill the freed bacteria, generating a rapid decrease in the number of colony forming units (Pizarro-Cerdá et al., 1998b).

Very similar events to those described in Vero and HeLa cells at 48 hours postinfection have been described in trophoblasts from experimentally infected animals (Anderson and Cheville, 1986a; Anderson et al., 1986b; Anderson et al., 1986c). Most if not all the *Brucella* cells are within the endoplasmic reticulum, and despite being filled with bacteria, infected trophoblasts do not show signs of degeneration, and the cellular junctions look normal (Fig. 30). Matching to what has been observed in cultured monolayers, bacteria remain within the endoplasmic reticulum compartments of individual cells, with no signs of horizontal movement from cell to cell. Actually, some noninfected cells are bound together with heavily infected trophoblasts, giving a clear indication that, even in vivo, *Brucella* organisms remain within vacuoles of their host cells until released. The trophoblast nucleus is never parasitized, although it is constrained by bacteria that lay very close or within cisternae that collide with the nuclear membrane. Similarly to epithelial cell monolayers, the infected trophoblasts seem to fracture at later times, owing to the large number of intracellular bacteria that eventually are released to the lumen.

Transient Interaction with the Early Endosomal Network During the first minutes after invasion, both the virulent *B. abortus* strain 2308 and the attenuated strain 19 interact with an intracellular compartment related to the early endosomal network (Fig. 36). This is confirmed by the presence of markers, such as the transferrin receptor, the small GTP-binding protein rab5, or the early endosomal antigen 1 (EEA1), in the *Brucella*-containing compartments (Pizarro-Cerdá et al., 1998). Several of these markers also have been observed in early phagosomes of other intracellular pathogens, such as *Salmonella typhimurium*, *Leishmania donovani*, *Mycobacterium tuberculosis* and *Listeria monocytogenes* (Alvárez-Domńguez and Stahl, 1999; Steele-Mortimer et al., 1999; Scianimanico et al., 1999; Via et al., 1997). All these parasites use very different strategies to associate and penetrate host cells, suggesting that there is an invariable minimal cellular machinery regularly required to accomplish the internalization steps of an external agent. This seems to be more important when the host cell is the entity that performs an active role in the process. A different phenomenon could be expected in the case of the *Brucella* close relative *Bartonella bacilliformis* or the protozoan *Toxoplasma gondii* and *Trypanosoma cruzi*, in which the motile forces of the pathogens themselves drive the invasion processes

(Doborowski et al., 1996; Tardieux et al., 1992; Scherer et al., 1993).

The association of *B. abortus* with the early endocytic network is transient, since after 10 min of internalization, the number of *Brucella*-containing compartments labeled either with rab5 or EEA1 decreases significantly, and no labeling is detected with these markers after 30 min postinoculation (Pizarro-Cerdá, 1998a). The integrity of the early endosomal system is relevant to the subsequent normal trafficking of *B. abortus* in host cells. For instance, in the cell line NIH3T3 rab5Q79L, in which the activated form of rab5 (bound to GTP) is expressed, an important fraction of the internalized parasites are unable to escape from the early *Brucella*-containing compartment supporting bacterial replication within giant vesicles labeled with rab5 (Pizarro-Cerdá, 1998a). However, after 48 h of infection, *B. abortus* proliferation is attenuated in NIH3T3 rab5Q79L cells in comparison to the wildtype NIH3T3 counterparts (Pizarro-Cerdá, 1998a). The augmentation of the endocytic activity of the mutant cells could be responsible for an increase in the delivery of gentamycin to intracellular compartments. Indeed, an important fraction of the intracellular brucellae remains associated with the early endosomal network, exposing the bacteria to the bactericidal activity of the antibiotic within this compartment. Alternatively, this unnaturally generated compartment may not be suitable for the adequate delivery of the necessary nutrients for intracellular bacterial replication.

Association with the Autophagic Machinery

After their transit through early phagosomes, neither the virulent *B. abortus* strain 2308 nor the attenuated strain 19 interacts with the late endosomal network at 30 min postinvasion (Pizarro-Cerdá et al., 1998b). In contrast, latex beads or dead bacteria-containing phagosomes interact transiently with late endocytic compartments, characterized by the presence of the small GTP-binding protein rab7 or the mannose 6-phosphate receptors. This result is confirmed after infection of NIH3T3 rab7Q67L cells (in which rab7 is expressed in its GTP-bound form) with *B. abortus* 2308. In this mutant cell line, the bacterial replication is similar to that in wildtype cells (Pizarro-Cerdá, 1998a). Although *Brucella* does not transit through the late endosome network, vacuole acidification seems to be required, since chloroquine, ammonium chloride and monensin (all substances that inhibit endosomal acidification) are capable of reducing the number of intracellular bacteria at early but not at later times after infection (Detilleux et al., 1991). Acidification step without the acquisition of lysosomal markers may be necessary for the activation of virulence genes as it occurs with other parasites (Antoine et al., 1990; Buchmeier and Heffron, 1990).

Following these initial steps, the *Brucella*-containing compartment is transformed gradually, and after 1 h of internalization, both virulent strain 2308 and attenuated strain 19 are present in an intracellular multimembranous compartment decorated with the lysosomal-associated membrane protein (LAMP) 1, but devoid of the luminal lysosomal hydrolase cathepsin D. This finding supports previous propositions in the sense that virulent *B. abortus* inhibits the fusion of its phagosome with lysosomal compartments (Frenchick et al., 1985). Several criteria permitted the identification of this late *Brucella*-containing compartment as an autophagosome (Fig. 36). First, the multimembranous nature of the LAMP-1-positive cathepsin D-negative vacuole is highly reminiscent of autophagosomes. Second, this compartment is labeled by monodansylcadaverine, a marker known to accumulate in autophagosomal bodies. Third, the endoplasmic reticulum marker sec61β is present in this *Brucella*-containing vacuole, attesting to an endoplasmic reticulum-related origin of this compartment. Fourth, modulation of the autophagocytic process regulates the intracellular fate of the internalized brucellae (Pizarro-Cerdá et al., 1998b; Pizarro-Cerdá et al., 1998c).

The presence of LAMP-1 in the late *Brucella*-containing compartment could be explained by a direct delivery of this molecule from the Golgi complex to the maturing autophagosomes. It is interesting to note that LAMP-1 has been widely associated with pathogen-containing compartments, such as the vacuoles of *S. typhimurium*, *L. donovani* and *L. monocytogenes* (Scianimanico et al., 1999; Steele-Mortimer et al., 1999; J. Pizarro-Cerdá, personal communication). This molecule could be present in these compartments accidentally as a bystander, only as an outcome of the different trafficking pathways followed by this molecule, transported in certain cases to the plasma membrane before being delivered to the lysosomes (Hunziker and Geuze, 1995). However, the actual function of the LAMP family of glycoproteins has not been clearly defined (Andrejewski et al., 1999), and it would be interesting to determine if this molecule actually plays an active role that could be relevant to the intracellular survival of all the intracellular pathogens described above. The association of an intracellular pathogen with the autophagic pathway is not unique to *B. abortus*, and it has also been observed in the case of *Legionella* (Swanson and Isberg, 1995). It is not known how these bacteria are able to interact with the autophagic cascade. An interaction between early endocytic compartments and

autophagic vacuoles has already been detected (Liou et al., 1997), indicating that a physical connection could exist between early *Brucella*-containing compartments and autophagosomes. Several scenarios could then be conceived to explain the transfer of the pathogen from one intracellular compartment to the other. First, there could be a fusion between the *Brucella*-containing compartment and an already formed autophagic vacuole. However, how the bacteria are finally found within the luminal space of a multimembranous compartment could not be directly explained by this hypothesis. A second, but highly improbable, possibility is the escape of *B. abortus* from the *Brucella*-containing compartment to the cytoplasmic space, where the bacteria could be captured by nascent autophagosomes, but free brucellae are seldom observed in the cytosol of infected cells. A third possibility would be that the autophagosomal vacuoles are formed by invagination of the endoplasmic reticulum membranes around *Brucella*-containing compartments. Nevertheless, the absence of other endoplasmic reticulum markers, such as BiP or ribophorin, in the *Brucella*-containing compartment (Pizarro-Cerdá et al., 1998b) contradicts this hypothesis. A modification of this alternative would be that only specialized regions of the endoplasmic reticulum, devoid of BiP or ribophorin, are involved in autophagosome formation.

Replication Within the Endoplasmic Reticulum In contrast to what is observed with attenuated and killed bacteria, most of the intracellular virulent *Brucella*-containing phagosomes lose the LAMP-1 labeling and never acquire lysosomal markers in nonprofessional phagocytes (Pizarro-Cerdá et al., 1998b; Pizarro-Cerdá et al., 1998c). However, this final *Brucella*-containing compartment retains the sec61β labeling and acquires other markers of the endoplasmic reticulum, such as the protein disulfide isomerase and calnexin (Pizarro-Cerdá et al., 1998b). The morphology of the final *Brucella*-containing compartment also differs from that of the autophagosomal stage: only a single membrane is detected around the replicating brucellae, and their intracellular location corresponds to the perinuclear area of the infected cells (Pizarro-Cerdá et al., 1998b; Pizarro-Cerdá et al., 1998c). All these data suggest that the virulent *B. abortus* transits from autophagosomes to the endoplasmic reticulum of host cells, where actual bacterial multiplication occurs (Fig. 36), confirming previous ultrastructural studies in trophoblasts and other mammalian cell lines (Anderson and Cheville, 1986a; Anderson and Cheville, 1986b; Detilleux et al., 1990a, 1990b). Additional evidence confirms the nature of the final niche of *B. abortus* replication in host cells. First, treatment of infected cells with brefeldin A, which normally induces the reorganization of the Golgi complex around the endoplasmic reticulum, induces the colocalization of Golgi markers around the *Brucella*-containing compartments (Pizarro-Cerdá et al., 1998b). Second, the treatment of infected cells with proaerolysin, a drug from *Aeromonas hydrophyla* that induces vacuolization of the endoplasmic reticulum in target cells, induces vacuolation of *Brucella*-containing compartment (Pizarro-Cerdá et al., 1998b). Treatment of target cells with proaerolysin before *Brucella* inoculation impairs the bacterial replication process and induces the degradation of virulent strain 2308 (Pizarro-Cerdá et al., 1998c), suggesting that the integrity of the structure of the endoplasmic reticulum is indispensable for the appropriate multiplication of *B. abortus*.

The benefits involved in the association of intracellular pathogens with the host-cell endoplasmic reticulum have not been characterized yet. Besides *B. abortus*, *L. pneumophila*, *T. gondii* and simian virus 40 multiply in this intracellular environment, revealing a path of convergent evolution in nonrelated organisms. In addition to being a strategy for avoiding lysosomal fusion during the final steps of intracellular invasion, association of *B. abortus* with the host endoplasmic reticulum could be a means of obtaining metabolites synthesized or translocated to this compartment (Sinai et al., 1997a; Stang et al., 1997; Swanson and Isberg, 1995). The strategy would be to take advantage of the biosynthetic enzymes, protein-conducting channels or peptide pores to increase the local nutrient supply (Sinai, 1997b), fulfilling the nutritional requirements for the bacterial growth. A possible prediction of this model would be that the cellular stock of short-lived molecules would decrease in *B. abortus*-infected cells due to the shortage of amino acids and peptides or to the blocking of the biosynthetic process of new proteins in the endoplasmic reticulum. However, heavily infected cells show no decrease in stock levels of short-lived molecules, such as LAMP-1 and LAMP-2 (J. Pizarro-Cerdá, personal communication). As with other intracellular parasites, such as *S. typhimurium* or *Leishmania*, it is still not clear why certain intracellular locations are preferred by different subsets of intracellular parasites to proliferate within host targets.

Trophoblasts as a Source of Growth Factors In the pregnant animal, *Brucella* organisms preferentially replicate in placental trophoblasts during the middle and late stages of gestation (Fig. 32), only after these cells actively secret steroids. The reason for this affinity and the process leading to

abortion after midgestation are not known. Infected trophoblasts produce cortisol, a steroidal hormone not normally generated by the placenta (Enright and Samartino, 1994). The increased levels of prostaglandin F2α and decreased production of progesterone, coupled with increased synthesis of estrogens and cortisol in the *B. abortus*-infected trophoblast at mid- and late-stages of gestation, are identical to the hormonal changes occurring at term in normal cattle with the initiation of parturition. Intracellular *Brucella* probably induces synthesis of steroids and modifies the metabolism of prostaglandin precursors, such as arachidonic acid, because these hormones may be used as growth factors by the bacteria. The increased hydrophobicity of the *Brucella* outer-membrane (Fig. 22), together with the preference of the bacteria for replicating within this cistern (Anderson et al., 1986b; Anderson et al., 1986c), may represent an evolutionary adaptation for using hydrophobic substances available within the endoplasmic reticulum of trophoblasts.

Life Within Macrophages Taking apart the innate differences in susceptibility among the various species and strains of mammals, as well as the different sources from which macrophages could be isolated, it is important to understand that intracellular trafficking and replication of *Brucella* within these cells could be studied from various dichotomous perspectives. Each of these dichotomies possess their own variables; for example, activated versus resting macrophages, immune versus naïve macrophages, phagocytosis of opsonized versus nonopsonized bacteria, and cell cultures in the presence or in the absence of antibiotics. It is obvious that combined models of these dichotomies are possible, complicating matters even more. Therefore, it is important to understand that each of the various scenarios may alter the intracellular trafficking and the replication of the ingested bacteria (Eze et al., 2000; Jiang and Baldwin, 1993a; Jiang et al., 1993c). Similarly to the ingestion of *Brucella*, the microbicidal activity seems to be better performed with opsonized rather than with nonopsonized bacteria and by activated rather than by nonactivated macrophages (Pomales-Lebron and Stinebring, 1957). In addition, the presence of antibiotics considerably alters the outcome of the infection, depending upon their concentration in the culture medium (Eze et al., 2000). In this sense, it is expected that bacterial opsonization and macrophage activation determine, to some extent, the outcome in the intracellular trafficking and the fusion events of vacuoles containing *Brucella*. With respect to opsonization, caution is necessary, since conflicting results have been obtained.

Structural and Morphological Changes During Macrophage Infection During the first two hours after macrophage *Brucella* infection, the bacteria localize within single phagosomes, with no signs of microbial degradation (Arenas et al., 2000; Pizarro-Cerdá, 1998a; Pizarro-Cerdá et al., 1998b; Pizarro-Cerdá et al., 1999b). The number of ingested *Brucella* depends upon the inoculum size, opsonization and macrophage activation (Kuzumawati et al., 2000). Fusions between lysosome-like granules and some *Brucella*-containing phagosomes are evident at these early times, and few intracellular bacteria localize within multimembrane compartments. After 12–15 h of ingestion, the number of *Brucella* decreases one to two logs, and more than one bacterium per vacuole is frequent (Gross et al., 1998; Gross et al., 2000; Jiang and Baldwin, 1993a; Jiang et al., 1993c; Porte et al., 1999). Microscopic observation reveals that an important proportion of *Brucella*-containing compartments have fused with lysosomal granules and many of the bacteria within look degraded, although a few appear intact, generally surrounded by a single vacuolar membrane (Arenas et al., 2000; Gay et al., 1981; Gay et al., 1986; Harmon et al., 1988). At later times (15–24 h), the number of intracellular bacteria increases in some but not all infected cells. While some macrophages are capable of controlling the infection, others become an adequate substrate for *Brucella* replication (Gay et al., 1981; Gay et al., 1986; Pomales-Lebron et al., 1957). Still, some bacteria look digested within vacuoles and bacterial debris are evident, but a proportion of nondegraded bacteria remain, generally surrounded by a single vacuolar membrane. Between 24 and 48 hours, the number of intracellular *Brucella* per cell rises, until the cytoplasm of the phagocytic cells is filled with parasitic bacteria (Jiang and Baldwin, 1993a; Pizarro-Cerdá, 1998a; Pizarro-Cerdá et al., 1999a; Pomales-Lebron et al., 1957). Similar to what has been described for nonprofessional phagocytes, the nuclear membrane looks constrained, owing to the large number of microorganisms surrounding the nucleus. However, none of the bacteria invade the cell nucleus (Fig. 30). These heavily parasitized macrophages do not look apoptotic, look vacuolated or present signs of necrosis. Nevertheless, beyond 48 h, cellular rupture seems to proceed as a consequence of *Brucella* overgrowth, and release of the bacteria occurs. The freed bacteria are normally killed by the antibiotics in the tissue culture medium, generating a rapid decrease in the number of colony forming units (Sola-Landa et al., 1998).

Trafficking and Replication Within Macrophages The fact that not all cultured infected macrophages sustain bacterial replica-

tion after 12 h is an indication of the powerful brucellacidal activity of these cells. Those bacteria that finally replicate intracellularly must escape from the digestive abilities of macrophages. It has been proposed that phagosome acidification dependent of proton ATPases, occurring at early (1 h) but not at later times (after 7 h), is essential for bacterial replication (Porte et al., 1999). Other investigators have observed that acidification of phagosomes takes place at early (0.5–2 h) as well as later (20 h) times (Arenas et al., 2000). Acidification of *Brucella*-containing phagosomes may work in two directions. One of them may just be the default outcome of phagosome-lysosome fusion with negative consequences for the bacterial survival. The second may work in favor of the parasitic bacteria. That is, the intracellular bacterium may require an acidic environment for activating genes necessary for an intracellular life cycle, such as the type IV secretion system apparatus (Alpuche-Aranda et al., 1992; Boschiroli et al., 2002). Even though lowering the pH of the phagosome may be necessary to prepare the *Brucella* replicating environment, this may not be sufficient, since phagosomes containing live bacteria or killed organisms acidify at a similar rate. Another consideration is the presence of gentamycin in the culture media. This antibiotic is readily pinocytosed by macrophages and considerably inhibits the intracellular growth of the *Brucella*, mainly when it is used in the culture medium at concentrations above 10 μg/ml (Eze et al., 2000).

The biogenesis of phagolysosomes and the ability to degrade invading microorganisms involve a regulated series of interactions between phagosomes and endocytic organelles (Desjardins et al., 1994; Finlay and Falkow, 1997b; Pitt et al., 1992). During the first stages after infection (0.5–2 h), an important proportion of phagosomes containing bacteria seem reluctant to fuse with newly internalized vesicles, with the characteristics of lysosomes (Pizarro-Cerdá et al., 1999a; Pizarro-Cerdá, 1998a). At ten minutes after inoculation, *Brucella* organisms are transiently detected in phagosomes, characterized by the presence of EEA1 (Fig. 35). Live but not dead *Brucella* exclude annexin I from early macrophage phagosomes (Harricane et al., 1996). At one hour postinoculation, bacteria are located within a compartment positive for LAMP but negative for mannose-6-phosphate receptor and cathepsin D protein, indicating that virulent *Brucella* avoids fusion with late endosomes and lysosomes (Pizarro-Cerdá et al., 1999a; Pizarro-Cerdá, 1998a). At later times (12–24 h), fusions between newly internalized vesicles and *Brucella*-containing vacuoles are common events. However, the lysosomal markers LAMP and cathepsin D are excluded from vacuoles containing replicating *Brucella* (Pizarro-Cerdá, 1998a), indicating that some bacteria have actively avoided the constitutive degradative pathway commonly followed by inert particles (Desjardins et al., 1994). Mature compartments containing live replicating *Brucella* (after 24 h) are devoid of the late endosomal marker mannose-6-phosphate receptor and lysosomal proteins (LAMP and cathepsin D) but are positive for the endoplasmic reticulum marker sec61β (Fig. 35), suggesting that at least some bacteria have reached the same replicating niche (the endoplasmic reticulum) as in nonprofessional phagocytes (Pizarro-Cerdá et al., 1999a; Pizarro-Cerdá, 1998a).

In general terms, phagocytic cells are more prone to destroy *Brucella* and control its intracellular replication than are nonprofessional phagocytes. For instance, when *Brucella* strains of low and high virulence are compared, it is clear that no strain displaying low virulence withstands the powerful destructive machinery of professional phagocytes, whereas some of these strains are capable of replicating within nonprofessional phagocytic cells (Detilleux et al., 1990a; Detilleux et al., 1990b; Harmon et al., 1988; Fig. 35). Similarly, macrophages defective in fusion events are more permissive cells not only for virulent *Brucella*, but also for the attenuated strains that are killed by healthy macrophages (Pizarro-Cerdá et al., 1999b). Moreover, microscopic examination reveals that while in nonprofessional phagocytes most of the internalized bacteria travel within intracellular compartments that do not fuse with late endosomes and lysosomes, in macrophages a relatively large proportion of the phagosomes fuse with acidic vacuoles and lysosome-like compartments (Arenas et al., 2000). In nonprofessional phagocytes, most of the ingested *Brucella* transit from early endosomes to autophagosomes and then to the endoplasmic reticulum (Fig. 35), whereas in macrophages just a small proportion of *Brucella*-containing compartments seem to reach the endoplasmic reticulum (Fig. 35).

In murine knockout macrophages deficient in fusion events, both virulent and attenuated *B. abortus* strain 19 replicate more readily than in normal macrophages (Pizarro-Cerdá et al., 1999a). Restoration of this defect re-establishes the microbicidal activity, indicating that fusion of vacuoles containing *Brucella* with newly internalized vesicles is necessary for controlling intracellular *Brucella* replication. Therefore, it seems that *Brucella* within nonfusiogenic vacuoles are more likely to reach the final intracellular replicating niche than those bacteria within vacuoles that fuse with lysosome-like compartments.

Electron microscopy of infected macrophages reveals that the replicating pattern displayed by *Brucella* within macrophages, at later times (Fig. 30), is reminiscent of the replicating pattern within the endoplasmic reticulum of trophoblasts and epithelial cells (Detilleux et al., 1990b; Anderson and Cheville, 1986a; Anderson and Cheville, 1986b).

Some investigators have proposed that in macrophages, *Brucella* organisms do not reach the endoplasmic reticulum but rather they delay maturation of phagosomes into phagolysosomes and that, during this process, acidification and subsequent modification of the compartment establish the replicating niche, which is compatible with a modified phagolysosome (Arenas et al., 2000). Others have proposed that virulent *Brucella* transit from early phagosomes to the endoplasmic reticulum in both macrophages and nonprofessional phagocytes (Pizarro-Cerdá, 1998a; Pizarro-Cerdá et al., 1999b). Although at this point these two views cannot be conciliated, it is clear from the pure microscopic point of view that a parallelism in the replication of *Brucella* within the cytoplasm of macrophages and nonprofessional phagocytes exists at later times. It may be that most of the *Brucella* organisms in macrophages are destroyed by lysosomes, while only a few bacteria arrive to the endoplasmic reticulum. However, once these few bacteria are within the endoplasmic reticulum, they are capable of replicating inside this compartment, which is nonfusiogenic with bactericidal lysosomes (Fig. 35). In nonprofessional phagocytes, the events are reversed: only a few internalized *Brucella* are destroyed within lysosomes, while most of the *Brucella* arrive to the endoplasmic reticulum, trafficking through the safer autophagocytic route (Fig. 36).

Obviously, the most economical pathway for the bacteria would be to use the same molecular machinery for intracellular trafficking and for subtracting resources in different host cells, rather than to possess a different molecular strategy for each cell type. An example of this can be seen in *Legionella* species, bacteria that use the same machinery and strategy to parasitize their free-living host amoebae and the resident macrophages in the lung of their victims (Barker et al., 1993). Thinking in this direction, the phagolysosome route establishes different constraints that must be surpassed. Similarly, the phagolysosomes and endoplasmic reticulum perform different functions and display a different set of resources for the intracellular bacteria. Therefore, it seems unlikely that *Brucella* could have evolved two different mechanisms to adapt equally well to two distinct intracellular environments as proposed by some authors (Arenas et al., 2000).

Cellular Functions During Infection Transit of virulent *Brucella* from autophagosomes to the endoplasmic reticulum requires cellular machinery that has not been identified. In CNF-intoxicated cells, the intracellular trafficking to the endoplasmic reticulum via the autophagocytic route remains intact, even though the actin cytoskeleton is functionally arrested (C. Guzmán-Verri et al., unpublished observations). Similarly, segregation of chromosomes and nuclei assembly are not defective, whereas the formation of a contractile ring for cell cytokinesis, mediated by an actin-myosin structure, is impaired in these CNF-intoxicated cells. Colchicine added during the infecting period has a modest effect on internalization, although it reduces the number of cells with intracellular replicating bacteria and has a profound effect on the morphology of the parasitized cells, generating polymicronuclei (Detilleux et al., 1991). It is possible that microtubule but not actin structures are involved in the retrograde transport of *Brucella*-containing compartment to the endoplasmic reticulum. The participation of molecular motors, such as dynein, which normally promotes the retrograde motion of membrane-bound vesicles through microtubules, is a mechanism that must be considered during the intracellular biogenesis of *Brucella*. Cycloheximide does not inhibit intracellular bacterial replication, and therefore, it is feasible to propose that de novo host protein synthesis is not required during *Brucella* parasitism (Detilleux et al., 1991).

Proteins from the coat protein I (COPI) complex, known to participate in the anterograde transport of vesicles in the Golgi apparatus, have recently been implicated in the retrograde transport of vesicles to the endoplasmic reticulum (Orci et al., 1986; Orci et al., 1997). The presence of several subunits of the COPI complex in compartments associated with the endocytic cascade (Whitney et al., 1995) suggests that these molecules could establish a link among endocytic compartments, autophagosomal vacuoles and the endoplasmic reticulum, a link that is necessary for the intracellular trafficking of *B. abortus*. Molecules from the SNARE family (SNAREs are membrane-associated proteins that play a central role in vesicle targeting and intracellular membrane fusion in eukaryotic cells) or small GTP-binding proteins of the rab family could also be implicated in the retrograde transport of the *Brucella*-containing compartments. Recently, it has been demonstrated that autophagocytosis could be blocked by GTP-γS (a nonhydrolyzable analogue of GTP), suggesting that this process requires GTP-binding proteins (Kadowaki et al., 1994). It is interesting to note that the

anterograde transport of vesicles from the endoplasmic reticulum is dependent on the small GTP-binding protein Sarpl and the COPI-like complex, COPII (D'Enfert et al., 1991). Similar or the same molecules could be implicated in autophagosomal formation and could be under *B. abortus* control to induce its retrograde transport to the endoplasmic reticulum.

Brucella Virulence Mechanisms Virulence can be understood as those bacterial mechanisms that cause cell damage or resist host defenses. Within this context, virulence factors are envisioned as bacterial products, structures or genes that, when absent or modified, alter the course of the pathogenesis without affecting the bacterial viability or the growth under regular culture conditions. There are overwhelming data demonstrating that the ability of *Brucella* organisms to produce disease relies in their capacity to invade cells of healthy immunocompetent hosts (Baldwin and Winter, 1994; Enright, 1990b; Liautard et al., 1996; Pizarro-Cerdá et al., 1999b; Pizarro-Cerdá et al., 2000). Two simple conclusions are derived from these clear cut facts: first, *Brucella* organisms are primary pathogens of mammals that do not require anomalous host conditions to establish infections; and second, the essential *Brucella* virulence strategy can be envisioned as the ability to replicate within host cells until more virulent bacteria are released. Therefore, the maintenance of these properties may be considered sine qua non for *Brucella* virulence and for successful parasitism.

In spite of the relatively large number of DNA sequences identified as potential virulence genes, very few structures and mechanisms related to pathogenesis have been described (Moreno and Moriyón, 2002; Sánchez et al., 2001; Ugalde et al., 1999). The *Brucella* mutants may be distinguished according to their replicating abilities in bacteriological media, cells and animals. Many of the attenuated mutants in cells or animals are metabolically defective strains displaying anomalous growth in vitro and requiring particular supplemented media and culture parameters. Others are impeded from making proteins necessary for confronting growth under stress conditions, whereas others have defects in repairing systems and division machinery. Although these general defects are interesting and prime for practical purposes, they are unlikely to be considered as virulence factors. Paragraphs in the sections Mechanisms of Entry to Host Cells through Modulation of the Immune Response summarize what it is known about the strategies followed by pathogenic intracellular *Brucella* and some of the genetic systems involved.

Mechanisms of Entry to Host Cells Only efficiency of invasion and intracellular replication, but not adherence to the cell surface, positively correlate to *Brucella* virulence (Fig. 21). As stated (Antitumoral and Antiviral Activity of *Brucella* Cells and Their Fractions), a number of natural or artificial engineered nonvirulent rough bacteria bind and penetrate cells in a proportion larger than that of wildtype *Brucella* (Detilleux et al., 1990a; Detielleux et al., 1990b; Freer et al., 1999; Pizarro-Cerdá, 1998a; Sola-Landa et al., 1998). Mutations in *bvrS* or *bvrR* genes (The BvrR-BvrS System) of a two-component, sensory-regulatory system (Fig. 28) hamper the penetration of smooth *B. abortus* into HeLa cells and considerably reduce the efficient invasion of murine macrophages without impeding bacterial binding (Sola-Landa et al., 1998). Dysfunction of either the *bvrR* or *bvrS* impairs the bacterial invasion, intracellular trafficking and virulence, while knockout of both *bvr* genes seems to be lethal (D. O'Callaghan, personal communication). Both of these avirulent smooth mutants have the tendency to accumulate on the surface of cells. The rough *perA* mutant (Table 5), deficient only in the expression of surface *O*-polysaccharide and NH (J. Pizarro-Cerdá et al., unpublished observations), binds to cells in larger numbers. However, the double rough/*bvrS* mutant binds to cells in the same proportion as the *bvrS* single mutant (C. Guzmán-Verri et al., unpublished observations). Therefore, the exposed elements on the surface of rough *Brucella* necessary for adherence to cells are absent in the bvrS mutant. Comparative studies reveal that *bvrS/bvrR* mutants are deficient in at least two sets of Omps (C. Guzmán-Verri et al., unpublished observations), which correspond to the group 3 of Omps present in outer-membrane blebs (Gamazo et al., 1989; Moriyón et al., 1987; Omp3a and Omp3b Family). Estimation of the Omp3a (Omp25) and Omp3b mRNA reveals low expression in both mutants, suggesting that the absence of this protein from the outer-membrane may be the result of reduced transcription. The role of Omp3a in virulence is further suggested by the fact that disruption of the *omp3a* gene attenuates *Brucella* (Elzer et al., 2000). Functional and structural analysis of the *bvr*S and *bvr*R mutants indicate that the lipid A and maybe the core, but not the *O*-polysaccharide of the LPS, have subtle but detectable changes with respect to the wildtype molecule. In this respect, the function of the BrvR-BrvS two-component regulatory system may be similar to that of other regulatory systems described in Gram-negative intracellular bacteria (Gunn and Miller, 1996). Although the BvrR-BvrS has low homology with PhoP-PhoQ, it is interesting that, among other characteristics, the PhoP-PhoQ activates the PmrA-PmrB system,

which in turn, regulates the lipid A structure. The overall conclusion is that multiple genes, several of them important for the expression of Omps and LPS synthesis, may be under the control of *bvr*R-*bvr*S, and that these elements are important for virulence. It has been proposed that the type IV secretion system coded by the *vir*B genes is involved in the penetration of *Brucella* to murine macrophages (Watarai et al., 2002); however, other investigators have indicated that the virB operon is not involved in cell invasion but rather in intracellular trafficking (Boschiroli et al., 2002; Comerci et al., 2001; Delrue et al., 2001; Sieira et al., 2000).

Controlling the Host Cell Eukaryotic cells have evolved strategies to destroy microorganisms within phagolysosomes by direct action of microbicidal substances. Intracellular survival requires the invader to be capable of escaping and resisting this cellular machinery. According to their functional roles, neutrophils and activated macrophages are the primary and ultimate defense cells against *Brucella* infections, respectively. Depending upon the initial inoculum, the bacterial strain and the host animal, it is likely that an ample number of *Brucella* infections are controlled on site by neutrophils (Fig. 33). In these cells, the engulfed *Brucella* seldom divides, but it must resist the assault of intracellular microbicidal molecules to survive. In the nonimmune host, *Brucella* replicates within naïve macrophages and nonprofessional phagocytic cells. Once the infection has been established, the activated macrophages, through a specific immune response, are the cardinal cells responsible for controlling and killing the invading *Brucella*. It seems that the difference in behavior observed among the various *Brucella*-infected cells is just a matter of degree in their killing capabilities. The survival strategy employed by *Brucella* within various cells seems to be basically the same and it can be resumed in the different but connected major episodes.

Brucella Resists Killing Mechanisms Professional phagocytes, such as polymorphonuclear leukocytes and macrophages, are adapted to engulf and destroy bacteria within phagolysosomes by direct action of bactericidal mechanisms that involve a collection of enzymes and cationic peptides and production of reactive oxygen and nitrogen intermediates. The respiratory burst involves a series of enzymatic reactions responsible for the conversion of oxygen to active metabolites, some of which exhibit microbicidal activities. It has been observed that ingestion of nonopsonized *B. abortus* by phagocytes induces very little respiratory burst and a very poor production of reactive nitrogen intermediates (Caron et al., 1994b; Jiang and Baldwin, 1993a; Jiang et al., 1993c; Kreutzer et al., 1979b). Alternatively, opsonized *B. abortus* organisms exposed to activated phagocytic cells stimulate significant levels of both superoxide-ion production and myeloperoxidase-hydrogen peroxide halide activity (Harmon et al., 1987; Harmon et al., 1988; Jiang and Baldwin, 1993a; Jiang et al., 1993c; Young et al., 1985). Lysosomal proteins and bactericidal cationic peptides fail to kill *Brucella* organisms (Kreutzer and Robertson, 1979a; Kreutzer et al., 1979b; Martínez de Tejada et al., 1995). Even attenuated *Brucella* are more resistant to the action of these molecules than are other intracellular parasitic Proteobacteria, such as polymyxin B resistant *Salmonella*, indicating by this the evolutionary adaptation of *Brucella* to intracellular life.

Outer Membrane Versus Bactericidal Substances The most conspicuous structural defect that renders *Brucella* organisms avirulent is the absence of the *O*-polysaccharide and the concomitant absence of the related NH polysaccharide molecules. In other words, a defect that results from the dissociation from smooth to rough phenotype (Allen et al., 1998; Detilleux et al., 1990a, 1990b; Freer et al., 1996; Kreutzer et al., 1979b; Martínez de Tejada et al., 1995; Riley and Robertson, 1984a; Stevens et al., 1994a). In general, smooth *Brucella* are more resistant than rough strains to the killing action of bactericidal substances of phagocytes.

The role of LPS in the permeability properties and in resistance to bactericidal substances has been definitively established in a series of experiments involving *Brucella* strains and the construction of LPS chimeras (Freer et al., 1996; Martínez de Tejada et al., 1995; Páramo et al., 1998). When the heterologous LPS inserted in the outer-membrane of susceptible bacteria corresponds to the less sensitive smooth *B. abortus*, the chimeras are more resistant to bactericidal cationic molecules. In contrast, when LPS is from the more sensitive bacteria, the chimeras are more susceptible to the action of bactericidal peptides. There is a direct correlation between the amount of heterologous smooth LPS on the surface of chimeric cells and sensitivity to bactericidal substances (Freer et al., 1996). Although this particular resistance to bactericidal molecules is related to the core and lipid A structures, there is a contribution of the *O*-polysaccharide and the associated NH, as suggested by the difference in susceptibility between the rough and smooth *Brucella* strains (Freer et al., 1996; Martínez de Tejada et al., 1995). It is worth noting that the resistance of *Brucella* LPS to cationic molecules is more conspicuous when it is integrated in its native outer-membrane. This is dem-

onstrated by the fact that *Brucella* smooth LPS micelles are partially permeabilized by the action of bactericidal peptides, whereas *Brucella* cells are not (Freer et al., 1996).

The *O*-polysaccharide and the NHs are only two of several factors necessary for virulence. Dysfunction of the BrvR-BrvS two-component, sensory regulatory system generates outer-membrane alterations manifested as increased susceptibility to bactericidal cationic substances and surfactants (Properties of the Outer Membrane). These defects are partially restored by inserting wildtype LPS in the outer-membrane of the *bvr* mutants (E. Moreno et al., unpublished observations), reinforcing the idea that, in addition to LPS, other outer-membrane molecules are also important. Because bactericidal cationic peptides are molecules devoted to cell defense against pathogenic parasites (Vaara, 1992), it is likely that some of the outer-membrane features relevant for resistance to lysosomal substances are under the control of the BvrR-BvrS system.

Stress Responses *Brucella* organisms generate a collection of proteins that theoretically could inhibit the bactericidal action induced during the respiratory burst, as well as enzymes that could neutralize the acid pH within the phagolysosome necessary for activating lysosomal hydrolytic enzymes. Significant changes in the pattern of *Brucella* proteins during intracellular growth have been recorded (Rafie-Kolpin et al., 1996). As expected, a proportion of the proteins expressed are heat-shock proteins, though others are possibly necessary to deal with other harsh conditions (Lin and Ficht, 1995; Teixeira-Gomes et al., 2000).

Neutralization of Oxygen and Nitrogen Intermediates *Brucella* organisms produce phosphomonoesterases, high concentrations of periplasmic cytochromes, Sod and catalase, all proteins that may be involved in the protection of the bacteria against free hydrogen peroxide and superoxide radicals generated by phagocytic cells (Kim et al., 2000; Saha et al., 1990; Tatum et al., 1992). In contrast to the enzyme of some intracellular parasites, such as *Legionella* or Leishmania, *Brucella* phosphomonoesterase does not block the production of superoxide anion and does not hydrolyze phosphatidylinositol diphosphate or IP3 molecules (Saha et al., 1990). A collection of *Brucella* mutants not expressing Cu^{++}/Zn^{++}-SodC or catalase proteins has been generated on the expectation that these defects would increase the sensitivity of the mutants to bactericidal action of oxidative intermediates produced during the respiratory burst (Kim et al., 2000; Tatum et al., 1992). It has been demonstrated that these two enzymes concomitantly increase after exposure of the bacteria to peroxide or superoxide ions (Kim et al., 2000), suggesting an adaptive response. In spite of their increased sensitivity to hydrogen peroxide (Kim et al., 2000), the catalase-deficient mutants replicate at the same rate as wildtype bacteria in mice, indicating that, at least in this model, catalase per se does not play a significant role in virulence (Grillǿ1997). Similarly, *Brucella* SodC-deficient mutants exhibit virulence and establish chronic infections in mice (Latimer et al., 1992). Mutants interrupted in the operon coding for cytochrome bd oxidase, which catalyzes an alternate terminal electron transport step in bacterial respiration, are highly attenuated and unable to replicate in cells. Superexpression of Cu++/Zn++ Sod and catalase in these mutants alleviates the loss of cytochrome bd oxidase (Endley et al., 2001), suggesting that these two enzymes play after all a role in virulence under certain conditions.

Role of Heat Shock Proteins Significant changes in the pattern of *Brucella* proteins during intracellular growth have been recorded. It has been shown that, in addition to variations in the expression level of 73 proteins, repression of 50 in vitro proteins and induction of 24 new proteins occur during growth of *B. abortus* within macrophages (Rafie-Kolpin et al., 1996). Acid and oxidative conditions, as well as nutritional and heat stresses, induce the synthesis of "new" bacterial proteins. However, the quantity of these "new" molecules produced in vitro is not equivalent to the amount expressed within macrophages (Lin and Ficht, 1995; Teixeira-Gomes et al., 2000).

Brucella *htr*A, which codes for the periplasmic heat shock-induced serine protease HtrA, is likely to participate in the degradation of oxidatively damaged proteins. Resembling *Salmonella* and *Yersinia* *htr*A mutants, *Brucella* *htr*A mutants demonstrate higher sensitivity to oxidative substances, reduced survival in neutrophils and defective replication in macrophages (Elzer et al., 1996; Phillips et al., 1995; Phillips et al., 1997). Comparable to other *Brucella* stress proteins, such as RecA, the mutation of which also reduces multiplication in mice, *htr*A *Brucella* mutants establish chronic infections, suggesting residual virulence (Phillips et al., 1995; Tatum et al., 1992; Tatum et al., 1993). In goats, *htr*A *Brucella* mutants demonstrate a more attenuated phenotype (Elzer et al., 1996).

Regulated expression of *dna*K under oxidative stress seems to be used by bacterial pathogens to withstand the respiratory burst of phagocytes (Caron et al., 1994a). Analysis of *Brucella* mutants carrying inactivated *dna*K and *dna*J (which code for the stress molecular chaperones DnaK and DnaJ) has led to the conclu-

sion that DnaK, but not DnaJ, is required for growth at 37°C. The *dna*K mutant survives but does not multiply within phagocytes at a temperature of 30°C, whereas the *dna*J mutant multiplies normally (Köhler et al., 1996). It has been proposed that intracellular *Brucella* organisms enter into a period of starvation that would favor their resistance to oxidative conditions found within vacuoles (Alcantara et al., 2000; Robertson and Roop, 1999; Robertson et al., 2000a). *Brucella abortus hfq* mutants (defective in the RNA chaperone host factor (HF-1)) do not replicate in macrophages, but initially they multiply in mice, suggesting that HF-1, normally required for maintenance at stationary phase, is also necessary during intracellular survival. The HF-1 protein participates, within several pathways, in the regulation of the sigma factor RpoS, required for maintenance at the stationary phase (Robertson and Roop, 1999). As a consequence, the deficient *hfq* mutant displays an impaired stress response and problems for adapting to the stationary growth phase. This mutant, impaired for long-term survival under nutrient deprivation, also demonstrates growth stage- and medium-dependent sensitivity to hydrogen peroxide and a decreased capacity to resist acidic environments, conditions likely to be found intracellularly.

Brucella lon mutants are impaired in their capacity to resist hydrogen peroxide and puromycin and display reduced survival in macrophages and significant attenuation in mice during the initial periods, but not at later times. The ATPase-dependent Lon protease is one of the principal enzymes involved in the turnover of stress-damaged proteins. The level of transcription of this protein increases in response to several environmental stresses. It has been proposed that Lon functions as a stress-response protease and is required in *Brucella* during the initial stages of infection, but it is not essential for the establishment and maintenance of chronic infections in the host (Robertson et al., 2000b). The role of other potential *Brucella* virulence genes, such as those coding for the heat shock protein GroEL and ClpATPase (Lin et al., 1996), has not been investigated in detail. *Brucella suis* null mutants for ClpATPase chaperonine behave similarly to the wild-type strain, indicating that ClpA by itself is dispensable for intracellular growth (Ekaza et al., 2000).

Role of the Urease Considering ammonium is the principal product and has a strong basic character, the decomposition of urea catalyzed by urease may serve to neutralize the acid pH within the phagolysosome. Urea is in all likelihood a product of the metabolism of *Brucella* (Response to Environmental Stress) and all *Brucella* species but *B. ovis* have a cytoplasmic urease. However, the urease-defective mutants do not display attenuation and behave similarly to the parental pathogenic strains in some virulence assays, evoking what has been observed with the catalase and SodC mutants (Jubier-Maurin et al., 2001; Grilló1997). This does not rule out a possible role for urease during the initial steps of host invasion in the penetration through the intestinal route (*Brucella* Invades Healthy Hosts).

Inhibition of Lysosome-Phagosome Function After 24 h, epithelial cells infected with virulent *B. abortus* display a significant increase in the number of intracellular bacteria distributed in the perinuclear region corresponding to the endoplasmic reticulum. In contrast, cells treated with killed *Brucella* harbor a small number of intact bacteria together with bacterial degradation products scattered throughout the cytoplasm, an action that proceeds with time. At these stages, cathepsin D, a well-known marker for lysosomes, colocalizes with vacuoles containing killed *B. abortus* and bacterial degradation products, attesting that phagosomes have fused with lysosomes (Pizarro-Cerdá et al., 1998a; Pizarro-Cerdá et al., 1998b). By contrast, intracellular virulent *Brucella* organisms seldom colocalize with cathepsin D in epithelial cells, indicating that this bacterium avoids fusion with lysosomes. In vitro fusion experiments between vacuoles containing *Brucella* and lysosomes isolated from macrophages show that although compartments containing killed bacteria fuse with lysosomes, vacuoles containing live *Brucella* do not fuse with these organelles (Naroeni et al., 2001). Moreover, intracellular *Brucella* organisms do not hamper the fusion of latex beads with lysosomes, a phenomenon that agrees with the cellular parasitism displayed by some rough attenuated *Brucella* mutants. Some rough intracellular brucellae follow the constitutive endosome-lysosome route, whereas others traffic to the endoplasmic reticulum in the same cell. The key virulence factor is not the general inhibition of lysosome-phagosome fusion in cells, but rather the active modification of the *Brucella*-containing compartment, making this organelle non-fusiogenic with lysosomes.

It has been found that phagosomes containing live *Mycobacterium* retain a host protein (TACO, a phagosomal coat protein that prevents degradation of mycobacteria in lysosomes) that prevents delivery of lysosomes into the parasite-containing phagosome (Ferrari et al., 1999). Similarly, it has been proposed that the *Leishmania* parasite inhibits phagolysosome biogenesis through insertion of a lipophosphoglycan into the phagosome membrane, precluding in this

manner the fusion of the phagosome with lysosomes (Desjardins and Descoteaux, 1997). Indirect evidence for inhibition of neutrophil "degranulation" by *B. abortus* has been obtained from studies of the effects of live or heat-killed organisms and bacterial extracts. *Brucella abortus* extracts apparently devoid of enzymes and LPS (but containing 5′-guanosine monophosphate and adenine) inhibited neutrophil degranulation (Canning et al., 1986). The same molecules seem to inhibit the myeloperoxidase-hydrogen peroxide-halide activity by specifically hampering degranulation of peroxidase-positive polymorphonuclear granules (Bertram et al., 1986). Similarly, studies conducted with *B. abortus* extracts were capable of inhibiting phagosome-lysosome fusion in macrophages (Frenchick et al., 1985). It has been observed that smooth *Brucella* LPS enhanced the intracellular survival of rough mutant bacteria in bovine neutrophils (Soto et al., 1991). Despite this, some authors have proposed that LPS does not participate in the inhibition of phagosome-lysosome fusion (Kreutzer and Robertson, 1979a; Frenchick et al., 1985). All these investigations, although valuable, need to explain the fact that only live virulent *Brucella* is capable of hampering lysosomal fusion (Pizarro-Cerdá et al., 1998c; Pizarro-Cerdá et al., 1998b; Naroeni et al., 2001).

Lipopolysaccharide Fails to Stimulate Lysosomal Activity Several studies have cited the *Brucella* LPS molecule as a virulence factor (Freer et al., 1996; Rasool et al., 1992; Velasco et al., 2000). However, in contrast to what has been proposed for other LPS, the virulence of *Brucella* LPS is not expressed in the classical form of an endotoxic active molecule (Fig. 18). It is known that LPS from most Gram-negative bacteria activates phagocytic cells by stimulating the respiratory burst, inducing the production of bactericidal nitrogen intermediates and the generation of active cytokines (Brade et al., 1988; Cline et al., 1968; Kelly et al., 1991). All these mechanisms contribute to the destruction of intracellular bacteria and promote the fusion of the ingested bacteria with lysosomes (Silverstein and Steinberg, 1990). In contrast, *Brucella* LPS practically does not stimulate the oxidative burst or stimulate the release of lysozyme in phagocytic cells and fails to generate significant amounts of bactericidal reactive oxygen intermediates (Jiang and Baldwin, 1993a; Jiang et al., 1993c; Rasool et al., 1992). Furthermore, *Brucella* LPS induces very little release of interferon gamma (IFNγ) or tumor necrosis factor (TNF), substances which are known to enhance lysosomal fusion and the microbicidal mechanisms of phagocytic cells (Goldstein et al., 1992; Keleti et al., 1974). In this respect, the low biological activity of *Brucella* LPS may be envisioned as an advantage of *Brucella* parasites to adapt to intracellular life. Within this context, the *Brucella* LPS is considered a virulent factor.

Iron Chelation and Bactericidal Action *B. abortus* organisms secrete 2,3 dihydroxybenzoic acid and the catecholic siderophore brucebactin (Denoel et al., 1997a; González-Carrero et al., 2002; Leonard et al., 1997; López-Goñet al., 1992; Uptake of Inorganic Nutrients). Hypothetically, iron-capturing molecules may compete for intracellular iron within the macrophage and inhibit iron-mediated bactericidal killing systems (Leonard et al., 1997). It has been demonstrated that iron-loaded macrophages have enhanced capability to kill or prevent the replication of intracellular *B. abortus* (Jiang and Baldwin, 1993b). This effect was demonstrated with opsonized and nonopsonized bacteria, as well as with attenuated and virulent strains of *B. abortus*. The augmented bactericidal activity in the presence of iron may be indirectly mediated by the Haber-Weiss-Fenton and related reactions (Jiang and Baldwin, 1993b). In these reactions, hydroxyl radicals are generated from hydrogen peroxide in the presence of Fe^{++}, which is oxidized to Fe^{+++}. Generation of more hydroxyl radicals and Fe^{+++} results from the reaction between superoxide and Fe^{++}. The fact that the bactericidal action could be blocked with hydroxyl scavengers supports this general idea. It is likely that, in activated macrophages, the concentration of superoxide ions and hydrogen peroxide increases within the lysosomes, thus providing the substrates for the above-summarized reactions. Similar phenomena have been observed with other Gram-negative and Gram-positive bacteria.

Although 2,3 dihydroxybenzoic acid has a comparatively moderate ability to chelate iron, it is able to block the Haber-Weiss-Fenton reaction. This compound protects killing of *Brucella* mediated by activated macrophages during the first 12 h and increases the number of intracellular brucellae recovered after 48 h of infection (Leonard et al., 1997). Mutations in *aro*C (the gene coding for chorismate synthase) block chorismate synthesis and therefore these mutants do not produce *para*-amino benzoic acid, a precursor of 2,3 dihydroxybenzoic acid. *Brucella aro*C mutants show reduced virulence, supporting a role for this molecule and/or the siderophore during intracellular survival (Foulongne et al., 2001; Hong et al., 2000). However, *aro*C mutants are pleiotropic, and Δ*entC B. abortus* mutants (which are defective in isochorismate synthase and thus do not produce 2,3 dihydroxybenzoic acid) are not attenuated in mice (Bellaire et al., 1999). Concurrent with this, *B. abortus* mutants in an *entF* homologue do not produce brucebac-

tin or excrete 2,3 dihydroxybenzoic acid but replicate normally in murine macrophages (González-Carrero et al., 2002). Therefore, neither brucebactin nor 2,3 dihydroxybenzoic acid seems to work as a virulence factor in the mouse model. However, there are reports on the attenuation of *B. abortus* Δ*entC* in pregnant goats, suggesting that the situation may be different in natural hosts (Bellaire et al., 1998). This is, however, somewhat contradictory to the fact that *Brucella* bacterioferritin deletion mutants replicate normally within human phagocytes (Denoel et al., 1997a).

Modulation of Intracellular Trafficking After phagocytosis, bacteria are found inside a membrane-bound compartment, which undergoes a maturation process that depends upon the nature of the ingested organism (Méresse et al., 1999). The "constitutive route" followed by inert particles, such as latex beads or killed organisms, is revealed by the sequential acquisition of molecules displayed on the vacuole-containing bacteria (Garin et al., 2001). Immediately after uptake, the phagocytic vacuole exhibits plasma membrane molecules, then markers of early endosomes followed by molecules distinctive of late endosomes, and finally elements characteristic of lysosome molecules. Among these molecules, small GTPases of the Rab family, involved in the regulation of fusion events along the endocytic pathway, reflect the capacity of the phagosomes to fuse with endocytic organelles. It has been proposed that phagosome maturation occurs by multiple transient fusion events, a process referred to as "kiss-and-run." Intracellular pathogens have evolved strategies to avoid this progressive transformation of their vacuole to a phagolysosome, thereby evading killing mechanisms. *Brucella* organisms, as do other intracellular pathogens, actively evade the constitutive route, promoting their migration to a compartment where they are capable of extracting nutrients, and replicate (Pizarro-Cerdá et al., 1998b). This process is commanded by the interaction of complex mechanisms with the intervention of several genes and molecules. The absence of one or more of these elements alters the intracellular biogenesis of the bacteria and breaks the natural equilibrium established between the parasite and its host cell.

Escaping from the Endocytic Pathway *Brucella bvrS-bvrR* mutants forced to penetrate CNF-treated HeLa cells follow the degradative pathway (C. Guzmán-Verri et al., unpublished observations), indicating that this two-component, sensory regulatory system is involved not only in penetration (Mechanisms of Entry to Host Cells) but also in controlling vacuole maturation. Cyclic glucans of plant pathogenic bacteria are essential factors for parasitism (Breedveld and Miller, 1994). *Brucella* possess a periplasmic cyclic-β-(1,2)-glucan, which is not osmotically regulated, in contrast to what happens in *Agrobacterium* or *Rhizobium* parasites (Briones et al., 1997). *Brucella cgs* mutants, unable to produce cyclic glucan, are avirulent in mice and incapable of avoiding fusion with lysosomes (Iñón de Iannino et al., 1998; J. P. Gorvel, personal communication). Since *Brucella cgs* mutants adhere and penetrate cells similarly to the wildtype bacteria, it is concluded that cyclic glucans are necessary for the correct biogenesis of these organisms.

Recently, it has been described that a genetic system (*virB*) encoding for a type IV secretion machinery (Boschiroli et al., 2002; Comerci et al., 2001; Delrue et al., 2001) is also involved in regulating the intracellular trafficking of *Brucella*. Type IV secretion systems are complex structures composed of several proteins, some of which concomitantly span the inner and the outer-membrane (Fig. 5). These systems are specialized in transferring molecules (proteins or DNA) from the internal to the external milieu of the bacterial cell (Christie and Covacci, 2000). The *Brucella* type IV secretion system is composed of 13 open reading frames and shows similarity with the VirB complex of other cell-associated bacteria, such as *Agrobacterium*, *Legionella* and *Rickettsia*. Polar mutations in the *vir*B1 and *vir*B10 abolish the ability of *Brucella* to replicate in mice and cells (Comerci et al., 2001). Nonpolar mutation in *vir*B8 and *vir*B10, coding for internal membrane proteins, generates attenuated bacteria. Mutations in *vir*B12 and *vir*B13 do not demonstrate defects (O'Callaghan et al., 1999; D. J. Comerci, personal communication). Mutations in *vir*B genes do not have an effect in the attachment and internalization of *Brucella* to cells (Boschiroli et al., 2002; Comerci et al., 2001; Delrue et al., 2001), although some authors claim that the VirB system is implicated in internalization (Watarai et al., 2002). *Brucella* organisms harboring either polar or nonpolar mutations in *vir*B10 are capable of penetrating cells, as is the wild-type *Brucella*, localizing in LAMP-1-positive compartments at early times of infection. However, after this period, *vir*B10 polar mutants are sorted to degradative compartments positive for lysosomal markers, whereas nonpolar *vir*B10 mutants remain within compartments devoid of lysosomal or endoplasmic reticulum proteins, but retain early endosome markers. After 12 h, a large proportion of intracellular nonpolar *vir*B10 mutant bacteria are recycled to the cell surface. Once outside, the bacteria seem to replicate adhered to the cell

envelope. These results indicate that although the *vir*B genes are not required for attachment or invasion, they are necessary for regulating the intracellular trafficking from early endosomes to the endoplasmic reticulum. In addition, the VirB10 product seems to be essential for preventing the fusion of *Brucella*-containing vacuoles with lysosomes. Therefore, the absence of VirB11 would preclude the correct assembling of the type IV secretion machinery necessary for secreting bacterial substances that prevent lysosomal fusion. It follows that the absence of VirB10 will allow a defective but partially functional secretory system competent for controlling lysosomal fusion, but incapable of releasing substances necessary for promoting retrograde *Brucella* trafficking to the endoplasmic reticulum.

The putative *vir*B10 and B11 genes seem to code for an internal transmembrane protein of unknown function (structural?) and for a cytoplasmic or inner membrane protein that has a conserved Walker A NTP-binding motif, respectively. Gene reporter analysis has revealed that the expression of the *Brucella* VirB system is activated during the internalization (from 3–12). Then the expression of the system diminishes, corresponding to the replicating time in the endoplasmic reticulum (Boschiroli et al., 2002; Comerci, personal communication). Some authors claim that *vir*B induction only occurs once the bacteria are inside the cells and phagosome acidification has occurred, being this the major signal for expression of this system (Boschiroli et al., 2002). Others, in contrast, sustain that *vir*B operon is turned on during stationary phase and that acidic conditions do not affect the expression of the VirB system (Sieira et al., 2000; Comerci, personal communication). Therefore, it seems that the type IV secretion machinery is required for controlling the brief trafficking of *Brucella* through the endocytic network until the bacterium reaches its replicating niche within the endoplasmic reticulum. Once the bacterium has reached the endoplasmic reticulum, the secretion apparatus may be turned off.

Trafficking from the endocytic network to the endoplasmic reticulum via autophagosomes requires not only live virulent bacteria, but a physiologically balanced *Brucella*-containing vacuole. For instance, in cells expressing an activated form of rab5 (bound to GTP), an important fraction of the internalized parasites are unable to escape from the early *Brucella*-containing compartment (Chaves-Olarte, 2002). Although a fraction of bacteria are capable of reaching the endoplasmic reticulum in these mutant cells, unexpectedly a few *Brucella* escape from these "early" giant vesicles to the cytoplasm (J.-P. Gorvel, personal communication). These events suggest that *Brucella* is capable of adapting to different intracellular environments by controlling its own intracellular trafficking through direct interaction with its host vacuole.

Escaping from Autophagosomes The first step in the biogenesis of autophagosomes is the acquisition of lysosomal membrane-associated proteins. Acidification of the maturating compartment occurs by inclusion of the H-ATPase, and finally delivery of acid hydrolases allows the degradation of intravacuolar isolated cytoplasmic materials (Dunn, 1994). In fact, it has been shown that nocodazole treatment causes the accumulation of acidic autophagosomes that lack acid hydrolases, supporting the concept that vacuole acidification and acquisition of hydrolytic enzymes are separate events. The presence of LAMP-1 and LAMP-2 but the absence of cathepsin D at 2 h postinoculation in *B. abortus*-containing phagosomes also supports the model of a stepwise maturation of autophagic vacuoles. Whether *B. abortus*-containing autophagosomes are able to acquire the H-ATPase remains to be established. *Brucella* phagosomes seem to acidify rapidly after infection in murine J774 macrophages (Arenas et al., 2000; Porte et al., 1999). This acidification step seems to be independent of phagosome-lysosome fusion. In Vero cells, repressors of endosome acidification, such as chloroquine and ammonium chloride, reduce the number of *Brucella* with respect to controls (Detilleux et al., 1991). Adjustment of intravacuolar pH has been shown as essential for the activation of virulence genes in certain intracellular parasites. Parasitophorous vacuoles of *Leishmania amazonensis* maintain an acidic pH in infected macrophages (Antoine et al., 1990). New sets of proteins are synthesized by *S. typhimurium* upon infection of host cells after modulation of the phagosome pH (Buchmeier and Heffron, 1990). This latter bacteria induces reduction of phagosome acidification to activate the virulence genes of the *phoP-phoQ* complex (Alpuche-Aranda et al., 1992). *Brucella* abortus is able to synthesize a new set of proteins during macrophage infection (Lin and Ficht, 1995; Rafie-Kolpin et al., 1996), suggesting that intracellular conditions (one of which could be intravacuolar pH) may contribute to the activation of genes necessary for trafficking from autophagosomes to the endoplasmic reticulum (Pizarro-Cerdá et al., 1998c). The critical difference between the attenuated vaccine strain 19 and the virulent *B. abortus* 2308 seems to be the inhibition of autophagosome maturation by the virulent strain (Fig. 36). The attenuation of strain 19 may lay in its incapacity to respond to environmental stimuli present in the autophagosome (acidification, for example) that could activate virulence

genes for the expression of proteins important to remodel the autophagosome.

Life Within the Replicating Niche In addition to a suitable source of carbon and energy, *Brucella* requires some cofactors and vitamins for growth (Nutritional Requirements). It is also able to use some amino acids as a source of carbon and energy and to eliminate the urea that could build up as a metabolite noxious for the host and the bacterium under some conditions (ATP Synthesis and Respiratory Chain; Oxidation of Amino Acids). Besides being a strategy for avoiding lysosome fusion during later steps of intracellular invasion, association of pathogenic *Brucella* with the endoplasmic reticulum could be a strategy for obtaining metabolites synthesized or translocated to this compartment (Simon and Blobel, 1991). By stimulating host cell autophagy, the bacteria would increase degradation of host proteins and availability of amino acids. However, the mechanism by which these small compounds would be delivered back to the endoplasmic reticulum and used by the bacteria should be defined. In contrast to professional phagocytes, it seems that the placental environment offers a privileged site for brucellae replication. It is becoming evident that trophoblasts are metabolically active cells capable of producing a variety of hormones and other factors which may stimulate the growth of *Brucella* organisms (Enright and Samartino, 1994). Genes coding for putative efflux pumps capable to serve as export of quorum sensing metabolites have been identified in Brucella (DelVecchio et al., 2002). Quorum sensing hydrophobic molecules such as acyl-homoserine lactone released by Brucella down regulate the expression of *vir*B genes in vitro (Taminiau et al., 2002), suggesting that this small hydrophobic molecule could play a role in the control of the type IV secretion system, necessary for the intracellular trafficking, but unnecessary and inhibitory during intracellular growth inside the endoplasmic reticulum.

Role of the Outer Membrane in Nutrient Uptake The overall higher hydrophobicity of *Brucella* cell envelopes, the close association among the macromolecules of the outer-membrane and the properties of the porins are the factors implicated in the selective penetration of nutrients inside the bacterial cell. It has been demonstrated that the absence of a barrier to hydrophobic substances is linked to the structure of the *Brucella* LPS core and lipid A (Freer et al., 1996; Martínez de Tejada and Moriyón, 1993; Velasco et al., 2000). The possible advantages of a hydrophobic envelope for intracellular α-2 subclass Proteobacteria also have come to light by the finding that *Rhizobium* LPS becomes highly hydrophobic during bacteroid development (Kannenberg and Carlson, 2001). The net result of this structural change in the LPS is that intracellular bacteroids have a more hydrophobic outer-membrane than the free-living rhizobiae have. This adaptive condition could promote the exchange of nutrients and favor intracellular life of the bacteroids. Obvious comparisons between the intracellular lifestyle of *Brucella* and *Rhizobium* emerge, since these two bacteria are phylogenetically close relatives (Moreno et al., 1990). The permeability of the *Brucella* outer-membrane to sexual hormones and siderophores is discussed elsewhere in the chapter (The Hydrophobic Pathway; Uptake of Inorganic Nutrients). As noted (Porin Proteins), *B. abortus* only expresses one of the two porin protein genes it carries, and it has been suggested that the second one may be specifically expressed during intracellular parasitism (Marquis and Ficht, 1993; Ficht et al., 1989).

Auxotrophic and Cell Cycle Genes During Intracellular Life Many of the mutations described in this section may hamper the adequate extraction of nutrients from the replicating niche. It is likely that these genes are devoted to the regulation of vital functions not directly involved in virulence, but with more general aspects of the *Brucella* physiology.

Mutants displaying reduced virulence and/or reduced intracellular survival within macrophages have been identified by signature-tagged transposon mutagenesis (Foulongne et al., 2000). Several of these attenuated mutants carry auxotrophic defects, such as those necessary for leucine, arginine or aromatic acid biosynthesis, whereas others carry deficiencies in the synthesis of chorismate for the generation of *para*-aminobenzoic acid necessary for quinone synthesis, 2,3 dihydroxybenzoic acid, brucebactin and folic acid. Mutations in genes involved in the glucose metabolism, such as in the gene coding for phosphoglucose isomerase, also attenuate *Brucella*, probably owing to several pleiotropic defects, including the synthesis of cell wall peptidoglycan. Similarly, transposon insertion in the *gpt*-like gene coding for hypoxanthine-guanine biosynthesis attenuates *Brucella*, probably owing to alterations in the nucleotide biosynthesis. In support of this are the *B. melitensis purE* (purine auxotrophic) mutants that display reduced growth in macrophages (Cheville et al., 1996a; Drazek et al., 1995). The *purE* mutation has minimal effect on internalization, but effectively blocks intracellular replication. The *purE* mutation may cause bacterial death simply as a result of starvation.

Other mutants, also identified by signature-tagged mutagenesis (Foulongne et al., 2000), have defects in regulatory systems, such as LysR transcriptional regulator, which is part of a positive regulator system of virulence genes in several bacteria. Mutants in the expression of NtrY protein (a sensor of an Ntr-related regulator; Dorrell et al., 1999) are weakly attenuated, probably as a result of a pleiotropic negative effect on the *ntr* regulon (The NtrBC System). As in other bacteria, mutations in genes involved in glutamine metabolism reduce the ability of *Brucella* to replicate in macrophages (Foulongne et al., 2000). The *Brucella ccrM* gene codifies for a CcrM DNA methyltransferase that catalyzes the methylation of the adenine in sequences GANTC (Methylation and Control of Chromosome Duplication and Cell Cycle). This gene performs important functions during cell division and it is, therefore, essential for viability (Robertson et al., 2000b; Wright et al., 1997). Increase in the *ccrM* copy number, in addition to altering the morphology of the bacterial cells, attenuates *Brucella*, indicating that controlled cell cycle and bacterial division are necessary for intracellular survival. Mutations in the *bacA* gene, which codes for a putative cytoplasmic membrane transporter, render *B. abortus* avirulent (LeVier et al., 2000). *Brucella bacA* mutants display altered transport of molecules and then deficient *Brucella* replication within cells. Auxotrophic mutants for ferrochelatase, the enzyme involved in the last step of the heme synthesis (catalyzing the incorporation of ferrous iron into the protoporphyrin molecule), are also attenuated (Almirón et al., 2001).

Maintaining the Host Cell Alive Some parasites may promote programmed cell death, whereas others are prone to prevent it, prolong cell life, or are even capable of stimulating replication of their host cells. Proteobacteria of the α subdivision, such as *Rickettsia*, *Agrobacterium*, *Rhizobium* and *Brucella*, as well as other intracellular parasites capable of establishing chronic infections (i.e., *Mycobacterium* and *Chlamydia*) prevent cell death. Heavily infected *Brucella* trophoblasts, epithelial cells or macrophages do not display signs of necrosis or apoptosis (Anderson et al., 1986b; Anderson et al., 1986c; Detilleux et al., 1990b; Jiang and Baldwin, 1993a; Tobias et al., 1993; Fig. 30). DNA synthesis, microtubule spin formation, chromosome migration, karyokinesis and cytokinesis are not inhibited by intracellular *Brucella* (Chaves-Olarte et al., 2002). As a consequence, dividing cells filled with brucellae are frequently observed in vivo and in vitro (Detielleux et al., 1990a; Detilleux et al., 1990b; Detilleux et al., 1991). In CNF-treated HeLa cells, cytokinesis is inhibited due to paralysis of actin filaments without affecting nuclear division. When these cells are infected with *Brucella*, karyokinesis proceeds without signs of degeneration, despite the large number of intracellular *Brucella* within the endoplasmic reticulum (Chaves-Olarte et al., 2002). Live but not killed *B. suis* prevent programmed cell death of infected human monocytes (Gross et al., 2000). This suggests that infection protects host cells from several cytotoxic activities generated during the immune response. Since both invaded and noninvaded cells are guarded against apoptosis, it has been suggested that this protective mechanism is mediated through soluble substances released during bacterial infection. Apoptosis inhibition is independent of LPS and requires the overexpression of the *A1* gene by infected cells, a member of the *bcl-2* family involved in the survival of blood-forming cells.

In contrast to other LPS, *Brucella* LPS practically does not display endotoxicity and is a poor inducer of cytotoxic mediators (Goldstein et al., 1992; López-Urrutia et al., 2000; Moreno et al., 1981; Rasool et al., 1992). This property shared by other intracellular animal pathogens (such as *Rickettsia*, *Legionella* and *Bartonella*) may be envisioned as an evolutive advantage of *Brucella* parasites for adaptation to intracellular life (Freer et al., 1996; Moreno, 1992; Rasool et al., 1992; Velasco et al., 2000). It is not surprising that lipid As of *L. pneumophila* and *B. abortus* parasites have coevolved to have a similar structure and, in consequence, display low endotoxicity and reduced ability to stimulate cells (Goldstein et al., 1992; López-Urrutia et al., 2000; Moreno et al., 1981; Rasool et al., 1992; Zähringer et al., 1995; Fig. 7). This property may be idiosyncratic and useful for intracellular bacteria.

Modulation of the Immune Response Once inside macrophages, pathogens might diminish or abrogate their antigen presentation capacity, thus reducing the T cell-mediated immune responses. The LPSs from different bacteria have been shown to modulate the immune responses in several systems (Cella et al., 1997; Knolle et al., 1999; Krieger et al., 1985; Uchiyama et al., 1984). *Brucella abortus* LPS molecules accumulate inside lysosomal compartments and associate with MHC-II proteins in antigen-presenting cells (Forestier et al., 1999a; Forestier et al., 1999b; Forestier et al., 2000). The intracellular LPS, which remains for long periods without being degraded, is exported to the cell surface where it forms stable macrodomains (Figs. 35 and 37). Once inside macrophages, *B. abortus* LPS impairs the MHC-II presentation pathway, but not MHC-I presentation of foreign peptide antigens (Fig. 37). This impairment is neither

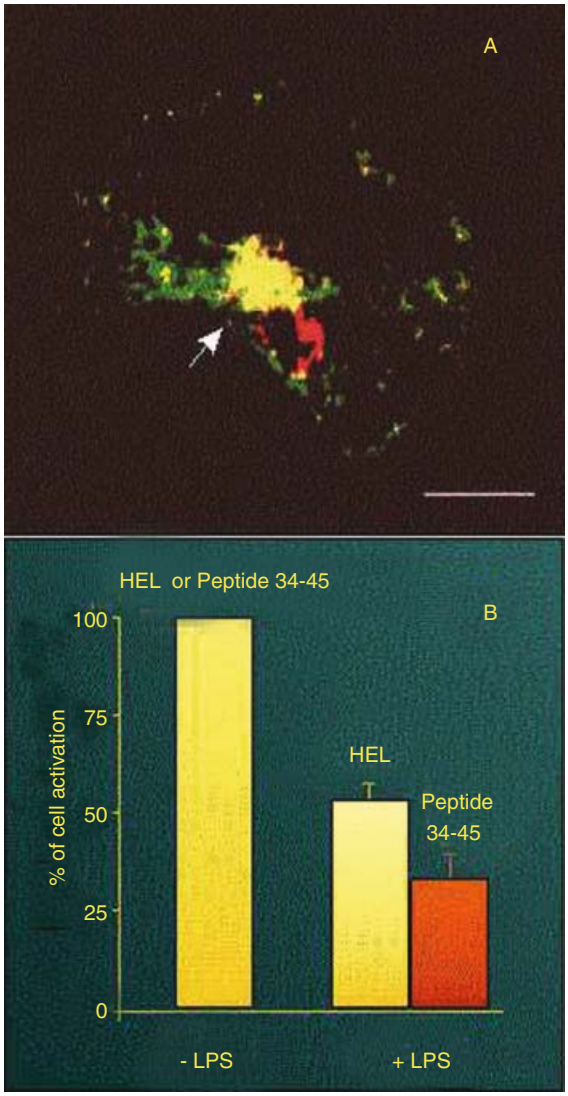

Fig. 37. *Brucella* LPS binds to MHC-II molecules and inhibits T cell responses to protein antigens. A) *Brucella* LPS (red) and MHC-II (green) colocalize (yellow) within compartments and on the surface of murine macrophages. B) Inhibition of antigen presentation of hen's egg lysozyme (HEL) peptides and derived synthetic peptide (34–45) to respective specific T CD_4^+ clones by *Brucella* LPS-treated macrophages. Colocalization was detected by double immunofluorescence and viewed in a confocal microscope. Notice that *Brucella* LPS-MHC-II complexes establish large macrodomains (white arrow points to area of yellow fluorescence) on the surface of phagocytic cells. Adapted from Forestier et al. (2000). from a deficient uptake or catabolism of the native antigen nor from a reduced MHC-II surface expression, reduced number of B7 membranous costimulatory molecules, or defective α/β dimer formation. In addition, this inhibitory effect is not due to a direct suppressive action of LPS on T cells, independent of macrophages (Forestier et al., 2000). *Brucella* LPS macrodomains at the macrophage plasma membrane are highly enriched in MHC-II molecules (Fig. 37), suggesting that the LPS-MHC-II macrodomains may impair the appropriate recognition of protein peptide-MHC-II complexes by CD_4^+T cells (Forestier et al., 2000). The presence of such MHC-II-LPS macrodomains does not prevent the binding of antigen peptides into the groove of MHC-II molecules. Therefore, the *Brucella* LPS-induced interference on MHC-II antigen presentation is likely to occur distal to intracellular events leading to the meeting of antigenic peptides and MHC-II molecules. The LPS molecules embedded in the membrane of MHC-II-positive compartments may interact with already peptide-MHC-II forming ternary complexes, which then recycle to the plasma membrane. In one model, the LPS *O*-polysaccharide, facing the external milieu, could prevent the accessibility of MHC-II complexes to their specific T cell receptor. Another model is related to a superantigen-like function in T cell activation. It is known that superantigens modify the geometry of TCR-peptide/MHC-II complexes, which may be less critical for T cell activation than certain other factors, in particular those involved in the stability of the resulting complex (Andersen et al., 1999; Kersh et al., 1998). The serial triggering (Itoh et al., 1999; Valitutti et al., 1995; Viola and Lanzavecchia, 1996) and kinetics proofreading models (Rabinowitz et al., 1996) of T cell activation suggest that the short half-lives of TCR-peptide/MHC-II complexes are required for efficient T cell stimulation. The presence of *Brucella* LPS-MHC-II macrodomains in macrophages has been detected even after 60 days, thus highlighting the remarkable stability of these surface LPS macrodomains. In this model, LPS could downregulate T cell responses by stabilizing the MHC-II/peptide complexes at the cell surface. Consequently, in contrast to super antigens, *Brucella* LPS would be less efficient at triggering T cells because they form TCR-LPS-MHC-II complexes with a very long half-life.

The in vitro inhibition of the immune response correlates to that observed in vivo upon infection by *Brucella*. It is worth noting that chronic brucellosis is accompanied by a general immunosuppression that can be revealed by using an IL-2 detection system (Zhang, 1992; Zhang et al., 1993; Forestier et al., 1999a). Infected macrophages may exert a negative feedback, diminishing lymphocyte proliferation in response to *Brucella* antigens (Cheers et al., 1980; Riglar and Cheers, 1980). It has been proposed that chronically infected macrophages may fail to act as targets of T cells and may downregulate T lymphocyte function (Baldwin and Winter, 1994). Moreover, it is known that *Brucella* inhibits the production
