Almost 50 years of Russian Antarctic studies can be conventionally divided into three stages: study of natural objects, processes, and phenomena in the Antarctic (1955–1969), research for resource exploration in the Antarctic (1970–1991), and determination of the role and place of Antarctica in the global natural and public processes (1992 to present).

During the first stage, an extensive expedition infrastructure was created based on a network of year-round Antarctic stations—Mirny, Vostok, Molodezhnaya, Novolazarevskaya, Bellingshausen, Oasis, Komsomol'skaya, Pionerskaya, and Sovetskaya. A series of inland sledge-caterpillar traverses to the most inaccessible regions of Antarctica were organized. Active aviation operations in the inland areas to investigate the structure of the ice sheet and mountain rock outcrops were carried out. Various oceanographic studies were conducted in the Southern Ocean. The first stage resulted in publication of two volumes of the *Atlas of the Antarctic* (1966–1969).

The resource stage of Antarctic studies was characterized by the large-scale development of expedition activities. The SAE fleet numbered up to eight cargo, research, and passenger ships and oil tankers. In the Pacific Ocean sector, Leningradskaya and Russkaya stations and in Prydz Bay, Progress Base were built. The Soviet stations covered the perimeter of the entire Antarctic continent. The expedition numbered 570 people during wintering and 980 people during summer operations without taking into account crews of ships and aircraft. Large special oceanographic and biological studies of the Southern Ocean were undertaken. Most active were geological and geophysical studies for which field bases Druzhnaya-1, 2, 3, and 4 were arranged. The work of geologists was supported by a large number of aircraft including heavy Il-18 airplane. For operation of such airplanes and Il-76 cargo aircraft, snow-ice air fields that were unique at the time were built at Molodezhnaya and Novolazarevskaya stations. Regular flights were organized via African airports. Extensive materials were accumulated providing support for Soviet ships in the Southern Ocean. Russian geologists collected a large amount of data for evaluating the mineral and hydrocarbon potential of the Antarctic.

The third stage was related to changes in the political-economical life of the country and entry into force of such international law acts as the Protocol on Environmental Protection to the Antarctic Treaty. The network of Russian Antarctic stations decreased to five (Mirny, Vostok, Novolazarevskaya, Progress, and Bellingshausen), and the number of seasonal field bases to two (Druzhnaya-4 and Molodezhnaya). The expedition activities are supported by the R/V *Akademik Fedorov* of Roshydromet and *Akademik Aleksandr Karpinsky* of the Ministry of Natural Resources. The number of expedition participants decreased to ninety people for wintering and eighty for seasonal operations. However, these changes did not influence the character of RAE main research directions. The focus was on the study of modern climate variability, reconstruction of paleoclimate characteristics, dynamics of the mechanisms of development of the "ozone hole" phenomenon, influence of "space weather" (solar wind energy in the interplanetary space) on the character of atmospheric processes, efficiency of technical equipment, and life activity of organisms.

A great deal of attention was given to the problems of Antarctic environment protection aiming both at removal and utilization of waste of the Russian activity during the past decade in Antarctica and introduction of modern technologies preventing its accumulation.

A unique Russian-US experiment on the establishment of the first scientific drifting station in the Weddell Sea in the Southern Ocean called "Weddell-1" can be referred to the studies of this period of activity of Russia. Before that, the international Antarctic community knew nothing like this experiment. The station team consisted of fifteen Russian and seventeen American specialists. A self-contained drift of the ice camp continued from February 12 to June 9, 1992. Over this time, the ice floe passed 750 km to the north with an average drift velocity of 6.6 km day^{-1}, maximum velocity of 25 km day^{-1} (May 24) and minimum velocity of 0.5 km day^{-1} (February 27). The research programs of the drifting station were devoted to physical and chemical oceanography, surface meteorology, ice-cover dynamics, and sea ice biology. The experiments were conducted in the practically unexplored western Weddell Sea. Unique data on the formation of cold bottom water on the Antarctic shelf were obtained. Parameters of heat-mass exchange in the ocean-ice-atmosphere system were determined and a wide range of sea ice cover deformation under the impact of natural forces was investigated. The specific features of biodiversity and factors of habitats of subice ecosystems were revealed.

In the 1990s, deep drilling at Vostok station was intensified in the framework of the Russian-French-American Agreement. As a result the deepest ice borehole in the world with a depth of 3623 m was drilled in 1999. Reconstruction of paleoclimatic changes based on data of this ice core allowed obtaining information on this process over the last 420 kyr.

The broad spread of Russian Antarctic stations allowed Russian specialists to estimate the tendencies of current climate variability and total ozone content over more than 40 years. The tendency for such variability has an ambiguous character for the regions of West and East Antarctica. Thus in the first region, a positive trend of surface air temperature changes is observed, while in the second there is a small negative trend. For the last few years, stabilizing of the "ozone hole" expansion processes and the total ozone decrease in it is noted. An analysis of measurement data indicates a purely natural character of this phenomenon rather than its anthropogenic origin. Importance of geomagnetic and ionospheric observations at the Russian Antarctic stations, especially at Vostok station was recognized long ago by the international community. In the late twentieth century, Russian geophysicists proposed a new integral indicator of the state of geomagnetic perturbations in Earth's polar caps—a "PC-index." Online publication of Vostok data allows estimation of the magnetosphere state not only in the South Geomagnetic Pole area but also in the Arctic, given conjugation of these processes in both hemispheres. A new direction of geophysical studies was investigation of the influence of different nonelectromagnetic origin fields on the peculiarities of life activity of biological organisms, in particular, on the biochemical reaction rates. These fields are most actively manifested in the Antarctic, and studies of their influence on living organisms are becoming increasingly more interesting.

One of the most important projects initiated in the 1990s was that of subglacial Lake Vostok studies. Russia began investigations of the largest Antarctic subglacial water body in 1995 obtaining unique materials on different geographical characteristics of the lake and structure of its bottom sediments. Microbiological studies of the ice core from the low borehole horizons at Vostok station using molecular biology methods turned out to be of the greatest priority. The obtained data not only revealed a possible biodiversity of surface lake water, but also suggested a hypothesis of its riftogenic origin.

The Russian sub-program "Study and Research of the Antarctic" is structurally comprised of five sections: basic studies, scientific-applied studies and developments, environmental monitoring, environmental protection, and logistics support of studies and activities. Specialists of twenty-seven research institutions and universities representing Federal Service for Hydrometeorology and Environmental Monitoring, Ministry of Natural Resources. Ministry of Education and Science, Ministry for Defense, Federal Agency of Geodesy and Cartography, Federal Agency on Fishery and Russian Academy of Science participate in the subprogram projects planned up to 2012. Parameters of RAE activity are determined by the corresponding Decisions of the Government of the Russian Federation for a 5-year period.

RUSSIAN NAVAL (*VOSTOK* AND *MIRNYY*) EXPEDITION (1819–1821)

The Russian expedition to the North and South Poles, and its first division, that is, the South Pole expedition group under the command of Fabian Gottlieb von Bellingshausen on the sloop *Vostok* and transport ship *Mirnyy* (commander Mikhail Petrovich Lazarev), are ascribed special importance in the history of Antarctic exploration, as this expedition is considered to have discovered the Antarctic continent on 28 January 1820 (three days before Britain's Edward Bransfield).

Not a great deal is known about the background of the expedition, and the archival files available (Samarov 1952) do not provide answers to the questions of why the Russian expeditions exploring the Arctic and Antarctic Oceans took place simultaneously, when the idea for them had come into being, and who initiated the concept. The expedition was prepared in a very short period (taking only half a year from the preliminary plan to launching of the four-ship squadron) but cost a great deal (100,000 roubles). In the Russian Empire, it was normal for the financing of exploring expeditions to take years to put into place. The speed with which this expedition was funded lends weight to the belief that Tsar Alexander I had approved it personally. However, the preparations were so hurried that there was not time to get the ships properly ready for a voyage into heavy ice. And the German naturalists who planned to join the expedition soon gave up the idea, as they were not able to get ready in such a short time (having been informed of the expedition only a month before it was launched). Because of the lack of time, the St. Petersburg Academy of Sciences was not able to compile scientific instructions for the expedition, so they were replaced by a set from the Minister of Naval Affairs. Only one scholar, Ivan Mikhailovich

Simonov, Professor extraordinary of astronomy of Kazan University, ultimately participated in the Antarctic part of the expedition.

The Antarctic expedition under von Bellingshausen had two goals: first, to sail as close to the South Pole as possible and discover new lands in this route, and, second, to improve the map of the southern part of the Pacific Ocean and record any new objects in the region.

Both parts of the expedition set off from Kronshtadt on July 16, 1819. In Portsmouth, England, the two groups separated. Von Bellingshausen headed for Tenerife and from there to Rio de Janeiro, which he reached on November 24, 1819. His first objective was to map the southern coastline of South Georgia—which had been discovered by James Cook but remained unmapped—and the hypothetical Sandwich Land. After South Georgia was mapped, on January 3, 1820, the Russians discovered the Traversay Islands group at the north end of the South Sandwich Islands. On January 11, 1820, they determined that Cook's "Sandwich Land" did not exist. Instead, there was a group of islands that von Bellingshausen gave the name South Sandwich Islands. From there, following instructions, they headed south, and in three months (from January to March) von Bellingshausen made six attempts to move through the ice to the South Pole, reaching his farthest south on January 28, 1820 (69°25′ S).

On April 11, 1820, the expedition reached Port Jackson (Sydney, New South Wales), where it was provided with new supplies. On May 19, they sailed for the Tuamotu Islands in the Pacific Ocean in an attempt to discover new islands there. A number of discoveries were made in June 1820. On September 21, 1820, the expedition returned to Port Jackson, where preparations were started for another attempt on the South Pole. On November 12, the anchor was raised and the expedition sailed south to map Macquarie Island.

From the beginning of December 1820 until the end of January 1821, von Bellingshausen made four attempts to approach the South Pole. The most successful was the last. On January 22, 1821, he reached 69°53′ S, 92°19′ W. The same day the Russian expedition discovered the first land—Peter I Øy—south of the Antarctic Circle, which they measured as lying at 68°57′ S, 90°46′ W. On January 29, von Bellingshausen made another discovery, which was given the name the Land of Alexander I (now Alexander Island). The expedition now headed for Brazil to check information forwarded by the Russian ambassador, according to which the coast discovered south of Tierra del Fuego was part of the southern continent. Von Bellingshausen passed through Bransfield Strait (February 5, 1821) and decided that the land that could be seen appeared to be a group of islands. He mapped it and gave Russian names to the South Shetland Islands discovered by William Smith in 1819 and mapped by Bransfield in 1820. From there, the expedition sailed to Rio de Janeiro. It returned to Kronshtadt on August 5, 1821.

Von Bellingshausen's expedition was the second (after Cook) to sail round the Antarctic, circumnavigating the globe at a high southern latitude. The expedition lasted for 751 days, 527 of which were spent on the sea (Shvede 1960). During that time, twenty-nine islands were discovered and mapped, and a vast numbers of observational data were recorded on the natural history, winds, temperatures, water regimes, currents, and ice conditions and types of the Southern Ocean (Bellingshausen 1831). However, European researchers learned so little about those observations that at the beginning of the twentieth century Robert Falcon Scott wrote that "unfortunately, little is known of Bellingshausen's voyage, as the narrative was never translated into English" (Scott 1905). The first German account on the Russian expedition was not published until published in 1842 (Lowe 1842), and it was partly translated into English in 1902. A complete translation into English of the story of von Bellingshausen's expedition did not appear until 1945 (von Bellingshausen 1945).

Although von Bellingshausen did not succeed in going farther south than Cook (who reached 71°10′ S), his expedition obtained the first authentic information on the existence of land south of the Antarctic Circle. Unfortunately, these data, like those of James Clark Ross and other expeditions taking place in the Antarctic in the nineteenth century, were too scanty and scattered to allow scientists to confirm with certainty the existence of a continent in the region of the South Pole. That happened only in the first decade of the twentieth century, when it was proven beyond doubt that an Antarctic continent actually existed. In spite of those discoveries, however, it was not until the 1930s that von Bellingshausen began to be regarded as the discoverer of continent, as the knowledge of the entire outline of the continent was still incomplete. Prior to this, arguments had been made in favour of Edward Bransfield of Britain of Nathaniel Palmer of the United States. The first to draw attention to the fact that on January 28, 1820, the Russians were only 20 miles from the continent and saw the extension of the continental ice shelf of Kronprinsesse Märtha Kyst (discovered in 1929 by a Norwegian expedition under Hjalmar Riiser-Larsen) reaching the Southern Ocean was Frank Debenham in the preface to the English version of von Bellingshausen's narrative (1945). On this basis, he declared that

Russians were the first to discover the Antarctic continent (von Bellingshausen 1945). In the hyperpolitical scholarly world of the Cold War period, this statement gave rise to a very sharp discussion as to what the members of the Russian expedition had actually seen and how they had described it. Today, that debate generally has ceased and it is now almost unanimously accepted that the Russian South Pole expedition discovered the Antarctic continent.

SCIENTIFIC COMMITTEE ON ANTARCTIC RESEARCH (SCAR)

SCAR is an interdisciplinary committee of the International Council for Science (ICSU, formerly the International Council of Scientific Unions). SCAR was established in 1957 to initiate, promote, and coordinate scientific research in the Antarctic with a view to framing scientific programmes of circumpolar scope and significance. SCAR also provides independent, international scientific advice to the Antarctic Treaty System.

The seeds of international scientific activities in high southern latitudes can be traced back to 1874–1875, the year of the Transit of Venus when four nations established observatories in the sub-Antarctic. The First International Polar Year was held in 1882–1883 and the Second International Polar Year in 1932–1933 when scientific investigations were confined to the Arctic and sub-Antarctic regions. By 1950, the advances made in all sciences, but particularly in geophysics, encouraged various scientists to propose to ICSU that there should be a third polar year to coincide with maximum activity of the solar cycle. The proposal to ICSU "assumed that the Antarctic region would receive its full share of attention." It quickly became clear that the natural phenomena to be studied required synoptic observations over the whole surface of the Earth. In 1952, ICSU decided that the programme should become global and changed its name to the International Geophysical Year (IGY). At the same time, ICSU formed the Comité Special pour l'Année Géophysique Internationale (CSAGI) to organize the programme.

At the first meeting of CSAGI attention was drawn to the desirability of establishing observing stations on the mainland of Antarctica. Four CSAGI Antarctic conferences were organized to plan the detailed arrangements for the scientific, technical, and logistic activities in the area. At the first of these Antarctic conferences (1955), G. R. Laclavère was elected President and he prefaced the proceedings by emphasizing that the overall aims of the conference were exclusively scientific and that it was not concerned with political questions. Laclavère's statement, adopted by a resolution of the conference, provided a foundation that was adhered to throughout the IGY and ever since has consistently distinguished international scientific activities in the Antarctic organized under the auspices of ICSU.

Fifty-five observatories were engaged in IGY programmes in Antarctica and the sub-Antarctic islands, operated by the twelve nations participating in the Antarctic IGY: Argentina, Australia, Belgium, Chile, France, Japan, New Zealand, Norway, South Africa, Union of Soviet Socialist Republics, United Kingdom, and United States of America.

On a recommendation from the Fourth CSAGI Antarctic Conference in 1957, the Executive Board of ICSU set up an ad hoc committee to examine the merits of continuing general scientific investigations in Antarctica. It recommended that ICSU should establish a committee to continue international organization of scientific activity in Antarctica and the Special Committee on Antarctic Research (SCAR) was established in 1958. Membership comprised a delegate from each nation actively engaged in Antarctic research and representatives of International Geographical Union (IGU), International Union of Geodesy and Geophysics (IUGG), International Union of Biological Sciences (IUBS), and International Union of Radio Science (URSI).

The first meeting of SCAR was held at The Hague, 3–5 February 1958, when the foundations were laid from which the committee—the title of which was altered to the Scientific Committee on Antarctic Research in 1961—has developed. SCAR has met biennially since the VIII SCAR Meeting in 1964.

For SCAR, the Antarctic region is considered to include Antarctica, its offshore islands, and the surrounding ocean including the Antarctic Circumpolar Current, the northern boundary of which is the Subantarctic Front. Île Amsterdam, Île St. Paul, Macquarie Island, and Gough Island lie north of the Subantarctic Front but are also within SCAR's area of interest.

The main purpose of SCAR is to provide a forum for scientists of all countries with research activities in the Antarctic to discuss their field activities and plans and to promote collaboration and coordination between them. The biennial SCAR meeting is held over two weeks with the scientific disciplinary subgroups meeting in the first week and reporting to the SCAR Delegates in the second week when scientific and administrative decisions are made. The membership of SCAR has grown over the years from the original twelve countries taking part in the IGY to a current (2005) total of twenty-eight Full Members and four Associate Members.

All SCAR Members send active Antarctic scientists as representatives to the Standing Scientific Groups (formerly Working Groups) in those fields where they have ongoing research programmes. National research programmes are discussed and, where appropriate, are coordinated to give greater scientific value and more cost-effective logistic support. Some discussions lead to proposals for major international research programmes and these are put to the Delegates' Meeting for consideration. If a programme is accepted a group of scientists will be established to develop full science and implementation plans. These then become SCAR Scientific Research Programmes and the group will coordinate the national research inputs to these programmes. Progress is monitored through workshops and reported to SCAR, and results are presented at SCAR scientific symposia and other international fora.

SCAR has currently five major Scientific Research Programmes that will contribute to the major research effort of the forthcoming International Polar Year (IPY). The programmes are Antarctic Climate Evolution (ACE); Antarctica and the Global Climate System (AGCS); Evolution and Biodiversity in the Antarctic (EBA); Inter-hemispheric Conjugacy Effects in Solar-Terrestrial and Aeronomy Research (ICESTAR); and Subglacial Antarctic Lake Environments (SALE).

SCAR's greatest achievement has been the Biological Investigations of Marine Antarctic Systems and Stocks (BIOMASS) programme. The programme was proposed in 1968 "to gain a deeper understanding of the structure and dynamic functioning of the Antarctic marine ecosystem as a basis for the future management of potential living resources." In 1980–1981, thirteen ships from eleven nations took part in the First International BIOMASS Experiment (FIBEX); a second (SIBEX) field season took place in 1983–1984. The BIOMASS data provided the fundamental dataset for the Commission for the Conservation of Antarctic Marine Living Resources (CCAMLR).

For the Antarctic Treaty System, SCAR provided the basis for the Agreed Measures for the Conservation of Antarctic Fauna and Flora, subsequently subsumed in the Protocol on Environmental Protection to the Antarctic Treaty. SCAR provides advice on Management Plans for protected areas and on Comprehensive Environmental Evaluations (CEEs). SCAR also responds to requests from the Antarctic Treaty on a wide variety of scientific matters that are within its competence.

List of Acronyms and Abbreviations

ACE	Antarctic Climate Evolution
AGCS	Antarctica and the Global Climate System
BIOMASS	Biological Investigations of Marine Antarctic Systems and Stocks
CCAMLR	Commission for the Conservation of Antarctic Marine Living Resources
CEE	Comprehensive Environmental Evaluations
CSAGI	Comité Special pour l'Année Géophysique Internationale
EBA	Evolution and Biodiversity in the Antarctic
FIBEX	First International BIOMASS Experiment
ICESTAR	Inter-hemispheric Conjugacy Effects in Solar-Terrestrial and Aeronomy Research
ICSU	International Council for Science (formerly International Council of Scientific Unions)

IGU	International Geographical Union
IGY	International Geophysical Year
IPY	International Polar Year
IUBS	International Union of Biological Sciences
IUGG	International Union of Geodesy and Geophysics
SALE	Subglacial Antarctic Lake Environments
SCAR	Scientific (formerly Special) Committee on Antarctic Research
SIBEX	Second International BIOMASS Experiment
URSI	International Union of Radio Science

SCIENTIFIC COMMITTEE ON OCEANIC RESEARCH (SCOR)

SCOR was created by the International Council for Science (ICSU) in 1957 to promote international cooperation in ocean sciences. Most of the nations that conduct extensive research in ocean science participate in SCOR. SCOR is directed by its Executive Committee, composed of officers elected by SCOR members and augmented by ex officio members from the International Association for the Physical Sciences of the Oceans, the International Association of Biological Oceanography, and the International Association for Meteorology and Atmospheric Sciences.

SCOR has sponsored five working groups relevant to the Southern Ocean. For example, the Scientific Committee on Antarctic Research (SCAR), SCOR (as SCOR Working Group 54), IABO, and FAO Advisory Committee on Marine Resources Research formed the Biological Investigations of Marine Antarctic Systems and Stocks (BIOMASS) Programme in 1976. This program's principal objective was to improve our understanding of the Antarctic marine ecosystem to enable management of the living resources of the Southern Ocean (El-Sayed 1994). BIOMASS was prolific in its production of reports and handbooks during its almost 10-year existence, contributing significantly to our knowledge of Southern Ocean ecology and providing a foundation for later SCOR-sponsored research projects such as the Joint Global Ocean Flux Study (JGOFS) and the Global Ocean Ecosystem Dynamics (GLOBEC) project. SCOR Working Group 74 on General Circulation of the Southern Ocean was formed in 1982 to (1) identify major gaps in the knowledge of the general circulation of the Southern Ocean, bearing in mind its relevance to biology and climate; and (2) to specify physical and chemical programs to investigate the Southern Ocean. The working group issued its findings in SCOR (1986), which contributed to the World Ocean Circulation Experiment (WOCE).

SCOR and the International Geosphere-Biosphere Programme (IGBP) have cosponsored two large-scale research projects with Southern Ocean activities in the past two decades: JGOFS and GLOBEC. JGOFS sponsored a Southern Ocean research program in 1991–1999, which helped improve our understanding of the role of the Southern Ocean in the global carbon cycle (Baliño, Fasham, and Bowles 2001). Southern Ocean GLOBEC (still ongoing) has brought together scientists from several nations and from the International Whaling Commission to study the year-round life cycle of Antarctic zooplankton, particularly krill, as well as predators of krill, such as marine mammals and seabirds (Barange and Harris 2003). This project is notable for its conduct of observations and research in every season, including the Antarctic winter. SCOR and other organizations are establishing three new research projects that will have Southern Ocean components: the GEOTRACES project (a study of the global cycling of trace elements and isotopes), the Integrated Marine Biogeochemistry and Ecosystem Research (IMBER) project, and the Surface Ocean–Lower Atmosphere Study (SOLAS). SCAR and SCOR have formed an Expert Group on Oceanography to encourage an interdisciplinary approach to Southern Ocean observations, modeling and research, recognizing the interdependence of physical, chemical and biological processes in the ocean at present and in the past.

SCOTIA SEA, BRANSFIELD STRAIT, AND DRAKE PASSAGE, OCEANOGRAPHY OF

The Scotia Sea is a region of the South Atlantic Ocean lying between the Antarctic Peninsula, South Georgia, and Tierra del Fuego, and named after the ship used in these waters by the Scottish National Antarctic Expedition (1902–1904). With an area in excess of 900,000 km^2 and an average depth of approximately 3800 m, it sits within a complex and tectonically active marine basin bounded to the south, east and north by the island-dotted Scotia Ridge. Nearly all of the Scotia Sea rests on its own tectonic plate (the Scotia plate), with only its eastern extremity forming part of the South Sandwich microplate. Deep passageways in the Scotia Ridge communicate the Scotia Sea with the adjoining ocean basins. Most notably, the Orkney Passage leads southward into the Weddell Sea, the Georgia Passage eastward into the wider South Atlantic, and the Shag Rocks Passage northward into the Malvinas Chasm and beyond, into the Georgia and Argentine basins. The Scotia Sea opens to the west into the South Pacific Ocean in a 600 mile (1000 km) wide and typically less than 4000 m deep waterway known as the Drake Passage. At the southern end of this passage, the 70 mile (120 km) wide, relatively shallow Bransfield Strait extends as a semienclosed sea over 50,000 km^2 between the South Shetland Islands and the Antarctic Peninsula.

Ocean Circulation

The oceanographic conditions of the Scotia Sea are shaped by the presence in the region of two of the major current systems of the southern hemisphere. First and foremost, the Antarctic Circumpolar Current (ACC) is a vigorous, primarily wind-driven, deep-reaching eastward flow that conveys approximately 140 million m^3 s^{-1} of water around Antarctica and enters the Scotia Sea through Drake Passage, sweeping the region from southwest to northeast. The ACC is not a homogeneous current, but is organized into several strong jets that are steered by submarine topography and reach typical peak velocities of 20–60 cm s^{-1}. These jets are associated with oceanic fronts, or thin bands across which the properties or depth of water masses change sharply. The ACC has three fronts that define many of the main circulation pathways in the Scotia Sea: the Subantarctic Front, which is the ACC's northern boundary and skirts the South American continental slope; the Polar Front, which accounts for most of the ACC's transport of water through the region and follows a curving trajectory from the central Drake Passage to Shag Rocks Passage; and the Southern ACC Front, which is the most tenuous and southerly of the three fronts and exits the region south of South Georgia. The reasons for the frontal zonation of the ACC are not well understood, but current evidence points to an explanation involving the Earth's rotation, topographic steering, and external forcing (e.g., by winds and sea ice). The ACC frontal jets are renowned for being highly variable in strength and location, forming meanders and eddies often as a result of internal instabilities or interaction with the ocean floor.

South of the ACC, the northern limb of the Weddell Gyre flows northeastward in the vicinity of the South Scotia Ridge. The gyre conveys water that broke off the ACC to join the clockwise Weddell Gyre circulation well to the east of the Scotia Sea (near 30° E), and that has been cooled, freshened, and ventilated (i.e., enriched in atmospheric gases) by interaction with near-freezing water over the continental shelves of the Weddell Sea. This influence is most pronounced in a vertically homogeneous, well-ventilated zone termed the Weddell-Scotia Confluence, which emanates from the Antarctic Peninsula and extends eastward for over 2500 miles (4000 km) to around 20° E. Cascading of Weddell Sea shelf water off the northern tip of the peninsula and subsequent mixing with warmer, more saline deep water masses are implicated in the formation of the Confluence. These processes are also central to forming the water masses of the Bransfield Strait, with the inflow of ACC water through gaps in the South Shetland Islands playing a lesser role. The circulation of the Bransfield Strait and the formation of the Weddell-Scotia Confluence are, in fact, closely related, as the northeastward flow of Bransfield Strait water masses along the northern rim of the Strait (known as the Bransfield Current) feeds the emergence of the Confluence.

Concurrent with the vigorous, northeastward currents that dominate the Scotia Sea circulation, a weaker flow exists that transports water masses across the region along an approximately north-south axis. This flow arises from a complex interplay between wind- and eddy-driven currents and, at typical speeds of 0.1–1 cm s^{-1}, it is roughly a factor of 10–100 slower than the ACC. The flow is the manifestation of the Southern Ocean component of the global thermohaline circulation, the great conveyor belt that circulates heat, carbon, and other tracers of climatic significance around the Earth as it slowly overturns the ocean. The distribution of water masses in the Scotia Sea largely reflects the thermohaline circulation. Thus, the bulk of the deep ACC is occupied by the relatively warm and saline Circumpolar Deep Water (CDW), a water mass that originally sinks to the abyss in the North Atlantic and that advances southward and upward across the ACC in the Scotia Sea. CDW is commonly classified into an Upper and a Lower variety with distinct properties. The shallower Upper class is characterized by a minimum in dissolved oxygen concentration that can be traced back to respiration by marine organisms in the South Pacific and Indian oceans, and that is therefore indicative of northward CDW excursions in those basins. The Lower class is in turn defined by a maximum in salinity attributable to the North Atlantic origin of the water mass. Whereas this characterization of Upper and Lower CDW is applicable circumpolarly, more subtle properties of the water mass in Drake Passage denote two peculiarities of the thermohaline circulation in the region: (1) a deep water mass from the subtropical South Pacific Ocean enters the ACC's CDW layer in northern Drake Passage after flowing southward along the western slope of South America; and (2) Lower CDW in the southern ACC mixes intensely with and entrains Ross Sea bottom waters closely upstream of Drake Passage. Further downstream, as it flows through the Scotia Sea, the CDW in the ACC is ventilated, cooled, and freshened by mixing with a colder, less saline type of CDW found in the Weddell-Scotia Confluence.

While CDW moves southward and upward across the ACC in the Scotia Sea, a number of water masses translate northward and downward in the return limb of the global thermohaline circulation. The relatively cold and fresh Weddell Sea Deep Water (WSDW) is formed in the southern and western Weddell Sea as Lower CDW mixes with near-freezing water over the continental shelves of the region. About 5 million m^3 s^{-1} of WSDW enter the Scotia Sea by spilling over the South Scotia Ridge (mainly through the Orkney Passage) and subsequently fill the basin's abyss. WSDW then undergoes intense mixing with overlying Lower CDW and contributes to the ventilation of this water mass in the ACC, ultimately escaping the Scotia Sea by flowing eastward through Georgia Passage. The significance of this stream of WSDW running through the Scotia Sea resides in its representing a considerable fraction (in the region of 20%–30%) of all the Antarctic bottom waters exported northward from the high-latitude Southern Ocean. These waters ultimately invade the abyss of much of the ocean and embody the deepest and coldest layers of the global thermohaline circulation.

Above the Upper CDW, a thin (100–200 m), fresh surface layer of Antarctic Surface Water (AASW) flows northward across the ACC driven by the prevailing westerly winds. This surface flow is fed by the upwelling of CDW in a broad zone situated around the southern edge of the ACC that is often referred to as the Antarctic Divergence. When AASW crosses the Polar Front, it gradually plunges downward and contributes to the formation of Antarctic Intermediate Water (AAIW) north of the Subantarctic Front. Whilst this process is widespread around the ACC, it exhibits some regional peculiarities in the Scotia Sea. There, two varieties of AAIW occur with different temperatures and densities. The colder, denser AAIW shows evidence of having been formed from AASW, as outlined above. In turn, the warmer, lighter AAIW is also influenced by an alternative formation process involving strong atmospheric cooling and deepening of the upper ocean mixed layer in winter. This mechanism is most compellingly manifested in the production of the overlying Subantarctic Mode Water immediately upstream of Drake Passage. The distinction between the two types of AAIW is preserved as they flow through the Scotia Sea following the South American continental slope. They are then modified in the Argentine Basin by mixing with surrounding water masses and, together with Subantarctic Mode Water, go on to ventilate the intermediate layers of much of the Atlantic Ocean.

Climate

The climate of the Scotia Sea is generally cold and stormy with year-round intense westerly winds. Air temperatures and precipitation are moderately low (typically, –1°C to 5°C and 300–700 mm yr^{-1} in the annual average) and exhibit a relatively narrow annual range. Geographical variations in the climate of the Scotia Sea are largely controlled by the banded ocean circulation that characterizes the region. The atmospheric jet stream crosses the Scotia Sea in broadly the same direction as the ACC and, as a result, there are striking climatic contrasts across the different frontal zones. This is most clearly illustrated by the distinct climates of the Falkland Islands and South Georgia, two island clusters located at broadly the same latitude but on different ACC frontal zones. The Falklands lie on the equatorward flank of the Subantarctic Front and, accordingly, have a maritime climate with cool temperatures and moderately low precipitation. South Georgia, on the other hand, sits poleward of the Polar Front and endures a harsher climate with annual-mean subzero temperatures, abundant snow, and extensive glacial cover. The oceanic control of the regional climate also transpires in a similarly pronounced climatic contrast between the northern reaches of Drake Passage and the Bransfield Strait.

The most apparent expression of a seasonal cycle in the climatic conditions of the Scotia Sea is provided by sea ice. But for localized sea ice pockets near some of the islands and in the Bransfield Strait, the Scotia Sea is generally sea ice–free at the height of summer. However, as autumn progresses, low air temperatures cause the ocean surface to freeze and the Antarctic sea ice tongue advances northward from the Weddell Sea to cover the southern third of the Scotia Sea (around 300,000 km^2), occasionally reaching as far north as South Georgia. Melting ensues in spring and the ice tongue retreats southward. The resulting cycle of freezing and melting affects the properties of the surface waters in the southern ACC and the Weddell-Scotia Confluence in ways that are significant for both the thermohaline circulation and the regional ecosystems. The southern Scotia Sea also hosts the passage and melting of numerous icebergs, most of which are detached from the Weddell Sea ice shelves to the south and transported to the region by the Weddell Gyre.

Superimposed on this background, seasonally evolving climatic state, a number of large-scale modes of southern hemisphere climate variability modulate the Scotia Sea climate over periods of months to decades. Amongst these, the Semiannual Oscillation (SAO) and the Southern Annular Mode (SAM, also known as the Antarctic or Southern Oscillation) are the most prominent. The SAO is a twice-annual intensification and weakening of the circumpolar trough of low sea level pressure around Antarctica and arises from the differing annual march of atmospheric temperatures over Antarctica and the midlatitude Southern Ocean. It is a strong driver of semiannual variability in a wide range of climatic parameters of the Scotia Sea, including sea surface temperature, precipitation, and the strength of the winds. The SAM instead reveals itself as a circumpolarly coherent seesaw in sea level pressure between high latitudes and the subtropics, resulting in westerly wind anomalies centred approximately along 60° S. The strength of the Scotia Sea winds fluctuates with a wide range of frequencies in response to the SAM, which also affects regional precipitation patterns, sea surface temperatures, and sea ice extent. It is through their influence on wind strength that the SAO and the SAM modulate the oceanic flow at all depths too, with the transport of water through Drake Passage varying by several million $m^3\ s^{-1}$ in a near-instantaneous reaction to changes in the wind. Further, the SAM is itself affected by a number of mechanisms of tropical climate variability (such as the Madden-Julian Oscillation, the dominant mode of intraseasonal variability in the tropical atmosphere) and thereby mediates the remote forcing of the Scotia Sea climate by the tropical atmosphere-ocean system.

Other mechanisms of remote modulation of the Scotia Sea climate operate in relative isolation from the SAM. The most significant example of these is provided by the El Niño Southern Oscillation (ENSO), a sporadic, several-season-long disruption of the ocean–atmosphere system in the tropical Pacific Ocean that regulates Scotia Sea climate in a variety of ways. For example, ENSO has been shown to affect atmospheric and upper ocean properties over the Scotia Sea via a near-instantaneous atmospheric teleconnection to the tropical Pacific. Additionally, ENSO influences sea ice extent and atmospheric and upper ocean properties in the Scotia Sea with much longer temporal lags. On the one hand, a lag of about 3 months results from the impact of ENSO events on the state of the Antarctic Dipole, a stationary wave pattern in climatic conditions reflecting a seesawlike relationship between Pacific and Atlantic polar regions. On the other, a 3-year delay arises from the time that the ACC takes to convey oceanic anomalies from their source region in the South Pacific, where ENSO variability is extended to midlatitudes by a train of large-scale atmospheric waves termed the Pacific–South American pattern.

Marine Ecosystems

The surface waters of the Scotia Sea, like those of many other Southern Ocean regions, are very rich in nitrate, phosphate, and silicate, the basic nutrients required to support marine plant life. This feature of the Scotia Sea environment is attributable to the large-scale upwelling of nutrient-rich CDW in the Antarctic Divergence and its subsequent northward transport as AASW. In spite of the abundance of nutrients, the biomass of phytoplankton (i.e., microscopic floating plants) in the Scotia Sea is modest and primary production (the assimilation of carbon by phytoplankton during photosynthesis, estimated at 50–200 grams of carbon per m^2 per year over much of the region) is moderate by global standards, although they are both elevated in relation to other deep Southern Ocean basins. The reasons for this apparent paradox are not fully understood, but likely involve one or a combination of two factors: (1) the poor light environment resulting from the considerable depth of upper ocean mixed layers in the Scotia Sea over much of the year, which has a negative impact on the phytoplankton's capacity to photosynthesize; and (2) the severe scarcity of dissolved iron, a nutrient that is needed in small concentrations for the chemical reactions of photosynthesis. In certain instances, one or both of these limiting factors are relieved and phytoplankton blooms occur that account for the bulk of the annual primary production in the Scotia Sea. Most conspicuously, phytoplankton thrives in shelf seas throughout the basin, the Bransfield Strait and along the Weddell-Scotia Confluence during spring and summer, in response to the seasonal thinning of the upper ocean mixed layer and the local availability of iron from sediment sources or ice melt. Often, primary production is also enhanced more subtly and patchily in the vicinity of ACC frontal jets and eddies, where the deficiency of light or iron may be alleviated by localized upwelling.

Sustained by its relative richness in phytoplankton biomass, the Scotia Sea hosts the highest concentrations of Antarctic krill *(Euphausia superba),* a keystone zooplankton (i.e., microscopic floating animals) species in the Southern Ocean ecosystem that is vital to the diet of many Antarctic predators (principally, whales, seals, squid, toothfish, icefish, penguins, albatrosses, and other flying bird species). It has also been the target of a large multinational fishery since the 1970s that yields an annual catch of approximately 100,000 tonnes at present. The stock of krill in the Scotia Sea (estimated at approximately 44 million tonnes) is, however, not self-sustaining. Rather, the krill are thought to originate in spawning grounds on the Antarctic Peninsula shelves (mainly between January and March), from which they are transported in swarms into the southern and eastern fringes of the Scotia Sea by the Weddell-Scotia Confluence and the southern ACC. The krill life cycle develops as they flow away from their native coastal waters and spans up to seven years. This itinerant lifestyle makes the krill population in the Scotia Sea very sensitive to environmental change. Accordingly, large interannual fluctuations in the abundance of krill in the region occur in response to changes in climatic conditions around the krill spawning grounds, partially associated with the previously outlined large-scale modes of southern hemisphere climate variability. A striking illustration of this sensitivity is the observation of a decline of krill biomass in the Scotia Sea and its substitution by other zooplankton species since the 1970s. This is apparently connected to the long-term reduction of sea ice cover around the Antarctic Peninsula, which implicates the loss of the krill's winter habitat and food supply. Owing to the unusual shortness of the Antarctic marine food chain, the abundance and distribution of higher predators in the Scotia Sea are largely shaped by those of krill and, to a certain extent, exposed to the same interannual variability. The environs of the Antarctic Peninsula, the southern Scotia Sea, the South Sandwich Islands and South Georgia thus support some of the largest populations of these predators anywhere around Antarctica. Other zooplankton species in the krill, salp, and copepod orders are found in the Scotia Sea in relatively high concentrations, but their function in the regional ecosystem is less significant.

SCOTT POLAR RESEARCH INSTITUTE

The Scott Polar Research Institute (SPRI) was founded in 1920 as a memorial to Robert Falcon Scott and his four companions—Lieutenant Henry R. Bowers, Petty Officer Edgar Evans, Captain L. E. G. Oates, and Dr. Edward Wilson—who died on their return journey from the South Pole in 1912. The idea for a "polar centre" was first raised on the slopes of Mount Erebus in November 1912 by two geologists on Scott's last expedition, Frank Debenham and Raymond Priestley. Debenham eventually wrote an outline of the idea and in 1919 sent his proposal for the founding of a polar institute to Sir William Soulsby of the Captain Scott Memorial Mansion House Fund, which had been set up by donations made by the British people in response to Captain Scott's final request: "for God's sake look after our people." The money raised was intended to be distributed amongst a number of recipients, including a Polar Research Fund.

With the assistance of Sir Arthur Shipley, Master of Christ's College, a grant was offered to Cambridge University to pay for a polar wing of a proposed new Geography Building. The Institute dates from the acceptance of this grant on 20 November 1920. Temporary accommodation was found in the Sidgwick Museum, where a collection of equipment, records, and books began to accumulate. The prospects of a new Geography Building faded, however, and the Trustees of the Captain Scott Fund made money available for the erection, endowment, and maintenance of the Scott Polar Research Institute. In 1934, the Institute moved to its present site on Lensfield Road, where its original historic building has been augmented by additional laboratory, library, and office space in 1968 and 1998.

Debenham served as the Institute's original director, and amongst his successors were Launcelot Fleming and Colin Bertram, both members of the British Graham Land Expedition (BGLE) 1934–1937, and Gordon Robin, a member of the Norwegian–British–Swedish Antarctic Expedition (1949–1952), who served as director from 1958 to 1983. Robin, a geophysicist and glaciology, together with his social-science colleague Terence Armstrong, developed the Institute into an important centre for academic research within Cambridge University. Others influential in the history of the Institute include Priestley, James Wordie, who had accompanied Ernest Shackleton on the Imperial Trans-Antarctic Expedition (1914–1917), and Brian Roberts who took part in the BGLE and was an important member of the

Foreign and Commonwealth Office and the Institute for many years.

Today, the Institute comprises about fifty staff and students and is a subdepartment in Cambridge University. Its main activities are, on the one hand, research into science and social science issues in both the Antarctic and Arctic and, on the other, a polar library and information service, together with rich holdings of polar historical manuscripts, artefacts, works of art, and photographs. It also has a polar museum in which themed selections of these broad and deep collections are displayed as part of its public outreach and education programme. The Institute's journal, *Polar Record,* is the oldest journal dedicated to polar research in the world, having begun publication in 1931. SPRI is also host to the secretariats of the International Glaciological Society (IGS) and the Scientific Committee on Antarctic Research (SCAR).

The scientific research of the Institute is currently centred on the investigation of glaciers and ice sheets and the surrounding polar seas, and the ways their behaviour is linked to environmental change at a global scale. A central theme is the response of ice sheets and glaciers to climate warming and the effects that melting ice has and will have on global sea level. Remote sensing from aircraft and satellites is a major investigative tool, and the Institute is well known, for example, for the development of radar techniques to measure the thickness of ice, and, in particular, the first comprehensive mapping of the thickness of the 13.7 million km^2 Antarctic Ice Sheet. Members of the Institute's staff also have considerable expertise in the history of the polar regions, and of social, economic, and political issues. In the Antarctic context, there is expertise in, for example, the history of geographical and scientific exploration of Antarctica and in the development of the Antarctic Treaty. There is an MPhil course in Polar Studies, which has both physical- and social-science pathways.

The SPRI Library has collections of both rare and contemporary books, journals, and papers on Antarctica that are unrivalled internationally, forming a research library and polar information service that is used by scholars worldwide. The Institute also holds, in its temperature and humidity controlled Archives, a very wide range of manuscripts and documents concerning the polar regions. Examples include Shackleton's personal diaries from his Antarctic expeditions and the last letters written by Scott, Wilson, and Bowers from their fateful camp on the Ross Ice Shelf. The Picture Library holds a wide range of photographs and negatives from the "Heroic Era" of Antarctic exploration, including annotated albums by Herbert Ponting and Frank Hurley, and more than 1000 original glass-plate negatives taken by Ponting on Scott's last expedition. These are iconic early photographs that first formed public perceptions of the Antarctic continent. The SPRI Polar Museum has displays concerning both contemporary polar scientific work by Institute staff and the history of the polar regions. Items include the reindeer skin sleeping bag used by Captain Oates, Roald Amundsen's written measurements of the position of the South Pole, and Frank Worsley's log from the boat journey of *James Caird* from Elephant Island to South Georgia. Among the artworks held at SPRI are several hundred watercolour paintings by Edward Wilson.

SCOTT, ROBERT FALCON

For most of the twentieth century, Robert Falcon Scott (1868–1912) was one of the greatest British heroes. His glorious death returning from the pole seemed the culmination of the Victorian tragic hero. A book by Max Jones discusses how Scott's memory served to inspire his fellow Britons through the decades after his death.

In 1979, the publication of *Scott and Amundsen* by Roland Huntford changed the impression that many people held of Scott. Huntford praised the Norwegian explorer but missed no opportunity to castigate his counterpart, upon whom Huntford heaped scorn and condemnation. Regrettably, despite Huntford's undeniable brilliance and scholarship, his view of Scott is deeply flawed. Seen in the context of his time and his mentors, principally Sir Clements Markham (1830–1916), Scott emerges as a naval officer and polar explorer who was capable of inspiring great devotion in his followers and of accomplishing important scientific work in the polar regions.

Scott made his career in the Royal Navy, but he languished without distinction until two events changed the course of his life: his sister married a high-ranking naval officer after which Scott's own career took a turn for the better, and he was selected to command the National Antarctic Expedition, the *Discovery* expedition (1901–1904). His appointment was not without opposition but Markham was an inveterate schemer and was able to cobble together the votes within the guiding committee to secure Scott's appointment. One immediate result was the resignation of the scientific director, J. W. Gregory (1864–1932) from the expedition. While the scientific accomplishments of this endeavor were considerable, Gregory's participation might have advanced the development of the continental drift theory.

The *Discovery* expedition was forced to stay an additional unexpected year because the vessel was caught in ice. Relief ships that came to Scott's aid freed his ship and the whole party returned to Great Britain in 1904. Scott published a highly regarded account of the endeavor and resumed his naval career, noting publicly that his polar career was over.

Scott was not alone in being drawn back to the magic of the south polar regions and in 1909 he announced his intention to launch a second expedition to complete the scientific work his team had begun on the first trip and to reach the South Pole.

This second endeavor included two important land journeys. Over the winter E. A. Wilson led two others in the deadly cold and darkness to seek the egg of the Emperor penguin. Wilson thought (mistakenly) that this discovery would unlock secrets related to evolution. This horrific journey in which temperatures averaged –55°F has never been surpassed in the annals of polar endurance.

The attempt on the South Pole was complicated by the arrival in the Antarctic of Roald Amundsen (1872–1928) who detoured en route to a drift across the Arctic to launch an assault on the South Pole using the expertise he had gained in previous polar work. Thus a race was forced upon Scott, one he was ill equipped to win, especially when bad conditions in the fall before his south polar journey had forced him to place an important depot 30 miles north of his original intention.

Although much has been made of the foolishness of using ponies for transport, one does well to remember that Sir Ernest Shackleton nearly made it to the pole in 1909 using ponies and that, thanks to the determination and hard work of Captain L. E. G. Oates, Scott's ponies got as far as he planned for them to go on the southern journey.

Scott's planning was deeply flawed in the sense that he refused to profit from the experience of others who had demonstrated that dogs could thrive in Antarctic conditions. Ultimately, Scott distrusted all animal support and put his faith in manhauling, a means of transport that relied on grit and determination, conditions over which Scott felt he could have some control.

Even as they marched southward, Scott had not announced who would be in the final four to the pole. Twelve men in three groups trudged step-after-step, two groups of four working in support for the final party that would complete the journey. Scott sent one team back and when it came time to send the second one back, he made a fateful decision. He asked his second-in-command Lt. E. R. G. R. Evans (1881–1957) if he would spare H. R. "Birdie" Bowers from his team so Bowers could join the polar party. Evans had little choice but to agree and headed back in the company of two seamen, Petty Officers William Lashly and Tom Crean.

Evans's threesome nearly did not make it. Evans came down with scurvy and his bluejackets had to take care of him and pull the sledge in his place when he became incapacitated. Eventually, Evans ordered his men to leave him to save themselves. In an action totally in opposition to how they had lived their entire lives in the Royal Navy, the two men refused and put their officer on the sledge and pulled him from one depot to next until Evans's health had deteriorated to the point that he would die without immediate medical attention. At that point, Crean volunteered to make a dash for help while Lashly agreed to stay with Evans, knowing that if Crean failed, Lashly would die with his officer. Despite having walked nearly 1400 miles by that time, Crean walked eighteen hours to reach the doctor and the dog team that went out and retrieved Evans, who lived. For their actions Evans and Lashly were given the highest award in the gift of the Crown for bravery in a civilian action, the Albert Medal.

Meanwhile Scott's party trudged southward, fearful that they would see in the distance some indication of Amundsen's party. One day, Bowers saw it: a black flag—they had been forestalled in their attempt to be the first persons at the last place on earth.

All provisioning was designed for parties of four and the addition of a fifth person complicated the process of cooking for Scott's team. Having failed to reach the pole before Amundsen, the party turned north without the sense of triumph they had hoped would accompany that part of the journey.

Theirs was a race with death. They retraced their steps across the polar plateau and back down the

Beardmore Glacier. By the time they reached the Great Ice Barrier (Ross Ice Shelf) Petty Officer Edgar Evans was showing signs of exhaustion and illness. Several severe falls into crevasses resulted in a concussion and he died in his sleep one night. The party was behind schedule, which meant that the inadequate food and fuel supplies (to heat meals and melt water) had to be stretched even more. By this time Captain Oates was suffering from severe frostbite, gangrene, and scurvy. Knowing his inability to maintain the pace needed for survival, in the middle of a whiteout storm when all safe movement outside the tent was impossible, he stood up—in great pain—and announced, "I'm going out now, and I may be some time." Oates walked to his death in the snow in the hope that, without him holding them up, his companions would survive.

The three men—Scott, Wilson, and Bowers—pitched their tent eleven miles from One Ton Depot confident that they could accomplish the short distance to the supplies the next day. But instead, a storm came up and lasted at least ten days. The three men died of exposure and starvation, complicated by scurvy.

Scott's last letters and final entries in his diary are the basis of fame that crowned his reputation in polar history. His last letter to Mrs. Wilson spoke of his affection for his friend and for the example of sacrifice Wilson had always maintained. In his final remarks to the public Scott noted:

> ...but for my own sake I do not regret this journey, which has shown that Englishmen can endure hardships, help one another, and meet death with as great a fortitude as ever in the past. We took risks, we knew we took them; things have come out against us, and therefore we have no cause for complaint, but how to the will of Providence, determined still to do our best to the last....Had we lived, I should have had a tale to tell of the hardihood, endurance, and courage of my companions which would have stirred the heart of every Englishman.

Over the past century, commentators have speculated as to the cause of the tragedy. All manner of explanations have been offered: taking the fifth man, using ponies, taking Petty Officer Evans instead of either Lashly or Crean, unlucky about weather condition. None of those issues would have resulted in the death of the final three men had Scott placed One Ton Depot where he planned to, instead of thirty miles farther north.

Ultimately why Scott died is not the issue. How he died matters most. Given his circumstances, his final notes are the highest expression of much of what Victorians believed about amateurism, courage, sacrifice, honor, and, above all, duty.

T. H. Baughman

SCOTTISH NATIONAL ANTARCTIC EXPEDITION (1902–1904)

On November 2, 1902, the Antarctic research ship SY *Scotia* sailed quietly down the lower Clyde from its berth in Troon, Ayrshire. There was no fuss nor fanfare, such as had accompanied the departure of Robert Falcon Scott's *Discovery* from the Thames a year earlier. This was the Scottish sabbath, and the expedition's leader, William Speirs Bruce, never courted publicity. The Scottish National Antarctic Expedition (SNAE) was inspired by Bruce: he was its progenitor, its organiser, and its leader, and its crew and its supporters were entirely Scottish. Bruce had been by rebuffed by Sir Clements Markham when he applied for a place on *Discovery,* and so was determined to prove that Scotland could raise an expedition for Antarctic research to rival the English. Markham accused him of "mischievous rivalry."

At that time, there were few in Britain who could match Bruce for his experience of the polar regions, and none who were so well qualified as a polar oceanographer. Endorsed by the eminent scientist Sir John Murray, and by both the Royal Scottish Geographical

Society and the Royal Society of Edinburgh, the expedition's principal aim was to carry out oceanographic research in high latitudes of the Southern Ocean, and thus to contribute to the general scientific surveys of Antarctica as proposed by Markham and Georg von Neumayer for the British National Antarctic Expedition and the German Antarctic expedition. The research would include systematic measurements of meteorology, biology, topography, and terrestrial physics, as well as deep-sea and other marine observations, and the aim was to land a wintering party, "for three years as near to the South Pole as possible." Although it became impossible to attempt to pioneer a route over the ice to the South Pole, all the other aims were successfully carried out.

Bruce purchased a former Norwegian Arctic whaler, *Hekla,* with the help of Colin Archer, the builder of Fridtjof Nansen's *Fram,* and had it converted at the Ailsa Shipbuilding Yards in Troon, and equipped with the latest marine engine, deep-sea dredges and trawls, and a fine laboratory. The total cost was £16,730, met chiefly though the munificence of the industrialists James and Andrew Coats of Paisley. The ship was barque-rigged, about 400 tons, length 140 feet (42.7 m), breadth 29 feet (8.8 m), and a drawing 15 feet (4.6 m) of water. It was well strengthened for working in ice and had a ship's complement of 35. The captain was Thomas Robertson, an experienced ice-master, and the crew, apart from Gilbert Kerr the piper, were all seasoned in Arctic whaling. The scientific staff, led by Bruce, included Robert Neal Rudmose Brown, botanist and zoologist; John H. Harvey-Pirie, medical doctor and geologist; Robert Cockburn Mossman, meteorologist; David Wilton, zoologist; and two junior members, Willie Cuthbertson, artist, and Alastair Ross, taxidermist. They were all recruited from amongst Bruce's friends in Scotland's academia.

Scotia met the first pack ice in latitude 60°28′ S on February 2, 1903, and steered a course for the South Orkney Islands, reaching them, for a brief landing, on February 4. They then pushed farther south, attaining 70°21′ S in the Weddell Sea on February 22. Not wishing to become icebound in an area where scientific work was limited, the expedition turned north and sailed to the South Orkney Islands, anchoring off Laurie Island on March 26. The expedition was frozen in and remained there until November 26, when *Scotia* left for Buenos Aires for re-victualling. On the second voyage Bruce came back to Laurie Island and then proceeded to 74° S, where he discovered new lands that he named "Coats Land," after his Scottish sponsors. He turned for home on March 31, 1904, reaching the Clyde to great acclamation on July 21.

The SNAE was the most successful of all those of the Heroic Age of polar exploration as regards its oceanographic work. In addition to a large quantity of data and specimens, a meteorological observatory, Omond House, was built on Laurie Island, which has since been transformed into the Argentine station Orcadas, as well as a magnetic observatory, Copeland House. One crew member, Allan Ramsay, died on the island of heart disease; otherwise the ship returned with everyone fit and well.

SCURVY

Scurvy is caused by a deficiency of vitamin C, to be found in fresh fruit, vegetables, and uncooked or lightly cooked fresh meat. This disease was notorious during the eighteenth century and earlier for the toll it took on mariners making long exploring or trading voyages, such as George Anson's round-the-world voyage of 1740–1744. In contrast, James Cook's circumnavigation of the Antarctic continent of 1772–1775, amounting to 60,000 miles, resulted in the loss of very few men. Two decades earlier, the naval surgeon James Lind had written *A Treatise of the Scurvy* (1753) in which he indicated that fresh fruit, particularly oranges, would cure this ailment, although he did not have an accurate concept as why this was so. The Admiralty instructed Cook and his chief surgeon to carry out trials of a variety of such potential preventatives. In a letter to the president of the Royal Society after his return (1776), Cook set out

"The method taken for preserving the health of the crew of His Majesty's Ship Resolution during her late voyage round the world." He set great store on cleanliness and on "the inspissated juice of malt," on "Sour Kraut," and on "potable soup" ("the means of making the people eat a greater quantity of greens that they would have done otherwise") all supplied by the Admiralty, although he was unsure whether the pints of liquid malt would cure scurvy "in an advanced state at sea." But the true secret of Cook's success in the fight against scurvy was his gathering of fresh food at every anchorage. His editor and biographer, J. C. Beaglehole (1974: 704), wrote: "the sovereign thing was the unremitting insistence on fresh food," in addition to or in place of the barrels of salt beef and salt pork, "at every conceivable opportunity, fish, flesh and fowl—walrus, penguins—'scurvy grass' and every other variety of wild vegetables, the fruits and roots of the islands, the berries of Tierra del Fuego and the Arctic, a new batch of spruce beer—anything as long as it was fresh."

The influence of both Lind and Cook was strikingly demonstrated during the long years of Vancouver's circumnavigation (Watt et al. 1981: 51–71). The remedy for, if not the true cause of, scurvy was thus known by the end of the eighteenth century, so that the widespread incidence of the disease during the British Arctic Expedition of 1875–1876, commanded by Sir George Strong Nares, came as a considerable shock. The use of lime juice, rather than lemon juice, was discredited and ideas as to the cause of scurvy became chaotic (Savours and Deacon 1981).

The first expedition actually to winter (involuntarily) in the Antarctic was that of *Belgica,* commanded by Adrien de Gerlache, 1898–1899. Numerous digestive and other ailments affected both officers and men, but scurvy (called "polar anaemia") seems to have been kept at bay by the killing and eating of penguins and seals, advocated by the surgeon Frederick A. Cook. "If you want there is always enough food," wrote mate Roald Amundsen after the doctor's shooting of a Ross seal on the pack ice (Decleir 1999: 170).

The interior of mainland Antarctica remained virtually unexplored until extensive sledging journeys were made in various directions from *Discovery* during the British National Antarctic Expedition (1901–1904) under Robert Falcon Scott, followed by others made by personnel from Ernest Shackleton's British Antarctic Expedition, Douglas Mawson's Australasian Antarctic Expedition, and Scott's last expedition. The sledging diet of these parties largely lacked fresh food. For example, that of Scott's polar party of 1911–1912 consisted of pemmican (dried meat pounded with fat), biscuits, butter, cocoa, sugar, and tea, plus a small amount of pony meat, the rest of the meat being fed to the dogs (Rogers 1981). Scott, Edward Wilson, and particularly Shackleton returned from the southern journey of 1902–1903 after 92 days away from *Discovery* suffering from moderately advanced scurvy. Neither of Shackleton's main parties—heading for the South Pole and the South Magnetic Pole—suffered from scurvy, to a great extent because, at the recommendation of Dr. Eric Marshall, they were "primed" with a diet heavy in fresh meat for a period before leaving base. The expedition members wintering at Hut Point, Cape Royds, and Cape Evans were able generally speaking to keep scurvy at bay (or to eradicate it in *Discovery*) by killing seals and birds.

The true cause of scurvy, the lack of ascorbic acid from the diet, was unknown during these pioneering British expeditions. One of the theories as to its cause advocated the existence of "ptomaines" in tinned meat, a hypothesis supported by Reginald Koettliz, senior surgeon in *Discovery,* who, with Wilson, opened and examined every tin before use. When an outbreak of scurvy took place on board ship, second-in-command Albert Armitage and then Scott ordered the serving of fresh seal meat to alleviate the problem, which it did.

The absence of scurvy during the dash to the South Pole and back made by Amundsen and his companions in 1911–1912, using dog teams for transport, can be attributed to the explorer's foresight in his plan to kill a number of the dogs in order not only to feed the other dogs but to provide fresh meat to the five men in the party, as well as to the speed with which the party reached the Pole and returned.

The last expedition of the "Heroic Age" to make long sledge journeys into the interior of the continent was Shackleton's Ross Sea Party. Its members were required to lay depots as far as the Beardmore Glacier to be picked up by the trans-Antarctic party from the Weddell Sea. All six of the advanced party were severely afflicted with scurvy during a very long sledging season—more than six months—one man (A. P. Spencer-Smith) dying. The main party of Shackleton's Imperial Trans-Antarctic Expedition survived the loss of *Endurance* by subsisting largely on seal and penguin meat during the following 10 months. In fact, by 1914 it was generally recognised that scurvy was a deficiency disease, and Shackleton took advantage of the new ideas as regards preparations for the crossing by taking capsules of lime juice to be used on sledge journeys and added dried milk to the sledging ration. However, with the loss of the ship, these measures were wasted.

With the growing understanding of vitamins between the World Wars, scurvy in the Antarctic was eliminated.

SEA ICE: CRYSTAL TEXTURE AND MICROSTRUCTURE

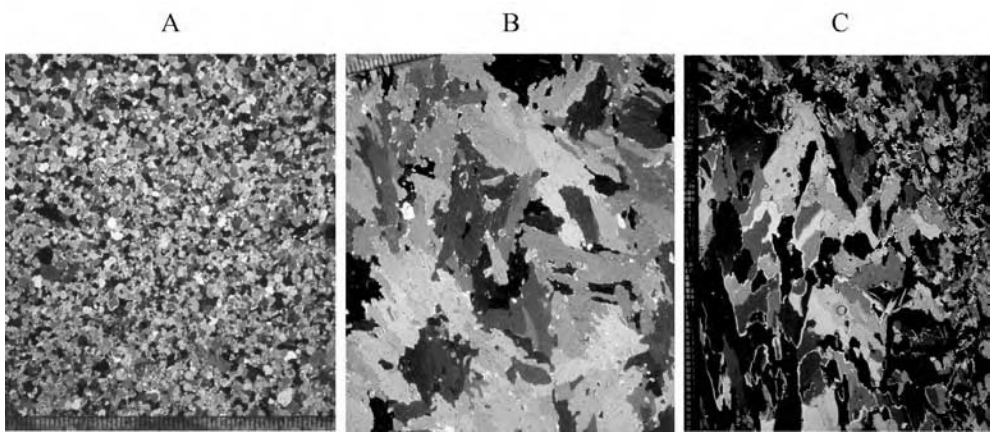
Introduction

The importance of the polar oceans' sea ice cover for global climate and polar ecology derives in significant part from the manner in which ice grows from seawater. Thus, sea ice contains large numbers of brine pockets, salt particles, and other inclusions, typically ranging from few micrometers to several centimeters in size. The size, morphology and distribution of these inclusions and the surrounding ice crystal matrix is referred to as the texture or microstructure of the material. The remarkable properties of sea ice, such as its high albedo (ability to reflect light) or its role as a habitat to microorganisms thriving within the pore space, are determined in large part by its texture and microstructure.

The microstructure of a sea-ice sample also contains a record of ice growth conditions, and researchers have made use of this fact to learn more about the complex evolution of the ice cover. Such studies, employing a wide range of methods, from the traditional approach of cutting sections out of ice cores drilled in the field to nondestructive use of magnetic resonance imaging, can also offer more general insights into the formation and evolution of rocks and industrial materials at temperatures close to the melting point.

Major Ice Textures

In the Antarctic, four principal modes of sea-ice growth and formation can be distinguished. The different ice-growth processes result in different morphologies and spatial arrangements of ice crystals (or ice grains), air and brine pockets and other inclusions. Typically, ice crystals are several millimeters to >10 cm in size and the term *texture* is used here in accordance with the glaciological literature (Shumskii 1964; Weeks and Ackley 1986) to denote the size, shape and orientation of these crystals. The distribution of liquid and solid inclusions within the ice matrix as well as the morphology and substructure of individual crystals is denoted as the ice or pore *microstructure*. Note, that while modern geological literature tends to use the terms texture and microstructure synonymously (Passchier and Trouw 1996), in the materials science field (and in some foreign languages, such as German or French) the terms may have different meanings. In describing and classifying different ice types based on crystal or pore attributes, it helps to distinguish between textural classifications that are purely descriptive of ice crystal texture (and possibly microstructure) and genetic classification schemes that distinguish between different formation modes as deduced from a number of different observations, including but not limited to the ice texture and microstructure.



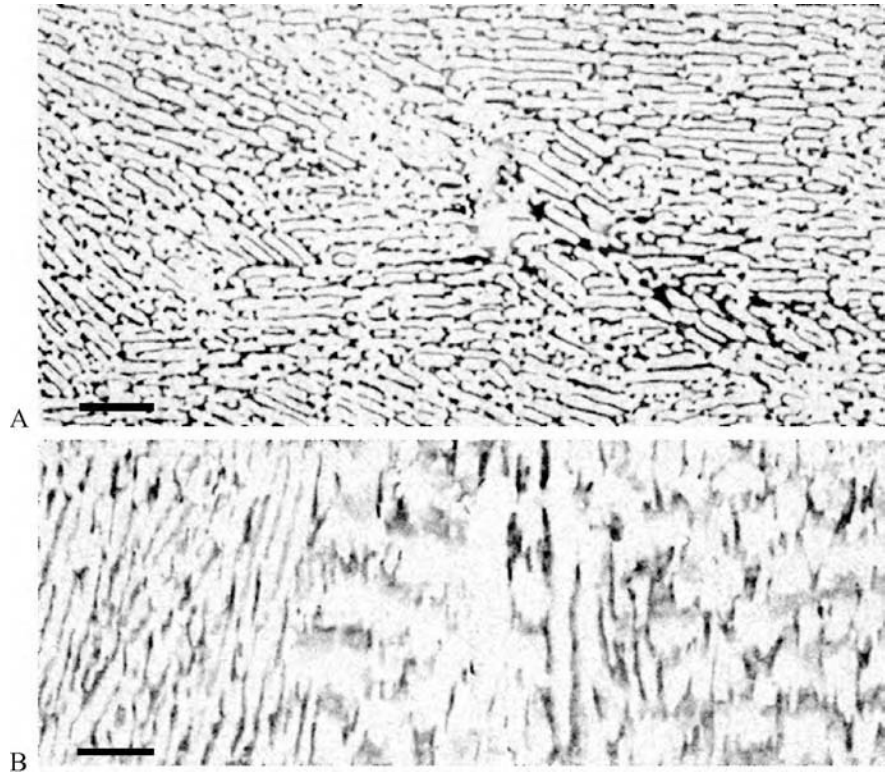
Thin sections of orbicular granular sea ice formed from frazil ice (A, horizontal section), columnar sea ice grown through congelation of seawater at the base of the ice cover (B, horizontal section), and mixed columnar/granular sea ice formed through consolidation of a mesh of ice platelets accumulating underneath the ice cover (C, vertical section). Samples were obtained in first-year sea ice in the Weddell Sea, Antarctica, and were photographed between crossed polarizers, rendering individual crystals in different colors.

During the onset of ice formation in open water, along the advancing marginal ice zone and within leads or polynyas, wind-mixing typically results in the formation of frazil ice. Frazil crystals are mm- to cm-sized spicules or platelets of ice, not unlike a submarine type of snow, often aggregating into flocs as they collide in the uppermost meters of the water column. Eventually, the crystals accumulate at the ocean's surface and through further growth and deformation form grease or pancake ice. The rate of ice growth in the water column is typically limited by the rate at which the latent heat of fusion that is released during the freezing of seawater can be transferred to a heat sink, either the cold atmosphere or the supercooled ocean (i.e., at a temperature below the freezing point, typically at –1.9°C). Frazil ice formation is typically associated with the highest rates of heat transfer. Hence, an unconsolidated, highly porous frazil layer of several decimeters thickness can easily be formed within a few hours under cold, windy conditions.

Once this surface grease ice layer dampens mixing in the water column to the extent that no further frazil formation is possible, it consolidates through freezing of seawater in the interstices between crystals. During this consolidation, salt is expelled from the ice. This expulsion is mostly driven by convective exchange, with dense, saline, cold brine overlying less dense, fresher and warmer brine, and to a lesser extent volume expansion of water during the freezing process. The ice formed through consolidation of frazil typically consists of isometric, small (few millimeters across) grains and is referred to as granular ice. Individual grains are typically rounded (orbicular granular) and contain few if any inclusions. Brine is confined to the interstitial pore space. Due to the dynamic ice-growth environment of the Southern Ocean, granular ice of frazil origin is the most common type of ice found in the Antarctic, accounting for more than half of the total ice volume (Eicken 1998; Jeffries et al. 1994; Lange and Eicken 1991; Weeks and Ackley 1986; Worby and Massom 1995).

The quiescent accretion of sea ice at the bottom of an existing ice cover results in the formation of vertically elongated (prismatic) crystals, typically several centimeters in diameter and more than 10 cm long. This type of ice is referred to as columnar ice, or, based on its mode of formation, congelation ice. The downward growth of a floating sea-ice sheet is very similar to the growth of ordinary lake ice, and this is reflected in similar grain textures. Columnar sea-ice crystals, however, contain numerous layered brine inclusions, with seawater and brine trapped between ice lamellae protruding downward from the base of the ice sheet. Vertically oriented ice lamellae possess a downward growth advantage, potentially enhanced by steady currents under the ice. This favours the growth of ice crystals composed of vertically oriented lamellae that are aligned within the horizontal plane if under-ice currents are consistently unidirectional.

In the Arctic, such strongly aligned columnar ice is the dominant ice textural type and accounts for roughly two thirds to three quarters of the total ice volume. Dynamic growth conditions in the Antarctic limit the occurrence of columnar ice to the lowermost layers of the ice cover, the landfast ice belt along the coast and within leads and polynyas that freeze over during calm conditions (wind speeds typically less than 5 to 10 m s^{-1}, Eicken and Lange 1989; Smith et al. 1990). Furthermore, while vertically oriented columnar crystals are common, horizontal alignment



Pore microstructure of artificially grown columnar sea ice obtained through magnetic resonance imaging. Shown are a horizontal (A) and a vertical (B) section, with very distinct brine layers (appearing dark) surrounding individual ice lamellae (appearing bright) within each crystal. Cylindrical brine tubes or channels can also be discerned in the central part of both A and B. Note how brine layers mimic grain textures apparent in parts B and C of the previous figure.

is observedly only infrequently and generally both horizontal and vertical dimensions of columnar crystals in Antarctic sea ice are smaller than their Arctic counterparts.

The formation of so-called platelet ice, common along the margins of the Antarctic ice shelves where it can account for up to half of the ice volume, is similar in many ways to that of frazil ice. Thus, platelet ice results from the accumulation of large (several centimeters diameter), platy ice crystals in layers decimeters to on occasion meters thickness underneath the ice cover. Due to the larger size of voids enclosed by the platelets, the shapes and sizes of individual crystals within consolidated platelet ice span the range from granular to columnar ice (mixed columnar/granular ice).

Underwater ice platelets form during the ascent of supercooled water masses that have come into contact with the base of the floating ice shelves (Lewis and Perkin 1986). The freezing point of seawater is both salinity and pressure dependent (approximately –1.92°C at the surface for seawater of salinity 35, and –2.00°C at 1000 m depth). As water circulates underneath an ice shelf it initially melts back the ice shelf base in deeper water, eventually cooling to the freezing point at depth. As the water rises along the sloping ice-shelf base, the pressure drops and supercooling with eventual ice formation sets in. Ice crystals grown under these conditions in the water column tend to be much larger (hand-sized plates have been found) than ordinary frazil ice and accumulate in thick layers underneath landfast and drifting sea ice in front of the ice shelves (Eicken and Lange 1989; Smith et al. 2001). In some locations, such as McMurdo Sound, the supercooled water can make it all the way to the ocean surface without ice crystal formation, leading to direct accretion of platelet ice onto the existing ice cover.

The Antarctic sea-ice zone receives substantial snowfall, with low pressure weather systems transferring moisture from the surrounding ocean areas. In some regions it is possible to accumulate as much as 1 to 2 m of snow on the sea ice. The ice surface is depressed below sealevel as a result of snow loading. If the underlying layers are sufficiently permeable (with pathways provided by brine channels or cracks), the ice surface and snow base floods and eventually refreezes. The snow ice formed in this fashion is composed of a mixture of frozen seawater, brine and snow crystals. Texturally, it is often difficult to distinguish from granular ice of frazil origin. On occasion, ice grains in snow ice exhibit polygonal outlines in thin sections and are then referred to as polygonal granular ice.

Superimposed ice, formed from snow meltwater that percolates downward and refreezes at the cold ice surface in late spring and early summer, is also typically of polygonal granular texture (Kawamura et al. 1997, 2004). The contribution of snow to the mass budget of Antarctic sea ice can be significant; in some areas as much as half of the total ice mass can be composed of snow ice (Jeffries et al. 1994, 2001; Kawamura et al. 1997, 2004). In all but the most extreme cases (i.e., snow accumulation rates of several meters per year) the net effect of snow deposition on sea ice is a reduction in total ice volume due to its small thermal conductivity which is lower than that of sea ice by one order of magnitude. However, snow-ice and superimposed-ice formation help to significantly offset this reduction in ice mass from snow deposition. While large-scale modeling has made significant progress in simulating snow ice formation (Fichefet and Morales Maqueda 1999; Wu et al. 1999), analysis of sea-ice cores (textural analysis and stable-isotope measurements) is the only means of directly determining the contribution of snow to the ice mass budget.

Pore Microstructure

The ice crystal lattice structure does not allow for substantial incorporation of the major sea salt ions into the solid ice. Instead, salt is rejected and builds up ahead of the advancing ice-water interface during ice growth. Typically between 60% and 85% of the total amount of salt is expelled completely from the growing ice in the form of cold dense brines. The remainder is trapped between and within the crystals. Salt buildup ahead of the ice-water interface is ultimately responsible for the development of parallel rows of ice blades (ice lamellae) that protrude from the bottom of growing columnar ice. Differences in the rate of salt and heat transport at the millimeter-scale result in a thin layer of supercooled water just below the ice. This supercooled water in turn fosters the establishment of a corrugated ice bottom where the ice lamellae shoot down into the supercooled layer and part of the brine remains trapped between the lamellae.

Traces of these ice blades and the interspersed brine layers can be discerned in a thin section photograph. An image obtained with the aid of magnetic resonance imaging (MRI) can provide a close-up view of parallel arrays of inclusions within individual crystals. Along the boundaries of crystals with differently oriented inclusion arrays, slightly larger, cylindrical brine tubes are apparent. These tubes merge into systems of interconnected channels that can reach several centimeters in diameter and more than a meter in length.

Gas inclusions typically only account for a small fraction of the total volume of foreign inclusions in sea ice. Frazil ice formed in a turbulent upper ocean can trap air bubbles in the ice. Gas or vapour inclusions can also appear in brine channels as a result of temperature changes and displacement of dissolved gases from the growing ice (Light et al. 2003). Solid salts precipitate as the temperature of growing sea ice decreases, with the two most prominent salts, mirabilite ($NaSO_4 \times 10\ H_2O$) and hydrohalite ($NaCl \times 2\ H_2O$) starting to precipitate as the temperature drops below approximately –6°C and –22°C, respectively (Marion and Farren 1999).

Methods of Studying Sea Ice Microstructure

In principle, the methods employed in obtaining samples and analysing sea-ice microstructure and properties are very similar to those employed by glacier geophysicists studying ice cores drilled deep into the Antarctic ice. Ice cores are typically drilled with a fiberglass-barrel, motor-powered coring system. With the use of extension rods, such corers can penetrate between 5 and 10 m of ice. In order to prevent loss of brine from the porous ice, cores are typically precut at the sampling site after photographing and temperature measurements, and then transferred to storage at temperatures of below –20°C to prevent loss of brine. A standard variable determined on most cores in addition to temperature is the ice bulk salinity, which involves melting of the sample and subsequent electrolytical conductivity measurements. Other biogeochemical and stable-isotope measurements are typically also carried out on melted core sections.

The standard approach to textural and microstructural analysis involves the preparation of thin sections that can be examined with magnifying lenses or under the microscope in both ordinary and polarized light. Slices sawed off the core are frozen onto glass slides and subsequently thinned to few tenths of a millimeter in thickness. Placed between crossed polarizing sheets, these thin sections exhibit interference colors that indicate the shape and crystallographic orientation of individual ice crystals. The pore morphology can be studied at higher magnification in ordinary transmitted light. Since samples are typically prepared at low temperatures to avoid brine loss and alteration during processing, the pore microstructure is artificially changed as pores shrink and salts precipitate during the cooling process. This creates the dilemma that in order to insure overall sample integrity, standard core analysis is completed at artificially low temperatures, significantly altering pore microstructure.

Many processes of scientific interest occur at higher temperatures, however. This has led to alternative approaches in studying ice microstructure, including x-ray computed tomography (CT; Kawamura 1988) or magnetic resonance imaging (MRI; Eicken et al. 2000; Menzel et al. 2000). These methods derive their power from the fact that samples can be studied nondestructively by determining density contrasts (x-ray CT) or can distinguish between water molecules part of the solid ice or liquid brine (MRI). Furthermore, experiments conducted in closed sample vessels allow analyses of the thermal evolution of pore microstructure. The most advanced approach to the problems posed by thermal alterations of sea ice after sampling has been taken by a group in New Zealand who have pioneered *in situ* studies of brine volume and mobility of liquid water in sea ice using magnetic resonance techniques that rely on the Earth's magnetic field (Callaghan et al. 1999).

Microstructure and Salt Distribution and Their Impact on Ice Properties and Ice Ecology

The transport of energy and matter through sea ice is controlled by its texture and microstructure. This derives largely from the contrasting physical properties of ice (poor electrical conductor, good thermal conductor, mechanically strong) and brine (excellent electrical conductor, poor thermal conductor—although brine movement can under certain conditions enhance thermal transport—and mechanically weak). The volume fraction of brine, the number density, morphology (tubular versus layered), and connectivity of brine inclusions are of particular importance in this regard. While the growth mechanism and growth rate as well as the grain texture determine the bulk salinity, spatial arrangement of pores, their volume fraction, micromorphology and connectivity are mostly controlled by temperature. With decreasing temperatures, pores shrink and brine tubes or layers segregate into individual, disjoint pores as part of the liquid freezes out, leaving behind a colder, more saline brine. This segregation and reduction in connectivity of pores greatly reduces the ice permeability, which in turn significantly reduces fluid flow through the ice. Cold horizons of lower salinity, typically found just below the ice surface, can hence become effectively impermeable. This can prevent surface flooding in cold ice that is submerged below sea level by deep snow cover. Once the ice interior and surface warm, however, ice permeability goes up and seawater and brine are free to percolate upward, resulting in formation of snow ice (Maksym and Jeffries 2000). Such flooding processes explain higher salinities found in the lower layers of the snow cover. High surface sea-ice salinities are due to both potential flooding and higher retention of salts in the upper portions of the ice cover, which experienced more rapid growth rates. Surface flooding is also of importance because it can supply large amounts of nutrients, allowing microalgae, which are prolific throughout the ice cover, to thrive in the uppermost layers where they are protected from grazers in the water column (Fritsen et al. 1998).

Texture and microstructure figure prominently in the role of sea ice as a habitat for a wide range of microorganisms. Algae attached to the ice bottom or residing within pores in the ice interior are provided with a stable platform for growth, while the size spectrum of the pore space serves to exclude larger grazing organisms (Krembs et al. 2000). Granular ice often contains much larger numbers of microorganisms since frazil-ice formation and aggregation represents a natural concentration mechanism (Thomas and Dieckmann 2003). Pore microstructure and the extreme brine salinities within individual pores are also of interest as analogs of potential extraterrestrial ice habitats (Thomas and Dieckmann 2002).

SEA ICE: MICROBIAL COMMUNITIES AND PRIMARY PRODUCTION

Sea Ice as a Habitat

Antarctic sea ice cover undergoes a dramatic seasonal expansion from a minimum of approximately 4 million km^2 of mostly multiyear pack ice in the austral summer to 19 million km^2 of mostly first-year pack ice in the winter. In the early stages of pack ice formation, dense concentrations of frazil ice develop rapidly under turbulent conditions as large quantities of heat are extracted from the surface ocean. As the sea surface calms, the frazil ice crystals float to the surface where they coalesce into semiconsolidated grease ice, and eventually, into thicker nilas and pancake ice. Additional freezing and horizontal movement fuses ice pancakes together to form a continuous ice pack; that is, the pack ice. Subsequent ice thickening beyond the consolidated pancake stage proceeds vertically downward as heat is extracted from the sea ice surface by the cold atmosphere. This new layer of ice is called congelation ice and is the primary component of land-fast ice, which does not have an initial frazil ice stage. The lowermost layer of the growing congelation ice, the skeletal layer at the ice–water interface, is highly porous with a temperature just below the freezing point of seawater. Rafting of ice floes as pack ice is moved by the wind and tides causes breakage and occasionally forces parts of the floe underwater, thereby flooding the ice surface with seawater. Similarly, heavy snow cover can also result in depression of the ice floe below the sea surface and flooding at the ice surface.

Platelet ice, a semiconsolidated layer of ice ranging from a few centimeters to several meters in thickness, is commonly observed beneath sea ice in regions adjacent to floating ice shelves. Platelet ice is the most porous of all sea ice types, being composed of approximately 20% ice and 80% seawater by volume. Although the extent of platelet ice habitats is not known, 45% of the continental margin in the Antarctic is associated with an ice shelf, suggesting this habitat may be relatively common. Platelet ice provides approximately five times more surface area for attachment of algae than the skeletal layer where most of the biomass within the congelation ice is concentrated. The platelet ice layer is also characterized by relatively rapid nutrient exchange; in contrast to much of the congelation ice, where physical nutrient replenishment is controlled by convection and brine drainage, the rate of nutrient exchange within platelet ice covaries with tidal height and sub-ice currents.

Sea Ice Microalgae

Frazil ice formation generally begins in the autumn when there are still substantial microbial populations left over in surface waters from the preceding spring blooms. As a result, organisms such as microalgae, protists, and bacteria are often scavenged from the water column as the newly formed frazil ice crystals rise to the surface. These organisms, especially diatoms, flourish within the distinct microhabitats which are created when sea ice forms and ages. The primary advantage afforded by sea ice is that it provides a platform from which sea ice algae can remain suspended in the upper ocean where light is sufficient for growth (except for areas where snow cover is extremely thick). However, sea ice habitats are often characterized by steep gradients in temperature, salinity, light, and nutrient concentration. Consequently, the greatest fraction of sea ice microalgae often reside in the bottom 20 cm of the ice sheet where environmental conditions are generally stable and more favorable for algal growth. Bottom ice communities that form in the skeletal layer can extend as far as 0.2 m up into the ice, their upward distribution generally being limited by nutrient availability and high brine salinity within the sea ice interior. Here, algal biomass has been observed to exceed 200 mg Chl *a* m^{-2}, a value comparable to a productive water column yet contained within a much smaller volume.

Surface microbial communities form in regions of the pack that become flooded with nutrient-rich seawater, due to ice rafting or snow loading. Such surface flooding occurs over 15%–30% of the ice pack in Antarctica and the communities that live there can attain levels of algal biomass ranging from 80 to 244 mg Chl *a* m^{-2}.

Under certain conditions, microalgae may also be found in internal layers, where they are often subjected to large environmental fluctuations. For example, brines with salinities as high as 173 psu and temperatures as low as –16°C have been measured in the topmost layers of sea ice, high enough to inhibit growth of most sea ice algae. In addition, increasing temperatures in the late spring may result in flushing of relatively fresh meltwater through the ice sheet, exposing microalgae to a lower salinity environment. Internal communities are generally located within a frazil ice layer or where seawater can infiltrate the ice floe. These communities are seeded by the particles scavenged during frazil ice formation and are especially dependent upon nutrient availability. The highest biomass accumulation recorded for internal communities is 50 mg Chl *a* m^{-2}, with most ranging from 0.5–30 mg Chl *a* m^{-2}.

Platelet ice, with its high surface area and high porosity, harbors some of the highest accumulations of sea ice algae found either in Antarctica or the Arctic, occasionally exceeding 1000 mg Chl *a* m^{-2}.

Other Sea Ice Biota

Sea ice algae sustain a wide variety of organisms, especially during the winter months when other sources of food are lacking. Because sea ice microalgae produce large amounts of dissolved and particulate organic matter, bacteria and fungi live in close proximity to the primary producers, as do viruses, which can be highly enriched in Antarctic sea ice. A wide array of single-celled protists, including ciliates, flagellates, and especially foraminifera, are components of the sea ice microbial community. Larger organisms residing in sea ice include flatworms and harpacticoid, calanoid, and cyclopoid copepods. At the ice-water boundary, even larger organisms such as fish (mainly *Pagothenia borchgrevinki*), amphipods, and euphausiids dominate along with other copepod species that are not found within the ice. Those organisms recorded from within the ice are evidently feeding directly on bacteria, protists, and algae within the brine channel system, although the size of the channels effectively limits how much of the ice these grazers are able to exploit. Organisms living below the ice feed on algae and bacteria covering the peripheries of ice floe surfaces, but also on the flux of particulate material being released from the ice.

The extent and persistence of sea ice has been linked to krill *(Euphausia superba)* recruitment and spawning. Although adult krill can withstand periods of starvation, juvenile krill cannot; therefore, the food contained within sea ice is vital to their winter survival. In winter, approximately three times more krill can be found under sea ice than in adjacent open waters, with the majority of the krill being found in a band between 1 and 13 km inside the sea ice edge (the boundary between open ocean and pack ice). During years of heavy sea ice or late melting of the pack ice in spring, krill spawn earlier in the season and reproduction rates are relatively high. In contrast, after winters with reduced ice extent and duration, krill reproduction is low. It is evident that extended sea ice cover fosters increased krill.

Methods for Estimating Primary Production in Sea Ice

Algal Biomass Accumulation

Early estimates of primary production in sea ice were based on the accumulation of algal biomass, generally either Chl *a* or particulate organic carbon, during the growing season. To derive an estimate of production in this way, a station would be sampled repeatedly over time and changes in algal biomass noted. This technique is well suited to the sea ice habitat because sea ice microalgae are anchored to the ice substrate and, therefore, the same population can be sampled repeatedly. In other marine systems, such as the open ocean, currents continually move algal populations around, making repeated sampling of the same population difficult.

However, estimating primary production on the basis of accumulating algal biomass is not without its drawbacks. Primary production derived from changes in standing crop are, by definition, net primary production estimates, which are necessarily smaller than gross primary production. This is because losses of material due to respiration are not accounted for. Neither is grazing, which also can result in the loss of algal biomass. Where these losses are important, biomass accumulation may severely underestimate gross primary production. Estimating production via changes in algal biomass accumulation is still of value, however, because it is a simple, direct measurement that does not require invasive techniques and yet yields a reliable minimum estimate for primary production.

Photosynthesis Versus Irradiance (PE) Determinations

One of the most widely used methods for estimating primary production in sea ice (and in the water column) is to collect ice algae from the field, bring them into the laboratory and measure, via incorporation of radiolabelled carbon (^{14}C, carbon-14), the maximum photosynthetic rate (P^*_m), and the photosynthetic efficiency (α^*) as a function of light intensity. When these photosynthetic parameters are combined with light measurements from the field, primary production can be estimated. Generally, sea ice microalgae and the associated microbial community are collected from sea ice by removing an intact core sample. Algae are removed from the sea ice matrix by scraping or by melting the core in a darkened bottle to which an appropriate quantity of 0.2 μm filtered seawater has been added to reduce osmotic shock.

A significant problem with estimating primary productivity in sea ice using this approach is that the spectral quality of the light source used to estimate P^*_m and α^* is often very different from that within the original, undisturbed sea ice. Incubation light sources are usually weighted towards the red end of the visible spectrum, while the natural light within the ice is dominated by blue or green wavelengths. Even though the amount of light measured under both circumstances may be equal, photosynthetic pigments produced by the algae are much more efficient at absorbing blue light than red light. As a result, the value derived for α^* (P^*_m is insensitive to spectral quality) is often underestimated during PE determinations.

One way to compensate for this effect is to apply a spectral filter to the light source used during the incubations so that it mimics the light field the algae would be exposed to in the ice. Although this correction is simple to implement, it cannot completely account for the fact that the spectral light distribution changes with depth within the ice. Above the algal layer, it is dominated by the blue wavelengths that are readily absorbed by algal pigments. Further down, however, selective absorption of the blue wavelengths by algae results in a spectral light distribution that is dominated by green light. In this case, the value of α^* derived during PE determinations will be greater than that actually expressed by algae in undisturbed ice and productivity will be overestimated accordingly. This correction works best under conditions where algal biomass is low and hence the spectral distribution of the incident light is not changing rapidly with depth within the algal layer. In this case, the α^* will be more appropriate to all depths within the algal layer, and not just those near the surface.

Oxygen Microelectrodes

Ideally, scientists would directly measure primary productivity in the original sea ice, without disrupting the sea ice habitat. New developments are coming closer to this ideal, although it has not yet been attained. Oxygen (O_2) microelectrodes are now used to measure the photosynthetic rates of ice algae in virtually intact cores, without seriously disrupting the algal community. With this approach, the lowermost 0.2 m of an ice core is placed bottom-up in a temperature-controlled water bath. The core is illuminated from below and O_2 concentration is measured across the diffusive boundary layer using an O_2 microprobe. By repeating the experiments at a variety of light intensities, and by using dark controls to correct for respiration, PE relationships can be evaluated just as they are using the ^{14}C approach.

There are a number of shortcomings to this method, however. First, the act of inserting the sampling apparatus through the diffusive boundary layer reduces the thickness of that layer by 25%–45%, thereby altering the actual O_2 flux. Fortunately, this effect is minimized where O_2 gradients are small and when there is no fluid flow around the tip of the O_2 probe. Given these caveats, this method is likely to be accurate to within ±20%. Finally, this method is only effective at measuring productivity in bottom ice communities. Internal, surface, and platelet ice communities have diffusion paths that are too long to evaluate O_2 diffusion reliably. However, considering that the majority of algal biomass in the Antarctic is found in the bottom layers of the congelation ice, this method is likely to prove valuable in the future.

In Situ ^{14}C Incorporation

An incubation technique has been developed recently to measure primary production in place in a wider variety of sea ice habitats. The concept behind this method is that an ice core can be extracted from congelation ice and cut into 1-cm slices which are placed into individual petri dishes for inoculation with ^{14}C bicarbonate. These petri dishes are then stacked in the order they were collected, placed in an acrylic-glass barrel, and returned to their original position in the ice floe where they are incubated. This method provides fine-scale resolution of primary productivity throughout the ice column without severe disruption of the sea ice structure and light field.

The primary advantage of this approach is that the algae are incubated under as natural a light field as possible, eliminating the need to correct for spectral light quality. In addition, because the algae are incubated in place, they are exposed to the same vertical gradients in temperature and brine salinity as undisturbed populations, resulting in more realistic productivity estimates. The major drawback to this technique is the disruption of the ambient nutrient field. Brine tubes and channels act as conduits in intact sea ice, providing nutrients to the upper layers that are not in intimate contact with underlying seawater. Severing these conduits by sectioning the core could alter the nutrient field and result in unrealistic rates of primary production. Under conditions where nutrient concentrations are not limiting, this method is likely to yield estimates of primary production that are superior to most other methods.

Numerical Modeling

One of the more complex methods for determining, and understanding, primary production in sea ice is through numerical modeling of the sea ice system. This complex technique requires a thorough knowledge of both the physics and biology of the sea ice system, and to date has been applied relatively infrequently. Nevertheless, using such numerical models, the complete annual cycle of primary production across the entire Antarctic can be simulated as a function of temperature, salinity, nutrient, and light availability to gain a better understanding of the processes controlling algal distributions in sea ice as well rates of primary production.

Estimates of Algal Production

Curiously, the two minimally invasive *in situ* techniques described above came to very different conclusions concerning the accuracy of standard ^{14}C incubation techniques used most often for estimating primary production in sea ice. Estimates of photosynthetic carbon fixation made using microelectrodes to measure diffusion of oxygen through the boundary layer were very low, with hourly production rates of 0–1.78 mg C m^{-2} hr^{-1}. These estimates are on the low end for Antarctic sea ice, particularly in the spring when rates are generally the highest. Because this technique is the least invasive of all known methods for estimating sea ice primary production, the low values obtained by this technique has led the developers to speculate that previous estimates of sea ice production may be too high. In contrast, the ^{14}C technique showed that production within the sea ice interior was much higher than previously reported and that estimates of primary production based on bottom ice communities were likely underestimates. Clearly, additional data need to be collected to evaluate the relative ability of these two approaches to estimate sea ice primary productivity.

Estimates of annual sea ice primary production from direct ^{14}C uptake rate measurements indicate that annual production in the Antarctic ranges from 5–15 g C m^{-2} yr^{-1} (grams of carbon per square meter per year). This range is consistent with biomass accumulation data which give a range of 0.04–20 g C m^{-2} yr^{-1} for Antarctic congelation ice, a value that increases to 0.04–44 g C m^{-2} yr^{-1} in regions with a platelet ice layer. Despite the small sample sizes, it is still probably fair to conclude that even in the most productive habitats, annual production in sea ice is below 50 g C m^{-2} yr^{-1}, an amount similar in magnitude to the least productive regions of the open oceans.

Annual primary production integrated over the entire Antarctic region is calculated to range from 30–70 Tg C (Tera grams of carbon). Total primary production is a function of both the sea ice extent and the rate of primary production per unit surface area and has an error associated with it of ±30%. Primary production in Antarctic sea ice is greatest in November (13 Tg C $month^{-1}$, or Tera grams of carbon per month) as spatially integrated rates of production increase by a factor of four and sea ice coverage remains high. Annually, over 90% of the algal growth takes place within first-year sea ice and approximately 60% takes place during November and December. Antarctic-wide production declines between December and April, due to the dramatic decrease in sea ice coverage. The production rate per unit area peaks in January in both first-year (2.2 g C m^{-2} $month^{-1}$) and multiyear sea ice (1.1 g C m^{-2} $month^{-1}$).

The production rate of 30–70 Tg C yr^{-1} for Antarctic sea ice is about 1%–2% of the annual primary production in the Southern Ocean. However, sea ice primary production is a much larger fraction (10%–28%) of total production in the ice covered waters of the Southern Ocean, which ranges from 141 to 383 Tg C $year^{-1}$ and includes the highly productive marginal ice zones. Therefore, in those waters that are ice covered for part of the year, algae growing within sea ice are an important component of the marine food web.

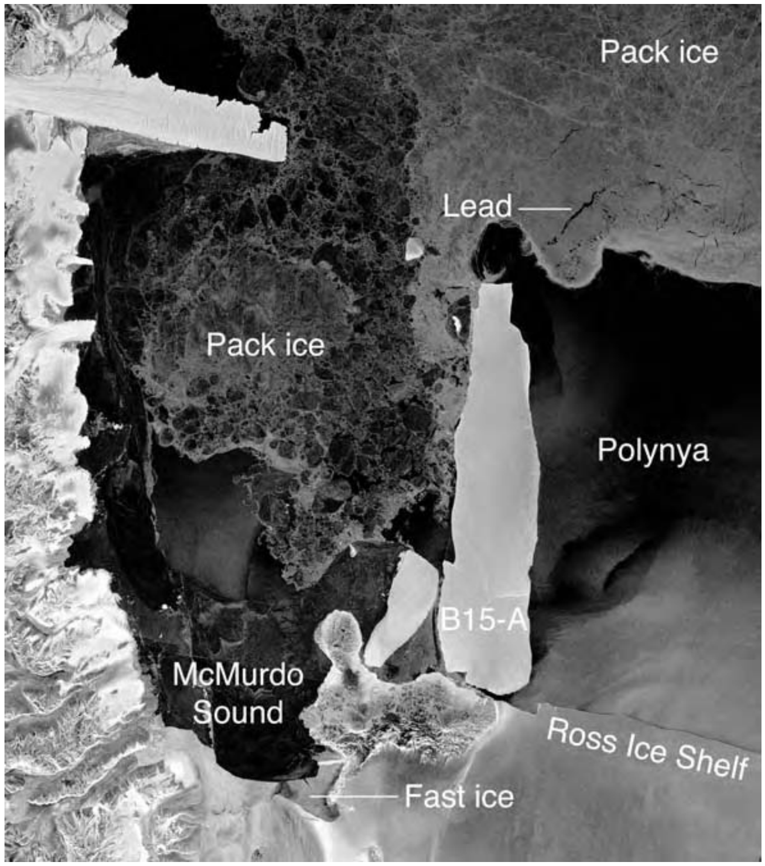
SEA ICE: TYPES AND FORMATION

Introduction

Sea ice is not simply frozen seawater. It is a complex and heterogeneous material of many different types and characteristics that reflect the conditions and processes of formation, and the subsequent history of the ice. "Ice types" includes the ages and stages



RADARSAT-1 synthetic aperture radar image of a 295 km by 330 km region of the southwestern Ross Sea on December 27, 2002. The image shows fast ice in McMurdo Sound, various ages and stages of ice development in the pack ice, iceberg B15-A abutting Ross Island, and the polynya that opens at this time each year to the north of the Ross Ice Shelf. of sea ice development at scales of millimetres to kilometres, as well ice features and characteristics at larger scales of tens to hundreds of kilometres. “Ice formation” describes the actual freezing of seawater and the thickening of the ice cover by different ice growth processes.

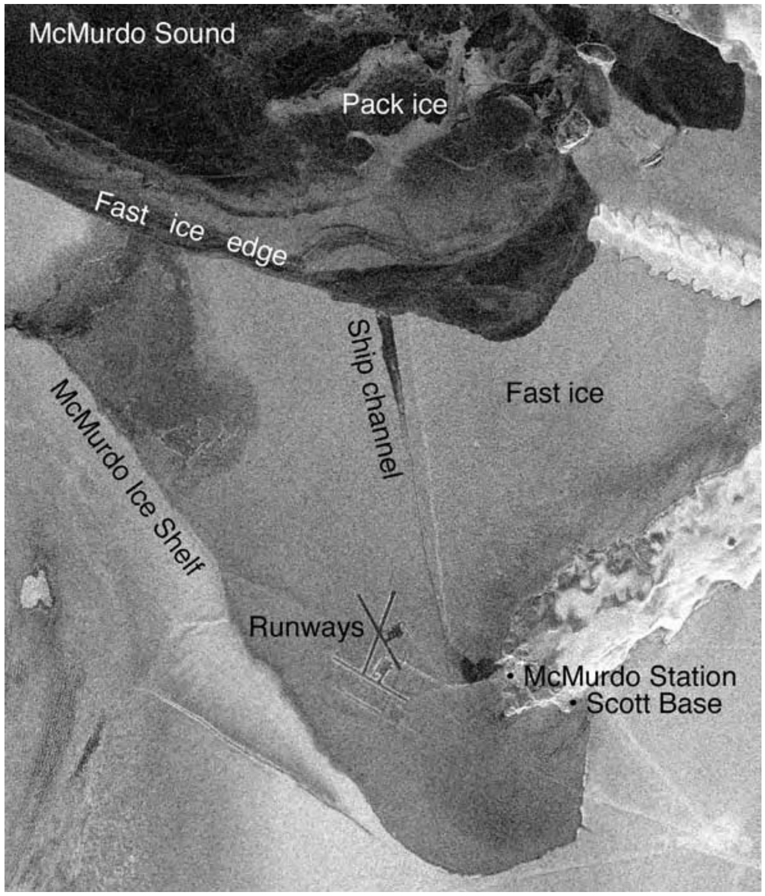
Twenty-first-century scientists continue to describe and classify sea ice types and formation using terms that were coined primarily by explorers and whalers in the nineteenth and twentieth centuries. For them, even summer sea ice was an obstacle to be overcome in underpowered vessels not designed particularly well for navigation in ice. Today, modern icebreakers and icebreaking research vessels take scientists into the Antarctic sea ice cover in all seasons to study ice types and formation, and how they affect: (1) ice crystal texture and microstructure; (2) ice thickness; (3) the electrical, mechanical, optical, and thermal properties of the ice; (4) microbial communities and primary productivity within the ice; and (5) heat and mass exchange between the ocean and atmosphere, and thus weather and climate.

Ages and Stages of Sea Ice Development

The age of sea ice varies between just a few seconds and a few years. The broadest categories of sea ice age are first-year ice and old ice. First-year ice is sea ice of no more than one winter’s growth. Old ice is sea ice that has survived at least one summer’s melt. Old ice includes second-year ice (survived one summer’s melt) and multiyear ice (survived two or more summers’ melt). In practice, whether the ice is viewed from a ship, from the air or from space, or investigated directly by, for example, examination of ice core samples or by ice thickness measurements, it is not easy to distinguish between second-year ice and multiyear ice. Consequently, the term old ice is not often used and scientists prefer, instead, the term multiyear ice to describe any ice that has survived one or more summers.

It is not always easy to unambiguously distinguish between first-year and multiyear ice, either. But, viewed from a ship, multiyear ice is likely to have a



RADARSAT-1 synthetic aperture radar image of a 26 km by 32 km region of southeasternmost McMurdo Sound on November 21, 2002. The image shows new ice in the coastal zone of the pack ice beyond the fast ice edge, runways on the fast ice, and the refrozen ship channel cut in the ice by US Coast Guard icebreakers in January 2002. (Copyright Canadian Space Agency.)

higher freeboard because it is thicker than first-year ice, and to have a deeper snow cover because snow has accumulated for longer than on first-year sea ice. Ice thickness measurements and examination of the snow cover and ice core samples might confirm that a piece of multiyear ice has been correctly identified. It is rare for the snow on Antarctic sea ice to melt completely away each summer, but it does metamorphose such that it can be distinguished from snow on first-year ice on the basis of differences in density, grain size and morphology, and stratigraphy. Examination of ice cores reveals variations in ice crystal texture and stratigraphy that can be used to interpret the history and thus age of a piece of ice.

First-year ice is further subdivided into the following categories: new ice, young ice, thin first-year ice, medium first-year ice, and thick first-year ice. New ice includes frazil ice, grease ice, slush, shuga, nilas, and pancake ice. Young ice includes grey ice and grey-white ice. Each of the new ice and young ice types are easily distinguished by eye from one another, since they have distinctive sizes, shapes, surface topography and greyness. As the names suggest, thin, medium and thick first-year ice are classified according to their thickness (i.e., 0.3–0.7 m, 0.7–1.2 m, and >1.2 m, respectively). Most Antarctic first-year sea ice falls into the thin and medium categories, and they are easily distinguished from new and young ice.

The first ice to crystallize on the sea surface is composed initially of spheres, which quickly become discs with diameters of no more than 2–3 mm, and then starlike crystals. In calm conditions (little or no wind, no waves or swell), the stellar crystals grow rapidly across the water surface to form a continuous skim of thin, level ice known as nilas, a Russian term. A snow-free nilas surface has a very dark appearance because it is thin and thus has a high optical depth (i.e., it is transparent and light can pass through it to the underlying water). The thickness of nilas increases by a process known as congelation, in which further ice forms as water freezes onto the bottom of the ice skim or sheet. As nilas thickens and less light passes through to the ocean below, the appearance of the ice changes from dark (<0.05 m thick) to light (0.05–0.1 m thick).

Once nilas reaches a thickness of 0.1 m, it enters the young ice category. Snow-free young ice appears grey (0.1–0.2 m thick) and grey-white (0.2–0.3 m thick). These terms describe its changing appearance as it grows thicker, by congelation, and becomes more optically opaque (i.e., it is no longer transparent and its appearance brightens as light scattering and reflection increase).

Conditions are often not calm in Antarctic waters and the spherical, discoid, and stellar ice crystals collide and break down into small fragments known as frazil ice. The suspension of frazil ice crystals is often herded by the wind to form a soupy layer known as grease ice, that gives the water surface a greasy or matte appearance. Slush is similar in appearance to grease ice, but forms as snow is deposited on the water surface. Shuga is Russian for marble-sized, spongy, white lumps that form among grease ice and slush. Where there are no waves or swell, grease ice and slush can freeze and form nilas.

In turbulent seas the action of waves and swell will rapidly transform frazil ice, grease ice, and slush, and occasionally nilas, into pancake ice. Pancakes are roughly circular, with diameters varying from a few centimetres to as much as 5 m. Most pancakes form from frazil ice and grease ice and have raised rims due to jostling and collisions, which pump frazil-loaded water onto the edges of the cakes. This also progressively enlarges the pancakes, which gradually harden and solidify as the frazil ice crystals freeze together.

The significance of pancake ice in the Antarctic context became apparent in 1986 during the first Winter Weddell Sea Project aboard the FS *Polarstern* (Germany). The sea ice scientists realized that ice formation in a "pancake-frazil cycle" was the source of most of the first-year ice observed between the open ocean and the coast, a distance of 1500 km (Wadhams, Lange, and Ackley 1987; Lange et al. 1990). As the ship penetrated into the ice cover from the northern ice edge, the following sequence was observed: (1) the pancakes began to raft, or ride up on each other, due to the continued influence of waves and swell, and freeze together into thicker and larger pieces of ice known as cakes; (2) as the influence of the waves and swell dwindled, the cakes coalesced into larger pieces of ice known as floes; and (3) ultimately, the floes coalesced into a continuous sheet of first-year ice, in which it was still possible to see the roughly circular outlines of the original pancakes and cakes through the thin snow cover.

An ice cake is any relatively flat piece of sea ice less than 20 m across. Floes are any relatively flat piece of sea ice more than 20 m across. Floes can reach enormous sizes and they are subdivided according to their horizontal extent: small (20–100 m), medium (100–500 m), big (500–2000 m), vast (2–10 km) and giant (>10 km). Sea ice is rarely flat. The pancake-frazil cycle creates a rough ice surface of rafted pancakes and cakes with their characteristic raised rims. Nilas and young ice remain flat only as long as they are not subject to deformation that mechanically thickens and roughens the ice by rafting and ridging.

The Antarctic Sea Ice Cover

The stages of sea ice development from millimetre-sized frazil ice crystals to kilometre-sized ice floes occur at small to medium spatial scales. At the largest or ocean scale, over distances of tens to hundreds of kilometres, the Antarctic sea ice cover can be divided into two zones: pack ice and fast ice.

Fast ice, sometimes also referred to as landfast ice, forms and remains along the coast, where it is attached to the land, to an ice wall, to an ice front, or between glacier/ice tongues, grounded icebergs, and shoals. Fast ice forms in place by the freezing of seawater and by the adfreezing of pack ice floes to the shore or to the seaward edge of the fast ice. Extending as much as a few tens of kilometres offshore, it moves vertically in response to tides and waves, but is otherwise stationary. Each November the fast ice attains a maximum area of approximately 550,000 km^2 (Fedotov, Cherepanov, and Tyshko 1998) or about 3% of the maximum area of pack ice around Antarctica.

The pack ice is the much larger expanse of sea ice that occurs seaward of the fast ice. It is a highly mobile ice cover, where the floes move in response to tides and waves, and, most importantly, to the wind and ocean currents. The latter cause the ice to move, or drift (pack ice is sometimes referred to as drift ice), over the ocean surface at rates of many kilometres per day.

There is a large seasonal variability in pack ice extent, which is nowadays measured routinely on a daily basis using satellite remote sensing from space. At the end of summer (i.e., late February/early March), the pack ice reaches a minimum extent of approximately 4,000,000 km^2. At the end of winter (i.e., late August/early September), it reaches a maximum extent of approximately 19,000,000 km^2. Evidence from whaling and ice core records suggest that there was a significant decrease in Antarctic maximum ice extent during the twentieth century, but this is subject to some debate (de la Mare 1997; Ackley et al. 2003; Curran et al. 2003).

As a consequence of the large seasonal variation in ice extent, ~80% of the Antarctic pack ice at the end of winter is first-year ice. In contrast, the Arctic pack ice is ~50% first-year ice at the end of winter. Since the discovery of the pancake-frazil cycle in the Weddell Sea in 1986, sea ice studies aboard other research vessels elsewhere in Antarctic waters have revealed the widespread occurrence of frazil ice and grease ice, and their transformation into pancakes, cakes and floes. Consequently, it is widely accepted that the pancake-frazil cycle is vital to the rapid, northward expansion of the Antarctic first-year pack ice each year.

Pack Ice

In addition to *Polarstern,* other icebreaking research vessels entered into service in the late twentieth century. The *Nathaniel B. Palmer* (USA) and *Aurora Australis* (Australia) in particular made it possible to pursue more systematic, quantitative and process-oriented studies of ice types and formation in the pack ice than had previously been accomplished. The discovery of the pancake-frazil cycle is an important example of this.

Prior to the appearance of the modern, icebreaking research vessels that could spend weeks in the pack ice for scientific purposes, the knowledge and understanding of ice types and formation was of a more qualitative nature. For most vessels entering the pack ice, it was an obstacle to be overcome in as short a time as possible en route to the coast to explore the continent and even reach the South Pole, and to supply research stations and bases. Any scientists aboard these vessels could do little more than observe and describe the ice cover.

Coupled with remote sensing from space and computer modelling, the modern research vessel-based studies have allowed a much broader view of the pack ice and the complex processes and interactions that occur there. For example, synthetic aperture radar (SAR) remote sensing at the time of maximum ice extent, from the open ocean to the coast, often a distance >1000 km, has revealed that the pack ice can be subdivided into as many as five zones: (1) a pancake zone at the seaward edge adjacent to the open ocean; (2) an outer first-year ice zone, where the generally loosely packed ice cover is composed of cakes and small to big floes; (3) an inner first-year ice zone, where vast and giant floes are often tightly packed; (4) a multiyear ice zone; and (5) a coastal zone of open water, and new and young ice immediately seaward of the fast ice or shore (Morris, Jeffries, and Li 1998). Zones 1–3 correspond to the zones encountered by FS *Polarstern* in 1986 in the Weddell Sea where the full significance of frazil and pancake ice was realized. Not all regions of the pack ice have multiyear ice zones because the pack ice recedes as far as the coast in summer.

Open water and new and young ice are common immediately adjacent to the coast and fast ice edge because winds blowing off the continent move the pack ice away from the shore, creating a shore lead or a polynya. A lead is an opening, often linear and extending for many kilometres, within the pack ice. Leads open and close, rather like a concertina, as the pack ice drifts with the wind and ocean currents. Once open, a lead can quickly freeze over as nilas and young ice grow. The closing of a lead squeezes the thin ice cover, and mechanically thickens the ice by rafting and ridging.

In many locations the offshore winds are funnelled by the topography inland so that they cross the coast at particularly high speed. These cold, katabatic winds cause locally extensive, recurrent and predictable areas of open water and new and young ice known as polynyas. Ice production is often so great in these coastal polynyas that they are sometimes referred to as ice factories. They are also regions of intense heat and mass transfer from the ocean to the atmosphere, and ocean water modification and transformation.

Because ice floes are in almost constant and often rapid motion due to winds and ocean currents, there are always leads and cracks and other openings somewhere in the pack ice. Leads are particularly important for navigation through the pack ice, and, like polynyas, sites of intense heat and mass transfer from the ocean to the atmosphere, and ocean water modification and transformation.

The occurrence of open water within the pack ice gives rise to the term ice concentration. Expressed in tenths, this is a measure of the amount of ice and open water in the pack ice. For example, a 10/10 ice cover is all ice and no open water, and if it was thick first-year or multiyear ice it would be a challenge for even a modern icebreaker to navigate. On the other hand, a 5/10 ice cover (50% ice, 50% open water) of thick first-year ice or multiyear ice could be negotiated by an ice-strengthened vessel.

The terms *ice area* and *ice extent* can be explained in the context of ice concentration. For example, a 10 km × 10 km region of pack ice with 7/10 concentration has an ice area of 70 km^2 and an ice extent of 100 km^2. Ice area describes only the area of ice. Ice extent describes the total area of ice and open water, and is always greater than ice area. Areas where ice concentration is less than 15%, mostly at the ice edge adjacent to the open ocean, are typically not included in calculations of ice extent.

The pancake zone is part of the Marginal Ice Zone (MIZ), a region where the pack ice is broken up by the flexural stress of waves and swell penetrating from the ocean (Wadhams 2000). The width of the MIZ is defined by the distance from the ice edge to which waves and swell can penetrate and break up the ice cover. For example, a severe swell that was observed concurrently from space by SAR and by scientists aboard *Nathaniel B. Palmer* in late August/early September 1993 in the western Bellingshausen Sea penetrated almost 450 km into the outer first-year pack ice and broke up a consolidated ice cover of small to big floes into a looser ice cover of ice cakes (Morris, Jeffries, and Li 1998). The penetration distance of waves and swell into the pack ice varies from a few tens to hundreds of kilometres; consequently, at times the MIZ will include both the pancake zone and the entire outer first-year pack ice zone.

Fast Ice

Prior to the advent of the icebreaking research vessels, quantitative scientific and engineering studies of ice types and formation focussed on the fast ice because it was easily accessible to researchers at coastal research stations, and because its very presence affected the operation and viability of those stations. McMurdo Station (USA) and Scott Base (New Zealand), located on the shore of McMurdo Sound, illustrate the role of fast ice in Antarctic operations and why it has been the subject of numerous scientific and engineering investigations.

McMurdo Station and Scott Base are conveniently located for scientists and engineers, who can easily drive from the land onto the fast ice, or take a flight by helicopter, to reach their study sites. On the other hand, depending on the time of year McMurdo Station and Scott Base are also separated from the pack ice or open ocean by the fast ice and a distance of many kilometres to the ice edge.

Most people arrive at and depart from McMurdo Station and Scott Base by air, and between early October and mid-December many aircraft operate from a temporary airfield on the fast ice. Fundamental to the safe operation of the airfield, because it affects the load-bearing capacity or strength of the ice, is knowledge of the ice thickness, which is determined by prior conditions and processes of ice formation.

The ability to move people and supplies between New Zealand and McMurdo Sound, and between McMurdo Sound and South Pole and other distant continental locations, aboard aircraft that land on the fast ice has great scientific and operational value. However, the fast ice is also an obstacle to the annual and vital resupply by sea of McMurdo Station and Scott Base. This occurs in January and February, and it is rare that the fast ice breaks up and drifts away so that McMurdo Sound opens naturally before the arrival of the fuel tanker and container ship. When it does occur, the natural breakup of the fast ice is promoted by the thinning of the ice due to bottom melting, and by the retreat of the Ross Sea pack ice to the north, which exposes the thinner and weaker fast ice to penetrating waves and swell that fracture it into small pieces. They then drift away northward into the open Ross Sea, often aided by southerly winds. The fast ice subsequently forms again as the sound freezes over beginning in March/April.

Since the supply ships must reach McMurdo Station and unload before the natural breakup of the fast ice, a US Coast Guard icebreaker cuts a channel through the fast ice and escorts the ships to the ice pier. Under normal circumstances this is a fairly routine operation for a single icebreaker to complete with minimum difficulty. However, circumstances were very different in January 2002, 2003, and 2004, when, because of thick multiyear ice that had persisted in the sound since 1999, two icebreakers were needed to break through to the ice pier.

The extreme ice conditions in McMurdo Sound were due to incomplete natural break out of the fast ice in 1999–2001 compounded by the effects of a number of icebergs, including the massive B-15A iceberg, that grounded on the seafloor at the north side of Ross Island in late 2000. It is believed that the icebergs changed the water circulation in McMurdo Sound, primarily by diverting the inflow of relatively warm seawater and thus reducing melting at the base of the ice in summer, and by sheltering the sound from the ocean waves and swell that contribute to the breakup of the thinning fast ice. Consequently, the ice grew older and thicker, and by January 2004 some of the multiyear ice was as much as 8 m thick. The maximum thickness of first-year fast ice in late winter in McMurdo Sound is typically only 2–3 m.

Most nations do not attempt to break through the fast ice that separates their stations from the supply vessels that have negotiated the pack ice, often with some difficulty. Instead, the ships tie up at the ice edge and transfer their cargo to the fast ice for transshipment to shore across the ice, which is often many years old. In fact, the oldest sea ice in Antarctica occurs in the fast ice zone.

Ice Formation

Frazil ice and pancake ice are not just distinctive ice types that are vital to the early and rapid development of the sea ice cover each autumn. The pancake-frazil cycle is also considered to be an ice formation process. But, once the ice cover has become established in this fashion, frazil ice no longer plays an important role in ice thickening by the freezing of water. This is accomplished primarily by two other widespread ice formation processes: congelation ice and snow ice.

Congelation was mentioned earlier in the context of the thickening of nilas. It grows at the bottom of any ice cover when there is a negative temperature gradient—the temperature at the top is lower than the temperature at the bottom—in the ice and snow, if present, and the resultant upward conductive heat flux exceeds the ocean heat flux at the bottom of the ice. If these conditions are met, the latent heat created by freezing at the bottom of the ice is conducted upwards to the atmosphere. Congelation sea ice has a distinctive columnar texture of vertically oriented crystals.

Snow ice formation occurs at the top of the ice. It is frozen slush that forms either when the snow cover is flooded by seawater washing over the ice, or when the mass of snow accumulated on the ice is sufficient to push the ice surface below the sea surface. In the latter case, seawater either flows up to the top of the ice via fractures or via networks of brine channels in the ice. The importance of snow ice was first realized during the Winter Weddell Sea Project in 1986 (Lange et al. 1990) and it has subsequently been shown to occur throughout the Antarctic pack ice (Worby et al. 1998; Jeffries et al. 2001).

Snow ice has a distinctive granular crystal texture that is quite different from the columnar crystal texture of congelation ice. Frazil ice also has a granular appearance and it is difficult to distinguish it from snow ice on the basis of crystal texture alone. To differentiate between frazil ice and snow ice, and determine their relative contributions to ice formation, it is necessary to measure the stable isotopic composition (typically oxygen-18/oxygen-16 ratios) of the ice (Lange et al. 1990).

The snow on the ice surface plays an important role in both congelation ice and snow ice formation. In the case of congelation ice, the snow affects the freezing rate at the bottom because snow has a much lower thermal conductivity than ice and is therefore an effective insulator. Couple the lower thermal conductivity (a measure of the ability of a material to conduct heat) to an increasing depth of snow and thus less negative temperature gradients, and the effect is to decrease the rate of congelation ice growth. Once the snow depth reaches a critical value and has sufficient mass to sink the ice, congelation ice growth ceases as the ice surface is flooded with seawater and the temperature gradient swings from negative to zero. Congelation ice growth will not resume until the slush has frozen completely and a negative temperature gradient has been restored to the entire ice thickness, thereby allowing heat conduction to resume.

In some areas of the pack ice, primarily in deep water regions beyond the continental shelf, there is so much heat in the ocean itself (the ocean heat flux) that congelation ice growth is not only not possible, but bottom ice growth is reversed (i.e., melting occurs). Thinning the ice by bottom melting increases the likelihood that it will sink under the mass of snow accumulating at the surface, leading to flooding and snow ice formation. Consequently, the amount of snow ice in floes often exceeds the amount of congelation ice, if it is present at all, and sometimes even the amount of frazil ice (Jeffries et al. 2001). Snow ice formation plays a vital role in simply maintaining the thickness of ice floes, let alone increasing their thickness in some deep water regions.

Congelation ice is more common in the pack ice and fast ice of the shallower waters over the continental shelf (Eicken and Lange 1989; Jeffries and Adolphs 1997; Jeffries et al. 1993; Gow et al. 1998). This has been attributed to a combination of lower air temperatures, thinner snow cover and lower ocean heat flux than the more northerly pack ice regions. Antarctic coastal waters also promote the formation of platelet ice, which has been found under and within pack ice floes and fast ice.

Platelet ice was first described in McMurdo Sound by scientists with the ill-fated British Antarctic *(Terra Nova)* expedition of 1910–1913 (Wright and Priestley 1922). It is associated with the outflow of cold, low salinity, and thus low density, water from below ice shelves and glacier/ice tongues. As the low-density water rises through the water column and decompresses, it supercools and platelet ice crystals form. They grow in the water column, where they have been mistaken for swarms of krill in echosounder charts (Dieckmann et al. 1986), and float upwards and accumulate against the bottom of pack ice floes or a fast ice sheet. Or, they grow only when the supercooled water finally comes into direct contact with the bottom of the floes or fast ice. Either way, the platelets initially form loose billows of ice crystals that are subsequently incorporated into the overlying ice as the water surrounding the platelets freezes by congelation (Eicken and Lange 1989; Jeffries et al. 1993; Gow et al. 1998).

The snow cover plays the key role in one final ice formation process, one that occurs in the summer and which involves freshwater not seawater. Unlike the Arctic, where the snow cover melts completely and accumulates in ponds on the ice surface in summer, the snow cover on Antarctic sea ice survives the summer. However, there is partial melting and the meltwater percolates down through the snow and refreezes directly on the ice surface as a layer of superimposed ice. It has also been observed in layers perched on top of the slush on seawater-flooded floes. Freezing of the slush in the autumn creates a layer of snow ice and integrates the perched superimposed ice into the total ice thickness. Superimposed ice formation occurs in the pack ice and on fast ice (Kawamura et al. 1999, 2004; Haas et al. 2001).

Antarctic and Arctic Sea Ice

Pack ice and fast ice, and the same ages and stages of sea ice development, occur in the Antarctic and the Arctic. The differences between the two regions are primarily a matter of proportion. The seasonal expansion and contraction of the Antarctic pack ice is much greater than that in the Arctic. Consequently, there is far more first-year ice than multiyear ice in Antarctica, and the area of Antarctic first-year ice at the time of maximum extent is roughly double that of Arctic first-year ice at the time of its maximum extent. Arctic sea ice is more evenly divided between first-year and multiyear sea ice. The pancake-frazil cycle also occurs in the marginal seas of the Arctic, but they cover a smaller total area than the Antarctic first-year pack ice at the time of maximum extent; consequently, frazil ice and pancake ice formation are more widespread in Antarctica than in the Arctic. Likewise, snow ice is more common in Antarctica because snow accumulation on thicker Arctic sea ice is generally not sufficient to overcome its buoyancy and flood the ice surface and the bottom of the snow cover. Arctic pack ice and fast ice growth is dominated by congelation ice formation that is promoted by a lower ocean heat flux and thinner snow cover that provides less insulation from lower air temperatures. Platelet ice has been reported in Arctic floes, but its growth is probably not associated with the outflow of low density water from below ice shelves, and the quantities are likely lower than in Antarctica. Superimposed ice occurs only briefly on Arctic sea ice, where it lasts only a little longer than the snow cover from which it formed. In Antarctica, superimposed ice survives much longer and becomes an integral part of multiyear pack ice floes and fast ice.

SEA ICE, WEATHER, AND CLIMATE

A spectacular feature of the Antarctic environment is the presence of large amounts of sea ice. In autumn and winter the amount of solar radiation falling on the Southern Ocean starts to decrease. As a consequence, the sea surface temperatures fall, and when they drop to near –1.8°C, conditions are conducive to the formation of sea ice. This region is subject to frequent, very intense storms. Under the associated strong wind conditions, large amounts of heat are extracted from the ocean, and frazil ice can form. When the winds abate the frazil ice crystals rise to the sea surface where they coalesce into a thin layer of "grease" ice. This eventually forms pancake ice, and continued freezing and horizontal transport produces expansive regions of pack ice. Because the surface of the ice is, in general, much colder than the sea water at its base there is an upward flux (or transport) of heat through the ice. The energy for this heat is provided by the latent heat released as water is frozen onto the bottom of the ice (Stefan's Law). Hence, as the winter proceeds the ice becomes thicker, and new ice also forms farther to the north. When the Sun returns in the spring, the temperatures rise and the northern limit of the sea ice retreats. By the end of summer most of the Antarctic sea ice has melted. The limited amount of ice that does survive ("multiyear" ice) is found in regions close to the Antarctic continent, and in the Ross, Amundsen, Bellingshausen, and Weddell seas (about 40% of the total in the last).

The sea ice distribution is strongly influenced by *dynamic* (mechanical) and *thermodynamic* (melting and freezing) factors. There is a large temperature difference between the cold Antarctic continent and the relatively warm, ice-free ocean to the north. This thermal contrast induces strong and frequent storms over the sea ice region. These, in turn, exert large stresses on the sea ice and may set it in motion. Hence, sea ice can be carried (at rates of up to 60 km in a day) large distances from its point of formation. In particular, ice that is formed in the frigid regions in the southern part of the Weddell Sea is carried north by the Weddell Gyre, and this dynamic transport is the reason the mean ice extent in the Weddell sector (and to the east) is greater than that in any other sector around the periphery of Antarctica.

In addition to the atmospheric wind stresses on the sea ice, it is subject to forces associated with ocean currents, tides, and waves. They also induce stresses and motion in the ice pack, and the resultant deformation of sea ice causes continual fracturing, rafting, and ridging. As a result, areas of open water (with predominantly linear shapes), called leads, frequently appear. When they do there are massive heat transfers from the exposed parts of the ocean to the (cold) atmosphere above. As a result of the heat loss the surface layer of water in the leads cools rapidly, and can refreeze very quickly. Ultimately a balance is reached between the opening and closing of open water areas and the sea ice in a given region will have a spatial concentration of less than 100%.

Whether sea ice is present or absent influences greatly the high latitude communication between the atmosphere and ocean, and hence the regional weather and climate. When the ocean is ice-free these two media interact directly, and the atmosphere provides kinetic energy to the ocean, which subsequently results in wave activity and currents. At the same time the ocean provides the high latitude atmosphere with moisture (through evaporation) and heat. When sea ice is present these interactions dramatically change, and the ice now acts as a rather inefficient intermediary. The atmospheric winds induce a horizontal force on the ice, but whether the ice will move in response to this will depend on a number of factors, including how compact the ice has become. Hence, the underlying ocean loses its local source of wave generation and, to a considerable extent, the momentum to influence currents. In a similar vein, the vertical transfers of moisture and heat change remarkably in the presence of sea ice (it can be seen to be acting as a blanket, and the decoupling effects become more marked for thicker sea ice). As noted above, in ice-free conditions the transfer of moisture and heat is almost always *from* the ocean *to* the atmosphere. When a cold ice surface is present the magnitude of the moisture exchange is greatly reduced and could be upwards (evaporation) or downwards (fog formation). Similarly, the cold ice will now draw down heat from the atmosphere.

This dramatic change in behaviour of these important fluxes can be understood in terms of the surface energy balance over the ice. This balance equates the energy losses and energy gains (steady state) of the floating ice, and allows one to determine other measurements (e.g., the temperature of the ice). The main components of this budget are the net radiation, the latent and sensible heat fluxes from the surface, and the conductive heat flux through the ice. The radiative forcing is conveniently broken up into shortwave (or solar) and longwave (or infrared or thermal) components. Only a small proportion of the solar radiation, which is incident on the ice surface, is involved in this budget because much of the insolation is immediately reflected by the bright surface. The proportion of radiation that is reflected is referred to as the albedo, and over Antarctic sea ice it has typical values of about 0.8–0.9. The sea ice albedo changes during the year and is high when the sea ice is thick, particularly when covered by fresh snow, and lower during the melting season when the snow properties change. The net longwave gain or loss itself depends on the temperature of the surface and the atmosphere. Atmospheric water vapor is a strong absorber of longwave radiation ("greenhouse" gas), and hence part of the infrared radiation emitted by the surface (loss) will be absorbed and re-emitted by clouds and moisture in the atmosphere. This results in a downward flux of longwave radiation *toward* the surface, and the magnitude of this will clearly depend on the amount of the cloud cover (and its height), as well as the moisture content of the air (and hence its temperature). Consequently, the energy balance over sea ice is very different to that over open water, and the net energy balance over a pack ice region of fractional ice coverage is complex.

To understand the associations of sea ice with weather and climate it is important to obtain comprehensive and reliable information on its characteristics. Making relevant observations of sea ice conditions has been very difficult in the past. The oceans over the high southern latitudes are remote and hostile environments, and historically were visited very infrequently. Hence, the number of observations were very few, and most of any such observations were effectively restricted to the region of the ice edge. For practical purposes the only reliable and continuous sea ice observations are those derived from satellites.

By the early 1970s satellites could produce images of the sea ice zone. Since then a range of instruments, including Landsat, Advanced Very High Resolution Radiometer (AVHRR), Synthetic Aperture Radar (SAR), Operational Line Scan (OLS), and the Moderate Resolution Imaging Spectroradiometer (MODIS) have provided very valuable data of the region at high to very high spatial resolution. Visible and infrared satellite imagery is of great value, but these approaches do have their drawbacks—mainly that they require light and cloud-free conditions, two conditions that are not satisfied a significant proportion of the time in the Antarctic sea ice region.

Passive microwave sensors on polar-orbiting satellites can circumvent some of these drawbacks. At many microwave wavelengths the sea ice has a substantially different emissivity to that of liquid water. The sharp contrast between ice and open water in the passive microwave data allows the sea ice distribution to be readily identified (although the summer melt season does pose some problems when the surface of the ice may become saturated). Passive microwave sensors have the advantage for regular and year-round monitoring that their transmission is relatively unaffected by the presence of atmospheric moisture or clouds between the surface and the satellite, and that they do not need the surface to be illuminated by the Sun. There are limitations, however, associated with the use of passive microwave satellite imagery (e.g., the spatial resolution of the products derived from these instruments is relatively modest [about 25 km] and hence cannot identify individual ice floes [nor determine their shapes, sizes, etc.]). However, for the purpose of identifying the interactions of sea ice with weather and climate, that spatial resolution is sufficient for most purposes.

Much of what we know today about the large-scale distribution of Antarctic sea ice has been obtained from the Scanning Multichannel Microwave Radiometer (SMMR) (aboard NIMBUS-7), Special Sensor Microwave Imager (SSMI) instruments aboard satellites of the US Defense Meteorological Satellite Program, and the Advanced Scanning Microwave Radiometer instruments aboard NASA EOS satellites. These instruments have provided snapshots of Antarctic sea ice every second day (and now every day) since 1978. The net effect of all the physical processes discussed previously is to produce a very large seasonal cycle in the area of the Southern Ocean covered by ice, and this is now quantified by nearly three decades of the microwave satellite data. The data reveal that the average maximum coverage is about 19 million km^2 and occurs in late winter/early spring (this area equals about 6% of the total area of the world's oceans), while the minimum coverage occurs in February/March and is about 4 million km^2. Hence most of the Antarctic sea ice is first-year ice. The microwave data provide a comprehensive picture of the horizontal distribution of sea ice concentration. The sea concentration in the pack ice zone in general decreases with distance from Antarctica, which leads to the question of how to identify the location of the ice edge. A practical and well-accepted definition of the ice edge is the point at which the ice concentration drops to 15%.

It was mentioned that not only is the ice concentration important in diagnosing the weather and ice associations, but so too is the thickness of the ice. The Antarctic pack ice assumes different thicknesses (and albedos) as a response to all the influences discussed earlier. Local measurements of ice thickness, obtained from, for example, holes drilled in the ice and from ship-based estimates (as ice breakers turn the ice on its side) are valuable, but for reasons similar to those cited earlier they present only a limited picture of this important variable (and there is obviously a bias for resupply vessels to choose tracks that are expected to have thinner ice). The modest thickness and liquid brine content of Antarctic sea ice makes its measurement a challenge for geophysical (and remote) measurement techniques. Techniques that have been used with some success include airborne and portable electromagnetic (EM) instrumentation, upward-looking sonars tethered to the ocean floor, and ice thickness derived from satellite altimeter measurements of ice freeboard. These techniques have shown that the mean thickness of Antarctic sea ice ranges from 0.5 m to 1.0 m, with thinner ice toward the ice edge and thicker ice in the more southerly regions.

The important role played by leads in terms of modifying the energy balance over the Antarctic sea ice region was discussed above. Important effects are also associated with polynyas. These are regions of open water surrounded by ice but, unlike leads, they do not have a predominantly linear structure. In addition, they are usually much larger, very regionally persistent, and are formed by different mechanisms. One class of polynya is kept open by events such as strong katabatic air flow off the continent whose winds can maintain regions of open water up to a few kilometers from the coast. New ice is continually being formed in this type of polynya, and they are referred to as latent heat polynyas because the surface water is warmed (and kept ice-free) by the latent heat released during the formation of ice crystals. These Antarctic "ice factories" are now believed to play an important role in the maintenance of the global thermohaline circulation. In other regions (away from the coast) so-called sensible heat polynyas can form from heat transferred from deeper waters. For similar reasons to those mentioned, the presence of these polynyas greatly influences weather and climate in the region. For example, it is estimated that the Weddell Sea polynya (which formed during the winters of 1974–1976 and had an area of approximately 350,000 km^2) caused local surface air temperatures to be some 20°C higher than normal, while total cloud cover was about 50% higher than average. It has also been estimated that the mean sensible and latent heat fluxes during the winter months were enhanced by 150 and 50 W m^{-2}, respectively, and precipitation increased by 1 mm day^{-1}.

The insights into the large-scale distribution of Antarctic sea ice provided by the modern satellite products have allowed climatologists and glaciologists to obtain quantifications of the complex connections between sea ice, weather, and climate. The mechanisms by which synoptic weather systems strongly influence Antarctic sea ice formation, evolution, and concentration have been mentioned. By the same token, the sea ice itself influences the synoptic systems. The sea ice distribution is an important factor influencing the distribution of horizontal thermal contrasts (or "baroclinicity") and hence can affect the growth, decay, and direction of motion of cyclonic weather systems. The distribution of sea ice is a critical influence on the magnitude of heat and moisture fluxes to the atmosphere and these, in turn, have major influences on the strength and longevity of these low pressure systems. While the low pressure systems may be regionally confined they do have significant frontal structures that can extend as far as the subtropics, and hence are able to influence weather over much of the Southern Hemisphere.

Sea ice also interacts with climate and on a range of time scales. Ice is of particular importance to the understanding of climate variability because of the role it plays in various feedback processes. One of these is the ice-albedo feedback. Suppose for some reason (e.g., an intense storm or a particularly cool season) the amount of ice in a given region were to increase. The surface albedo (of the ice) will now be much greater than that of the ocean water that previously occupied that region. Hence more solar radiation will be reflected from the region, and this will lead to lower temperatures and encourage further growth of sea ice. Hence this is a positive feedback loop that results in an ultimate ice change greater than the original perturbation.

On a near-global scale, complex relationships have been identified between El Niño occurrences and Antarctic ice variability. The El Niño Southern Oscillation phenomenon is one of the major causes of multi-year and decadal climate (particularly precipitation and temperature) variability over much of the world. During El Niño events a quasi-stationary "teleconnection" pressure wave pattern can be found to originate in the central tropical Pacific Ocean and propagate to high southern latitudes, with nodes in the Amundsen and Bellingshausen seas and in the Weddell Sea. The persistent pressure pattern features associated with these greatly influence the sea ice distribution for the reasons discussed previously. On the other hand, there is evidence to indicate that Antarctic sea ice conditions in turn can influence the initiation and evolution of El Niño events.

Another major mode of variability in the Southern Hemisphere climate is the Southern Annular Mode. This mode essentially represents a predominantly meridional (i.e., north-south) exchange of mass between 40° and 65° S. In the "positive" phase of the mode meridional pressure gradients over the mid- to high latitudes are increased and stronger westerlies are experienced over that domain (and weaker westerlies in the "negative" phase). Interannual variations in high latitude cyclone behavior are known to be associated with this mode. These hemispheric-scale variations impact on sea ice in accord with the physical processes discussed previously. The disposition of the Antarctic sea ice is also believed to affect this mode.

As a final example of the range of sea ice–climate associations, the role of sea ice in driving the global thermohaline circulation and the production of Antarctic Bottom Water (AABW) should be mentioned. When the surface waters freeze, most of the salt is expelled from the ice formed. This in turn increases the density of the waters just beneath the new ice and causes a pulse of cold, saline water to flow onto and then off the continental shelf and ultimately descend into the deep ocean. This bottom water can be found over much of the world's oceans and its presence is one reason why the ocean bottom temperatures are close to 0°C over most of the world. The total production of such water masses will depend on the seasonal *range* of sea ice. Because the Antarctic sea ice region has no effective boundary at its northern margin (a situation very different from the Arctic), the sea annual ice range is large (about 15 million km^2). Oceanic climate (and particularly subsurface oceanic structure) is particularly affected by this production of AABW.

Overall these weather and climate links have been explored with statistical techniques applied to the quality sea ice data sets, which the passive microwave satellite sounders have provided for almost three decades. The complex associations are also investigated with a range of numerical computer models which represent our best representations of the physics of weather, climate and sea ice. The coupling of such models has even allowed us to obtain estimates of Antarctic sea ice distributions over time (e.g., the last few centuries).

SEABIRD CONSERVATION

Introduction

The Antarctic region is known for its seabirds: huge colonies of penguins ashore and resting on ice floes and bergs at sea, and an ocean seemingly filled with majestic albatrosses and a myriad of smaller birds wheeling in the wakes of ships, sometimes passing by in flocks so big they might reach to the horizon. In a region of the world that has hardly been inhabited by humans, where natural, seemingly unaltered environments, both at sea and on land, prevail, it might be assumed that all must be well with such a plethora of life. After all, most southern islands are proclaimed national nature reserves, with a very high level of conservation management (and several are World Heritage Sites). The Antarctic continent is well protected via the Antarctic Treaty and its various instruments. Unfortunately, the assumption that all should be well is wrong, and the seabirds of the high latitudes of the Southern Hemisphere face a number of human-induced threats, so severe in some instances that many species are currently deemed to be threatened with extinction.

The region covered in this entry includes the Antarctic continent and the maritime Antarctic, sub-Antarctic, and uninhabited cool temperate islands of the Southern Ocean, as well as the Southern Ocean itself. The threats facing Antarctic seabirds may be conveniently divided into those operating on land (such as disturbance from ecotourism) and those taking place at sea (such as fishery-induced mortality). However, some more general threats, such as from climate change due to anthropogenic causes, may operate in both environments, and their effects may only act indirectly, and thus are harder to observe (for example, from changes in the distribution, abundance, and availability of the prey of seabirds).

The breeding seabirds of the region are classified into four orders. The most iconic are the penguins (Family Sphenisciformes), with five species breeding on the continent, and others breeding on islands in the Southern Ocean, with some overlap. The next order, the Procellariiformes (albatrosses and petrels, collectively called "tubenoses") has the greatest number of species occurring, mainly occurring on the islands, but with a few continental breeding species. The remaining orders of seabirds are the Pelecaniformes (represented by a number of cormorant species) and the Charadriiformes, consisting of gulls, terns, skuas, and sheathbills (the last group, however, not being considered to be seabirds, but rather shorebirds). A number of species of land birds occur on Southern Ocean islands, but these are not considered further.

The most important conservation threats facing Antarctic seabirds are described next, with the species or species groups, and regions, particularly affected identified. For each identified threat, information is given on what has and is being been done to address it, and what actions might still be appropriate to adopt or consider to further the conservation of southern seabirds.

Habitat Alteration

Alteration or outright loss of breeding habitat has affected Southern Ocean islands to a greater or lesser extent. One driving force in the past has been fire, restricted to the drier cool-temperate islands. French Île Amsterdam and Inaccessible Island in the Tristan da Cunha Group have both suffered from comprehensive burning in the nineteenth century, leading to loss of tussock grass and woody vegetation and thus breeding habitat for burrowing petrels. Although such islands remain permanently at risk from fires, current management procedures are such that the risk is low. The introduction of alien plants also may lead to breeding sites becoming less suitable. Feral herbivores have also altered habitats. Examples are the now removed domestic rabbits *Oryctolagus cuniculus* and cattle *Bos taurus* of Enderby Island in the Auckland Islands, and the cattle still present on Île Amsterdam. On the latter island two fences have been built to exclude cattle from the breeding habitats of the endemic and Critically Endangered (facing an extreme risk of extinction) Amsterdam albatross *D. amsterdamensis*. At other islands feral domestic pigs *Sus scrofa* have altered habitats by rooting (and have consumed seabirds directly).

The relatively recent increases in the populations of fur seals *Arctocephalus* spp. at the more southerly islands (e.g., South Georgia and the South Orkney Islands) has led to the alteration of habitats by the trampling of plants, as well as the physical displacement or disturbance of breeding birds, including surface nesters, such as the wandering albatross *Diomedea exulans,* as well as burrowing petrels. Since fur seals are indigenous members of the communities they affect, are recovering from massive exploitation in the nineteenth century, and are specially protected species in terms of the Antarctic Treaty, their expansion presents a conservation dilemma not yet fully addressed. Should nature be allowed to run its course, or should active management, to maximize biodiversity, for example, be practiced?

Habitat alteration on the Antarctic continent appears to be less of an issue, although some seal colonies are increasing in size on the Antarctic Peninsula, displacing breeding penguins, and changes in ice shelves and the positioning of icebergs may cause the displacement and lowered breeding numbers and success of individual colonies of emperor penguins *Aptenodytes forsteri*. At certain localities the establishment of national stations and associated infrastructures has displaced breeding penguins and surface- and crevice-nesting petrels. A notable example is the now-abandoned attempt by the French to construct a "hard rock" airstrip by flattening and connecting a number of small islands in Terre Adélie. At the species level, this is probably not a significant conservation issue. Nevertheless, the establishment of new bases, and any other human activity for that matter, should always avoid displacing breeding seabirds.

Introduced Predators, Avian Diseases, and Human Exploitation

Introduced predators have been, and on some islands continue to be, the greatest risk southern seabirds face on land. Feral domestic cats *Felis catus* are the prime culprit, massively reducing breeding numbers of burrowing petrels, and causing local extinctions of several species on islands such as New Zealand's Marion Island, Australia's Macquarie Island and Australia's Campbell Islands. Thankfully eradication programmes utilizing a suite of methods (shooting, trapping, and use of poisons) at all three islands have been successful, and affected birds are returning to breed in numbers, assisted by the introduction of captive-reared birds in the case of the endemic Campbell teal *Anas nesiotis*. Feral cats still exist on several French sub-Antarctic islands in the southern Indian Ocean, and their eradication, given the proven methods now existing, should become a priority.

Rodents are present on many of the southern islands, where rats *Rattu*s spp. especially have been considered to have reduced the numbers of the smaller burrowing petrels such as storm petrels and diving petrels, including causing local extinctions, although definite evidence is sometimes lacking. Several successful eradication campaigns have now taken place with more planned. The method of choice is the aerial broadcasting of poison bait by helicopter: a technically difficult and very expensive, exercise. Undoubtedly the greatest success to date was the eradication of the Norwegian rat from 11,300 ha Campbell Island in 2001. A similar operation is now planned for even larger (12,785 ha) Macquarie Island, to remove black rats *R. rattus,* as well as rabbits and house mice *Mus musculus*. Until recently, the house mouse was not thought to be direct predators of birds, but on Gough Island in the Tristan Group it has been proven that in winter months food-deprived mice attack and kill the young of the Critically Endangered Tristan albatross *D. dabbenena* and the Vulnerable Atlantic petrel *Pterodroma incerta*. Both species are endemic to the island group. Modelling has shown that neither species is likely to survive such an onslaught, and an eradication feasibility study is to be undertaken in 2006. Once again, this will be a difficult and expensive exercise, and with the largest southern island at which mice have so far been eradicated being only 710 ha in size (Enderby) against the 6400 ha extent of Gough, success cannot be assured. There is now a pressing need to look for mouse predation of seabirds at other islands where both occur, such as on New Zealand's Antipodes Island. Circumstantial evidence of mouse predation on wandering albatrosses on Marion Island has been very recently reported and is being investigated further by South African biologists.

Seabirds breeding on the Antarctic continent and on maritime Antarctic islands thankfully face no introduced predators. The extremely harsh winters, when nearly all birds are absent, would seem to disallow any surviving for very long. In the past when sledge dogs *Canis familiaris* escaped or were allowed to roam free around continental stations, local mortality of penguins occurred. Dogs are no longer allowed within the Antarctic Treaty Area. This has also caused the cessation of another "introduced" predator: the human occupants of Antarctic stations who killed seals to feed their dogs, and in the early days of exploration, to feed themselves. Humans, mainly sealers on the islands, also killed many seabirds for food, and sometimes for their feathers. The most notorious example of such exploitation was the killing and boiling down of moulting royal penguins *Eudyptes schlegeli* (known as "fats") on Macquarie Island for their oil, where the digesters used are now a macabre tourist attraction. Thankfully, the halting of this operation ranks as one of the first conservation successes in the Southern Ocean.

Infectious bacterial and viral diseases can also be considered to be analogous to predators. Much less is known about avian disease-causing agents in the region, but antibodies of the viral Newcastle Disease have been found in southern penguins, and avian cholera, caused by the bacterium *Pasteurella multicida,* has been blamed for causing mortality of macaroni penguins *Eudyptes chrysolophus* on Marion Island and Indian yellow-nosed albatrosses *Thalassarche carteri* on Île Amsterdam, both Vulnerable species with declining global populations. The elimination of an established disease would seem to be much harder an undertaking than eradicating mammalian predators, so the best way of combating the issue is to introduce strict quarantine measures, such as disallowing the importation of poultry products to island stations, and the halting of keeping domestic poultry ashore. The latter has taken place at most, but not yet quite all, sub-Antarctic islands, the former at only a very few to date.

Disturbance and Ecotourism

Undoubtedly human activities in the region have caused deleterious effects on seabirds. These may be temporary, such as caused by the loss of eggs and small chicks of breeding birds frightened off their nests by passing humans (and their vehicles, including aircraft) to skuas *Catharacta* spp. Where disturbance is of a more chronic nature, declines of populations and the abandonment of some breeding colonies can occur. An example is that the numbers of wandering albatrosses breeding within the close vicinity (and within visual distance) of the meteorological station on Marion Island have steadily declined since the station was established in 1967. It is hypothesized that this reduction has been more a case of drastically reduced recruitment by the more sensitive prebreeding birds than due to a lowered breeding success. In effect as breeding birds die, they have not been replaced by new birds, which prefer to recruit elsewhere to less disturbed areas (which may be less suitable habitat). Such an effect is most probably causing the observed shifting of some penguin colonies near Antarctic bases.

Ecotourism in the region is growing apace, and favoured sites to visit are usually "hotspots" for breeding penguins and albatrosses. Most tourist visits are ostensibly well managed, with minimum approach distances and maximum party sizes voluntarily adopted by members of the International Association of Antarctic Tour Operators (IAATO). However, repeated visits within a single breeding season may well lead to a lowered breeding success, as birds are temporarily halted from reaching their nest sites, perhaps leading to chicks missing meals—without overt signs of any disturbance being noted by the visitors, or their guides. Lectures aboard tourist vessels and the issuing of codes of conducts can help educate tourists about such dangers.

Research has shown that apparently oblivious breeding penguins and albatrosses may have accelerated heart rates as humans approach their nests, leading to energy imbalances that could push birds "over the edge" in the harsh environments in which they occur. Minimum approach distances may help address this problem, and research of disturbance effects on wandering albatrosses at Marion Island has suggested that breeding birds should not be approached closer than 25 m. At this island, three more sensitive species (gentoo penguin *Pygoscelis papua,* southern giant petrel *Macronectes giganteus* and Crozet cormorant *Phalacrocorax [atriceps] melanogenis*) may not be approached closer than 100 m when breeding, unless a research permit has been issued. Research itself can also lead to reduced breeding success, but local and national regulations are generally in place to control this (through the use of ethics committees judging project proposals and the issuing of permits by management authorities).

Aircraft pose a special threat to seabirds. Some species seem more susceptible than others to their presence: an incubating or brooding wandering albatross may literally "hang on" to its nest in the face of helicopter downwash, but king penguins *Aptenodytes patagonicus* may start showing signs of nervousness upon hearing a helicopter, before it comes into visual range. Indeed, an overflight by a fixed-wing aircraft at Macquarie Island once caused the death of some thousands of king penguin chicks, which piled up into heaps against rock faces and suffocated as a consequence. This was an isolated occurrence, and although birds continue to be disturbed (southern giant petrels breeding near Antarctic bases, such as on King George Island, South Shetland Islands, are regularly disturbed by aircraft flying overhead), the discussion and adoption of guidelines by the Antarctic Treaty Consultative Parties in 2004 should go some way to solving the problem. Currently aircraft should not fly below 2000 feet (c. 610 m) over colonies and should avoid landing within half a nautical mile (c. 930 m). Similar national regulations exist for most Southern Ocean islands, via Management Plans and Codes of Conduct documents.

Pollution, Ingestion, and Entanglement

Compared to lower latitudes, most especially in the Northern Hemisphere, and along the world's major shipping routes, Antarctic seabirds have largely escaped the effects of pollution. Oil spills in the Southern Ocean tend to be few and far between (and not the result of the loss of huge quantities of crude oil from stricken tankers). An exception was the grounding of the *Bahia Paraiso* in the Antarctic Peninsula region in 1989, when leaked fuel oil caused oiling of local cormorants and other birds.

Pesticides, such as DDT and dieldrin, and PCBs have been found in the bodies of Antarctic and sub-Antarctic penguins, presumably reflecting a global background fallout, but seemingly not at levels that have led to eggshell thinning and reduced breeding success.

Ingestion of surface-floating plastic items, mistaken as prey by a wide suite of southern seabirds from huge albatrosses to tiny storm petrels, is a source of concern, as such nondigestible items may cause physical damage to the gut, release harmful chemicals, and also give a false sense of satiation. Industrial plastic pellets, bottle tops, and broken fragments are all found in seabird stomachs. Plastic items can even be transferred to predatory seabirds such as skuas when they catch and swallow small storm petrels and prions *Pachyptila* spp. whole. Again, the problem is not as bad as it is in, for example, the North Pacific, which is bordered by the industrial world, and no species seem at serious risk from plastic ingestion at the population level.

Seabirds are prone to becoming entangled in fishing equipment and plastics discarded at sea, but whereas such incidents are dramatic when encountered at a breeding colony, it is not thought the levels attained are of particular conservation significance. A more serious concern comes for surface scavenging species, notably albatrosses, giant petrels, and some *Procellaria* petrels, ingesting discarded fish heads with lines and hooks still attached. This can lead to mortality of adults, and even of their chicks if the offending items are transferred during feeding. Fishing regulations aim at reducing the discarding of hooks, so the problem can be solved with sufficient will.

Fisheries and At-Sea Mortality

Most probably the greatest threat facing southern seabirds, outside the more insidious effects of climate change, is the increased levels of mortality that a suite of scavenging species face from longline and trawl fisheries. Long-lining for Patagonian toothfish *Dissostichus eleginoides* around sub-Antarctic islands and over sea mounts has led to massive mortality of albatrosses and the larger petrels as they seize baited hooks, are dragged below the sea surface and drown. Pelagic long-lining for tuna *Thunnus* spp. has also held to much mortality. Other birds die from colliding with the cables of bottom trawls. The high levels of mortality have led directly to most of the affected birds being accorded a high category of threat by the World Conservation Union, and, indeed, of the world's multispecies bird families the albatrosses are now the most threatened with extinction.

The problem is a relatively new one, first coming to attention as a serious threat in the 1980s. It has been exacerbated by the "gold rush" nature of the toothfish fishery with "pirate" (illegal, unreported, and unregulated) fishing vessels plundering the fish stocks without adopting any bycatch mitigation measures. Massive international attention and pressure, still ongoing, from nongovernmental organizations such as the World Conservation Union and BirdLife

International have led intergovernmental bodies, such as the Food and Agriculture Organization of the United Nations (FAO) and the Commission for the Conservation of Antarctic Marine Living Resources (CCAMLR) to set guidelines and regulations to reduce seabird mortality. Simple mitigation measures such as only setting lines at night and deploying a bird-scaring line above the hook-bearing longline can greatly reduce mortality. The challenge remains to ensure that these and other mitigation measures are adopted by all fishing vessels and that the pirate fishing scourge is driven from the high seas.

Climate Change

The Antarctic continent, the Southern Ocean, and its islands are not escaping the effects of climate change, especially of global warming. Sea and air temperatures are rising at sub-Antarctic islands, ice shelves are breaking up and shrinking around the continent, and the positions of oceanic fronts, and the prey of seabirds that they delimit, are shifting. Direct effects of climate change on seabirds are hard to assess, but, for example, the worldwide decline in populations of rockhopper penguins *Eudyptes chrysocome* may well be ultimately due to climate change affecting the availability of their preferred prey. It seems hard to imagine how such effects can be ameliorated at the regional level, and it can only be hoped that international efforts to curb the emission of greenhouse and other gases will eventually bear fruit, and not too late to allow affected species to recover.

International Conservation Measures

As well as the efforts of the FAO and CCAMLR, several other international initiatives bode well for improving the conservation status of southern seabirds. The Antarctic Treaty Parties are working toward the listing of Specially Protected Species within the Antarctic continent, and the creation and management of Antarctic Specially Protected Areas (ASPAs) lends a level of protection to a number of seabird breeding colonies that might otherwise be overly disturbed by tourists and scientists alike.

A recent and potentially important development has been the coming into force of the international Agreement on the Conservation of Albatrosses and Petrels (ACAP). With most of the sub-Antarctic nations being parties to the agreement, it is expected that collaborative efforts and information exchange will eventually improve the conservation status of the species covered.

A more intractable problem comes from attempting to persuade the various Regional Fisheries Management Bodies (RFMOs) whose areas of jurisdiction overlap with southern seabirds to consider seabird incidental mortality as a problem they must address. However, the role taken by CCAMLR can be seen as an exemplar to followed, and NGOs such as BirdLife International are actively encouraging recalcitrant RFMOs to face up to their responsibilities.

Lastly, moves are afoot internationally to establish Marine Protected Areas (MPAs) on the high seas. If sufficient international will can be garnered, such sanctuaries may go a long way to protecting southern seabirds from various at-sea threats, most especially from fisheries.

SEABIRD POPULATIONS AND TRENDS

Seabirds are globally recognised as providing a variety of signals (as "bio-indicators") on many aspects of their marine environments. Because seabirds breed and forage within the marine environment year-round and typically for many years, aspects of their biology such as diet, annual breeding success and population size reflect changes in their prey and their physical environment. Perhaps the best studied example is when an El Niño Southern Oscillation (ENSO) occurs in the Pacific Ocean: all breeding seabirds abandon their nests with eggs or chicks, and there is complete breeding failure associated with the altered physical oceanographic conditions (warmer surface waters) and the absence of their prey species.

Seabirds can provide information on marine environmental conditions at time scales ranging from a day to more than a decade and over spatial scales between local to ocean-basins, depending on what questions are being asked, or which data are under examination. Studies have shown that seabirds can provide information on abundance and changes in prey species, levels of marine debris and pollution, the impacts of introduced predators such as cats and rodents, responses to climate-change, and human disturbance at nesting sites.

Many Southern Ocean seabirds are long-lived, with individuals of some species, notably the great albatrosses, known to live for more than 40 years. Individuals of many species of penguins can live between 10 and 20 years, and skuas for more than 20 years. Such long-lived species allow researchers to examine aspects of the Southern Ocean over a spectrum of time scales extending from days to almost half a century. However, these long life expectancies require long-term data to assess and interpret any observed changes and trends in their breeding populations. With the growing awareness of the value of long term data, there are greater efforts being made around the Antarctic and sub-Antarctic islands to collect such data. There are currently data sets for several species of Southern Ocean seabirds that span 50 years (see below for a summary), but most are between 10 and 30 years.

Individuals of the majority of Southern Ocean seabird species breed annually, and research studies report and use annual breeding populations for analyses, comparisons among localities for the same species and assessing long-term trends. Some Southern Ocean species such as Adélie penguins (see following list) are monitored under the CCAMLR Ecosystem Monitoring Programme (CEMP) and additional parameters such as foraging trip durations and arrival mass are measured.

Individuals of some species breed biennially, but their breeding population sizes are generally reported as annual populations. King penguins breed twice in 3 years on average or may breed biennially. Their breeding frequency is dependent on their breeding success during the previous attempt—successful breeders can fledge two chicks in 3 years as their breeding cycle extends for more than 12 months, while unsuccessful breeders will attempt breeding the following summer.

Several methods are used by researchers to assess annual seabird breeding populations. The standard census protocols collect data on the size of breeding populations at the onset of incubation to estimate the breeding effort. Various assessments of population size and trends, comparisons among localities, and the population's conservation status (e.g., IUCN Red List) use these estimates of breeding populations at localities, or for data on the species as a whole. Current estimates of breeding populations reflect the ease with which census data can be collected. For many species breeding on the Antarctic continent, the data may be years or even decades old, collected during the last visit to a colony/locality. Breeding populations close to occupied research stations are more easily and more frequently visited, allowing for long-term data to be collected with relative ease.

Counts are made during field surveys where all nesting birds or all individuals in a colony are counted. Counts can also be derived from aerial or ground photographs. More recently, colony extents are measured from satellite imagery, and a density is used to estimate the breeding population—for example, this approach has been used for the very large king penguins whose breeding population can no longer be estimated by traditional methods.

Above-ground colonial nesters such as penguins are easier to count than burrow-nesting species such as the prions, petrels, diving petrels, and some of the *Procellaria* and *Pterodroma* petrels. Counts of burrow entrances for these species may not accurately reflect the true size of the breeding population, as entrances may be shared among multiple nests and not every burrow may be occupied.

There are very few data on the sizes of the nonbreeding populations (comprising prebreeding, failed, and nonbreeding individuals). In some cases, it is believed the size of the nonbreeding population approaches 40% of the breeding population. Some data for intensively studied species such as Adélie penguins in the Ross Sea may provide data suitable for extrapolation to other localities and to other species. Species that breed biennially, such as some albatrosses, are more difficult to assess abundance and trends as breeding failure in one season can result in these birds joining the breeding individuals in the following season.

The species accounts below are for the species that breed on the Antarctic continent, the Antarctic Peninsula, the South Shetland and the South Orkney Islands. Where additional information is available for these species elsewhere (away from the Antarctic) that is relevant, it has been included here. Nonbreeding species that visit the Antarctic, such as many species of petrel and albatrosses, are reviewed briefly below.

- **Emperor penguin, *Aptenodytes forsteri*.** The total population is currently estimated at 220,000 breeding pairs in more than forty colonies around the Antarctic continent and the Antarctic Peninsula. The species is endemic to the Antarctic. Some colonies have not been visited for more than 30 years. All but two of the known colonies are located on the winter sea ice. Long term (>25 year) data are few—the best-studied colony is that at the French station of Dumont d'Urville in Terre Adélie. This colony has halved in breeding numbers since the initial counts in the 1950s, and changes in the sea ice and nearby Astrolabe Glacier have been identified as contributing to the observed decrease. Tourist vessels have recently discovered a number of small colonies in previously unvisited areas.
- **Adélie penguin, *Pygoscelis adeliae*.** This is probably the best-studied and best-understood of the Antarctic-breeding seabird species. Adélie penguins are the most widely distributed species of penguin in the Antarctic, but not the most abundant (see macaroni penguin, below). The current estimated population of Adélie penguins is approximately 2.3 million breeding pairs. The population is distributed around the Antarctic coastline, with three major population centres in East Antarctica, the Ross Sea, and the Antarctic Peninsula. Several long-term data sets spanning 40 or more years are available from throughout their range and permit trends to be assessed. Breeding populations in East Antarctica have shown sustained and continuing increases since the 1960s, but the reason(s) are presently unknown. The breeding population in the Antarctic Peninsula region has decreased in the last 50 years, largely due to a decrease in the persistence and extent of winter sea ice. The breeding population in the Ross Sea has exhibited a number of trends over the last 50 years, but recent changes have been related to the presence of massive icebergs such as B-15, that have drastically altered the sea ice conditions that have affected breeding success.
- **Chinstrap penguin, *Pygoscelis antarctica*.** This species is confined almost exclusively to the South Atlantic sector of the Southern Ocean, with large breeding populations present on islands of the Scotia Arc and on the Antarctic Peninsula. There are small populations on the Balleny Islands and on Bouvetøya. The current estimate of the breeding population is approximately 4 million pairs. Different populations in the Antarctic Peninsula region have exhibited different trends over the last 40 years, with some populations increasing and others decreasing. The recent increases in the Palmer region have been correlated with regional warming since the 1950s; the same correlates that have been implicated in the regional decrease of Adélie penguins. Increasing populations of Antarctic fur seals have been implicated in population decreases at Bouvetøya.
- **Gentoo penguin, *Pygoscelis papua*.** This species' breeding populations are primarily located on the sub-Antarctic islands, with small populations on the Antarctic Peninsula and islands of the Scotia Arc. The total breeding population is approximately 300,000 pairs. It is difficult to assess annual populations in this species as there are large interannual fluctuations in breeding effort, typically reflecting a combination of deferred breeding and/or variability in recruitment. Further, breeding is less synchronised than other penguin species. Small breeding populations have recently been reported from South America, possibly the result of regional increases. Population trends elsewhere are less consistent.
- **Macaroni penguin, *Eudyptes chrysolophus*.** This is the most abundant species of penguin in the Southern Ocean, with a current estimate of approximately 5 million pairs. Breeding populations are present on the sub-Antarctic islands, the Scotia Arc and the Antarctic Peninsula. Recent surveys in the South Atlantic suggest rapid

decreases approaching 50% in the last 30 years; the cause(s) for this decrease are presently unknown. Populations at some Indian Ocean islands suggest stable or slightly increasing populations since the 1980s. Recent volcanic activity on the McDonald Islands west of Heard Island may have affected the large population there (previously estimated at 1 million pairs).

- **Southern Giant Petrel, *Macronectes giganteus*.** This species breeds at four localities on the Antarctic Continent, on the Antarctic Peninsula, and on many of the sub-Antarctic islands. Recent surveys in the Falkland Islands have increased the estimated global population to approximately 40,000 pairs. Many breeding populations of this species have decreased in the last 40 or more years, primarily due to birds being caught on fisheries' long lines at sea and from human disturbance at nesting localities. Breeding birds at most breeding localities will readily abandon nests with eggs or chicks if disturbed. Southern giant petrels are taken as bycatch in longline fisheries, especially for Patagonian toothfish *Dissostichus patagonicus*.
- **Southern Fulmar, *Fulmarus glacialoides*.** This surface-nesting species is found on ice-free areas of the Antarctic and some sub-Antarctic islands. The breeding population is estimated at 2 million pairs. Only one population has been examined for more than 20 years—that at the French station of Dumont d'Urville in Terre Adélie. That population has shown a small increase since the mid-1960s and exhibits a high interannual variability in breeding numbers due to snow conditions. No other population has been studied, and there are no other data available with which to assess trends. There have been no conservation threats identified for southern fulmars.
- **Antarctic Petrel, *Thalassoica antarctica*.** This surface- and crevice-nesting species is endemic to the Antarctic. There are no colonies under investigation, and the global estimated breeding population is half a million pairs. There have been no conservation threats identified for Antarctic petrels.
- **Cape Petrel, *Daption capense*.** This surface-nesting species is found on ice-free areas of the Antarctic and many of the sub-Antarctic islands. The breeding population is estimated at 75,000 pairs, but this is likely to grossly underestimate the total population. Only one population has been examined—that at the French station of Dumont d'Urville in Terre Adélie, which has been affected by the construction of a hard rock runway at the station. No other threats have been identified for Cape petrels.
- **Snow Petrel, *Pagodroma nivea*.** This surface- and crevice-nesting species is endemic to the Antarctic. Its crevice-nesting habit makes assessing populations and trends difficult. The current estimate of the breeding population is approximately 100,000 pairs. No assessment of population trends is available for this species. Periods of extensive snow fall and sea ice extent appear to affect breeding success, but no other threats have been identified.
- **Antarctic Prion, *Pachyptila desolata*.** This burrow-nesting species is found predominantly on the sub-Antarctic islands and on the Antarctic Peninsula. At present, there are no long term data available for this species from anywhere in its range. It is believed that breeding populations at localities on the Antarctic Peninsula may have decreased. Breeding localities on the Antarctic continent are no longer used. At present, approximately 10% of the estimated global population of 25 million pairs breeds in the Antarctic, but this global estimate has low confidence, and there are no other known population trends. The greatest threat to breeding Antarctic prions comes from introduced predators such as cats and rats that prey on eggs and chicks.
- **Wilson's Storm Petrel, *Oceanites oceanicus*.** Often described as the world's most abundant seabird (a claim for which there is little supporting evidence), Wilson's storm petrels breed on most of the sub-Antarctic islands, the Antarctic Peninsula, and the Antarctic continent. They are crevice-nesting in the Antarctic and burrow-nesting elsewhere. The current global estimate is 3 million breeding pairs, of which half are believed to nest in the Antarctic. This estimate is largely highly conservative as very few surveys of breeding populations have been undertaken, and there are no long term data on trends at any breeding locality. The largest threat to breeding birds comes from introduced predators such as cats and rats that prey on eggs and chicks. Carcasses of adults with plastic particles in their stomachs have been recorded in the Antarctic. The adults had eaten the plastic mistaking the floating particles for food.
- **Black-Bellied Storm Petrel, *Fregetta tropica*.** It is believed that between 10% and 25% of the global population estimated at 100,000 breeding pairs nest at South Georgia, the South Orkney and the South Shetland Islands. Black-bellied storm petrels are burrow-nesting birds, and

most of the breeding population is found on the sub-Antarctic islands. The greatest threat to breeding birds comes from introduced predators such as cats and rats that prey on eggs and chicks.

- **Pale-Faced (Greater) Sheathbill, *Chionis alba*.** This species' distribution is confined to the Antarctic Peninsula, the South Orkney and South Shetland islands, and South Georgia. Few population surveys have been conducted, and the current estimate of 1000 pairs is a highly conservative underestimate. No population trends are available, and no threats have been reported.
- **South Polar Skua, *Catharacta maccormicki,* and Sub-Antarctic (Brown) Skua, *Catharacta lonnbergi*.** Two species of skuas breed in the Antarctic—the South Polar skua, which is found on the Antarctic continent, the Antarctic Peninsula, and the South Shetland Islands, and the brown skua, which is present on all sub-Antarctic islands and on the Antarctic Peninsula. Mixed-species pairs and hybrids have been regularly observed from the Antarctic Peninsula and from Dumont d'Urville. The estimated breeding populations are 12,000 and 11,000 pairs, respectively. The breeding population at Dumont d'Urville has been monitored since the late 1960s and has shown an increase with considerable interannual fluctuations. Populations in the Ross Sea were stable during short periods (less than 20 years), while the breeding population at Palmer increased fivefold since the late 1970s before levelling off in the late 1990s; increases have also been reported in the South Shetland Islands. There are no hypotheses to explain these differing population trends, but changes in rubbish management and disposal at research stations may have affected local populations. No other threats have been identified.
- **Kelp Gull, *Larus dominicanus*.** This species is widely distributed throughout the Southern Hemisphere, with breeding populations present on all southern continents, on the sub-Antarctic islands, and on the Antarctic Peninsula. Many populations have increased, largely due to an increase in food availability from inappropriate human waste management. The global population is estimated at more than 1.2 million breeding pairs, of which the Antarctic population is believed to be fewer than 20,000 pairs. Few surveys have been conducted in the Antarctic Peninsula, so this estimate is preliminary. No threats to the species have been identified.
- **Antarctic Tern, *Sterna vittata*.** This species is somewhat misnamed as there are no breeding populations on the Antarctic continent itself, only on the Antarctic Peninsula and on the sub-Antarctic islands. This species is considered to be the most highly sensitive to human disturbance at breeding sites and will readily abandon nests. Many breeding populations close to research stations and other sources of human disturbance experience almost complete breeding failure and have decreased dramatically in the last 30 or so years. Approximately half of the total population of 60,000 pairs is believed to nest on the Antarctic Peninsula, the South Shetland and South Orkney Islands. Introduced predators such as cats and rats reduce breeding success, and skuas and gulls readily take eggs and chicks from disturbed nests.
- **Blue-Eyed Cormorant, *Phalacrocorax atriceps*.** The taxonomy of the Antarctic species of cormorants is presently under revision, as there may be as many as seven different species. Various authors use various taxonomies for the cormorants breeding on the sub-Antarctic islands and the Antarctic Peninsula. As a result of this confused taxonomy, total breeding population estimates vary considerably, between 15,000 and 40,000 pairs. No threats have been identified for the species or the various island forms.

At least sixteen species of seabirds are known to be regular visitors to the Antarctic, and of these, populations of at least six species (wandering, black-browed, grey-headed and light-mantled albatrosses, northern giant and white-chinned petrels) are believed to be decreasing due to individuals being caught in longline fisheries in the Southern Ocean. Other than global warming, longline fisheries represent the greatest threat to seabirds in the region, with more than twenty species now known to be taken as bycatch on longline fisheries.

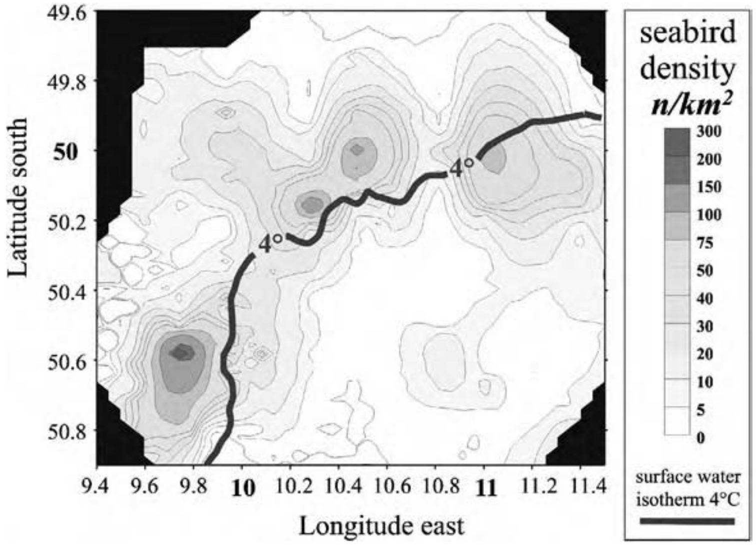
SEABIRDS AT SEA

Fully adapted to a life on the open ocean, seabirds have conflicting interests in coming to land. Solid ground is essential for reproduction or sometimes for moulting. But visits to shore often imply hunger, thirst, discomfort, and all sorts of danger. Out at sea is the place to find food and to fully exploit the capacities of a perfect flying or diving machine. Young seabirds prefer to spend many years out at sea before their hormones urge them to make a first visit to the breeding colonies on shore. But even in adult life, the time spent on shore will be as short as possible.

Much of our current knowledge of seabirds stems from these short periods on shore, mainly during the breeding season. This is especially true for Antarctic seabirds, where poor weather and short periods of light have effectively discouraged biologists to work during the nonbreeding seasons either on land or at sea. Attendance patterns of breeders and the composition or frequency of meals brought to chicks supply some limited information on the at sea life during the reproductive period. But how little do we really know of their fight for survival when they do not return to land? Where do they go, how do they find their way, what do they eat, how do they locate food, what issues are critical for their survival? There are many more questions than answers, and it is only fairly recent that, mainly by technological progress, knowledge of Antarctic seabirds at sea has improved.

The "old-fashioned" way of learning about seabirds at sea is by observations from ships. Over time there has been progress from simply plotting incidental records on maps indicating ranges of occurrence to more dedicated quantitative censuses relating species composition and abundance of birds to environmental factors. The first integrated approach to quantify seabird distribution was developed in the BIOMASS programme *(Biological Investigations of Antarctic Marine Systems and Stocks),* which incorporated standardized bird counts from ships in 300 m wide strip-transects. For some areas, these methods have stimulated the compilation of extensive data-sets. In the Indian Ocean sector, more than 20 years of consistent shipboard observations during resupply trips resulted in distributional maps offering insights in seasonal and migratory shifts, interannual variability, and population trends. In the Ross Sea, marine bird distributions and populations were surveyed in context with habitats and ecology. However, the BIOMASS methods were semiquantitative, with biases originating from birds flying over the transect band during the period of observation. Later international investigations like the *Joint Global Ocean Flux Study* (JGOFS) and the *Global Ocean Ecosystem Dynamics Study* (GLOBEC) made increasing demands on quantitative accuracy of bird abundance. True densities of seabirds in numbers per surface area are needed to model the energy and carbon fluxes between different ecosystem compartments. Two count methods have been developed to account for the error of flux of birds over the transect-strip. These are the snapshot method, which makes intermittent photographic counts of birds in flight, and the continuous vector method, which corrects for relative flight speeds. While these are clear improvements for process studies into the interactions between Antarctic seabirds and their physical and biological environment, integration of different data-sets becomes more complicated.

Records of the distributional abundances of seabirds at sea show the complexity of the strategies that seabirds utilise for their survival. During the breeding season, reproductive tasks evidently limit the spatial range over which seabirds can forage. Breeding penguins may effectively be limited to a radius of some tens of kilometres around the colony, whereas under the same conditions albatrosses and smaller petrels are still able to cover thousands of kilometres on a foraging trip. However, the direction of such flights may not be a free choice but rather determined by wind and weather. The Southern Ocean, which may look dull and uniform to us, is in fact an extremely variable environment with favourable foraging conditions distributed in patches, some of which may be predictable, but others occurring in a seemingly random fashion. Frontal systems and upwellings linked to continental shelf slopes, sea-mounts or ridges are important oceanic features that enhance local productivity through the mixing of water masses. Increased primary production in these areas is passed through the foodweb and ultimately nourishes marine birds and mammals. In the Southern Ocean, the most prominent of such features is the Polar Front. This circumpolar front forms the boundary of northwards flowing cold Antarctic surface water that descends

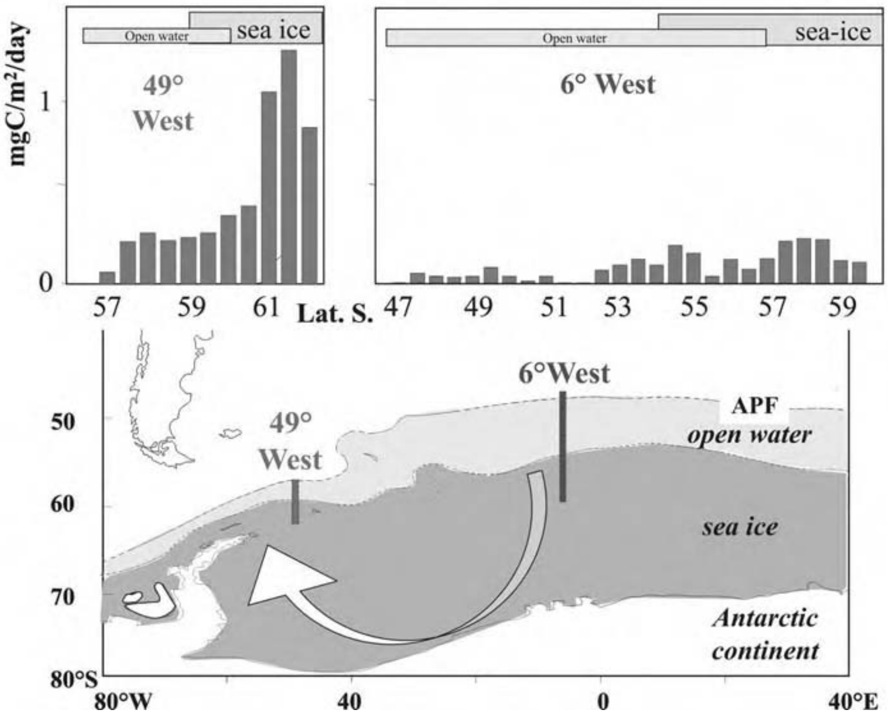


Close linkage between physical features of the meandering Polar Front, characterized by the 4°C surface isotherm and concentrations of birds, mainly Antarctic Prions, January 1–5, 1996.

below temperate waters moving south. Many bird species, especially the tubenoses, but also penguins such as king, macaroni and rockhopper penguins, travel great distances to forage in the Polar Front area. Occasionally the Polar Front is sharply pronounced and detectable by swarms of foraging birds. High density areas of up to hundreds of birds per km^2 were observed in a grid transect over the Polar Front in the first week of January 1996. The birds were associated with patches of high primary production and zooplankton. In turn, these biological phenomena closely followed temperature and salinity discontinuities related to the meandering Polar Front. The main bird species was the Antarctic prion, which probably preyed on small copepods. How seabirds initially locate the Polar Front or other rich foraging areas is not always clear. Part of it may depend on individual or community experience. One definite clue is the use of smell, as a number of seabird species was shown to use the smell of dimethyl-sulfide (DMS) to locate food patches. DMS is released by algae damaged from grazing zooplankton. Once a rich food patch has been located by a number of birds, their foraging behaviour probably attracts others from wider surroundings.

An even more important Antarctic oceanic feature that influences seabirds at sea is the seasonal sea-ice zone. Each winter up to 20 million km^2 of the ocean surrounding the Antarctic freezes up, effectively doubling the size of the frozen continent. At its summer minimum, the residual sea ice still covers an area of around 4 million km^2 teeming with wildlife that prefers the remainders of the ice habitat above the open water. Only a limited number of specialized bird species can efficiently utilize the ice habitat itself, whereas others can only operate along its outer rim. The champion of the ice specialists are emperor penguins, the only seabird that has even escaped from breeding on land. Other birds that associate with the sea ice throughout the year are Adélie penguins, snow and Antarctic petrels. Misguided by the practice of preserving food in freezers, people are inclined to consider ice as a sterile environment and imagine a frozen ocean to be an unproductive desert. Although the water below the sea ice indeed is rather poor, the underside of sea ice itself and infiltration layers are thriving with ice algae and a wealth of microbial life. These are grazed by small zooplankton and krill, which in turn nourish fish stocks and ultimately top predators. Sea-ice foraging appears to be a crucial part of the life cycle of krill: winters with reduced extent of sea ice are followed by lower krill abundance. Although many bird species are not adapted to life in the ice itself, they can still take profit from its productivity when the ice retreats. Materials are released by the melting ice and algal blooms develop along the retreating edge. Many seabirds and marine mammals, including large whales, enter the seasonal sea-ice zone for foraging when the ice retreats.

The importance of sea ice in nourishing Antarctic birds can be illustrated by surveys made in the western and eastern sectors of the Weddell Sea. Food consumption by seabirds was calculated from counts made during repeated north to south transects from open water into the sea ice. The observed pattern of food consumption by the seabird community is very



Seabird food consumption (in units of carbon) in spring and early summer in the open water and ice zones of the opposite sides of the Weddell Sea.

similar on both sides of the Weddell Sea. Bird food intake in sea ice and over the melt zone exceeds that in open water, including that in the productive Polar Front. Food intake by marine mammals follows the same pattern as evidenced by large populations of seals and whale species small enough to maneuver in the pack ice. Overall, the western Weddell Sea is much richer than the eastern part. For the open water zones in the west this may be explained by the high productivity associated with the mixing of a variety of water masses flowing along the Antarctic Peninsula and out of the Weddell Sea. In addition, rich stocks of krill and other zooplankton are concentrated towards the tip of the Antarctic Peninsula by currents flowing out of the Bellingshausen and Amundsen Seas. However, these explanations do not apply to the situation farther south in the pure Weddell Sea water under the ice. The much higher food intake rates for birds in the western ice area may be explained by the fact that the sea ice here has "matured" during the multiyear circular passage with the Weddell Sea Gyre. On the opposite eastern side of the Weddell Sea, the sea ice is always young as it either melts after winter before the ice-associated biology can fully mature, or the floes drift into the Weddell Sea interior. The annual sea ice is thus not a limiting factor for life in the Antarctic but rather a biological engine that supports large populations and diversity of wildlife and structures the life of many seabirds at sea. From this point of view, reductions in the extent of Antarctic sea ice as a consequence of climate change will have a major impact on Antarctic seabird populations.

Observations at sea can only provide limited information on the strategies used by individual seabirds in where they go, which choice of food they take, and how their food is obtained. Fortunately, rapid technological developments are providing a wealth of new information. There has been great profit from the use of ever smaller, smarter, and more energy-efficient satellite-tracking and other positioning devices. One fascinating study after the other on foraging strategies and nonbreeding migrations is being published. Circum-Antarctic navigation by albatrosses, long debated, has now been simply demonstrated. For example, biennially breeding grey-headed albatrosses from Bird Island (South Georgia) were tracked during the 18 months in between subsequent breeding attempts. Tracking data show that a majority of the birds circumnavigates the Antarctic during this period, some of them more than once. The albatrosses travel eastward on the prevailing western winds and have favourite stopping-over areas. Travels between such areas were performed at speeds of up to 950 km per day. A speed record for the full circum-Antarctic travel was established at 46 days. It is only a matter of time before technology is developed that will allow smaller devices that can be fitted to smaller species.

A major result of these seabird tracking data has come from the compilation of all available data from different sources. BirdLife International initiated the integrated analysis of tracking data for all albatrosses and a few petrels. This effort was made because of concern over the population decreases in many albatross species, linked to mortality in longline fisheries. All available information on bird distributions, effort in longline fisheries, and available management regimes was combined in a Geographic Information System (GIS). Such integrated information is indispensable if marine Important Bird Areas (IBAs) or Marine Protected Areas (MPAs) have to be considered by member states of ACAP (Agreement on the Conservation of Albatrosses and Petrels). Protection of breeding colonies or nearby areas is a frequently applied conservation tool but insufficient to protect seabirds during the major part of their life cycles while at sea. Ultimately, the conservation of threathened seabirds will depend on further development of the concept of specially protected or managed areas in the open ocean.

Further improvements in tracking devices will also provide more detail on some of the astonishing aspects of seabird migration. Observations of live birds, beach-cast specimens, and band recoveries have already revealed the general outline of some migration paths. The best known example is perhaps that of the Arctic tern. In between breeding seasons in the far north, Arctic terns commute to the marginal sea-ice zone of the Antarctic. Some Antarctic breeding seabirds perform similar but opposite migrations. Great, sooty, and short-tailed shearwaters are southern hemisphere species that partly forage in the cold waters of Southern Ocean. After breeding, they perform long migrations over the Atlantic or Pacific Oceans flying north to Arctic waters. The crossing of calm tropical waters must present a challenge. Terns use flapping flight and have little problems with the absence of wind and waves. However, the shearwaters, like all tubenosed seabirds, are adapted to flight modes that take advantage of the interactive forces generated by wind and waves, and the calm conditions in tropical waters likely make their travels energetically expensive. At least as spectacular is the migration of the small Wilson's storm petrel, which weighs no more than about 40 g but manages to breed on the hostile Antarctic continental coasts and migrates to the northern hemisphere in winter. Finally, evidence has been growing that at least some of the skuas breeding in the Antarctic, migrate to the northern hemisphere.

Tracking studies can also assist to confirm details of the complicated at sea movements of seabirds when they are bound to frequent visits to breeding sites. For an increasing number of petrel species, a dual foraging strategy is being demonstrated. Irregular nest-attendance patterns of adults, variations in their body mass, and differences in composition of meals brought to chicks indicate that several seabirds use special strategies to ensure their individual survival when raising a chick. It appears that shorter foraging trips to nearby oceanic areas may be sufficient to provide the chick with food but are insufficiently profitable to ensure that the parent can also maintain its own body condition at an adequate level. To solve this problem, several tubenosed species appear to have developed a strategy of alternating short, nearby trips with priority for chick-feeding with long, distant foraging trips during which replenishment of the energy reserves of the adult birds themselves has priority.

The capture of prey at sea by seabirds is a topic where much is still to be discovered. Foraging associations among different species may be important, where predators under water (large predatory fish, diving birds or mammals) may force prey concentrations to the surface and make them available to surface feeding species. Where such foraging strategy is important, this implies that reductions in populations of one of several apparent competitors may not be beneficial to the others but rather disadvantageous because of reduced "catchability" of the prey. As with at sea distributions, technological improvements are providing more and more detail in the field of seabird foraging tactics. Dive depth recorders have shown that emperor penguins may chase prey at depths over 500 m during dives that last up to 20 minutes. But even shearwaters were shown to make dives to 50 m to obtain food. Stomach temperature recorders can indicate frequency of meals and ingested volume in which prey is swallowed, while activity recorders measure to the second any changes in speed and movement of the animal. Videorecording systems, after initial usage on seals, have now been further miniaturised for their application on emperor penguins diving below sea ice. The emperor penguins were found to use a remarkable tactic of diving to several tens of meters depth, but not to catch food there: it appeared that from that depth they were able to locate fishes hiding along the rough undersurface of the ice, which were then captured after a fast upward swim.

In spite of definite progress, much of the life of seabirds at sea remains a mystery. Even a major subject such as quantitative diet information is still very incomplete. There is an increasing body of information on diets delivered to chicks during the breeding season, but very little information is available on food taken during other times of the year. Parent birds may select other prey types to feed chicks than they would for themselves, and an additional problem is that much stomach contents are already fairly digested when adults arrive at the nest. Another problem is that traces of soft-bodied prey may have disappeared completely, or may be underestimated if original prey size is not estimated from remaining parts. In one of the few studies that collected Antarctic seabirds in the marginal ice zone during nonbreeding seasons, fish and squid dominated in the diet of virtually all species and salps were also regularly found. Only a minor part of the food consisted of krill, often considered to be the bulk item in the diet of most common Antarctic seabird species. New indirect methods of dietary research are being developed on the basis of isotope ratios or fatty acids in the tissues of the birds. These methods cannot provide detail of prey species taken, but are particularly useful to indicate general trophic status of bird species of which we have no information at all, or to indicate major differences between breeding and nonbreeding diets.

The life of seabirds at sea still holds many secrets to discover. Step by step, the available knowledge is improving, which is not only the addition of interesting facts but rather a necessary development to enhance conservation and protection of Antarctic seabirds in the environment on which they totally depend, the Southern Ocean.

SEALING, HISTORY OF

During the eighteenth century, sealers, mainly from the United States and Britain, hunted seals in South America, South Africa, and Australasia. Their quarry was several species of fur seal and the southern elephant seal. As the numbers of sealers increased and populations of seals diminished, they were forced to search farther afield in search of fresh stocks.

Captain James Cook's report that "sea bears [fur seals] were pretty numerous" on South Georgia attracted the attention of many sealers. The first to arrive there was probably an English sealer, Thomas Delano, on *Lord Hawkesbury,* which returned to London with a cargo of fur seal skins in 1787. The first Americans were Elijah Austin, on *Nancy,* and Roswell Woodward, on *Polly,* sailing from New England in 1790 or 1792 (accounts differ).

Edmund Fanning on *Aspasia* took 57,000 skins in 1800–1801, and the estimated season's harvest was 112,000 skins taken by seventeen vessels. In 1822, James Weddell calculated that 1.2 million fur seals had been taken from South Georgia and the species had virtually ceased to exist there. A similar slaughter took place in the South Shetland Islands. Their discovery by William Smith in February 1819 precipitated a rush of sealers to the archipelago. In the summer of 1819–1820, three sealing vessels were at work there, but one year later there were at least forty-four British and American, and two Russian, vessels at work. By the 1821–1822 season there were at least ninety-one vessels sealing around the islands, and the numbers of fur seals were already declining. Not surprisingly, there were hostilities as sealers came into competition.

By only the fourth season of operation, 1822–1823, some vessels were leaving almost empty. HMS *Chanticleer* failed to find a single fur seal in the South Shetlands in 1829, and the species had disappeared from Macquarie Island by 1820, 10 years after the island's discovery. However, populations of fur seals on South Georgia and the South Shetlands recovered sufficiently for sealers to return at intervals throughout the nineteenth century and to take a few thousand or a few hundred in some years.

The drive by sealers to find new stocks resulted in further discoveries in the Antarctic Peninsula region and of several sub-Antarctic islands. The location of sealing grounds were trade secrets for the sealers, who would even leave unreliable members of their gangs ashore while they returned to port, so they could not reveal the whereabouts of seal colonies. However, of the few logbooks that have survived most do not reveal details of vessels' movements. Nevertheless, many sealers contributed to the geographical discovery and exploration of the Antarctic regions. Macquarie and Campbell islands were discovered by Frederick Hasselburg, on *Perseverance,* in 1810 (although he found the remains of a recent shipwreck at Macquarie). The Balleny Islands were sighted by John Balleny in 1839, and Heard Island was also probably first sighted by sealers. In 1821, two sealers, the American Nathaniel Powell and Briton George Powell, combined to search for new sealing grounds to the east of the South Shetlands and discovered the South Orkney Islands.

Some sealing companies were interested in more than commercial gain. The Enderby Brothers, a London shipping, whaling, and sealing company, promoted geographical exploration and the collection of natural history specimens by their captains, but this pursuit contributed to the company's financial problems. John Biscoe, on *Tula,* circumnavigated Antarctica between 1830 and 1833 and discovered Enderby Land, but returned with only thirty seal skins. Peter Kemp, on *Magnet,* working for David Bennett & Sons, discovered Kemp Land on the mainland of Antarctica in 1833 but was drowned on the way home. The best known of the sealer-explorers, however, is James Weddell, who is famous for his deep penetration into the Weddell Sea and observations on wildlife.

Sealers arrived mostly in small vessels; Weddell's *Jane* and *Beaufoy* were 160 and 65 tons, respectively. Others employed larger vessels and took "shallops" of about 30 tons, which were carried in frame and assembled on site. The parent ship remained at a safe anchorage while the shallops visited the seals' breeding beaches along the coast. Sealing gangs also camped ashore while the vessel moved to other beaches. The men lived a hard life in caves, under upturned boats, or in rough shelters built of stones or timber and roofed with timber, whalebone, and canvas. They endeavored to start sealing as early as possible in the breeding season and concentrated on killing cows and young bulls, which had the best skins.

The seals were killed with a 5-foot wooden club and stabbed to bleed; the larger bulls were lanced. Flensing or flaying started as soon as possible, the technique depending on the market to which the skins were taken. Initially, American sealers had a monopoly of the China market, where the skins could be sold at a greater profit. The Chinese shaved the skins and felted the fur for use in winter clothing, although it seems likely they also used the leather. The sealers removed all the blubber, sewed up the flipper holes and then stretched the skin out on the ground to dry. Skins destined for the American and European markets had some of the blubber attached and were piled into a "book" under heavy stones to squeeze out as much water as possible. A day or two later, the book was rebuilt with alternate layers of salt. Care had to be exercised because nicks and cuts in a skin reduced its value, while slipshod salting allowed it to rot. One year, *Pegasus* arrived in London with a prime cargo of skins, but they had rotted and could only be sold as manure.

The European market was mainly for leather, which was used for shoes and gloves. Then, in 1795, a London hatter, Thomas Chapman, discovered a way of removing the long, coarse guard hairs to leave the dense, fine underfur, a very valuable product. The guard hairs have longer roots so, if the skin is carefully pared away from the underside, these are cut and the guard hairs can be combed out, leaving the underfur intact.

From the start, sealers visiting the Antarctic augmented their harvest of fur seal skins with oil rendered from the blubber of elephant seals. Until fur seal skins could be processed into fine pelts, the high quality of seal oil made it the more valuable cargo. A large bull elephant seal yielded about one third of a ton of oil. As with fur seals, killing was indiscriminate, the cows and pups being clubbed and the bulls shot. The blubber was soaked for two days to remove the blood then cut into "horse-pieces" or "blanket-pieces." These were cut into fine slices and boiled in large cauldrons or "try-pots" to render (or try) the oil, which was decanted into a second pot and given a second, and sometimes a third, boiling. The solid residue, the "fritters," was used as fuel for heating the pots, as were the carcasses of penguins. At Yankee Harbour, Greenwich Island, there is a penguin corral above the remains of sealers' huts and a try-pot. Elephant seal oil was used for heating, lubrication, and treating leather, but towards the end of the nineteenth century seal and whale oils were being replaced by mineral oils.

Sealing continued though the nineteenth century, spasmodically toward the end as stocks recovered and were exploited again. Often, and especially at Heard and Kerguelen, whalers took the opportunity to augment their catch of whales by sealing. The last of the old-time sealers and whalers was Benjamin Cleveland, on *Daisy,* who visited South Georgia in 1908 and 1912–1913 and took small numbers of elephant and fur seals.

At this time, a new sealing industry had started on South Georgia. In the 1890s expeditions were dispatched from Europe to investigate the possibilities of whaling and sealing. They met with little success until Carl Anton Larsen established a whaling station at Grytviken, South Georgia, in 1904. Some elephant seals were harvested in the first year, and in 1909 the Falkland Islands and Dependencies government introduced the Seal Fishery (Consolidation) Ordinance to regulate sealing and granted a license to Larsen's company, the Compañia Argentina de Pesca. The operation used obsolete whalecatchers to land sealing gangs at the many bays and coves around the coast of the island during the breeding and molting seasons. The method of killing and dismembering the seals was much the same as in earlier years, but the blubber was taken back to Grytviken to be boiled in the whaling station. Although a logistically minor operation, elephant sealing was economically important because, for a small outlay, it produced up to 2000 tons of high quality oil, which amounted to 16% by volume and 19% by value of Grytviken's total oil production. Sealing effectively ceased with the closure of Grytviken in December 1964 after some 260,950 elephant seals had been killed to produce 83,146 tons of oil. In the early years, ninety Weddell seals, 752 leopard seals, and one fur seal had also been taken. The last sealing at South Georgia was in 1968 from the "pirate" vessel *Run,* later *Sierra,* which took five seals to familiarize the crew with sealing techniques.

Sealing licenses at South Georgia set limits on the harvest. The coastline of South Georgia was divided into four divisions (with some areas as reserves where sealing was forbidden). Only three were worked in any single year and 2000 adult male elephant seals could be killed in each. The quota was later increased to 8000, but a study revealed that the population was declining. As a result, a new regime based on scientific management was instituted in 1952. Under the control of a government-appointed sealing inspector, quotas were set for each division according to its seal population. Only seals above a body length of 11.5 ft (3.5 m) could be taken, and samples were collected to monitor the age composition of the population. As a result, a sustainable harvest developed in which the body size of the seals and therefore oil yield increased.

However, proposals for regulated culling were not new. In 1798, John Leard of the Royal Navy wrote to Lord Hawkesbury, President of the Council for Trade and Foreign Plantations in London, making suggestions for the regulating of the sealing industry with limits on sex, age, and numbers taken. Nothing was done, and Antarctic fur seal stocks were rapidly destroyed, as they had been in other parts of the world. James Weddell had also commented that a sustainable harvest was possible if sealers exercised restraint and did not kill female fur seals at least until their pups were independent.

The experience of elephant sealing shows how a sustainable harvest can be taken where there is strict governmental control. Farther south in the Antarctic Treaty area south of 60° S, no such control existed, and in 1964, the Norwegian vessel *Polarhav* hunted crabeater seals in the pack ice near the South Orkneys. Only 852 were taken, and the expedition was not a commercial success. Although the Antarctic Treaty had banned the killing of native animals, it referred only to land and fast ice. A further international agreement was needed to cover the sea and floating ice, so the Convention on the Conservation of Antarctic Seals was signed in 1972. Fur seal, elephant seal, and Ross seal became fully protected, while catch limits were set for crabeater seal, leopard seal, and Weddell seal. Seals are the subject of local legislation on sub-Antarctic islands outside the Antarctic Treaty area.

SEALS: OVERVIEW

Seven species of seals inhabit the Southern Ocean. All belong to Suborder Pinnipedia, which is a term derived from the Latin *pinnipes,* for wing- or fin-footed. Debate is ongoing as to whether this suborder is diphyletic or monophyletic. Of the three families of pinnipeds, only the odobenids (walruses) are not represented amongst Antarctic seals. Worldwide the family Phocidae (true seals) consist of nineteen species in thirteen genera. Antarctic phocids include the four lobodontine pinnipeds: crabeater seal *(Lobodon carcinophaga),* Ross seal *(Ommatophoca rossii),* leopard seal *(Hydrurga leptonyx)* and Weddell seal *(Leptonychotes weddellii)* in addition to the southern elephant seal *(Mirounga leonina)*. Of a total of seven genera and sixteen species, otariids are represented in Antarctic waters by only one genus and two species: the Antarctic fur seal *(Arctocephalus gazella)* and the sub-Antarctic fur seal *(Arctocephalus tropicalis)*.

The Phocidae are characterised by an inability to rotate the hind flippers under the body, which dictates their characteristic locomotion on land or ice (hunching, wriggling, flopping, inch-worming). Also characteristic are the absence of pinnae, a short muzzle, beaded vibrissae, a dark coloured skin, short fur, furred fore flippers and hind flippers, five claws on each fore flipper, generally two teats in females, and internal testes. The hind limbs provide propulsion in water except in leopard seals, which, like the otariids, swim primarily with fore flipper strokes. In the otariids the hind limbs are used in steering when swimming. Otariids can rotate the hind limbs under the body and move on all fours on land. They have pinnae, smooth vibrissae, a light coloured skin, a double layer of fur, partially hairless fore- and hind flippers, four teats in females and scrotal testes. Claws on the fore flippers are vestigial or absent.

With a skull in hand, phocids are easily separated from otariids as they have no supraorbital processes, their nasal bones do not penetrate between the frontals on the midline, and their incisors are not transversally grooved, as in the first two upper incisors of otariids. While males grow larger than females in most species of pinnipeds, the reverse is true for the lobodontine seals. Although sexual dimorphism in size is much less pronounced in phocids than in otariids, the greatest disparity is found in elephant seals, which is the largest species of seal. Adult males reach masses of 2000–4000 kg, while females only reach masses of 400–900 kg. Adults of the lobodontine species weigh 200–600 kg. Adult male fur seals reach masses of 200 kg while the females reach masses of approximately 50 kg. Elephant seals experience an annual catastrophic moult, with the skin sloughing away in large patches rather than the hairs falling out individually, as happens in almost all other species of phocids and all species of otariids.

While Antarctic pinnipeds are marine mammals, and therefore spend the majority of their lives at sea, they are constrained by the need to return to land or stable ice substrates to give birth, to lactate and to moult. However, they feed almost exclusively at sea. As carnivores they typically have differentiated teeth, including incisors, canines, and postcanines. Adapted to both terrestrial and aquatic conditions, all pinnipeds have a similar morphological appearance. They have a coarse pelage of guard hairs, with or without a layer of underfur. Their body shape is adapted to reduce turbulence and resistance (drag) and is thus fusiform. A subcutaneous layer of fat (blubber) provides stored energy, insulation, and buoyancy, and the limbs are relatively short, stout, and modified to form paddle-like flippers. Eyes of seals are relatively large and modified to focus underwater by means of greater corneal curvature and spherical eye lenses, and to see effectively under conditions of reduced light with a well-developed, specialized membrane behind the retina. Physiological processes for diving include slowing of the heart rate (bradycardia), shunting blood from peripheral areas to the brain and heart, a high tolerance for carbon dioxide levels in the blood, a high concentration of haemoglobin in their red blood cells and myoglobin in their muscle tissue, a relatively large blood volume, an ability to withstand enormous pressures at depth, and an ability to avoid developing either nitrogen narcosis (an anaesthetic effect on the nervous system that may lead to unconsciousness and death) or the "bends" (dissolved nitrogen coming out of solution, forming gas bubbles that may cause embolisms and result in death) upon rapid return to the surface.

The four lobodontine species inhabit the pack ice and fast ice zones of Antarctica, and are among the dominant predators in the Southern Ocean ecosystem. Their distribution is circumpolar, and while the ranges of all four species overlap, they also reflect their unique adaptations.

Ross seals are more common in regions of consolidated pack ice, especially during the breeding season, but are also seen in more open pack ice and occasionally on fast ice. They undertake long foraging trips to open water north of the pack ice.

Weddell seals tends to inhabit fast ice or the heavier pack ice close to the Antarctic continent. They use tidal cracks to gain access to shallow benthic waters beneath. They tend to move northward with the expansion of the ice in winter, foraging in open waters. Small groups of Weddell seals, largely isolated from the main populations, may haul out on some of the islands of the Antarctic Peninsula.

Crabeater seals are common in pack ice areas, with the highest densities over the continental shelf. Their distribution also moves northward with the pack ice in winter. While leopard seals are also generally distributed within the pack ice throughout the year they tend to move northward with the expanding pack in winter. Numbers of primarily nonbreeding animals move frequently and regularly to the sub-Antarctic islands (distributed approximately between 40° S and 60° S) during late winter and spring. They are more common at these sites in years in which the pack ice is more extensive. Vagrants occasionally haul out on the southernmost coasts of South Africa, Australia, New Zealand, and South America. Vagrants of the other three species of lobodontine seals are rare and are seldom recorded beyond the sub-Antarctic islands.

The fifth phocid, the southern elephant seal, breeds almost exclusively on the sub-Antarctic islands, but also as far south as the South Shetland Islands in the Antarctic Peninsula. Individuals from all populations of southern elephant seals in the sub-Antarctic also feed within the Antarctic maritime zone, and elephant seals frequently haul out to moult on the Antarctic continent at a number of sites, such as the Vestfold Hills. They share their island haulout sites with one or both of the species of Antarctic otariids. Antarctic fur seals inhabit islands that lie mostly south of the Polar Front, while sub-Antarctic fur seal populations are found on islands to the north of the Polar Front. Populations of both species are present at three islands or island groups north of, but close to, the Polar Front. Breeding colonies of the two species are generally found on beaches of different terrain, which ensures that hybridization is limited at two of the island groups. At the third island, Macquarie Island, the populations are small and breed sympatrically. A small number of adult males of another species of otariid, the New Zealand fur seal *Arctocephalus fosteri,* are also associated with the breeding colonies at Macquarie Island. Hybrids are common within this population.

The breeding season for most pinnipeds is spring or summer, with the Antarctic phocids giving birth between October and December, while the otariids give birth in November and December. Pinniped females give birth to a single offspring after a gestation period of about one year, including a period of delayed implantation of the fertilized egg. Twinning is extremely rare, and twins rarely survive in the wild until weaning. Pinniped males do not care for the young. All otariids have a polygynous mating system and pronounced sexual dimorphism. Mating generally takes place on land. Males defend onshore territories against other males, which results in access by relatively few dominant males to numerous females. These come into oestrus soon after producing their pups and before their first foraging trip to sea. This does not, however, ensure that dominant adult males inseminate all the receptive females within their territory, as alternative male strategies and female choice seem to play important roles. The southern otariid females are income breeders, alternating between periods of foraging at sea and suckling their pups on land. The lactation periods typically vary between four and ten months. Otariid males are capital breeders that gain condition at sea before the breeding season and remain on land without feeding for the duration of the summer breeding season.

The mating systems of the southern ocean phocids vary from polygynous in different degrees (Weddell seals and southern elephant seals) to serially monogamous (crabeater seals), with mating taking place on land and/or at sea. Females of all species are capital breeders, generally storing energy and nutrients in their subcutaneous blubber while foraging before the breeding season. They then come ashore or haul out on ice to fast while nursing their pups for between 3 and 8 weeks. Adult female Weddell seals, however, will forage to some extent during the lactation period.

During the breeding season elephant seals haul out in large aggregations, which may number in the thousands. Females come into oestrus a few days after their pups are weaned. Mating access to females is determined by the dominance hierarchy amongst males. Males generally remain ashore for most of the 3-month breeding season.

During the breeding season Weddell seal females congregate near access holes and tidal cracks in colonies of 10–250 individuals. The mother and pup will remain on the ice for some 7–10 days after parturition. They will then take to the water together on short foraging trips until the pup is weaned. Adult males do not haul out to the pupping sites, but defend underwater territories around access points. This allows them exclusive mating access to a number of adult females. Mating takes place underwater near the end of weaning. Females of the remaining three species of lobodontine seals do not aggregate during the breeding season. Female crabeater seals will be guarded by an adult male, generally from shortly after she has given birth. An adult male and female will form what is known as a mated pair for the 1–2 weeks between weaning and copulation. Subsequent to copulation the adult male may try to find another female with pup and form another mated pair. Adult males do not attend to adult females during the lactation period for either leopard or Ross seals. Auditory displays are used by the sexes to locate one another after the pups are weaned. Mating is thought to take place in the water.

The foraging behaviour and diet of the Antarctic seal is strongly affected by the major seasonal changes of the Southern Ocean, which affects the distribution and abundance of potential prey species, and by the depauperate variety, but great abundance of a number of prey species, especially krill *Euphausia superba*. Krill comprises an estimated 37%–95% of the diet of the crabeater seal. Due to its abundance and biomass, this species of seal is perhaps the most important consumer of this crustacean and is the krill specialist amongst Antarctic seals. Their teeth have multiple cusps that allow them to strain krill from seawater, and their foraging behaviour follows seasonal changes in the behaviour of their prey. During the summer most foraging takes place at night and at depths of less than 50 m. Foraging depths are deepest during dawn and dusk and shallowest during periods of complete dark. In the winter, foraging takes place during the day, and is most likely benthic, taking place at depths of 50–450 m.

Krill also forms an important part of the diet of the leopard seal, and the South Atlantic populations of the Antarctic fur seal. While both species feed on krill year round, it is a far more important part of the diet in winter, with leopard seals feeding on little else. The dentition of leopard seals is also modified for krill consumption, with tricuspid molars. They do, however, also have large canines and molars that allow them to hold and rend warm blooded prey. During the summer they feed on penguins and immature seals (especially of crabeaters), in addition to krill and benthic and pelagic fish. They are also known to occasionally scavenge on whale carcasses.

Antarctic and sub-Antarctic fur seals are also know to eat penguins seasonally, though this behaviour is likely limited to adult and subadult males. In populations away from the South Atlantic, Antarctic fur seals follow a diet very similar to that of sub-Antarctic fur seals, mainly fish and squid. Both species forage at shallow depths but often over deep waters. The duration of foraging trips and their distance from terrestrial haulout sites changes seasonally. During the summer adult females of both species are lactating and therefore forage close (<300 km) to the pupping colonies. During the winter adult female Antarctic fur seals are no longer lactating and forage at distances of up to 1000 km from their terrestrial haulout sites. While adult female sub-Antarctic fur seals continue to feed pups for most of the winter, foraging trip duration is longer at this time of the year. Relatively little is known of the foraging habits of adult males, but it is possible that they forage at greater distances from their terrestrial haulout sites.

Weddell seals also feed on a variety of species of fish and squid, but they concentrate on the abundant Antarctic silverfish *Pleuragramma antarcticum*. They alternate seasonally between benthic and pelagic waters. Foraging dives are typically less than 400 m and up to 15 minutes duration. Both the Ross seal and southern elephant seal are thought to feed mainly on squid, in addition to a number of species of fish.

Ross seals feed at depths of 100–150 m, and their dives seldom last longer than 10 minutes. Elephant seals are believed to eat between 19% and 36% of the entire squid biomass in the Southern Ocean. The fish component of their diet comprises both pelagic and benthopelagic species. While southern elephant seals may dive to depths of 1500 m, for up to 120 minutes, foraging is believed to take place primarily between 300 and 600 m during shorter trips. They may migrate distances of 5000 km to reach foraging grounds, and they show fidelity to these foraging sites. A number of studies have found differences in the diets of adult males and females, with males foraging both pelagically and benthically, while females forage pelagially. Immatures tend to feed more on fish prey species than do adults.

Commercial exploitation of the four lobodontine seals was limited to brief experimental harvests of crabeater seals, which proved commercially unviable. This, and limited harvesting of all four species for food for humans and their dogs, and for scientific specimens, is thought to have had little effect on the size of their populations. Numbers of the lobodontine species are particularly difficult to ascertain, but Crabeater seals are particularly abundant with a population possibly in excess of 15 million. Weddell seals number between 500,000 and 1,000,000, while leopard seals number less than 500,000, and Ross seals number around 130,000.

The southern elephant seals and the two species of fur seals were all driven close to extinction by commercial harvesting within decades of their discovery. The height of the commercial harvest occurred during the nineteenth century. The last commercial harvests of fur seals took place during the 1920s. A limited commercial harvest of southern elephant seals continued at South Georgia up till 1964. Southern elephant seals were primarily taken for their blubber, which was rendered down to high quality oil. Fur seals were killed for their skins. Subsequent to the cessation of harvesting the populations of both species of fur seals and the southern elephant seal began to increase and many islands were recolonised. Today, Antarctic fur seals number more than 4 million and breed at some ten island groups. The largest population is at South Georgia, which accounts for more than 90% of the global total. Sub-Antarctic fur seals presently number over 300,000 at seven island groups. The largest populations are at Gough Island and the Prince Edward Islands. The total for all populations of southern elephant seals is believed to exceed 500,000, approximately half of which come from South Georgia. While many populations of elephant seals have increased in the last few decades, a number are known to be stable or declining slowly. All seven species of Southern Ocean pinnipeds are currently protected by the Convention on the Conservation of Antarctic Seals. Present harvesting is limited to small takes for scientific purposes.

SEASONALITY

The term *seasonality* can be applied to any feature (biological, physical) that varies on seasonal timescales. As a simple illustration, the solar radiation climate (visible light and other wavelengths) anywhere on Earth is defined by latitude and date. At latitudes within either of the polar circles, there are periods with no exposure to sunlight in winter, and 24-hour exposure in summer, the duration of these periods increasing toward the poles.

Antarctic environments include those at the extreme limits (even more so than the Arctic) available on Earth in terms of many seasonally related environmental characteristics—low temperature, presence of liquid water (including precipitation patterns), ice cover, and light. On land, tight seasonal covariance between light, temperature, and water (and interrelated parameters such as freeze-thaw cycles) at latitudes within the polar circles imposes tight limitations on periods when biological activity is possible.

Geographical contrasts underlie fundamental differences in the intensity of seasonality between Antarctic and Arctic regions. The Arctic consists of the northern fringes of large continents surrounding a small ocean, while the Antarctic is a large, permanently frozen continent surrounded by cold ocean. In summer, expanses of Arctic snow-free land absorb solar energy, generating air temperatures 10°C or more greater than those at comparable Antarctic latitudes. This increase in available thermal energy is fundamental to the rate at which biological processes can occur. In contrast, c. 99% of the Antarctic is ice- or snow-covered, with high albedo (reflecting solar energy back into space).

The influence of seasonality on biology can be complex. Antarctic terrestrial and marine environments show fundamental differences even though, in both, many adaptations are interpreted as responses to one or more seasonal features. On land, extreme thermal seasonality restricts biological activity, with further limits being imposed by desiccation, such that activity is possible in some habitats for only a handful of days in a year, or even not at all in specific summers. The intensity of seasonality is modulated by location within the Antarctic: regions close to the coast and with a strong maritime meteorological influence, such as the Antarctic Peninsula and Scotia Arc, experience a climate buffered by proximity to the sea, and receive greater precipitation, than those inland which have a more extreme, continental climate. At the fringes of the Antarctic, the climate of most sub-Antarctic islands is sufficiently buffered to allow the continuation of year-round activity.

While Antarctic marine environments are characterised by extreme physical characteristics (low temperatures, extremes in light, ice, wind speed and disturbance), there is increasing emphasis on the constancy of many aspects, especially that of temperature. Sea temperature fluctuation, as elsewhere, is seasonal, but the annual fluctuation reaches a maximum of only c. 3.5°C west of the Antarctic Peninsula and Scotia Arc islands, and is as little as 0.2°C at sites on the continental Antarctic coast. Rather than temperature, light has the strongest seasonal influence in the Antarctic marine environment, tightly restricting autotrophic production and resource availability for primary consumers, while seasonal ice formation plays a key role in controlling colonisation and structuring communities.

Microphytoplankton (photosynthesising groups >20 μm in size, mainly diatoms) dominate primary production, but are restricted to a 2–3 month summer "bloom." Smaller nanophytoplankton (2–20 μm, mainly ciliates and flagellates) contribute much less biomass but a longer bloom. The smallest group, picoplankton (<2 μm, mainly bacteria), are the least seasonal element. They are unlikely to support macrobiota but are ingested by some and may be important for larvae. Most marine consumers must rely on patterns of primary production, though timings will be offset temporally and may be expanded for benthic suspension and deposit feeders. Thus, resource availability for foragers is thought to be the most important seasonal factor in the thermally stable marine environment. As long as sufficient resources are obtained during their peak period of availability, these biota are not physiologically limited by their thermal environment (as is the case on land) and have more control over the timing of other important biological processes such as somatic growth and reproduction.

SEAWEEDS

In Antarctica seaweeds grow attached to submerged rocky surfaces below the bare zone created by ice scour, which typically extends to 15 m depth. In West Antarctica, large brown algae of the order Desmarestiales dominate the seaweed communities with various smaller, more delicate species forming an understory. At high latitudes in East Antarctica red algae dominate the seaweed communities. The lower limit of seaweeds is probably about 70 m depth. Intertidal species are mostly small filamentous or crustose forms able to survive winter as cryptic, rock-bound stages. In some localities, e. g. on King George Island seaweeds are stranded in large quantities on beaches and support various animal species, in particular nematodes. Even birds use seaweeds as nesting material.

Seaweeds contribute significant amounts of nutrients to Antarctic coastal food webs. Research has shown that in the 2000 m deep King George Basin seaweeds contribute strongly to the total organic carbon pool of the deeper basin waters. Although part of the seaweed biomass in Antarctica is degraded via a detrital pathway, as in temperate regions, physical fragmentation probably plays a more important part in this process than bacterial decomposition.

The Antarctic seaweed flora has a high degree of endemism, and approximately one third of the species is endemic to Antarctica. There are higher levels of endemism in the brown and red algae than in the green algae. In a synopsis of Antarctic seaweeds by Wiencke and Clayton (2002) the number of species was estimated to be around 120–130. With further collections and taxonomic studies, this number will certainly rise in the future.

The Antarctic seaweed flora is characterised by low species richness compared with temperate and tropical regions of the world. Species richness is highest in West Antarctica and decreases dramatically in East Antarctica and at higher latitudes. Few species grow in the Ross Sea and at latitudes above 76° S. The largest nonendemic element of the Antarctic seaweed flora comprises species that also occur on subantarctic islands and Tierra del Fuego. A second group is formed by species that extend to temperate regions of the Southern Hemisphere. Only a few seaweed species have a disjunct, amphiequatorial distribution, occurring both in the Arctic and the Antarctic. Such species probably evolved in one Hemisphere and spread across the equator during a period of lower sea temperatures during the ice ages.

The presently known species number of seaweeds is most likely to be underestimated. Various species known from the temperate region such as the green alga *Enteromorpha intestinalis* were recently collected on Deception Island. They were most likely transported to Antarctica attached as fouling weeds to the hull of ships. Another transport mechanism is through kelp rafting (i.e., the transport of organisms on floating seaweeds). However, this plays a minor role in Antarctica itself, as there is only one species capable of floating through the presence of gas bladders, *Cystosphaera jacquinotii*. This type of transport is much more important in the sub-Antarctic region, where large masses of the brown algae *Macrocystis pyrifera* and *Durvillaea antarctica* support long distance transport with the West Wind Drift around the Antarctic continent.

Most endemic Antarctic seaweeds grow in late winter and spring, although some of them also reproduce in winter. This way they take advantage of the high water transparency in spring and use the incoming light for photosynthesis. Seasonal growth and reproduction in these species is controlled by daylength and intrinsic circannual rhythms. Other Antarctic seaweeds have an opportunistic life strategy and grow predominantly in summer.

Antarctic seaweeds can tolerate dark periods of up to 1 year without suffering damage, and their light requirements for photosynthesis and growth are very low. Many species from the Antarctic only grow (and reproduce) at temperatures below 5°C. The low light demands explain the occurrence of seaweeds down to about 70 m; the low temperature demands determine their northern distribution boundary around the Antarctic convergence.

SEDIMENTS AND PALEOCEANOGRAPHY OF THE SOUTHERN OCEAN

The Southern Ocean was created some 35 million years ago (Ma) when the surrounding continents separated from Antarctica. The sediments accumulating in the Southern Ocean contain the oceanographic history of this basin. The composition of the sediments varies throughout the Southern Ocean and has varied throughout time, governed primarily by the magnitude and type of biological productivity in the overlying water. Remarkably high productivity of diatoms—marine microbes producing opaline shells—is responsible for the Southern Ocean opal belt, a zone of almost pure opal sediments circling the Southern Ocean.

The Southern Ocean was formed during a time of warm global temperatures. As the ice sheets on the Antarctic continent grew, beginning 1 Ma, the Southern Ocean experienced a series of cycles of regular warming and cooling: the Pleistocene glaciations. The circulation, biological productivity, and chemistry of the Southern Ocean were profoundly affected by these changes in climate. Paleoceanographers continue to refine the records of these changes and the tools necessary to interpret them. Moreover, the Southern Ocean does not simply react to climate change; by virtue of its volume, its high latitude, and its communication with all major ocean basins, the Southern Ocean plays a key role in driving and amplifying global climate change.

Surface Sediment Composition

Scientists aboard HMS *Challenger* first noted the major patterns of surface sediments in the Southern Ocean. The most striking feature is the presence of the "opal belt." This band of sediment with high opal (silica derived primarily from the shells of diatoms) content (up to 90%), also called siliceous ooze, is roughly bounded to the north by the Sub-Antarctic Front and to the south by the northern extent of summer sea ice. The existence of the opal belt was once thought to be a paradox: how could sediments rich in opal underlie waters that were traditionally considered to be a biological desert? It was suggested that the preservation of opal is unusually high here relative to other parts of the ocean. Recent work has shown that preservation is in fact typical of global values (Pondaven et al. 2000) and has resolved the paradox by noting that the productivity of diatoms, and in particular their export to the deep sea, is very high in the region overlying the opal belt. Burial of opal in Southern Ocean sediments represents a significant sink in the global oceanic silica cycle. Recent work estimates roughly 45% of all oceanic biogenic silica burial occurs in the Southern Ocean, a downward revision of previous estimates, taking into account the fact that older measures of opal accumulation were too high because of biased coring at sites where sediment was being added by deep ocean currents (DeMaster 2002).

South of the opal belt, where diatom growth is limited by a short growing season, the sediments are primarily composed of silts and clays from Antarctica, including ice rafted debris. North of the opal belt, where growth of diatoms is limited by low silicate concentrations, the ocean floor is covered with either clay or, at depths above the carbonate compensation depth (between 3–4 km, south of the Polar Front), with calcium carbonate. In general, Southern Ocean sediments contain very little calcium carbonate, which presents a problem for paleoceanographers, since many of the common climate proxies are found in biogenic carbonate, such as the shells of single-celled animals called foraminifera. Recently, paleoceanographers have begun to explore the use of opal and diatom-based proxies in the Southern Ocean.

The Tertiary (65–2 Ma)

Much of what is known about the early history of Antarctica and the Southern Ocean has come from cores drilled as part of the Deep-Sea Drilling Project, beginning with leg 26 in 1972. Plate motions positioned the Antarctic continent at high southern latitude since the middle to Late Mesozoic (~150 Ma). During the early Cenozoic the Southern Ocean expanded as plate motions caused the spreading of Australia, New Zealand, and South America from Antarctica. The exact timing of the opening of these seaways is still debated, but clearly by the Eocene-Oligocene boundary (~33 Ma) there was an unrestricted passage for deep water around Antarctica (Kennett et al. 1974). With the opening of this passage, the Antarctic Circumpolar Current (ACC) was formed, and waters were able to flow unimpeded around Antarctica. The ACC is a deep-ocean current that reaches to the ocean bottom and causes dramatic sediment erosion; its development is seen in deep-ocean cores as an abrupt break in sediment deposition. The thermal isolation of Antarctica following the evolution of the ACC during the late Eocene/early Oligocene, coupled with ongoing global cooling induced by declining atmospheric CO_2 levels, led to rapid cooling of Antarctica and eventually to the appearance of Antarctic ice sheets.

There is evidence that a transient but extreme glaciation during the early Oligocene (designated Oi-1) was accompanied by increased fertility of the Southern Ocean, presumably through an intensification of upwelling (Salamy and Zachos 1999). The high rates of carbon burial at this time may have acted as a positive feedback to global cooling, further reducing atmospheric CO_2.

A warming trend in the late Oligocene (27–26 Ma) reduced the extent of the Antarctic ice sheets, and bottom water temperatures gradually rose, reaching a maximum in the Miocene climatic optimum (17–15 Ma). The ice sheets gradually grew back during the late Miocene into the early Pliocene (6 Ma). After a brief period of warmth during the early Pliocene, the Southern Ocean entered a new stage in its climatic history.

The Quaternary (2–0 Ma)

With the appearance of ice sheets in the Northern Hemisphere around 3.2 Ma began a new phase of global, well-documented cycles of waxing and waning of polar ice caps; the Pleistocene glaciations. Cyclical changes in temperature and ice volume, as documented by preserved foraminifera, first appear about 2.5 Ma and continue through the present interglacial period (the Holocene). Several cores from the opal belt in the Atlantic and Indian sectors of the Southern Ocean show 100 thousand-year (denoted 100 Ka) cycles of opal content extending back 450 Ka (Charles et al. 1991). Sediments north of the Polar Front were rich in opal during warm periods and poor during cool periods, while those south of the Polar Front showed the opposite trend. Not surprisingly, the details of Southern Ocean paleoceanography are better known for the more recent glacial cycles particularly the Last Glacial Maximum (LGM $\sim$18 Ka). Reconstructing the biology, chemistry, and physical oceanography of the Southern Ocean during the LGM is a key focus of paleoceanographers studying the region.

Recently there has been much interest in rapid climate change in the Southern Ocean. Cycles of rapid (over 1000 years) warming and cooling (called Dansgaard-Oeschger cycles) were first identified in the Northern Hemisphere ice and deep-sea cores. The Antarctic ice cores also record rapid changes, but their amplitude is smaller and out of phase with those in the northern hemisphere. The few continuous high-resolution records available from Southern Ocean sediments suggest changes in sea surface temperature tracked the climate over Antarctica. There is also evidence from ocean cores that during warm phases of the Dansgaard-Oeschger cycles there was increased delivery of ice rafted debris to the South Atlantic. This is an area of active research.

The following summarizes what is known of Southern Ocean circulation and ocean productivity during the LGM. Included within each section is a brief description of the paleoceanographic tools, or proxies, used to make deductions about past conditions. Proxies, geochemical and paleontological, allow paleoceanographers to indirectly reconstruct past ocean conditions, by making measurements of properties of the sediment that are correlated with the ocean properties to be reconstructed, such as temperature, currents, and nutrient content. In many cases the proxies are open to multiple interpretations. A successful method has been to use many proxies together, each with their own limitations and assumptions, but which together weave a stronger story (multiproxy approach).

Reconstructions of Circulation

Physical oceanographers studying the modern ocean use detailed maps of ocean temperature and salinity, together with other information such as wind strength to deduce the movement of water masses. No such detailed measurements exist from 20,000 years ago, so paleoceanographers use more indirect methods. Several geochemical tracers can be used to “tag” water masses. These include the isotopic composition of dissolved inorganic carbon, $^{13}C/^{12}C$ ($\delta^{13}C$), and the cadmium (Cd) content of the water. They are both roughly correlated with nutrient concentrations. Both of these are incorporated into the shells of foraminifera in proportion to their concentration in seawater. The buried shells are preserved in the sediments and produce a record of past changes in the chemistry of the water at a given location and depth. By combining many such measurements, maps of these distributions are generated that can be used to deduce the movement of water masses. Foraminifera living in the surface (planktonic foraminifera) and at or near the seafloor (benthic foraminifera) document the properties of surface and deep currents, respectively.

In areas of formation of deep water, geochemical gradients in the vertical are minimized due to deep mixing; the similarity between benthic and planktonic $\delta^{13}C$ can then be used to study changes in sites of the formation of deep water (Duplessy et al. 1988).

The densest water mass in the Southern Ocean is Antarctic Bottom Water, which is produced at far southern latitudes and flows northward. This is overlain by Circumpolar Deep Water, which derives from North Atlantic Deep Water (NADW) that flows southward into the Southern Ocean. Mixtures of these two water masses make up the deep water of the world's oceans. The Southern Ocean is a key region in which to examine changes in the global influence of these two water masses. Early evidence based on $\delta^{13}C$ suggested a dramatic reduction of NADW in the Southern Ocean during the LGM. However, Cd records suggested little to no change. Another view is that the water entering the Southern Ocean from the Atlantic was an intermediate water that may then have entered the Pacific via the ACC. Less work has been done to reconstruct the strength of AABW. Several studies, including one based on grain-size analysis and $\delta^{13}C$ find evidence for intensified AABW out the Pacific during glacial periods of the past 1.2 million years. This is still an active area of research, and understanding of the relative strength of the deep water masses evolves as new proxies and new information about existing proxies become available.

The most prominent surface hydrographic features in the Southern Ocean are the fronts of the Antarctic Circumpolar Current. These fronts are areas of strong gradients in temperature, salinity, and in some cases nutrients and ecosystem composition. Some of the earliest studies of Southern Ocean paleoceanography argued for equatorward displacement of the Polar Front during glacial times. These inferences were based on observations that the opal belt was shifted northward during glacial times (Hays et al. 1976) and that front-associated species of foraminifera were also shifted northward. A recent reconstruction of sea surface temperature in the Southern Ocean did not find evidence for such movement, and the current location of the Polar Front is constrained by bottom topography. It thus may have moved less than a few degrees latitude, although a shift might have occurred in biological and chemical features that are today associated with the physical location of the Polar Front.

Reconstructions of Ocean Productivity

One of the great unsolved mysteries of paleoclimatology is the cause of the $\sim$80 parts per million (ppm) lower levels of CO_2 in the atmosphere during glacial times. This pattern appears to be a critical amplifying mechanism, via a reduced greenhouse effect, for sustaining the magnitude of glacial cooling. In the 1980s a number of advances in ocean science led to the proposal of a promising new theory to explain these changes, based on changes in productivity of the Southern Ocean. It was recognized that weak vertical stratification in the Southern Ocean makes it one of the few areas in the ocean where deep water communicates with the atmosphere. Herein lies the possibility for the Southern Ocean to essentially pump CO_2 from the atmosphere into the deep sea (where it is sequestered for about 1000 years) and vice versa. Furthermore, nutrients in the surface waters of the Southern Ocean are currently not completely used by phytoplankton growth. Models suggested that if Southern Ocean phytoplankton were to be 100% efficient in their use of these nutrients then the corresponding uptake of CO_2 during growth could account for the full 80 ppm decrease in CO_2 during glacial times. The recognition that iron limits phytoplankton growth today in much of the Southern Ocean offered a logical mechanism for driving such changes in productivity: increased dust flux during cold periods relieved the phytoplankton of iron limitation and allowed it to make full use of the available nutrients and CO_2.

Evidence consistent with greater iron input to the Southern Ocean during glacial times exists from ocean cores. However, finding conclusive evidence for a glacial increase in the biological productivity of the Southern Ocean has been more difficult. There are essentially two approaches. One can either reconstruct the nutrient concentration of surface waters, which gives direct information on the biological removal of CO_2, or one can reconstruct the rain of biological material to the seafloor (also called the export production). The export production method needs to be coupled with additional information about upwelling intensity, because the net effect on atmospheric CO_2 depends only on the biological consumption of nutrients and CO_2 relative to their supply by upwelling.

The nutrient approach is more direct but has been plagued by problems with interpretation of proxies. The same proxies used to determine the temperature of deep water masses—$\delta^{13}C$ and Cd, among others—can be used to reconstruct nutrient concentrations in surface waters when they are applied to surface-dwelling organisms. A recent reevaluation of the Cd approach (Elderfield and Rickaby 2000), correcting for a temperature bias, finds evidence that during glacial times the consumption of phosphate was less efficient than present day south of the Polar Front and the same as present day north of the Polar Front.

The biological rain, or export production approach, is somewhat less ambiguous, but still open to multiple interpretations. The classic method of using the mass accumulation rate of biogenic material (such as organic carbon or opal) to infer past surface productivity is prone to large errors in the Southern Ocean. This is because strong bottom currents here cause sediment to accumulate in some locations and erode it away from others (Dezileau et al. 2000). The mass accumulation rate can easily be different from the local, vertical rain of material from the surface and might reflect changes in the horizontal supply of sediment from currents. A solution to this problem is to use the naturally occurring radionuclide, ^{230}Th, to obtain an estimate of the flux of material to the seafloor that is corrected for any lateral input (Frank et al. 1999).

The use of these "Th-normalized fluxes" together with other tools including nutrient utilization proxies, has produced a reasonably consistent, if incomplete, picture of qualitative patterns of surface productivity in the Southern Ocean during the LGM. Diatom productivity, and probably all phytoplankton productivity, was almost certainly lower during the LGM than it is today, south of the Polar Front. There is evidence for this in all three sectors of the Southern Ocean (Pacific, Atlantic, and Indian). A reasonable explanation for this is that the greater extent of sea ice during cold periods shortened the growing season and inhibited phytoplankton productivity. Sea ice can be reconstructed by examining the distribution of diatom species. Most reconstructions agree that the winter maximum extent of sea ice was greatly expanded during the LGM. However, the northward extent of sea ice in summer is still not well known. One detailed study suggests summer sea ice extent during the LGM was no different than today (Crosta et al. 1998). North of the Polar Front the records are less clear. In the Atlantic there is evidence for substantially greater diatom productivity and carbon export during the LGM than today. In the Indian sector diatom productivity and carbon export were slightly higher during the LGM than today, and in the Pacific sector preliminary records from a limited number of sites suggest productivity during the LGM was essentially the same as it is today.

A conceptual model to explain these changes has been proposed (Chase et al. 2003). Briefly, if circulation during the LGM were not much different than today, then nutrient-rich waters would continue to upwell south of the Polar Front. If ice cover were substantial there, the consumption of silicate by diatoms, and their export to the seafloor, would have been reduced. The unused silicate would be transported northward. The Atlantic, being closest to continental sources of iron-rich material (e.g., South America), would have received sufficient iron to allow diatoms there to bloom and consume all of the displaced silicate. This can explain the apparent northward migration of the Polar Front. Iron fertilization via dust and continental shelf sediments would be much less in the Pacific, since it is furthest downwind (and downstream) of South America. According to this theory, in the Pacific there was not enough iron for diatoms to use the displaced silica north of the Polar Front. That silica would have been exported northward to the rest of the oceans, where it may have promoted diatom productivity in low latitudes.

SEI WHALE

Sei whales are order Cetacea, suborder Mysticeti (meaning moustache, which refers to baleen plates), family Balaenopteridae, genus and species *Balaenoptera borealis* (Lesson 1828). The name *borealis* means "northern," reflecting the fact that it was first known from the northern North Atlantic. Other common names used in the past include coalfish whale and pollock whale. The name "sei" is derived from its tendency to arrive in Norwegian waters at the same time as the *seje,* the Norwegian name for the saithe otherwise known as the coalfish or pollock *(Pollochius virens)*.

General Appearance and Size

Sei whales are the third largest of the balaenopterids. In the Southern Hemisphere, they average about 15–16 m in length and weigh around 20 tonnes. Females are generally about 5% longer than males. The largest animals can reach up to 20 m.

The slender sei whale is perhaps the most streamlined of all the whales. Its narrow head has a single well-defined head ridge running to the paired blowholes. Its closest relative, the Bryde's whale *(B. edeni)* is characterised by three head ridges. The dorsal surface of the sei whale is generally dark grey in colour. The skin shows little mottling (although it is sometimes covered in pale oval scars thought to be caused by lampreys or remoras). The ventral surface is paler. The dorsal fin is relatively tall (0.25–0.75 m) and generally falcate. It is set about two-thirds of the way along the back. Sei whales are rorquals and have 38–65 ventral grooves that run from the lower jaw and end well before the umbilicus, unlike in the blue *(B. musculus)* and fin *(B. physalus)* whales; these grooves allow the mouth to expand when feeding. They have about 350 relatively narrow, black, triangular baleen plates hanging from the upper jaw on each side (about 0.8 m in length and 0.3 m at the widest part) spaced 1–3 cm apart, used in filtering food from the water. The bristles are much finer than those for the blue and fin whales. The flippers reach about 10% of body length and are dark grey on top and paler underneath, as are the broad flukes.

In Antarctic waters, all or portions of the body may have a dark yellow-green to brown sheen from the presence of diatoms.

Distribution and Migration

Sei whales are found throughout the Southern Hemisphere (and indeed, the Northern Hemisphere). They migrate between subtropical breeding areas (although the location of the breeding grounds is unknown) and their Antarctic feeding grounds, which appear to be related to the Polar Front; most sei whales being found around the Polar Front north of about 55° S. Like the other large whales, sei whales rarely feed outside the Antarctic and so in the 4 months (December to March) they are in the Antarctic they must store energy in their blubber to last them for the migration to and from the breeding grounds. Although detailed information on stock structure is lacking, there are probably at least six separate populations of sei whales in the Southern Hemisphere.

Life History and Behaviour

Sei whales are thought to live up to 40–50 years old. They reach sexual maturity at around 14 m (females) and 13 m (males) when they are about 8–10 years old. The gestation period is thought to be around 11–12 months; new born calves measure around 4.5 m. They are weaned at about 6 months, by which time they have reached about 8 m. There is some evidence that pregnancy rates increased and animals reached sexual maturity earlier as a result of whaling, perhaps as more food per individual became available.

Little is known about the social structure of sei whales. They are usually seen as single animals or in small groups, although larger concentrations are known in areas of high prey density. Sei whales feed on a wider range of species than the other rorquals, primarily the Euphausiid *(E. vallentini)* but also copepods (e.g., *Calanus tonsus*) and amphipods (e.g., *Parathemisto gaudichaudii*).

Unlike other balaenopterids, which can be classified as "gulpers," sei whales often skim feed somewhat like right whales *(Eubalaena australis)*. It has been postulated that this method of feeding allows them to exploit less dense patches of prey. Sei whales are the fastest swimming whales with normal travelling speeds of around 6–7 knots with short bursts of as much as 20–25 knots occurring if chased.

Conservation/Status

Sei whales became a serious target of commercial whaling in the Antarctic only after blue whales and fin whales had been heavily depleted. About 179,000 were killed south of 40° S between 1905 and 1977, with over 65% of these being killed between 1964 and 1972. They have been protected by the International Whaling Commission in the Southern Hemisphere since 1978.

There are no good estimates of the abundance of sei whales in the Southern Hemisphere before they were exploited. Some scientists have suggested that sei whales may have begun to increase in numbers prior to their heavy exploitation as a result of the decrease in numbers of blue and fin whales, but it is not possible to test this theory. Similarly, there are no recent estimates of abundance. The reason for the latter is that most abundance surveys occur south of 60° S.

Aside from man, the only likely predator of sei whales is the killer whale, *Orcinus orca,* although there are no documented reports of attacks. The effect of climate change on stocks of krill and other sei whale prey species is unknown.

SHACKLETON, ERNEST

Ernest Henry Shackleton (February 15, 1874–January 5, 1922) was the most charismatic of all Antarctic explorers and is best remembered for rescuing his party from the Weddell Sea after their ship *Endurance* had been crushed by ice. The qualities he displayed during that trying time have made him a paradigm for modern leadership skills. The *Endurance* story has overshadowed his other achievements and obscured his failings in organisation and business aptitude.

Shackleton was born in Kilkea, County Kildare, Ireland, and the family moved to south London when he was 10. He was educated at Dulwich College until the age of 16, when he signed on the square-rigger *Hoghton Tower* as a ship's boy. After 11 years of working his way up the promotion ladder, his last voyage as a merchant seaman was as third officer on the liner *Carisbrooke Castle*.

It appears that Shackleton was attracted to join the British National Antarctic Expedition (1901–1904) both for adventure and as a means of improving his financial prospects. By making use of intermediary contacts, Shackleton was appointed third officer on the expedition ship *Discovery*. Robert Falcon Scott's decision that *Discovery* would winter in Antarctica allowed Shackleton to participate fully in the land-based activities of the expedition. He made the second balloon ascent in Antarctica and took the first aerial photographs. He led the first overland journey, which lasted four days and showed how ill-prepared the expedition was for Antarctic travel. From the beginning, Shackleton had difficulty mastering the use of skis and dogs; failings that most likely later cost him the South Pole and might have jeopardised the crossing of Antarctica.

The next summer, Shackleton accompanied Scott and Edward Wilson on the major southward journey. All three men suffered from scurvy, and Shackleton was invalided home as unfit for further duty. On this expedition, Shackleton was already showing his enthusiasm, drive, and ability to win the admiration of his fellows.

Shackleton benefited from being the first officer to return from Antarctica, because he made a name for himself through lectures, articles in the press, and by forming personal contacts. He became Secretary to the Royal Scottish Geographical Society but resigned within the year to stand, unsuccessfully, as a candidate for Member of Parliament for Dundee in the 1904 General Election. He also married Emily Dorman, and they had the first two of their three children, Raymond and Cecily. (Shackleton's youngest child, Edward, would later become Lord Shackleton.)

During this period Shackleton was employed by William Beardmore, a Clydeside ship builder. On February 11, 1907, he announced his plans for the British Antarctic Expedition, the primary objective of which was to reach the South Pole. He then discovered that Scott was planning a second expedition with the same aim. Shackleton signed an undertaking with Scott not to land in McMurdo Sound and use the *Discovery* base. He tried to set up base at the other end of the Great Ice Barrier (now known as the Ross Ice Shelf), but he could not find a suitable landing place and reluctantly established his base at Cape Royds, not many miles from Scott's old base at Hut Point. He was later severely criticised for this decision.

Shackleton, with Frank Wild, Jameson Adams, and Eric Marshall, reached 88°23′ S, before being forced back by shortage of food. This was arguably the most important attempt on the Pole because it revealed that the Pole lay on a high, ice-covered plateau. Covering the final 97 geographical miles (112 statute miles or 180 km) to the Pole would not have added significantly to geographical knowledge. The expedition also reached the South Magnetic Pole and made the first ascent of Mount Erebus.

The expedition returned to great popular enthusiasm in Britain, and Shackleton was knighted. However, the expedition was seriously in debt. It was aided by a large government grant but the financial situation was not helped by Shackleton's habit of donating to charities funds raised by lectures and public exhibitions on the expedition ship *Nimrod,* even though he still owed expedition members their salaries. Shackleton also had to combat allegations, from Sir Clements Markham among others, that calculation of latitudes by his navigator, Marshall, had been faulty.

In 1911, Amundsen and Scott reached the South Pole, with Shackleton watching from the sidelines. During this period, he gave advice to the Argentines on the relief of Otto Nordenskjøld's Swedish South Polar Expedition. On December 29, 1913, Shackleton publicly announced The Imperial Trans-Antarctic Expedition in a letter to *The Times*. The aim was to cross the continent via the South Pole from the Weddell Sea while other parties explored to the base of the Antarctic Peninsula and the coast of Enderby Land. Another party was to land at McMurdo Sound and lay depots for the crossing party.

The expedition set sail in August 1914, as war was declared. It was delayed at South Georgia because of the late dispersal of ice in the Weddell Sea and was eventually trapped in pack ice not far from the proposed landing site at Vahsel Bay. Having weathered the disappointment of failure of his plans and survived the months of wintering on board, Shackleton's leadership skills were tested to the utmost when *Endurance* was crushed and the ship's complement took to the ice. It soon proved that there was little the men could do to help themselves by travelling over the ice, and they had to wait while they drifted northward toward open water. The subsequent journey in three small boats to Elephant Island, the voyage to South Georgia in *James Caird,* and the crossing of South Georgia form the basis of Shackleton's reputation as a leader. Extreme courage and the ability to maintain the morale of his men were paramount.

Following the rescue of the Ross Sea Party and his return to Britain, Shackleton attempted to find military work, although he was too old to be required to join the armed forces. He was eventually sent, unpaid, to Buenos Aires to spread British propaganda but was recalled 5 months later and attached as winter-equipment officer to an expeditionary force sent to Murmansk, Russia. With him went Worsley, Hussey, Macklin, and Stenhouse from the Imperial Trans-Antarctic Expedition. After the war he planned an expedition to look for new lands in the Arctic but, when the Canadian government withdrew support, he headed south aboard *Quest* on the Shackleton-Rowett Expedition and died on reaching South Georgia.

Shackleton's reputation was for a long time eclipsed by Scott's, but there was a remarkable revival in the 1990s, in what the *New Yorker* called "Shackleton-mania." Shackleton is sometimes said not to have achieved any of his objectives, but this obscures the importance of his achievements on the *Nimrod* expedition. His fame, however, depends on his qualities of leadership and endurance when rescuing his men from the Weddell Sea, rather than his success as an explorer. Despite ill health (he refused to let doctors examine him), he undertook incredible feats of endurance, such as the return from the attempt on the South Pole and the crossing of South Georgia. As a leader, he emphasised care for his men and easy communication, and he always extolled group efforts. To quote Percy Blackborow of the Imperial Trans-Antarctic Expedition: "He had a genius for keeping men in good spirits and, need I say more—we loved him as a father."

SHACKLETON RANGE

The Shackleton Range is situated between 80° S and 81° S, and 31° W and 19° W in the Atlantic continuation of the Transantarctic Mountains, sometimes included, mostly not. It extends 200 km from east to west with a width of 80 km from north to south. It was first visited during the Commonwealth Trans-Antarctic Expedition (1955–1958) and studied by British expeditions in 1967, 1968–1971, 1977–1978, by Soviet expeditions in 1976–1977 and 1978–1979 (including German geologists from the former DDR), by a German Expedition (GEISHA: 1987–1988), and by a European Expedition (EUROSHACK 1994–1995).

The Shackleton Range forms a key area for all concepts concerning the geological architecture of Antarctica and even Gondwana. Firstly, its main phase of deformation and metamorphism is dated at about 500 Ma (Pankhurst et al. 1995; Tessensohn et al. 1999) and is therefore directly related to the formation of Gondwana. Secondly, its internal grain is oriented nearly orthogonal to Gondwana's paleo-Pacific margin, corresponding in Antarctica to the c. 500 Ma old Ross Orogen of the Transantarctic Mountains.

From the paleo-Pacific margin the range extends eastward and then disappears under the extensive and thick ice cover of southern Dronning Maud Land, which traditionally was attributed to the East Antarctic Craton (e.g., James and Tingey 1983). In spite of their contemporaneity, the main orogenic processes are fundamentally different in the Ross Orogen proper in the Transantarctic Mountains on the one hand and in the Shackleton Range on the other hand. Predominantly subduction-related processes in the former contrast with predominantly collision-related processes in the latter (Tessensohn et al. 1999). One of the most relevant results is the discovery of an ophiolitic complex traceable for more than 100 km, the oceanic past of which must have been in the period between 1000 and 500 Ma (Talarico Kleinschmidt, and Henjes-Kunst 1999) (i.e., the right time and the right place for having formed part of the Moçambique Ocean that separated East and West Gondwana before final amalgamation of the supercontinent in late Pan-African times).

A Simplified Tectono-Stratigraphic Column from Top to Bottom.

Permo-Carboniferous glacial deposits (Tessensohn, Kleinschmidt, and Buggisch 1999; see also Beacon Supergroup)	*very eastern end of central strip*
Blaiklock Glacier Group (Ordovician molasse)	*western end of northern and central strips*
- - - unconformity - - -	
Pioneers Group (mainly medium-grade metamorphic "supracrustals," including the ophiolite)	*northern and central strip (ophiolite: northern strip)*
- - - mainly thrust contact - - -	
Stratton Group (high-grade metamorphic basement)	*northern and central strip*
- - - main thrust - - -	
Mt. Wegener Nappe • Mt. Wegener Formation (Cambrian flysch) • Wyeth Heights Formation • Stephenson Bastion Formation.	*(all formations consist of low-grade metamorphic rocks; southern strip plus four tectonic windows in the central strip)*
- - - main thrust - - -	
Watts Needle Formation (epicratonic, autochthonous Eocambrian sediments: soil, arkose, sandstone, limestone, shale)	*southern strip*
- - - unconformity - - -	
Read Group (high-grade metamorphic basement of the East Antarctic Craton)	*southern strip*

The Shackleton Range consists mainly of three rock complexes:

1. Relatively low-grade metasediments.
2. A large variety of medium- to high-grade metamorphic rocks (including ophiolites).
3. A cover of molasses-like sediments, the Ordovician Blaiklock Glacier Group.

These rock types can be attributed to three east–west running topographic units (strips) of the range: a northern strip dominated by the Lagrange Nunataks and the Herbert Mountains, a central strip largely covered by ice (Fuchs Dome, Shotton Snowfield), and the southern strip dominated by the Read Mountains.

There is a large and confusing number of stratigraphic terms, some of which are unnecessary and obsolete (see Clarkson et al. 1995). A simplified tectono-stratigraphic column from top to bottom is shown in the table.

The structural characteristic of the Shackleton Range is a large-scale nappe tectonics, as indicated in the tectono-stratigraphic column. Nappe tectonics has already been assumed by Marsh (1983). Nappe tectonics of Pan-African age concerning the Mount Wegener Nappe in the Read Mountains was firstly proven by Buggisch et al. (1990, 1994) and confirmed by additional evidence throughout the southern strip (Buggisch and Kleinschmidt 1999). That nappe tectonics dominate the entire structure of the Shackleton Range with the formation of several tectonic windows, was shown by Kleinschmidt et al. (2001). The tectonic transport directions change systematically: it is southward directed in the south, westward directed in the north, and south-westward in between (Kleinschmidt et al. 2002). Compressional tectonics is overprinted by late to post-tectonic collapse producing abundant low-angle normal faults and kink bands with dip-slip displacement (Kleinschmidt and Brommer 1997).

SHACKLETON-ROWETT ANTARCTIC EXPEDITION (1921–1922)

After the end of World War I, Sir Ernest Shackleton planned an expedition to search for new lands in the Arctic. Thinking he had obtained the backing of the

Canadian government, he bought a 125-ton sealing vessel, *Foca I,* and recruited some members of the Imperial Trans-Antarctic Expedition. However, the Canadian government withdrew its support, and Shackleton decided to head for Antarctica instead. John Quiller Rowett, who had known Shackleton when they were pupils at Dulwich College, agreed to underwrite the expedition, which was named the Shackleton-Rowett Antarctic Expedition.

Shackleton's new proposal for an "oceanographical and sub-Antarctic expedition" was exceedingly ambitious. The expedition vessel would be called *The Research* and it would visit the South Pacific as well as Antarctica. Geographical research would include searching for doubtful and badly located islands and rocks and filling in 2000 miles (3200 km) of Antarctic coastline, from Enderby Land to Coats Land. There would be comprehensive projects on meteorology, geology, mineralogy, earth magnetism, botany, marine biology, and anthropology. There would be an emphasis on economic aspects, such as searching for precious metals, phosphates, wolfram, iodine-rich kelps, and sealing and whaling grounds. The expedition would also "ascertain, once and for all the history and methods of the Pacific natives in their navigation across Pacific spaces." Shackleton also planned to make the first use of an aircraft in Antarctica and, according to one account, even proposed flying to the South Pole. The reality was very different.

The nucleus of the expedition was the "old guard" from *Endurance:* Frank Wild, Frank Worsley, Alexander Macklin, James McIlroy, Leonard Hussey, Alfred J. Kerr, Thomas McLeod, and Charles Green. Other members included James Marr, a Boy Scout who was chosen from 1700 applicants and who later became a leading Antarctic marine biologist, and the Australian Hubert Wilkins, who later became the first man to fly in Antarctica.

The expedition was made ready in 3 months. *Foca I,* renamed *Quest,* was modified with the addition of a deckhouse for accommodation and an enclosed bridge, and sailed from London on September 17, 1921. St. Paul's Rocks were visited, but there were also several unscheduled stops to repair the engine, and four weeks was spent on a major refit at Rio de Janeiro. It was now too late to proceed to Cape Town, where the aircraft—an Avro "Baby" seaplane—and many stores were waiting, so a course was set for South Georgia. *Quest* rode out a huge storm for 4 days and developed a leaking boiler before reaching the shelter of Grytviken and the company of old friends among the whalers, on January 4, 1922. They also met up with Wilkins and Vibert Douglas, who had travelled ahead from Rio de Janeiro to undertake scientific work (natural history and geology, respectively) on South Georgia.

That night Shackleton suffered a heart attack and died. The shocked crew took his body ashore at Grytviken where a postmortem revealed longstanding heart disease. Wild, who took over as leader, decided to send Shackleton's body to England for burial, accompanied by Hussey. Meanwhile the expedition would continue, but as many of the men had joined Shackleton rather than the expedition, the expedition had lost much of its *raison d'être*.

Shackleton had discussed two plans with Wild. One was to penetrate the pack ice and reach Enderby Land and survey the coastline, but Wild considered this too dangerous with the poor state of *Quest*. The alternative was to overwinter on the western coast of Graham Land (now the Antarctic Peninsula) and travel overland to the Weddell Sea in the following season. This plan had to be rejected because the specialist clothing, food, and dogs left at South Georgia by Wilhelm Filchner's *Deutschland* expedition, which Shackleton had hoped would replace the stores left at Cape Town, were no longer available.

After fuel and stores had been obtained from the whaling stations, they sailed from South Georgia on January 18 with the aim of penetrating the Weddell Sea and proceeding along the southern coast. *Quest* headed south via the South Sandwich Islands, where a running survey was made of Zavodovski Island and soundings taken. Bouvetøya had to be missed through lack of time, but they altered course to search for Pagoda Rock, which had been reported in 1845. There was no sign of it, as it had probably been a large iceberg. Heavy ice now thwarted their progress into the Weddell Sea, and they were forced to turn back at 69°17′ S, 17°9′ E. On the way north, James Clark Ross's "Appearance of Land" was investigated, but, although ice prevented reaching the precise spot, there was no sign of land and a sounding nearby gave a depth of 2331 fathoms.

Skirting westward along the ice edge, *Quest* reached Elephant Island, where a number of the crew had been forced to stay in 1916. Landings were made at Cape Lookout and Minstrel Bay to collect seal blubber for eking out the meager supplies of coal, but deteriorating weather prevented a landing at Point Wild and deprived McIlroy of the chance to retrieve the diary he left there in 1916. With another gale blowing up and causing considerable damage, together with the serious shortage of coal, Wild turned *Quest* toward South Georgia.

On April 16, *Quest* reached Leith Harbour whaling station, where the crew was surprised to find Hussey. He told them how he had brought Shackleton's body back to South Georgia for burial at Grytviken.

For two weeks *Quest* lay at Leith Harbour and Stromness while storm damage was made good. Prince Olav Harbour was visited for coal, and soundings were made around the northwest end of South Georgia. On April 2, *Quest* left for Grytviken, where the crew constructed a memorial cairn and cross for Shackleton at Hope Point and the men from *Endurance* visited Shackleton's grave to say farewell to "The Boss."

Following a visit to Royal Bay, where the station of the German Transit of Venus expedition was inspected and more soundings made, *Quest* headed for Tristan da Cunha. On their arrival on May 19, they found the islanders in a fairly destitute state and gave them what they could spare of stores and food. Visits to Nightingale, Inaccessible, and Middle islands were followed by a week at Gough Island. Cape Town was reached on June 18, and *Quest* left on July 13 for the long run up the Atlantic. Calls were made at Ascension Island, St. Helena, St. Vincent, and the Azores. On September 16, 1922, *Quest* finally anchored at Plymouth, one year after it had left England.

The Shackleton-Rowett Expedition is remembered for the untimely death of its leader. The proposed program was ambitious but vague, and the small, underpowered, unseaworthy *Quest* was lucky to survive the voyage to the Antarctic and back. Despite the limitations of an inadequate vessel and the loss of its leader, the expedition persevered and made some useful contributions to the knowledge of little-known places in the South Atlantic.

SHEARWATERS, SHORT-TAILED AND SOOTY

The short-tailed shearwater, *Puffinus tenuirostris,* and sooty shearwater *P. griseus,* represent two of the nineteen medium-sized petrels in the genus *Puffinus*. The sooty is slightly larger than the short-tailed shearwater, ranging between 650–980 g and 480–800 g, respectively. Both species are all dark above except the sooty shearwater is identified by having more white in the area of primary coverts. The phylogenetic history is little known for either species. Most of the modern species-groups, or subgenera, of *Puffinus* were in existence by the Middle Miocene, and there has been very little morphological change within these lineages in 15 million years or so. Fossil remains suggest that the short-tailed shearwater and its congeners were differentiated in the North Atlantic Ocean–North America regions. On mainland Australia, Tasmania, and New Zealand, the earliest short-tailed and sooty shearwater remains are from coastal deposits of the late Pleistocene or Holocene. Having settled in the Southern Hemisphere, the post-breeding migration of the short-tailed and sooty shearwaters may be an instinctive response to return to their ancestral "home."

Like most seabirds, the two species spend 90%–95% of their life at sea, ranging to the Antarctic Circle in the breeding season and migrating to the North Pacific Ocean in the nonbreeding season, with a small proportion of birds remaining in home waters all year round. South American populations of sooty shearwaters also migrate to the North Atlantic Ocean. In terms of numbers and biomass, the short-tailed shearwater is the dominant seabird around the Aleutian Islands and Bering and Chukchi seas. The sooty shearwater is most abundant over the deep-water basin of the central Pacific Ocean, and along the west coast of North America. The northern water masses are richer in food than subtropical waters, and it is likely that both species pass relatively quickly across these transitional regions without pausing to forage.

Shearwaters make landfall at the breeding colonies at the end of September. Their breeding timetable is highly synchronised to the extent that it was once thought all birds laid on the same day (which is close to the truth, because 85% of all eggs are laid within 3 days either side of 24–25 November). Eggs are incubated for 54 days, and the chicks fledge approximately 100 days after hatching. The chick receives its last meal about 10 April, enters a "starvation period," and fledges 2–3 weeks later in late April to early May. Long-term research of more than 55 years on the short-tailed shearwater reveals that they first breed between 4 and 15 years of age, and can live up to 38 years. On average, male shearwaters live for 9.2 years and females for 9.4 years after commencing breeding. Reproductive success at first increases with age but then decreases as birds become older, and overall, 8% of breeding shearwaters produce 53% of all young returning to breed. In the last years of their breeding life, shearwaters tend to change mates and burrows, miss years and form associations that do not result in reproduction.

The short-tailed and sooty shearwaters are two of the most aquatic of the *Puffinus* genus, having a long narrow pelvis, compressed tarsus, well developed knee joint process, a long sternum, short thick compressed humerus and a short smooth body plumage. During daily foraging trips, they are capable of making regular and almost continuous dives to 60 m for several successive hours. At night, they spend most of their time floating at the water surface. They feed, in successive order of importance, by pursuit plunging, surface seizing, pursuit diving, scavenging, hydroplaning, and bottom feeding. During the breeding season, shearwaters forage over vast areas of the southern temperate, sub-Antarctic and Antarctic biogeographical sea zones, with sooty shearwaters more abundant in both the sub-Antarctic and Antarctic zones.

During the chick-rearing phase, parent birds maintain themselves in highly productive areas in the subantarctic and Antarctic zones, located vast distances from breeding colonies, and provision chicks from local sources. A cyclic pattern results of two or three short trips of 1–2 days duration followed by a long foraging trip of 8–13 or more days. Capable of flying 1000 km per day at speeds of up to 58 km per hour, a parent bird consumes food equivalent to 40% of its body mass daily in order to meet its own and the nestling's energy needs. The Antarctic zone is very rich in phytoplankton, and productivity is enormous during the short Antarctic summer, with krill, specifically *Euphausia superba* the most frequent food taken. In the southern temperate zone, the main food items are krill such as *Nyctiphanes australis,* squid, fish and crustaceans with the diet changing in response to the seasonal abundance and distribution of prey species.

Both shearwater species are very abundant, and one of the main reasons postulated is that where prey densities are high enough to render underwater pursuit viable, both species essentially forage in three dimensions. Feeding offshore and underwater opens more areas to locate food. The short-tailed shearwater only breeds in southern Australia with an estimated population of 23 million adults. Tasmania contains 80% of total population with approximately 9 million pairs in 211 colonies covering 1813 ha. The largest colony is Babel Island in Bass Strait with 2.86 million burrows. The sooty shearwater has a much wider distribution. In New Zealand, colonies centre on islands lying south of South Island. The largest population is 2.01 million burrows on the Snares Islands, 105 km south of Stewart Island (Rakiura). Colonies in southeastern Australia total several thousand pairs. Numerous colonies also occur on the eastern side of the South Pacific Ocean in southern Chile, Argentina and on the Falkland Islands, which may number several million birds. The estimated total population for all regions may be 20 million birds. There are no major genetic differences between the New Zealand and Chilean populations, suggesting mixing among colonies. It also breeds in very small numbers on Tristan da Cunha.

Mortality is mainly due to starvation, predation, and human activities. In New Zealand sooty shearwater numbers have decreased by up to 54% in the past 50 years. Historically, they bred all around New Zealand but most mainland colonies are functionally extirpated due to predation, mainly by introduced mustelids and habitat loss. Off the coast of California, sooty shearwater numbers have decreased by 90% since the late 1980s. Climate change has been implicated with links to a corresponding decrease in abundance of zooplankton, rather than simply a distributional shift in feeding location and change in migration route. No similar population changes have been detected in short-tailed shearwaters, but the recent deliberate introduction to Tasmania of red fox *Vulpes vulpes* is a major cause of concern. Large episodic mortality does occasionally occur, however, during termination of transequatorial migrations due to food shortages brought about by anomalous weather events. Shearwaters in good body condition have the capacity to fly approximately 8300 km before succumbing to starvation. The great circle distance between New South Wales and the far North Pacific Ocean is approximately 9500 km, so if food is unavailable en route large mortalities could result, but the impact on the population is largely unknown.

Human impacts include harvesting or "muttonbirding" of short-tailed shearwaters in Tasmania and of sooty shearwaters in New Zealand. Both species are commonly known as "muttonbird," a term coined in 1790 when wedge-tailed shearwaters *P. pacificus* were consumed by convicts to supplement food on Norfolk Island in the central Pacific Ocean. Then, they were described as remarkably fat with the taste resembling that of sheep or mutton. Because of the birds' high nesting densities and site fidelity, the short-tailed and sooty shearwaters are highly vulnerable to exploitation. Present-day harvesting takes up to several hundred thousand chicks annually in both these countries.

Shearwaters in particular ingest more plastic than any other seabird group recorded to date. Chlorinated hydrocarbons, including dioxin and heavy metals, have been detected in shearwaters at breeding grounds and on their migration routes. Oil spills are another irregular hazard. North Pacific Ocean driftnet fisheries for salmon and squid previously caused the largest bycatch of sooty and short-tailed shearwaters of all seabirds. The United Nations ban on pelagic driftnet fishing on high seas in 1992 removed some of this risk, but the high mortalities caused by these fisheries in the past may have had long-term effects on the demographics of these two long-lived shearwaters.

The short-tailed and sooty shearwaters occur in seemingly high numbers and have long breeding lives but are vulnerable to many outside factors. Monitoring programs and management decisions that are based on best available data are required to ensure the two species survive into the future.

SHEATHBILLS

There are two varieties of sheathbill: the black-faced sheathbill *(Chionis minor)* and the pale-faced sheathbill *(C. alba)*. It belongs to the order Charadriiformes.

The body length of the sheathbill is 34–41 cm, and its body mass is 450–750 g. Males are generally larger than females. Size varies among the different subspecies of *C. minor, C. m. minor,* and *C. m. nasicornis* being the largest. The plumage is entirely white; the animal is also marked by a stout conical bill, strong legs, and unwebbed feet. It has a gait recalling both the pigeon and domestic fowl. Sheathbills typically walk and can run fast but are usually reluctant to fly. In flight, sheathbills display broad wings and fast wingbeats.

The *C. alba* has dark grey legs, pale pinkish facial caruncles, a yellowish-horn bill and a greenish-yellowish-horn sheath (but bill tip and ridge on upper mandible are brownish). Among *C. minor,* leg colour varies among subspecies, from pink to blackish. It displays black caruncles on lores and sides of upper mandible (also at the base of lower mandible and on chin in *crozettensis* and *marionensis,* which also have a small head crest), a black bill, and a slaty blackish grey sheath. Both species have a pink orbital circle, a brown iris, black claws, and a black, blunt, carpal spur (sometimes two in *C. m. crozettensis*). Juveniles have very small or no caruncles, no head crest, and a less prominent sheath, and they utter feeble, shrill, and cheeping calls, contrasting with the strong stacatto calls of adults.

General Description of Population Status

The sheathbill is not globally threatened. *C. alba* is monotypic and occurs from Antarctic Peninsula to 34° S; its estimated population is about 10,000 pairs. *C. minor* is present at only four sub-Antarctic localities in the Indian Ocean, each locality holding an endemic subspecies: Prince Edward Islands (*marionensis,* c. 4300 individuals, including 1400 pairs) where the population is decreasing due to competition for food (terrestrial invertebrates) with introduced mice *Mus musculus* during the winter; Îles Crozet (*crozettensis,* 1000 pairs); Îles Kerguelen (*minor,* 3000–6000 pairs), and Heard Island (*nasicornis,* estimated 1000 pairs). Population estimates at the latter three localities lack any accuracy. The sheathbill's habitats include shores, especially seabird (penguin and cormorant) colonies, occasionally southern elephant seal *Mirounga leonina* colonies when females give birth to their pups; they do not generally venture far inland. Sheathbills cannot breed without access to a seabird colony, except at Îles Kerguelen where the presence of an extensive intertidal zone on some islands provides pairs with sufficient alternative food.

Life History

C. alba breeds from South Georgia to the Antarctic Peninsula. The northernmost populations are sedentary, whereas the southernmost ones migrate as far as Patagonia and the Falklands. *C. minor* is sedentary.

At Îles Crozet and Prince Edward Islands, however, many individuals breed among crested penguins *Eudyptes* spp. and move to king penguin *Aptenodytes patagonicus* colonies (where food availability is highest and most predictable) in winter, whereas those breeding among king penguins maintain their territories throughout the year. At Îles Kerguelen, many pairs, including those breeding on seabird-free territories, remain on their territory all year, but some individuals can wander a few tens of kilometers. In both species, laying occurs from early to mid-December until mid-January. Nests are situated under rocky boulders, in caves, crevices, sometimes in abandoned petrel and rabbit burrows (where present), or under human settlements. Clutch size is one to four or five eggs, usually two to three. Eggs are a pale creamy-brown color, with irregular dark brown or olive brown blotches. Incubation is 27–32 days, starting with first egg. Asynchronous hatching takes place. Chicks are semi-precocial, nidicolous, and hatch with mottled brownish down, replaced by dark grey mesoptile at 14 days; they are fully feathered by 7–8 weeks. Chicks of *C. minor* are almost continuously brooded by the parents during the first 2 weeks. Chicks are fledging at 50–70 days, but young often fed by parents for several more weeks. The age at first breeding is 3–7 years *(C. minor)*, breeding attempts at 3 years being scarce and often unsuccessful. Survival rates are as follows: *C. alba*: out of seventy-three adults banded at Signy Island, sixty-six returned the next year. *C. minor* has a high adult annual survival (Prince Edward Island: 0.88, Îles Crozet: 0.85, Kerguelen: 0.894 between 1989 and 2002). Maximum longevity is at least 19 years *(C. minor)*. Breeding frequency is one clutch per year. Replacement clutches may occur on the Prince Edward Islands. When considering individual *C. m. minor* monitored for at least 5 years after their first known breeding attempt, 77% of the breeders in year n that survive until year $n + 1$ will breed in year $n + 1$ (fifty-eight individuals monitored between 1989 and 2002).

Social Structure (Breeding Behaviour, Group Structure)

Sheathbills form long-term, monogamous pair bonds. One female-female pair was observed at Îles Kerguelen. The maximum known pair bond duration is 12 years, observed at Îles Kerguelen. The divorce rate at Îles Kerguelen between 1988–1989 and 2001–2002 was 6.7%, or 15 out of 224 pairs; at Îles Crozet between 1978–1979 and 1987–1988, the rate was 2.4%, or 2 out of 82 pairs; divorce was not observed on Marion Island. Both genders can initiate divorce. Pair mates share parental duties during incubation and chick-rearing. Adults carry food in their bills to chicks, walking from the feeding area to the nest.

Each pair has its territory in which mates breed and, generally, feed. Strong territorial behaviour is associated with intense competition for territories. Îles Kerguelen is the only locality where nonbreeders can possess a territory. Sheathbills exhibit a high year-to-year territory fidelity (87.1% at Kerguelen, n = 550 adult individuals). In king penguin *Aptenodytes patagonicus* colonies, nonbreeders can form groups of "floaters." The social structure is related to food availability and quality in winter, when large flocks can be observed. A great variety of agonistic displays occur.

Diet and Trophic Interactions

Sheathbills forage mostly diurnally, among kleptoparasiting seabirds when the latter are feeding their chicks, to obtain fish and crustaceans, and entering burrows of large petrel species to take their eggs and small chicks. Sheathbills also feed on invertebrates, carrion, faeces, placentae, blood, human wastes, and the milk of female elephant seals when the latter are suckling their pups; on many islands of the Kerguelen archipelago, however, the bulk of the diet appears to be algae. *C. minor* can prey on introduced mice *Mus musculus*.

Other Special Features of the Biology

Winter pairings occur at Îles Crozet, in king penguin colonies. Such pairings enable birds to defend high quality feeding territories. Bonds are disrupted in spring, when birds reunite with their previous breeding partners at the onset of the new breeding season.

SHIRASE, NOBU

Nobu Shirase was born on June 13, 1861, in the small fishing port of Konoura in Akita Prefecture in northeast Japan. As the eldest son of a Buddhist priest, Shirase was expected to follow his father into the priesthood. However, even as a young boy he showed an adventurous spirit, and his interest was caught by the story of the expedition under Sir John Franklin to navigate the Northwest Passage. After months of pestering, his teacher gave him five precepts for an aspiring polar explorer: no alcohol, no tobacco, no tea, no hot drinks of any kind, and never warm yourself at a fire, even in the depths of winter. He also suggested that the army might provide useful mental and physical preparation.

In 1879 Shirase was sent to a Buddhist seminary in Tokyo, but he absconded to join the newly modernised Japanese Army. Posted to Sendai in northern Japan, he had transferred to the Reserves in order to mount a private expedition to the sub-Arctic Kuril Islands when he learnt that Lieutenant Gunji of the Imperial Navy was about to establish a colony there. He persuaded Gunji to take him on despite his army connections and spent from 1893 to 1895 in the northern Kurils. Many of the would-be colonists died, and on his return Shirase wrote a book that was highly critical of the expedition's leader, starting a rift that later almost brought an end to his own Antarctic ambitions.

In the Russo-Japanese War of 1904–1905, Shirase was a reserve second lieutenant in the Medical Corps. He participated in a number of battles, was wounded, decorated, and put in charge of transporting his division back to Japan at the end of hostilities.

By 1909 he was planning an expedition to the North Pole, but on learning of Frederick Cook's and then Robert E. Peary's claims to have attained that point, he, like Roald Amundsen in Norway, turned his attention to Antarctica. In 1910 his sincerity and determination secured the backing of two great men of the Meiji period, General Maresuke Nogi and Count Shigenobu Okuma, and the Antarctic expedition captured the imagination of the Japanese public, eager to show that anything the West could do, Japan could do too. The expedition was funded entirely by private donations and through a public subscription campaign organised by the popular press.

Shirase fought off attempts to postpone the expedition for a year, and when the first attempt to land in Antarctica failed he opted to remain in Sydney with his men to ensure that they would be given another chance. Their successful second effort in the far south vindicated his decisions. They landed on the Ross Ice Shelf, explored, and all returned alive and well to a hero's welcome.

Although the 1910–1912 Japanese Antarctic expedition itself was Shirase's major achievement, he was an honourable man, ensuring by years of poverty and hard work that the expedition's remaining debts were paid by 1935. Two monuments to the expedition were erected in his lifetime, but in the confused and hungry period at the end of WWII, he died in obscurity, aged 85, on September 4, 1946.

SIPLE, PAUL

Polar explorer and geographer Paul Allman Siple (born December 18, 1908, in Montpelier, Ohio) capped a long career in Antarctica, to which he made six expeditions, by leading the first group of eighteen men, and a malemute-husky named Bravo, to live at the South Pole in 1957–1958.

Siple first went to Antarctica in 1928, when he was only 19 years old, as a member of Richard E. Byrd's first Antarctic expedition. Siple was chosen from among 60,000 Boy Scouts of America who applied for the position, and although he was the youngest man on the expedition, he earned the respect of Byrd and his fellow expedition members through his dedication and hard work. His duties included caring for the team's huskies and collecting and mounting seal and penguin specimens.

Upon his return to the United States, Siple earned his BS in biology from Allegheny College in 1932, and later earned a doctorate in geography from Clark University. In 1933, he returned to Antarctica as chief biologist with the Byrd's second Antarctic expedition. He also directed the construction of Advance Base 100 miles south of Little America (at which Byrd spent 5 months alone) and led a group that explored Marie Byrd Land, east of Little America.

On the US Antarctic Service Expedition of 1939–1941, Siple was the leader of West Base, known as Little America III, located at the Bay of Whales on the Ross Ice Shelf, and was the navigator on exploration flights over the continent. He also devised, with Charles Passel, the windchill index to measure the cooling effects of moving air on the human body.

During World War II, Siple served in the US Army Quartermaster Corps and performed research on clothing for polar and tropical climates. He was the Army's senior observer on Operation Highjump (also known as the US Navy Developments Project) of 1946–1947, and returned to Antarctica two more times, in 1955–1956 with Operation Deep Freeze, and in 1957–1958 for the International Geophysical Year (IGY).

At Byrd's personal insistence, Siple served as scientific leader of the US station at the South Pole during the IGY. Although the divided command structure, with a scientific leader and a military leader, could have been problematic, Siple's long polar experience and his large capacity for labor, despite being the oldest member of the team, helped ensure a harmonious year. Lieutenant John Tuck, the base's military leader, wrote in the foreword to *90° South:* "It was leadership by leading, not pushing." The group not only proved that it was possible to survive a winter at the South Pole but also investigated the area's weather and ionosphere as well as the snow layers beneath the base.

When Siple died in his office in Arlington, Virginia, on November 25, 1968, he had spent more cumulative time in Antarctica than anyone before. "Once you've been here," he told a reporter in Antarctica, "there's something a little special about you—everyone feels it, and so do you."

SKUAS: OVERVIEW

The skuas are seabirds in the family Stercorariidae, closely related to the gulls. The smaller skuas are called jaegers in North America. In the Southern Hemisphere, there are three species: the South Polar skua *Catharacta maccormicki,* the Chilean skua *C. chilensis,* and the brown skua "group" comprising the Tristan skua *C. antarctica hamiltoni,* the Falkland skua *C. antarctica antarctica,* and the Subantarctic or brown skua *C. antarctica lonnbergi*. In the Northern Hemisphere, there are four species, the great skua *C. skua,* and three smaller *Stercorarius* species, the Arctic skua or parasitic jaeger, *S. parasiticus,* the pomarine skua or jaeger *S. pomarinus,* and the long-tailed skua or jaeger *S. longicaudus,* with the two subspecies *S.l. longicaudus* and *S.l. pallescens*. There are three species of jaegers, which are quite distinct. No such certainty exists for the great skuas, which are all rather similar. Hybridisation between Subantarctic and South Polar skuas occurs along the Antarctic Peninsula and nearby islands, and at Dumont d'Urville in East Antarctica, between Chilean and Falkland skuas in Patagonia, and between Chilean and South Polar skua on the South Shetland Islands.

Skuas are in general medium-sized to large birds, typically with brown or grey plumage. They have conspicuous white patches at the base of their flight feathers, wedge-shaped tails, a mostly black, heavy bill with a hooked tip, and webbed feet with sharp claws. In appearance, skuas look like immature gulls, although heavier and more robust. Their flight is usually heavy, with much flapping and relatively little gliding. In the past, two groups of skuas were recognised: the large skuas—big, heavy, brown birds, with several species in the Southern Hemisphere and one on North Atlantic islands, and the small skuas or jaegers—smaller, lighter, often with patterned and barred plumage and, when breeding, long tail feathers. The skuas and jaegers show variation in plumage in three circumstances: adults exhibit breeding and nonbreeding plumages, young birds take several years to achieve adult plumage, and polymorphism—there are dark and light adult morphs of the same species. It is relatively difficult to identify the large skuas of the Southern Hemisphere. They are all closely related and very variable, and they are all oceanic between the time they leave the natal colony as juveniles and their return as adult birds to their breeding grounds. The taxonomy of the brown skua "group" is uncertain, and different authorities follow different taxonomies.

The South Polar skua is smaller than other southern skuas, and has a smaller head, a flatter crown, shorter legs, and a shorter (black) bill. The body mass ranges between 0.7–1.7 kg. With their narrower and relatively longer wings, these birds appear less heavy in flight than many other species. They are polymorphic and highly variable, with light (cream), brownish, or blackish-brown plumage. The pale (and intermediate) morphs have a pale head and underparts, a greyish creamy-brown or buffy-cream (to medium or dark cold brown) colour, but the wings and the rest of the upperparts are very dark. The nape is streaked with light colour and buff forming a large patch with golden hackles in summer. The dark morphs are entirely sooty blackish-brown with a darker face and upperparts. In the breeding season, they also have golden hackles on the nape. Juveniles of all morphs look like intermediate morphs: they are greyish with dusky-brown upperparts, a black-tipped grey bill and greyish legs. They have no neck patch.

Tristan skuas (body mass 1.2–1.8 kg) are generally brownish, gull-like skuas with bold white flashes on the primaries visible in flight. Their appearance seems to be intermediate between brown and Falkland skuas. They are smaller than brown skuas but have relatively longer legs and a longer bill. The adults have a uniform dark brown head and neck, intermediate between Falkland and brown skuas. Juveniles, which are also generally intermediate between brown and Falkland skuas, are dark brown all over with a slightly darker hood. The underparts are a warmer reddish-brown, and the upperwing coverts are buffy-rufous in colour.

The Falkland skua is similar to brown and Tristan skuas but smaller and slighter with proportionally longer legs and stronger bill in relation to a more rounded head shape. This species looks intermediate between the great skua and the brown skua but closer to the former in shape and general plumage. The adults are quite variable in colouring but often have a contrasting darker cap and numerous streaks on the neck and breast. The mantle and upperwing-coverts have nearly no pale streaks, but the flanks and breast are streaked. Juveniles are principally dark brown, with a darker hood.

The brown skua is larger and heavier than all other forms, with proportionally shorter legs, a smaller head, and a more powerful bill. The neck looks very thick. The head of adults is generally dark, but the degree of pigmentation varies, and sometimes the crown is dusky and there are yellow streaks on the nape of the neck. The plumage is variable; the base colour is brownish, ranging from a deep chocolate brown to fairly light brown. The underparts are generally lighter than the upperparts. One important feature is pale streaks on the mantle and upperwing-coverts. Juveniles are uniformly dark chocolate brown. The underparts are buffish-cinnamon. Brown skuas fly fast, with fairly rapid powerful wingbeats, and they can be extremely agile.

Chilean skuas, compared to the brown skua group, are smaller and slighter, with a proportionally less powerful bill, narrower wings, and slimmer tail, body and neck. Most of the adults are characterised by a blackish-brown cap contrasting with the paler neck and body. They have light cinnamon underparts (including the underwing-coverts). A blue bill with a dark tip is an additional feature that contrasts with other skua species. The neck and mantle are streaked with cinnamon. Juveniles are generally much more uniform in colouring, with more intensive cinnamon colouration of the underparts.

The *Stercorarius* skuas or jaegers are generally a small or medium-sized species, different from the much larger, mostly brown, *Catharacta* species. They are lightly built skuas, and most are typically fast flyers on long wings. The flight is relaxed and elegant with powerful wingbeats. From afar, they appear dark with extensive grey-brown patches. In adults, the middle tail feathers are prolonged in breeding plumage. In the Antarctic, birds with winter plumage are seen, and species determination requires very careful observation of the diagnostic species-specific differences.

The pomarine skua or jaeger is the largest *Stercorarius,* heavier, longer winged, and with more direct flight than other species. There are pale and dark adult morphs. The pale patch on the primaries is similar to, or bigger than, that in Arctic skuas but narrower than that in *Catharacta* species. In the Antarctic summer, the period in which they have sometimes been observed in the far south, the characteristic long and broad oval-ended tail streamers are absent. The bill is yellowish/greyish-brown with a black tip. The light morph looks almost dark dorsally and has a dusky breast band on whitish underparts. The dark phase has whitish wing patches but is otherwise browner than during breeding plumage. The juveniles and immatures, mostly barred on the underparts, are more difficult to distinguish from those of the other two species.

The Arctic skua or parasitic jaeger, is a medium-sized, dark-looking seabird with long narrow wings that are completely dark, and pale patches at the wingtips. Its elegant flight shows falcon-like wing beats. There are two phases, a dark and a predominant pale one. In the southern summer, the characteristic long, narrow tapering tail-streamers are almost entirely absent, but these are partially regrown by February/March. Arctic skuas have a blackish grey-brown bill. Light morphs have a pale rump, whereas dark morphs are entirely sooty-brown except for the whitish wing patches. In the southern summer, they look less uniformly coloured on the body and appear variably light barred.

The long-tailed skua or jaeger is the smallest *Stercorarius* species and, especially in flight, is slighter, more slender-bodied, and narrower-winged than other species. The flight is ternlike and appears relaxed. During the breeding season, the birds have remarkably long tail feathers. The adults are variable in coloration and, unlike other *Stercorarius,* they have no pale primary patches under the wings. Light coloration is restricted to whitish shafts of the outermost primaries. In the southern summer, the long tail streamers are almost lacking, but they begin growing at the end of the summer. During this time, the blackish cap is less solid, and they have a dusky breast band and barred flanks.

The *Stercorarius* skuas all breed in the Arctic and migrate to the Southern Ocean after breeding. Arctic skuas are circumpolar breeders on the Arctic tundra, coastal areas and islands, sometimes in small colonies. In March to May and August to November, they migrate to the Southern Hemisphere. In the southern summer, some individuals reach Antarctic waters as far as 65° S.

Long-tailed skuas are circumpolar breeders in the Arctic tundra and coastal mountains. They disperse and are found over all the World's oceans in March to May and August to November. In the southern summer, they reach the overwintering oceanic areas around southern Africa, near the Patagonian coast, and in the South Pacific Ocean. During this period, individuals have been observed in Antarctic waters (reaching 70° S) more often than other *Stercorarius* species.

Pomarine skuas have an almost circumpolar distribution and breed in Arctic tundra, shore areas, and coastal mountains. Outside the breeding season, they migrate over all the World's oceans in March to May and August to November to reach the wintering areas near northwest South America, the western Atlantic Ocean, and west Africa. The wintering areas are more northerly than those of the two other species, as only a few have ever been observed in Antarctica.

All large skua (genus *Catharacta*), with the exception of the great skua in the North Atlantic Ocean, have their breeding range in the Southern Hemisphere. The South Polar skua (5000–8000 estimated breeding pairs) breeds on the Antarctic coast and on a few islands at the northern tip of the Antarctic Peninsula. Falkland skuas breed on the Falkland Islands (5000–9000 breeding pairs) and the Patagonian coast. Brown skuas have a circum-Antarctic distribution while breeding, mainly on sub-Antarctic islands and on islands in the Antarctic Peninsula region. This distribution is partly sympatric with that of the South Polar skua. Tristan skuas breed only on Tristan da Cunha and Gough Island (2500 breeding pairs). The breeding range of Chilean skuas is in southern Chile and southern Argentina (several thousand breeding pairs), but the number of birds observed in the Antarctic Peninsula region is presently increasing.

Skuas use marine habitats most of the year, especially when not breeding. Long-tailed skuas are more oceanic, especially in winter, whereas great skuas use areas over the continental shelf. Arctic skuas migrate and overwinter not far from coasts. Chilean skuas winter in the channels, straits and fjords of southern Chile and Argentina. The wintering areas for different species range from sub-Antarctic areas for long-tailed and brown skuas to tropical oceans for pomarine skuas. Only some of the most northerly distributed subspecies of the brown skua group on sub-Antarctic islands remain at their breeding sites over winter, feeding on winter-breeding birds and visiting seabirds.

Antarctic skuas breed during the summer months. South Polar skuas arrive at their breeding colonies in late October to mid-December, depending on latitude. Most skuas show high site fidelity and are monogamous. An exception is that some female brown skuas breed with two males, forming breeding trios. Breeding pairs renew the pair bond after returning to the territory that they used in former years. Few birds lose their partner over winter, since adult survival is very high. After courtship, one or more nest scrapes are formed and the eggs are laid in one of them in December or January. The eggs are mottled, and usually the two are laid 2 days apart, although there is sometimes only one egg. If eggs are lost, they are usually replaced by replacement laying. Breeding skuas are highly territorial and will attack unwelcome intruders (including humans) by flying straight at their heads, claws outstretched. Incubation begins with the first egg, and the chicks hatch asynchronously after 29–30 days. In the South Polar skua, lethal sibling aggression is common and results in brood reduction from two hatchlings to a single chick. The first chick to hatch attacks the second within a day or two of its hatching and either chases it from the nest area or maims it so severely that it dies. Young birds are fully fledged by early February and are capable of flight within 35–40 days of hatching. In relation to other seabirds, the breeding success is relatively high but very variable. It depends not only on variations in the amount of food but also on the weather. Fledged skuas tend to return to the natal area after some years but until then remain in the wintering areas throughout the year. Skuas are long-lived, with a 34-year-old skua known.

Skuas are primarily predatory or kleptoparasitic in their foraging behaviours. When attacked by a skua, other birds will often drop or regurgitate their food that the pursuing skua then seizes and consumes. Tundra-nesting *Stercorarius* skuas feed on small mammals, especially lemmings, but also on small birds including waders, eggs, carrion, insects and sometimes berries. The exact combination of items taken differs among species. *Catharacta* skuas are an opportunistic species, preying mostly on marine invertebrates and fish in winter, and on birds in the breeding season. Brown skuas are the main predators of penguins and other seabirds, mostly during the daytime. However, they will also hunt at night for burrowing nesting petrels because these are inactive in the colonies during the daytime. South Polar skuas mainly eat fish, which are often obtained by robbing other seabird species.

SNOW BIOGENIC PROCESSES

The Antarctic ice sheet records present and past biological activity through the presence of biochemical markers and life particles (bacteria, viruses, microalgae) incorporated in the snow. Since biological activity in the snow is believed low, the biomarkers are mainly related to biological activity in the Southern Ocean (SO), whose proxies are transferred to the snow by wet and dry deposition. Antarctic ecosystems show two peculiar features: the role of sea ice in controlling the phytoplankton seasonal pattern and the possible preservation of ancient microbic life in fossil ice and subglacial lakes.

Southern Ocean Relevance

The SO is an important sink for atmospheric CO_2, at least during phytoplankton blooms. Mechanisms governing vertical stability and thermohaline circulation make the SO sensitive to climate change, with consequences for CO_2 regulation. The seasonal sea-ice cover (20 million km^2 in winter) inhibits gaseous ocean/atmosphere exchange, but the growth of sea-ice microbial communities has important implications for carbon, sulphur, and nitrogen cycles. Microphytoplankton, predominantly diatoms, contribute much of the SO primary production, especially in frontal and neritic areas and at the ice edge. However, nanoplankton and picoplankton dominate in some areas and seasons. In the Polar Frontal Zone (PFZ), and in the Marginal Ice Zone (MIZ) in winter, biomass and productivity are low, nutrient concentrations are high, and aqueous CO_2 concentrations exceed atmospheric concentrations. Only zooplankton, mainly krill and large copepods, are abundant and active under the ice and between ice floes. In spring, phytoplankton blooms involve different species assemblages; in the PFZ, diatom *Corethron* spp. and *Fragilariopsis kerguelensis* dominate. Bacterial biomass follows phytoplanktonic development. Grazing by zooplankton (mainly copepods and *Salpa thompsoni*) impacts phytoplankton production. In the MIZ, the seasonal pattern of biological and biogeochemical processes is dominated by changes in sea-ice cover, which influence the ocean-atmosphere fluxes of heat and materials and modify underwater illumination. When ice melts, the superficial low-salinity water prevents vertical mixing, enhancing the nutrient availability and leading to ice-edge phytoplankton blooms. The MIZ might contribute as much as 40% of the SO total photoautotrophic carbon fixation. Large-celled diatoms in open water conditions dominate phytoplankton, whereas small algae, mainly flagellates, prevail under the ice. Phytoplankton biomass concentration exceeds 7 mg Chl *a* per m^3 in the bloom, which comprises large centric diatoms together with *Phaeocystis*. In coastal Weddell Sea areas, *Eucampia balaustium, Trichotoxon reinboldii, Chaetoceros dichaeta,* and *Phaeocystis* spp. are dominant. Grazing pressure (protozoan species such as oligotrich ciliates and dinoflagellates, and smaller zooplankton dominated by copepods) is very high during the phytoplankton bloom.

Iron Hypothesis

The SO is the major high-nutrient, low-chlorophyll (HNLC) oceanic region, where low annual primary production occurs although efficient vertical mixing supplies high-nutrient concentrations. Here, the lack of oligo-elements or micronutrients constitutes a limiting factor for the phytoplankton growth. Fe may play a relevant role in controlling primary productivity in HNLC areas and, subsequently, in atmospheric CO_2 uptake, as shown by seawater iron-enrichment experiments where small amounts of Fe sped up the growth of large-celled diatoms (e.g., Nitzchia). Fe availability in superficial seawater potentially affects the climate by controlling the biogenic emissions (which rule cloud formation) and the greenhouse-gas global balance. In glacial periods, when higher dust atmospheric loads occurred, larger deposition of Fe on the ocean surface could have increased the phytoplankton activity, contributing to lower atmospheric CO_2 concentrations. Fe, dust, methanesulphonic acid (MSA), and CO_2 measurements are currently carried out on ice cores to assess the correlations between mineral supply, paleoproductivity, and greenhouse gases.

Biogeochemical Cycles

Several chemical compounds are measured in ice cores to reconstruct the oceanic biological activity and its relationship with climate.

CH_4 and volatile organic compounds (VOCs) dominate the sea-atmosphere-snow C-cycle. Atmospheric CH_4 mainly arises from microbial breakdown of organic compounds in anaerobic conditions, such as in SO anoxic seawater layers and sediments. A large range of VOCs (hydrocarbons, alcohols, carbonyls, carboxylic acids, fatty acids, and esters) is produced in surface seawater by photochemical mechanisms, phytoplankton activity, and/or microbial breakdown of organic matter, so showing a strong seasonal pattern. The ocean-atmosphere flux is dominated by alkenes and is small compared to terrestrial emissions (<1%). While VOCs are rarely measured in Antarctic ice cores, CH_4 in ice air-bubbles is used in understanding the greenhouse gas–climate correlations, in reconstructing the past wetland extension and in synchronising ice-core time scales.

NH_3 is the dominant gas-phase alkaline compound in the marine atmosphere and is produced in seawater and sediments by degradation of organic nitrogen-containing compounds. Penguin colonies constitute a major source of NH_3 in coastal regions, via microbial breakdown of urea and uric acid in animal waste. Atmospheric NH_3 reacts with nitric and sulphuric acids to give ammonium salts, which are scavenged to the ice sheet by wet deposition. High-resolution ice-core NH_4^+ stratigraphies are used in reconstructing past biogenic activity in oceans and wetlands around Antarctica.

Biogenic dimethylsulphide (DMS) is the main volatile sulphur compound in oceanic remote regions. Atmospheric DMS is oxidised to H_2SO_4 and MSA, which act as Cloud Condensation Nuclei (CCN), affecting cloud albedo, the hydrological cycle and, consequently, the climate. Large-scale climate changes, in turn, influence the phytoplankton productivity, completing a feedback loop. However, the spatial correlation between DMS and phytoplankton concentrations is not straightforward because intracellular concentration of its metabolic precursor, dimethylsulphoniopropionate (DMSP), in different phytoplankton species varies over a range of five orders of magnitude. Very high DMS and DMSP concentrations have been measured at high latitudes, especially during phytoplankton blooms of coccolithofore *Emiliania huxleyi* and prymnesiophyte *Phaeocystis pouchetii*. Diatoms are less important DMS producers. DMSP lyase enzymes, present in some phytoplankton species, increase the DMS emissions. Zooplankton plays a role by grazing, or avoiding, DMSP-rich cells. Bacteria can metabolise DMSP through different pathways, decreasing DMS production. Viral infections can cause a total release of intracellular DMSP in species such as *Emiliania huxleyi* and *Phaeocystis* sp. Several physical-chemical parameters (solar radiation, vertical mixing, temperature, sea-ice cover) affect the sea-atmospheric DMS exchanges (10–50 Tg S yr^{-1}). Atmospheric DMS oxidation pathways to form non-sea-salt sulphate ($nssSO_4^{2-}$) and MSA are complex, and relative yields are influenced by temperature and latitude.

MSA and $nssSO_4^{2-}$ ice-core stratigraphies potentially allow us to reconstruct past phytoplanktonic activity. Unfortunately MSA, univocally originated from DMS, is affected by post-depositional processes, which make difficult the interpretation of its temporal changes in low accumulation-rate sites. Where preserved, MSA is correlated with sea ice cover, southern atmospheric circulation, and phytoplanktonic activity. During the sea ice buildup, impurities and nutrients are excluded from the ice latex and incorporated in the pack interstitial spaces (brine pockets). In winter, different algae assemblages survive in brine pockets protecting itself against the high salinity and the low temperatures by producing intracellular DMSP, which is an osmolyte and a cryoprotectant. DMSP is excreted out from the cells when they experience a much lower salinity due to the sea ice melting in spring. In addition, the low-salinity layer stratification concentrates the nutrients coming from sea-ice melting and, together with the increasing solar radiation, primes the phytoplanktonic blooms. Ice-core measurements revealed higher MSA and $nssSO_4^{2-}$ concentrations in glacial periods, suggesting higher phytoplankton productivity occurred; however, recent measurements at Dome C revealed that $nssSO_4^{2-}$ fluxes were quite constant at least in the last 45 kyr.

Subglacial Lakes

Subglacial lakes constitute a peculiar Antarctic feature. The unique extreme characteristics of Lake Vostok (–3.2°C, 400-bar pressure, absence of light, possible absence of oxygen, unknown conditions of salinity, nutrient concentration, and energy sources) evolved for millions of years in almost total isolation from the biosphere. The presence of autochthonous microorganism and the preservation of ancient life species appears to be plausible, as well as the slow (about 1-million-year) sinking of living species from the outer atmosphere through the ice column. Preliminary studies show the presence of 10^3–10^4 bacterial cells/cm^3 of Actinomyces in glacial ice under Vostok and estimate that the Antarctic subglacial lakes and ice sheet contain 1.2×10^{25} – 8.8×10^{25} prokaryotic cells, corresponding to a total bacterial carbon content of 2.8×10^{-3} Pg C. This value approaches that reported for Earth's combined lakes and rivers, making the icy systems of Antarctic a significant organic carbon reservoir. Taxonomic analysis by molecular techniques showed that the largest number of the sequences belong to Proteobacteria α and β (*Acidovorax* and *Comamonas*). Subglacial lake studies have relevance in understanding the adaptation mechanisms to extreme life environments and in refining noncontaining methods for extraterrestrial sub-ice explorations (Europe, Jupiter's satellite).

SNOW CHEMISTRY

Accumulating snow strata faithfully record the local atmospheric aerosol composition. On the other hand, gases are entrapped in ice bubbles formed far below the snow surface (up to 1–2 millennia later) when firn transforms into ice. Most atmospheric particulate impurities are incorporated in the snowflakes at cloud level. However, due to the penetration of air into surface snow (an effect called wind pumping), the filtering of atmospheric particles by porous snow is suspected to be responsible for an additional "dry" contribution to impurity deposition, particularly in central regions where accumulation rates are extremely low (<5 g/cm^2/yr). The deposition mechanism of HCHO (formaldehyde), acid gases like, HCl, HNO_3, methanesulfonic acid (MSA), and carboxylic acids is more complex. The incorporation of these compounds in snow is reversible, and in central regions, due to low accumulation rates, they partially return to the free atmosphere during firnification.

Analytical methods used in glaciochemistry (the study of polar snow chemistry) are derived from rain analysis, with many additional precautions required by the extreme cleanliness of polar precipitation. For soluble ionic species, ion chromatography is commonly used. Insoluble materials are generally analysed by microparticle counting, Inductively Coupled Plasma Mass Spectrometry (ICP-MS) or Atomic Absorption.

Antarctica is surrounded by large ocean surfaces. It is therefore not surprising that the chemical composition of snow is typical of a marine region, with an important contribution of sea salt and secondary aerosol derived from gaseous sulphur species emitted by marine biogenic activity. Coastal regions are strongly influenced by the marine boundary layer, with a high concentration of sea salt in the air and in the snow, whereas the high central Antarctic plateau is more influenced by the middle free troposphere where the impurity content is extremely weak. Sea salt concentration in Antarctic snow decreases rapidly with elevation. Its composition may be modified (in particular the Cl/Na ratio) by post-deposition processes. The amount of continental dust is extremely weak everywhere on this continent (less than 10% of total mass deposition).

Regional volcanic eruptions may form ash deposits at the surface of the ice sheet, but such events are not frequent. On the other hand, cataclysmic volcanic eruptions located at midsouthern or tropical latitudes inject gaseous sulphur compounds into the stratosphere. Such eruptions are recorded in Antarctic snow by sulphuric acid spikes of 1–2 year duration. The background level of sulphate in the snow is linked to marine biogenic activity (dimethylsulfide, or DMS, emissions by zooplankton), as at other latitudes around the world. Its typical concentration in the snow is 1–3 μ Equivalent/l. The second important sulphur species is MSA. It is directly related to oceanic DMS emissions, but the information recorded in Antarctic snow is frequently plagued by post-deposition effects.

There is still a debate concerning the origin of nitric acid, the major nitrogen species found in Antarctic snow. Photochemical reactions in surface snow, detected only recently, may change initial nitrate concentrations, but the most important perturbation in central regions is caused by the firnification process. Organic compounds, in particular carboxylic acids, are interesting atmospheric chemistry markers, but their study in Antarctic snow is still in its infancy.

Concentrations of the various chemical compounds vary as a function of depth in relation to seasons and global and regional climate. Their study along ice cores provides information on the environmental conditions of the past.

SNOW PETREL

Snow petrels (*Pagodroma nivea,* the smallest member of the petrel family Fulmarinae) nest in coastal and inland regions of Antarctica (up to 440 km inland from the coast) including the Antarctic Peninsula but also in South Georgia, islands of the Scotia Arc, Bouvetøya, Balleny and Scott Islands. This species is highly associated with snow and sea ice in its habitat use and in its name, for *pagos* is the Greek for ice, and *niveus* is the Latin for snowy.

Snow petrels are medium-sized, all-white petrels with contrasting black eye, and a bill that is blue-black. The legs and feet are also blue-black. Compared with most petrels, the flight involves little gliding, and the birds fly among the pack ice and icebergs with shallow wing beats. Their white plumage, specialised for life in the high-polar habitats and buoyant flight make the snow petrel the ecological counterpart of the ivory gull *Pagophila eburnean* in the Arctic. A peculiarity of snow petrels is the great body size range among individuals and the great sexual dimorphism. The largest individuals are c. 50% heavier than the smallest. Although snow petrels have been divided into two subspecies based on body size differences, there is no consensus on their validity since some colonies have varying proportions of small and large birds. It has been suggested that the larger form evolved around the Balleny Islands, and a smaller form around the Scotia Sea during the Pleistocene, and that in today’s climate the two forms have spread from their respective refugia and hybridize at several localities. Today, several selective forces, such as predation by South Polar skuas *Catharacta maccormicki,* shape the proportions of small and large individuals within populations.

The size of the world population is poorly known. Although the at-sea estimates include around 2 million individuals in the Ross Sea and 1.7 million in Prydz Bay, counts at known breeding localities total only 63,000 pairs. This marked mismatch suggests that many breeding localities remain to be discovered on ice-free coastal areas but probably also on inland nunataks at substantial distances from the Antarctic coast.

Because of the relatively small size of snow petrels, which prevents their tracking with satellite tags, and makes it difficult to observe the behavior of individuals in their natural habitat (pack ice), the at-sea feeding behavior is poorly known. Snow petrels usually feed in the vicinity of the ice, especially where ice cover is 10%–50%, finding food in the leads between the pack ice and around icebergs. Most individuals were observed feeding by dipping, surface-seizing, and surface diving. They take mainly fish, but also crustaceans and cephalopods, with the proportions varying with season and location.

Snow petrels breed during the short Antarctic summer, usually in colonies of tens to hundreds of pairs. The largest known colony has c. 20,000 pairs. Snow petrels return to their traditional nesting sites in late October or early November. Nests are in crevices on cliffs or steep slopes and are sparsely lined with small pebbles, bones, and feathers. Competition to obtain a nest not obstructed by ice is high, and nest entrances may be surrounded by solidified oil (wax spat against intruders to protect the nest) accumulated over centuries or longer. Once at the breeding sites, laying occurs during the first 2 weeks of December, after a prelaying exodus at sea of nearly 20 days, and is highly synchronized and similar at most sites. Incubation is approximately 44 days. Male and female share the incubation duties and alternatively incubate the egg and forage at sea in approximately 8-day shifts. Once hatched, the chick is brooded by the parents for 4–7 days and then left unattended until fledging. During the chick-rearing period parents make foraging trips of 40–70 hours in average. The chick period lasts approximately 47 days, and most chicks leave the colonies by late February or early March. As for the other fulmarine petrels, snow petrel chicks grow at a considerable rate, about twice as fast as predicted allometrically.

Adults breed in only 52% of seasons during their reproductive lifetime, and half of the eggs laid fledge a chick on average. The percentage of fledged chicks increases when air temperatures in spring are higher than average, and the proportion of eggs hatched is higher when females are in good physical body condition. Because of the high competition to obtain an unfrozen nest site, nest and mate fidelity are very high (c. 90%). After fledging, individuals stay at sea for several years and the average age at first breeding approaches 9–10 years. The annual adult survivorship is high, (95% for males, 94% for females). After winters with greater sea ice extent and cover, the number of breeding pairs and the proportion of breeding adults in a colony may increase.

SNOW POST-DEPOSITIONAL PROCESSES

Firn is the porous and permeable layer of compact snow encountered on top of polar ice sheets. It represents the interface between the atmosphere and the impermeable ice strata where atmospheric gases are permanently encapsulated and thus plays an important role in the formation of polar environmental archives. Its thickness is typically 50–120 m, depending on local temperature conditions and the snow accumulation rate.

Recent measurements in the high Arctic have revealed that photochemical processes may occur within surface snow in summer, leading to high levels of NOx (NO + NO_2) and formaldehyde (HCHO) in the interstitial air of snow. These reactions, probably also present in Antarctic snow, may have a significant impact on the tropospheric ozone budget of these regions and could change the original HNO_3 or HCHO content of deposited snow. Wind pumping, another phenomenon affecting the upper snow layers, is responsible for dry deposition of atmospheric impurities by air filtering and for the mixing of the upper firn strata (down to 10–15 m) where gas convection is active and exchanges with the free atmosphere are still observed.

Marked chemical changes are observed in the snow layers during firnification, the physical process that turns snow into ice. The transformation can take several decades to centuries. It involves the internal distillation of water vapour and sintering of ice crystals.

After snow deposition and during firnification, gases entrapped in snowflakes at cloud level or eventually formed *in situ* by chemical reactions can be released into the gaseous interstitial phase of firn (initially containing only atmospheric air) and modify its composition. If the release occurs within the convective zone (0–10 m), the final effect is negligible since released gases escape readily to the free atmosphere. However if it occurs deeper, the perturbation can be significant. This process could explain the difficulty of obtaining reliable CO_2 concentration measurements from Greenland ice cores for glacial climatic periods: at that time, carbonate dust reaction with snow acidity produced extra amounts of CO_2, disturbing markedly the air bubble CO_2 content.

The region of open pore space where molecular diffusion and gravitation are dominant extends down to a depth referred to as the close-off depth. Gravitational settling enriches the heavier molecules at the bottom of the stagnant air column whereas diffusion triggers a separation of the molecules according to their diffusivity properties. Therefore the interpretation of gas records from ice cores requires the use of a reliable model quantifying all these physical and chemical processes that affect gas composition (and isotope ratios of several trace gases) along the firn strata.

At extremely low accumulation sites (a<5 g cm^{-2} a^{-1}), the concentrations of Cl and NO_3 ions and methanesulfonate (an indicator of marine biogenic activity in the sub-Antarctic ocean) show a steep decrease in the first 5 m of firn, as opposed to dust and salt particle concentrations that remain far more stable. Post depositional processes affecting the three gases HCl, HNO_3, and methanesulfonic acid cast doubt on the reliability of their records obtained from central Antarctic ice cores as indicators of past atmospheric contents. For the case of Cl (a species associated with sea salt aerosol), this observation indicates that part of this ion is in the form of hydrochloric acid (HCl) and that this gas is released from the ice matrix after deposition. This has an indirect negative consequence regarding the use of the cosmogenic radionuclide ^{36}Cl (half-life 301 Kyr) as a dating tool for deep ice cores.

SOILS

Antarctic soils lie at the extreme end of the global soil spectrum. They occur in an environment where the essential factors for soil formation (available moisture, temperature or climate regime, and biological activity) are at minimal levels; consequently Antarctic soils express the interaction of some of the most extreme terrestrial conditions found on earth. In global terms, Antarctic soils are classed as Cryosols, or soils subject to continuing disturbance by freeze/thaw action. They are also referred to as Cold Desert soils, or Polar Desert soils in the Antarctic Peninsula region where conditions are a little warmer. These terms emphasise that soil formation takes place under the coldest and driest conditions on Earth. A distinguishing feature of Antarctic Cold Desert soils is the absence of a significant organic component, which elsewhere in the world provides the mechanism for recycling nutrients and assisting the chemical decomposition of mineral materials. The two main processes operating in Antarctic soils are salinization, or the accumulation of salts and oxidation, and the slow release of iron oxides.

The severity of Antarctic environmental conditions for soil formation, as well as for the existence and survival of the few organisms that are found, is illustrated by soil climatic data from a station near Lake Vanda (altitude 200 m) in the Dry Valleys. The mean annual air temperature at the recording site is approximately –23°C while surface soil temperatures range from +15°C for a few days in summer to –45°C in winter. In summer, the surface soil temperature fluctuates by up to 15°C daily, with freeze and thaw cycles occurring from mid-November to mid-February, after which the soil remains frozen. During winter, soil temperatures may fluctuate by 35°C with changing weather systems. Below the soil surface, temperatures are much cooler with the thaw depth reaching 35 cm on just a few days. Elsewhere the climate differs markedly from this site, with a warmer climate and soil temperatures in the coastal regions and much colder temperatures in inland valleys and at higher altitudes. The main source of water for soil processes is moisture derived from periodic summer snowfalls. However, much of the snow that falls sublimates, and the small amounts that may enter the soil are usually lost through evaporation within a few days. Soil moisture, an essential requirement for life and geochemical processes, is normally present at low levels and in some Dry Valley soils is less than 1% gravimetric (by weight).

The area of exposed land on the Antarctic continent has been estimated to cover only about 0.3% or approximately 46,000 sq km, the majority of this occurring in the Transantarctic Mountains and Dry Valleys. Most of this land is covered with glacial till, the principle material from which the soils are formed. Antarctic soils have a number of distinctive characteristics. The active layer is that part of the soil that is subject to annual freezing and thawing. In coastal and northern regions, the active layer may exceed 1 m, but the depth decreases with increasing altitude and is less than 10 cm in inland mountain areas. Permafrost, or permanently frozen soil, underlies the active layer and is commonly icy and very hard in the warmer and moister coastal regions but is loose or dry-frozen inland, where colder and more arid soil conditions prevail. The surface of the soil is typically covered with a stone pavement that in the initial stages of soil formation may comprise unstained boulder material left after glacial retreat. Below the ground surface, younger soils are typically loose, unoxidised, olive grey coloured sandy gravel, overlying ice-cemented permafrost. On the oldest land surfaces, the surface boulders are reduced by weathering (abrasion and disaggregation) to form a stone or desert pavement of flattish, oxidised and sometimes polished or pitted pebbles. As the land surface and soil age increase, the subsurface soil colour changes from olive grey to yellowish brown or red, the increasing redness resulting from cumulative oxidation with increasing time. The depth to which oxidation occurs in the soil also increases with time and increasing surface age. Older soils are usually a little more cohesive, contain rocks that are partly decomposed or disaggregated, are dry frozen, and have accumulations of soluble salts. The salts may occur in a distinct layer, 10–15 cm below the soil surface, or as scattered precipitations. They are dominantly chlorides, nitrates, and sulphates of sodium, potassium, calcium, and magnesium. Some of the salts are released through rock weathering but most are derived from the atmosphere, having been transported via the global atmospheric circulation system. Nitrate salts are common in the most arid inland regions, and chlorides and sulphates in the coastal regions, reflecting differing atmospheric pathways. The salts remain in the soil because the climate is arid with evaporation potential exceeding precipitation, and the amount of salt present increases along with soil age.

Biological activity in Antarctic soils is at minimal or very low levels; consequently accumulations of organic matter are scarce. In the Antarctic Peninsula region, small peaty patches are associated with plant occurrences. Elsewhere, the main organic accumulations are pockets of algal matter around ponds, patches of moss, and the more extensive guano deposits at penguin rookeries. Biological legacies are also important sources of carbon.

The clear development pathway of the soil properties with time, allows Antarctic soils to be used as a tool for estimating land surface ages and constructing the glacial history of Antarctica. Correlation of some soils with deposits of 15 my volcanic ash indicates that in places, the soils and land surfaces date from the Miocene period. The preservation of these ancient soils and associated surface features indicate that Antarctic landscapes are very stable and that the soil weathering processes operate extremely slowly.

Because soil development is very slow and there is no vegetative cover or soil structure, Antarctic Cold Desert soils are very fragile. Disturbances and contaminations from most forms of human activities range from very long lasting to permanent. The soils are an important component of the Antarctic terrestrial ecosystem and require careful management.

SOLAR WIND

The solar wind is a supersonically expanding extension of the atmosphere of the Sun, extending out past the planets to form a cavity in the interstellar medium (the Heliosphere). The solar wind originates in the hot corona of the Sun, where temperatures are in the million-degree range. Consequently the material of the solar wind is highly ionised, and so as it expands into space it carries the solar magnetic field with it. The solar wind is thus the agent which carries disturbances in the solar atmosphere out to the Earth and beyond, becoming the driving term for geomagnetic storms and other "space weather" phenomenae.

The first suggestions of a medium carrying magnetic disturbances from the Sun to the Earth were made following the great solar storm of 1859, and between 1888 and 1931 numerous proposals explaining geomagnetic storms in terms of the impact of solar particles on the Earth's magnetic field were put forward. The concept of a continuous, high-speed wind dates from the 1950s, when Biermann suggested that a high-speed electrically neutral outflow of ions and electrons would explain the appearance of comet tails. In 1958 Parker showed that high temperatures in the solar corona would give rise to a continuous supersonic outflow: the existence of this "solar wind" was confirmed in 1962 by measurements from the *Mariner 2* spacecraft.

At periods of minimum solar activity the solar wind is highly bimodal, comprising distinct fast (600–800 km/s) and slow (300–400 km/s) components, with the fast wind filling the majority of the heliosphere and the slow wind confined to within 30° of the solar equator. The slow solar wind is denser than the fast wind by a factor of approximately 3 and is considerably more variable in velocity, density, and composition. The fast wind overlies regions of low density and temperature in the solar corona—"coronal holes"—and it is now generally accepted that it has its origin in these regions of largely open magnetic field. The slow wind, by contrast, lies above brighter corona, and while its average composition indicates an origin in regions that are hotter than coronal holes, the large degree of variability in all parameters suggests that the slow wind may consist of several components with different sources.

During periods of maximum solar activity the situation is very different, with the heliosphere dominated by slow wind. Narrow streams of fast wind may be present at any latitude, so paradoxically the Earth within its magnetosphere is more likely to be bathed in fast wind at solar maximum than at minimum.

Geomagnetic disturbances and aurora on Earth are most likely to be caused by the passage of pressure enhancements in the solar wind. These can be caused by the passage of ejecta from solar eruptions or by compression regions developing on the leading edge of fast streams as the rotation of the Sun carries them under slow flow from longer longitudes (recurrent storms). In either case the disturbance will be more intense if the pressure enhancement is accompanied by a southward deviation of the magnetic field carried out by the solar wind.

SOOTY ALBATROSS

The sooty albatross *(Phoebetria fusca)* is a small and slender dark brown albatross with long narrow wings and a conspicuous white crescent above and behind both eyes. Sooty albatrosses weigh between 2 and 3.5 kg and have a wingspan of 2 m. The bill is slender with a creamy yellow-orange stripe on the lower bill. The legs and feet are a grey-mauve colour. The juveniles and immatures appear broadly similar to the adults, except that the bill stripe and eye ring are a greyer colour.

Sooty albatrosses were listed as Vulnerable in 2000, with this evaluation being revised in 2003 to Endangered on the basis of a 75% decrease in numbers over 90 years (three generations). However, the negative population trends from three sites may require this species be relisted to Critically Endangered if these trends are found to be more widespread.

Sooty albatrosses breed at five island groups in the Indian and Atlantic Oceans. This biennially breeding species is estimated to have an annual breeding population of 12,500 to 19,000 pairs, equivalent to a total breeding population of 42,000 individuals. The largest populations occur on Gough Island and Tristan da Cunha, the Gough Island population decreasing by about half in 28 years. At Marion Island the population has decreased by 25% since 1990, and the Crozet population on Possession Island has decreased by over 50% since 1980. The observed population decrease in the Indian Ocean Crozet population is a result of increases in both adult and juvenile mortality rates, with the adult mortality rates being significantly related to longline fishing effort in the ocean sectors where the birds overlap with fishing operations.

Sooty albatrosses breed on vegetated cliff ledges or steep slopes, their nesting density varying with terrain. The nests are constructed with mud and plant material, and both sexes participate in nest building. The single egg is laid in early October and is incubated alternately by both parents for 10 weeks. The chick hatches in mid-December and is brooded for 3 weeks. Chicks fledge from the nests in May when they are between 5 and 6 months old. Sooty albatrosses are generally biennial breeders with most successful adults returning to breed in the second year after success. Juvenile Sooty albatrosses generally do not return to land until they are at least 8 years of age and do not breed until 12 years.

Sooty albatrosses are dispersive and solitary at sea. During the summer breeding season their oceanic range includes the South Atlantic and southern Indian Oceans, between 35° and 50° S in subtropical and sub-Antarctic waters, particularly in the vicinity of the subtropical convergence. In winter, most sooty albatrosses are observed between 30° and 40° S in the subtropical zone, where immatures remain throughout the year. The diet includes squid, fish, carrion, and crustacea, with the proportions of each varying with location. The few observations of feeding behaviour include prey being seized at the surface, but the morphological similarity of the two *Phoebetria* albatross species would suggest that sooty albatrosses may also be accomplished diving birds.

Sooty albatrosses are known to scavenge behind longline fishing vessels and to be drowned after ingesting the baited hooks. This source of mortality has been recognised as a key threatening process for this species. Sooty albatrosses have previously been harvested for human consumption in the Tristan da Cunha group, but this practice is now illegal, and its occurrence today is considered a rare event. Introduced predators, and possibly disease, have also been identified as threats that impact on this species at their breeding colonies.

SOUTH AFRICA: ANTARCTIC PROGRAM

The Republic of South Africa is one of the twelve original signatories of the Antarctic Treaty and maintains a continuous scientific operation at the base Sanae, located at Vesleskarvet. The sub-Antarctic Prince Edward Islands are South African territory with a continuously manned weather station on Marion Island.

South Africa's contact with the Antarctic region can be traced back to the voyage of the Dutch East Indiaman *Maerseveen* which, after sailing from the Cape of Good Hope in 1663, reported the discovery of two islands in the southern ocean. After more than 100 years the islands were rediscovered and designated the Prince Edward Islands by James Cook in the report of his southern voyages. Until the early twentieth century they were occasionally visited by sealers. The last such activity ceased when the whaling and sealing concession to the South Africa–based sealing company was terminated by the British government in 1934.

South Africa's formal involvement in the region came when the British government transferred control of the islands to the Union of South Africa in 1950. South Africa established a permanent presence in Antarctica in 1959 when the first South African National Antarctic Expedition, led by Hannes La Grange, who had participated in the Commonwealth Trans-Antarctic Expedition, took over Norway Station on the ice shelf (70°30′ S, 2°52′ W) from the Norwegian government. In 1960 the first base Sanae (an acronym from the name of the expedition) was built on the ice shelf. Since that time South African scientific expeditions have overwintered in Antarctica every year except 1996, when the new base under construction at Vesleskarvet was still incomplete and the old Sanae base on the ice shelf was judged to be unsuitable for occupation. Other summer bases used by South African field expeditions include Borga (72°58′ S, 3°48′ W), and Grunehogna (72°02′ S, 2°48′ W).

A succession of three Sanae bases were constructed at a location (70°19′ S, 2°21′ W) on the ice shelf. Each was in turn abandoned as it sank below the surface due to accumulation of snow. In the early 1990s the decision was made to construct a new and elaborate base on the nunatak Vesleskarvet (71°40′ S, 2°51′ W). This was opened at the end of 1997. It is a modern high-tech facility, which has aroused great interest in the Antarctic community. Situated at the top of a 300 m cliff, it commands spectacular views of the Antarctic landscape.

South African Antarctic activities have been the responsibility of government ministries. They were originally managed by the Department of Transport with scientific support from the Council for Scientific and Industrial Research. Responsibility for all activities was transferred to the Department of Environment Affairs in the 1980s. In 2005 the scientific programme was transferred to the National Research Foundation, with logistics remaining with the Department of Environment Affairs and Tourism.

During overwintering the scientific programme has concentrated on the physical sciences (ionospheric and magnetospheric physics, upper atmosphere research, meteorology). There has been an ongoing summer programme in geological exploration on the continent. There is a strong programme in the biological sciences, concentrating on the islands. There is an extensive oceanographic programme undertaken from the research ship *SA Agulhas* and other vessels. The South African National Antarctic Programme is identified as a key area for research the current science policy of the South African Government.

SOUTH GEORGIA

South Georgia is a narrow island, 100 miles (160 km) long and 1.25–20 miles (2–32 km) wide, situated between latitudes 53°56′ and 54°55′ S and longitudes 34°45′ and 38°15′ W. Approximately half its area is covered with ice and permanent snow, and many glaciers run down to the sea. The island is dominated by two mountain ranges, the Allardyce and Salvesen Ranges, with Mount Paget being the highest mountain at 9626 ft (2934 m). The coastline is deeply indented with bays and fjords, especially on the northeast side. There are about twenty small lakes, and numerous streams run down the valleys.

Offshore islands include Bird Island and the Willis Islands off the northwest tip, Cooper Island off the southeast tip, and Annenkov Island off the southwest coast. The four Shag Rocks and Black Rock lie 155 miles (250 km) to the northwest of South Georgia and the Clerke Rocks and Office Boys lie 40 miles (65 km) to the southeast.

The first sighting of South Georgia was in 1675 by the London merchant Antoine de la Roché, whose ship was blown off course while rounding Cape Horn. The second was by the Spanish ship *Léon* in 1756. The first landing was by Captain James Cook, on board *Resolution,* in 1775, during his second circumnavigation of the world. Cook landed in Possession Bay on January 17, and formally took possession in the name of King George III of Great Britain. At first, Cook and his crew thought they had discovered the conjectured Antarctic continent but later realized that they had only found an island.

The British claim to South Georgia was not consolidated until the publication of Letters Patent of July 21, 1908, when it was incorporated with parts of Antarctica as Dependencies of the Falkland Islands. A resident magistrate was appointed in 1909, and a permanent administration established at King Edward Point to oversee the whaling industry. The magistrate was sometimes assisted by a customs officer, a police constable, and other officials. An Argentine counterclaim dates from the late nineteenth century, but the first assertion of sovereignty by an Argentine president came in 1938. Argentina regards South Georgia as part of the territory "Islas del Atlantico Austral" administered from Ushuaia. South Georgia was captured by Argentine forces as a prelude to the invasion of the Falkland Islands in 1982, and they held the island for 22 days. A British army garrison was then maintained at King Edward Point until 2001, when it was replaced by the British Antarctic Survey.

In 1985 South Georgia and the South Sandwich Islands (SGSSI) became a British Overseas Territory, with the Governor of the Falkland Islands as *ex officio* Commissioner. Local administration is conducted by government officers based at King Edward Point, and the commander of the British Antarctic Survey station at King Edward Point acts as magistrate. All of South Georgia is Crown Land. Permits are required by all visitors, including cruise ships and private expeditions. There are no permanent inhabitants, but the British Antarctic Survey operates two permanently manned stations at King Edward Point and Bird Island. The former specializes in fishery research and the latter in the ecology of seabirds. The post office at King Edward Point is open on request, and mail is posted with South Georgia stamps. The South Georgia Museum, which incorporates a gift shop, was established at Grytviken in 1992 and is open all year.

South Georgia lies halfway along the Scotia Arc that runs from South America to the Antarctic Peninsula. When the Atlantic Ocean opened about 200 Ma, an arm of the Pacific Plate pushed eastwards between the South American and Antarctic Plate to form the Scotia Sea bounded by the Scotia Arc. About 35 Ma, the South Sandwich Plate started to move east and dragged South Georgia from Tierra del Fuego. The Salvesen Range has the oldest rocks on South Georgia, which are remains of the Gondwana supercontinent. Much of the remaining rock is shale and sandstone derived from sediments eroded from volcanoes that were active in the neighborhood 140–110 Ma. Fossils are rare and are mostly of marine mollusks.

A harsh climate is due to the island's position in the track of deep atmospheric depressions sweeping through the Drake Passage. The weather is generally wet and windy, but it is variable and can change suddenly to calm and warm. There can also be sudden gusts of hurricane-force winds sweeping down the mountains. The mean annual temperature is +1.8°C, with a winter mean of –1.0°C and a summer mean of +5.0°C. Snow accumulates through the winter but may melt at any time, and there may be frost and snow in the summer. The sea sometimes freezes in bays.

Fauna and Flora

South Georgia's biogeographical significance is that, although it is north of Antarctica (on the equivalent latitude to northern England and Labrador in the Northern Hemisphere), it is south of the Polar Front (previously known as the Antarctic Convergence) and so is bathed by the cold waters of the Southern Ocean. On the other hand, proximity to South America and a milder climate allow temperate plants and invertebrate animals to flourish. South Georgia is particularly noted for the large breeding colonies of seals and seabirds. These feed on an abundance of marine invertebrates, notably krill and squid. It is estimated that the seabird population consumes 7.8 million tons of food each year, of which nearly three-quarters is krill. Krill is carried in currents from the Antarctic Peninsula region and concentrated in an upwelling zone at the edge of the continental shelf off the northeast side of the island. In some years, krill fail to appear around South Georgia and the seal and seabird species that feed on it either fail to breed or suffer a huge mortality of young. There are also long-term decreases in some bird species, which are believed to be due to a decline in the krill population.

There are many colonies of penguins, including those of king, macaroni, gentoo, and chinstrap. Rockhopper and Adélie penguins have nested on occasion. King penguin colonies dominate some beaches on the northeast coast. The breeding population of 200,000 pairs is rising. There are 2.5 million pairs of macaroni penguins, mainly at the northwestern end of the island, but their numbers have decreased by half in the last 30 years. Most flying seabirds belong to the order Procellariiformes and include wandering, black-browed, gray-headed and light-mantled sooty albatrosses, northern and southern giant petrels, and a variety of smaller, burrow-nesting species. The latter include blue petrels, white-chinned petrels, South Georgia and common diving petrels, cape petrels, snow petrels, Wilson's storm petrels, and an estimated 22 million pairs of Antarctic prions. Other seabirds are the South Georgia shag, brown skua, kelp gull, and Antarctic tern. Land birds comprise yellow-billed sheathbill, the endemic South Georgia pipit (the world's most southerly songbird), South Georgia pintail (an endemic subspecies), and a few pairs of yellow-billed teal. Forty-nine species have been recorded as vagrants. Most are seabirds, but barn owl, peregrine falcon, turkey vulture, two species of swallow, and six species of shorebirds have been observed.

Whales gather in the summer months, mainly in the krill-rich zone on the northeast side of the island. They were extremely abundant before the start of Antarctic whaling a century ago, and there are signs that two of the overhunted species, the southern right whale and humpback whale, are recovering. These two species had been extensively hunted at the start of the whaling era because they are slow-moving and frequently feed near the shore. Only male sperm whales are seen around South Georgia, and other toothed whales include southern bottlenose whale and long-finned pilot whale. Killer whales are not common, but they, and sperm whales, have developed the habit of stealing Patagonian toothfish from fishing lines.

The main species of seals are southern elephant seal and Antarctic fur seal, both of which were hunted excessively in the nineteenth century but have now recovered. The fur seals returned from near extinction over the second half of the twentieth century. Breeding colonies are still increasing and spreading along the coastline, and the population now numbers several million. Elephant seals were subjected to a sustainably managed harvest during the first half of the twentieth century, and they now number over half a million. The colony of fewer than 100 Weddell seals breeding in Larsen Harbour at the southeastern end of the island is the most northerly breeding population of the species. Leopard seals are seen mainly in winter and are mostly young animals that have wandered north of the usual range.

The vegetation is related to that of southern South America but the small number of species reflects the cold climate and the difficulty of seeds crossing the open sea. There are twenty-five native species of higher plant, including six ferns, and the vegetation is dominated by tussock grass or tussac. There are also extensive stands of greater burnet, Antarctic hairgrass, tufted fescue grass, and greater and brown rushes. There are many more lower plants, including about 125 species of moss, 80 liverworts, 150 lichens, 10 algae, and 50 fungi. Coastal waters are dominated by three species of giant kelp, which form an important habitat for fishes and marine invertebrates.

The terrestrial invertebrate fauna is similarly simple and related to southern South America, although about one-third are endemic species. Free-living invertebrates number about forty species of insects, ten crustaceans, several mites, four spiders, worms, and one snail. Insects include seven beetles, including a water beetle, thirteen flies, including one that forms swarms, and a parasitic wasp. The birds and mammals are hosts to lice, mites, and fleas. The nose of the elephant seal is infested with a mite that causes the frequent snorting and thick nasal discharge associated with this seal.

Like so many other islands, South Georgia has been afflicted by alien species introduced by human agency. The whalers deliberately introduced a number of animals, including sheep and cats, but only reindeer have survived. Brown rats are widespread and abundant in the northwest and along the northeast coast, where they have had a serious effect on populations of the pipit, pintail, and small burrow-nesting petrels. There are also two small colonies of house mouse. Several species of alien invertebrate have become established, including mites, springtails, and carabid (ground) beetles. Introduced plants include dandelion, creeping buttercup, chickweed, and the grass *Poa annua*.

Expeditions

James Cook's report of "sea-bears" (fur seals) led to visits by sealers, some of whom were interested in geographical and scientific discoveries. The best-known of these is James Weddell, who published a detailed account of the island and its wildlife. In 1877–1878, the Austrian naturalist Heinrich Klutschak visited on an American sealing vessel. The island was visited in 1819 by Fabian von Bellingshausen's Russian expedition on board *Mirnyy* and *Vostok,* and a survey was made of the southern coast. The first scientific expedition to be based on land was the German International Polar Year Expedition of 1882–1883. Eleven men spent a year at Moltke Harbour in Royal Bay, where a varied scientific program was carried out and the Transit of Venus observed. The Swedish South Polar Expedition made an extensive visit over 2 months in 1902. While the ship *Antarctic* carried out a hydrographic survey, a three-man shore party carried out biological and geological investigations. The German *Deutschland* expedition under Wilhelm Filchner made three visits to South Georgia in 1911 and 1912. Moltke Harbour was reoccupied, and charting and surveying was carried out as well as extensive geological and meteorological investigations.

Much of the scientific work in the first half of the twentieth century relied on logistic assistance from whalers. The Swedish naturalists Eric Sörling and Carl Skottsberg were guests of Carl Anton Larsen in 1904 and 1909, respectively, and David Ferguson was employed by Christian Salvesen's to make a geological survey in 1912. Robert Cushman Murphy carried out ornithological studies when *Daisy* became the last old-time sealer and whaler to visit South Georgia in 1912–1913. Ludwig Kohl, who had been on the *Deutschland* expedition, and his wife Margit, one of Larsen's daughters, together with the photographer Albert Benitz, formed the Kohl-Larsen Expedition in the summer of 1928–1929. They made the first surveys of the interior of South Georgia and carried out glaciological and biological investigations. After the Second World War, C. S. Gibson-Hill and Niall Rankin made private ornithological expeditions and Duncan Carse led a series of four expeditions from 1951–1957 to make the first full survey of the island. Other biological expeditions were led by Bernard Stonehouse and Lance Tickell. From 1969, research has been carried out mainly by the British Antarctic Survey.

South Georgia is famous for the three visits by the explorer Sir Ernest Shackleton, none of which were in his original plans. In 1914, the Imperial Trans-Antarctic Expedition made South Georgia its forward base instead of the Falkland Islands. A month was spent preparing *Endurance* for the Weddell Sea, and some scientific work was undertaken. After *Endurance* had foundered in the Weddell Sea and its complement had reached Elephant Island, Shackleton and five companions reached King Haakon Bay on the southwest coast of South Georgia in *James Caird*. Shackleton and two companions then crossed the unexplored interior of the island to reach Stromness whaling station. In 1922, delays forced the Shackleton-Rowett Expedition on *Quest* to visit South Georgia rather than Cape Town. Shackleton died within hours of arriving at Grytviken, and he was later buried in the whalers' cemetery.

Exploitation

Since the island's discovery, the natural resources of South Georgia have been subjected to three forms of exploitation: sealing, whaling, and fishing. The first sealers arrived about 1786 to exploit both fur and elephant seals. Records are scant, but most sealers were British or American and operated from small vessels and shore camps. Seals on crowded breeding beaches were easily slaughtered and, when profitable markets were developed for their skins, fur seals became increasingly rare and eventually almost extinct. Elephant seals did not suffer so badly. The first peak in sealing occurred around 1800 and, after a lull, there was a second peak around 1820. After this it took longer for the seals to recover, and there was a third, smaller peak around 1870. Elephant sealing was also undertaken by the whaling company at Grytviken from 1904 to 1964. The harvest was regulated by the government, and the production of high-quality oil was a significant factor in the continued profitability of the whaling station.

The whaling industry started in 1904 when Larsen established the first whaling station at Grytviken. The success of this operation attracted other companies, and within 10 years shore stations and floating factories were operating in seven bays, and there were sometimes more than 1000 men employed. Until 1919 whaling took place throughout the year but thereafter it was limited to the summer months. Profits were very good and demand for whale oil increased during the First World War. However, the shore stations began to have difficulties during the 1920s when pelagic factory ships started to operate on the high seas. There followed overproduction of oil, and only two stations survived: Grytviken and Leith Harbour. Husvik reopened for a few years after the Second World War when oil prices were high, but whales became increasingly scarce, and whaling ceased on South Georgia in 1965.

From the start, there was concern that whales were being overexploited and, in 1918, the British government established the Discovery Committee to investigate the Southern Ocean and the biology of its whales to provide information necessary for the sustainable management of whale stocks. Whales were studied at Grytviken by a team of scientists based in a laboratory, Discovery House, at King Edward Point. The carcases of 1683 whales were studied to yield information on growth, diet, and breeding. Unfortunately, the findings of these studies were not applied to the regulation of whaling because the industry was controlled by economic interests.

Large-scale fishing was started by the Soviet bloc around South Georgia in 1969–1970, and within a very few years, stocks of marbled rock cod had been so seriously depleted that they have never recovered. Since then fisheries have developed for krill, mackerel icefish, and, most importantly since the 1990s, Patagonian toothfish. These fisheries were brought under control in 1993 when the Government of South Georgia created a Maritime Zone that extends 200 nautical miles around the coastline of South Georgia, the South Sandwich Islands, and outlying rocks. Within this area, management is based on measures laid down in the Convention on the Conservation of Antarctic Marine Living Resources (CCAMLR). The CCAMLR Commission monitors fish populations in the Southern Ocean and sets a quota, called the Total Allowable Catch (TAC), for each exploited fish species within designated blocks. The relevant blocks for the South Georgia Maritime Zone are 48.3 and 48.2 (48.4 for the South Sandwich Islands).

The South Georgia government awards licenses to fishing vessels, which must comply with local regulations for the management of fisheries. These are monitored and enforced by government officers and by fisheries' protection vessels. Prosecution for infringement may result in heavy fines. The bycatch of albatrosses and other seabirds in the toothfish fishery has been of great concern. The numbers of breeding albatrosses on South Georgia have decreased considerably in recent years. However, the stringent application of mitigation techniques, such as deploying streamers over lines as they are shot, has effectively eliminated the bycatch in South Georgia waters.

SOUTH KOREA: ANTARCTIC PROGRAM

A few pioneer polar scientists working with Korea Ocean Research and Development Institute (KORDI) formed a task force on Antarctic programs and started to make plans for Antarctic research, infrastructure, and governmental framework in the mid-1980s. They established the Polar Research Division within KORDI in 1987, launched the Korea Antarctic Research Program (KARP) in 1987, and dispatched the first Korean Antarctic Scientific Expedition Party in 1988.

Building on the first governmental framework and Antarctic research plan, Korea joined the Convention on the Conservation of Antarctic Marine Resources (CCAMLR) in 1985, acceded to the Antarctic Treaty in 1986, and became an Antarctic Treaty Consultative Party (ATCP) in 1989. One of the greatest achievements of those pioneer polar scientists was to successfully push forward their plan of the first Korean Antarctic Station. In 1988, Korea built the first Korean Antarctic Station on King George Island, which later played a critical role in the success of Antarctic science programs both on land and at sea.

After setting up the first Korean Arctic Station on Svalbard in 2002, the Polar Research Division of KORDI became the Korea Polar Research Institute (KOPRI), an independent research body in 2004. As KOPRI is preparing to expand its role in international polar science community, it is in the process of conducting a wide variety of Arctic and Antarctic research with international institutes, starting to construct a new icebreaker, and planning to build a second Antarctic station.

Korea Polar Research Institute (KOPRI)

In 1987, the Polar Research Laboratory was established by a group of polar scientists within KORDI and was initially led by Dr. Byong-Kwon Park, known as the founder of the Korean Polar Research Program. They dispatched seventeen Antarctic expedition parties between the inauguration of the Antarctic King Sejong Station in 1988 and 2004. Later the Polar Research Laboratory was expanded to a research division in KORDI.

In 2004, the Polar Research Division was separated from KORDI and became KOPRI, an independent research body. The first director of KOPRI was Dr. Yeadong Kim, leader of the pioneering group of polar scientists in Korea. KOPRI consists of the Planning and Administration Division and two research divisions: Polar Environmental Research and Polar Applied Science Division.

KOPRI aims to promote comprehensive polar-region scientific research in cooperation with Korea National Committee on Polar Research (KONPOR), to administer scientific programs, and to provide logistic support. The missions of KOPRI are (1) to promote and support polar scientific research, survey, and long-term observations addressing key issues of global concern, (2) to conduct logistic support for research and station maintenance, (3) to develop research infrastructure, and (4) to assist governmental decision making on policies related to the polar regions. Currently, major research activities conducted by KOPRI scientists are (1) geologic/geophysical studies on tectonic setting, tectonic evolution, and crustal structure of Antarctica, (2) studies on paleoclimatic change, (3) past climatic signature in snow and ice, (4) oceanographic studies on Antarctic marine life resources and ecosystems, (5) Antarctic marine living resources program, (6) polar atmospheric research, and (7) optical aeronomy studies and environmental monitoring at Antarctic/Arctic stations.

KOPRI will endeavor to make a unique contribution toward finding solutions to global concerns, including environmental change. KOPRI scientists continue to collaborate with colleagues from international institutes in various global monitoring programs such as cooperation with International Seismological Center, World Meteorological Organization, and global sea-level observation.

KOPRI actively participates in various committees and working groups of international organizations to share benefits from scientific outcomes by enhancing internationalization of research programs. KOPRI became the twenty-second member of the Scientific Committee on Antarctic Research (SCAR) in 1990, and joined the Council of Managers of National Antarctic Programs (COMNAP) and the International Arctic Science Committee (IASC) in 2002. Also as a founding member of Asian Forum of Polar Sciences (AFOPS), KOPRI keeps contributing toward the development of Asian polar community through a commitment to AFOPS and a leading role in activities of its working groups.

Antarctic "King Sejong" Station

On February 17, 1988, King Sejong Station began functioning as a permanent research station for KARP. King Sejong Station is located on the Barton Peninsular, King George Island, and its coordinates are 62°13′ S, 58°47′ W. The station consists of ten buildings for accommodations and facilities and two observatories for research after extension in 1991 and 2000. The location of the station is best for detecting environmental changes and for studying the behavior of high-energy cosmic particles from outer space. The station is also equipped with geophysical and GPS observatories. The station accommodates two major expeditions every year, a summer expedition and an overwintering research party.

Arctic "Dasan" Station

Dasan station is located at Ny-Alesund (78°55′ N, 11°56′ W) on the high Arctic island of Spitsbergen, Svalbard. Dasan station was established on April 29, 2002. The Station buildings and facilities are leased from a Norwegian company, and they accommodate laboratory space with some scientific equipment, computers, internet connection, and communication facilities. The location of the station is particularly suitable for ecological research, glacial/periglacial geomorphology, hydrology, and atmospheric chemistry.

Korea National Committee on Polar Research (KONPOR)

Following the first governmental framework and Antarctic research plan, Korea established the Korea National Committee on Antarctic Research (KONCAR) in 1987. KONCAR expanded to the Korea National Committee on Polar Research (KONPOR) as KOPRI established Arctic Dasan Station and joined the International Arctic Science Committee (IASC) in 2002. The mission of KONPOR is to enhance and expand scientific programs in polar region through national support and guide. KONPOR is also responsible for reviewing scientific research programs and intermediate and long-term plans conducted and prepared by KOPRI.

SOUTH ORKNEY ISLANDS

The South Orkney Islands (latitudes 60°50′ to 60°83′ S, longitudes 44°25′ to 46°25′ W) were discovered and charted on 6 December 1821 by George Powell and Nathaniel Palmer on the sealers *Dove* and *James Monroe*. Powell claimed the islands (the Powell Group) for Great Britain, naming the largest Coronation Island for George IV's coronation. James Weddell visited the islands in 1823, gave the archipelago its present name and renamed some of the islands.

The islands held little interest for the sealers, and only six visits are recorded before the Scottish National Antarctic Expedition of 1902–1904, led by William Speirs Bruce aboard the *Scotia,* surveyed the islands, reverted some of Weddell's name changes and established a meteorological station at Scotia Bay on Laurie Island during March 1903. In 1908, the South Orkneys became part of the British Crown colony of the Falkland Islands. Argentina also claims the South Orkneys (Orcadas Islands), but the archipelago is now subject to the Antarctic Treaty (1959) under which all territorial claims south of 60° S are set aside.

Floating whaling stations visited the South Orkney Islands annually from 1907–1908 until 1914–1915 taking some 2029 whales. During 1912–1913, the whaling captain Petter Sørlle charted the island group, naming the small island south of Coronation Island after his wife, Fru Signy Sørlle. In the early 1920s a licence was granted to Tønsberg Hvalfangeri (Norway) to establish a shore whaling station on Signy Island in Factory Cove, the only reasonable anchorage around the island. This station operated but briefly, giving way to floating factory ships anchored in the Cove, processing 3500 whales over the period 1921–1929.

With the onset of pelagic whaling Factory Cove was abandoned until 1947 when the Falkland Islands Dependencies Survey (FIDS) established a research station there. A four-man station complement began a science programme that continues to the present day, with FIDS ultimately becoming the British Antarctic Survey (BAS) in 1962. Bruce's old meteorological station on Laurie Island (renamed Orcadas Station in 1951) has been continuously operated by Argentina since 1904 and is the oldest continuously staffed research station in the Antarctic. Its unique meteorological record, extending over 100 years, has provided valuable evidence of significant climate warming in the region.

The South Orkney Islands have a total surface area of about 620 km, and many have an ice sheet. The archipelago comprises four main islands of which Coronation Island is the largest (and most ice-covered) with a high point (Mount Nivea) of 1266 m. Laurie Island, the second largest, is the easternmost of the islands with terrain rising to over 400 m characterised by bold headlands, precipitous cliffs, and deep glacier-filled valleys. There is very little flat ice-free land, and the only landing beach of any size is at Scotia Bay. The other islands are the smaller Signy Island and Powell Island and a number of very small rocky islands (notably the Saddle Islands). Signy Island (60°43′ S, 45°38′ W), scientifically the best known of the group, has approximately 30% of its area under an ice sheet, though this has been in significant retreat since the 1960s. In common with the other islands, Signy Island is formed primarily of metamorphic rocks comprising an interlayered sequence of mica-schist (gneiss), marble, and amphibolites. Ridges of the igneous rock, dolorite, are visible on Coronation Island.

The climate of the South Orkneys is generally cold, wet, and windy. The mean annual temperatures are around –4°C and mean monthly temperatures are above 0°C for at least one month per year. In winter, mean monthly minimum temperatures are around –17°C, and temperature extremes of +25°C and –44°C have been recorded on very rare occasions. The South Orkneys lie toward the outer edge of the maximum extent of Antarctic winter sea ice so there is substantial variability in the sea-ice coverage within the island group each year.

The warm northerly "Fohn" winds sweeping down from Coronation Island have promoted extensive deglaciation on Signy Island, in contrast to the other islands, allowing the creation of many lakes and pools and a greater focus for wildlife. Extensive vegetation and vast numbers of nesting birds occur together with substantial seal colonies. The dominant plants on the islands are mosses (around fifty species) and lichens (about 120 species) with lesser numbers of liverworts (about twelve species) and two flowering plants. Mosses carpet much of the lower lying wet habitats though large areas of moss peat banks around 1 m in depth and up to 5500 years old occur on Signy Island. Higher ground comprises more sparsely vegetated fellfield (sorted, patterned ground) dominated by lichens, and occasional low moss cushions whilst a range of colourful lichens cover the large boulders. In areas where birds, and more particularly seals, are present in large numbers, green mats of the alga *Prasiola* cover most damp surfaces.

The largest terrestrial animals are Acarid mites (c. 1 mm) preying on Collembola (springtails), which graze microalgae, fungi and plant cells. Such small invertebrates have developed physiological strategies for surviving freezing and desiccation. There are no native winged insects or spiders on the South Orkney Islands.

The seasonally ice-covered freshwater environments (some over 7000 years old) range from nutrient-poor lakes through to grossly enriched seal wallows. Extensive beds of aquatic mosses and, more often, cyanobacterial mats cover the bottom sediments. The largest animal is the herbivorous "fairy shrimp," *Branchinecta gainii,* which grazes on the cyanobacterial mats. The zooplankton is dominated by a tiny red copepod, *Boeckella poppei.*

The coastal marine environment is rich and varied with well-colonised rock faces and shallow sandy areas that have been extensively studied and documented. Whilst initially, commercial exploitation of several fish species (notably Nototheniids, "Antarctic cod") was undertaken in the South Orkney Islands, commercial trawling is now restricted to a small krill fishery. Sixteen species of bird breed on the island, notably four species of penguin (the very numerous Adélie and chinstrap penguins, and gentoo and macaroni penguins). Around 2000 elephant seals arrive at Signy Island in spring, and a number of pups are born each year. At the end of winter Weddell seals pup on the sea ice around the island. Crabeater seals are also present at this time, and leopard seals occur around the penguin colonies in summer. Since the 1970s fur seals *(Arctocephalus gazella)* have arrived in increasing numbers in late summer, peaking at around 20,000 individuals.

SOUTH POLAR SKUA

The South Polar skua *(Catharacta maccormicki)* is the southernmost-recorded bird species—they have been seen at Amundsen-Scott Base at the South Pole. Circumpolar in distribution, they breed around the coast of Antarctica and the sub-Antarctic islands. They are even found nesting long distances inland on nunataks near remote colonies of snow petrels *Pagodroma nivea*. At sea, South Polar skuas are primarily seen over the Southern Ocean, but they have the longest migration of all the southern skuas. Nonbreeding birds and juveniles migrate north into the northernmost reaches of the Atlantic and Pacific Oceans and at least as far north as the equator in the Indian Ocean. One South Polar skua has been recorded from Greenland.

Skuas as a group diverged from the gulls about 10 Ma, but their similarities still cause debate about whether they should be considered a separate family, the Stercorariidae. Within the family, there is further debate regarding the number of species. In all accounts, however, the South Polar skua is separated from the various brown, Sub-Antarctic or Antarctic skuas. Their breeding distribution extends north on the Antarctic Peninsula and the South Shetland Islands where they overlap with the breeding distribution of the Sub-Antarctic (brown) skua. Where their breeding populations overlap (e.g., Anvers Island) mixed pairs occur regularly, and they produce hybrid offspring. Mixed species pairs and hybrids have also been reported from the French station at Dumont d'Urville in East Antarctica.

The South Polar skua is considerably smaller than the Subantarctic skua, but is about the same size as the Falklands, Tristan, and Chilean skuas. Compared with the Subantarctic skua, the South Polar skua has a slighter body with shorter legs and smaller head and bill. With a wingspan of 130–140 cm and mass of 900–1600 g, they are still formidable predators. Their close relationship with gulls is clear from their general body shape and size, however, skua bills are more strongly hooked than those of the gulls and they have strongly curved claws on their webbed feet. The wings, back and tail of South Polar skuas are dark brown, and they have the characteristic white flashes at the wrists. Otherwise, they are highly variable with pale, intermediate, and dark color morphs. The dark birds are most common in the Antarctic Peninsula, and they have a dark head, neck, and body. These dark morphs may be difficult to distinguish from the similar Sub-Antarctic skua, but the nape is generally paler, so there is usually a contrast between the nape and the darker back. In addition, many show pale feathers at the base of the bill. The pale and intermediate morphs are more common in continental populations. In these the head, neck, and body vary from a slightly buffy white to a medium brown color. In all cases, however, the lighter feathers of the neck and body contrast distinctly with the darker wings.

South Polar skuas are predators and scavengers. They also steal food from other species as they return from their own foraging trips. This kleptoparasitic behaviour led Herbert Ponting, the photographer on Scott's Terra Nova Expedition, to dub them "Buccaneers of the South." They prey on storm petrels and other petrels and on the eggs and chicks of penguins and other seabirds. They even eat each other's eggs and chicks when opportunities arise. Around most of their breeding areas on the continent, the South Polar skua is the top avian predator and accounts for considerable mortality of penguin and petrel eggs and chicks. In the northern parts of their breeding distribution, they are supplanted by their larger cousins the Sub-Antarctic (brown) skua. Where they co-occur, Subantarctic skuas are able to occupy all the territories that have access to penguin colonies, and the South Polar skuas are forced to go to sea to fish for their food, especially Antarctic silverfish *(Pleurogramma antarctica)*. Nonbreeding and migrating birds forage at sea for fish and are known to scavenge around fishing boats. Where it is available, South Polar skuas will scavenge around Antarctic stations or camps for food scraps, and until recent changes in environmental policies, some skua populations were larger than natural conditions would allow because of the extra food obtained from around stations.

After their long migration, South Polar Skuas return to the Antarctic in late October to early November to breed. They breed in loosely structured colonies that are typically associated with colonies of other breeding seabirds. They nest in the highest concentrations around large penguin colonies, but not all nesting skuas are associated with penguins or petrels. They also nest in lower densities in many ice-free areas where they go to sea to forage. South Polar skuas are faithful to their mates and territory sites, so there is little turnover of adults on territories from year to year. Their mating patterns appear to be very stable, but extra-pair matings have been observed. In many cases, the adults arrive before the snow cover is gone, so they spend several weeks courting and defending their territory. At this time, the males do most of the foraging at sea and then feed the females when they return. The male will make several nest scrapes in the territory, and the female will eventually settle on one of them where she will normally lay two eggs 2–4 days apart.

South Polar skuas are strong and agile flyers, and they are extremely aggressive in defense of their territories. The characteristic territory defense display is the "long call." One or both of the adults stand up tall and hold their wings high behind their back. They then throw their head back and with mouth wide open they call loudly: "ha...ha...ha...ha." If that is insufficient to keep intruders off the territory, they fly up and give chase. These chases can become impressive aerial combats with high speed aerobatic maneuvers and vicious attacks. At times they seem more motivated by territory defense and leave the eggs or chicks unguarded for long periods. Consequently, the loss of eggs to other skuas is often a major cause of nest failure.

When they are off their territory, skuas are very social. There is usually a nearby lake or pond that they use as a bathing site where many birds come together to bathe and preen. Alternatively, there may be a "club" site without the usual bathing pond. There is little aggressiveness at these sites, and young nonbreeders have a chance to socialize without the usual aggressiveness associated with territories.

The South Polar skua is also well known for the frequency of siblicide by the nestlings. Because the eggs are laid several days apart, they hatch 1–3 days apart. The first chick has a size advantage on its younger sibling, and in many populations the older chick will attack its younger sibling. The older chick sometimes kills its sibling outright, but more often they intimidate the younger chick so that it is unable to feed adequately and dies as a result. The chicks in about 5% of bird species in the world show similar aggressiveness, but the South Polar skua is the only species where the parents intervene in the sibling fights. The surviving chicks depart in March and roam the ocean for several years. Most young do not begin to arrive back at their breeding colonies until they are 3 years old. They make attempts at finding a territory, but with the lack of experience and the tightly held territories, they normally do not succeed until they are 6 or 7.

With an estimated population of 5000–8000 pairs of South Polar skuas, they are the least common of all birds species breeding in Antarctica. Their reproductive success is variable and dependent on local conditions, but they are widespread and not globally threatened.

SOUTH POLE

The South Pole—or South Geographic Pole—is the Earth's southernmost point, at latitude 90° S, where the meridians of longitude converge. The South Pole marks the southern end of the Earth's axis of rotation and is generally considered in a fixed location, although its position actually shifts slightly as the Earth wobbles on its axis (known as the Chandler wobble) over a period of about 14 months.

At the South Pole, the Sun rises on or about September 21, the vernal equinox, and does not set again until about March 21, the autumnal equinox. The Sun's maximum elevation above the horizon is 23.5° on the summer solstice (about June 21). During the period of its ascent, the Sun daily makes a 360° circuit around the horizon.

The South Pole is located on the South Polar Plateau at an elevation of approximately 9300 feet (2835 meters). Amundsen-Scott, a United States scientific station, is located very close to the South Pole, and from there the Plateau is generally featureless as far as can be seen, other than for sastrugi. The winter low temperature recorded at the station was –82.8°C, and the summer high temperature –13.6°C. The wind averages 12.1 miles/h (5.5 m/sec). The closest land is actually straight down through the ice, approximately two miles (3.2 km) away. On the surface, the closest rock is Mount Howe, a nunatak approximately 181 miles (290 km) distant. The closest coastline is approximately 790 miles (1270 km) away.

The first individuals to reach the South Pole were the five members of a Norwegian party led by Roald Amundsen, who did so on December 14, 1911. A little more than a month later, on January 17, 1912, a British party led by Robert Falcon Scott reached it as well. The first flight over the Pole, on November 29, 1929, was accomplished by four men, the leader of the party being Richard E. Byrd. The first plane to land at the South Pole was piloted by Conrad S. Shinn, as part of Operation Deep Freeze, on October 31, 1956. A month later, construction of Amundsen-Scott station began in preparation for the International Geophysical Year. The next year, a party became the first to winter at the South Pole, under the scientific leadership of Paul Siple. As part of the Commonwealth Trans-Antarctic Expedition, a group under Sir Edmund Hillary became the first to reach the Pole in motorized transport—and the first to do it overland since Scott—on 4 January 1958. Fifteen days later, they were joined by Vivian Fuchs' part of the expedition, which then continued across the continent. In recent years, many adventurers have trekked to the South Pole, the first solo effort being by Erling Kagge in 1993.

In addition to the South Geographic Pole, three other poles are recognized in the Antarctic. The South Magnetic Pole is the point in the Southern Hemisphere where a dip needle (a freely suspended magnet on a horizontal axis) points towards the Earth's centre. The south-seeking end of a compass needle or any magnet is attracted toward this Pole. Both the North and South Magnetic Poles wander as the Earth's magnetic field changes. The general region of the South Magnetic Pole was first reached at 72°15′ S, 155°16′ E (in Victoria Land) on January 16, 1909, by a party of T. W. Edgeworth David, Douglas Mawson, and Alistair Mackay on Ernest Shackleton's British Antarctic Expedition. It was next approached from the north in December 1912 by a party under Robert Bage on Mawson's Australasian Antarctic Expedition, who estimated it to be at 71° S, 150° E. It has subsequently migrated north and is currently located off the coast of Terre Adélie, in the area of 65° S, 138° E.

The South Geomagnetic Pole is the southern end of the axis of the Earth's geomagnetic field, from which emerge the lines of force that extend far into space, forming the magnetosphere. Convergent lines above the Pole, where electron flux from the Sun is concentrated, create an intense magnetic field in a ring of 23° in the stratosphere, meaning that displays of the Aurora Australis are concentrated in this area. The South Geomagnetic Pole lies at 78°30′ S, 110°00′ E, on the plateau of Greater Antarctica. This area was first attained by a Soviet Antarctic expedition in 1957, the goal of which was to establish Vostok Station, which is situated nearby.

The Pole of Inaccessibility is defined as the point farthest from any coast, and, in theory, therefore the most difficult location to reach. It lies at 77°15′ S, 104°39′ E for the contiguous continent (also close to Vostok Station) or at 85°50′ S, 65°47′ E for the continent and ice shelves, a position south of the Prince Charles Mountains. The latter, at an elevation of

12,150 feet (3700 meters), was first reached on 13 December 1958 by a Soviet expedition, which established a temporary scientific station.

SOUTH SANDWICH ISLANDS

The South Sandwich Islands are an isolated chain of eleven volcanic islands lying between 56° and 60° S latitude and 26° and 28° W longitude, in the South Atlantic sector of the Southern Ocean. Being north of 60° S, the islands do not come under the Antarctic Treaty, and they are administratively one of the British Overseas Territories. The eight southern islands were discovered in 1775 by James Cook (Britain), and the three northern islands in 1819 by Fabian von Bellingshausen (Russia). Until the mid-twentieth century, human involvement was limited mainly to poorly documented activities of sealers and whalers. Landings on some islands were not achieved until the early 1950s, and the islands continue to be visited rarely. The only attempts at coordinated topographic and scientific surveys have been by British expeditions in 1930, 1964, and 1997. Small huts were built on Thule Island in 1955 and 1976, in pursuance of Argentina's political claim to territory in the South Atlantic, contested by Britain. Apart from a small refuge hut, the buildings were destroyed by a British naval vessel following the Falklands War in 1983.

Snow and ice almost wholly cover each island except for the four smallest islands, which are largely ice-free. They are the summit expressions of seven major submarine volcanoes 2.5–3.5 km high, with basal diameters of 30–50 km, which rise from the sea floor to a maximum height of 1370 m above sea level. Ten islands form a simple north–south-orientated arc, but one (Leskov Island) is situated about 55 km off-axis to the southwest. They are small, ranging from 2 to 12 km in diameter, and entirely volcanic, dominated by basalt and andesite lavas. Volcanic ashes, formed in explosive eruptions, are uncommon, although the South Sandwich Islands have been the most prolific contributor of ash to the East Antarctic Ice Sheet. Summit calderas (caused by collapse into a lava chamber) are present on several of the islands, and a 5 km-wide submarine caldera between Thule and Cook islands was discovered in 1997. All of the islands are young (less than 3 million years) and eruptions have been observed on most. Protector Shoal, a shallow seamount situated 56 km northwest of Zavodovski Island, erupted rhyolite pumice in 1962. Small persistent lava lakes are frequently present in summit craters on Montagu and Saunders islands. Montagu Island, with no previous record of historical eruptions, began a long-lived eruption in late 2001; it was still erupting in June 2005.

The South Sandwich Islands are within the maritime Antarctic biogeographical zone. Five species of penguin (Adélie, gentoo, chinstrap, macaroni, and king) breed in the islands, but the chinstrap is the most numerous by far. King penguins are uncommon and confined to Zavodovski and Candlemas islands. Other bird species recorded breeding include giant petrel, Antarctic skua, Cape petrel, kelp gull, Wilson's storm petrel, blue-eyed shag, and Antarctic tern. Numerous albatross species have been observed offshore. Only fur seals and elephant seals are known to breed on the islands, but Weddell, crabeater, and leopard seals are present in small numbers. Whales regularly occur, mainly humpback but also minke, southern right, southern bottlenose, and other fin whales. The terrestrial invertebrate fauna consists of relatively few species of arthropods, nematodes, tardigrades, and rotifers; a springtail species and possibly two species of enchytraeid worm discovered in 1997 were previously unrecorded from the maritime Antarctic.

Most snow-free areas are spectacularly barren of vegetation. Only a small number of species is present, including lichens, mosses, algae, and rare small stands of grass *(Deschampsia antarctica)*. Conversely, the warm, moist conditions provided by the volcanic fumaroles support a strikingly more luxuriant plant cover. These show a concentric zonation of plant communities associated with the outward-decreasing temperature gradients, and some vegetation types are restricted to the fumaroles.

SOUTH SHETLAND ISLANDS

The South Shetland Islands are a group of eleven large islands and nine islets, situated at the western extremity of the South Scotia Ridge and extending over a total distance of about 500 km. They lie on the southeast side of Drake Passage, about 700 km south of Tierra del Fuego and about 100 km off the northwest coast of Graham Land (northern Antarctic Peninsula). The group comprises two island clusters: a main southwest group extending 250 km between Low and Smith islands and King George Island; and the Elephant and Clarence Island Group in the northeast, separated from King George Island by a gap of about 90 km.

William Smith discovered the islands on February 18, 1819, in the brig *Williams* during a voyage between Buenos Aires and Valparaiso, making them the first part of Antarctica (south of 60° S) to be formally discovered. Smith returned to the islands and landed at North Foreland, the northeastern extremity of King George Island, on October 17, taking possession in the name of King George III of Great Britain and calling the land New South Britain, then New South Shetland. The remains of a Spanish 74, *San Telmo,* with 644 hands, which was last seen on September 4, 1819, drifting rudderless and dismasted at 62° S following a storm, were subsequently discovered at Cape Shirreff, Livingston Island. The *San Telmo* crew were conceivably the first people to live and die in Antarctica, although no human remains attributable to the ship have been discovered. Joseph Herring, the English mate on the Argentine sealer *Espirito Santo* (a British charter), landed on one of the islands and took possession of "the entire archipelago" on December 25, 1819. Edward Bransfield, RN, with William Smith, landed in King George Bay (probably at Turret Point) on January 22, 1820, where he again formally took possession for Great Britain. Bransfield also produced the first charts of the islands and (on January 30 and 31) saw the north coast of Graham Land and d'Urville Island, between 63° S and 64° S. This was one of the first two authentic sightings of the Antarctic mainland. Bransfield also landed at Cape Bowles, southernmost Clarence Island, on February 4, 1820, and claimed the Elephant and Clarence Islands Group for Great Britain. A letters patent of July 21, 1908, consolidated the earlier British claims to the South Shetland Islands as Dependencies of the Falkland Islands. However, conflicting overlapping territorial claims to the South Shetland Islands (and Antarctic Peninsula) have subsequently been maintained by Great Britain, Argentina, and Chile. They were advanced by Argentina in 1925–1927, 1942, 1946, and 1948, and for the first time by Chile in 1940.

The commercial exploitation of the South Shetland Islands took place immediately after their discovery, with visits by sealing vessels from the United States, Argentina, and Great Britain. At least ninety-one vessels were recorded working in the islands in 1821–1822 and, by the end of that season, the valuable fur seal population was almost completely exterminated and has never recovered. Several of the islands still contain low stone-wall remnants of small, originally canvas-roofed sealing shelters. Human skeletal remains from the period have been unearthed at Cape Shirreff (Livingston Island), Desolation Island, and Deception Island. That at Cape Shirreff consisted of the skull of a South American native Indian, supposedly female. Uniquely for Antarctica, stone spearheads were dredged from sediment in Admiralty Bay (King George Island) and Discovery Bay (Greenwich Island). The possibility that the spearheads were proof of an indigenous population of Indians who reached the islands 1000–2000 years ago from Tierra del Fuego has been discredited. Sealer artefacts recovered from caves and huts include timbers, seal and penguin bones, a pig's mandible, a metal gaffe, iron nails, blubber lamps, bottle glass, leather boots, sealskin moccasins, pieces of cloth and canvas, a cloth waistcoat, inscribed whale vertebra, metal knives, a wooden knife sheath, a clay pipe bowl, wax, and fire hearths. Sealing continued sporadically until 1828, and it was during that period that the coasts and harbours of the islands became well known. A brief revival took place between 1871 and the end of the century, when commercial activity then shifted to hunting whales, based mainly at Deception Island and King George Island (Admiralty Bay).

Several scientific and exploring expeditions visited the islands, mainly from the late 1880s, but few paused long enough to make more than cursory observations. Two important exceptions are the first scientific expedition to Antarctica, by HMS *Chanticleer* (1828–1831; Captain H. Foster), during which magnetic observations were made and Earth's gravity was measured on Deception Island (hence Pendulum Cove, named in honour of the gravity experiment); and the geological observations of several islands by David Ferguson during a whaling expedition in 1913–1914. However, the earliest accurate geological observations of any part of Antarctica were by Midshipman C. W. Poynter, RN, who on January 22, 1820, correctly deduced the youthful volcanic origin of Penguin Island. The survivors of Sir Ernest Shackleton's Imperial Trans-Antarctic Expedition (1914–1917) reached Elephant Island in April 1916, from where they were rescued by the Chilean tug *Yelcho* in August later that year. For logistical reasons, most scientific investigations in the islands were of limited geographical extent, and the first attempts at region-scale scientific surveys did not take place until 1965–1966 (geomorphology, botany), 1970–1971 (botany), and 1974–1976 (geology) (by the UK).

The first permanent scientific stations in the region were established on Deception Island in 1944, and King George Island in 1948 (by the UK). That on Deception Island included the first snow-free aircraft runway in Antarctica and hosted a British aerial survey expedition in 1955–1957 (FIDASE); most of the buildings were damaged or destroyed by volcanic eruptions on the island in 1967 and 1969, and the base was abandoned. Other scientific stations were established between the late 1940s and early 1960s on King George Island (Chile, Russia), Deception Island (Argentina, Chile), Greenwich Island (Chile) and Half Moon Island (Argentina), together with a few small huts *(refugia)* that were typically only occupied briefly for part of a single summer. Poland built a station on King George Island (Point Thomas) in 1978, and, because of the presence of numerous easily accessible snow-free coastal sites with running water, there was a further flurry of station building in the late 1980s and 1990s, by Bulgaria, Spain, Brazil, Ecuador, China, Uruguay, and Peru, almost all on King George Island. As a result, the South Shetland Islands contain the greatest number of scientific stations in any region of Antarctica.

The South Shetland Islands consist of two physiographic types. Most are low ice domes that rise gently to about 500 m, encircled by 30 m-high ice cliffs and infrequent small headlands that are briefly snow-free during the short austral summer. The coasts of King George and Livingston islands are indented by deep fjords (e.g., Admiralty Bay, False Bay). Other islands are considerably more mountainous and rise locally to more than 2000 m in jagged snow-clad peaks. The latter include Elephant Island, Clarence Island, Smith Island, and parts of Livingston and Greenwich islands. At 2103 m, Mount Foster (Smith Island) is the highest peak. The island with the least snow cover is Deception Island, an active volcano with glaciers covering just 57% of the island surface. The two largest islands are King George Island and Livingston Island, each measuring 70–80 km in length and 25–30 km in width. Their western extremities (Fildes Peninsula and Byers Peninsula, respectively) are the largest snow-free headlands in the group, measuring 10–12 km in length and 4–6 km wide. They contain numerous small lakes. Small streams are also present on many of the snow-free headlands. Smith and Elephant islands are 32 km and 45 km in length, respectively, whereas the other islands are substantially smaller, typically only 15–20 km in their longest dimension. The northern coasts abound with islets and rocks, whereas the southern coasts, which face the much deeper water of Bransfield Strait, are largely clear of such dangers. Broad beach terraces, rare elsewhere in Antarctica, are common.

The climate is Antarctic maritime. Wind directions are variable but westerlies and easterlies are about equally frequent. Skies are mainly overcast and mists, light rain, and wet snow are common. Average monthly temperatures are above freezing between December and March, whilst winter temperatures seldom fall below –25°C. During winter, the South Shetland Islands are normally entirely ice-bound. Sea ice is extensive in Bransfield Strait between July and October and it commonly extends a considerable distance north of the islands.

The South Shetland Islands contain twelve Antarctic Specially Protected Areas (ASPAs), the second-highest number for any part of Antarctica. They comprise ten terrestrial and two marine sites:

five on King George Island; one each on Nelson, Robert, and Greenwich islands; two on Livingston Island; and two on Deception Island. The ASPAs are defined on the basis of their unusually important geological and/or biological attributes. The islands also contain two sites in the process of becoming formally adopted as Antarctic Specially Managed Areas (ASMA). These are Admiralty Bay, King George Island, and Deception Island, designated due to their outstanding environmental, scientific, scenic, and historic values. There are also fourteen Antarctic Historic Sites and Monuments: five on Greenwich Island, four on King George Island, two on Elephant Island, two on Deception Island, and one on Livingston Island.

Although the South Shetland Islands are predominantly volcanic, they have a very varied geology that also includes metamorphic rocks, fossiliferous and barren sedimentary sequences, and plutonic intrusions. The different resistances of those rocks to weathering and erosion have been largely responsible for the variable physiography seen today, with mountainous terrains underlain mainly by plutonic and metamorphic rocks, and more subdued terrain associated with volcanic and sedimentary rocks.

The Elephant and Clarence Island Group and Smith Island are composed of high-pressure–low-temperature metamorphic rocks, including the first blueschists to be discovered in Antarctica. Together they form a highly deformed, mainly metasedimentary, unit 80–120 million years old in the Elephant and Clarence Islands Group, and 40–60 million years old at Smith Island. The rocks are a product of accretionary processes associated with subduction of ancient Pacific Ocean crust and associated with concurrent volcanic arc activity in the islands. A slice of oceanic crust is represented by tectonically emplaced ultramafic rock (dunite) within the metamorphic sequence on Gibbs Island.

The basement to the arc is made up of at least 3000 m of Triassic (about 240 Ma) sedimentary rock, mainly thick beds of quartzoze sandstone, which form an overturned sequence on Hurd Peninsula, Livingston Island. Deposition probably occurred in submarine fans along a continental margin, possibly within a subduction complex, although the tectonic setting is not well defined.

Marine sedimentary sequences of late Jurassic age (160–155 Ma) are exposed on Low Island. They are sparsely fossiliferous and are composed of volcanic ash derived from contemporary eruptions in the Antarctic Peninsula and deposited in a fore-arc basin. There is no evidence for volcanism located in the South Shetland Islands at that time. The main volcanic arc migrated from the Antarctic Peninsula to the islands in the earliest Cretaceous (about 140 Ma), as indicated by the highly fossiliferous marine sedimentary sequence on Byers Peninsula, which was deposited in a marine intra-arc basin and which also contains rhyolite and basalt lavas and ash deposits. These are the only rhyolites in the South Shetland group. Other Cretaceous sedimentary sequences include a striking unfossiliferous blocky deposit formed by large-scale collapse of a volcano flank (known as the Moores Peak Formation) and the Williams Point Beds, both on Livingston Island. The Williams Point Beds are volcanic sandstones and mudrocks that were deposited in a river and lake about 90 Ma. Their well-preserved fossil plants have proved to be of critical importance in understanding late Cretaceous plant evolution and radiation in high-latitude regions.

Subaerial volcanic sequences that are about 80–90 million years old (Late Cretaceous) crop out widely between eastern Livingston and northern Robert islands. They are dominated by basalt lavas. Compared to the early Cretaceous volcanism, the late Cretaceous volcanism was centred in the middle islands, indicating a trend of northeasterly volcano migration that continued into the early Cenozoic (about 60–50 Ma, the Palaeocene epoch) in western King George Island and are now found mainly on Fildes Peninsula. The geology of King George Island is the most intensively studied of all of the islands. For example, Polish geologists have identified more than twelve geological groups and thirty formations, resulting in a very complicated stratigraphy. The next major eruptions took place around 45–40 Ma, in Eocene times, from a volcano situated in central King George Island. Unlike the older volcanic sequences, the Eocene volcano was constructed of relatively evolved very thick lavas, mainly andesites, which are very well seen at Point Hennequin. The Palaeocene and Eocene sequences on King George Island also contain former lake beds with important well-preserved plant leaf fossils. They represent the most complete fossil leaf record in Antarctica.

Younger volcanic sequences are confined to eastern King George Island and continue the trend of northeasterly volcano migration previously noted. They are basaltic once again and include some of the most primitive lava compositions erupted in the islands' history. They also contain evidence for at least three major glacial periods in the geological past: the Polonez Glaciation (30–26 Ma), Melville Glaciation (23–22 Ma) and Legru Glaciation (age uncertain), and a single interglacial period (25–24 Ma). In each case, the associated ice sheets were local to the islands, although some picked up detritus derived from East Antarctica and dumped locally by far-travelled icebergs.

All of the volcanic activity was caused by subduction of Pacific Ocean crust at the South Shetland Trench. Inexplicably, despite subduction continuing to the present (although at a very slow rate today), no volcanic rocks were erupted in the South Shetland Islands between about 20 and 1 Ma. Volcanic eruptions then resumed, but were situated mainly within Bransfield Strait, where they formed volcanoes at Bridgeman, Deception, and Penguin islands and numerous submarine seamounts. Several small ash cones were also constructed on Livingston and Greenwich islands at that time. Bransfield Strait is a very young marine basin formed by stretching and rupture of the Earth's crust between the South Shetland Islands and northern Antarctic Peninsula over the past 4 million years.

The South Shetland Islands are extremely rich in breeding birds and other wildlife. There are numerous large colonies of several penguin species. They include chinstrap, gentoo, Adélie, and macaroni penguins. Chinstrap penguins are the most common and the islands contain some of the world's largest colonies for this species. By contrast, macaroni penguins are known to breed at only eight confirmed sites, although more than 14,000 breeding pairs are present. Other confirmed nesting bird species include blue-eyed shag, sheathbill, kelp gull, Cape petrel, South Polar skua, Antarctic tern, snow petrel, southern giant petrel, black-bellied storm petrel, and Wilson's storm petrel. Piles of empty limpet shells are a common sight near kelp gull nesting sites. Most of the world's population of Antarctic terns breed in the South Shetland Islands (35,000 pairs, compared with 50,000 pairs worldwide), whilst Elephant Island hosts most of the Cape petrel, black-bellied petrel, and sheathbill breeding pairs in Antarctica.

Nonbreeding species include black-browed, grey-headed, and light-mantled sooty albatrosses, which frequently visit the region and are commonly seen (in small numbers) in Bransfield Strait. Accidental migrants such as king, emperor, and rockhopper penguins are seen extremely rarely.

Marine mammals are dominated by several seal species. Fur and elephant seals are ubiquitous. Whilst fur seal populations have never recovered from depredations of the sealers in the 1820s, their numbers are now increasing steadily. From being scarce in the 1970s (when the largest concentration seen on any island was only sixty animals), they are now a common sight on many beaches, although numbers of breeding pairs are probably quite small. Weddell, crabeater, and leopard seals are also present but relatively scarce. Sei, fin, humpback, minke, and killer whales are all relatively common in Bransfield Strait, and their numbers appear to have increased significantly over the past few decades. Breaching humpbacks are a common sight off Livingston Island (South Bay). A composite fin-whale skeleton (with bones from several species) is present on a raised beach on Keller Peninsula, King George Island, and was reassembled by a team led by Jacques Cousteau in the 1970s.

The South Shetland Islands have a simple vegetation. This is generally typical of the maritime Antarctic and is dominated by over 200 lichen and 100 bryophyte (moss and liverwort) species. Two flowering plants are present: the Antarctic hairgrass *Deschampsia antarctica* and the cushion-forming pearlwort *Colobanthus quitensis*. They are the only two higher plants found in Antarctica. Both occur intermittently along the west coast of the Antarctic Peninsula (to c. 69° S), but they reach their greatest abundance and degree of ground cover at locations in the South Shetland Islands. Red and green unicellular snow algae are locally conspicuous, and there are rare occurrences of a fungi species. A striking feature is the much greater development of plant communities on the southern than on the northern coasts of the islands, with some species found only at south coast localities. The major factors affecting plant distribution and growth appear to be the degree of exposure particularly to wind, aspect (e.g., north-facing), availability of water, ground stability, and availability of nitrogen. Some plants (e.g., *Deschampsia* and the thin sheetlike green alga *Prasiola crispa*), are best developed around penguin rookeries. Elephant Island is unique in the South Shetland Islands in having a moss-derived peat bank up to 3 m deep (at Walker Point). The peat also contains remains of ash layers erupted from Deception Island over the past few thousand years, and its base has been radiocarbon-dated as approximately 5000 years old. Deception Island also contains communities of bryophytes associated with active fumarolic fissures that are unique in Antarctica.

The terrestrial fauna is also generally simple, composed primarily of microarthropods (mites and springtails) and smaller groups of soil fauna such as nematodes, tardigrades, and rotifers. The South Shetland Islands are unique in hosting populations of both higher insects found on the Antarctic continent. Both are chironomid midges (Diptera): the brachypterous (wingless) *Belgica antarctica* is endemic to Antarctica, and found from the South Shetland Islands southwards to Marguerite Bay, on the western Antarctic Peninsula; *Parochlus steinenii,* the only flying insect in the Antarctic, is found associated with water bodies on the South Shetland Islands, with a wider distribution including sub-Antarctic South Georgia and southern South America.

SOUTH SHETLAND ISLANDS, DISCOVERY OF

One of the most important events in the interaction of man with the Antarctic took place soon after dawn on February 19, 1819. At that time, William Smith, commander and part owner of the small merchant brig *Williams,* on passage from Buenos Aires to Valparaiso, saw "land or Ice...bearing South East by South, distance two or three leagues—Strong gales from South West with Snow or sleet..." The next day, Smith, in clearer weather, confirmed that it *was* land, noting a difficult rocky coast. Smith's landfall appears to have been off Williams Point on Livingston Island. This was the first authenticated sighting of land in the region close to the Antarctic coast.

William Smith (1790–1847), from Seaton Sluice in Northumberland, was a skilled mariner who had probably learned his craft on the east coast coal run and in Greenland whaling. By 1819, he was trading between east and west South America and had made the diversion south in order to avoid contrary winds around Cape Horn. This was unusual but, due to his Arctic experience, Smith was probably less anxious about ice than were some masters. One suspects that there was also an element of inquisitiveness about his decision.

Smith, appreciating that he was "perhaps deviating" from his insurance policy in being so far from the normal track, then resumed his voyage. On arrival in Valparaiso, he reported his discovery, plus the observation that the area had many seals and whales, to Captain W. H. Shirreff of HMS *Andromache,* the senior British naval officer on that station. Shirreff was skeptical, assuming that what Smith had seen was merely ice.

On his next voyage, which was west to east, Smith—seemingly undeterred by the insurance problem—attempted to revisit the land that he was convinced he had seen. On June 15, 1819, the wrong season for a voyage in those latitudes, Smith's progress was seriously impeded by loose ice, even though the sea was calm, and he decided to head north. On arrival in Montevideo, Smith found that the news of his discovery had preceded him, presumably overland, and the "Americans at that port" offered him money for the information. However, Smith, "having the Good of his Country at heart & as he had not taken possession of the land in the name of his Sovereign Lord the King," resisted their offers.

Smith decided on a third attempt as soon as possible. However, it took time to assemble a cargo. This had the disadvantage that in the meantime the first sealing voyages had set out for the new land. On the other hand, there was an advantage from the delay in that *Williams* was sailing at a more propitious time of year. Despite excellent weather off Cape Horn, which would have permitted an easy passage westward, Smith continued in a southerly course. This demonstrates the tenacity in his character. On October 15, 1819, Smith neared his previous position and sighted land. The precise movements of *Williams* on the next day are unclear, but it appears likely that Smith proceeded along the north of Greenwich, Robert, Nelson, and King George islands and landed by boat at North Foreland in order to take "formal possession of the land in the name of His Majesty King George the Third." Smith originally named it New South Britain but later changed it to New South Shetland on account of it lying in about the same latitude as the Shetland Islands. One source indicates that Smith, himself, did not land but sent his mate to perform the ceremony. From what is obvious in Smith's character, this seems unlikely. *Williams* then proceeded westward and on October 18, Smith sighted the island now named after him. He then bore towards Valparaiso. In the course of this third voyage, he had charted more than 200 km of new coastline. Smith arrived at Valparaiso on November 24 and reported his new findings to Shirreff, who had had second thoughts after Smith's previous report and now reconsidered the matter.

Shirreff decided to charter *Williams* with the aim of surveying Smith's new land. A one-sided contract was drawn up in which Smith accepted all the liabilities regarding the condition of the ship while the government was to pay "such amount...per month as...His Majesty's Navy shall think adequate." A party consisting of the master of *Andromache,* Edward Bransfield, three midshipmen, and a surgeon was placed on board.

Edward Bransfield (c. 1783–1852), from Cork, had been "pressed" into the Royal Navy, but became an extremely competent seaman and had rapidly risen in rank. There was an obvious potential source of friction between him and Smith because the formal relationship between them was not precisely defined. However, from the results of the expedition, one may conclude that they cooperated well.

Williams departed on December 19, 1819. Retracing her previous course, she came in sight of Livingston Island on January 16, 1820, and proceeded northeastward along the coasts of the islands noted by Smith on the previous voyage. Bransfield went ashore at King George Bay to claim the land for the King, and *Williams* put to sea from thence on January 27. They proceeded along the southern coasts of the islands, and Bransfield and the other naval personnel were heavily engaged in charting as they went. On January 29, in poor conditions, they set a southerly course, and the day after they sighted Deception Island. Later that afternoon, the weather cleared. They were "half encompassed with islands" and sighted a "high rude range (of mountains) running in a NE and SW direction" beyond them. It has been argued that this was the first sighting of a landmass on the Antarctic continent, although it is likely that a Russian expedition under Fabian von Bellingshausen had spied it several days previously.

Williams proceeded in a northeasterly direction for several days, continuous surveys being made. On January 31, they reached Hope Island, named "from the hope...that the range might continue to stretch Easterly untill joined by the Thule." They then discovered O'Brien, Seal, Gibbs, Elephant, and Clarence islands. Bransfield landed on the last for another possession ceremony. He then determined to head south in compliance with his instruction to ascertain if there was any connection with the South Sandwich Islands, discovered by Cook. *Williams* reached her farthest south, nearly 65°, on February 23, being prevented from proceeding farther by ice. She was the first vessel to penetrate what was later named the Weddell Sea.

By this time, the season was advancing, so Bransfield decided to head north. *Williams* arrived safely in Valparaiso on April 14, 1820. The expedition was a complete success because it did what it set out to do and with no loss of life.

Smith undertook a sealing voyage in *Williams* in 1820–1821 after the end of the charter. Both Smith and Bransfield continued at sea, but while the latter retired in modest prosperity, the former died in conditions of near poverty.

SOUTHERN ELEPHANT SEAL

General Description

Southern elephant seal *(Mirounga leonina)* is the largest member of the pinniped family. Male southern elephant seals have been recorded to weigh up to 3700 kg. The species also exhibits the most pronounced sexual dimorphism in a mammal; females weigh 400–800 kg, which means that males can weigh 8–10 times as much as females. There are other pronounced secondary sexual differences in morphology, all of which are related to the highly polygynous mating strategy of the species. Most notable of these is the large proboscis of the male that plays a key part in dominance displays with other males.

Southern elephant seals have a circumpolar range, with breeding sites on islands scattered right around the sub-Antarctic. Very occasionally, pups are born on the Antarctic mainland.

Genetic analysis has shown that Southern elephant seals have four distinct populations; one in the southern Pacific Ocean, one in the south Atlantic, one in the southern Indian Ocean, and a small but increasing population on Peninsula Valdés in Argentina. The integrity of the populations appears to be maintained by the extremely high fidelity of animals to their natal population. Although genetically distinct, animals from the populations are indistinguishable from each other based on external features alone.

Southern elephant seals were hunted extensively throughout their range during the 1800s and early 1900s for their blubber, which yielded unusually high quality oil. This resulted in dramatic reduction in numbers at all of their major breeding sites. With the cessation of hunting, numbers increased, but since the 1950s and 1960s the populations in both the southern Indian and South Pacific oceans have declined by about 50%, although the population in the Indian Ocean appears to have stabilised since 2000. At the same time, the populations in the South Atlantic have been stable, or increasing. The underlying cause of the declines are presently unclear but are thought to be related to changes in the distribution and abundance of the seal's prey. The current estimated total population size for southern elephant seals is about 700,000.

Today elephant seals are relatively free of adverse interactions with humans. Southern elephant seals are only rarely captured in the nets of Southern Ocean fishing fleets. There are some grounds for concern that future, large-scale fisheries may compete with the seals for preferred prey species.

Life History

Elephant seals range widely from their breeding and haulout sites, and the distributions of seals from the different populations are known to overlap when they are at sea. For example, a 1-year-old seal marked at Macquarie Island was seen at Peter I Øy (68°51′ S 90°35′ W), 5200 km away in the Bellinghausen Sea, an area that is within the range of seals tracked from the Antarctic Peninsula. Most of what is now known about the movements of elephant seals comes from telemetry studies, which have radically altered our perceptions of the role of this species in the Southern Ocean ecosystem. Although elephant seals are rarely sighted in the Antarctic pack ice, we now know many adult seals spend a large proportion of their winter (post-moult) foraging trip in the pack ice and even over the Antarctic continental shelf. During this 280-day period, the seals move between 1000–3500 km from their sub-Antarctic breeding and haulout sites to foraging areas. Recent studies, which have tracked the same individuals in several years, have found the seals often return to the same feeding areas in successive years.

Female elephant seals can live, and breed, until at least 23 years of age. Females reach their maximum body size at 6–8 years but breed for the first time between 3 and 6 years. There is evidence for site-specific differences in the age at first breeding. Seals from the South Atlantic population may breed 1–2 years earlier than from the others, and this may be associated with higher growth rates in that region. Once mature, females breed most years and produce a single pup each year (although twins are occasionally born). Male elephant seals continue to grow until 10–12 years of age; the much longer period of growth enables them to reach their massive adult size.

The annual breeding cycle begins when the largest males haul out on deserted beaches in August. Pregnant females then haul out in large numbers, aggregating into harems, and giving birth to their single pup 2–5 days after arriving. The females stay with their pup throughout the ensuing lactation period, never feeding, but rather relying on their thick blubber layer to sustain them and to supply the many litres of rich, high-fat (40%) milk required by the rapidly growing pup. At birth the pups weigh between 30–40 kg, but by the time they wean at 23–25 days, pups weigh 120–130 kg.

Several days before weaning their pups, the females come into oestrus and are mated by the dominant males. Although fertilization takes place at this time, the blastocyst does not implant until several months later. This is known as delayed implantation. Once the pup is weaned, the females depart to sea, leaving the pups to fend for themselves. The pups spend the next 4–6 weeks teaching themselves to swim and hunt, during which time they rely heavily on the large reserves of blubber that they received from their mothers while suckling. When the pups eventually leave their natal beaches they spend the next 6 months at sea. This is a difficult period for the pups and as many as 30% of them die at this time.

Monacine seals, which include the elephant seals and monk seals, all have an unusual annual moult, which entails the shedding of epidermal tissue in addition to the hair. The rich supplies of blood required at the body surface for the new skin and hair requires the animals to leave the water to conserve body heat. The seals therefore spend 3–5 weeks fasting ashore in January to March, once again relying on stored blubber to supply their energy requirements.

Social Structure

Southern elephant seals are highly polygynous with large, dominant males (“beach masters” or alpha males) presiding over large aggregations of females known as harems. Males do not seriously compete for access to harems until they reach their full adult size at age 10–12. Before this time young males, although sexually mature, are not large enough to fight established males successfully, and remain at the periphery of harems trying to mate with unattended females. Competition between the males for the alpha position is intense and leads to spectacular fights. Successful males will have almost exclusive access to harems consisting of up to 100 females, and so the reproductive benefits of success are very high. Although males rarely retain beach-master status for more than 2 years, during that time they may sire over 100 pups. This has led to the evolution of the pronounced secondary sexual characteristics of immense body size and exaggerated proboscis.

Diet and Trophic Interactions

The diet of elephant seals is difficult to study because of their wide-ranging and protracted trips to sea when it is impossible to observer what they are eating. Conventional methods of diet analysis, which examine stomach contents of seals that have recently hauled out, can only provide information on what has been eaten in the few days prior to returning, and this is not likely to be representative of their diet during the entire trip. Nonetheless these types of studies have now been conducted on several age groups of seals from several populations. The general trend is for the prey to be dominated by squid, with small amounts of fish and crustaceans. There is evidence of differences in diet between males and females, and between juvenile and adult seals, but these are largely due to differences in the species of squid found, or the size of the squid taken. The dominance of squid in the diet is characteristic of all the seals that have been examined.

Recently, other techniques have been used to try to gain a more comprehensive and integrated picture of elephant seal diet. One of the most promising, although still experimental, is to use fatty acid profiles in the seals’ blubber to obtain broad-scale diet information. As prey species have characteristic fatty acid profiles, these may be incorporated in the seal’s blubber, which can then be sampled when the seal returns to shore and analyzed to give a picture of diet during its time at sea. This approach has indicated that adult female elephant seals have different fatty acid profiles between their summer and winter foraging trips, and that seals feeding in different regions also have different profiles. Seals that fed over the Antarctic Continental Shelf had fatty acid profiles consistent with a diet dominated by fish, while those feeding in regions associated with the Antarctic Polar Front had profiles consistent with diets dominated by squid.

When information on foraging location and diet are combined it is possible to estimate prey consumption rates by elephant seals in different regions of the Southern Ocean. Recent studies suggest that elephant seals are the largest consumer of squid in the pack-ice zone, particularly in the winter months.

Other Special Features

One of the most remarkable features of elephant seals is their diving behaviour. Elephant seals spend more than 90% of their time at sea submerged, feeding intensively to build up the blubber stores required to support them during the breeding and moulting haul-outs. The seals' diet of deep-water squid means that they have developed the remarkable ability to dive to depths in excess of 1900 m and for as long as 120 minutes. While these values are the extremes of those recorded, even the average values are impressive. Adult females routinely make dives of 20 minutes, and reach depths of 400–800 m. Paradoxically, although the males generally dive for longer, about 30 minutes, they do not often go as deep. This is a reflection of their tendency to feed over continental shelves, while most females tend to use deeper, oceanic water.

Another unique characteristic of elephant seal diving is the presence of "drift" dives, where the seals swim to depth of between 200–400 m, then stop and drift motionless in the water column for up to 30 minutes. The purpose of these dives is unknown, but may be associated with resting, or processing of food and metabolites that have been postponed during intensive periods of diving. What ever their purpose, drift dives offer valuable insights into other aspects of elephant seal biology because the rate of their drift has been shown to be a consequence of their buoyancy, which is in turn due to the relative amount of fat and other tissue in the seal's body. Studying drift rates can therefore provide information about changes in relative body composition throughout an individual's time at sea.

Elephant seals exhibit extremely long, deep drives. During an average dive to 500 m, a seal will experience 680 pounds of pressure per square inch (psi), or 4688 kPa. The seals avoid some physiological complications, such as the bends, by expelling almost all air from their bodies before diving, and thereby minimizing compressible air spaces. How they avoid other problems such as nitrogen narcosis and maintain cellular metabolic process at these pressures requires further research. Simple calculations based on the amounts oxygen stored in the blood and muscle of the seals and their dive durations indicate that seals must be reducing their metabolic rates while diving. For an average-sized female, dives in excess of 30 minutes would require diving metabolic rates to be less than their resting metabolic rate. Heart rates recorded on free-diving female elephant seals reflect this, declining to less than 10 beats per minute on the longest dives. An active, swimming elephant seal uses less oxygen than when sleeping on land. This is achieved through several physiological changes, such as restricting blood flow to major organs, which result in decreasing oxygen requirements.

SOUTHERN FULMAR

The southern, or Antarctic, fulmar (*Fulmarus glacialoides,* a member of the family Procellariidae, order Procellariiformes) is a broadly distributed petrel species of the Southern Ocean. It is a member of the fulmarine petrel complex, which also includes the Antarctic petrel, snow petrel, Cape petrel, northern and southern giant petrels, and the northern fulmar.

The genus *Fulmarus* contains two species, the southern and northern fulmar. The name "fulmar" likely derives from the combination of two Gaelic or Hebridean words meaning "foul gull." Presumably, this is a reference to the fulmar's habit of spitting stomach oil when threatened. Chicks are particularly adept at deterring potential predators with their stomach oil marksmanship. Of the two species, the southern fulmar is considered likely to be the more primitive, or ancient, species, with the northern fulmar presumed to have arisen from populations of southern fulmars that moved northward from the

Southern Hemisphere and were subsequently isolated by changes in global climate and oceanographic regimes.

Southern fulmars are a large petrel, ranging in body mass between 700–1000 g. Their plumage resembles that of gulls in both pattern and coloration. The underparts are white and contrast with the pale silver-gray upperparts. The wings are primarily silver-gray with a striking white rectangular patch, bordered by black outer primary feathers, on the upperwing. The bill is fleshy pink with a dark tip and lavender-blue nasal tubes. The plumage does not differ between the sexes or by age. Fulmars employ a stiff-winged soaring mode of flight interspersed with brief periods of rapid wing beats.

The species has a circumpolar distribution, occurring predominantly in the Antarctic and on some sub-Antarctic islands. Southern fulmars breed in colonies ranging in size from tens to thousands of breeding pairs. Although fulmars breed in colonies on the East Antarctic mainland and offshore islands throughout East Antarctica and along the Antarctic Peninsula, the center of their breeding distribution appears to be island groups in the Scotia Arc (e.g., the South Orkney and South Sandwich islands), based on our knowledge.

Precise estimates of the total world population do not exist, but global numbers possibly exceed 2 million birds. There are few conservation concerns for the species, given its large global population, broad geographic distribution, and generally remote and inaccessible breeding colonies. The only potential long-term threat may be interactions with commercial fisheries, although currently this does not appear to be an issue.

Breeding colonies tend to be located on cliffs or on steep slopes where birds can easily take off and land at nest sites. Southern fulmars nest on the surface, using nest sites that are simple scrapes in gravel or on flat rocks and frequently augmenting them with a few pebbles or stones. Like most petrels, southern fulmars exhibit a high degree of natal philopatry, the tendency to return to their colony of birth to establish a nest and begin to breed, and nest site tenacity, meaning that they tend to return to the same nest site to breed year after year. They are also highly monogamous, with more than 80% of breeding pairs typically maintained between seasons.

Timing of the highly synchronous breeding season shows remarkable consistency among years and regions. Birds typically begin to arrive at the colonies in October to claim and defend their nest sites and to mate. Southern fulmars, like all procellariiformes, lay a single egg. Egg laying occurs within a 10–14-day window from the first to the third week of December. Incubation of the egg, shared by both members of the pair, lasts an average of 47 days, with hatching occurring in late January. Both parents also share in the care and feeding of their chick, which remains in the nest for approximately 52 days before fledging in the second half of March. Fledglings are independent and receive no parental care once they depart the colony.

Chicks of procellariiformes typically grow much more slowly than predicted for birds of the same size. Interestingly, relative to other species in the order Procellariiformes, the fulmarine petrels (including the southern fulmar) grow considerably more quickly, nearly twice as rapidly as predicted. Their pattern of growth, however, is comparable to that of other petrels and albatrosses, with development beginning slowly but increasing throughout a linear phase before tapering off toward the end of the chick period. The breeding patterns of fulmarine petrels, characterized by highly synchronous and tightly timed breeding, a relatively compressed breeding season and rapid nestling growth, suggest that they may be an evolved response to constraints on breeding imposed by a short high-latitude season in which environmental conditions are conducive to breeding and to opportunities presented by seasonally highly abundant food sources.

The biggest survival challenge for southern fulmars is their first year of life. Mortality rates decrease significantly for birds that survive their first year. The few estimates of adult survival that exist suggest annual survival rates of 93%–95%. Age at first breeding varies but is commonly 6–8 years.

Southern fulmars forage opportunistically, which is typical of many species of petrels. Their diet is comprised primarily of fish, euphausiids (krill), and squid. Diet during the breeding season appears to vary regionally, with krill dominant in some areas and fish in others. Fulmars forage by seizing prey items from the surface and occasionally making shallow surface dives. They will also scavenge carrion when available. Although it has not yet been demonstrated for fulmars, many species of petrels are known to use olfactory as well as visual cues when foraging.

Foraging ranges are restricted during the breeding season because birds have to return to the colony to relieve their mate and/or provision their chick. Thus, breeding southern fulmars usually forage in the surrounding inshore and shelf waters within a few hundred kilometres of colonies. They feed amongst pack ice but also commonly in open water far from any ice. Foraging trips during the chick-rearing period are usually 2–4 days in length.

During the nonbreeding season, fulmars disperse out of the Southern Ocean, with most birds wintering in sub-Antarctic waters. Some individuals reach temperate waters, with some birds ranging considerably farther north and occasionally reaching the tropics along the west coast of South America.

SOUTHERN GIANT PETREL

Southern giant petrels (*Macronectes giganteus,* order Procellariiformes) are large, surface feeding predator-scavengers with a circumpolar distribution throughout the Southern Hemisphere. With a wingspan of approximately 2 m, these petrels resemble a small albatross in flight, although their build is somewhat stockier. Adult giant petrels weigh 3.5–5 kg; males are larger than females, which is the principal difference between the two genders. Known to sailors and explorers as the Nelly, Stink-pot, Glutton, Stinker, or Bone-shaker, southern giant petrels are a familiar sight within the Southern Ocean and may venture north into the lower latitudes (20°–25° S) as juveniles and nonbreeding adults. The generic name, *Macronectes,* meaning "the long swimmer," is a reference to the species' ship-following tendency and affinity for oceanic foraging.

Until 1966, giant petrels were regarded as a single species. The northern species, *Macronectes halli,* was distinguished on the basis of breeding timetables and morphology, and there is some speculation that a third, intermediate form may exist at some sub-Antarctic breeding localities. The two recognized species are reproductively isolated where they co-occur, although limited interbreeding has been documented. While the breeding distribution of northern giant petrels is limited to the sub-Antarctic islands and more northerly latitudes, southern giant petrel breeding localities span a much wider latitudinal range (45°–68° S) that includes continental Antarctica to coastal South America, suggesting they are perhaps better adapted to breed in diverse environments. Southern giant petrels are abundant at higher latitudes (e.g., on the Antarctic Peninsula), although populations can be found on all of the island groups of the Scotia Arc, on many sub-Antarctic islands, the Falkland Islands, and throughout the coastal regions of Patagonian Argentina and southern Chile. Nonbreeding adults, juveniles and fledglings range farther north than breeding adults, and tend to disperse farther than their congener, *M. halli*.

Like many other Procellariiformes that have vast oceanic feeding ranges, southern giant petrel breeding populations are also decreasing throughout much of their range. Over the past 25 years, the global southern giant petrel breeding population has decreased by approximately 18%, with current population estimates at just over 30,000 breeding pairs. Recent surveys at the Falkland islands in 2004–2005 may result in greater abundance estimates. Breeding localities in proximity to sources of chronic disturbance show the most dramatic population decreases (e.g., some sub-Antarctic islands; South Shetland Islands, Antarctic Peninsula). Despite this relatively coherent downward trend throughout much of their breeding range, some southern giant petrel breeding populations are increasing at some localities on the Antarctic Peninsula and also on the Antarctic continent. Interestingly, there have been substantial breeding population increases (approximately 50%) reported in some South American colonies during the mid-1990s.

Southern giant petrels rely on windswept landscapes to nest. Such landscapes facilitate both take-offs and landings, especially during calm conditions, and provide reliable access to snow-free nest sites to populations breeding in the higher latitudes. Nests are typically found in open areas (e.g., raised outcroppings, ridge tops, or beaches) and breeding pairs are often colonial, although colony density varies by breeding locality. Nests are often used annually by the same breeding pair and are constructed of stones, limpet shells, and moss in Antarctica, or tussock grass and other locally abundant herbaceous materials in the sub-Antarctic. Both genders partake in nest building and maintenance, and adults typically remain associated with their breeding sites during the winter

while still engaged in long foraging trips away from their colonies.

Southern giant petrels are mainly monogamous, but there are well-documented cases of divorce, mate-swapping, and mate changes resulting from the disappearance of a breeding partner. A single egg is laid between late September and early November, with later timetables characteristic of Antarctic breeders. Incubation shifts are split nearly equally between both members of the pair, and incubation time is approximately 55–65 days. Chick hatching and rearing tends to be timed with maximum food abundance, in order to accommodate rapid chick development. Hatching in southern giant petrels appears to be coincident with the availability of predominant local resources (e.g., penguin carrion, krill/squid, other birds). Given the southern giant petrels' propensity for opportunistic scavenging, and a parental tendency toward gender-specific foraging, the likelihood of young chicks receiving adequate food is increased, even if one type of prey should become unavailable. Chicks fledge in 110–125 days, and fledgling dispersal patterns based on band recoveries suggest a generally eastward progression, assisted by prevailing winds, within the Southern Hemisphere. Juveniles spend the first 3–6 years at sea with occasional resightings concentrated in the Antarctic during summer and in sub-Antarctic and subtropical regions during winter. Age at first breeding is between 6 and 10 years of age, with males entering the breeding population at an earlier age than females. Interestingly, although some southern giant petrels may breed annually, approximately 30%–50% of any given population is usually on "sabbatical," meaning they may skip a year without nesting. In contrast to northern giant petrels, southern giant petrels are polymorphic, ranging in color from dark to light. A small percentage of the population (up to 15%) is represented by a nearly completely white form.

Annual reproductive success varies widely by locality, from a low estimate of 6% for some populations in the South Shetland Islands, to nearly 85% for other localities within the Antarctic Peninsula region. Common causes of reproductive failure include human disturbance, station activity and construction, overflights, starvation, trampling by a parent or neighbor, predation, and exposure during severe weather. Although records are sparse, longevity estimates are minimally 30–40 years, possibly reaching 50 years.

Southern giant petrels are both predators and scavengers. During summer, carrion (seal and penguin) is an important component of the diet. Foraging segregation between the genders occurs, with the females undertaking offshore and oceanic foraging and the males specializing in terrestrial or inshore feeding. Important prey items vary by locality and include penguins, carrion, cephalopods (squid), crustaceans (krill), fish, and other seabirds. Satellite tracking studies have revealed that foraging birds make repeated trips to the same locations where predictable food resources are available. These areas may include ice edges or polynyas, which are typically known to have higher primary production and enhanced food abundance. Southern giant petrels do not typically dive for prey but rather approach prey while sitting on the water, from which they will also feed by surface-seizing. Prey can be located by olfaction, and, although disputed, southern giant petrels may actively follow ships as part of their oceanic foraging strategies. Interactions between individuals at a food source are typically agonistic and comprise the majority of social interactions away from the nest. They have been reported attacking the corpses of drowned sailors; thus the nickname "Bone-shaker." Needless to say, southern giant petrels are effective and voracious predators, in addition to opportunistic scavengers.

Although this species is highly susceptible to some types of human disturbance near their breeding colonies, studies suggest that the observed population decreases are due primarily to mortality through entanglement in commercial longline fishing operations. These operations are rapidly expanding in the Southern Ocean, thus posing an increasing hazard to these wide-ranging predators and scavengers because they are attracted to the baited hooks associated with these fisheries. If hooked, giant petrels drown or are mortally wounded when trying to escape. Indeed, southern giant petrels are now listed as "vulnerable" by the International Union for the Conservation of Nature (IUCN), joining many other threatened and endangered populations of seabirds that are decreasing due to the massive mortality (estimated at >100,000 birds annually) associated with these Southern Ocean longline fisheries. Immature southern giant petrels are especially vulnerable because they spend several years circumnavigating the Southern Ocean in the interval between fledging and recruitment to the breeding population. The recent increase in commercial longline fishing may, in effect, become the most serious factor limiting the survival of this long-lived species.

SOUTHERN OCEAN

The Southern Ocean and Its Early Scientific Exploration

The Southern Ocean has been described in former times as the Antarctic Ocean. Some geographers deny that there is any such thing as the Southern Ocean, believing that the Atlantic, Indian, and Pacific Oceans extend south all the way to the Antarctic continent. Others consider that the unique polar character of the surface waters south of the Polar Front, or Antarctic Convergence as it was formerly known, which lies near 50° S in the Atlantic and Indian Ocean sectors and near 60° S in the Pacific sector, define a water mass sufficiently different from those in the other three oceans to deserve its own name, and limit the Southern Ocean to that area. Yet others regard the Southern Ocean as extending all the way north to the Subtropical Convergence near 40° S, where warm subtropical surface waters meet the cooler surface waters of the Subantarctic Zone. This last definition seems reasonable from an oceanographic perspective in that the Southern Ocean so defined encompasses all surface waters influenced by oceanographic processes related to Antarctica, and incorporates the major oceanographic feature of the region, the great Antarctic Circumpolar Current, formerly called the West Wind Drift, which transports 135 million cubic metres of water per second from west to east around Antarctica. This is the world's largest current, four times as large as the Gulf Stream and 135 times the flow of all the world's rivers combined. The Antarctic Circumpolar Current is the central and dominant feature of the Southern Ocean. According to Pollard et al. (2002) it is bounded to the north by the Subantarctic Front and to the south by the southern edge of the surface outcrop of Upper Circumpolar Deep Water. The northern part of the current forms the Polar Frontal Zone; the southern part forms the Antarctic Zone, the two zones being separated by the Polar Front, identified by the northernmost extent of the 2°C subsurface temperature minimum. The different zones between the major fronts within and outside the main body of the current tend to have different water masses and different communities of plants and animals. The structure of the Current is not simple. It comprises a broad band in which the Polar Front is one of several fronts, all associated with narrow eastward current jets. South of the Current, the surface waters move to the west along the Antarctic coast, under the influence of the prevailing winds.

For centuries, the raging westerly winds, stormy seas and huge waves of the Southern Ocean deterred the hardiest of sailors from probing south. Those hardy enough to brave the winds and the waves soon had to contend with another hazard–icebergs the size of small islands. Further south yet they met another deterrent—sea ice, which in the southern winter months covers an area as large as Antarctica itself, extending north as far as 61° S on average but reaching 52° S near South Georgia. As if that were not enough, the blasting rain froze on the rigging, coating masts, yards, and ropes in thick layers of ice making ships top heavy and sails difficult to work. Just as mountain ranges and deserts prevented communication between adjacent peoples in times gone by, so the harsh and unforgiving Southern Ocean protected Antarctica from intrusion, not least by scientists.

Some believe that the great Chinese fleets of exploration in 1421–1423 were the first to sail the Southern Ocean, discovering the Straits of Magellan, visiting the Falkland Islands, the South Shetlands, and South Georgia, and sighting the northern part of the Antarctic Peninsula, as well as coming across Kerguelan and Heard Islands in the Indian Ocean, and Campbell and Auckland Islands south of New Zealand. However, conventional history credits Ferdinand Magellan with being the first to sail into Southern Ocean coastal waters, hugging the coast and reaching 53°–54° S, where in 1520 he penetrated the Strait that bears his name. Other Spanish expeditions followed the same route. In 1578, Francis Drake's ship *Golden Hind* was struck by a severe storm as he entered the Pacific Ocean from the Strait. The ship was blown south to 57° S and found indications of open water between Cape Horn and Antarctica. The existence of what became called Drake Passage was confirmed when Isaac Le Maire rounded Cape Horn in 1616. Gradually other southern lands were found, many by ships blown off course in storms, like John Davis, who discovered the Falkland Islands, at around 52° S, in 1592; Anthony de la Roche, who discovered South Georgia at around 54° S in 1675; and William Smith, who discovered the South Shetlands at around 62° S in 1819. A rich literature describes these early geographical discoveries, which set the physical framework for later ocean science.

True scientific studies of the Southern Ocean began with the second voyage of Captain James Cook in 1772–1775. Others before him had reported seeing icebergs, but Cook was the first to surmise that the tabular bergs broke away from ice sheets terminating in high cliffs extending into the sea at coasts as yet unseen. He also appears to have been the first to observe the vast fields of sea ice around Antarctica, which stopped his excursions south. Nevertheless he managed to cross the Antarctic Circle at 66.5° S three times, reaching a furthest south of 71°10′ S in the Bellingshausen Sea in January 1774. Cook's scientists measured air and sea temperatures and found that in the Antarctic region cold surface water sat on top of warmer water at a depth of 200 m. We now know that this is because the Antarctic surface water is relatively fresh from melting ice and floats atop the warmer saltier water that is spreading south below it. His main results proved that there was an ocean all the way around Antarctica, and that there must be a frozen continent to the south to produce so much ice.

Scientific studies continued with the voyage of Bellingshausen in 1819–1821, who circumnavigated Antarctica and filled the gaps left by Cook. He expanded the extent of the Southern Ocean by sailing across over 242 degrees of longitude south of 60° S, of which 41 degrees were within the Antarctic Circle. Using a tow-net he was able to show that small drifting animals (plankton) move up in the night and down in the day. In addition he made the first clear reference to the small shrimplike krill *Euphausia superba,* which dominates the zooplankton and feeds whales, seals, albatross, and penguins.

A cruise across the Drake Passage, by *HMS Chanticleer* in 1829, observed wide variation in the directions of currents, and measured current speeds of between 6 and 41 miles per day. Durmont D'Urville showed from his voyages in 1822–1825 and 1826–1829 that the temperature at great depths in the open Southern Ocean was nearly constant between 4° and 5°C. Charles Wilkes' expedition in 1839–1840 remarked on the multitudes of shrimp (i.e., krill) and concluded that they were responsible for the abundant populations of whales and penguins. The expedition led to publication of the first drawing of *Euphausia superba,* in 1855.

James Clark Ross made comprehensive studies of the Southern Ocean from the *Erebus* and *Terror* in 1839–1843, during which he discovered the Ross Sea. He was the first to make extensive soundings, which showed that abyssal depths separated Antarctic from neighbouring continents. He made many deep temperature measurements with maximum and minimum thermometers, which showed temperatures like those observed by D'Urville below 1000 m. As pointed out by Deacon (1984), the true temperature near the bottom is close to 0°C, the difference from Ross's figures being due to the effect of pressure on the early thermometers. Ross was the first to measure the motions of the tides in the region, and he deduced mean sea level at places where he stopped for long enough, as in the Falkland Islands. His scientists dredged the seabed down to 800 m and used deep-sea grabs to collect samples from deeper depths. Sadly, much of Ross's collection of fish and deep-sea animals was lost by decomposition. Nevertheless, 145 species of fish new to science were described, and Joseph Hooker's *Flora Antarctica,* published in 1858, laid the foundations for Southern Ocean botanical studies, among other things noting the importance of winds and currents in governing plankton distribution patterns.

In 1894, *HMS Challenger* made a brief excursion across the Antarctic Circle. Interpretation of the results from this and other cruises suggested that tropical water must move south to balance the effect of the cooling and dilution that goes on in the Antarctic. The cruise also led to the first overall picture of the distribution of atmospheric pressure over the Southern Ocean, finding a circumpolar ring of low pressure some 30 degrees wide in which the mean pressure falls to about 980 mb at 63° S, following which it rises towards the continent. The *Challenger's* collections of seabed rocks and sediments led to the conclusion that icebergs had carried fragments of coastal rock to the north, dropping them on the seabed as the ice melted, and showed the continental nature of Antarctica.

In 1897–1899, the *Belgica* made a rich collection of fish and bottom-dwelling animals from the continental shelf off West Antarctica and used modern deep-sea reversing thermometers to make measurements down to 4000 m that are comparable to those we would make today. They showed that water temperatures were close to –1°C at a depth of 100 m, rose to above 2°C in the warm deep layer, and fell to near 0°C near the bottom. Krill were found to be abundant in the Bellingshausen Sea.

The *Valdivia* carried out a comprehensive scientific investigation in the South Atlantic and Indian Oceans in 1898–1899, confirming the three layer structure of the Southern Ocean, with cold Antarctic surface water, warm deep water, and cold bottom water. They showed that the surface water was relatively fresh, the warm deep water quite saline, and the deep water somewhat less saline, and they identified the Weddell Sea Current, that carries cold water and ice east to Bouvetøya.

These early efforts and later complementary activities in the early part of the twentieth century, such as the first description, by the *Gauss* (1901–1903), of the sinking of cold surface waters between 40° and 60° S, and the explanation by the *Deutschland* (1911–1912) of the origin of deep cold Antarctic Bottom Water, established in outline the physical circulation and biology of the Southern Ocean. They were not surpassed until the advent of the UK's Discovery Investigations, which operated first the *Discovery,* and then *Discovery II* in the Southern Ocean between 1923 and 1951. The Discovery Investigations provided the first systematic scientific studies of whales in the region, and the ships covered the whole of the circumpolar ocean with routine measurements of temperature and salinity, and made many collections of plankton and other organisms. The result was the first detailed picture of the structure and currents of the ocean, and of the distribution of phytoplankton, zooplankton (especially krill) and whales, and other mammals in relation to ocean currents and nutrients.

Exploitation of the Living Resources of the Southern Ocean

Cook's voyage was to have an immediate and unexpected impact. He visited (and named) South Georgia, and reported on the abundance of the seals to be found there. Within 3 years English sealers were at work on the island. In 1778 they brought back from South Georgia and the Straits of Magellan 40,000 seal skins and 2800 tonnes of elephant seal oil. By the time James Weddell visited the island in 1823 the fur seals and the elephant seals were almost extinct. 1.2 million fur seals were slaughtered there between 1786 and 1825. It is no accident that South Georgia's main port was named Grytviken (meaning "pot-harbour," for the seal cooking pots). Similar slaughter followed the discovery of the South Shetland Islands by William Smith in 1819, and subsequently spread to Antarctica and all the sub-Antarctic islands. By 1829 the sealers had done their work in the South Shetlands too; the *Chanticleer* observed not a single fur seal there in 1829. Fur seals continued to be caught sporadically at a small scale through the nineteenth century. As fur seal stocks declined, the emphasis shifted to the exploitation of elephant seals for blubber oil. Exploitation was sustainable under license, and continued into the twentieth century, ending in 1964 on South Georgia. Around a quarter of a million of these animals were harvested there. The scattered knowledge on Antarctic seals was brought together by the Scientific Committee on Antarctic Research (SCAR) in 1972 and led to acceptance of the protection of fur, elephant, and Ross seals south of 60° S, and the adoption of quotas for catch limits on the crabeater, leopard, and Weddell seals under the Convention on the Conservation of Antarctic Seals (CCAS), which was finally ratified in 1978. Fur seals began recovering in about 1980 and now have a population of several million.

On many islands penguins were also harvested for skins and oil, with up to 150,000 per year being taken on Macquarie Island at the end of the nineteenth century. The impact on the penguin population does not seem to have been significant.

Mention by early explorers of the abundance of whales led inevitably to the pursuit of these creatures into the Southern Ocean. Whalers began hunting the Sperm Whale on a small scale in the northern parts of the Southern Ocean, between latitudes 30° and 50° S, almost as soon as maps of new lands there were published from the seventeenth century onwards. Sperm whaling reached a peak in 1837. Large numbers of the southern right whale were caught at the same time, before they too began to decline after the 1840s. Modern commercial whaling of the Southern Ocean south of 50° S did not begin until 1904, when harpoon guns and boats became powerful enough to hunt for the "great" whales, the rorquals like the blue, fin, and humpbacked whale. This hunting began around South Georgia, through the Compañia Argentina de Pesca, founded by the Norwegian Captain C. A. Larsen. It then grew apace, fuelled from 1926 onward by the new technology of "factory ships" that could operate independently of ports and allowed widespread exploitation of the open ocean. The industry was dominated by the UK and Norway. The harvest was not sustainable, despite regulation of the whale fisheries by bodies such as the Falkland Islands government, and, from 1946, by the International Whaling Commission (IWC). Consequently, different whale species declined one after another, with peaks in catch of the humpback whale around 1910, blue whale around 1930, sperm whale around 1953, fin whale around 1955, sei whale around 1965, and minke whale around 1975. In 1972 the UN Conference on the Human Environment called for a 10-year ban on whaling, and in 1982 the IWC declared the region to be a whale sanctuary. By 1985–1986 the IWC introduced zero catch quotas for all commercial whaling there. This ban remains in force. Whale catching came to an end at the end of the 1986–1987 season, except for limited annual catching of 300–600 of the abundant minke whales for scientific purposes by Japan. Before the whaling ban, 1.4 million whales were caught in the Southern Ocean. Recovery is slow.

The krill first observed by Bellingshausen provide the basis for a modern fishery. Much of our understanding of krill comes from the Biological Investigations of Antarctic Marine Systems and Stocks (BIOMASS), a programme of the Scientific Committee on Antarctic Research (SCAR) between 1977 and 1991. Swarms of krill may contain up to 30,000 animals per cubic metre, turning the water red or orange. Estimates suggest a standing stock of some 500 billion tonnes, of which humans could take between 80 and 150 million tonnes per year without harm to the system. The krill are found south of the Polar Front, mostly between 50° and 65° S and from the tip of the Antarctic Peninsula east to the longitude of Cape Town (20° E), with large numbers around South Georgia. Krill fishing began commercially in the early 1970s around South Georgia, the South Orkney Islands, and the South Sandwich Islands, with the catch reaching a peak of 528,000 tonnes in 1982. Since then, many of the Russian vessels doing the catching left the area, and the catch declined to

83,000 tonnes in 1998. Russia, the Ukraine and Japan are the key countries involved.

Since 1969–1970, fishing has been the most important economic activity in the Southern Ocean. It is carried out mostly around South Georgia and Kerguelen, largely for bottom-dwelling fish. The industry was started by eastern bloc countries, and is now dominated by Australia, New Zealand, South Africa, Chile, Argentina, Uruguay, and the Ukraine. Large scale harvesting of finfish began with trawl fisheries in the southwestern Atlantic sector. The main commercial species are mackerel, icefish, and Patagonian toothfish. Squid are also taken, largely around the Falkland Islands. The fishing industry is regulated by the Commission for the Conservation of Antarctic Living Marine Resources (CCAMLR), which came into force in 1982. Overexploitation has caused stocks to decline, leading to the implementation of conservation measures. In 2001 the fishing of several finfish species was banned, and the Total Allowable Catch was reduced for others. Longline fisheries were introduced in the 1980s to catch Patagonian toothfish, which sell for as much as US $6000 per tonne. As a consequence this fishery suffers from illegal and unregulated fishing. The longline fishery leads to the deaths of albatrosses and petrels, which dive for the bait when the lines are launched, and get dragged under and drowned.

The management of Antarctic Living Marine Resources by CCAMLR, and the management of environmental protection by the Antarctic Treaty mechanisms are helping to stem exploitation and to restore the ecosystem to a healthy level. These developments are all aided by scientific advice provided by the nongovernmental Scientific Committee on Antarctic Research (SCAR).

SOUTHERN OCEAN: BATHYMETRY

The Southern Ocean surrounds Antarctica south of 60° S. It is formed by three major deep ocean basins that are, in general terms, contiguous with the southern parts of the Atlantic, Pacific, and Indian oceans. It covers an area of approximately 20.3 million km^2 and reaches a maximum depth of 7290 m at the southern end of the South Sandwich Trench. Although the term "Southern Ocean" has been in common use for many years, it has only recently been defined, by international agreement under the auspices of the International Hydrographic Organisation in 2000, as the oceanic region south of 60° S. This decision delimited a fifth world ocean from the southern parts of the Atlantic, Indian, and Pacific oceans, from 60° S to the Antarctic coast. The northern boundary corresponds to the extent of interest of the Antarctic Treaty System. However, it cuts across major oceanic basins south of Africa, Australia, and the eastern Pacific Ocean. A more morphologically consistent northern limit would be about 50°–55° S and would include most of these major circum-Antarctic deep ocean basins (and abyssal plains). Therefore, the general large-scale features south of 55° S are discussed, together with a more detailed description of bathymetry south of 60° S. The more extended region, incidentally, would be close to the area of interest to Convention on the Conservation of Antarctic Marine Living Resources, based on an ecosystem approach.

The bathymetry of the Southern Ocean is the morphology or shape of the seafloor that underlies the Southern Ocean. In general terms the bathymetry of an ocean has two main components: the continental shelves that surround the continents, and have an average depth of some 500 m off Antarctica; and the deep ocean basins that are often several kilometres deep. The two are separated by steep continental slopes. The ocean basins were generally formed by the rifting of the Earth's crust at spreading centres and the formation of new oceanic crust at these spreading centres. They therefore contain morphological features that are generally related to their formation during the plate tectonic evolution of the region. These features include (1) deep ocean trenches: narrow, linear to arcuate asymmetric deeps that may reach 8000 m deep and several tens of kilometres wide; (2) broad linear ridges, also called midocean ridges, that are the spreading centres in plate tectonic evolution of the oceans; (3) fracture zones: narrow asymmetric linear ridges that extend from the spreading centres and mark the location of breaks in the oceanic crust (faults) causing offsets in the spreading centres; (4) abyssal plains: broad, deep, extremely flat regions of the older oceanic crust; (5) continental rises: gentle sloping regions between the abyssal plains and the continental shelves, where the older oceanic crust has been overlain by sediments that thicken towards, and in part are sourced from, the continents; and (6) seamounts (guyot if flat-topped): submarine volcanic edifices often associated with the spreading centres and fracture zones.

The deep seafloor of the Southern Ocean corresponds to the areas of oceanic crust surrounding Antarctica that were formed by seafloor spreading during the past 150 million years. The depth of the ocean and many of the morphological features are therefore intimately related to seafloor spreading and associated processes that took place during the breaking away (rifting) of South America, Africa, Madagascar, India, Australia, and New Zealand from Antarctica. The evolution of this oceanic crust (e.g., rifting, cooling) has given the present bathymetry of the Southern Ocean. The evolution of the Southern Ocean allowed the circum-Antarctic ocean currents to develop, which contributed to the thermal isolation of Antarctica and the formation of the major East and West Antarctic icesheets, and provided the gateway for the global deep ocean thermohaline current system to pass from the Atlantic Ocean through the southern Indian Ocean to the Pacific Ocean.

Three major oceanic basins lie around the perimeter of Antarctica at the southern ends of the Atlantic, Indian and Pacific Oceans. The deepest parts of these circum-Antarctic basins are the extremely flat areas called abyssal plains. Around Antarctica, these are the Weddell and Enderby abyssal plains that lie south of the Atlantic Ocean, the South Indian abyssal plain that lies south of the eastern Indian Ocean, and the Amundsen and Bellinghausen abyssal plains that lie south of the Pacific Ocean. These basins lie to the south of the seafloor spreading centres that caused the rifting of the continents from Gondwana and correspond in general terms to the southern oceanic crust formed at the spreading centres. As the oceanic crust cools with time after it formed at the spreading centre, its depth increases as its distance from the spreading centre increases, until the depth becomes gradually shallower again towards the continents due to the increasing amount of sediment being deposited on the ocean crust from the adjacent land mass (Antarctica). The Southern Ocean is formed generally of the southern part of these basins and the intermediate shallower areas (Kerguelen Plateau, Macquarie Ridge/Pacific–Antarctic Ridge, Antarctic Peninsula/southern Scotia Sea). A number of subbasins within the major basins or parts of these basins, particularly along the Antarctic margin, have been named as seas (e.g., Weddell Sea).

Starting at the Antarctic Peninsula and working eastwards, the main bathymetric features are as follows. The Weddell and Enderby abyssal plains stretch from about 15°–75° E, and coincide with the southern part of the Atlantic Ocean and western part of the Indian Ocean. The abyssal plains reach depths in excess of 5500 m. The Weddell abyssal plain lies in the west. The western part of this basin is the Weddell Sea. The northern margin of the abyssal plain corresponds to a complex of ridges and continental fragments forming the southern margin of the Scotia Sea in the west and with the plate boundary of the America–Antarctica ridge and the Southwest Indian ridge east of about 30° W. These latter two features form the southern boundary of the oceanic crust formed by the mid-Atlantic ridge spreading and join near Bouvetøya. Fracture zones extend from these ridges into the northern Weddell abyssal plain. The Enderby abyssal plain is east of the Weddell abyssal plain. Its northern margin of the corresponds to an offset (the Andrew Bain Fracture Zone) of the Southwest Indian Ridge in the west, and the Conrad Rise, a major seamount complex with minimum depths of less than 100 m. The major fracture zone (the Andrew Bain Fracture Zone) that offsets the Southwest Indian ridge, can be traced as the boundary between the Weddell and Enderby abyssal plain to the Antarctic coast at the Astrid ridge. The eastern margin of the Enderby abyssal plain is formed by the complex Kerguelen Plateau (a thinned continental fragment). The Valdivia abyssal plain lies between the Kerguelen

Plateau and the Antarctic continental shelf. The southern margin of the Weddell and Enderby abyssal plains comprise a number of seas separated by ridges extending north from the Antarctic continental shelf. These are—from the east—the Cooperation Sea, Cosmonaut Sea, Gunnerus Ridge, Riiser-Larsen Sea, Astrid ridge, and the Lazarev Sea. The Maud Rise (1200 m minimum depth) lies on the northern margin of the Lazarev Sea.

Kerguelen Plateau separates the Enderby abyssal plain from the South Indian abyssal plain and is itself separated from the Antarctic coast by the 3500 m deep Princess Elizabeth Trough. It is elongate in a northwest–southeast direction, is about 600 km wide, and extends for over 2000 km to the northwest from the Princess Elizabeth Trough. It rises above sea level at Îles Kerguelen and Heard Island, but most of the plateau generally lies at about 2000 m depth. At about 57° S, the Elan Bank forms a major ridge to the west for about 400 km at depths of about 2000 m. On the eastern side of the plateau, the Labuan Basin forms a 200 km wide indent into the plateau.

Kerguelen Plateau is a continental fragment, with associated igneous ocean rocks, that was detached during the early breakup history of India and Australia from Antarctica.

The South Indian abyssal plain extends from the southern end of the eastern Indian Ocean eastwards south of Australia to the Macquarie Ridge region south of New Zealand. The abyssal plain lies solely on the oceanic crust of the Antarctic plate south of the Southeast Indian Ridge, which follows close to latitude 50° S from about 100°–145° E. The deepest part of the abyssal plain (5300 m) lies between 55° and 60° S. Few seamounts of any significance have been detected there. The eastern margin of the South Indian abyssal plain, from about 135° E to the Macquarie Ridge at about 155° E, is marked by a series of north-northwest to south-southeast trending ridges and troughs corresponding to a series of fracture zones (George V Fracture Zone, Tasman Fracture Zone, and Balleny Fracture Zone) that extend from the spreading centre of the Southeast Indian Ridge to close to the Antarctic margin, and were formed during the generation of the oceanic crust of the Antarctic plate in this region. These ridges and troughs are up to 1200 km long, have a depth range of more than 1000 m, and a width of about 50 km. Just east of the southern end of the Balleny Fracture Zone lie the volcanic Balleny Islands and associated seamounts that form a linear chain of seamounts about 350 km long. Off the Antarctic continent lie the Dumont D'Urville Sea and the Davis Sea. The continental rise is relatively featureless, but a number of submarine canyons are inferred from limited bathymetric coverage.

A region of complex morphology lies south of Tasmania and New Zealand and marks the boundary between the South Indian abyssal plain south of Australia and the Amundsen abyssal plain south of the Pacific–Antarctic ridge. At the north end of this region are South Tasman Rise and the Macquarie Ridge, both features forming morphological barriers to eastwards ocean current flow. The region is marked by the major fracture zones linking the Southeast Indian Ridge to the Pacific–Antarctic Ridge as noted earlier, and a broad shallow (1450 m) region lies between the two ridges. Probably associated with the southern parts of these fracture zones are seamount chains—the Balleny Islands and seamounts noted earlier, Scott Island and associated seamounts, and several unnamed seamounts. The Adare seamounts with depths to less than 1000 m form the rift flanks of an enigmatic rift structure off northwestern Ross Sea.

The Amundsen and Bellinghausen abyssal plains lie between the West Antarctic margin and the Pacific–Antarctic ridge, a spreading centre associated with the plate tectonic development of the southern Pacific Ocean and the movement of the New Zealand region northwards away from Antarctica. The Amundsen abyssal plain lies to the west of the Bellinghausen abyssal plain. Depths are in excess of 5400 m. The Pacific–Antarctic ridge trends northeast from just north of Scott Island. It is offset to the east by two major fracture zones, the Eltanin Fracture Zone at about 54° S, and the Udintzev Fracture Zone at about 56° S. Both can be traced to the southeast for more than 1200 km from the Pacific–Antarctic ridge axis. Their cross sectional profiles are of adjacent ridges and troughs with depth range of up to 1000 m over a 50 km width. Antipodes, Pitman, Heirtzler, and Emerald fracture zones are more subdued features lying west of the Udintzev Fracture Zone towards Scott Island. At the south of the Amundsen abyssal plain, off West Antarctica at about 125° W, there is a group of seamounts—the Marie Byrd seamount and the Amundsen ridges. Existing data define seven major seamounts in the group that reach depths of less than 1000 m. Farther east, at 90° W, a 200 km long, northerly trending, ridge extends from the De Gerlache seamount. The seamount reaches less than 100 m depth. Peter I Øy lies immediately to the south, and the two may be related. The Amundsen and Bellinghausen seas lie south of the Amundsen and Bellinghausen abyssal plains, along to the continental margin of West Antarctica to the east of Ross Sea. At the eastern end of the Bellingshausen Sea (80° W) a well-developed sediment fan—the Charcot Fan—lies at the ocean end of the Charcot Canyon at the base of the continental slope. Further east, along the western margin of the Antarctic Peninsula is a series of subdued ridges oriented perpendicular to the margin and corresponding to fracture zones in the underlying oceanic crust (from the north these are the Hero, Anvers, and Tula Fracture Zones). On the upper continental rise between these fracture zones are a series of broad mounds about 700 m high, formed by contour currents on the seafloor. At the northern end of the Antarctic Peninsula margin a subdued trench (the South Shetlands Trough) occurs. The Shackleton Fracture Zone abuts the northern end of the South Shetland Islands sector of the Antarctic Peninsula margin and extends northeast across Drake Passage to South America. Drake Passage is the major ocean passage between the southern end of South America and the Antarctica Peninsula, separating the Bellinghausen abyssal plain from the Scotia Sea, the most southwestern part of the Atlantic Ocean. It is about 550 km wide and a depth of about 4000 m. It is traversed by the Shackleton Fracture Zone, a ridge that formed during the separation of South America from the Antarctica Peninsula, and has a minimum depth of about 1000 m.

The main techniques used for recording depth information measure the time for an acoustic pulse to travel from a ship to the seafloor and return. Converting the time to a depth requires an accurate knowledge of the speed of sound in seawater. Instruments have been developed that measure the travel time for acoustic pulses sent out as a fan of beams across the path of the ship, providing swath or multibeam measurements. Typically, some 120 beams or pulses are sent out over a fan about 120° in width, thus providing a swath of depth measurements over a strip of seafloor with a width about 5–6 times the depth of water below the ship. This provides highly detailed measurements, but very accurate sound velocity measurements are needed for seawater to enable the reflection (depth) points to be located accurately as well as calculate the depth precisely. Detailed bathymetric charts can be built up by running survey ship tracks parallel to each other at the swath width.

Satellite measurements of the height of the sea surface detect changes in this height that reflect the changes in the gravity over the sea surface, caused to a large degree by changes in bathymetry. These height changes can be used to calculate the changes in gravity under the satellite, which in turn can be used to calculate the changes in water depth. As satellite coverage is global in extent, these data can be used to provide estimates of depths where no ship-based data exist. A global digital bathymetric map incorporating satellite coverage to 70° S has been produced by Smith and Sandwell. Unfortunately, for the Antarctic region, calculations of this sort are not possible where sea ice exists, and significant gaps in information exist in some coastal regions.

Antarctic bathymetric datasets are lodged in the United States at the National Geophysical Data Centre (NGDC) at Boulder, Colorado. NGDC also operates a worldwide digital databank of oceanic soundings on behalf of the member countries of the International Hydrographic Organisation. The national Antarctic data centres (NADC) of the Antarctic Treaty System hold metadata of research databases—accessed through the Antarctic Data Directory of the Scientific Committee for Antarctic Research (SCAR). Data sets also exist at several research institutions. Multibeam bathymetric data are being managed by Lamont Doherty Earth Observatory of Columbia University.

Antarctic bathymetric charts and gridded data sets have been compiled by several organizations, and detailed bathymetric compilations have been produced by research groups working in the Southern Ocean. The General Bathymetric Chart of the Oceans (GEBCO) maps compiled in 1981 have been published. The NGDC have compiled the ETOPO2 gridded global database, using ship-based bathymetric data and the Smith/Sandwell models. GEBCO has updated its database as a gridded database, which includes a new compilation of the Indian–Australian sector of Antarctica. A new compilation, the International Bathymetric Chart of the Southern Ocean, was started in 2004 under the auspices of SCAR and GEBCO.

SOUTHERN OCEAN: BIOGEOCHEMISTRY

Biogeochemistry as a scientific field recognizes the dominant influence of organisms and ecosystem processes on the cycling of elements in the planetary system. The Southern Ocean surrounding Antarctica is one of the largest contiguous biomes on the planet and exerts powerful controls on the ocean carbon and silicon cycles, and on the exchange of carbon dioxide (CO_2) between the ocean and atmosphere. The Southern Ocean below 50° S, with 10% of the total ocean area, is responsible for ~20% of the global ocean CO_2 uptake and 50% of sedimentary opal accumulation. Here the focus is on the roles played by the open Southern Ocean and the Antarctic marginal ice zone and coastal regions in these elemental cycles as well as on some of the ecological processes influencing the cycles.

CO_2 Exchange

The exchange of carbon dioxide across the air-water interface is influenced by the gradient in partial pressure of dissolved CO_2 gas (pCO_2) between the atmosphere and the ocean water, termed the ΔpCO_2. Atmospheric pCO_2 is about 380 ppm, and the pCO_2 in seawater varies between about 200 and 500 ppm although the range in some coastal areas can be larger. When seawater pCO_2 is below 380 ppm, CO_2 is driven into the water; when it is greater, CO_2 degasses from the ocean into the air. When the gradient is large, the gas flux is faster. The ocean in the past century became a net sink for atmospheric CO_2 because anthropogenic emissions have elevated the atmospheric pCO_2 by about 30% above its preindustrial level of 280 ppm. The ocean is now responding to this relatively rapid change in atmospheric chemistry, but the time to establish a new air-sea equilibrium (assuming anthropogenic emissions are eventually stabilized) is poorly known and will take centuries to millennia. Gas exchange is also directly proportional to turbulent mixing caused by wind shear. Faster winds increase the exchange rapidly as the cube of the wind velocity.

The Southern Ocean is responsible for ~20% of the global ocean CO_2 uptake (0.47 of 2.2 Pg C yr^{-1}; Takahashi et al. 2002; 1 petagram Pg = 10^{15} g). Polar continental shelves covered by seasonal sea ice have been hypothesized to act as rectified (one-way) CO_2 pumps, due to the phasing of sea ice cover and biological activity. In summer, when primary production is high and pCO_2 is low, Antarctic seas act as strong sinks for atmospheric CO_2. In winter, when respiration dominates over production and pCO_2 is high, gas exchange is prevented by the sea ice capping the ocean surface. Sea surface temperature is almost constant near Antarctica (relative to lower-latitude systems), and the CO_2 partial pressure excursion governing gas exchange is almost entirely due to biological drawdown and respiration. The Ross Sea polynya may function as a rectified sink for atmospheric CO_2 because it is strongly undersaturated in CO_2 in summer in response to the *Phaeocystis* bloom (Takahashi et al. 2002) and covered by ice during the rest of the year.

Whether the continental shelves of other areas such as the Antarctic Peninsula act as rectified or even unrectified net annual CO_2 sinks is not established. The Peninsular region is characterized by large spatial and temporal variability and by the co-occurrence of various biological (e.g., respiration and photosynthesis) and physical (e.g., heating, cooling, ice formation and ablation, freshening, and dilution) processes, all of which makes understanding and budgeting the carbon cycle very challenging. In summer (January), different regions of the Peninsula showed different patterns of CO_2 and O_2 (dissolved oxygen) over- and undersaturation, resulting from spatial variation in dominance of various physical or biological processes. Dissolved CO_2 was near atmospheric equilibrium in some regions, particularly offshore and toward the north. Net primary production is the dominant process in the inshore areas and especially in Marguerite Bay, leading to strong drawdown of DIC (dissolved inorganic carbon) and undersaturation of dissolved CO_2 ($pCO_2 < 200$ ppm). Other areas had excess CO_2 as a result of strong respiration.

The interior shelves and coastal regions of the Antarctic are small, however, and their influence on the global CO_2 exchange is slight. The regional fluxes are dominated by the larger areas of the Southern Ocean surface further away from the continent. The outer areas of the marginal ice zones 60°–70° S seem to exhibit low net CO_2 uptake from the air. In the permanently open areas of the Southern Ocean beyond the northern extent of the annual sea ice, CO_2

exchange occurs year-round but the pCO_2 excursions are less dramatic than in the coastal areas. The region between 50°–60° S is a net sink for CO_2 with fluxes of 1–2 moles CO_2 m^{-2} y^{-1}. These are moderate to low fluxes, but the area is vast, and the region serves as an important zone of CO_2 storage on the global scale.

Carbon Cycle

Air-sea gas exchange itself is strictly a physical-chemical process governed by gas solubility as it is influenced by temperature, salinity, alkalinity, partial gas pressure, and wind. However the amount of CO_2 dissolved in the water is also influenced profoundly by biological processes that produce and consume this important biogenic gas. Biological, chemical, and physical processes are linked through the action of the Solubility Pump and Biological Carbon Pumps (Volk and Hoffert 1985; Ducklow et al. 2001). CO_2 solubility is a function of temperature: more CO_2 dissolves in cold water than warm. The Solubility Pump transports dissolved inorganic carbon (DIC or TCO_2) against the vertical concentration gradient toward long-term storage in the deep ocean as cold waters with high CO_2 concentrations sink to depth (Feely et al. 2001).

The Biological Pump is responsible for vertical sedimentation of particulate and dissolved organic matter from the illuminated (euphotic) zone in the upper 100–200 m. The components of the biological pump are plankton organisms: autotrophic phytoplankton, bacteria, protozoans and larger zooplankton, and the trophic (feeding) interactions linking these groups in the foodweb. Phytoplankton fix inorganic nutrients into organic matter, a fraction of which is exported passively through gravitational sedimentation of organic matter and actively by zooplankton migration. The biological pump operates most efficiently when blooms of larger phytoplankton like diatoms sink without being grazed upon. Zooplankton like krill and salps repackage phytoplankton and other small particles into larger, rapidly sinking fecal pellets and marine snow. Primary production in the Southern Ocean, especially in the marginal ice zone is dominated by diatom blooms, and as a consequence particles sink rapidly in conspicuous pulses. The zooplankton community alternates over interannual scales between dominance by krill and salps which influence export in contrasting ways. Krill may decrease flux, even while producing rapidly sinking particles, by reingesting them as they sink. Salps vacuum the water column of a wide range of particle sizes and produce very rapidly sinking aggregates which themselves scavenge particles and grow as they sink. Krill versus salp dominance seems to be related to watermass variations and ENSO (El Nino Southern Oscillation); thus climate change may affect the biological pump (Loeb et al. 1997).

Sedimentation has been monitored throughout the annual cycle and over several years using sediment traps deployed in the Ross and Weddell Seas and off the Antarctic Peninsula. Sedimentation on the mid-continental shelf of the Antarctic Peninsula near 64° S ranges between 1%–10% of the annual primary production (1%–10% efficiency) with an annual flux of 0.5–4 gC m^{-2} y^{-1} and peak short term rates of 40–80 mgC m^{-2} d^{-1}. Particle flux exhibits extreme seasonality with a strong peak in the summer following the ice retreat and phytoplankton bloom when more than half the total flux may occur. In the Austral winter flux is generally negligible. The summertime peak includes both the remnant sea ice community, mostly pennate diatoms, as well as water column forms. The timing of the annual sedimentation episode is remarkably consistent, but the duration, amplitude, and total size (integrated flux) all exhibit significant interannual variability. In particular the annual sedimentation varied by nearly an order of magnitude over an 11-year observation period. In the Ross Sea sedimentation ranged from 2–14 gC m^{-2} y^{-1} with a strong north-south gradient from 73°–76° S (Collier et al. 2000). The peak flux occurs later than in the Peninsula with highest fluxes in March–April. Export efficiency as measured by sediment traps is quite low in both regions, indicating that much of the production is consumed and recycled in the upper 200 m.

Export efficiency is likely low because primary production is limited by iron availability over most of the Southern Ocean which is generally remote from continental sources of windborne dust. Iron limitation is seasonal in coastal regions and marginal ice zones and more persistent over the open sea.

Biogenic production can be in dissolved as well as particulate forms. A major difference between lower latitude and Antarctic polar ecosystems is the partitioning of organic carbon production and export between these two forms. In the subtropics dissolved organic carbon (DOC) may constitute up to half the export, with strong seasonal variation. However, the net production and subsequent export of DOC in higher southern latitudes appears to be negligible. In the Sargasso Sea, about 70% of the annual production flows through the dissolved phase, whereas in the Ross Sea about 70%–80% of the production remains in particulate form and sinks or is respired back to CO_2. The reasons for this global-scale contrast are not clearly understood, but they have important consequences for carbon storage in the deep sea.

Rapidly sinking particles are transported to greater depth before they are respired back to CO_2 than dissolved organic carbon, which depends on the slow mixing and sinking of water for downward transport. Thus organic carbon transport and storage is generally deeper in the Southern Ocean than in the subtropics.

Silicon Cycle

Diatoms are large phytoplankton (c. 20–200 μm long). They are the dominant primary producers in Antarctic waters and require silicon for growth. They have dense, ornamented opal plates or frustules covering their cells that serve as a deterrent to predation and, after the cell dies or loses buoyancy, enhance sinking rates. Thus besides their role as primary producers, diatoms are important vectors for export from the upper ocean. Silicon exists in seawater in dissolved form as silicate, Si(OH)4. The highest surface concentrations in the world ocean, 30–70 μM, are found in the Southern Ocean below the Antarctic Polar Front Zone (~60° S). These high concentrations, resulting from deep mixing, support the high diatom productivity. As a consequence of high production and rapid sinking rates, the sediments underlying the Southern Ocean are highly siliceous (>5% opal by weight) and account for about 50% of opal accumulation in the world ocean.

Silicate deposition (silicification) by diatoms is an active physiological process closely tied to cell wall synthesis and regulated by ambient nitrogen to iron concentration ratios in addition to silicate concentrations. When diatoms are iron-replete, cellular Si:N ratios are about 1 but can be much greater (~10) when iron is limiting, as it usually is in the Southern Ocean. This effect further enhances silica deposition in Antarctic waters. The opal cell wall is not a simple mineral covering, which would dissolve readily, but is instead deposited within an organic proteinaceous matrix maintained by the cell. Healthy active diatoms maintain neutral buoyancy by producing lipids, but buoyancy is lost when the cells die. As they sink, the protein matrix protecting the opal cell wall is attacked by bacteria through extracellular proteases (Bidle et al. 2002), exposing the opal to physical dissolution. The rates of proteolysis are a function of temperature, and are about three times faster at 20°C than at 2°C. In low latitude waters where surface temperatures are 10°C–30°C in the upper 500 m, diatoms rapidly lose their organic matrices, and opal dissolves before they sink into colder deep water. In the cold Southern Ocean the bacteria-enhanced decomposition and dissolution of the opal is inhibited, and the opal is preserved. Diatom dissolution and silicate remineralization was once believed to be a strictly chemical process but is now understood to be under strong biological as well as temperature control. This effect may explain the vast siliceous plains of sediment below the Southern Ocean.

Like other nutrients such as N and P, Si is stripped from surface ocean waters by biological uptake and sedimentation. If the organically bound silica were not remineralized back to silicate and returned to the surface by mixing and upwelling, diatom production would cease as the silica was depleted. Some fraction of the bound silica is regenerated *in situ* by bacteria and zooplankton, but most occurs in the midwater column between 100–500 m. The silica in this layer is returned to the surface, but not necessarily in the same geographic locations where it was originally fixed by diatoms and sank to depth. Diatom silicate produced in the Southern Ocean and regenerated in deeper water is transported horizontally in Subantarctic Mode Water (SAMW) far from its origin. SAMW sinks in the Subantarctic Zone and Antarctic Polar Front region and then flows north, spreading throughout the world ocean, returning to the surface in the upwelling regions of the eastern Pacific off South America and in the North Atlantic. In this way silica originally fixed by diatoms in the Antarctic is returned to surface waters to support diatom production globally. Computer simulation experiments suggest that silica in SAMW may support 75% of the diatom production north of 30° S latitude throughout the world ocean (Sarmiento et al. 2004).

Climate Change

The critical involvement of biological processes controlling geochemical cycles suggest that Southern Ocean element cycling may change greatly—though in still unexpected ways as climate warms in the next decades and centuries. Primary production, organic matter sedimentation, and silica cycling and deposition are all active biological processes under control by temperature and associated with the cycle and extent and duration of sea ice cover. As the Southern Ocean warms and sea ice declines, these processes will be altered, but it is not certain if they will increase or decrease. Primary production and sedimentation may decline if sea ice extent is the dominant control but could increase as more ocean area is exposed to solar irradiance. Ocean warming may enhance silica dissolution and retard the large-scale transport of Antarctic silica to remote regions, inhibiting primary production globally but increasing it locally. Biogeochemistry illustrates the important interplay of physical, chemical, physiological, and ecological processes governing the current, past and future state of the Earth System.

SOUTHERN OCEAN CIRCULATION: MODELING

A fundamental problem in physical oceanography is determining the evolution of the state of the ocean over time. To do so, we have to solve equations for the ocean's momentum (mass times velocity) and its equation of state (essentially its density, a function of temperature, salinity, and pressure), and account for the constraint imposed by mass conservation. Those equations are complex, but numerical models with suitable boundary conditions have been widely used to simulate the circulation of the Southern Ocean. These models solve the pertinent equations on a discrete grid across time and space. For coarse resolution models, the horizontal grid spacing is typically 100–500 km, while high-resolution models have a grid spacing of 10–50 km or less. High-resolution models provide a more detailed description of the processes, but require much more computer time to perform a simulation. It is thus difficult to model the circulation at high resolution over long periods or large areas or to test hypotheses requiring a large number of simulations. Coarse and high-resolution models are thus complementary tools, the choice between them depending on the problem studied.

Models may cover domains ranging from a particular basin or region, in which case they can be at a relatively high resolution, to the entire Southern Ocean. In addition, the Southern Ocean provides the only deep connection between the Atlantic, Pacific, and Indian oceans; indeed, some of the Earth's major water masses acquire their characteristics in the Antarctic region before invading the other oceanic basins. It is therefore crucial to correctly reproduce the characteristics of this region in global models, which are widely used to analyze the Southern Ocean circulation, its global influence, and its response to remote changes.

Models must also take into account the influence of processes that occur at small scales, such as the turbulence that is responsible for vertical mixing near the sea surface. This usually involves parameterization of those processes (representation of physical effects in a model by simplified parameters), based on the dynamic equations and empirical evidence. High resolution models are able to simulate or permit the development and evolution of mesoscale eddies, swirling horizontal structures that are generally smaller than 100 km, whereas the influence of such eddies must be parameterized in coarse resolution models. This is particularly important for the Southern Ocean, where eddies play a large role in meridional (north–south) exchanges and in maintaining the vertical structure. Another difficulty of Southern Ocean modeling is the intrinsic coupling between ocean circulation and the sea-ice cover, which has a paramount influence at high latitudes on heat, salt and freshwater fluxes, as well as on stress exerted at the ocean surface. As a consequence, Southern Ocean models are generally coupled to a sea ice model and driven by atmospheric conditions derived from observations or "reanalysis" products generated by weather forecast centers. The quality of those products is lower in the Southern Ocean than in other regions due to data scarcity. Alternatively, ice-ocean models coupled to atmospheric models can be affected by problematical boundary conditions at the ocean surface, a large source of uncertainty in Southern Ocean modeling.

Despite those difficulties, models can reasonably simulate general characteristics of the ocean circulation, as well as the large-scale water mass properties. Comparison between the observed and simulated tracer evolution, in particular of the chlorofluorocarbons which provide relatively straightforward information about ocean "ventilation," has proven to be valuable in assessing model performance. Coarse resolution models are unable to precisely reproduce the details of circulation on the continental shelves or exchanges between the continental shelves and the deep ocean. Higher resolution models appear to be more capable in that domain, allowing a quantitative comparison between the characteristics of observed and simulated water masses. Such models have also been used to analyze processes responsible for the formation of water masses on the continental shelves, including exchanges between the ocean and ice shelves and the role of tidal mixing. In some regions of the Southern Ocean, the models experience difficulty simulating vertical mixing and the weak vertical stratification below the surface mixed layer. This stratification results from a delicate balance between horizontal and vertical processes and appears to be very sensitive in some models to the surface freshwater flux. Uncertainty in that quantity could strongly impact the stratification, the vertical heat flux, the ice cover simulated by the model, and the properties and formation of deep waters.

Models have been used to examine the formation processes of Antarctic Intermediate Water and Antarctic Bottom Water, two of the major water masses in the global ocean. For example, the production and properties of bottom water are strongly influenced by the large amount of brine released during sea ice formation on the Antarctic continental shelf. As the waters there are generally maintained at temperatures close to the freezing point, added salt can increase their density enough to enhance mixing and sinking along the continental slope. Shelf waters thereby become one of the major constituents of bottom water. On the other hand, net sea ice melt and higher precipitation at slightly lower latitudes tends to stabilize the water column and may contribute to the low salinity signal characteristic of intermediate water.

A dominant characteristic of the Southern Ocean is the absence of any continental barrier between 56° and 62° S, at the Drake Passage between South America and the Antarctic Peninsula. This allows the existence of a strongly zonal (west to east) Antarctic Circumpolar Current. Models have shown that the transport of this current through the Drake Passage is set by the strengths of the wind-induced near-surface northward oceanic transport and the deep northward export of dense water formed close to Antarctica. These transports are partly compensated by a southward flow of intermediate water, between roughly 200 and 2500 m, which is diverted eastward by the Coriolis force, contributing to a stronger circumpolar current.

Model results have indicated that the wind-driven upwelling of intermediate and deep water at Drake Passage latitudes could control deep water production in the North Atlantic, where that process has a large impact on ocean heat transport and climate. This hypothesis requires that Southern Ocean upwelling be the only sink for deep water produced in the North Atlantic. Any change in wind stress and upwelling in the Southern Ocean would influence deep water production in the North Atlantic, the source and sink being necessarily equal at equilibrium. More recent model results have suggested that this "Drake Passage effect" is relatively weak because of other deep water sinks. This does not mean that the role of the Drake Passage in the oceanic circulation is only restricted to its direct impact on the circumpolar current. For example, if the Drake Passage is closed in a model, then a strong warming occurs south of 60° S due to increased southward ocean heat transport. This warming is associated with a reduced sea ice cover, an increase in deep water formation close to Antarctica, and a decrease in deep water formation in the North Atlantic.

In addition to modeling of the time-averaged circulation, it is also possible to model processes responsible for temporal variability of the Southern Ocean. Most studies devoted to that subject have focused on surface variability in relation to the sea ice cover, probably due to the larger applicable data inventory. When driven by appropriate forcing, such models can simulate the dominant characteristics of the major modes of atmospheric variability, allowing analysis and description of the Southern Ocean response. Variability below the surface layer has also been described in models, and the responsible mechanisms analyzed, but the scarcity of subsurface data makes it difficult to assess the reality of the modeled features.

In the examples presented above, data are used a posteriori in order to test model skill and suggest model improvements. It is also possible to combine observational data and dynamical principles using techniques such as data assimilation and inverse methods. The goal is to profit from available observational information and ocean physics to derive essential parameters that cannot easily be measured, such as vertical diffusivity and viscosity. In inverse box models (e.g., the ocean is divided into boxes whose boundaries are defined by vertical sections of ocean data and continental barriers). In the Southern Ocean, meridional sections south of Africa, Australia and South America, and zonal sections at various latitudes are often used. Within the boxes, conservation of mass and some tracers are assumed for specific layers in order to obtain a set of equations that account for vertical exchange between the layers. The tracers can be temperature, salinity, or biogeochemical parameters, but conservation will not apply in the top layer for some variables because of air-sea fluxes. The oceanographic data provide the tracer values at lateral interfaces between the boxes that are used to compute the fluxes. The data also provide a dynamic constraint on the unknown velocity at those interfaces, using the "thermal wind" equation, which states that the horizontal gradient of density is proportional to the vertical gradient of geostrophic velocity (a flow where the Coriolis and horizontal pressure forces are balanced). Information about wind stress is then applied to estimate transport in the surface layer. This method often provides an "underconstrained" system, from which one of several solutions must be selected. Nonetheless, this method provides an estimate of the flow across key ocean sections, along with the heat and salt transport, the production and the conversion of water masses between layers, and the error bars on those values. Such estimates are instructive as they are consistent, within defined bounds of uncertainty, with both the ocean physics and observations.

SOUTHERN OCEAN: CLIMATE CHANGE AND VARIABILITY

The Southern Ocean surrounding Antarctica, the coldest, driest, windiest, and highest continent in the world, is the only ocean in the world with currents that circle the entire globe, thus transporting and mixing climate signals from one oceanic basin to another. Extremely cold temperatures and excessive salt content from the process of sea ice formation in winter produce the densest sea water on the continental shelf along coastal regions of Antarctica, which is the source of the densest water on the bottom of global oceans. In contrast to the Arctic Ocean, seasonal sea ice around the periphery of Antarctica can freely grow and extend northward under the influence of seasonal atmospheric and oceanic forcing without the restriction of landmasses. The atmospheric variability above the surface is not only influenced by the regional geography (e.g., land-ocean distribution in the Southern Ocean) but is also closely connected with climate variability in the tropics. Therefore, the three components of the climate system in the Southern Ocean, atmosphere, ocean, and sea ice, exhibit a high degree of covariability regionally and a high degree of connectivity with the rest of the world. These climatic characteristics have been documented in modern instrumental records.

The most important feature of the Southern Ocean is the Antarctic Circumpolar Current (ACC), which flows within the circumpolar belt around Antarctica and provides the deep ocean link among the major ocean basins. The ACC transports water from west to east at a rate of well over 100 Sv along a 21,000 km path, propagating and mixing climate anomalies along its way. Because of the connectivity of the Southern Ocean, the ACC becomes a key component of global thermohaline circulation, allowing oceanic route telecommunication of climate anomalies to remote regions in both hemispheres at a variety of time scales. The thermohaline circulation linked with the ACC, consequently the meridional transport of climate signals, occur at different depths of the Southern Ocean.

At surface and mid-depth of the ocean, the ACC acts as a barrier, limiting poleward heat transport and forcing an everlasting glacial state of Antarctica. Near the ACC, the northwards Ekman transport forces low salinity surface water sliding into subsurface layers in midlatitudes, forming the Antarctic Intermediate Water and Subantarctic Mode water north of the ACC. These waters spread at mid-depth of the subtropical gyres, transporting fresher water northward and playing a major role in the uptake of atmospheric CO_2. They are also mixed with the surface water above, influencing sea surface temperature in regions away from their formation sites at decadal time scales. Below them is the North Atlantic Deep Water, which is formed near the Labrador Sea and Greenland Sea, flows to the South Atlantic and then spreads over other ocean basins via the ACC. The Subantarctic Mode Water and Antarctic Intermediate Water also plays an important role in recycling the North Atlantic Deep Water and closing the thermohaline circulation.

At many sites along the continental margins of Antarctica, intensive cooling and salt ejection from sea ice formation in austral winter produces the coldest and densest water that sinks to the bottom of the ocean along the continental slope, forming the Antarctic Bottom Water. This water floods the deepest part of the global ocean. Changes in polar climate in complex interaction with sea ice and glacial ice would be carried away a great distance with the spread of the bottom water. Sinking of the Antarctic Bottom Water in high latitudes and Antarctic Intermediate Water in midlatitudes balances the upwelling of Circumpolar Deep Water in between, which results from the mixing of the penetrating North Atlantic Deep Water with surrounding waters. That completes the thermohaline circulation in the Southern Ocean.

Therefore, the vertical thermohaline structure in the Antarctic Zone, the region south of the ACC, consists of relatively fresh and cold surface water above the warmer but saltier Circumpolar Deep Water, on top of the densest Antarctic Bottom. This region is influenced under seasonal sea ice cover, which is intricately involved with water mass modification processes. In addition, the Circumpolar Deep Water provides a tremendous heat resource that can be released to the atmosphere under the condition of deep convection. That potentially can impact regional climate or even global climate. The Weddell polynya in the mid-1970s is such a deep convection event. (The Weddell polynya is a large open water area [about 350,000 km^2] within the ice covered Weddell Sea during the austral winters of 1974–1996, within which the ocean stratification was destroyed by vigorous deep reaching convection.) The heat storage in the upper Circumpolar Deep Water was vented to the atmosphere. Even though the quantitive climatic impact of such an event is uncertain, abrupt temperature cooling was observed to nearly 3000 m depth and significant changes in air-sea heat flux were found.

A unique feature of Southern Ocean climate variability is a number of clearly identifiable climate patterns in the atmosphere that are generated by different physical and dynamical processes. First, the Southern Annular Mode is marked by quasi-zonally symmetric but out-of-phase pressure anomalies between mid- and high latitudes. The Southern Annular Mode is a counterpart of the Northern Annular Mode in the northern hemisphere. The positive phase of the Southern Annular Mode represents a pattern of below-normal pressure on the Antarctic Continent and above-normal pressure in southern midlatitudes. This donut-shaped pressure anomaly pattern dominates variability of the pressure field in the Southern Hemisphere with maximum variability at 10 days period and explains over 50% of the sea level pressure monthly mean variance over Antarctica. The mechanism that maintains this climate mode is suggested by a positive feedback between eddy activity in mid-high latitudes and zonal mean flow. The Southern Annular Mode has experienced a significantly increasing trend toward its positive phase over the last 50 years. This increasing trend indicates a stronger westerly over the subpolar Southern Ocean, consequently enhancing meridional overturning in the ocean through the changes of Ekman transport as suggested by modeling studies. In addition, long-term annual and seasonal mean changes in extratropical cyclone frequencies in the southern hemisphere are also in line with the increasing trend of the Southern Annular Mode. Reduced occurrences of cyclones over higher latitudes and increased occurrences of cyclones in midlatitudes in the Southern Ocean are observed during 1958–1997. Numerical modeling suggests that this positive trend in the Southern Annular Mode will likely continue through the twenty-first century as global warming proceeds.

The Semi-Annual Oscillation is another quasi-zonally symmetric mode in the southern extratropics.

It consists of the twice-yearly contraction and expansion of the pressure trough around Antarctica, in response to differences in heat storage between Antarctica and midlatitude oceans. Thus the Semi-Annual Oscillation is characterized by the twice-yearly enhancement in meridional gradients of temperature and pressure fields. In response to the variation in the pressure gradient, the westerlies show equinoctial maxima that are 20%–30% stronger than those in summer and winter. The atmospheric convergence line with a strong half-year cycle exerts significant influences on the seasonal asymmetric behavior of ice extent: slowly advancing equatorward in fall and fast retreating in spring. In the western Antarctic Peninsula, the timing of the semiannual migration of the Circumpolar Trough dynamically influences the timing of sea ice advance and retreat. Moreover, in conjunction with pressure rises over Australia, Africa, and South America the expansion of the low pressure belt in autumn causes an amplification of the wavenumber 3 structure in midlatitudes of the Southern Ocean. This enhances meridional circulation and directly influences air transport from lower latitudes toward the Antarctic Continent, consequently causing the reduction of seasonal cooling on the continent. Even though the direct mechanism generating the Semi-Annual Oscillation is the seasonal solar heating and differential heat storages between mid- and high latitudes, the variation of the Semi-Annual Oscillation is not limited at seasonal time scale. It exhibits variability from synoptic to interannual and longer time scales due to modification by and interaction with other climate patterns. An observed change in the Semi-Annual Oscillation is the dramatic weakening of its amplitude since the mid-1970s. Studies have linked this change to the decrease of meridional air exchange that causes the cooling trend in coastal east Antarctica.

Another distinct climate pattern is the quasi-stationary wavenumber 3 pattern in midlatitudes of the Southern Ocean, a predominant winter mode in pressure/wind fields. The land/ocean distribution in midlatitudes is suggested that creates and maintains the wavenumber 3 pattern. Research showed that three southerly branches of the wavenumber 3 pattern coincide with three northward maximum extent of sea ice edge during late winter 1996, indicating the role of the wavenumber 3 pattern in advancing the ice edge. The wavenumber 3 pattern is also positively coupled with the ice edge distribution, promoting eastward propagation of the ice edge maxima and providing preferred locations for cyclonegenesis in the open ocean north of the ice cover. The long term variability of this climate pattern has not been thoroughly studied yet.

The Pacific South America pattern, which dominates climate variability in the subpolar South Pacific, is also a distinct climate mode in the Southern Ocean. It consists of three anomalous pressure centers with alternating phases in east of New Zealand, Amundsen /Bellingshausen Seas, and over South America/the South Atlantic. This climate pattern is part of the stationary Rossby wave train, which is usually generated by the changes of the tropical convection associated with the sea surface temperature variation during El Niño Southern Oscillation (ENSO) cycles. The Rossby wave train is responsible for propagating the ENSO signal to southern high latitudes. Therefore, at the interannual time scale, the Pacific South America pattern is associated with the ENSO variability, creating persistent high (low) pressure centers in the southeast Pacific in response to ENSO warm (cold) events, respectively. This anomalous pressure center consequently has a significant impact on the sea ice variability in the South Pacific and South Atlantic through thermodynamic and dynamic processes.

The ENSO variability in the tropics does not influence the climate variability in the southern hemisphere only through the stationary Rossby waves. It has caused changes and modifications of many aspects of atmospheric circulation in the Southern Ocean, particularly in the South Pacific. For the mean atmospheric circulation, El Niño events generate more vigorous Hadley Cell overturning due to the increased sea surface temperature gradient, accompanied by the stronger subtropical jet and weakened polar front jet in the South Pacific. The Amundsen Low, a dominant variability of surface pressure in the South Pacific that has a strong impact on heat and moisture transports between Antarctica and South pacific, tends to be shallower in response to the warm ENSO events. During La Niña events, storm activities move towards higher latitudes, accompanying a stronger polar front jet, deeper Amundsen Low but a weakened subtropical front jet. Cyclone activities also alter their distributions accordingly: reduced frequencies of cyclones happen over the south Indian Ocean, Australasia, and the Amundsen Sea during El Niño, and vice versa during La Niña events. In association with the Pacific South America pattern and the Rossby wave, blocking highs present another circulation characteristic in the Southeast Pacific influenced by ENSO cycles. The blocking events, usually identified by persistent anomalous high-pressure centers that interrupt the mean zonal flow, frequently occur in both the Southwest Pacific and the Southeast Pacific. In the Southeast Pacific, the blocking highs occur near the high-pressure center of the PSA aforementioned during ENSO warm events. However, the Southern Ocean's response to ENSO variability could change over the time. Studies showed that the net precipitation and moisture budget in the west Antarctic have a positive correlation with the Southern Oscillation index during the 1980s but a negative correlation in the 1990s, implying a decadal change of ENSO teleconnection.

All aforementioned climate modes in the atmosphere interact with sea ice below, producing spatially coherent patterns in the ice field. Sea ice in the Southern Ocean advances from March to September, reaching a maximum extent of about 18 million km^2. More than 80% of the winter sea ice melts in austral summer. Since the late 1970s, satellite passive microwave imagers have been providing continuous sea ice observations in both northern and southern hemispheres. More than 25 years of satellite sea ice observations play a key role in modern climate studies in polar regions. In the Southern Ocean, sea ice not only responds to regional climate variability in the atmosphere, but also is linked to remote forcing in the tropics. The largest interannual variability in Antarctic sea ice is a quasi-standing wave in the western hemisphere called the Antarctic Dipole. The Antarctic Dipole is characterized by out-of-phase temperature and sea ice anomalous centers in the northeastern Ross Gyre in the Pacific sector, and the central Weddell Gyre in the Atlantic sector of the Southern Ocean. The Antarctic Dipole represents the strongest teleconnection between ENSO variability in the tropics and climate variability in southern high latitudes. Temperature anomalies in the Pacific center of the dipole represent the largest ENSO signal in the world outside of the tropical Pacific. In response to ENSO warm events, warmer temperature and less sea ice occur in the Pacific center while colder temperature and more sea ice occur in the Atlantic center of the dipole, vice versa to ENSO cold events. The changes of the basin-scale pole-ward atmospheric heat transport in the South Pacific and South Atlantic, and Pacific South America pattern associated with the ENSO variability are two main mechanisms that directly contribute to the formation of the Antarctic Dipole. After the tropical signal being transported to the southern subpolar regions, temperature and sea ice anomalies grow and amplify reaching their maximum as the southern hemisphere enters its winter. The Antarctic Dipole persists three to four seasons after ENSO matured in the tropics, establishing itself as a distinct high latitude climate mode in temperature and sea ice fields.

Under the influence of atmospheric wavenumber 3 pattern, the similar pattern also exists in the sea ice concentration and sea ice edge, as the second important climate pattern in the ice field. A less dominant pattern is the Antarctic Circumpolar Wave—a wavenumber 2 pattern propagating eastward arguably around Antarctica in sea surface temperature, sea surface height and sea ice. The Antarctic Circumpolar Wave is more visible during the period of 1982–1992 than other times in the satellite era.

In contrast to the Arctic Ocean where sea ice extent has drastically reduced during the last 25 years, Antarctic sea ice extent experiences only a marginally significant increasing trend on average. The most recently documented trend in monthly total ice extent is 8170 ± 3240 km^2/year during the period of 1978–2002. Compared to the maximum ice extent in winter, 18 million km^2, this increasing trend is rather trivial. However, large spatial variability exists in the long-term trend of sea ice around Antarctica. In response to the dramatic warming in the Antarctic Peninsula region, sea ice in the Amundsen Sea, Bellinshausen Sea, and Weddell Sea has significant decreasing trends in its extent, concentration, ice edge, and ice season. In the western Antarctic Peninsula, the early ice retreat in spring and late advance in fall is attributed to the shorter ice season in the recent decade. On the other hand, sea ice extent and ice season in the Ross Sea have experienced significant increasing trends. Even the major climate variability in southern high latitudes, such as the Southern Annular Mode and ENSO related Pacific South America pattern, strongly influence sea ice variability at interannual and longer time scales, but their trends cannot explain the trends in Antarctic sea ice. What causes the trend in Antarctic sea ice, particularly the increasing trend in the Ross Sea ice field, still remains unresolved. Certainly, Antarctic sea ice is very sensitive to global climate. A modeling study suggests that 38% of global mean surface warming for a double CO_2 scenario is due to a change in the sea ice of polar regions. Seventy percent of this change comes from Antarctic sea ice, through changes in sea ice albedo and ease of ice melting. Therefore, any significant changes in future Antarctic sea ice could play a key role in global change.

The most noticeable climate change in the Southern Ocean is the rapid regional warming at the Antarctic Peninsular. At Faraday/Vernadsky station in the western Antarctic Peninsular, surface air temperature exhibits a startling mean warming rate of 2.8°C over the last 50 years, contrasting the global mean warming rate of 0.5°C during the same period. More striking is the warming rate in winter at this station: 5°C–6°C over the last 50 years, the highest rate of warming observed anywhere on earth. The temperature trend gains worldwide attention when the Larsen B ice shelf dramatically and catastrophically collapsed in January–March 2002. The Larsen B ice shelf is now one of seven ice shelves in the Antarctic Peninsula region that collapsed over the last several decades. The collapse of ice shelf also changes the variation of glacier ice sheet behind ice shelf. The summer melting and changes in stress field due to shelf removal become key factors causing the increased glacier flow acceleration towards the ocean, glacier thinning and retreat. However, the rapid warming in the Antarctic Peninsula does not represent temperature changes in the rest of Antarctica. Studies of Antarctic weather station data indicate that rest of Antarctica has a warming rate similar to the global mean. Many coastal stations along the eastern Antarctic and on the plateau of Antarctica surface air temperature even show a moderate cooling, indicating the spatial complexity of changes in recent decades. Satellite observations since the 1970s further confirm the spatial variability of temperature trends. Why Antarctica has such a spatially complicated temperature trend pattern is still an open question.

SOUTHERN OCEAN: FRONTS AND FRONTAL ZONES

The Southern Ocean contains a series of oceanic fronts, relatively narrow zones of enhanced horizontal gradients of water properties that separate broader, relatively uniform zones with distinctly different vertical structures and water mass characteristics. Most of these fronts are circumpolar, so that anyone traveling to the Antarctic by sea would invariably cross these fronts and notice drastic changes in air and water temperature, weather and ice conditions, ocean color, krill, fish, and sea birds. Some fronts play key roles in various ocean–ice–atmosphere processes. For example, fronts are associated with along-front current jets that transport the bulk of water, heat, and salt. They can meander, forming rings that detach and persist for many months. Fronts are major ecosystem boundaries, often associated with zones of higher biological productivity. Meteorological parameters like surface heat flux and wind stress can change sharply across major thermal fronts, making them important to weather forecasting and climate monitoring. Some Antarctic fronts are related to sea ice conditions, and others can affect the acoustic environment. Sedimentation regimes, largely determined by the ocean circulation, will be related to the distribution of fronts. In addition, sea-born pollutants can be concentrated thousands of times along oceanic fronts.

The northernmost front in the Southern Ocean, sometimes utilized as that ocean's northern boundary, is the Subtropical Front, also called the Subtropical Convergence. This front is found between 30° and 35° S, but is interrupted by Africa, Australia, and South America. Closely spaced hydrographic stations reveal a complex structure consisting of two fronts separated by the Subtropical Frontal Zone. Surface temperature and salinity are generally used to delineate this front, since it is hardly noticeable below 500–1000 m depths. Temperature and salinity characteristics of the frontal zone depend on locations and season. In winter, surface temperature across the front can range from 8°C to 16.9°C, and in summer from 12°C to 19.5°C. Summer surface salinity across the front ranges from 34.3 to 35.58 parts per thousand (or practical salinity units).

The Agulhas Front occurs off South Africa, where it retroflects, extends eastward, and eventually merges with the Crozet Front north of the Crozet Plateau (Del Cano Rise). The Agulhas Front is best defined by the 10°C isotherm, which can vary from $<$300 m to $>$800 m across the front. Another reliable criterion of this front is the presence of a thermostad (thick layer of relatively uniform water) on its warm side, in the 150–300 m layer. A variety of salinity and temperature values have been used in different studies to delineate the front, and these typically change alongstream to reflect substantial cooling and freshening toward the east.

The Subantarctic Front is the northernmost continuous circumpolar front of the Southern Ocean. It marks the southern boundary of a well-developed salinity minimum at ~500–1000 m depths, associated with Antarctic Intermediate Water. A considerable variety of other criteria have been used to identify this front, including a thick ($>$400 m) isothermal layer of sub-Antarctic mode water in the Australian sector, where a double front has also been observed. Considering the strength and robustness of this front, it is surprising that it was ignored for decades until a seminal work by Burling (1961), who distinguished the Subantarctic Front in the Australian–New Zealand region; further studies demonstrated its circumpolar nature. The past situation with this lack of recognition was exacerbated by a terminological confusion, a mix-up between the Subantarctic and Subtropical fronts.

The Polar Front is the northernmost boundary of the subsurface temperature minimum, a hallmark of the Antarctic vertical thermal structure. That minimum is a remnant of winter convection that cools the surface 100–150 m layer, the upper half of which is then capped by summer warming. While the temperature minimum descends and gradually disappears northward, traces of it can occasionally be found as far north as the Subantarctic Front. On meridional vertical temperature sections, the Polar Front is located in summer at the northern terminus of the subsurface temperature minimum, bounded by 2°C isotherm in the 100–300 m layer. In winter it coincides with the vertically oriented 2°C isotherm. In several sectors, more than one Polar Front can be observed, probably accounting for reported positions both north and south of Îles Kerguelen.

The Southern Antarctic Circumpolar Current Front and the Southern Boundary of the Antarctic Circumpolar Current, farther south, were originally defined as intermediate to deep fronts without any surface manifestations. Sea surface signatures have since been reported in some locations. Criteria for the more northerly front have included potential temperature greater than 1.8°C at the temperature maximum at depths greater than 500 m and less than 0°C at the temperature minimum at depths less than 150 m, salinity greater than 34.73 along the salinity maximum at depths greater than 800 m, and dissolved oxygen less than 4.2 ml l-1 along the oxygen minimum at depths greater than 500 m. Not all of these properties are found at all locations. The more southerly front is defined as the southern boundary of the upper Circumpolar Deep Water, the most voluminous water mass in the Southern Ocean. While this front separates different water masses, it is not necessarily associated with enhanced water property gradients.

The Continental Water Boundary has mainly been identified in the upper 500 m near the continental shelf break in the Atlantic sector and may be a local manifestation of the Antarctic Slope Front. It has also been called the Weddell Gyre Boundary. In the Drake Passage it can be identified by a temperature range of 1°C–2°C, salinity range of 33.9–34.0 ppt, and potential density range of 27.1–27.2.

The Weddell-Scotia Confluence, bordered by the Scotia Front and Weddell Front, is a peculiar double frontal zone that forms at the contact between the Weddell Gyre and the Antarctic Circumpolar Current. A characteristic feature is its uniformity, which can be attributed to vigorous vertical and lateral mixing. It is distinguished by a low temperature ($<$0°C), high salinity ($>$34.2), and high potential density anomaly ($>$27.4), with both salinity and density higher that those of adjacent water masses.

The Scotia Front is mainly a regional subsurface feature marked by maximum temperature and salinity gradients along the temperature and salinity maximum core layers of the Circumpolar Deep Water. The temperature maximum decreases southward across the front from 1.5°C–2.0°C to below 0.5°C, while the salinity maximum decreases from 34.70–34.72 ppt to

34.67–34.68 ppt. The most reliable criterion of this front's axis is the 1°C isotherm in the 300–500 m layer.

The Antarctic Ice Boundary Front has been identified only in the Indian sector and appears to form near the northernmost extent of sea ice cover in winter. At that time its surface temperature range is 0°C to –1.8°C, while in summer its temperature range is 2°C–1°C. The surface salinity ranges within 0.1–0.3 ppt. This front can also be detected by a sharp southward cooling and shoaling of the subsurface temperature minimum.

The Bransfield Strait Front is usually associated with the 1.0°C isotherm and 34.1 ppt isohaline, forming a boundary between cold and salty Weddell Sea waters and warm and fresh Bellingshausen Sea waters that enter the strait from opposite sides. Aligned with the main axis of the Strait, this front sometimes extends well beyond 45° E in summer. Outside the Bransfield Strait, the front is oriented along 62° S, parallel to the Southern Antarctic Circumpolar Current front at 60° S.

The Antarctic Slope Front is a distinctive boundary between warm and salty off-shelf waters and cold, fresher or saltier waters of the Antarctic continental shelves. It is best defined below the surface mixed layer, although high-resolution measurements can often pick up subdued surface signatures. This front and an associated westward shelf break current have been reported along much of the circumpolar upper continental slope but are weak in the southeast Pacific sector. Cross-frontal horizontal temperature gradients can exceed 2°C over less than 5 km. A double, V-shaped feature often characterizes the upper front in the Ross and Weddell seas, with colder, fresher water within the V. In locations where the continental shelf is narrow, the frontal zone cannot reliably be distinguished from the northern boundary of the Antarctic Coastal Current. The Antarctic Slope Front extends deep into the water column over the continental slope, where Circumpolar Deep Water is entrained across the front into newly forming Antarctic Bottom Water.

SOUTHERN OCEAN: VERTICAL STRUCTURE

The vertical structure of the Southern Ocean, which is ordinary and remarkable in equal measures, is easy to describe. The water density increases with depth and increases towards the south (poleward). Thus, lines of constant density rise towards the south. Water density depends on water temperature and salinity (amount of dissolved salts) so these two properties have a similar structure to that of density. With a few exceptions, temperature decreases while salinity increases with depth and towards the south.

In the ocean, water density must increase with depth so that lighter water will float on heavier. At high latitude, surface water density can increase (for example, by cooling), which causes the upper part of the ocean to overturn. Although these situations are important, they are confined to limited times and places and are not part of the general vertical structure of the ocean. So the increase in density with depth is not remarkable but a property of almost all water in the ocean. The southward increase in density has a similar simple explanation.

Large Scale Vertical Structure

Flow in the Southern Ocean, the Antarctic Circumpolar Current (ACC), is mostly from west to east around the continent of Antarctica. The current is fastest at the surface and decreases with depth due to the drag effect of subsurface seamounts and mountain ranges.

This water movement is governed by a relatively simple force balance (the geostrophic balance) in which horizontal pressure change (or gradient) opposes the Coriolis acceleration. The Coriolis acceleration occurs because we observe the ocean from a moving point of view (the surface of the spinning Earth). It causes objects moving on the surface of the Earth to be deflected. Water in the Southern Hemisphere deflects to the left of its direction of motion; the deflection is larger as the water moves faster.

Pressure in the ocean is due to the weight of the water above it (the hydrostatic balance). In different parts of the ocean, the pressure is different because there is more water (the sea surface is higher) or the overlying water is denser. These horizontal pressure changes try to push water from higher to lower pressure.

The hydrostatic and geostrophic balances are combined to explain the density increase towards the south. The slowing with depth requires that the deeper pressure gradient becomes smaller. The pressure on the south (low pressure) side of the current is increased by increasing the density of the water above. Thus, if the density at any depth level across the Southern Ocean increases towards the south, the flow speed will decrease with depth.

The vertical structure of density in the Southern Ocean is consistent with our dynamical ideas about how the ocean works, so in that sense, it is not remarkable. However, this structure allows water on the north side of the Southern Ocean at a depth of about 4 km to rise to the surface as it moves southward towards the Antarctic Continent. Note that this vertical excursion does not require any change in water density. So, water from deep in the ocean circles around Antarctica side-slipping southward along its density surface until it appears near the surface south of the ACC where it can interact with the atmosphere. Thus, the vertical structure of the Southern Ocean is a critical part of the thermohaline overturning circulation in the World Ocean, which allows deep water to move to the surface where it is changed—a remarkable property indeed.

Distinct Water Types and the Thermohaline Circulation

Water in the ocean has distinctive values of temperature and salinity. Water properties are set at the surface in a limited number of places in the World Ocean where the surface water density is increased sufficiently for it to move into the ocean interior, sometimes all the way to the bottom. Once the water is away from the ocean surface, its properties change only slowly due to relatively weak internal mixing.

Water types are named by their observed depth and place of origin. For example, very salty and cold (near freezing) water is produced at several places around the Antarctic Continent. This water slides off the continental shelf (and mixes a bit on the way down) to produce the densest water in the ocean—Antarctic Bottom Water (AABW). The very cold water (around –0.8°C) at the bottom of the Weddell Sea is an example of AABW.

Another dense water type (North Atlantic Deep Water or NADW) is created in the North Atlantic between Greenland and Norway by severe winter cooling (and freezing of sea ice). This water, which fills the deep parts of the North Atlantic, is warmer and saltier (and less dense) than AABW. NADW moves southward in the Atlantic Ocean above AABW. Circumpolar Deep Water (CDW) is a slightly modified form of NADW, which is identified by higher temperature and salinity compared to surrounding waters. It is mainly this water that climbs along the sloping density surfaces of the Southern Ocean. This water can be traced by the high salinity at 3 km depth, which rises to the surface on the south side of the ACC.

At the surface, CDW is made colder and fresher to produce Antarctic Surface Water (AASW). Surface wind forcing and the Coriolis acceleration, push

AASW northward until it finds a density horizon matching its own density, at which point it sinks below the surface as Antarctic Intermediate Water (AAIW). This cold and somewhat fresh water proceeds northward in the Atlantic Ocean to return to the North Atlantic where it closes one part of the global thermohaline overturning cell. The northward flowing surface water, driven by the wind, is the mechanism that pulls the CDW up from depth.

The interplay of heat change (heating by solar radiation; cooling by infrared radiation, evaporation and contact with the cold atmosphere) and salinity change (decrease by precipitation and melting of sea ice; increase by freezing of sea ice) creates surface water density changes, which results in an elaborate three-dimensional circulation in the World Ocean. Wind forcing at the ocean surface also helps drive this large scale circulation. The Southern Ocean is a critical element of that circulation and its observed vertical structure is the result of (or at least allows) the circulation.

Seasonal Changes in Vertical Structure

Due to its high latitude, the Southern Ocean experiences a strong seasonal change in sunlight, being largely absent in the winter and continuously available in the summer. This pattern leads to strong warming of the surface water in the summer and equivalent cooling (to the cold atmosphere) in the winter. The winters are so severe that the surface of the ocean freezes over about half of the Southern Ocean. This cycle has a strong influence only on the upper ocean (to a depth of 100 m or so) with almost no effect on the water below. Over most of the Southern Ocean, this seasonal cycle of solar heating and atmospheric cooling creates a cold layer at the ocean surface in winter of 50 to a few hundred meters thick and a warm layer in summer of 10–40 m thick. Winds over the Southern Ocean are stronger in spring and fall and weaker in summer and winter. These changes in wind strength change the depth of mixing near the surface of the ocean by a few tens of meters but otherwise do not cause a strong seasonal change in the vertical structure of the ocean.

During the winter in the southern half of the Southern Ocean, the water from the surface down to about 100 m cools to the freezing point (about –1.8°C). In a few places, this cooling creates water dense enough to mix to 400–600 m depth. Next to the Antarctic Continent, intense cooling due to katabatic winds (very cold air draining off the Antarctic Polar Plateau) creates very cold and salty water that falls to the bottom (around 500 m) and eventually flows off the shelf to create AABW.

As the surface water freezes to make sea ice, most of the salt accumulates in brine which flows into the ocean increasing the salinity of the upper ocean. However, in the spring the sea ice melts releasing the water back to the ocean and almost balancing the salt release in the winter. There is a small seasonal change in the surface salinity (a few hundredths of a percent) due to this seasonal melt-freeze cycle of sea ice.

The ACC is constrained to flow through Drake Passage, south of South America, which is the narrowest constriction to the flow (about 800 km wide). More importantly, the ACC flows along several mid-ocean ridges and is constrained to pass through several narrow gaps in these ridges, for example the Udintsev Fracture in the South Pacific Ocean. In spite of these constrictions and the perturbations that they cause, the vertical structure of the Southern Ocean maintains the general pattern seen at the Greenwich Meridian. Thus, the observed vertical structure is resistant to change. Since there are many ways that the structure might change (mixing, topographic effects, speed changes, surface forcing, etc.), we must conclude that the processes that create this vertical structure remain active, constantly pushing the Southern Ocean into the state that we see.

The smooth structure of the water properties in the Southern Ocean is broken by several narrow fronts, which are locations of strong horizontal change in water properties. From north to south, the Southern Ocean fronts are the Subantarctic Front (SAF), the Polar Front (PF), the Southern ACC Front (SACCF), and the southern boundary of the ACC (SBndy). As with much of oceanography, different names are chosen at different times or by different investigators. For example, the Polar Front has been called the Antarctic Convergence by some authors, though this term is now rarely used. All of these fronts are continuous around the Southern Ocean.

ACC fronts are distinct from other oceanic fronts in that they extend throughout the water depth. Because water density changes across these fronts, they are also zones of strong horizontal pressure change, which gives rise to narrow, fast currents (referred to as "jets"). Southern Ocean fronts are locations of strong flow in addition to being transition zones for water properties.

Frontal jets introduce another complicating factor to the oceanography of the Southern Ocean: frontal meanders. Rapid, narrow flows in an otherwise still ocean are susceptible to wiggling (or meanders), which develops into extended loops of current that wrap around on themselves producing a ring of current called an eddy.

These eddies are essential to the way that the ACC works. An eddy acts as a sort of container (or thermos bottle) transporting water properties (like heat, salt, nutrients, and momentum) across the ACC. Thus, the presence of the narrow jets allows the creation of eddies which produces the movement of properties across this broad flow that circles the Earth. These eddies are thought to be a part of the process that creates the fronts in the first place!

There is considerable study at present on the processes that drive the circulation in the Southern Ocean and produce the structure and variability of the flow and water properties that are observed. These efforts involve computer models as well as observations. Questions now being addresses are the size and reason for the changes in the speed of the ACC, the effect of changing sea ice on the ocean, the importance of the ocean in melting the ice over the Antarctic Continent, the role played by the Southern Ocean in the global thermohaline circulation, and others.

Computer-based numerical ocean circulation models are being used by many groups to study various aspects of the oceanography of the Southern Ocean. Some of the models consider the Southern Ocean in isolation from the rest of the World Ocean while others represent the whole (global) system. Most circulation models are driven by the atmosphere (and solar radiation). Some studies couple freely evolving atmosphere and ocean models allowing the two parts of the global system to interact. Both types of model approaches allow the study of the changes to the Southern Ocean vertical structure that would be expected from variations in the ocean-atmosphere-cryosphere that have been observed as past climate changes.

Vigorous observational programs measure the structure and variability of the water properties and the circulation over many parts of the Southern Ocean. Some measurements are based in the ocean (attached to moorings or based on ships) while others are taken through sensors on satellites.

SOUTHERN RIGHT WHALE

The southern right whale *(Eubalaena australis)* belongs to the Balaenidae family. Members of this family are characterised by a narrow, highly arched upper jaw and long baleen (the large food filter plates that hang from the roof of its mouth). The earliest known balaenid fossil, discovered in South America, is early Miocene ($\sim$25 Ma; Fordyce and Barnes 1994). There are many later Miocene and Pliocene records of Balaenidae from around the North Atlantic and the North Pacific. However, the fossil records offer no obvious clues to the origins of right whales.

There are three taxonomically recognised species of right whales: the North Atlantic right whale *(Eubalaena glacialis),* the North Pacific right whale *(E. japonica),* and the southern right whale *(E. australis)*. Because of differences in timing of southern and northern breeding seasons and apparent discontinuity of distribution across the Equator, there appears to be no mixing between the Northern and Southern Hemisphere taxa. The presence of an intervening continent also precludes mixing between North Atlantic and North Pacific right whales. Recent genetic studies further suggest reproductive isolation between North Atlantic, North Pacific, and South Atlantic right whales (Rosenbaum et al. 2000).

Southern right whales are large, stocky baleen whales that weigh between 40 and 80 tons. They are identified by their black colouration, lack of dorsal fin or ridge, and the presence of callosities on their heads. The callosities are outgrowths of tough, cornified skin to which cyamid amphipods (or whale lice) attach. These cyamids survive by apparently feeding on whale skin. Barnacles are also present on callosities of right whales in some populations (e.g., South Africa). Roger Payne first recognised that the head callosities formed different patterns on individual whales that changed little over time. This special feature became a useful form of individual identification in population studies (Payne et al. 1983).

These whales are easily recognisable from other whales at a distance at sea, as their widely separated nostrils create a V-shaped blow when they exhale. Their cruising speed is between 5 and 8 km h^{-1} (2–3 knots).

Adult southern right whales measure between 12 m and 16 m in length. There are no obvious differences between sexes, although females are usually slightly larger than males, and Payne found that males may have more and larger callosities on their heads than females.

Although southern right whales are predominantly black with occasional white blazes on their belly and chin, some whales also show variation in pigmentation, including light brown, mottled gray, and white dorsal markings such as spots and blazes. White-phased calves have been reported in several populations. These calves turn into light gray animals as adults.

The right whale is so named because it was considered to be the "right" whale to hunt. It was slow-moving, so easier to reach, it had plentiful oil and baleen, and its buoyancy meant that it floated when harpooned. Therefore it became one of the most hunted of all species of whales.

As a result of worldwide exploitation, southern right whales have been reduced to levels less than 10% of their original abundance. First hunted in the early 1600s along the Brazilian coast, the spread of pelagic whaling to other grounds in the late 1700s and early 1800s rapidly depleted species numbers. Despite gaining international protection in 1935, this species continued to be hunted illegally by the Soviet Union until the 1970s. The species currently numbers around 8000 individuals and is listed as "threatened" by the IUCN.

The southern right whale has a circumpolar distribution and generally inhabits sub-Antarctic water between about 20° and 55° S, although they have been seen as far as 63° S. They appear in coastal waters in winter months to mate, calve, and rear their young, and tend to migrate offshore to feeding grounds during summer months when supplies of krill are greater.

Historic calving grounds include areas in Mozambique, Tristan da Cunha, Namibia, Angola, Chile/Peru, Îles Crozet, the central Indian Ocean (around Île St. Paul), the New Zealand mainland, the New Zealand sub-Antarctic, the coastal waters off South Africa, Argentina (Península Valdés), southern Brazil, and off the coast of southeast and southwest Australia. Currently, only the later six of these calving grounds are showing signs of recovery from whaling. Based on aerial surveys conducted by Peter Best, the South Africa population is increasing at an average rate of 7% each year, and the total population size is around 3100 animals. Surveys by Payne show a similar rate of increase for the Argentina population, with a population size of about 2500 whales. In the waters of south and western Australia, the rate of increase has been estimated at 7%–13% per annum, and the population size of the entire Australian population is around 1000 individuals. The New Zealand sub-Antarctic population numbers less than 1000, and the Brazilian population in the low hundreds (International Whaling Commission 2001).

In the Northern Hemisphere, there appears to be a north–south migration between low-latitude calving grounds and high-latitude feeding grounds. In the Southern Hemisphere, the migration patterns between winter calving and summer feeding grounds are less clearly associated with latitudinal clines. There appears to be some north–south migration (e.g., South African calving ground to subtropical convergence feeding grounds) as well as some east–west movements (e.g., South Africa calving ground to Gough Island feeding grounds) (Best et al. 1993). The recent resighting in waters at 64°26′ S of an animal previously identified in Western Australian waters provided the first evidence of direct movement between Antarctic feedings grounds and winter coastal breeding grounds (Bannister et al. 1999).

Baleen whales have two main feeding techniques: lunge-feeding and skim-feeding. Lunge-feeders feed by engulfing a vast volume of water and then filtering their prey (krill and/or fish) by pushing the water through their baleen. These include whales with ventral pleats such as humpback, minke, fin, Bryde's, and blue whales. Right whales, like bowheads and sei whales, are skim-feeders, which is open-mouth slow skimming through dense patches of prey (krill) at or near the surface, filtering the water. Inside each side of a right whale's mouth are 200–270 long, thin baleen plates that may reach up to 3 m in length. These finely fringed plates act as a sieve during feeding, retaining zooplanktonic prey species.

Southern right whale courtship behaviour can be very spectacular. It may involve waving of flippers, breaching (leaping out of the water), tail slapping, stroking, splashing, rolling over, and rubbing each other. Courtship of a female right whale may take many days, and the females may mate with more than one male.

Male right whales do not occupy breeding territories or sing like humpback whales; rather females apparently vocalize to attract males. There is no apparent aggressive behaviour between males during courting bouts. The male right whales have enormous testes in proportion to their body weight. This suggests that the mating system involves sperm competition where males compete to inseminate females not by physical aggression but by delivering large quantities of sperm and displacing that of other males.

The age of sexual maturity varies between females and males. Age of sexual maturity for female southern right whales ranges from 6 to 13 years, with a mean of 9 years. This is based on long-term photo-identification studies by Best and Payne, where female calves were photographed and seen with their own first calf years later. No such information exists for males. However, it is thought that males mature earlier, probably between 3 and 6 years of age.

The duration of gestation is about 1 year, and only one calf is produced at a time. When the calf is born, it will measure between 5 and 6 meters and weigh 1000 kg. The calf is born tail-first and is gently nudged to the surface to take its first breath. The newborn calves have virtually no blubber to insulate them from the cold and must put on fat quickly. The calf does not suckle per se; rather the mother squirts the milk into the calf's mouth from a nipple on her ventral surface. The mother's milk has a 40% fat content, and a right whale calf can consume up to 600 liters of this rich milk per day. As a result, a right whale calf may add 50 kg per day and grow 1 m per month for the first few months of its life.

However, during this time the mother will fast, as there is little food available on the calving grounds. The demands of gestation, birth, and care are such that after one year of gestation and one year of weaning, a mother will take a full year to recover before she is ready for the next pregnancy. Thus mean calving interval in southern right whales is approximately 3 years.

Calves stay close to their mothers and will do so for up to a year or more until they are weaned. During this time the bond between the mother and calf is very strong. Southern right whale females will always place themselves between the calf and danger. Unfortunately, this motherly instinct was severely exploited by whalers who targeted calves, knowing that once secured, mothers would not leave.

The maximum life span for right whales is unknown but is likely to be 90–100 years. Little is known about natural mortality in southern right whales. Killer whales and sharks are the only known predators.

SPAIN: ANTARCTIC PROGRAM

The Antarctic Program of Spain was officially established in 1988. At that date Antarctic scientific research was included into the quadrennial Research and Development National Plan, and it has continued this way.

Previously, historical Spanish expeditions (as the Gabriel de Castilla one in 1603 or the tragedy of *San Telmo* in 1819) were documented, and the scientists' work was hosted by Antarctic programs of other countries. In 1986–1987 and 1987–1988 two Spanish Antarctic expeditions to Scotia and Bransfield seas took place.

Spain ratified the Antarctic Treaty in 1982 and became a Consultative Party in 1988. In January 1988, the first Spanish Antarctic station, named Juan Carlos I, was established at 60°23′20″ W, 62°39′46″ S, in Hurd Peninsula, in the southern coastal area of Livingston Island, South Shetland Islands. It has a total building surface of about 390 m^2, with 85 m^2

dedicated to laboratories. It is a summer station that is normally open from late November to early March. Its sixteen places are usually occupied half by scientists and half by technician personnel.

A second Spanish station, Gabriel de Castilla, was established in 1989 at 60°40′30″ W, 62°58′40″ S, close to the western coast of Port Foster, in Deception Island, South Shetland Islands. Its total building surface is 290 m^2, of which 93 m^2 is dedicated to laboratories. It is open every year during the same period as Juan Carlos I station, having a similar number of places and type of occupation.

During the first three campaigns after the establishment of the Spanish Antarctic Program (1988–1991), Spanish expeditions were supported by the vessel *Las Palmas*. This 1978 ship is 41.2 m in length and has a displacement of 1500 Tm. The 1991–1992 season was the first one for the new R/V *Hesperides*. This modern ice-strengthened multipurpose ship was built in 1991 and has an overall length of 82.5 m, 14.3 m breadth and 2700 Tm displacement. It has 665 m^2 of laboratories and room for thirty scientists, apart of the crew. Its equipment includes multibeam and other echo sounders, seismic multichannel systems, and other modern instruments for geological, biological, and physical oceanographic researches.

After a modernization of *Las Palmas* that increased its passenger capacity to twenty places, it returned to Antarctica as a support vessel for the Spanish expeditions. Since the 2000–2001 season *Las Palmas* and *Hesperides* have taken part at the same time in the Spanish Antarctic campaigns, except in 2003–2004, when Hesperides was not able to participate due to half-life maintenance and modernization operations.

The Spanish Antarctic program depends at present on the Ministry of Education and Science. Every year a call for research projects is officially published. Proposals can come from universities and public research organisations and institutes. They are evaluated by pairs at the National Evaluation Agency (ANEP) and later selected by a committee. To date, participating researchers have come from twenty universities, six institutes of the Scientific Research Council (CSIC), and six other public research organisations.

The coordination of the Antarctic program, the selection of the scientific projects, and the vessels' calendar is determined by the Ministry of Education and Science. Juan Carlos I station is operated by the Scientific Research Council (CSIC), Gabriel de Castilla station by the Spanish Army, and the two vessels by the Spanish Navy. The Ministry of Foreign Affairs is responsible for relationships with the Antarctic Treaty Consultative Meetings.

In 1998 the Spanish Polar Committee was established to coordinate the different ministries involved in Antarctic activities. At present this committee is located at the Ministry of Education and Science. A National Antarctic Data Centre was also set up in 1999, including a polar library and a bank of metadata related to the Spanish Antarctic research, being linked to the Antarctic Master Directory. Information about the mentioned organization, environmental procedures, stations and vessels can be found at www.mcyt.es/cpe.

Although it is difficult to have an accurate figure for the total expenditure of Spain in Antarctic activities, due to the participation of different organizations, a mean annual figure of about 3.5 million Euros could be estimated for recent years. This includes costs of science and operations but not staff, crews, station personnel, and scientists' salaries, as well as other costs borne by the involved organisations.

Spain became an associate member of the Scientific Committee on Antarctic Research (SCAR) in 1987 and a full member in 1990. Since then, the annual SCAR reports from Spain collect the data of the research projects carried out and identify the research groups. In 2003 the composition of the Spanish SCAR Committee was adapted to the new structure adopted by SCAR after its review. Spain is also a member of the Council of Managers of National Antarctic Programs.

An overview of the subjects of the Spanish Antarctic Research can be obtained by means of the published results. A compilation and analysis of the Antarctic publications by Spanish authors up to 2001 has been published (López-Martínez and Durán 2002). It contains 936 references, including 830 scientific and 106 informative publications. More than 98% of the references belong to the 15-year period between 1987 and 2001. Marine researches cover 55% of the scientific publications. Subjects of publications are biology (42%), geology and geophysics (30%), atmosphere (7%), oceanography (5%), glaciology (4%), cartography and mapping (3%), and miscellaneous (9%).

Spain ratified the Protocol on Environmental Protection to the Antarctic Treaty in 1992 and is a member of the Committee on Environmental Protection. Procedures for environmental impact assessment, issue of permits, and fulfilling the Protocol recommendations have been established for Spanish Antarctic activities.

SPRINGTAILS

Springtails (Collembola) are the most numerous, and after mites the most diverse, group of terrestrial arthropods in the Antarctic. However, they are easily overlooked as they are small (adults being at most 2 mm long) and cryptic in habit, but extremely widespread animals that can be very abundant at a local level. There are about 8000 species known globally in thirty families and nearly 600 genera, but the world fauna is estimated at 50,000 species (Hopkin 1997).

The morphology of Collembola is similar to insects as they have a body divided into three parts, a head with one pair of jointed antennae and two pairs of mouthparts, a three-segmented thorax with a pair of jointed legs on each segment, and a segmented abdomen with paired appendages ventrally on some segments. They differ in being soft bodied, in lacking a hard exoskeleton and wings, in the mouthparts being internal, and in possessing simple eyes, maximally eight, on each side of the head. Uniquely, Collembola possess a ventral tube ventrally on abdomen I and a paired jumping organ ventrally on abdomen III, hence the name Springtail. The ventral tube regulates osmotic conditions and is adhesive in some species. Antarctic species are white, black, or grey.

Two of the three orders are represented in Antarctica. The Arthropleona, to which most species belong, are elongate with the majority of the body segments separate and equal in length, and the rarer Symphypleona are globular with anterior body segments fused.

The first species described from Antarctica were by Willem in 1901 from the Peninsula; *Cryptopygus antarcticus* and *Isotoma octooculata* (now *Folsomotoma octooctulata*) and in the next year *Isotoma klovstadi* by Carpenter in 1902 from Victoria Land, all Isotomidae. Twelve species are now known from Victoria Land, including one probable translocation and one not fully described, two species from Queen Maud Land including the same probable translocation, and fifteen from the Antarctic Peninsula and Maritime Antarctic. Of the latter, two are probable synonyms and one an incorrect identification, leaving twelve. Endemism is highest in Victoria Land with six endemic genera and all ten species endemic contrasting with no endemic genera and only six endemic species in genera *Friesea* (Neanuridae), *Cryptopygus,* and *Tullbergia* (Onychiuridae) in the other regions (Greenslade 1985, and unpublished data). Current genetic studies suggest that cryptic, sibling, but parapatric, species occur so numbers may be revised upwards in future (Stevens and Hogg, in press).

Collembola only live in ice-free areas, in soil, under stones, in mosses and algae and other vegetation and interstitially in the marine littoral zone. High densities can be found in some habitats and up to 500,000 individuals of *C. antarcticus* per m^2 have been recorded in soil under the grass *Deschampsia*. The most widespread, abundant, and speciose genera are *Cryptopygus* (Isotomidae), *Friesea* (Neanuridae), and *Tullbergia*. (Onychiuridae). Species of *Cryptopygus* feed on filamentous fungi and algae, *Friesea* on rotifers, and *Tullbergia* in the mycorrhizal zone. As no macrodetrivores occur, Collembola play a larger role in nutrient cycling than in temperate regions. Predators of Collembola here are few and comprise mesostigmatid and prostigmatid mites.

The ecology and physiology, including cold tolerance, of a few species, notably *C. antarcticus, F. octooculata, I. klovstadi,* and *Gomphiocephalus hodgsoni* (Carpenter 1908) (Hypogastruridae) have been studied. All show adaptation to cold desert conditions by reducing water content and synthesising thermal hysteresis proteins, polysaccharides such as lactose and trehalose, and avoiding ice nucleation (Block 1997; Sinclair et al. 2003). Cold conditions induce inactivity resulting in longevity, with *G. hodgsoni* individuals able to survive 2 years and *C. antarcticus* over 3.

SQUID

Since the search for Antarctic cephalopods began onboard the *Challenger* Expeditions in 1872, about eighteen species of squid spanning thirteen families have been identified in the Southern Ocean. In the early years, knowledge of squid was based on fragments of specimens or remains found in the stomachs of predators, particularly certain whales. In more recent years, the development of scientific and commercial fishing methods and studies of land-based predator diets has revealed more about the biology and ecology of Southern Ocean squid. Compared with those at lower latitudes, Southern Ocean squids are represented by just one of the two suborders (Oegopsida) and many families of this oceanic group (that are normally abundant in temperate areas) are absent. Although the reasons for these differences are not clear, it has been suggested that low water temperatures and the vast sea ice belt around Antarctica is responsible for the absence of the neritic Myopsida. This group lays egg masses in shallow, coastal waters which, together with long development times that are typical of Southern Ocean species, would make them susceptible to ice scour. The Southern Ocean squid fauna, like other marine invertebrates there, show a high degree of endemism, meaning that the endemics are found nowhere else in the world's oceans. This is probably a result of the long evolutionary history of the Southern Ocean and the formation of the Polar Front that acts as a biological barrier between the cold Antarctic waters and the warmer sub-Antarctic waters.

Southern Ocean squids are predominantly pelagic, ranging in depth from a few metres below the surface to the deep ocean, and their distribution may be influenced by physical factors such as water masses, sea ice extent, and bathymetry. Some species are restricted to waters south of the Polar Front *(Psychroteuthis glacialis, Galiteuthis glacialis, Kondokovia longimana, Alluroteuthis antarcticus, Moroteuthis knipovitchi, Brachioteuthis picta, Histoteuthis eltaninae, Batoteuthis skolops,* and *Mastigoteuthis psychrophila),* whilst other deep-water species (e.g., *Chiroteuthis verenyi*) and highly mobile, migratory species (e.g., *Martialia hyadesi* and *Moroteuthis ingens*) are found either side of it. Species with circumpolar distributions include *Galiteuthis glacialis, Mesonychoteuthis hamiltoni, Psychroteuthis glacialis, Alluroteuthis antarcticus, Kondokovia longimana,* and *Moroteuthis knipovitchi*. All species occur in oceanic waters, but some are found in coastal waters (e.g., *Alluroteuthis antarcticus, Histoteuthis eltaninae* and *Psychroteuthis glacialis*), around groups of islands (e.g., *Moroteuthis knipovitchi*), continental shelves (e.g., *Moroteuthis ingens, Galiteuthis glacialis,* and *Martialia hyadesi*), and the slopes of continental shelves (e.g., *Galiteuthis glacialis, Histoteuthis eltaninae, Todarodes filippovae,* and *Psychroteuthis glacialis*). There still remain vast areas of the Southern Ocean for which there is little or no data on squid distribution.

Although many squid species undertake daily, ontogenetic and long-distance migrations, there are insufficient data to interpret the migratory patterns of most Antarctic species. *Slosarczykovia circumantarctica* and *Gonatus antarcticus* are known to undertake vertical migrations from deep water (400 m and 525–1000 m, respectively) during the day to shallow water (subsurface and 60–200 m, respectively) at night, possibly to avoid visual predators. *Galiteuthis glacialis* and *Alluroteuthis antarcticus* also undertake vertical ontogenetic migrations from shallow to deep water as they mature. It is likely that Southern Ocean squids undertake long-distance migrations that are typical of temperate and tropical oegopsids. Passive migration in Southern Ocean currents may distribute eggs and paralarvae downstream, where after juveniles and adults may actively migrate towards feeding grounds and then upstream to their original spawning grounds to complete their life cycle.

Relatively little is known about the life-cycle and growth of Southern Ocean squid. Standard methods for measuring growth have yet to be validated for Antarctic species. It has been suggested that, owing to low temperatures, Antarctic squid may experience lower growth rates and live longer than the 1-year lifespan typical of their temperate and tropical zone counterparts. *Kondokovia longimana* and *Mesonychoteuthis hamiltoni* also reach very large sizes (over 1 and 2 metres in mantle length, respectively) and are therefore likely to live longer than 1 year. Southern Ocean squid appear to produce larger eggs and have longer development times than temperate counterparts (as shown in benthic invertebrates). The maturation and spawning patterns of Southern Ocean squid are unknown, but the presence of distinct size classes in populations of *Psychroteuthis glacialis* and *Galiteuthis* *glacialis,* and the size frequency of eggs in the ovaries of *G. glacialis,* suggest discrete spawning periods.

Squid appear to play an important role in the Southern Ocean food web as both predators and prey. They form an important food source for marine mammals, seabirds, fish, and other cephalopods. Southern Ocean whales, seals, and seabirds have been estimated to consume ~28 million tonnes of squid per annum. In comparison, global fisheries land an average of 2 million tonnes of squid per annum. Less is known about the diet of Southern Ocean squid, and only *Moroteuthis ingens* and *Martialia hyadesi* have been studied in any detail. Most species, however, appear to consume a wide variety of prey including crustaceans (e.g., krill, hyperid amphipods, and mysids), fish (e.g., myctophids and gonostomatids), and squid (including cannibalism). In common with many squid species, they also appear to shift from predation upon crustaceans to fish and squid with increasing body size.

There are currently no commercial fisheries for Southern Ocean squid. There has been commercial interest in two Southern Ocean ommastrephid species (*Martialia hyadesi* and *Todarodes fillipovae*) but exploratory fisheries have not produced consistent catches. Should any fishery for these species develop in the Southern Ocean, they would be overseen by the Commission for the Conservation of Antarctic Marine Living Resources, which takes an ecosystem approach to fisheries management.

ST. PAUL ISLAND (ÎLE ST. PAUL)

Île St. Paul is not an Antarctic island. Located in the Indian Ocean at 77°30′ E, 38°44′ S, it is 90 km to the southwest of Amsterdam Island and 3000 km to the south of the Réunion.

Probably discovered in 1559 by Portuguese sailors, it is supposed to have been visited for the first time by a Dutchman called Vlaming in 1696. There are also traces left from a village of French fishermen from the Réunion dating back to 1843. Today, it is a deserted island.

This extinct volcano with a triangular shape and an area of 7 km^2 (3 km from West to East and 5 km from North to South), is a breached crater that opens onto the sea in the northeast. The thin rocky stretch that used to close the crater collapsed in 1780, letting in the sea through a channel less than 100 m. This rocky block now lies only a few meters under water, which allows only very small ships to enter. The interior basin, 1 km wide and 50 m deep, with continually still waters, is splendid. The internal walls of the crater are almost perpendicular all around, up to 270 m. From this height, winds can blow in heavy gales, with moments of respite, which makes for very dangerous anchoring.

The crater is protected from the sea by to low jetties made up of rocks, one 200 m and the other 500 m. All around, the island gradually lowers up to a cliff about 100 m high that dominates the seashore. Right outside the basin, to the north of the channel, a remarkable great rock 83 m high, called La Quille, consists of horizontal strata of variegated colors. Other rocks are like balsatic columns, proofs of past lava flows.

The vegetation is sparse, made up mostly of graminaceae. The intense violence of the winds and the total lack of shelter prevent the growth of species of a certain height. As for the fauna, fur seals, exterminated for their fur in the nineteenth century, are now back in numbers, feeding profusely on the abundant fish. Numerous rockhooper penguins, petrels (blue petrels, white-bellied storm petrels, and Antarctic petrels), terns (Antarctic and sooty), some great skuas, and a few sooty and yellow-nosed albatrosses can also be found on the island.

Large supplies of sea crayfish around the island are now controlled, with three or four French factory-ships having official fishing permits to be renewed yearly.

Île St. Paul has been described many times as ships sailed by. The *Novara,* an Austrian training ship sailed in front of St. Paul for 2 weeks in 1857 and drew the first good map of the island. In 1874, a French astronomical mission was set up there for 2 months to observe the transit of Venus in front of the sun. A young geologist, Charles Vélain, took this opportunity to make a significant geological survey of the island.

Île St. Paul definitively became French in 1893. With Amsterdam Island, it is part of the district of the Overseas Territory of the Southern and Antarctic French Lands (Territoire d'Outre Mer des Terres Australes et Antarctiques Françaises; TAAF) under the authority of a senior administrator who lives in the Réunion. A science base of about twenty people has been on Amsterdam Island since 1949, but today Île St. Paul is home to only a few scientists on temporary missions and researching specific projects.

STREAMS AND LAKES

Although most of the Antarctic continent is deep frozen and offers little opportunity for aquatic life, air temperatures around the margins of the continent rise above zero each summer and allow a remarkable diversity of lakes, ponds, and streams to develop and persist. Some of the lakes are freshwater and are fed by the melting snowpack and glaciers, while others contain saline bottom waters that are overlain by freshwater and further capped and insulated by thick, perennial ice. The streams typically flow for only a few weeks to months each year before refreezing and often show large variations in discharge associated with seasonal and daily fluctuations in solar radiation. The extreme biogeographical isolation of all of these environments in combination with the severe conditions of light, temperature, and freeze-thaw cycles has strongly influenced their biota. These ecosystems contain truncated food webs in which fish are absent. Unlike equivalent habitats in the Arctic, even arthropod communities (insects and crustaceans) are limited in distribution and diversity, although a few species can reach large population densities at some locations. Many types of microscopic life-forms survive, grow, and even thrive in these unusual environments. Antarctic lakes and streams are proving to be useful model systems for the wider understanding of microbial, biogeochemical, and ecological processes, as well as sources of novel microbes for research and biotechnology.

The early explorers to the McMurdo Dry Valleys region of Antarctica noted that the valleys contained frozen lakes, with evidence of brightly coloured plants growing in the waters beneath the thick ice. Research on these waters subsequently showed that these were meromictic lakes, so-called because they never completely mix. Their 3–7 m thick ice cover persists through summer and protects them from the wind, and their dense saline bottom waters remain stagnant and without oxygen throughout the year. These lakes act as natural greenhouses, and over a period of millennia the deeper waters have trapped solar energy, heating to surprisingly warm temperatures. The extreme example is Lake Vanda, in the Wright Valley. Its surface waters are cool and fed by the Onyx River that flows 30 km inland from the Lower Wright Glacier. However its bottom waters, 70 m beneath the ice cover, are three times saltier than seawater, and long term solar heating has resulted in temperatures up to 25°C. The Dry Valley lakes are highly structured in their chemistry and microbiology, with layers of different microbial communities at different depths. The photosynthetic communities include flagellated algae from diverse phyla in the upper water column such as *Chlamydomonas, Pyramimonas, Chroomonas,* and *Ochromonas,* and a thick layer of orange or pink mats of cyanobacteria growing on the sediments. The latter are the "water plants" observed through the ice, and their pigments include the red protein phycoerythrin to capture low levels of sunlight for photosynthesis, and orange carotenoids to protect them from bright sunlight including harmful UV-B radiation. Some of these algal mats precipitate a calcium carbonate crust as they photosynthesize, leading researchers to label them "living stromatolites" that closely resemble the earliest fossils of life on Earth. A microscopic consortium of cyanobacteria and heterotrophic bacteria has also been discovered to reside in pockets of meltwater contained within the lake ice.

Subsequent exploration of the continent has revealed several regions containing saline lakes, notably in the Vestfold Hills, Bunger Hills, and Langhovde (near Syowa Station). Isostatic uplift in those regions has resulted in trapped basins of seawater that have been subsequently overlain by dilute meltwaters. Unlike the Dry Valleys ecosystems, the saline lakes and lagoons contain small planktonic animals (zooplankton), in particular the calanoid copepods *Drepanopus bispinosus* (restricted to seasonally isolated marine systems) and *Paralabidocera antarctica*. One of the Vestfold Hills lakes is so saline (Deep Lake) that it never freezes up, and in late winter its hypersaline waters cool to –18°C yet remain ice-free. Freshwater lakes also occur in these regions and contain the 2.5 mm-long water flea (cladoceran) *Daphniopsis studeri* and the copepod *Acanthocyclops mirnyi.*

One other class of saline-brackish waters in Antarctica is epishelf lakes. These are formed by a floating ice shelf blocking the mouth of a fjord or embayment, and although they are mostly restricted to several locations in Antarctica, a few examples are also known from the Arctic. These lakes are contiguous with the sea beneath the ice shelf and are therefore tidal. Their surface waters, however, are fed by streams and other meltwaters, and the freshwater is dammed behind the ice shelf. Epishelf ecosystems therefore contain the unusual combination of freshwater, brackish, and marine biota in different layers of the same water column.

Freshwater lakes are found in many parts of the continent but particularly in maritime Antarctica where temperatures are warmer and the precipitation much greater. These lakes have more complex food webs than in the continental regions, with copepods (notably *Boeckella poppei*), fairy shrimps *(Branchinecta gaini),* and in some locations such as the abundant lakes on the Byers Peninsula of Livingston Island, a species of insect (the dipteran *Parochlus steinenii*). The large (up to 7.5 mm at Signy Island) predatory copepod *Parabroteas sarsi* is also known from some maritime antarctic lakes. Moss and green algae, in addition to cyanobacteria, are found growing profusely on the bottom of freshwater lakes at several locations, including Yukidori Lake in the Langhovde region of the continent (where *Leptobryum* sp. forms curious underwater "moss towers") and Signy Island lakes in maritime Antarctica. Long term measurements at Signy Island have shown a clear warming trend in the lakes, and evidence of the effects of changing ice cover on plankton dynamics.

A variety of extreme ice-dependent lakes and pools are found throughout Antarctica. Meltholes called cryoconite ("cold rock dust") holes, first described and named on the Greenland ice cap, form in the glacier ice, fill with water, and provide a habitat for cyanobacteria and other biota. These microecosystems are typically initiated by local heating of sediments on the glacier surface. Larger meltwater pools form in shallow perennial basins in the ablation zone of certain ice shelves, notably the McMurdo Ice Shelf. These contain red, brown, or orange mats of cyanobacteria up to several cm thick, with a variety of other microbes including heterotrophic bacteria, protists and microinvertebrates such as rotifers and nematodes. One common rotifer species, *Philodina gregaria,* forms conspicuous bright-red clusters of animals on the surface of the mats and was first described by James Murray in his work on Ross Island algal mats during Shackleton's expedition.

Some of the most intriguing lakes in Antarctica have yet to be sampled. Geophysical surveys have shown that more than 140 water bodies occur deep beneath the Antarctic ice cap where the geothermal heat flux in combination with latent heat and the insulating effect of the ice cover allows liquid water to persist throughout the year. The largest of these is Lake Vostok which has a surface area of 14,000 km^2, lies beneath 3700–4300 m of ice, and has a maximum liquid water depth of 800 m. Analyses of deep, lake-derived ice has provided indirect evidence of an active microbial community in Lake Vostok, but the physical, chemical, and biological properties of this and other subglacial Antarctic lakes currently remain an enticing mystery.

SUB-ANTARCTIC FUR SEAL

The sub-Antarctic fur seal *(Arctocephalus tropicalis)* is one of the two species of otariid ("eared" seals) that are found in the Antarctic regions. The other is the Antarctic fur seal *(A. gazella)*. Both species occur in the Prince Edward Islands, where they can be distinguished by the fact that sub-Antarctic fur seals are smaller, tend to be paler, and have shorter, broader foreflippers. Interbreeding between the two has been described both at the Prince Edward Islands and on Macquarie Island, so hybrids can occur. Taxonomists have argued for years about the relationship between these two species (and between these two and the other species of the genus *Arctocephalus*), although the debate is soon likely to be resolved by DNA analysis.

Like all members of the genus *Arctocephalus,* sub-Antarctic fur seals are characterised by their thick fur, a feature that allows them to keep warm in relatively hostile environments but that also made them attractive to humans, who have traditionally killed them for their rich pelts. Males average an approximate weight of 88–130 kg, and females 34–36 kg. They are compact in appearance, with short, thick necks and short, broad foreflippers. Adults of both sexes are dark grey-brown with pale, gingery chests and faces. The whiskers are long and white. Males have a tuft of guard hairs on the head that forms a distinctive crest, or topknot, which can appear larger when the animal is agitated.

These fur seals breed at a number of subtemperate islands of the Indian, South Atlantic, and South Pacific oceans. Most populations are increasing gradually now that they are not being hunted, although their remote locations mean that it is difficult to estimate the total population with any accuracy.

In the Tristan da Cunha Island group, the breeding population is greatest on Gough Island, although smaller colonies also occur on Inaccessible and Nightingale islands. Sealers arrived in the late eighteenth century, and were so thorough that by the 1830s they were complaining that there were too few animals left to make for an economically viable season. Once left alone, however, the population recovered well, and Gough Island now boasts the largest sub-Antarctic fur seal population in the world.

A smaller breeding colony is centred in the Prince Edward Islands, mostly on Marion Island. Because the fur seals here were never very abundant, they were not hunted as rigorously as some of the other populations, and in the 1970s their numbers were estimated to be just below 10,000 animals. They tend to inhabit the rocky coasts on the west side of the islands.

Îles Crozet also had a small population, but this was virtually exterminated by hunters in the nineteenth century, and although recolonisation has occurred, it has not done so at the same rate as Gough.

The population at Île St. Paul and Île Amsterdam, sometimes called the Amsterdam Island fur seal, has recovered from intensive culling and the islands now have thriving colonies. Finally, a small population has been recorded on Macquarie Island, where it can be confused with the New Zealand fur seal *(A. forsteri)*. The sub-Antarctic fur seal is a wide-ranging species, and stragglers have been recorded as far afield as Brazil, South Georgia, South Africa, and southern New Zealand.

In terms of reproduction, adult males arrive at the breeding grounds in September and begin to stake out their territory. In the following months, the juveniles and females arrive, the younger males keeping well away from the beaches occupied by the dominant bulls. Pups are born between November and February, depending on location, usually within a few days of the cows' making landfall. The black or dark brown pups are about 60–65 cm long at birth and weigh 4–5 kg. Mating takes place 8–12 days after the birth of the pups, after which the females begin to make short feeding trips to sea. Pups of this species suckle for almost a year, probably until the next pup is born.

Sub-Antarctic fur seals are generalised feeders, and will take squid, fish, and krill. On Île Amsterdam, they have also been observed eating rockhopper penguins. In turn, they are predated upon by killer whales and sharks.

SUB-ANTARCTIC ISLANDS, GEOLOGY OF

This article describes the geology of those oceanic islands in the Southern Ocean that are not described in other specific entries. Many of the sub-Antarctic islands have been visited only rarely and knowledge of them, especially of their geology, is extremely limited.

Balleny Islands

The Balleny Islands (66°15′ to 67°35′ S, 162°30′ to 165°00′ E) comprise three main islands, Young, Buckle, and Sturge islands, extending for about 160 km in a southeast–northwest direction about 350–450 km north of the Oates Coast of northern Victoria Land. They cover an area of about 400 km^2, reach a maximum height of 1524 m on Sturge Island, and are about 95% glaciated.

The islands are entirely volcanic and comprise interbedded tuff, agglomeratic scoria, and lava flows. Compositions of rock specimens examined include trachybasalt, basalt, and hawaiite. No radiometric age determinations have been made, but the rocks are probably of late Cenozoic age, and a maximum age of 10 Ma may be inferred from seafloor magnetic patterns. Seafloor sediments in the south Pacific Ocean, deposited during the past 2.5 Ma, contain windblown rhyolitic volcanic dust that is considered to have been derived from violent eruptions in the Balleny Islands. In 1839 and 1899, mariners described Buckle Island in eruption, but an infrared survey of the islands in 1967 failed to define any thermal anomalies. Some of the small islands may be volcanic plugs or necks.

Bouvetøya

Bouvetøya (54°25′ S, 03°22′ E) is the remotest island on the planet, being about 1700 km from the nearest other land, the Prinsesse Astrid Kyst of Dronning Maud Land. It covers an area of about 54 km^2, rising to 935 m at Olavtoppen, and is about 93% glaciated. Larsøya is an islet lying off the southwest coast.

Bouvetøya lies on the Mid-Atlantic Ridge where it turns eastward and separates the African Plate from the Antarctic Plate. It forms a volcanic cone of basalt with a prominent central crater. Radiometric dating of the lavas have shown the oldest to be 1.3 Ma, and the youngest to be 0.1 Ma. The volcano is still active, as indicated by the presence of fumaroles. At some time between 1955 and 1958 a relatively flat platform was formed extending from the western side of the island south of Kapp Circoncision, probably as a result of volcanic activity and localized tectonic uplift. This area, Westwindstranda, is about 1500 m long and up to 300 m wide.

The island is entirely volcanic and the lavas belong to the alkali-basalt–trachyte–rhyolite series. Specimens of basalt, rhyolite, and obsidian have been recorded together with pumice and tuffaceous strata and rare trachyte lavas from the recently formed platform. Numerous dykes have also been recorded along the west coast. The summit of the island is a flattish, circular crater about 2 km in diameter that is assumed to have been the source of the eruptions that provided the main bulk of the island.

In 1825, George Norris commanding the sealing vessel *Sprightly,* reported sighting "Thompson Island" about 72 km north-northeast of Bouvetøya and described it as volcanic. The island was sighted again in 1893 by Joseph Fuller, commanding the sealing vessel *Francis Allyn*. This island has never been seen since then and has been described, with early sightings of other islands, as "nonexistent." However, more recent research has suggested that the island did exist and that it probably disappeared in a volcanic eruption in 1895 or 1896.

Heard Island

Heard Island (53°05′ S, 73°33′ E) and Shag Island about 11 km to the north cover an area of about

385 km^2. Mawson Peak rises to 2745 m, and the island is about 80% glaciated.

Heard Island is dominated by the central volcano of Big Ben. The oldest rocks are the marine limestones of Lower Tertiary age that crop out on Laurens Peninsula and Rogers Peninsula in the northwest and at some other points along the north coast. These are intruded by trachy-basalt intrusions, a composition not found in the later volcanic sequences. A period of erosion followed with the deposition of glacial sediments and the eruption of submarine lavas in Late Tertiary or early Pleistocene times. Above these are the lava formations that constitute the main edifice of the island. There are some younger lavas around the coast, probably from subsidiary vents on the main volcano, but the main bulk of Big Ben was probably formed by eruptions during the Pleistocene. There are also younger volcanic rocks in the cone of Mawson Peak.

Macquarie Island

Macquarie Island (54°37′ S, 158°58′ E) covers an area of 128 km^2 and rises to 433 m on Mount Hamilton. Judge and Clerk Islands lie about 16 km to the north, and Bishop and Clerk Islands lie about 29 km to the south. The islands are not glaciated.

Macquarie Island lies on the Macquarie Ridge Complex and represents a section of the ocean floor formed by sea-floor spreading processes, possibly about 27 Ma, that has been uplifted over the past 10 Ma by plate tectonic processes between the Indian and Pacific–Australian plates. The island has been above sea level for about 0.7 Ma and continues to rise at about 0.8 mm per year. The island's morphology is due to uplift, erosion, and sea level changes giving rise to raised beaches that indicate the island has never been glaciated.

In the southern two-thirds of the island, the bedrock geology comprises basalt pillow lavas, with pockets of *Globigerina* ooze between the pillows, and volcanic breccias. In the northern third of the island an ophiolite complex is exposed, comprising serpentinized peridotite, gabbro, layered gabbro, and pillow lava. Dolerite dykes are common, including some areas of sheeted dolerites in the north.

Peter I Øy

Peter I Øy (68°51′ S, 90°37′ W) covers an area of about 157 km^2 and rises to 1640 m on Lars Christensentoppen. The island is about 95% glaciated.

The island is the exposed top of a volcanic edifice rising 4000 m from the sea floor, close to the oceanic–continental crust transition and close to a former transform fault in the Tharp fracture zone. The rocks are predominantly alkali basalt and hawaiite lavas, probably all extruded during the last 0.5 Ma. Older ages of 12.5 Ma suggest that the original formation of the volcano began some 10–20 Ma.

Scott Island

Scott Island (67°24′ S, 179°55′ W) covers an area of about 0.1 km^2 and rises to 39 m. Haggits Pillar lies off-shore to the west and is 63 m high. The island is about 80% glaciated.

The island is volcanic but the only known rock specimen from the island (collected in 1902 during the *Morning* expedition) is a phonolite that is considered to be of Cenozoic age. Dredge specimens from the vicinity of the island are also phonolite.

SUB-ANTARCTIC SKUA

Sub-Antarctic skuas (*Catharacta* ssp., members of the family Stercorariidae, Charadriiformes) inhabit coastlines and islands in the Southern Ocean between the austral part of South America and New Zealand. They share the brown plumage and white wing patches with other *Catharacta* species but are of larger size, prey mainly on seabirds, and show less expanding migratory behaviour (compare South Polar skua; see also skua overview for general characteristics). Sub-Antarctic skuas breed in loose colonies in close vicinity to other seabird nesting sites, incubate a clutch with normally two eggs (inexperienced birds lay one egg) for 28–32 days, and defend their chicks until fledging at an age of c. 50 days. In the following weeks, breeding sites are abandoned, and in springtime partners meet again in the same territory to reproduce.

Sub-Antarctic skuas are divided in the three subspecies brown skua *C. a. lonnbergi,* Falkland skua *C. a. antarctica,* and Tristan skua *C. a. hamiltoni* (an alternative classification nominates *C. antarctica spp.* as brown skuas and *C. a. lonnbergi* as Sub-Antarctic skua). Hybridisation is known for brown and South Polar skua and with Falkland and Chilean skuas.

Brown skuas are the largest and most widespread of the three forms, showing increasing measurements from the Antarctic Peninsula, on the peri-Antarctic islands towards New Zealand (total 7000–10,000 pairs). The plumage can vary from dark to light brown with irregular pale streaking on the upper parts. Brown skuas show the widest food spectrum partly holding feeding territories. Many feed in penguin colonies on eggs, chicks, and adults. Some also specialise in hunting burrowing petrels on land or seal carcasses and placentae at sea. To a lesser extent, they follow fishing boats and use human food waste in Antarctic research stations.

The smallest subspecies, the Falkland skua (local name: sea hen) breeds on the Falkland Islands and the coasts along southern Argentina with a population of 3000–5000 pairs. They can be recognised by a marked dark cap lacking any rusty body colouring that would suggest a Chilean skua. Falkland skuas feed in penguin, petrel, and cormorant colonies. Adults and juveniles disperse northwards up the coast of South America for the winter.

The third subspecies has its name from the remotest inhabited island in the world—Tristan da Cunha. Due to high human persecution in the past, the Tristan skua population is currently about 200 pairs on the archipelago. Additionally, this form can be found in higher numbers (c. 2300 pairs) on uninhabited Gough Island that lies some 320 km southwest of Tristan. This skua form appears more uniformly dark with less white streaking, and although slightly smaller than brown skuas, bill and legs are proportionally longer. They prey on penguins, burrowing petrels, and small mammals. Outside the breeding season, Tristan skuas usually remain close to their nesting areas.

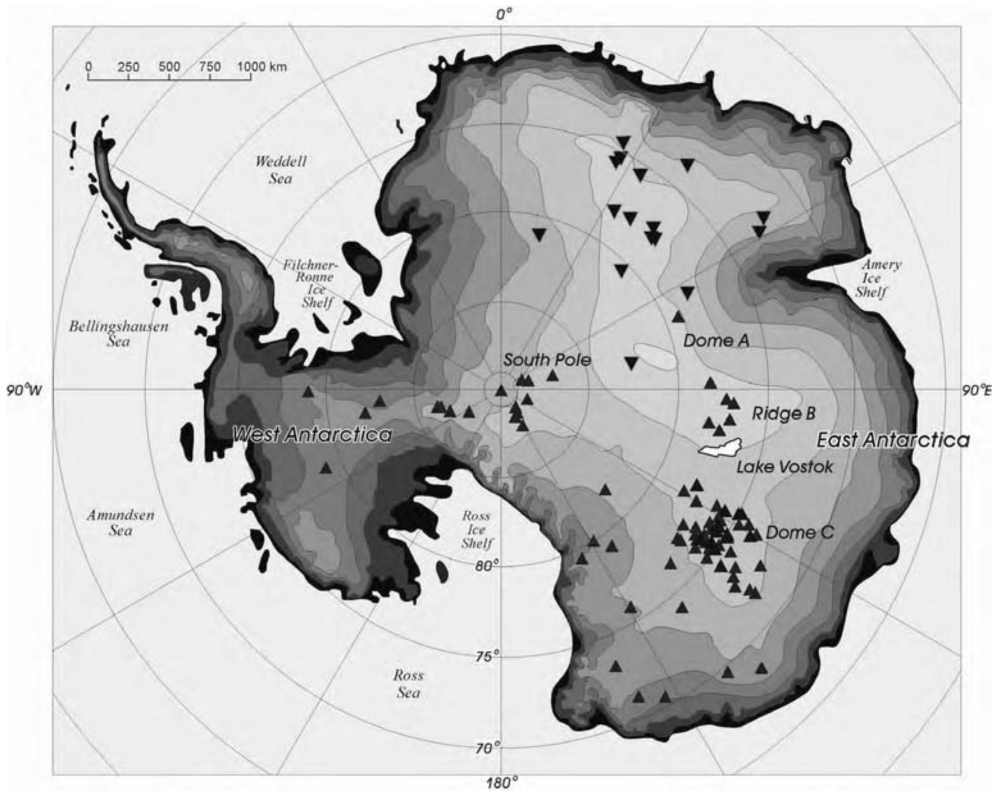
SUBGLACIAL LAKES

Subglacial lakes are bodies of liquid water that exist at the base of large ice sheets. They occur as a consequence of geothermal heating from the Earth, the insulating effect of the overriding ice, and the pressure of the ice overburden, which collectively allow the ice temperature to reach around –3°C, whereupon it melts. Meltwater flows under gravity and the pressure of ice, and collects in topographic hollows to form lakes.

Subglacial lakes were discovered in the late 1960s using a technique called radio-echo sounding. Radio waves travel well in cold ice but reflect off boundaries where there is a contrast in electrical properties. Reflections off the ice-rock interface are very different than those from the ice-water surface of a subglacial lake, which are stronger and flatter. The first inventory of subglacial lakes, published in 1996, identified over seventy lake-type surfaces. Since then, thirty new lakes have been identified, bringing the total up to one hundred.



Distribution of Antarctic subglacial lakes.

The largest subglacial lake, by an order of magnitude, is Lake Vostok, which is 250 km long. The next largest is Lake Concordia, which is over 30 km in length. Several other subglacial lakes have dimensions in excess of 10 km in length. In contrast, however, the bulk of Antarctic subglacial lakes are between 3 and 5 km long. Subglacial lakes in excess of 5 km in length manifest themselves as flat regions on the ice surface, and are detectable from satellite altimetry. These flat regions allow the aerial extent of large subglacial lakes to be mapped approximately.

Radar represents an excellent means by which subglacial lake surfaces can be identified, but as radio waves do not penetrate well in water it cannot be used to determine information on the depth of subglacial lakes if they are deeper than a few metres. Seismic sounding is the only feasible way of gaining information about the water depths of subglacial lakes from the ice surface. Very few seismic experiments have been undertaken over subglacial lakes, however. The gradient of side-wall slopes bordering lakes provides an indication of the water depth to be expected in many cases. This has often shown the water depths of subglacial lakes likely to be several tens if not hundreds of metres. Analysis of side-wall slopes allows the total volume of water stored beneath the Antarctic ice sheet to be estimated between 7000 and 15,000 km^3.

Subglacial lakes occur in a variety of topographic and glaciological settings. They can be classified into three distinct groups: (1) lakes in subglacial basins in the ice-sheet interior, (2) lakes perched on the flanks of sub-glacial mountains, and (3) lakes close to the onset of enhanced ice flow. The majority of subglacial lakes are located within 200 km of ice divides of both the East and West Antarctic ice sheets. The bedrock topography of the ice-sheet interior involves large subglacial basins separated by mountain ranges. Subglacial lakes in the first category are found mostly in and on the margins of subglacial basins. These lakes can be divided into two subgroups. First, there are those located where subglacial topography is relatively subdued, often towards the centre of subglacial basins. Second, some lakes occur in significant topographic depressions, often closer to subglacial basin margins, but still near the slow-flowing centre of the Antarctic Ice Sheet. Where bed topography is very subdued, deep subglacial lakes are unlikely to develop. Lake Vostok is the only subglacial lake that occupies a whole section of a large subglacial trough. Other troughs, such as the Adventure Subglacial Basin contain a number of smaller lakes. “Perched” subglacial lakes are found mainly in the interior of the ice sheet, on the flanks of subglacial mountain ranges. In several cases, small (<10 km long) subglacial lakes have been observed perched on the stoss face of large (>300 m high), steep (gradient > 0.1) subglacial hills. At least sixteen subglacial lakes occur at locations close to the onset of enhanced ice flow, some hundreds of kilometres from the ice-sheet crest. The highest density of known subglacial lakes occurs in the Dome C region of East Antarctica, where more than forty have been identified. Some of these lakes are so close that they may be connected hydrologically within the same watershed.

Many subglacial lakes have been shown to have ceilings that slope at ten times the ice surface slope (but in the opposite direction). This condition is achieved under hydrostatic equilibrium and suggests that lakes are stable features, in balance with the ice sheet above and topography beneath. Perturbations to this balance are likely to occur over glacial-interglacial cycles, because the thickness and surface elevation of the ice sheet is expected to change. Such change, even if slight, will cause a response ten times as great at the ice water interface (for the lake to remain in hydrostatic equilibrium) and, consequently, we may expect subglacial lake size to be affected over periods of 100,000 years.

Water circulation processes are likely in subglacial lakes and will be driven by the slope of the ice-water interface. The slope of a lake's ceiling results in differential rates of melting, which is likely to induce mixing and circulation of water. Ice that melts into subglacial lakes will supply impurities to the lake, such as gases, dust, and rock flour. Conversely, lake water frozen to the underside of the ice sheet, as has been recovered by the Vostok ice core, contains little other than pure ice. Thus, there is likely to be a buildup of material within subglacial lakes over time. This has led some to believe that the subglacial lake waters may be enriched in dissolved gases and, if this is the case, gas hydrates (crystal lattices formed by water molecules around gas molecules under conditions of low temperatures and high pressures, often called "clathrates").

The age of a subglacial lake is dependent on two factors. The first is the date at which the ice sheet most recently allowed the lake to exist. For many lakes of the order of several tens of metres deep in East Antarctica, this date could be as old as 15 Ma, as some believe the ice sheet has been stable for this length of time. However, some shallow lakes may not survive glacial cycles because of ice sheet flow change and colder ice temperatures. Further, the ice sheet in West Antarctica is thought to have changed significantly during the last 2 million years. Hence, lakes here are likely to be younger than in East Antarctica. The second factor relates to the age of the lake water, which is controlled by the age of the basal ice melt. In East Antarctica this may be upwards of 1 million years. In West Antarctica, on the other hand, the age of the basal ice is likely to be no older than 150,000 years. Consequently, subglacial lakes in West Antarctica will be younger than their East Antarctic counterparts.

There has been a huge degree of scientific and media interest in subglacial lakes, following the discovery 10 years ago that subglacial lakes, and Lake Vostok in particular, were deep. Discussion about whether to make *in situ* measurements of the lake has been driven by two scientific hypotheses. The first is that unique microorganisms inhabit subglacial lakes. The second is that a complete record of ice sheet history is available from the sediments that lie across lake floors. Future exploration of subglacial lakes will be focussed on testing these hypotheses. If the hypotheses are correct future investigations of subglacial lakes could enable valuable insights into the history of Antarctica, detailing its response to and control on climate change, and our understanding of biological functioning within extreme environments.

The Scientific Committee on Antarctic Research, the international body that oversees Antarctic science, commissioned a Subglacial Antarctic Lake Exploration (SALE) "group of specialists" to "consider and recommend mechanisms for the international coordination of a subglacial lake exploration program." The techniques necessary for the exploration of subglacial lakes depend on the hypothesis to be tested. Testing whether microbes live in the lake requires totally sterile equipment, which must be miniaturised to fit within an ice borehole. It seems unlikely that the traditional ice core boreholes can be used for this purpose, as they are filled with a drilling fluid that contains impurities that need to be excluded from the lake. Hot water drilling appears to be the only feasible means of boring down to a subglacial lake without risking contamination, but no hot water drill has ever penetrated through in excess of 3 km of ice above most subglacial lakes. There are, consequently, substantial technological hurdles to overcome in order to set up an appropriate experiment to find life in subglacial lakes. Testing whether climate records exist in sediments on the lake floor does not require contamination controls. There is strong opinion, however, that lake environments should not be polluted. This will almost certainly mean that geological investigation of the lake is undertaken with contamination controls, which is likely to increase the cost of such work hugely.

Although the scientific rational for subglacial lake exploration is well defined, the identification of the first lake target is less clear. Some argue that Lake Vostok is the most appropriate site. Others argue its huge size makes it difficult to comprehend in a detailed manner, and that access technologies should be tested on other less ancient lakes first. This makes the exploration of West Antarctic subglacial lakes particularly appealing for exploration in the first instance.

SURFACE ENERGY BALANCE

The surface energy balance (SEB) describes the partitioning of energy fluxes towards and away from the surface (unit: W m^{-2}). For an infinitesimally thin surface layer without heat capacity, these fluxes *balance* (i.e., their sum equals zero). The local SEB is of extreme importance for it determines the temperature of the Earth's surface. When the surface consists of snow or ice, the SEB also determines the amount of energy that is available for sublimation and melting. These processes directly couple the SEB to the *surface mass balance* (see entry elsewhere). The major components of the SEB are

- *Net radiation,* consisting of four components: *incoming and reflected shortwave (solar) radiation* and *incoming and upwelling longwave (terrestrial) radiation*. These two radiation types are distinguished on the basis of their wavelength, determined by the temperature of the body that emits the radiation through Stefan-Boltzmann's law. If radiation originates from the surface of the Sun ($T \approx 5800$ K), either directly or scattered in the Earth's atmosphere, nearly all energy is confined in wavelengths below 5 micrometer, hence the name *shortwave radiation*. Note that visible light is shortwave radiation but that not all shortwave radiation is visible light. If the radiation originates from the Earth-atmosphere system ($T \approx 200$–300 K), nearly all energy derives from wavelengths greater than 5 micrometer, hence the name *longwave radiation*.
- *Turbulent heat fluxes,* consisting of the *sensible* and the *latent* heat flux. The sensible heat flux describes heat exchange between the surface and the air just above it. This flux is directed towards the surface when the air is warmer than the surface and vice versa. The latent heat flux equals the amount of heat extracted from or added to the surface as a result of sublimation (the phase change from solid ice to water vapour) or deposition (phase transition from vapour to solid [i.e., rime formation]). Both sensible and latent heat fluxes are *turbulent* heat fluxes (i.e., they arise from the presence of turbulent eddies in the air that mix heat and moisture vertically). For the sensible/latent heat fluxes to be nonzero, turbulence must be present *and* there must be a temperature/moisture difference between the surface and the air.
- *Subsurface heat flux,* representing the conduction of heat into the subsurface strata; this flux is almost entirely driven by molecular conduction (i.e., by vertical temperature gradients in the snow).

The annual mean SEB of a typical midlatitude grass surface has net radiation as the main heat source and turbulent exchange of latent heat (evaporation) followed by sensible heat (convection) as main heat sinks. Judging from the very low temperatures, the Antarctic SEB must be very different. To start with, all energy fluxes are an order of magnitude smaller than at midlatitudes. The incoming longwave radiation flux is relatively small because the Antarctic atmosphere is thin, cold, dry, clear, and clean. The shortwave radiation balance is even more extreme. The downward annual mean shortwave radiation flux through the top of the atmosphere at the pole is only 40%–50% of that at the equator. Of that already reduced amount, only 5%–15% is finally absorbed at the dry and clean snow surface, which is highly reflective for shortwave radiation (i.e., it has a high *albedo*). As a result, net radiation is *negative* in the annual mean, implying that net radiation represents a *heat sink* in the Antarctic SEB. Elsewhere on Earth, this feature is only found in the dry snow zone of the Greenland ice sheet.

The surface heat sink caused by radiation must be balanced by a significant heat source in the other SEB terms. The subsurface heat flux is ruled out as a possible candidate because this would require a continuous cooling of the snow pack. The latent heat flux is no candidate either, for it only deviates significantly from zero only in summer, when sublimation acts as a net heat *sink*. This leaves the sensible heat flux. Two conditions must be met for transport of sensible heat to the surface to occur: first, the air must be warmer than the surface. Measured temperature profiles indicate that a surface based temperature inversion (i.e., temperature increasing with height) indeed is a common feature of the lower Antarctic atmosphere (see entry on the Atmospheric Boundary Layer). Second, strong near surface winds are required to generate the turbulence needed to effectively transport heat towards the surface. This condition is fulfilled by the notorious Antarctic katabatic winds, forced by gravity acting on the cold, negatively buoyant near-surface air (see entry on katabatic winds). A significant surface slope is a prerequisite for katabatic winds to develop; for flat areas, such as the coastal ice shelves and the interior plateau, katabatic winds will be weak or absent. As a result, sensible heat gain and radiative heat loss are considerably smaller at these sites.

The fact that the subsurface and latent heat fluxes are not dominant in the seasonal cycle does not mean that they are unimportant components of the Antarctic SEB. On time scales of several hours, the sub surface heat flux is the main SEB component to balance rapid changes in the radiation balance when turbulence is weak. During summer the latent heat flux becomes the major heat sink at daytime. A latent heat flux of –10 W m^{-2} (the negative sign indicating energy removal from the surface) suffices to sublimate over 9 kg of snow per square meter per month. Especially in dry areas, this constitutes a significant component in the surface mass balance.

SURFACE FEATURES

The Antarctic continent is essentially circular in shape, except for the flaring Antarctic Peninsula and for two principal embayments (Ross Sea and Weddell Sea). The continent is divided by the Transantarctic Mountains into two distinct regions: West, or Lesser, and East, or Greater, Antarctica. At some locations around Antarctica, ice flowing from the grounded portion of ice sheet forms large floating ice shelves, which account for about 10% of the total continental ice area. The three largest ice shelves are the Ross and the Ronne-Filchner ice shelves in West Antarctica and the Amery Ice Shelf in East Antarctica. The surface extension of contiguous continent is about 12 million km^2. The bulk of the continent's ice is contained in the Greater Antarctic (9.86 million km^2). The highest point of the East Antarctic Ice Sheet is Dome Argus (77° E, 81° S); it reaches a maximum height of 4078 m and it is situated above the subglacial Gamburstev Mountain (about 3000 m above sea level), whereas the highest rocky peak on the continent is the Vinson Massif (82°25′ W, 78°35′ S), which rises to an altitude of 4897 m, and is situated in the Ellsworth Mountain Range. West Antarctica (2.23 million km^2) is smaller and lower in elevation than East Antarctica. Antarctica presents an average elevation of 2500 m, and it is the highest and flattest continent on Earth (about 70% of surface presents slope less than 4 m/km). This enormous mantle of ice is piled onto a rocky substratum that extends for large stretches below sea level. The average thickness of ice layer is around 2160 m, though extensive areas can reach down over 4000 m in the Bentley Valley (110° W, 81° S), in West Antarctica, as well as in East Antarctica at Aurora (120° E, 74° S) and Astrolabe Basin (135°12′ E, 69°54′ S), where it reaches its maximum thickness (4776 m) in the latter zone.

The Antarctic continent is almost completely covered with snow; only 0.3% of its surface is exposed rock/sediment, and 1% is blue ice. Exposed rock/sediment is found in the Transantarctic Mountains, on the Antarctic Peninsula, and in some coastal areas. Blue ice areas are scattered widely over the continent, mainly in the vicinity of nunataks and mountain range and close to the coast in katabatic wind confluence zone. Many types of surface microrelief and macromorphology, such as at metre scale sastrugi, snow dunes, barchane, wind crust and pitted patterns and at kilometre scale megadune, longitudinal and transverse dune, are distributed on the surface of the Antarctic ice sheet in various sizes (from decimetre to kilometre) and occur as a result of interactions between the air and the ice sheet surface.

An ice divide longer than 5000 km crosses the inner part of East Antarctica from the Atlantic to Pacific Ocean and summits in four domes (Dome Fuji or Valkyrie, Dome Argus, Dome B, and Dome Circe or Charlie). West Antarctica consists of an archipelago of mountainous islands covered and bonded together by ice, without any well-formed dome shape. A dome is a rounded and gently sloping elevation in the surface of an inland ice sheet; it does not have precisely defined margins and may cover very large areas (more than 100,000 km^2). An ice divide defines the inner margins of ice drainage basins and may be defined as the plane extending from the base to surface, through which there is no transport of mass. Thus, an ice divide separates ice flowing in opposite directions. The divide plane (the plane from the surface to bedrock that separates ice flowing in opposite directions) may present a slope such that the ice divide at the ice-bedrock interface does not directly underlay the ice divide at the surface. The different location of ice divide at surface and at bedrock could be due to the asymmetric conditions in basal topography and snow accumulation across the highest point of ice sheet. The movement of the ice spreads down radially from the domes, and ice divides towards the coast. The ice speed varies from a few centimetres per year close to domes and ice divides to hundreds of meters per year in fast-flowing rivers of ice, known as ice streams. About 90% of the ice discharge from the interior to the ice margin is drained through a small number of ice streams and outlet glaciers. These penetrate up to 1000 km from the grounding line into the interior of the ice sheet by complex tributary systems. Outlet glaciers and ice streams fill troughs and could reach incredible dimensions. For example, the Lambert Glacier-Amery Ice Shelf basin (about 1.32 million km^2) is over 700 km long and occupies the widest trough on earth.

The shape of an ice sheet is mainly convex and is primarily determined by the changing properties of ice, ice thickness, ice temperature, bedrock condition, accumulation, and ablation rate. The shape is in turn modified by the ice flow, which usually tends to adjust to reach a balance between the mass input (snow accumulation) and output (ablation). Bedrock topography cause irregularities in the ice surface in the inland, and near the coast much of the flow is channelled either by mountain or by deformable sediments beneath the ice. Peculiar surface areas are the regions' overlying subglacial lakes (mainly in the East Antarctica); the absence of friction contact between ice and water at the ice sheet base above the subglacial lake provides itself evidence as an anomalous near-flat region on the ice-sheet surface.

Grounding/floating migration induced by sea level changes is the primary factor governing the temporal evolution of the Antarctic ice volume and morphology. However, when considering the topography of the East Antarctic Plateau the influence of grounding line migration is weak, and ice divide location and elevation appear to be complex functions of spatial and temporal variations in the snow accumulation rate. Ice sheet models revealed that surface elevation at the dome varied by up to 100–150 m whereas the lower portion of ice sheet close to the coast thickened up to 1000 m between glacial and interglacial period.

SURFACE MASS BALANCE

The surface mass balance is defined as the annual sum of solid mass fluxes directed towards and away from the surface (unit: kg m^{-2} year). These mass fluxes usually do not balance so that one frequently encounters the somewhat strange expressions *positive surface mass balance* (or *accumulation*) and *negative surface mass balance* (or *ablation*). In the absence of a well-defined ablation zone, Antarctica is usually regarded as one big accumulation area. When summed over the grounded ice sheet, the surface mass balance constitutes the largest positive contribution to the *ice sheet mass balance*. Only about 1% of the Antarctic surface consists of *blue ice areas,* where the surface mass balance is negative. They owe their name to the milky-blue appearance of old glacier ice that surfaces when the 70–100 m thick snow and firn layer has been removed by snowdrift erosion and/or sublimation. Because of the local upward ice movement, blue ice areas are major meteorite collection sites. The components of the Antarctic surface mass balance are

- *Solid precipitation* (snowfall) is by far the biggest positive component of the surface mass balance in Antarctica. Precipitation in Antarctica consists mainly of snowfall from frontal clouds, with topographic effects playing a very important role. It has been suggested that in the high interior a substantial part of the solid precipitation flux falls as "clearsky precipitation" or "diamond dust," ice crystals that form when near surface air cools and becomes saturated. The ice crystals do not noticeably affect visibility but are often accompanied by spectacular optical phenomena.

- *Surface sublimation* is the largest negative term in the surface mass balance of Antarctica. Current estimates show that sublimation removes about 7% of the solid precipitation but with large regional and temporal differences. Sublimation can be very important for the regional mass balance and is believed to be responsible for the formation of blue ice areas on large outlet glaciers, where adiabatic heating and drying of the air may cause considerable latent heat fluxes.
- *Melt* is generally confined to the low-lying parts of the ice sheet and ice shelves. Nearly everywhere in Antarctica, meltwater that is formed at the surface and penetrates the snow pack, refreezes at some depth, where temperatures are generally still below zero (internal accumulation). Exceptions are the ice shelves in the northern Antarctic Peninsula, where extensive meltwater lakes are detected on satellite imagery. This collection of meltwater at the surface has been linked to the recent disintegration of some of these ice shelves.
- *Snowdrift,* snow blown by the wind, can cause significant variability in snow accumulation from place to place, even between closely spaced sites. It affects the surface mass balance in two ways. *Snowdrift sublimation,* the sublimation of suspended snow particles, is a potentially important process because a suspended snow particle has a maximally exposed surface. However, the sublimation process is so effective that after its onset the surrounding air quickly becomes saturated, halting further sublimation. *Horizontal gradients in drifting snow transport* cause erosion or deposition at the surface. For the Antarctic surface mass balance as a whole this process is probably unimportant, but in the vicinity of topographic obstacles this process may be locally important. More snowdrift experiments and better models are needed in order to quantify the potentially important influence of snowdrift processes on the Antarctic surface mass balance.

The surface mass balance can be rather easily measured using stakes, snow pits, and snow cores. The latter two methods are only applicable in accumulation areas and use well-known dating horizons such as volcanic eruptions, providing the average mass balance for a known time interval. For a better temporal resolution, a sonic height ranger mounted on an Automatic Weather Station can be used. If all mass balance observations are painstakingly collected, quality controlled, interpolated, and mapped, a new *mass balance compilation* of Antarctica is born (e.g., Vaughan 1999). A background interpolation field is often used for data sparse regions, commonly provided by remotely sensed characteristics of the upper snow layers.

The individual mass balance components are not easily measured. Precipitating snow, for instance, cannot be distinguished from drifting snow, and classical precipitation gauges do not work well in Antarctica. Fortunately, mass balance simulations using regional atmospheric models nowadays compare favorably with compiled observations. The big advantages of a modeling approach are the complete spatial and temporal coverage and the ability to study the individual mass balance components. There is a very strong topographical effect on the precipitation distribution: the coastal, predominantly easterly circulation produces pronounced precipitation shadows west of topographic obstacles in coastal East Antarctica. The northern Antarctic Peninsula, situated in the subpolar westerly circulation, casts a precipitation shadow that reaches all the way east to coastal Dronning Maud Land.

Sublimation is largest at the foot of the ice sheet, where the relative humidity is low and temperatures are relatively high due to adiabatic compression of the descending air. The combination of low precipitation and strong sublimation may result in areas with a negative mass balance. This occurs on a large scale in the Lambert Glacier basin, at the foot of the Transantarctic Mountains, and in Victoria Land. These areas are known for their extensive blue ice fields. Melting occurs mainly on the coastal ice shelves and becomes especially large in the northern Antarctic Peninsula; here, melting exceeds solid precipitation, which also leads to a negative mass balance. These areas have seen rapid disintegration of ice shelves as a result of meltwater collection in crevasses.

SWEDISH SOUTH POLAR EXPEDITION (1901–1904)

The Swedish South Polar Expedition was not an officially sanctioned expedition. Despite the ambitions of Dr. Otto Nordenskjöld as he departed from Göteborg, Sweden, on October 16, 1901, he was, in fact, leading an underfinanced, private expedition.

Partly inspired by the discussions at the international geographical congresses held in London, in 1895 and 1897, Nordenskjöld began to coordinate his plans for an Antarctic expedition with the geographical societies of Great Britain and Germany. He was working on a number of projects to be carried out in Graham Land on the Antarctic Peninsula, primarily related to climate studies, but geomagnetism also figured prominently, and research programs in geology, biology, zoology, glaciology, and hydrography were also presented. A winter station was planned for the highest latitude possible on the east coast of the Antarctic Peninsula, at Graham Land, and a party aboard the whaler *Antarctic* would work in areas around the Beagle Channel, the Falkland Islands, and South Georgia.

Nordenskjöld managed to raise some private funding, arrange loans, and receive some of the equipment, food supplies, and fuel free of charge, but his request for 35,000 crowns from the Swedish government was rejected. A three-person committee at the Academy of Sciences stated that the expedition was ill-equipped and underfinanced and that the leadership qualities were poor. Nordenskjöld was accused of instigating the extinction of mammals in the Antarctic and his interest in international cooperation was not deemed important, nor were, for that matter, the fields of study proposed for the land party.

Although severely disturbed by the resulting lack of funding from the Swedish government, Nordenskjöld continued his efforts to find provisions and a suitable team of scientists. Reluctantly he leased his vessel during the summer of 1901 to increase his income, and this, along with some necessary repair work, caused the departure of the expedition to be delayed. Yet another setback was the tragic suicide of Third Officer Otto Håkansson, in Göteborg.

Long in advance, Nordenskjöld had contracted the physicist Gösta Bodman, and later he recruited the medical doctor Gunnar Ekelöf and Lieutenant José Maria Sobral, who joined the team following an agreement between Nordenskjöld and the Argentine government. Ole Jonassen was a skilled carpenter also taken on to manage the dogs needed for the sledging, and Gustaf Åkerlundh was chosen to cook.

Johan Gunnar Andersson (geologist) became second-in-command and leader of the ship party. Karl Andreas Andersson (zoologist), Carl Skottsberg (botanist), and Axel Ohlin (zoologist) were all to become members of the ship party, but Ohlin had to leave the expedition due to illness in July 1902. At the very last moment cartographer Samuel Duse was recruited.

Among the first to be hired by Nordenskjöld was Captain Carl A. Larsen, who had a fine reputation due to his two earlier voyages to Antarctic waters. Larsen had been entrusted with the job of finding a crew capable of ice navigation, sealing, and whaling, and he was also given the assignment of obtaining equipment such as harpoons and barrels. Between October 16 and 19, 1901, *Antarctic* was equipped in Sandefjord. Even though no large-scale operations were planned, both sealing and whaling were on the agenda because parts of the salaries, for both the crew and the scientists, depended on the size of catch. Larsen, on his return from Antarctica in 1904, was to continue working with large-scale whaling enterprises for many more years.

Regardless of its private status, Nordenskjöld's expedition had strong moral support as well as other types of backing in Sweden. Professor Gunnar Andersson, not to be confused with second-in-command Johan Gunnar Andersson, acted as liaison between the expedition and influential people in Göteborg and Stockholm, both those funding the expedition and politicians. Economic problems were frequent, and on several occasions Gunnar Andersson had to intervene in order to ensure the continuation of the expedition.

Nordenskjöld himself had seemingly excellent contacts with the Foreign Ministry because just before departure he asked for, and was given, extensive support from the Swedish-Norwegian consuls in the harbours along the way to Antarctica. Favours were also extended from the representatives of the United Kingdoms of Sweden and Norway in Le Havre, London, Buenos Aires, Ushuaia, Port Stanley, and Montevideo. The expedition was favoured with reduced harbour fees, and free or reduced prices for, amongst other things, coal, food supplies, medical services, social visits, and assistance with media relations. Apparently the authorities did have some idea of the potential value of the Swedish South Polar Expedition, either in terms of its scientific or practical merits.

After a stop in Falmouth, *Antarctic* embarked for Buenos Aires. Additional water and coal supplies were arranged in St Vincent, Cape Verde Islands, on November 14–15, and one month later the expedition anchored on the roadstead of Buenos Aires, where the North American artist Frank William Stokes and Lieutenant Sobral joined the expedition. On December 20, the ship proceeded towards Port Stanley, Falkland Islands, with the mission of finding more dogs to add to those brought from Scandinavia, and on December 30, the expedition departed for Staten Island in order to visit an Argentine meteorological station to coordinate the measurement instruments. There had, however, been a lack of sufficient preparation, and after only a few hours' stopover, on January 5, 1902, *Antarctic* headed for the South Shetland Islands.

Although the weather had been favourable, Nordenskjöld commented on the snow and ice conditions upon arrival at Nelson Island, on January 10. During the week that followed several crew members were occupied with sealing, while the scientists trawled for zoological purposes but also to gather water-depth measurements. The expedition, after passing Astrolabe Island and Lois Philippe Island and visiting Paulet Island, reached Cap Seymour on January 16, whereupon Nordenskjöld set up a depot. The ship then proceeded south to find a suitable site for the winter party, but at 66°19′ S it became impossible to pass the heavy ice, and Larsen had to redirect the ship. Even though there was little time left to complete the installation of the winter station, the expedition took a trip into the Weddell Sea. Hydrographical work was carried out, and zoological material was collected from deep layers. Whales were spotted at a distance, and there was time for sealing as well. On February 11, 1902, most of the men went ashore, and on the days that followed a geomagnetic and meteorological laboratory as well as the winter station were erected on Snow Hill, 64°22′ S, 57°00′ W. The ship then set up a depot to assist the sledge tours planned by Nordenskjöld, and on February 21, Larsen and his crew along with the scientific ship party headed for Ushuaia.

At the base, weather observations were made without a break for 20 months, sometimes during harsh conditions: storms, gales, and snow. They discovered that Snow Hill was actually an island, and several minor sledge tours were made as well as two major ones. Sobral and Jonassen accompanied Nordenskjöld on one such trip between September 30 and November 4. Passing Larsen Ice Shelf and facilitating mapping of the eastern peninsula down to 66° S, the winter party engaged in geological studies and collected fossils in the vicinity of the station. In January 1903, they awaited the arrival of the *Antarctic*.

The ship party had returned safely to Ushuaia on March 5, 1902. The Argentine government generously provided both coal and water supplies, but unfortunately the coal had to be reloaded with assistance from prisoners. The ship departed on March 22 for the Falkland Islands, where the artist Stokes now left the ship.

The sealing and its aftermath soon became a major occupation for the crew aboard *Antarctic,* with considerable effects on the scientists. On April 22, the party reached Cumberland Bay on South Georgia, from where the ship departed for the Falkland Islands, where blubber boiling and the reloading of blubber was carried out during the next 4 months. The scientists made excursions and were kept busy with geological, glaciological, hydrographic, and botanical studies along with mapping the region.

On September 15, the ship entered Ushuaia after short stops in Albernal Bay, where Andersson and Ole Wennergard encountered some Ona. Passing Harberton on November 6, the ship left Tekenika and headed for the South Shetland Islands once again. The first and foremost task was to fetch Nordenskjöld and his men, and the second one was to map the western coast of Graham Land and the offshore islands along with the surrounding waters, as far south as to 64°30′ S. The ship party established that there was no strait through the peninsula as indicated on earlier maps. Mapping and the collecting of botanical and geological materials was carried out between November 26 and December 5, after which it was time to proceed to Snow Hill Island. The ice conditions, however, impeded all their efforts.

On December 29, 1902, Andersson, Duse, and Toralf Grunden landed on the west side of the

Antarctic Sound in order to set up a depot at Hope Bay. They were to connect with the party at Snow Hill Island, but if *Antarctic* had not reached Snow Hill Island by February 10, all nine men were to march to Hope Bay to await the ship.

Andersson, Duse, and Grunden failed to reach Snow Hill Island and were forced to return to Hope Bay on January 13. With only summer clothes, they spent the winter in a small stone hut, surviving on penguins, other birds, and some provisions brought from the ship. When not hunting, Andersson searched for fossils from the Tertiary and Jurassic periods, resulting in the discovery of some twenty new species.

Meanwhile, *Antarctic* faced a struggle of 6 weeks in the ice before on February 12, with a severely damaged engine room, it sank 45 km from Paulet Island. The nineteen men, led by Larsen, spent 16 days transporting small boats, clothes, and provisions, as well as a stove, towards safety on Paulet Island. There they built a hut of 5.4×6 m, with stone walls and sails and sealskins for a roof. The health of the party remained fairly good although a young seaman, Ole Wennergaard, died on June 7, 1902. The next spring Larsen took five men and set off for Hope Bay, only to find the small base abandoned.

On September 29, 1903, Andersson, Duse, and Grunden once again left for Snow Hill Island. On October 12 they actually met Nordenskjöld and Jonassen on their way back from their second sledge tour, whilst rounding James Ross Island. After 4 days joint sledging, they reached the southern base. In the coming weeks, Nordenskjöld and Andersson continued with their geological work. The extent of previous glaciations was discussed and judged to be more extensive than at present. On the morning of November 8, later remembered as "the day of the miracle," Bodman and Åkerlundh, the cook, set out on a minor tour and met Captain Julian Irizar, his officers, and crew, sent from Buenos Aires to rescue the members of the expedition. The Snow Hill party was stunned, but their astonishment had increased by midnight. On the very same day, Larsen, Karl A. Andersson, and four crew members from *Antarctic* arrived at Snow Hill Island, having found a message left at Hope Bay indicating that the party there had proceeded to Snow Hill. They had continued to Nordenskjöld's base themselves, helping to avert a catastrophe.

The Snow Hill base was evacuated on November 10, 1903, and soon thereafter the men remaining at Paulet Island were picked up. The rescue was the cause of much festivity in Buenos Aires, and helped set off a debate involving the Swedish Foreign Ministry as to whether Nordenskjöld should accept Argentine transport back to Sweden. Ultimately, the journey home was arranged privately. Shortly thereafter, Selim Birger (brother to the liaison Gunnar Andersson) was sent to the Falkland Islands to retrieve the scientific collections. In late March 1904 he returned to Sweden before the unsuccessful Swedish relief expedition, under the leadership of Olof Gyldén, returned (on April 4, 1904).

The scientific results were published between 1904 and 1920, and Nordenskjöld became a respected scientist in both Sweden and abroad.

SWEDISH SOUTH POLAR EXPEDITION, RELIEF EXPEDITIONS

On February 12, 1903, *Antarctic*, the expedition ship of Otto Nordenskjöld's Swedish South Polar Expedition, sank some 45 km from Paulet Island. Although it would still be some months before the disaster would be known to the outside world, members of the expedition had earlier established with various people in Sweden and Argentina that if *Antarctic* had not reached the Falkland Islands by April 30, 1903, a relief expedition should be sent out. During April 1903 a number of Swedish scientists, including Alfred Gabriel Nathorst, from the Museum of Natural History in Stockholm, presented a bill to raise both private and governmental funding for this relief. A few members of Parliament expressed the opinion that a privately funded expedition should also be rescued by private means, and, indeed, Nordenskjöld's relatives raised significant sums, but the Swedish Parliament also granted the sum of 200,000 Swedish crowns. In addition, the Swedish navy released Captain Olof Gyldén to command a Swedish relief expedition, with the sole mission of rescuing the Swedish South Polar Expedition. The relief expedition departed Sweden on August 18, 1903, aboard the Norwegian whaler *Frithiof*.

Rescue activities were also launched in several other countries. William Speirs Bruce's Scottish National Antarctic Expedition and Jean Baptiste Charcot's French Antarctic expedition were among the potential rescuers. Charcot, initially heading for the Arctic, switched in haste to the Antarctic and the rescue. However, Charcot's expedition was delayed and did not join the final phases of the rescue operation. Instead, the actual rescue was carried out by the Argentine Captain Julian Irizar aboard the corvette *Uruguay*. Irizar visited Stockholm and London and initially, in spring 1903, liaised to some extent with the Swedish government. The route his expedition was to follow was on the agenda, as was possible assistance from Argentina to Gyldén's expedition. Ultimately Irizar was instructed to await the French and Swedish expeditions until the first week in November. Thereafter, he should set off for Graham Land in *Uruguay*.

The operation included several dramatic events. On November 8, representatives of the Argentine navy met two members of Nordenskjöld's party in the vicinity of Snow Hill Island. In the meantime, a six-man party led by Captain Carl Anton Larsen had struggled to reach Snow Hill Island, setting out from Paulet Island, where nineteen people had wintered out the harsh condition in a stone hut. Larsen and his men arrived just in time because the plan was for *Uruguay* to leave as soon as possible due to fear of severe ice conditions. Yet another group of scientists, who had spent a winter in miserable conditions at Hope Bay, had joined Nordenskjöld's main party in October. Through these spectacular events, three widely dispersed parties had managed to reach each other at the last moment, and as a result Nordenskjöld and his expedition departed safely, picking up the men remaining at Paulet Island on the way north.

Meanwhile, the Swedish relief expedition had tried to get in touch with the Argentine expedition whilst on its way southwards, only to realise that *Frithiof* was lagging far behind. Stops were made at the Cape Verde Islands, Buenos Aires, and Ushuaia. The openly admitted competition between France and Argentina was beneficial to neither the French nor the Swedish. On December 4, 1903, after a march of some 20 km, Gyldén, scientist Axel von Klinckowström, and the expedition's medical doctor reached the Snow Hill Island base, only to find it abandoned and a letter from Nordenskjöld detailing the expedition's departure on November 10, 1903. Gyldén was requested to sail for the Falkland Islands in order to collect scientific material left there by Nordenskjöld, but Gyldén refused this request because his ship was in urgent need of repair, and he wanted to keep the costs down. He therefore returned to Sweden without delay, via Buenos Aires, Le Havre, and Bremerhafven. *Frithjof* was practically shipwrecked en route, and the expedition returned to Sweden without any positive media attention. In the lengthy press debate that followed, Gyldén was taken to task for his failure to locate Nordenskjöld in time and for not recovering the scientific collections.

On December 9, 1903, *Uruguay* safely reached Buenos Aires. Before entering the inner harbours, the ship was repaired and painted, in preparation for its participation in the magnificent festivities that had been planned. Argentine and Swedish expedition accounts, as well as South American and European press reports, presented uniform images of the mass greetings given to *Uruguay* and the members of the Swedish South Polar Expedition.

SYNOPTIC-SCALE WEATHER SYSTEMS, FRONTS AND JETS

Synoptic-scale weather systems are large, cyclonic disturbances or depressions (lows) that are a significant feature of the atmospheric circulation over the Southern Ocean and Antarctic coastal region. Air circulates around the centres of these lows in a clockwise direction, with the winds near the surface spiralling in towards the centres of the vortices. Lows are characterised by strong winds, large-scale ascent, and the formation of cloud and precipitation, which is often concentrated along frontal bands. Any broadscale satellite picture of the Antarctic continent and the Southern Ocean reveals a large number of major lows over the ocean areas around the continent. The individual lows can be identified on satellite pictures by their high, cold frontal cloud bands wrapped around the centres of the depressions.

Depressions typically have a horizontal length scale of 1000–3000 km and a lifetime of 1–3 days, although some lows can last longer. A vast range of synoptic-scale weather systems is found around the Antarctic, and in fact a spectrum of weather systems exists from very small vortices to major depressions occupying extensive areas of the Southern Ocean. The smaller, shorter-lived cyclonic vortices are called polar lows or mesocyclones and are dealt with in a separate section.

Synoptic-scale lows play a crucial role in the general circulation of the Southern Hemisphere through their part in the poleward (equatorward) transport of warm (cold) air towards the Antarctic (tropics). This happens through the individual lows carrying warm, midlatitude air poleward on their eastern flank and cold, polar air equatorwards on their western side. The lows also release large amounts of latent heat at high latitudes when water vapour condenses into cloud. Without this poleward transport of heat the Antarctic would be much colder than presently recorded in winter when there is no incoming energy from the Sun.

The lows are also extremely important in the weather that they bring to the Antarctic coastal zone. Synoptic-scale lows are responsible for many of the strong wind events that occur around the periphery of the Antarctic, and they also give the largest falls of precipitation. The strong winds give rise to major blowing snow events, which are a serious hazard to operations. They can also break up and move sea ice and have a significant impact of air-sea interactions around the continent.

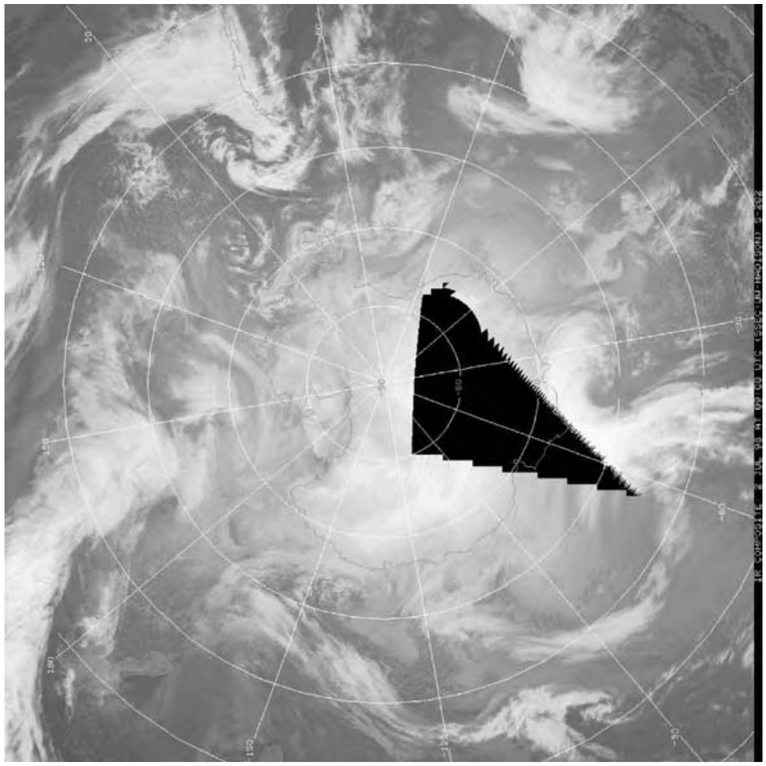
Analyses of satellite pictures and routine surface pressure charts have shown that the largest number of depressions is found just north of the Antarctic coast, at the latitude of the circumpolar trough over 60°–70° S. The lows here generally consist of two types, which satellite studies suggest occur with about equal frequency. Firstly, lows are observed that have developed in midlatitudes and spiralled in towards the Antarctic. The second type of system develops at the latitude of the circumpolar trough and then generally moves towards the east. The net result of so many depressions in the circumpolar trough is to give climatological easterly winds along the coast and westerlies on the northern flank of the circumpolar trough.

The tracks followed by the depressions is determined to a large extent by the winds in the mid- to upper-troposphere, which in turn are dictated by the location and amplitude of the atmospheric long waves (Rossby waves). When the long waves have a relatively small amplitude, the lows tend to follow a more zonal (west to east) track. In contrast, the depressions move in a more meridional direction towards the Antarctic coastline when the Rossby waves have a greater amplitude.

Very few synoptic-scale depressions penetrate onto the high Antarctic plateau, with most of the lows moving eastwards parallel to the coast once they reach the circumpolar trough. However, if the Rossby waves have a very large amplitude the steering level winds may be almost from the north so that the lows arrive at the continent almost perpendicular to the coast. In such a situation the steering level winds may extend for a considerable distance into the interior of the continent, and this scenario is the one most commonly associated with active synoptic-scale lows that are observed on the Antarctic plateau. When large-scale lows reach the interior of the Antarctic they bring very anomalous conditions, including relatively high temperatures, moderate snowfall, and strong winds.

The development of new lows is called cyclogenesis, and this can come about via a number of mechanisms. These are the same as occur in midlatitudes so they will only be described briefly here. Most lows develop via baroclinic instability, which is the formation of lows on horizontal temperature gradients where there is a conversion of the potential energy associated with the temperature gradient into the kinetic energy of the low. Horizontal temperature gradients are rather weak over the interior of the Antarctic so very few large lows develop there.

The greatest number of cyclogenesis developments takes place within the circumpolar trough, with a rapid decrease into the interior of the Antarctic and a slower decrease towards midlatitudes. The circumpolar trough, just north of the Antarctic coast, is a



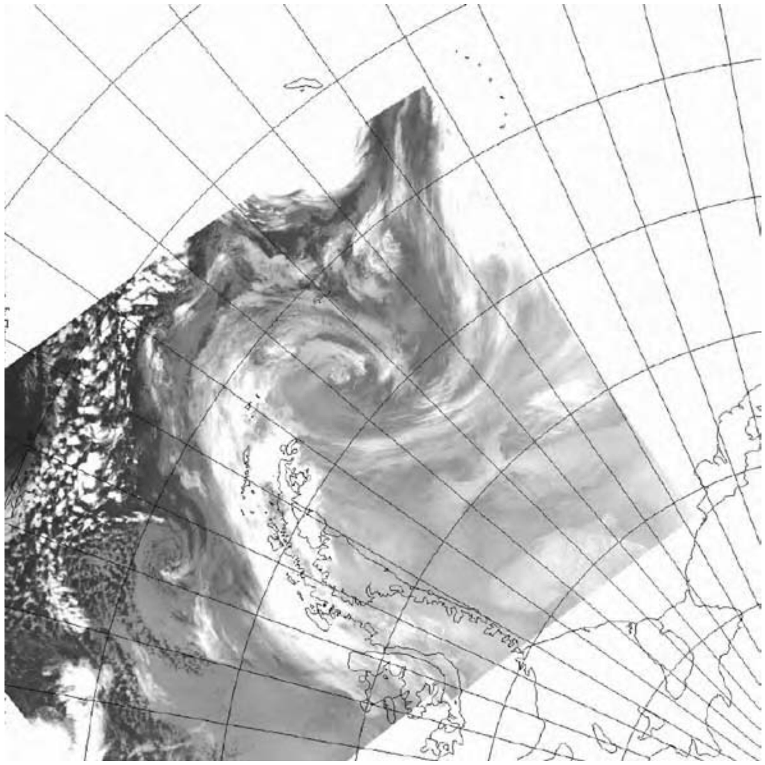
A composite infrared satellite image of the Antarctic and Southern Ocean showing the cloud associated with synoptic-scale weather systems and fronts. Cold clouds appear white while the relatively warm ocean is dark. The triangular black area indicates where no imagery was available. (Image provided by the Space Science and Engineering Center, University of Wisconsin-Madison.)

zone where relatively mild, midlatitude air masses moving southwards meet cold, continental air coming off the Antarctic continent. We therefore observe many lows developing in this zone. As lows move eastwards around the Antarctic the serial development of new depressions from mature or declining lows is often observed within the circumpolar trough. This often occurs because well-developed lows bring relatively warm air southwards on their eastern side which meets cold, polar air that has come off the continent. This can lead to a strengthening of the horizontal thermal gradient and the development of new lows. Sequences of satellite pictures therefore frequently show serial development of depressions, with new lows forming in the vicinity of existing depressions, often in association with frontal cloud bands.

The distribution of cyclone developments around the continent is rather uniform, which is perhaps not surprising given the fairly symmetric nature of the Antarctic orography. However, there are maxima over the Amundsen Sea, in the Indian Ocean sector, and close to the Greenwich Meridian.

One type of development that is frequently observed to the east of the Antarctic Peninsula is lee cyclogenesis. This occurs as air flows perpendicular across mountain barriers and results in an increase in cyclonic vorticity (spin) in the lee of the mountain range. Lows can form in isolation to the east of the Antarctic Peninsula or develop as a front crosses the mountains in association with a low over the Bellingshausen Sea. Lows that develop in the lee of the Peninsula tend to move towards the east, crossing the Weddell Sea and sometimes moving towards the northeast and joining the main belt of storms to the north of the Weddell Sea. Besides the Antarctic Peninsula, there are no other major orographic barriers where the prevailing wind flows perpendicular to the mountains, so the western Weddell Sea is unique in the Antarctic as a major area of synoptic-scale lee cyclogenesis. Lee cyclogenesis events observed in other parts of the Antarctic tend to be much more sporadic or occurring on smaller horizontal scales.

The decline and dissipation of depressions is called cyclolysis and is the result of the cessation or weakening of the forcing factors that maintain the structure of the depressions. The distribution of cyclolysis events around the Antarctic during winter is remarkably similar to the distribution of cyclogenesis, with a maximum at the latitude of the circumpolar trough.



An infrared satellite image of a synoptic-scale low pressure system centred just northeast of the tip of the Antarctic Peninsula.

The coastal region of the Antarctic is therefore characterised by the formation of many depressions, the systems moving towards the east and then dissipating at approximately the same latitude. Although cyclolysis is a feature of all sectors of the Antarctic, some areas experience more events than others. One such area is the Bellingshausen Sea, to the west of the Antarctic Peninsula. Depressions frequently decline here as they become slow-moving when they come up against the high orographic barrier of the Peninsula. There is also frequent cyclolysis just north of the coast of East Antarctica.

There have been few detailed case studies of the structure of synoptic-scale lows around the Antarctic because of the lack of three-dimensional *in situ* data within the lows. Therefore, most of our knowledge of the form of these systems has come from analyses of sequences of satellite images. Of course these show only the cloud associated with the lows, but much can still be gleaned regarding the life cycle and form of the lows from these images. A few lows over the Southern Ocean have the classical structure of midlatitude cyclones with well-defined warm, cold, and occluded fronts. This is the case with one low that was centred to the northeast of the tip of the Antarctic Peninsula with a warm front extending down the spine of the Peninsula and a cold front lying east-west along the northern Weddell Sea. However, studies show that such systems are very much the exception and that most lows have a much less clear structure.

The Antarctic coastal region is characterised by extensive cloud and many lows have only a weak cloud signature within an extensive field of fairly uniform, relatively featureless cloud. The task of identifying the locations of fronts within synoptic-scale lows, which is important for weather forecasting, is therefore not easy. Satellite pictures have also revealed that many large lows have multiple centres. This is particularly the case for declining depressions, when the low may develop a number of small, mesoscale lows within the large area of low pressure. If a short-wave, upper level trough moves over one of these mesoscale lows it can cause it to develop into a new, large-scale low. So sequences of satellite images of the Southern Ocean reveal a highly dynamic picture of depression formation and dissipation that is in stark contrast to the view held in the presatellite era of the Antarctic coastal region being characterised by only the decline of depressions.

Atmospheric fronts are found at the boundaries between air masses of different characteristics and are usually apparent on satellite pictures as bands of cloud indicating the ascent of air that takes place in these areas. Most fronts are found at the boundaries of air masses with different temperatures, and the greater the temperature difference the more active the front tends to be. In the case of active fronts, there is strong vertical motion that results in deep cloud that is very apparent on infrared satellite pictures via the very cold cloud tops.

The most active fronts tend to be associated with deep, synoptic-scale depressions that form on strong horizontal temperature gradients. Such very active lows usually form in midlatitudes, and the most marked, high frontal cloud bands are often found in midlatitudes and the northern part of the circumpolar trough.

Weak fronts can frequently be observed on satellite images as linear cloud features, often well removed from the large weather systems. Such fronts often indicate the boundaries between air masses of slightly different characteristics. For example, a minor front can often be seen running parallel to the edge of the sea ice separating warmer, moister air over the ice-free ocean from colder, dryer air lying over the sea ice.

Jets (or jet streams) are narrow belts of strong winds that are found in association with moderate or strong horizontal temperature gradients. Two types of jets are found. Firstly, those in the upper troposphere associated with the atmospheric long waves and the major storm tracks and depressions. These can be thousands of kilometres in length, and the location of these varies considerably on a day-to-day basis. They are always closely associated with the large synoptic-scale lows. The strongest jets are found in midlatitudes in association with strong horizontal temperature gradients existing through deep layers of the atmosphere where the most active depressions are located. The second type of jet is found at much lower levels and is usually only tens or hundreds of kilometres in length. They are found above the warm, cold, and occluded frontal surface associated with synoptic-scale lows, along with some other minor frontal zones.

The accurate forecasting of the location and strength of synoptic-scale lows, along with the associated winds, cloud, and precipitation is of critical importance to the complex logistics that takes place on and around the Antarctic today. Many nations operate weather forecasting centres at their stations that provide routine forecasts for their aviation, maritime, and deep-field operations. The forecasting of the movement and development of major depressions for periods beyond about 6 hours ahead is today based almost entirely on the output of computer models runs outside the Antarctic. Fields of surface pressure, winds, and heights at upper levels and precipitation from global models are sent several times a day to the stations and used to infer the future locations of the major weather systems. The current generation of models provide very good guidance on the locations and depths of the major lows for several days ahead, and they have some skill up to about a week ahead. A number of nations are now running higher resolution, limited area models either on the stations or at forecast centres outside the Antarctic. These are better able to represent the complex orography of the Antarctic in areas such as the Antarctic Peninsula.

For forecasting up to about 6–12 hours ahead extensive use is made of sequences of satellite images. These provide a dynamic illustration of the recent movement of the weather systems and their frontal bands, along which most of the precipitation is located. Such imagery allows the locations of the weather systems to be extrapolated over the coming hours, providing an essential supplement to the model output.

T

TARDIGRADES

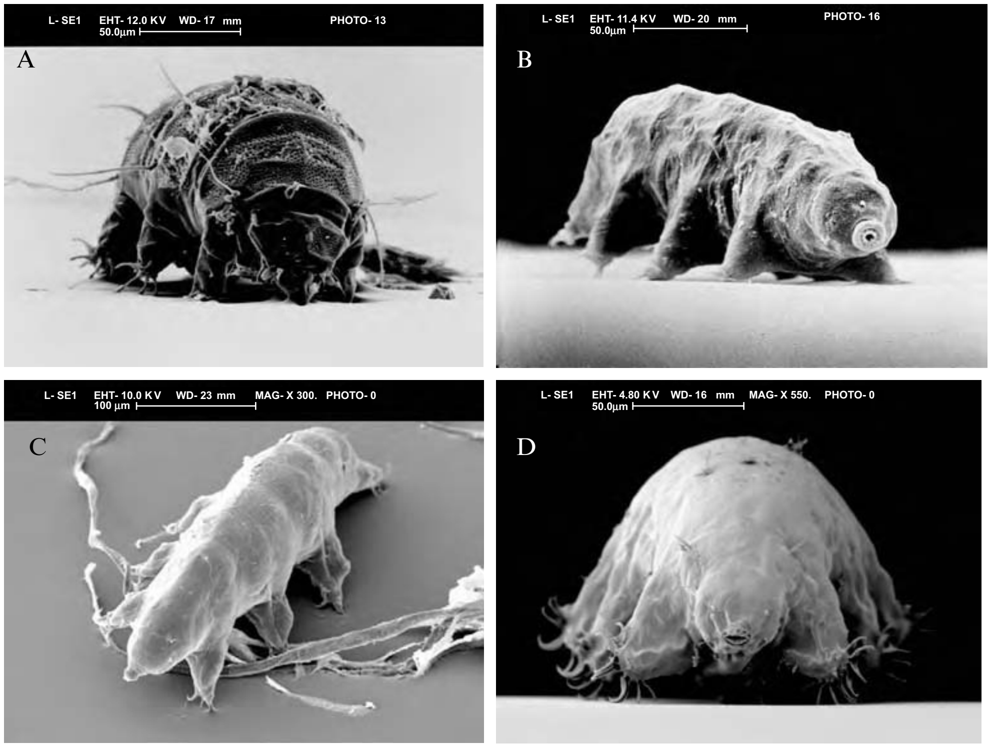
One of the "lesser-known" phyla, the Tardigrada are a cosmopolitan group, including approximately nine hundred species worldwide, found in diverse habitats within freshwater, terrestrial, and marine environments. In the early 1770s, a German pastor, Johann August Ephraim Goeze, described the animals as *kleiner Wasserbär,* giving them their descriptive common name of "water bears." About the same time, an Italian monk (Lazzaro Spallanzani), describing their lumbering gait, called them *il Tardigrado* (*tardi,* slow, and *grado,* walker), from which are derived both the Latin (Tardigrada) and the common (tardigrade) names. The phylum is divided into two classes: the Heterotardigrada, which includes mainly the marine and "armoured" terrestrial tardigrades; and the Eutardigrada, which comprises the "unarmoured" freshwater and terrestrial species.

Tardigrades are roughly cylindrical with four pairs of short stubby legs, terminating in claws. Their body length varies from about 50 μm (0.05 mm), after hatching from the egg, to a maximum of 1200 μm (1.2 mm) in a few exceptionally large species. Adults of most species fall within the range of 200–500 μm. Tardigrades have a complete digestive system and a fluid-filled body cavity (haemocoel) that functions in circulation and respiration. The nervous system consists of a dorsal lobed brain and ventral nerve cord with fused paired ganglia.

Tardigrades are found wherever "free" water is available, even intermittently. In terrestrial and freshwater habitats this includes mosses, lichens, leaf litter and soils, sediments, algal mats, and submerged plants, or within the interstices of sandy substrata. In marine environments tardigrades are present from the intertidal coastal zone of sandy shores, algal holdfasts, and shells of barnacles on rocky shores through the deeper shelf zone to the abyssal depths. They are one of the very few animal phyla that are found from the world's highest mountains to the deepest seas.

The relationship of the Tardigrada within the hierarchy of animal classification has been debated for many years, with no satisfactory conclusion as to whether they should be aligned with the Aschelminthes (nematodes, rotifers, etc.) or Arthropoda (crustaceans, insects, etc.). More recently, molecular studies (in particular those using 18S rRNA) have established a new grouping of "Ecdysozoa," made up of invertebrates that moult. This has offered an explanation of the morphological similarities between tardigrades, the arthropod line, and the aschelminth complex, and indicates that tardigrades are a sister group of the arthropods.

Early microscopists were fascinated by the ability of tardigrades to be "resurrected after death." This ability, shared with other groups such as Rotifera and Nematoda, is a form of cryptobiosis, or suspended animation, where the animal can cease (detectable) metabolism during unfavourable conditions (e.g., drought, extreme cold) and reactivate when conditions are again suitable for life. Life history attributes such as parthenogenetic reproduction (in the absence of males), well-developed cold tolerance, and resistant anhydrobiotic life stages are thought to preadapt tardigrades for the colonisation of new or remote habitats, harsh conditions, or for survival in refugia



(A) *Echiniscus punctus,* terrestrial Heterotardigrada. (B) *Macrobiotus furciger,* terrestrial Eutardigrada. (C) *Ramazzottius* sp, terrestrial Eutardigrada. (D) *Echiniscoides sigismundi,* marine (intertidal) Heterotardigrada.

(e.g., in the Antarctic, small pockets of terrestrial habitat that were not obliterated during glacial advances).

Tardigrades from the terrestrial habitats in the Antarctic and sub-Antarctic islands number approximately seventy species, with more being added as new sites are studied and taxonomic knowledge advances. Marine species are present in the Southern Ocean, and have been reported from the European "Polarstern" Study (EPOS) cruise (1989) to the Weddell Sea and the Antarctic deep-sea biodiversity (ANDEEP) programmes (2001) to the Scotia Arc and the Weddell Sea. To date, only four marine species have been described in literature from the Antarctic, but as very few areas have been specifically studied for marine tardigrades, the potential for new records and new species is very high.

Though microscopic in size, tardigrades are important to the biomass of Antarctic terrestrial sites, where competition and predation are more reduced than in equivalent temperate or tropical sites. Indeed, the most southerly inland sites studied in detail, on nunataks (rocky mountain tops exposed from surrounding glaciers) in Ellsworth Land (c. 75°–77° S, 70°–73° W), revealed an exceptionally simple faunal community including only five tardigrade and two rotifer species. All other fauna normally present in Antarctic terrestrial communities (particularly nematode worms and microarthropods) were absent. Population densities of tardigrades in the terrestrial Antarctic are generally between 10 and 1000 times greater than those of temperate or tropical zones.

TELECONNECTIONS

A teleconnection is a positive or negative correlation in the fluctuations of an atmospheric field, or fields, at widely separated points, and is mostly applied to variability that occurs on monthly or longer timescales. Several teleconnections can be found linking Antarctica with the rest of the world and within the South Polar region.

The dominant mode of atmospheric variability around Antarctica is the Antarctic Oscillation (AAO), or as it now more often called, the Southern Annular Mode (SAM). This zonally symmetric mode is essentially a teleconnection between approximately 40° S and 65° S. A meridional index can be constructed by taking the pressure difference between high and low latitudes, and this index can explain over 50% of the mean monthly variance surface pressure over Antarctica.

Another mode of variability that can be found around Antarctica is characterised by an atmospheric wave number 1 (one crest and one trough on a latitude circle around the Earth) in the pressure/height fields. This pattern produces opposing anomalies between the Australia–New Zealand and Antarctic Peninsula–South America sectors. This mode can be represented by a Trans Polar Index (TPI), constructed by taking the mean sea-level pressure anomaly difference between Hobart and either Stanley, Falkland Islands or Grytviken, South Georgia.

These modes of variability (and others) are described in detail elsewhere in this encyclopaedia. They explain most of the teleconnections found within the middle and high southern latitudes. However, teleconnections do exist between Antarctica and the tropics and even possibly the Northern Hemisphere. One of the best-known teleconnections between the tropics and Antarctica is that associated with the El Niño/Southern Oscillation (ENSO). A correlation can be found between the sea-surface temperature in the tropical Pacific and the pressure in the Amundsen–Bellinghausen Sea (ABS) or the temperature on the west coast of the Antarctic Peninsula. These correlations are rather weak. The correlation with pressure in the central ABS is 0.5, which is significant, while the correlation with temperature on the west of the Peninsula is –0.23, which is not significant at the 90% level. This teleconnection is associated with planetary scale waves in the atmospheric circulation. These waves are generated in the tropics by the divergent flow aloft resulting from deep tropical convection and propagate polewards to high latitudes. The tropical forcing mechanisms for the Rossby wave and the factors affecting the propagation of the wave through mid latitudes are complex and it is not surprising that simple linear correlations are often weak.

Despite the fact that the teleconnection between the tropical Pacific and the circulation around Antarctica is often weak, an ENSO signal is found in ice cores taken at the South Pole and in some high-latitude living organisms. In an ice core taken from South Pole it was found that levels of methanesulfate, which is normally associated with marine biogenic activity, could be correlated with ENSO and with southeastern Pacific sea-ice variations. Some correlations have been found between ENSO and pelagic ecosystems. The age structure of crabeater seals around the Antarctic Peninsula, juvenile leopard seal occurrence at Macquarie Island, and Weddell seal reproductive rates have all shown peaks at around the 4- to 5-year interval that is normally associated with ENSO and generally in phase with the ENSO signal. However, these signals do not show a completely consistent picture, probably because we do not understand the complex, nonlinear connections between the tropical pacific and the sea ice and ocean circulation around Antarctica.

The ENSO–Antarctic teleconnection is associated with one of the Pacific–South American (PSA) modes. The PSA modes are the two most dominant modes of variability of the Southern Hemisphere circulation. The two patterns are in quadrature with each other and are dominated by a wave number three wave train propagating from just north of Australia across the Pacific and South America and into the South Atlantic. The amplitude of the wave pattern is large in the PSA sector. ENSO produces variations in the PSA pattern on interannual time scales; however, variations in the PSA can be found on much shorter time scales. Variations in the PSA modes with timescales from weeks to months are found and these variations are thought to be associated with convection anomalies in the western Pacific and Indian oceans.

A study using a numerical model has shown that changing the radiative properties of Antarctica clouds can create significant changes in the tropics and even the extratropics of the Northern Hemisphere. This suggests the possibility of some Tropical–Antarctic teleconnections being forced from the Antarctic. Studies looking at the connection between sea-ice extent around Antarctica and the rest of the world reveal strong teleconnection between the sea ice in close to the Antarctic Peninsula and ENSO, which are assumed to be driven by the tropics, but also connections with Indian Ocean sea-surface temperature and tropical Pacific precipitation. With these last two connectivities it is not possible to identify the direction of causality; we may have the Antarctic climate driving variability in the tropics.

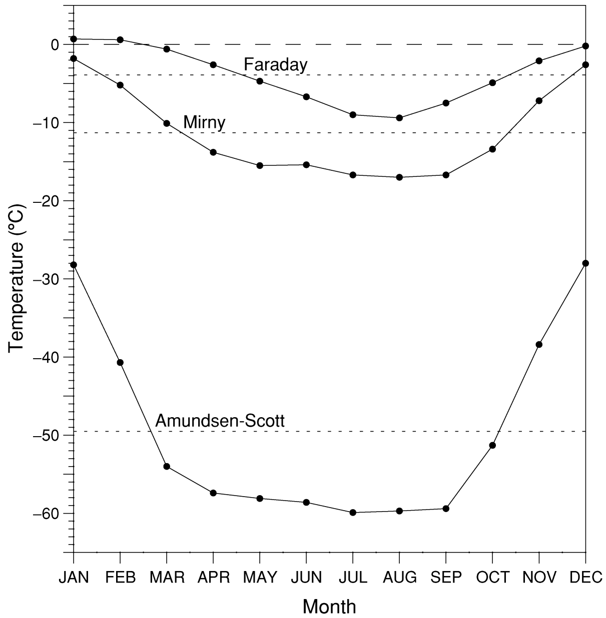
TEMPERATURE

Several factors combine to cause Antarctica to be the coldest continent. Antarctica is located at high latitudes, which means that it receives less solar radiation per year than lower latitudes and thus acts as a heat sink for the Southern Hemisphere. The high albedo of the snow and ice, which covers more than 99% of the continent, reflects 80%–90% of incident solar radiation, hence enhancing the cold temperatures. The extreme dryness of the air causes any heat that is radiated back into the atmosphere to be lost to space instead of being absorbed by water vapour within the atmosphere. Furthermore, Antarctica is also the highest continent, with a median elevation of 2150 m asl. At its highest the interior, known as the Antarctic Plateau, exceeds 4000 m asl. Its domed shape, with relatively steep gradients near the coast, prevents the frequent intrusion of warmer maritime air from coastal cyclones. The coldest temperatures on Earth are found during the polar night on top of the plateau, where no direct sunlight is received during winter months and where slopes are sufficiently shallow to prevent mixing through significant katabatic wind flow. The lowest measured temperature, –89.2°C, was recorded at Vostok station (78.5° S, 106.9° E, 3488 m asl) on 21 July 1983, but it is estimated that temperatures on parts of the Plateau may occasionally dip below –100°C.

Radiosonde (balloon) soundings reveal a strong temperature inversion above the Antarctic surface that is maintained by radiative cooling of the surface and lower atmosphere as described previously. Thus, as we might intuitively expect, the inversion is strongest on the plateau during the polar night (winter), when there is no incoming solar radiation and surface cooling is at a maximum. However, significant inversions can occur at any time of year, even in coastal regions. The resulting radiation deficit at the surface is balanced by turbulent heat flux from the atmosphere, whereas at the top of the boundary layer this flux divergence is zero (by definition). Hence, the boundary layer cools relative to the surface, producing a stably stratified temperature profile and surface inversion. When strong katabatic winds occur they mix the cold air vertically through a deep layer, destroying the inversion; therefore, near-surface temperatures covary strongly with wind speed.

Antarctica may be separated into three distinct zones based on the annual temperature cycle. In the northern part of the Antarctic Peninsula (Faraday), monthly mean temperatures exceed zero in summer, and here the annual cycle of temperature has a form found across many regions of the Earth, with a broad maximum in summer and a slightly shorter winter minimum. However, on the Antarctic Plateau (Amundsen-Scott) the form of the cycle changes completely. As well as temperatures being much colder, summer is now very short (December/January) with rapid changes in temperature defining the ends of a long or coreless winter period that encompasses several months with broadly similar mean temperatures. This rapid cooling and warming is due to the abrupt removal and return of surface radiation south of the Antarctic Circle at the beginning and end of the polar night. The annual temperature cycle at Mirnyy, representative of East Antarctic coastal stations, has a profile in between the other two regions mentioned: while monthly temperatures are much closer to those on the peninsula, the winter period is much longer, more similar to the polar plateau. Above the inversion, temperatures in the Antarctic troposphere follow a broadly similar seasonal pattern to that observed at the surface at East Antarctic coastal sites. The range between maximum and minimum monthly mean temperatures is ~10°C at 500 hPa (~5 km asl) across the whole continent.

The significant modification of the seasonal cooling that produces the coreless winter is thus observed



Annual cycle of temperature at Faraday (Antarctic Peninsula), Mirny (coastal East Antarctica), and Amundsen-Scott (Antarctic Plateau). The dotted line shows the mean annual temperature.

across much of Antarctica. It is a consequence of the semiannual oscillation (SAO), a twice-yearly expansion and contraction of the circumpolar low-pressure belt around Antarctica. This results from the different thermal capacities of the continent and surrounding Southern Ocean. The magnitude of temperature modification by the SAO appears largely determined by the strength of the winter surface-temperature inversion. Hence the impact is largest on the plateau, followed by coastal East Antarctica and then Peninsula stations: this can be observed in the above figure with regard to the duration of the coreless winter at the three stations. Heat stored within the winter snowpack also dampens any temperature fluctuations. In coastal East Antarctica, the coupling between the SAO and near-surface temperature can be explained by seasonal changes in the meridional circulation brought about by the former. Its influence on winter temperatures on the plateau is less well understood, although stronger katabatic wind drainage during this season may be important.

Antarctic temperatures are also influenced by climate variability in other parts of the earth, as evidenced by so-called teleconnections. The principal mode of variability in the Southern Hemisphere is the Southern Annular Mode (SAM), which comprises zonally symmetric synchronous pressure anomalies of opposite sign in Antarctica and the mid-latitudes. Statistical studies suggest that SAM variability impacts temperatures across much of Antarctica, although not necessarily in the same direction. Also important is the Pacific South American (PSA) pattern; this reflects the phase of tropical El Niño–Southern Oscillation (ENSO) variability and primarily affects Antarctic Peninsula winter temperatures.

The longest Antarctic temperature records are from manned stations, and the longest of all, at Orcadas in the South Orkney Islands, now exceeds 100 years. However, with a few exceptions in the Antarctic Peninsula, most temperature records did not begin until the International Geophysical Year of 1957–1958. Until relatively recently temperatures were observed manually, but now many countries have automated their data collection, using similar technology to that employed in Automatic Weather Stations (AWSs). These allow temperatures to be obtained from the more inaccessible parts of Antarctica, typically coastal islands, ice shelves, or the interior. Analysis of Global Telecommunications System (GTS) data reveals that there are now more Antarctic observations derived from AWSs than from manned stations.

Current mean annual air temperature at the snow surface is often estimated by assuming that it is equal to the snow temperature measured at a depth of 10 m. The accuracy of this assumption is dependent on the snow stratigraphy, shape of the annual cycle of temperature, and long-term trends, but methodologies are available to remove these effects. As a 10-m core can be drilled relatively quickly and simply, this is a very useful way to obtain temperature measurements away from manned stations. Longer-term temperatures can be obtained from chemical proxies within ice cores, such as the oxygen–isotope ratio. The deepest ice core ever drilled was recently completed by the European Project for Ice Coring in Antarctica (EPICA) at Dome C (75.1° S, 13.3° E); it is over 3270 m in depth and encompasses more than 900,000 years.

Today surface temperatures across the whole of Antarctica can be obtained from satellite instruments. Two types of data have been utilised to produce long time-series of temperatures appropriate for climate studies. First, the thermal infrared channels of the Advanced Very High Resolution Radiometer (AVHRR) instrument have provided a good estimate of near-surface air temperature at a resolution of ~5 km since 1979. The principal problem with this type of data is that it can only be obtained in cloud-free conditions. As clouds have a positive effect on surface temperatures over high-reflectance surfaces, this leads to a negative clear-sky bias in average AVHRR-derived temperatures, particularly in very cloudy regions such as the Antarctic Peninsula. Passive microwave brightness temperatures, also available since 1979, from the Scanning Multichannel Microwave Radiometer (SMMR) and subsequently the Special Sensor Microwave Imager (SSM/I) instruments are unaffected by cloud cover. However, their spatial resolution is only 25 km and their exact relationship with surface temperature is dependent on temperature and emissivity changes in the snowpack through which the radiation penetrates. Nevertheless, both these datasets are very useful in examining spatial temperature variability across Antarctica at regional and continental scales.

Continent-wide temperatures may also be derived from numerical weather prediction models, typically with a spatial resolution of about 100 km. Such analyses are useful for examining spatial variability in temperature, similar to satellite data. However, in comparison with observations there can be significant biases, even in relatively homogeneous regions like the Antarctic Plateau. Errors may be caused by incorrect elevations used in the model or by deficiencies in surface and boundary flux parameterisations, which are often tuned for midlatitudes.

The largest changes in temperature from station observations are seen in the Antarctic Peninsula. At Faraday, on the western coast, the annual warming of almost 3°C between 1951 and 2004 is believed to be the largest recorded anywhere on Earth over the last 50 years. A statistically significant warming has occurred throughout the northern part of the Peninsula. However, a seasonal analysis indicates that those stations on the north and west coasts have the greatest temperature rise in winter while those on the east coast show the most marked changes in summer and autumn. This is because different aspects of climate change are primarily responsible for the warming in the two regions. For example, in winter there is a strong negative correlation between western coastal temperatures and the extent of sea ice west of the peninsula in the Bellingshausen Sea. From sporadic ship reports in the 1950s and 1960s and satellite observations from the 1970s it appears that, uniquely for Antarctica, there has been a reduction in winter sea ice in this area. This has allowed greater seasonal exchange of heat from the ocean to atmosphere, thus contributing to the winter warming. In the northeast peninsula, the strength of the westerlies in autumn and summer has increased in recent decades, leading to a higher frequency of air masses passing eastward across the Antarctic Peninsula in these seasons. This relatively warm maritime air has caused a seasonal temperature increase that exceeds 2°C in 40 years, and is responsible for the substantial surface melting that has initiated the collapse of the northern sections of the Larsen Ice Shelf.

Over the full length of records there has been very little statistically significant temperature change across Antarctica away from the peninsula. This is partially a function of the relatively short time-series available and the high interannual temperature variability in coastal regions. The trend with the greatest magnitude is the autumn cooling at Halley. However, the largest and/or most significant seasonal trend is a warming in winter at a number of stations in East Antarctica. There are few distinct regional patterns, although stations in relatively close proximity can reveal similar seasonal trends in temperature (e.g., Mirny and Casey). Amundsen-Scott station, at the South Pole, is the only station to have a cooling in every season: a contemporaneous reduction in wind speeds suggests more stable boundary conditions and hence increased heat loss to the atmosphere as a possible mechanism. Recently, there have been several studies linking a summer/autumn cooling in East Antarctica over the last 30 years or so, with changes in the SAM. Interestingly, this is the same climate change that has caused the strong warming in the northeast peninsula. However, unlike in the latter case, the exact processes through which the mechanism operates are not yet clear.

Relatively little analysis has been undertaken on tropospheric temperature trends above Antarctica although the discovery of the "ozone hole" has led to the stratospheric cooling's being studied in great detail. In contrast, within the Antarctic troposphere there does appear to have been a warming at 500 hPa throughout most of the year during the last 30 years. Despite the shortness of the examined time-series, these trends are often statistically significant and are not limited to the Antarctic Peninsula region. Winter is the season that demonstrates the clearest warming signal with a statistically significant trend above most Antarctic radiosonde stations. At the South Pole, in direct contrast to surface temperatures, those in the troposphere show a warming in all seasons over the period of study.

TERNS: OVERVIEW

Terns are seabirds in the family Sternidae, previously considered a subfamily, Sterninae, of the gull family Laridae. They evolved from gull-like ancestors and are closely related to the gulls and skimmers. Most terns (two-thirds of all species) belong to the large genus *Sterna*. The other genera are small, though some authorities split the genus *Sterna* into several smaller genera. Although terns are closely related to gulls (Laridae), they are more specialized in terms of nesting habitats, diet, and foraging methods, and their morphology reflects these specializations.

Terns are generally small to medium-sized birds, typically with grey or white plumage, often with black markings on the head. They have longish bills and webbed feet. They are lighter-bodied and more streamlined than gulls, and look elegant in flight with long tails and long, narrow wings. Terns in the genus *Sterna* have deeply forked tails, those in *Chlidonias* and *Larosterna* have less forked tails, and the noddies (three genera) have unusual notched wedge-shaped tails, the longest tail feathers being the middle-outer, not the central or the outermost ones.

Five tern species have been regularly observed in the Southern Ocean: the Antarctic tern *(Sterna vittata),* Kerguelen tern *(S. virgata),* Arctic tern *(S. paradisaea),* South American tern *(S. hirundinacea),* and common tern *(S. hirundo)*. Some of these species are difficult to distinguish from one another.

Antarctic terns are medium-sized and appear very similar to Arctic and common terns, but these last two species occur in the southern summer in nonbreeding or immature plumages. At this time, the plumage of breeding adult Antarctic terns features a black cap and long tail streamers. Both genders have blood-red bills and red legs, while only the juveniles have winter-plumage-like feathers. The differences between Antarctic, Kerguelen, and South American terns are relatively minor—the deeply forked tail with long streamers, relatively short legs, and a strong bill are typical features of Antarctic terns. The juveniles are dark-brown-barred on the upper parts; the cap is black-streaked with buff and is extended below eye level. They are 32–40 cm long, with a body mass of between 114 g and 205 g.

The Arctic tern, a northern breeding species, can be observed in the Southern Hemisphere in the southern summer. The nonbreeders, which regularly occur in Antarctic waters, have white lores, forehead, and fore-crown, and whiter underparts. The upper wings have some dusky areas. The feathers from rump to tail are mainly greyish-white. The bird has a thin, sharp, red bill, sometimes with a black tip, and short, red legs. Its long tail extends beyond the wingtips on the standing bird. They are 33–36 cm long, with a body mass of between 86 g and 127 g. It is most readily confused within its range with the common tern. In winter, the forehead and underparts are white. Juvenile Arctic terns lack the extensive ginger coloration of young common terns.

The common tern as a species of the Northern Hemisphere has a deeply forked tail and relatively long legs. Nonbreeders have white lores, forehead, and fore-crown, and whiter underparts. The upper wings have large dusky areas on the outer primaries, forming a dark wedge. Rump and tail are mainly greyish-white, with darker outer webs to streamers. The bill is always black-tipped and the legs are red or duller in nonbreeding plumage. They are 32–37 cm long, with a body mass of between 92 g and 140 g.

The South American tern is a medium-sized, very-light-coloured species with pale-grey upperparts and paler underparts. This species is distinguished from the other four by its overall grey tone and plumage pattern, especially of the primaries. The red bill is stronger and more curved. The tail is deeply forked with long streamers, and the cap is black, extending to the upper hindneck. They are 41–43 cm long, with a body mass of 172–196 g.

Kerguelen terns have grey plumage, a black cap, and a not-too-deeply forked tail with relatively short streamers. The red bill is relatively short. The underwings are diagnostically grey. The legs are bright orange to dull red. They are 33 cm long, with a body mass of 85–170 g.

Terns have a worldwide distribution. They breed on all continents, including the northern tip of the Antarctic Peninsula. Many terns breed in temperate zones and are long-distance migrants. While about half of the species of terns in the world are primarily birds of tropical oceans and coastlines, small *Sterna* terns occur in a wide range of habitats. They are found in many different breeding habitats: oceanic islands, rocky cliffs, sandy or rocky beaches, coastal marshes, estuaries, inland rivers, and lakes. Only a few species breed inland; the majority nest in coastal areas. During migration, most of the inland species have been observed near the coast and coastal species mostly not far from the coast or seldom away from the continental shelf. Oceanic migration is typical of a few species. A special overwintering area is that of the Arctic tern in the Antarctic pack-ice zone. This species is renowned for its exceptionally long migration route from the high Arctic latitudes to Antarctic wintering areas. There are other migratory species that nest around the Bering Sea (Aleutian tern, *S. aleutica*) and on the Antarctic Peninsula (Antarctic tern, *S. vittata*). Many of these are oceanic species, but others (e.g., little tern in the Old World, least tern in the New World) follow rivers and wetlands to nest well inland.

Accomplished flyers and long-distance travelers, terns are a familiar sight in most coastal waters around the globe. Away from land, terns seen at sea are most likely to be Arctic terns, which are migrants from the Northern Hemisphere. Antarctic, and the less common Kerguelen, terns breed mainly on southern islands in the sub-Antarctic, the former also being found on the Antarctic Peninsula. Antarctic terns migrate several thousand miles each winter to feed in coastal South African waters.

The common tern is a widespread breeder in the temperate zone of the Northern Hemisphere (to tropical West Africa) and then migrates in high numbers to the Southern Hemisphere in winter. The wintering areas extend south to South Africa, Australia, and southern South America, but not south of the Polar Front. The world population is estimated to be between 250,000 and 500,000 breeding pairs. Arctic terns breed in the northern Holarctic and winter south of South America and South Africa, and in large numbers in sub-Antarctic and Antarctic waters. The world population is estimated to be 500,000 breeding pairs.

The South American tern breeds on the coastlines of South America between Peru and Brazil to Tierra del Fuego, including the Falkland Islands, but not south of the Polar Front. In the winter the birds migrate to the north. Antarctic terns breed from Tristan da Cunha to sub-Antarctic islands and south to the Antarctic Peninsula. The population consists of about 50,000 breeding pairs. Kerguelen terns breed on sub-Antarctic islands of the Indian Ocean. The population totals approximately 25,000 breeding pairs.

Most species of this group, which is present around the world, have a more restricted range. The global population sizes of tern species range from a few thousand to tens of millions. The smallest population is that of the Kerguelen tern, a breeding species of the Southern Ocean. Some species are threatened. Egging, hunting, exploitation for feathers, and destruction of nesting habitats are the most common reasons for population decreases. Locally, a high density of predators and human disturbance are the main reasons for low breeding success.

Many terns of the Northern Hemisphere are long-distance migrants, and the Arctic tern probably sees more daylight than any other creature, since it migrates from its northern breeding grounds to Antarctic waters. Other species migrate to the tropics or to the Southern Hemisphere. They migrate partly in huge flocks that sometimes include different species. The time spent by terns in the colonies or on their migration routes varies greatly among species.

Terns are fairly specialized foragers, but not complete specialists. Different species have different feeding methods. Plunge-diving includes flights back and forth at a height of 3–15 m above the water to search for prey below the surface. After fixing the location of prey, they plunge directly into the water. Normally they submerge themselves completely. Sometimes they pursue their prey underwater for a short distance. Normally they leave the water just after submerging and catching their prey. Another method is hover-dipping. This involves hovering 1–2 m above the water and dropping down to seize food items from the surface. Contact-dipping involves flying closer to the water, swooping down, and plunging only the bill under the surface, especially when there is plenty of prey near the surface. In this case contact-dipping will be repeated frequently. A special method is aerial-dipping: in this case, there is no contact with the water surface. Surface-dipping, a rare feeding technique for terns, features swimming or sitting on the surface of the water.

Most terns prefer aquatic (freshwater or marine) feeding areas and few species forage in terrestrial habitats. Most terns and noddies prey on fish by diving, often hovering first, but the marsh terns *(Chlidonias)* pick insects off the surface of fresh water. Terns glide only infrequently, but a few species, notably the sooty tern, will soar high above the sea. Terns are quite gregarious by nature, fishing in flocks of up to several hundred birds within sight of land just beyond the surf zone and often within the kelp bed zone, if present. They feed by swooping down and making shallow dives into the water to snatch prey. Their principal diet includes small fish and various crustaceans, krill probably being the most important and abundant. Antarctic terns also scavenge in the intertidal zone for stranded organisms. Most terns are short-distance foragers over shoals of fish. Within a few hours, they can obtain enough fish for themselves and their chicks in the breeding colony. Many tern species forage together with other marine animals, such as porpoises or predatory fish.

Terns are normally monogamous, but in a few cases, other mating systems have been observed, including trios and female–female pairs. Most terns breed annually outside of the tropics and usually with a special annual breeding cycle. The age of first breeding varies. Only a few species breed at the age of 2 years and the first breeding age is more often 3 or 4 years. In many cases, birds have visited the colony earlier than the age of first breeding.

Most terns are colonial, sometimes they form huge colonies, and this for many years. For other species habitat changes, human disturbance, or high predation rates force birds to move the colony, sometimes during the breeding season. The density of colonies varies. Sometime birds breed only a few centimetres apart. In many cases, they defend one another against predators. The establishment of territories is the first step for males to establish or reestablish the pair bond. After a highly specialised and ritualized courtship, the males feed the females with fish, an activity often connected directly with copulation. Nest site selection takes place a few days before egg laying. Sometimes more than one scrape is made.

The clutch size varies from one to three eggs, depending on the species or on food supply. The incubation time is normally 21–28 days. Birds often start to incubate after laying the second egg. The incubation shifts vary between the sexes and among species. Hatching takes place within 1 or 2 days. Chicks are generally inactive in the first week; later they spend more time preening and walking. Normally the adults feed their chicks several times a day, mostly with only one fish on each occasion. Chicks of ground-nesting species leave the nest when they are not older than 4 days. Some species form crèches. The chick-rearing phase or fledging period is about 4 weeks. The mortality varies from species to species and from year to year. Terns are generally long-lived birds, with several species now known to live in excess of 25–30 years. An Arctic tern reached 34 years and a sooty tern 32 years.

TERRESTRIAL BIRDS

Land Birds of the Antarctic

The Antarctic continent is predominantly ice covered (approximately 98%); hence, there is only a small proportion of it that is exposed land. This limited ice-free habitat, combined with the harsh climate, has led to a low diversity of plants within Antarctica, and hence little or no insect fauna. Since birds need either seeds or some form of prey to forage on, there are no regularly occurring species of land birds either on the Antarctic continent or on the sub-Antarctic islands, such as the South Shetland, South Orkney, or Balleny Islands. Nevertheless, on those islands slightly to the north, land birds do occur. These islands are Île Amsterdam, the Auckland Islands, Bouvetøya, Campbell Island, Îles Crozet, Heard Island, Îles Kerguelen, Macquarie Island, the McDonald Islands, the Prince Edward Islands, and South Georgia.

Many species are either vagrants or only infrequent visitors, but there are a number of species breeding on peri-Antarctic islands. The number and variety of land birds occurring on these islands depends on the size of the islands and their proximity to other islands and to continental land masses such as South America, Africa, and Australia. The islands closest to New Zealand (Auckland Islands, Campbell Island, and Macquarie Island) have the greatest number of species breeding or occurring as vagrants. Further factors that increase the likelihood and diversity of birds on islands are their size and their latitude, with more birds present on islands farther north (where the weather is warmer and hence more benign).

Thus, in the different sectors of the Southern Ocean, certain patterns of land bird occurrence can be seen. In the Australian/New Zealand sector (Auckland Islands, Campbell Islands, and Macquarie Island), the greatest diversity is on the Auckland Islands, which are farthest north, largest, and closest to another land mass (New Zealand). Campbell Island is then closer to New Zealand and has greater diversity than Macquarie Island.

In the Indian Ocean, the Prince Edward Islands and Îles Crozet are at a similar latitude. However, the Prince Edward Islands are closer to Africa and have had a greater number of land birds recorded from them (although no breeding species, whereas Eaton's Pintail breeds on Îles Crozet).

Of these peri-Antarctic islands, eight (including island groups) are south of the Polar Front. Heard Island, Bouvetøya, and the Balleny Islands are

Notes: 1 Species recorded visiting island
2 Species recorded breeding on the island

predominantly ice capped (and are isolated from other large land masses), and have had no land birds recorded from them. The South Sandwich Islands have significant ice-free areas, but are distant from major land masses. The McDonald Islands are small (and have been visited only twice). However, South Georgia, which is large but mostly ice covered, has had at least eighteen species of land birds recorded, including three breeding species. It is relatively close to a major land mass (1300 km from the Falkland Islands and 1700 km from South America) and has a relatively benign climate on the north coast, due to its high mountain ranges, shielding it from the full force of the westerly winds. The South Shetland Islands, while closer to South America than South Georgia is, are almost 10° of latitude farther south, and so have a much harsher climate and hence have had fewer recorded visiting birds (and no breeding land birds).

Groups of Birds Recorded

At least seventy-six species of land birds have been recorded from the sub-Antarctic islands. Of these, twenty-five species have been recorded breeding (including the now-extinct Auckland Island merganser), while the others are visitors (either vagrants or regularly occurring).

Of the twenty-five breeding species, there are a number of common groups, including eight species of ducks, nine species of introduced European birds (including a number that self-introduced from neighbouring islands, where they had initially been introduced) and eight endemic New Zealand species (including three endemic ducks). Two species of pipit also breed in these islands (the South Georgia pipit at South Georgia, and the New Zealand pipit at the Auckland Islands and Campbell Island).

The ducks include two closely related flightless ducks occurring on neighbouring islands to the south of New Zealand (the Campbell teal and the Auckland teal). The high number of New Zealand endemic birds occurring on peri-Antarctic islands is likely due to the relative proximity of the islands to New Zealand, and the number of islands in that region. The introduced European birds are yet another example of the profound effects humans have had on these islands. A number of these have become pests (while additionally, the Weka, a type of rail, was introduced to Macquarie Island, where it was a significant pest as a predator of small species of seabird).

A number of species of land birds are restricted to these peri-Antarctic islands. These are the Eaton's pintail (from Îles Kerguelen and Îles Crozet), the Auckland teal, the Campbell teal, the Auckland Island rail, the South Georgia pipit, and the Auckland Island tomtit. All species that are restricted to these islands are vulnerable due to the small size of their populations (with the population of Campbell teals estimated to be as few as 50–100 individuals) and restricted ranges, with many breeding only on single islands. They are therefore particularly vulnerable to introductions of mammalian predators, such as rats *Rattus* spp., cats *Felis catus,* and mice *Mus* spp. This vulnerability is further accentuated by the fact that these species evolved in the absence of predators, and the habitats they nest in lack trees and shrubs, so they have to nest on or near the ground.

The nonbreeding species include six species of heron, seven species of gallinule, six species of cuckoo, and five species of swallow. In addition to the eight species of duck breeding on peri-Antarctic islands, a further four species have been recorded as vagrants.

Of the species of herons, it is particularly noteworthy that three species occur on multiple islands, particularly the cattle egret, which has occurred on Île Amsterdam, Îles Crozet, the South Shetland Islands, the South Orkney Islands, the Auckland Islands, and Campbell Island, and the great egret, which has occurred on South Georgia, the Auckland Islands, and Campbell Island. These species are capable of great movements.

A number of species of gallinules also occur. In general, gallinules appear to be poor flyers. Despite this, they are capable of flying substantial distances, and occur on many of the islands of the world (including tropical, temperate, and polar islands).

Cuckoos and swallows are both groups of birds that make long-distance migrations, hence their occurrence as vagrants is perhaps not surprising. Welcome swallows have been recorded as vagrants on all groups of islands close to New Zealand, while barn swallows, a long-distance migrant, have occurred on the three different islands in the regions of Africa or South America.

THERMOHALINE AND WIND-DRIVEN CIRCULATIONS IN THE SOUTHERN OCEAN

Hot air rises and cold water sinks—or does it? This entry explores the nature of Antarctic circumpolar convection, which is the sinking and rising motion around the continent that occurs due to changes, often subtle, in the density (mass per unit volume) of seawater, and also to the force the wind exerts on the ocean surface as it blows, steadily or in gales across its surface.

Heated air rises in a process called convection. House radiators, hot air balloons, and thunderstorms all derive from the fact that air becomes less dense when heated, therefore buoyant compared to surrounding air, and rises. The same process occurs upside-down in lakes and oceans, with cooler water sinking, and warmer water rising to take its place and remaining at the surface until cooled in turn. This usually is not observed, since it is all happening below the ocean or lake surface. However, the steam sometimes coming off relatively warm water, and the moderation of temperature extremes for a milder climate near coasts, is a result of convection and the large heat capacity of water. Why aren't the coasts of Antarctica mild? Of course, the term is relative, and they are milder than the extreme cold temperatures found further inland; the main effect of convection near the Antarctic continent, however, is not so much to warm the air as to melt the ice, whether it be sea ice offshore or glacial ice adjacent to the continent. The combination of freezing temperatures, ice, and salty seawater leads to the curious situation that the ocean surrounding Antarctica is colder at the surface than it is below the surface. This was one of the earliest observations in scientific reports from expeditions to the Southern Ocean.

Heat and Salt

Fresh water, without any salt, has the unusual property, known for over 200 years, that at near-freezing temperatures it actually reaches a maximum density at a point near 39°F or 4°C. This means that at temperatures between freezing and this point, density *increases* as temperature increases. Since the ocean is at freezing temperatures around the Antarctic continent it is natural to wonder whether this effect is relevant to Southern Ocean convection too. Early scientific explorers knew that near the continent, the temperature was colder at the surface than it was at greater depths, and reasoned that this was consistent with the fact that (fresh) water had a maximum density above freezing, hence the colder, less-dense water near freezing could float on top of the denser, warmer, deep water. It followed that there should be a zone of maximum density at some intermediate latitude between the coldest water next to the continent and warmer water as one progressed north, and that furthermore, the ocean should have this maximum density from the surface all the way to the bottom, since the water is dense and would naturally sink. Thus the existence of cold water at the surface; somewhat warmer water below, filling the depths; and yet warmer water at lower latitudes fit a consistent framework.

This was the first theory of Southern Ocean convection and the associated temperature field. That it was wrong did not stand in the way of the notion that it was reasonable, and explained some basic facts about the region. The early temperature measurements were difficult to make at sea and often only temperature maxima and minima were recorded. Salinity—the concentration of dissolved salts in seawater—affects density but was not systematically measured until much later. It is the presence of salt that not only lowers the freezing point of water (and thus salt is spread over roads to help melt ice) but also eliminates the phenomenon of a maximum density at a temperature above freezing. Seawater freezes at about 29°F, or –1.8°C, and reaches its maximum density at this point. The reason there is cold water near the freezing point at the surface is that ice is formed and melts at the surface. Where it forms, salty water is left behind and sinks, and where it melts, fresher, less-salty water is left behind and floats. In both cases the temperature is close to freezing. In general, salinity has a controlling effect on the stratification or layering of the ocean near Antarctica because, all other things being equal, the temperature tends toward the freezing point, whereas salinity is free to vary according to the ice cycle. (How salt changes the properties of water is a subject of thermodynamics.)

The sinking of the salty water or brine rejected by ice as it forms leads to the buildup of dense, relatively salty water on the continental shelf, which around Antarctica has numerous deep basins. This seasonal buildup and subsequent spilling off the shelf and down the slope into the surrounding ocean is the primary way Antarctica contributes to the global ocean convection cell, which brings relatively warm deep water south and sends cooler bottom water back north. Spilling occurs in numerous places distributed around the continent according to the geography of the continental margin and ocean circulation. As the water flows down the slope, it gathers momentum and turns left under the influence of Earth's rotation, tending to flow parallel to the coast in the westward direction. Gradually, under the influence of friction against the bottom, it sinks to greater depths and follows undersea ridges leading it away from the Antarctic continent.

There are other consequences of the salt's effect on density, or, in technical terms, the haline part of convection, as opposed to the thermal part, that play a role in heat and salt transport. If one mixes equal parts of seawater at a different temperature and salinity, but with the same density, the resulting water has a slightly greater density. This second new effect is called cabbeling, and is due to the rate at which temperature changes control density. A given change in temperature in cold water has a smaller effect on density than the same change in warm water. Hence, when the two parts of seawater mix, and the cold one is warmed and the warm one is cooled, the cold one cannot lower its density as much as the warm one can raise its density. Therefore they meet at the average temperature and salinity with a slightly greater density. This can happen within the ocean since salinity permits two water masses to have the same density despite being at different temperatures. As water moves around and comes into contact with water at the same density from a different region, they mix, producing internal convection as the mixed water sinks.

Finally, the third major heat and salt convective process, double diffusion, also depends on the interplay of temperature and salinity in the ocean. This effect arises from the fact that heat diffuses faster than salt in water. Thus, when layers of contrasting temperature and salinity form in the ocean—as they normally do because of, for example, the ice freeze-and-melt cycle or surface gradients in rainfall and evaporation—the interface between the layers can be unstable. That is to say, slight movement up or down allows the temperature to rapidly equalize with its surroundings while the salinity does not. If cold fresh water overlies warmer saltier water, as is typical in the Antarctic Zone, then heat passes into the colder upper layer and the water below becomes denser and eventually mixes; if warm salty water overlies cooler fresher water the salty layer loses heat at the interface and starts to sink. It cannot sink as a body—there must be an upward compensating motion. Rather than mixing down uniformly, however, small convective plumes form because of the intensity of the buoyancy forces on the fluid. These fingers are small enough (less than an inch wide) to exchange heat like little radiator fins with neighboring plumes, and allow the salt to be transported downward.

To put these different convective processes in perspective, consider their strength in terms of the amount of water put in motion as a result of each effect. The first process of dense water buildup by the ice freezing cycle generates on average several million cubic meters per second (one million cubic meters per second flow is called one Sverdrup and abbreviated Sv) each year of dense cold water spilling off the shelf and down the continental slope away from Antarctica, more than the flow in of all the world's rivers. These plumes of dense water, concentrated in the Ross Sea and Weddell Sea, drag surrounding water along and mix with it to produce a net flow of more than 10 Sv, by the time they leave the continental margin and enter the main part of the Southern Ocean. This bottom water eventually spreads into the major ocean basins of the Atlantic Ocean and the Pacific Ocean, filling them to the brim (that is, to the level of the sills formed by the midocean ridge) with cold Antarctic Bottom Water. Thus, early oceanographers were impressed to find cold, near-freezing water at the bottom of the ocean even at the equator, where the surface temperature can be 80°F/26°C or more.

The second process, cabbeling, is thought to generate vertical exchanges between water masses of an amount, several Sv, similar to the first, initial overflow process, but rather than reaching from the surface to the bottom of the ocean, it is restricted to relatively small steps in the interior of the ocean. Thus, its role is harder to observe, and estimates of the strength of its effect are mostly based on ocean model studies. Cabbeling is sometimes thought to work in concert with the temperature dependence of compressibility, an effect called thermobaricity. Thermobaricity means that colder water is more compressible than warmer water, so when cold water sinks its volume decreases relatively fast compared to the surrounding water, hence its density increases, giving an added push to the sinking plume. In certain special places where the stratification is weak and the temperature and salinity contrasts are strong, such as near the ocean surface, these processes can produce strong localized convection and might be responsible for maintaining ice-free zones or polynyas.

The third process, double diffusion, is primarily a means to transfer heat upward and salt downward. The associated downward shift in mass is usually neglected. This effect tends to drive an internal heat and salt transport between ocean water masses, rather than an overall convective overturning of the Southern Ocean. Evidence for double diffusion is clear so long as the appropriate temperature and salinity layering is present. It may be important to the global heat and salt balance, but its role in the Southern Ocean is still under investigation.

Deep and Shallow Convective Cells

The processes that have been described thus far are associated with a system of circulation that may be called the deep overturning circulation of the Southern Ocean, since it consists of a broad, dense, and cold outflow near the bottom balanced by flow toward Antarctica in overlying layers. This inflow takes place mainly below the level of midocean ridges. Ridges provide a boundary against which the deep currents can move with little effort, since Earth's rotation generally makes currents turn in circles if there is no boundary to support their pressure gradient. This is the situation commonly seen, for example, on weather maps of circulating high-pressure and low-pressure systems. In contrast, along mountain ranges, in the atmosphere, or on the mountain ranges of the seafloor, barrier winds and deep currents can flow long distances without being deflected. The Scotia Arc, the Kerguelen Plateau, and the midocean ridge of the Southern Ocean are examples of ocean mountain ranges along which deep currents exist.

There is another major overturning circulation called the shallow or upper circulation cell. This cell is driven strongly by the wind, which blows from west to east all around the Southern Ocean, in the descriptively named roaring forties and screaming fifties. To understand the role of the wind one must consider not just the fact that it will generate waves and drag the surface of the ocean along with it, that is, from west to east; one must also recall that the earth's rotation tends to turn the current—to the left in the southern hemisphere. The surface current is constantly dragged downwind, but the level just below is shielded somewhat from the wind and freer to feel the influence of the earth's rotation; hence, it turns to the left. And so on to deeper levels, leading to the famous Ekman spiral and the transport of water near the surface to the left of the wind in the Southern Ocean (and to the right in the northern hemisphere).

This Ekman transport is large, amounting to roughly 20 Sv when added up along a circumpolar track near 50° S. As outlined above, it flows to the left of the wind, or north, and carries Antarctic Zone properties with it, including sea ice, nutrients, and cold, less-saline surface water. These modify the water on the northern side of the Southern Ocean. To conserve mass, water must rise within the Antarctic Zone to supply this northward flow, sink in the sub-Antarctic region, and return south in subsurface layers. This constitutes the upper or shallow overturning cell of the Southern Ocean.

In the case of the upper cell, the subsurface return flow is less easily located, and several theories exist to explain the closure of the cell. The traditional view is that some of the same water that flows south along ridges as part of the deep cell upwells into the Ekman flow rather than sinking in convection zones near the continent. This is satisfying in the sense that no further explanation is required. An examination of the particular water mass layers that outcrop in the upwelling zone suggests that layers above the midocean ridges outcrop, but this poses a problem since some sort of boundary is needed to permit north–south flow in the Southern Ocean, as described previously. The problem can be reconciled by the turbulent nature of fluid motion, which allows for turbulent transports of mass (and heat and salt and other properties) in layers that are not bounded by ridges. This occurs in much the same way that surface waves, which appear to pass by floating objects without causing any net motion, can actually generate significant mean flows or net displacements of objects on the surface if they are large enough.

Among the strongest components of turbulence in the ocean are vortices, often called eddies. They are the swirls one sees in images of the surface temperature or ocean chlorophyll color, and they can be tens to hundreds of miles or kilometers across. They are common in the Southern Ocean because the strong Antarctic Circumpolar Current spawns them to lose some of the energy put in by the wind and focused by bathymetry. They are implicated in the process of closing the upper cell, returning part of the water carried north in the Ekman flow. Some theories even have them canceling part of the Ekman flow itself, saving them from the problem of returning it south at deeper levels. At present, estimates of the overturning circulation in the upper and deep circulation cells from available observations suggests that the lower cell is a bit stronger, at about 17 Sv, than the upper cell, at about 14 Sv. Acting in combination, these two cells carry about 24 Sv of deep water to the Southern Ocean from the rest of the World Ocean farther north, and provide a compensating outflow near the bottom and in the surface layer.

Variability

The picture of upper and lower convection cells, with sea-ice formation and brine rejection, plumes spilling off the shelf, and Ekman transports, is not a static one; it shows variability at many time scales. The most important of these is of course the seasonal cycle. Within the seasonal cycle there are periods of warmer or colder days, stronger or weaker winds, a good example being the occurrence of katabatic wind events. These are the strongest source of variability at the surface near the continent. Farther offshore, storms drive variability in the low-pressure belt centered near 65° S, and affect Ekman transports in a complicated fashion as they grow and decay in their circumpolar course.

Recent research has synthesized some of this variability into what are called large-scale modes of variability. Analyses show that one mode, called the Southern Annular Mode for its roughly circularly symmetric appearance, dominates the wind variability at large scales. This mode can vary rapidly in time, as rapidly as 1 week or so, but also shows longer period phases of activity. It represents the expansion and contraction toward the South Pole of the high-latitude component of the atmospheric jet stream system that rings the Southern Hemisphere near 50° S. The role of this mode in the development of the various convective elements described previously is just now starting to be revealed.

At longer than seasonal time scales, over periods greater than 1 year, say, another mode of variability with a large impact appears to be the El Niño–Southern Oscillation mode. This mode derives from tropical temperature anomalies and produces the well-known El Niño phenomenon. El Niño reaches as far as the Southern Ocean, in the southeastern Pacific, because large-scale atmospheric waves propagate from the tropics to higher latitudes and modify the wind pattern. This also modifies sea-surface temperatures and the movement of fields of sea ice. El Niño is thought to have an irregular period of recurrence of 4–7 years. At longer time scales, the question of which mode of variability is most important remains open.

Ecosystems

There is also a relationship between thermohaline and wind-driven modes of convection and biology, shown in the long-established research on coastal and equatorial upwelling, the flux of nutrients into the sunlit levels of the upper ocean, and the consequent productivity. In the Southern Ocean, the upwelling extends over vast interior areas of the ocean, and other mechanisms of upper-ocean mixing, including eddy transports, may play a role as well. Closer to the continent, communities of organisms live in sea ice, so processes that influence the distribution and amount of sea ice will have an impact on this part of the ecosystem. Both the upwelling of warmer water and Ekman transport exert some control on sea ice in this context.

The larger-scale modes of variability also have an impact on ecosystems through the control they exert on broad-scale upwelling and upper-ocean physics. Modern observational techniques such as remote sensing by satellites are giving us opportunities to find the links between physics and biology at the largest scales in the ocean surrounding Antarctica.

Conclusion

The rich dynamics of the ocean circulation permit many physical processes to interact, interfere, or coexist. These processes produce exchanges between different components of the ocean atmosphere–ice system and create links that are important for weather, climate, and living organisms. Observational, analytical, and numerical studies are helping to sort out the dominant processes at work in the Southern Ocean.

This scientific sorting process is important for a number of reasons, not the least of which is to satisfy curiosity about nature and about natural cycles of the Earth system. But another reason of growing importance is the pressing need to develop climate models up to the task of predicting the consequences of human-induced global change. What is not yet known is how to quantify the net effect of large-scale turbulence and many small-scale phenomena into a formula that depends only on more easily observable quantities, like the wind forcing and surface properties. When these are developed and tested it will be possible to make better climate forecasts.

THWAITES AND PINE ISLAND GLACIER BASINS

Thwaites and Pine Island glaciers occupy a central role in the stability and evolution of the West Antarctic Ice Sheet. They spread between 100° and 110° E and 75° and 81° S, and drain 390,000 km^2 of ice into the Amundsen Sea, South Pacific. They are the fastest-flowing glaciers in the Antarctic and the largest dischargers of ice into the ocean. More importantly, they are grounded on bedrock several kilometers below sea level, which deepens towards the interior. This configuration makes them prone to rapid retreat and they are designated "the weak underbelly of West Antarctica." Their divide overlays Bentley Subglacial Trench, a trough 1500 m below sea level that connects the Ross ice streams, Thwaites/Pine Island, and the Ronne ice streams. Retreat of the grounding line of Thwaites and Pine Island glaciers into Bentley's trench would shrink the drainage area of the Ross and Ronne ice streams, thereby affecting the entire West Antarctic Ice Sheet. Despite its importance, few observations of this sector have been gathered due to its heavy sea-ice cover, the harshness of its weather, and its remoteness from manned stations.

Pine Island glacier was discovered in 1947 from the USS *Pine Island* during Operation Highjump. It is a 30-km-wide, 400-km-long confined glacier, with an unusually bow-shaped catchment basin of 165,000 km^2 that flows at 3 km per year into a 60-km-long floating ice shelf. Thwaites Glacier, directly to the west, is much wider (110 km) and drains an oblong-shaped basin of 180,000 km^2. Thwaites Glacier comprises a 50-km-wide fast trunk on its western flank that flows at 2.5 km per year into a protruding, unconfined ice tongue subject to multidecadal calving, and an eastern flank slowly moving (500 m per year) into a fractured, mottled ice shelf buttressed by ice rises. Satellite Interferometric Synthetic Aperture Radar and radar altimetry indicate that the two glaciers result from the merging of many (8–10) tributaries, several hundred kilometers inland, which is an unusual characteristic compared to other Antarctic glaciers. Seafloor bathymetry in Pine Island Bay shows that Thwaites and Pine Island glaciers used to coalesce to form one giant ice stream, with deeply incised meltwater subglacial channels, that reached the edge of the continental shelf at the last glacial maximum.

Snow accumulation is high compared to the rest of Antarctica, about 35–50 cm water equivalent per year. This high precipitation results from synoptic-scale cyclones travelling around the Antarctic and coming ashore at the Amundsen Sea where the circumpolar trough is the deepest. The area is dotted with many emerging rocks and mountains, most of which are volcanoes.

Oceanographic data show that the glacier floating sections bathe in warm circumpolar deep water that intrudes onto the continental shelf and generates the highest bottom melt rates yet measured in Antarctica, about 50 m per year near the line of grounding of the glaciers. This means that two-thirds of the glacier ice melts into the ocean before it reaches the ice front and calves into large, tabular icebergs.

Until the 1990s, the few available observations of Thwaites/Pine Island glaciers suggested a gain in mass, which was contradictory to a collapse. Observations from the ERS-1/2 radar satellites, however, revealed that the glacier grounding lines, where ice meets the ocean and becomes afloat, are retreating fast (1 km per year), ice elevations are dropping meters per year, and ice discharge has been accelerating 1% per year over the last 30 years. This situation is not unique and affects neighboring glaciers Haynes, Smith, Pope, and Kohler as well. Yet no other sector of continental Antarctica is changing as fast as the Amundsen Sea sector. Ice thinning and ice flow are strongly correlated, which means that mass losses are not caused by changes in precipitation but by dynamic strain-thinning of the glaciers, i.e., accelerated flow.

Total discharge from the Amundsen Sea Sector is 241,000 km^3 ice per year. This volume of ice exceeds total snow accumulation in the catchment basin by 60%. Hence, the glaciers are losing mass to the ocean. They contribute more than a 0.25 mm to global sea-level rise per year at present. If all ice contained in their catchment basin were to melt into the ocean, global sea level would rise by more than one meter.

The glacial history and evolution of Thwaites and Pine Island glaciers are not fully understood at present, so one can only speculate about the future. The flow acceleration and thinning are attributed to the strong melting of the floating ice shelves by a warm ocean. Ice-shelf melting and grounding-line retreat reduce the buttressing force of ice shelves on grounded ice, thereby allowing faster rates of ice discharge than required to maintain equilibrium with snow accumulation in the interior. The zones directly upstream of the grounding lines are only slightly grounded, a few tens of meters above hydrostatic equilibrium, and named ice plains. At the current rate of ice thinning, these ice plains will soon become afloat and allow faster rates of ice discharge. The glaciers may then retreat into deeper ice, and the process may accelerate, become irreversible, and lead to the demise of ice over the entire basin. Continuous observation of this sector of West Antarctica is therefore of great relevance to the future of the West Antarctic Ice Sheet in a warming climate, with potential impacts at the global scale.

TIDES AND WAVES

Waves are the fairly regular motions associated with the transmission of energy through the ocean. Familiar examples are surface waves caused by the local wind ("wind waves") and by distant storms ("swell"). The tide, which is a type of wave, is the regular rise and fall of the ocean surface caused by the gravitational forces of the moon and sun acting on the earth and its ocean. The ocean's vertical stratification (less-dense surface water overlying denser deep water) sets the scene for another type of wave called a baroclinic (or "internal") tide. These and other waves influence the Antarctic oceans, sea ice, floating ice shelves, and the adjacent grounded ice streams and plains. Tides are produced by the difference in the gravitational attraction of the moon (and sun) between the earth's surface and its center of mass. The complex geometry of the orbits and rotation of the sun–earth–moon system creates complex time variation in forcing. This forcing is, nevertheless, easily represented as the sum of many tidal "harmonics," where each harmonic is a sine wave of known frequency.

The main tidal harmonics are divided into two species. Semidiurnal tides have periods that are semidiurnal (roughly 12 h, and more energetic), while diurnal tides have periods of about 24 h. Most locations on the earth experience semidiurnal tides (two high tides per day), since the tide-generating forces are stronger for M_2 and S_2 than for K_1 and O_1. In many regions, however, there is a pronounced difference between the two high or low tides; these are "mixed" tides. In some regions the tides are diurnal (one high tide per day). The superposition of many tidal harmonics leads to tidal variation with a fortnightly cycle. The largest and smallest tides during this period are called "spring" and "neap" tides. Long time-series also contain variability at fortnightly, monthly, semiannual, and annual periods, and an 18.6-year-period "lunar node" tide can be found in extremely long records.

Tides are semidiurnal in the Weddell Sea but are predominantly diurnal in the Ross Sea. Statistics of tide height and velocity fields from a tide model show that the largest tide heights are in the Weddell Sea under the Filchner, Ronne, and Larsen Ice Shelves. The tidal range in these regions can exceed 5 m at spring tides. Moderate tides are also found along the Siple Coast under the eastern Ross Ice Shelf. The tide heights elsewhere around Antarctica are smaller, with a typical spring tidal range of 1.5–2 m. Tidal currents range from negligible to greater than 1 m s^{-1} at spring tides. The largest currents are along the edge of the continental shelf in the northwest Ross Sea, and under the northern edge of the Ronne Ice Shelf in the southwestern Weddell Sea. Our knowledge of tidal variability around Antarctica comes from two sources: recorded time-series of ocean height and currents, and tide models. Compared with coastal regions of populated continents, tide height records around Antarctica are sparse. Most coastal tide gauges are near manned bases, and most of these are along the coast and islands of the Antarctic Peninsula. Several time-series of ice-shelf elevation were obtained with gravimeters on the Ross Ice Shelf in the 1970s. A few more-accurate and longer-duration records are now available from bottom pressure recorders. Sources of Antarctic tide-height information include measurements of the surface elevation of both the ocean and ice shelves using satellite radar and laser sensors, and geodetic positioning system (GPS) measurements from ice shelves. Current meters deployed on moorings provide information on tidal velocities. Hundreds of current meter records have now been retrieved from Antarctic seas, including meters placed under the Ronne Ice Shelf by the British Antarctic Survey.

Most practical applications require that tide height or currents be predicted from models. The simplest models are based on analyses of time-series of elevation or velocity. The amplitude and phase coefficients for each of the tidal harmonics in the time series are calculated, and these coefficients are then recombined to predict height or velocity at other times. These predictions can be very accurate, especially for elevation, but only work near where data have been obtained. A better view of the spatial variability of tides comes from numerical models, which are solutions to the equations of fluid motion for a system forced by the gravitational attraction of the moon and sun, and with specified conditions at the model's ocean and coastal boundaries. There are several sources of error in these models, including uncertainties in the location of ice-shelf grounding lines (where glacial ice flowing off the continent first starts to float), open-ocean bathymetry and water-column thickness under the ice shelves, and model simplifications required for computational speed. Nevertheless, recent models are sufficiently accurate to be useful for assessing the role of tides in Antarctic glaciology and oceanography.

Tidal influence on Antarctic geophysical processes begins on the landward side of the grounding line and extends seaward into the deep water north of the continental shelf break. Data from GPS receivers mounted on grounded ice show that the rate of seaward flow of ice streams can be modulated by the ocean tide. For example, east of the Ross Ice Shelf, ice that remains stationary most of the time maintains a net seaward flow by rapid "slip" events, each only a few minutes long, occurring exactly twice per diurnal tidal cycle. A few kilometers offshore from the grounding line, ice shelves float freely on the ocean surface as it rises and falls with the tide. The flexure of the ice between the grounding line and the free-floating shelf forms crevasses that can pose navigational challenges to people trying to cross these regions. The tide's large contribution to ice-shelf surface elevation complicates the interpretation of satellite remote-sensing data sets used to monitor long-term changes in ice shelves.

Underneath ice shelves, tides are the primary source of ocean velocity, and turbulence caused by these currents moving against the ice contributes to the rate at which ice melts. Basal melting is one of the main processes by which ice is lost from the Antarctic Ice Sheet, the other major source being iceberg calving. Basal melting occurs when the temperature of ocean water in contact with the ice is higher than the local freezing point. If the ocean is not turbulent, melting ice creates a stable layer of relatively fresh, cold water directly below the ice, insulating it from further melting. Tide-driven turbulence can overcome this stabilization, with strong tidal currents under the front of the Ronne Ice Shelf contributing to melt rates exceeding 2 m of ice per year.

North of the ice shelves, the primary role of tides comes from mixing driven by friction at the seabed, and by the transfer of energy from the "barotropic" to the "baroclinic" tide. The barotropic tidal current is the current that results directly from the gravitational forces of the moon and sun. This current is fairly constant with depth. The baroclinic tidal current has more vertical structure, and exists because the ocean density varies with depth. Barotropic currents are important in polar oceanography because they increase the friction at the seabed, causing more mixing than would be found if there were no tides. This mixing affects the characteristics of the water masses, including the cold, dense Antarctic Bottom Water that is formed around Antarctica and contributes to the deep circulation of the world's oceans. Baroclinic tides are created when barotropic tidal currents flow across steep and/or rough topography, and, if large, can contribute to ocean mixing. Whereas barotropic tides cause most mixing near the seabed or at the base of land-fast sea ice and ice shelves, baroclinic tides can create mixing in the interior of the water column, away from boundaries. Thus, baroclinic tides can contribute to the mixing of water masses at intermediate depths in the ocean. Baroclinic tides in the Southern Ocean are usually weak because density differences between surface and deep waters there tend to be small. Exceptions occur near "critical latitudes," where the tidal period equals the local inertial period.

Tidal currents also apply a force to the base of the ice. Drift tracks of buoys that have been deployed on sea-ice floes show that the ice moves with the tidal currents, although not always at the same speed. Spatial gradients of the tidal forcing can cause the ice floes to diverge and converge at tidal periods. While a solid cover of thick sea ice is a very effective insulator, the temporary open-water fractures ("leads") created by the tides weaken this insulation, causing an increase in heat exchange between the ocean and atmosphere and leading to more sea-ice formation than would occur if tides were absent. Recent numerical modeling of barotropic tidal currents suggests that these leads can increase area-averaged heat-loss and ice-formation rates in winter by about 50% in parts of the western Weddell Sea. When baroclinic tides are present, the mean fraction of open water due to tides may be further increased.

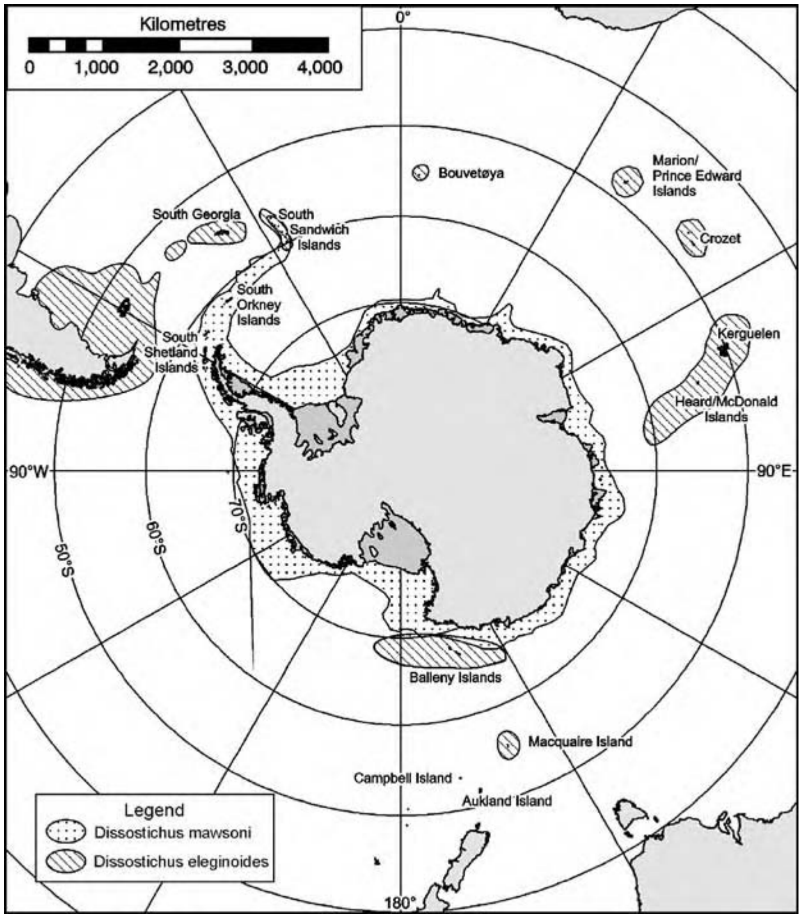
TOOTHFISH

Toothfish, named for the sharp teeth on the upper jaw, belong to the genus *Dissostichus* in the family Nototheniidae (Antarctic cods), which are endemic to the Southern Hemisphere and dominate Antarctic fish assemblages. There are two species of toothfish: the Antarctic toothfish *(Dissostichus mawsoni)* is found at high latitudes around Antarctica, whilst the Patagonian toothfish *(Dissostichus eleginoides)* occurs farther north around sub-Antarctic islands such as South Georgia and around the southern tip of South America. There is some overlap in their distribution in intermediate areas. Both species grow to large sizes, reaching lengths in excess of 2 m and weights greater than 100 kg, and can be distinguished by the pale edge of the caudal and pectoral fins and the longer lower lateral line in *D. eleginoides*.

Toothfish are active predators and scavengers, occupying a broad depth range, but the biology and ecology, particularly of the Antarctic toothfish, are poorly known. Juvenile fish generally occur in shallow water, with the mean size of fish increasing with increasing depth, to a maximum depth in excess of 2000 m. Toothfish are believed to spawn in deep water (500–1000 m), with the main spawning period around South Georgia probably in the austral winter (Agnew et al. 1999). Females produce between 50,000 and 500,000 relatively large (4–5 mm) pelagic eggs that hatch into small pelagic larvae. The duration of the pelagic larval stage is not known, but by the time fish have reached 200 mm in length they are found associated with the sea floor at depths of 100–200 m.

Growth rings from scales and otoliths (ear stones), which record seasonally alternating periods of rapid and slow growth, have been used to estimate the age of toothfish (Horn 2002). These studies suggest that, in contrast to other deep-sea fish, toothfish grow reasonably quickly for the first 10 years, reaching up to 1 m in length. As the fish grow there is a gradual migration to deep water, with an associated change in diet, and although large fish are still caught in shallow water, they are most abundant at depths of 750–1500 m. After the initial, relatively rapid growth, toothfish reach maturity and subsequent growth is slower. The reduced growth may be associated with an annual investment of energy in reproduction, but also with the reduced availability of food in the deep



The distribution of the two species of toothfish. The distribution of *Dissostichus mawsoni* has been inferred from catch records and extrapolation to the 2000 m depth contour.

sea. Females generally grow faster and reach a larger size than males with maximum longevity in both sexes of up to 50 years (Horn 2002).

Juvenile toothfish are essentially visual predators and use their sharp teeth to catch the fish, crustaceans, and cephalopods that make up a considerable portion of their diet. As the growing fish migrate deeper, light levels decline and toothfish probably rely less on vision and more on alternative senses such as olfaction and mechanoreceptors in their lateral lines, which detect movement and sound. The diet changes accordingly and larger, deep-living toothfish will scavenge carrion (such as dead fish and squid) that falls to the sea floor, to supplement their diet of benthic fish and decapod crustaceans (Arkhipkin et al. 2003; Collins et al. 1999; Pilling et al. 2001). Large toothfish probably have few predators, particularly when they are in deep waters, but juveniles have been reported in the diets of penguins, sea lions, sperm whales, and elephant seals.

In addition to the bathymetric migrations, there is evidence that toothfish undertake local, small-scale movements, probably related to feeding and reproduction. However, despite their large size, the results from tagging studies suggest that adults do not undertake large-scale migrations (Williams et al. 2002). The single incidence of a toothfish being caught in the North Atlantic (Moller et al. 2003) is dubious and deep ocean basins probably present a physical barrier to migration between distant populations. Genetic studies suggest that geographically distant populations of toothfish are separate stocks (e.g., Shaw et al. in press), with a major genetic break between populations of Patagonian toothfish found in the Southern Ocean and those on the South American Plateau. Within the Southern Ocean there are genetic differences between the isolated populations of the sub-Antarctic islands, which suggests that each small, localised population is a separate stock.

Patagonian toothfish are a major target for commercial fishermen, and the high value of the catch has attracted pirate vessels to the Southern Ocean. The fishery began in the late 1970s, when juvenile toothfish were caught by trawlers as a bycatch in shallow-water fisheries around South Georgia. In the late 1980s, a targeted longline fishery for larger adults began in Chilean waters, but rapidly spread to the Patagonian shelf, and sub-Antarctic islands. The FAO-reported landings of Patagonian toothfish increased from less than 5000 tonnes in 1984 to 40,000 tonnes in 1992. The expansion of the fishery caused concern about overexploitation and the Commission for the Conservation of Antarctic Marine Living Resources (CCAMLR), which is responsible for managing resources in Antarctic waters, sought to control the expansion of the fishery in its area of jurisdiction by setting precautionary catch limits. Unfortunately, the value of the catch and the difficulties of enforcing regulations in such a large and inhospitable ocean led to the development of significant illegal fishing in the mid-1990s, which had a detrimental effect on the toothfish stocks as well as causing large-scale mortality of seabirds. On a more positive note, the recent introduction by CCAMLR of a catch documentation scheme, which means that legally taken fish can be traced to supermarkets, and the high-profile arrests of pirate vessels have reduced the take by illegal vessels. An experimental fishery for Antarctic toothfish has recently started in the Ross Sea.

The longline fishery operates in deep waters (700–1500 m) where the large adults are most abundant and are readily attracted to hooks baited with squid or fish (Agnew 2004). Long-lining is a more selective fishing method than trawling, generally only catching scavenging fish and doing less damage to the sea floor and its associated fauna. In the toothfish fishery at South Georgia, there is a small bycatch of skates, grenadiers, and deepwater hake, but problems with the incidental mortality of seabirds, particularly albatrosses, have caused greater concern. When the baited hooks are deployed from the stern of the long-lining vessels, many seabirds, including albatrosses and petrels, are attracted. In attempting to take the bait they become caught on the hooks and drown when the hooks sink. Incidental seabird mortality was initially a problem with the toothfish fishery, but this has been addressed by CCAMLR, and mitigation measures to keep birds away from baited hooks have almost eliminated seabird catches.

TOURISM

During the past 50 years, Antarctica and its neighbouring island groups have become tourist venues. The first sightseeing tourist aircraft overflew the Antarctic Peninsula from South America in December 1956; the first shipload of paying passengers followed a similar route in January 1958. Since then both airborne and ship-borne tourism to Antarctica have increased radically. In the summer of 2003–2004, almost 25,000 tourists were estimated to have visited the area by air or sea, some 20,000 of whom landed on the continent or nearby islands. These numbers are tiny compared with those visiting other tourist attractions worldwide, but remarkable for a continent that, up to 50 years ago, was visited almost exclusively by explorers, scientists, and their support staff. Antarctica's main attractions for tourists are spectacular scenery and natural history, followed closely by the history of exploration (exemplified by historic huts), and evidence of current research activities, especially visits to working stations. Relatively few visit for climbing, skiing, or trekking to the remoter parts of the continent.

Ship-Borne Tourism

The most popular area for ship-borne visits remains the South American sector—the South Shetland and South Orkney Islands and Antarctic Peninsula, which lie within 1 or 2 days' sailing from the ports of Ushuaia (Argentina), Punta Arenas (Chile), and Stanley (Falkland Islands). The sub-Antarctic island of South Georgia lies some 3 to 4 days' sailing from these ports. To reach other areas of mainland Antarctica, for example, historically interesting McMurdo Sound, Cape Adare, and Commonwealth Bay, requires voyages two to three times longer, mainly from Hobart (Australia) or Lyttleton (port of Christchurch, New Zealand), across wider stretches of the world's least hospitable ocean. Macquarie Island and the southern islands of New Zealand are often included in these itineraries.

In January and February 1958, *Les Eclaireurs,* an Argentine naval transport, carried one hundred paying passengers to the Antarctic Peninsula in each of two voyages. In the following season, both Chilean and Argentine government ships made similar voyages, between them carrying over three hundred passengers. The first cruise dedicated solely to tourism occurred in 1966, when Lars-Eric Lindblad, an entrepreneur of worldwide adventure travel, chartered the Argentine naval vessel *Lapataia* for fifty-eight passengers on a voyage to the Antarctic Peninsula. In 1967, Lindblad promoted two further cruises, again to the peninsula, and in 1968 he arranged for two voyages to the peninsula in the Chilean transport *Navarino* and two to the Ross Sea region in the Danish ice-strengthened ship *Magga Dan*. So began regular summer cruises to Antarctica, and the establishment of the benign "Lindblad pattern" of tourist management that has since permeated the whole of the industry. In the following decades, Antarctic ship-borne tourism grew erratically but surely, involving more ships making more voyages and carrying more passengers each year.

Typically visits are made between mid-November and mid-March, when weather and ice conditions are best, and wildlife is most spectacular. Visits that promise landings are necessarily restricted to readily accessible parts of the coast. Most of the ships involved alternate visits to Antarctica with voyages in warmer waters and the Arctic. Passenger numbers per ship range from fewer than fifty to seven hundred or more, though operators who land passengers restrict numbers to five hundred or fewer. Some ships are ice-strengthened; two or three with ice-breaking capacity can take their passengers on more adventurous cruises into the pack ice.

Some indication of the industry's growth can be gained from statistics provided annually by the US National Science Foundation and International Association of Antarctica Tour Operators (IAATO). In the 1992–1993 season, twelve ships made a total of sixty-three voyages, landing almost seven thousand passengers. In 2003–2004, 29 ships made a total of 168 voyages, landing over 19,000 passengers. Within the past 5 years a few larger liners with the capacity for 1000 or more passengers have visited the peninsula area each season, without attempting landings. In 2003–2004, three "big" ships made five cruises, carrying over 4900 visitors. At the other end of the scale, a few privately owned and chartered yachts, some with paying passengers, appear in Antarctica each year. Most are summer visitors; a few remain over winter. Paying passengers continue to be carried on naval transports and other expedition ships, usually in less luxury though more cheaply than on scheduled cruises.

Under Antarctic Treaty regulations, operators and masters of tour ships are licenced by their governments and provided with regulations and guidance that outline the ground rules for taking parties ashore, and the location and extent of protected areas (which for practical reasons are seldom marked in the field). A strong duty is imposed on them to ensure the good behaviour of both passengers and crew, ashore and afloat. Except in areas set aside for scientific research or strict conservation, and in the immediate environs of active stations, operators are free to land passengers virtually anywhere. In practice, ships use a limited number of sites that are recognized for their intrinsic interest and safety of operation. Over 270 such sites have been identified in the Antarctic Treaty area, though of these only about half are visited in any one year. The dozen most popular sites may be visited every second or third day throughout the season; some have now been visited regularly for over 40 years.

Fortunately for these areas (which some ecologists regard as particularly fragile), Antarctic tourism is dominated by a strong ethic of environmental concern and conservation, based largely on Lindblad's management concept, which many of today's cruise directors and expedition leaders continue to follow. Lindblad also cofounded IAATO, an organization that since 1991 has promoted safe and environmentally responsible private-sector travel, and represented the industry in dealings with the Antarctic Treaty System, its ultimate governing body. IAATO produces codes of conduct and other guidelines and recommendations for members and clients that have formed the basis of legislation under the Treaty System.

Typical small Antarctic cruise ships carry 100–140 passengers, operating under an experienced captain and cruise leader. Each voyage is treated as an adventure expedition, with shipboard lectures, briefings, and one or more daily landings. Lecturing staff are themselves often experienced Antarctic researchers or administrators. Landing sites are selected by expedition leaders for their historical associations, natural history (penguin colonies are particularly favoured), scenic beauty, or other qualities. Before their first landing passengers are briefed on the requirements of the Antarctic Treaty covering visitors, and issued with a set of treaty-based guidelines that cover their behaviour ashore, possible hazards, the need to avoid interference with wildlife, and other points of conduct. Landed by inflatable boats in parties of ten to fifteen, the passengers are helped ashore, accompanied, and supervised by well-informed guides. For safety reasons, and to ensure satisfactory guide-to-passenger ratios, ships avoid having more than about one hundred passengers ashore at a time.

Visitors wear gumboots, which they are required to wash before and after landings, and are usually provided with bright padded jackets, to ensure that they can be seen from a distance. They are usually free to wander from their parties, but required to keep off glaciers, avoid climbing and other hazardous pursuits, avoid harassing animals or damaging plants, and stay within sight and easy reach of the embarkation point. Visitors who drop litter, knowingly trample vegetation, or interfere seriously with wildlife are likely to be reminded of their responsibilities by their guides, or more often by fellow passengers. Parties remain ashore for 1–3 hours, moving within a radius of few hundred metres, seeking photo opportunities and watching wildlife.

There may be up to three such landings per day, interspersed with prearranged visits to scientific stations, or to abandoned bases, whaling stations, and historic monuments, or hour-long scenic boat tours among icebergs and islands. Evenings before dinner are usually taken up with a "recap" session, in which the day's events are discussed, and plans for the following day announced. This is often the occasion for cruise leaders and staff to reinforce the expedition spirit, and reiterate the conservation ethic that all the well-organized tours actively promulgate.

The "Lindblad pattern" of management continues to be favoured, at least in principle, by most operators, but is challenged by fundamental changes in a developing industry. Its most serious challenge appears in ships carrying more than 150 passengers, which for economic reasons are likely to become the majority in the future. Larger, more heterogeneous communities of passengers are likely to include wider age ranges and more diverse backgrounds than the mainly retired clientele to whom Lindblad catered. They may not all accept without question the same underlying conservation ethic. They are likely to include several language groups, which need to be addressed separately. Bigger ships offer alternative forms of entertainment, from bingo to dancing troupes. Two sittings for dinner make it impossible for all the passengers to meet in one place at one time, and share their experiences each evening with the cruise director and staff. Younger age groups demand more active participation than the pattern allows. Forward-looking operators meet these challenges by finding alternative management methods for the larger numbers and greater diversity of passengers who make up the modern clientele.

Airborne Tourism

The pioneering overflights of 1956 from South America were repeated irregularly during the following years. From February 1976, Boeing 747s from Australia and DC-10s from New Zealand carried several thousands of passengers in flights over the East Antarctic mainland. These ended on 28 November 1979 when a low-flying New Zealand aircraft crashed on the slopes of Mount Erebus, Victoria Land, with the loss of 257 passengers and crew. Flights from Australia resumed in 1995 and continue to prove popular.

In 1979–1980, the Chilean government installed a 1300-m-long hard runway and a hostel for visitors at Teniente Rodolfo Marsh Station, King George Island, South Shetland Islands, making possible tourist flights with landings from Punta Arenas. These gave passengers the choice of returning the same day, staying briefly on King George Island for walks or helicopter flights, or joining tour ships for cruises of the Antarctic Peninsula. Marsh Station continues to be used in this way: two other hard runways have been developed in the Peninsula area and may become available as the industry expands. However, bare-ice patches in the interior of Antarctica are also being used as runways for wheeled aircraft, making possible a much wider range of tourist flights. Adventure

Network International, for example, flies exploring parties, camera crews, and climbers, trekkers, ornithologists, and other kinds of tourists from southern Chile to the Patriot Hills, Vinson Massif (Antarctica's highest peak) in the Ellsworth Mountains, the South Pole, and other remote corners of Antarctica. Supporting both national and private expeditions, this and similar enterprises are opening virtually the whole of Antarctica to airborne tourism. The main factor limiting expansion is the high cost of safe and ecologically sound operations, currently restricting uptake to a few dozen passengers per year.

Regulation of Tourism

Tour operators and their clients whose governments are signatories to the Antarctic Treaty are responsible for their activities under the Protocol on Environmental Protection. This requires the same degrees of accountability that applies to scientists, support staff, and all other visitors to Antarctica. In the absence of any form of policing or ranger control, more stringent regulations would not at present be practicable. Fortunately most operators find it advantageous to join IAATO and subscribe to its precepts, so the industry remains effectively, and on the whole benignly, self regulating. In addition, the Antarctic Treaty Consultative Parties are now taking a more direct interventionist role with the development of site guidelines to provide agreed-upon control mechanisms for the most visited sites.

The first half-century of Antarctic tourism has provided little evidence of environmental damage, and far fewer permanent changes to the environment than have been effected by scientific research or politically motivated activities. There would therefore be little to justify more rigorous controls. However, the industry continues to grow, entirely in response to market demands, with no controlling authority licensed, financed, or willing to impose restrictions should they later be judged necessary.

TRANSANTARCTIC MOUNTAINS, GEOLOGY OF

The Transantarctic Mountains (TAM) are one of the earth's great mountain belts. They extend over 3500 km from the Oates Coast and northern Victoria Land areas of the Australia–New Zealand sector, to the Pensacola and Shackleton ranges along the eastern Ronne Ice Shelf. Although geographically separate, Paleozoic and Mesozoic rocks in the Ellsworth Mountains correlate with TAM geology. Physiographically they represent a major divide between East and West Antarctica, rising to elevations of more than 4000 m (>14,000 feet) directly from sea level along the Ross Sea coastline. Vinson Massif in the Ellsworth Mountains is the highest point in Antarctica (5140 m). Antarctica today is largely surrounded by passive margins and spreading centers, but the TAM represent a significant intraplate mountain belt with a long history of events marking the tectonic evolution of West and East Antarctica. To the east, the TAM are flanked by igneous and metamorphic rocks of the Precambrian East Antarctic craton, although these rocks are mostly ice covered and known from scattered coastal outcrops and geophysical surveys. Westward, along the margin of the Ross Sea and in Marie Byrd Land, the TAM are bounded by heterogeneous crust of West Antarctica, composed primarily of Paleozoic and Mesozoic sedimentary and igneous rocks, as well as Cenozoic volcanics. Present-day topographic expression in the TAM is related to geologically recent extension along the Ross Sea margin, yet rocks exposed in the range reflect a protracted history of continental rifting, mountain building, and renewed crustal extension between late Precambrian and Mesozoic time.

Sailing expeditions crossing from the southern Pacific Ocean first sighted high peaks of the TAM in the mid-nineteenth century, and the region was named Victoria Land by the British Antarctic (*Erebus* and *Terror*) expedition (1839–1843) under James Clark Ross. A later British expedition (1898–1900) led by Carsten E. Borchgrevink made landings between northern Victoria Land and Ross Island, sampling volcanic rocks in the region.

The first geological studies to penetrate inland in the TAM were carried out by members of early polar

The Transantarctic Mountains.

exploring expeditions. Members of the British National Antarctic Expedition were the first to find their way through the TAM and onto the Polar Plateau. Then historically significant overland traverses were made into Victoria Land and onto the Polar Plateau by Ernest Shackleton's British Antarctic *(Nimrod)* Expedition and Douglas Mawson's Australasian Antarctic Expedition, which helped determine the position of the South Geomagnetic Pole. On their fateful return from the South Pole in early 1912, Scott's polar party collected rock specimens along Beardmore Glacier, as had Shackleton's 3 years before.

Geologists accompanying US and Australian expeditions in the 1920s and 1930s did periodic reconnaissance. Comprehensive surveying, geological mapping, and study of rock exposures began in earnest with activities of the International Geophysical Year, begun in 1957. Active geological research in the TAM today is sponsored primarily by the national programs of Germany, Italy, New Zealand, the United Kingdom, and the United States.

No mineral deposits of economic value are known in the TAM. Large volumes of early Paleozoic and Jurassic igneous rocks underlie the mountain belt, including granites of continental-margin volcanic-arc affinity and gabbros found in mafic layered intrusions. Similar occurrences of igneous rocks host important economic mineral deposits in other parts of the world (for example, copper and platinum-group elements), but no indications of such mineralization are known here. Thin coal seams in Gondwana strata of the Beacon Supergroup are of low rank, making them of greater interest for paleoclimate reconstructions than as a potential economic mineral resource.

The TAM sit astride the western limit of Precambrian crustal rocks representing the East Antarctic craton. This is one of Earth's oldest continental assemblies, dating to nearly 4 billion years ago, and shows evidence of tectonic reactivation during mountain-building events about 1 billion and 600–500 Ma. Nearly the entire shield is covered by the modern East Antarctic ice sheet, so knowledge about its age and composition comes primarily from scattered coastal exposures. Presence of Precambrian basement underlying the TAM comes from rare exposures within the mountain belt and geophysical imaging of rocks beneath the adjacent polar ice cap.

Exposures of Archean and Proterozoic basement in the TAM are restricted to the Nimrod Group, mapped in the central region of the mountain belt. Despite the effects of younger metamorphism and deformation during the Ross Orogeny, these high-grade metamorphic and igneous rocks record a rich Precambrian geologic history of the East Antarctic craton that spans 2.5 billion years of Archean to early Paleozoic time. Recognized events include primary Archean magmatism from 3150–3000 Ma, crustal stabilization and metamorphism from 2955–2900 Ma, partial melting at about 2500 Ma, deep-crustal metamorphism and magmatism from 1730–1700 Ma (Nimrod Orogeny), and basement reactivation involving high-grade metamorphism, magmatism, and penetrative deformation during the Ross Orogeny from 540–515 Ma.

The presence of Precambrian cratonic basement along the eastern side of the TAM, where such rocks are not exposed, is revealed by geophysical methods that image through the ice cover. Gravity and magnetic data, for example, show that thick continental lithosphere beneath the ice cap traces the western limit of the modern TAM. East Antarctic lithosphere is thought to be a key part of the late Precambrian supercontinent of Rodinia, which formed by collision and amalgamation of several large continental cratons about 1 billion years ago (Grenville Orogeny). Beneath and to the west of the TAM, Antarctic lithosphere is thinner and younger. The coincidence of this change in lithospheric character with the TAM suggests that the modern mountain belt overlies an ancient continental rift margin. Geological, stratigraphic, and geochronological data from rare outcrops indicate that rifting occurred from about 750–680 Ma, separating what became East Antarctica to the east from a conjugate continental plate to the west. Some workers interpret paleogeographic and paleomagnetic data to indicate that East Antarctica rifted from present-day North America, but this interpretation is controversial. Although the identity of the conjugate margin to East Antarctica is debated, the geometry and nature of the late Precambrian rift margin in Antarctica shaped subsequent geologic events in the TAM. Between the time of rift separation and convergence associated with the Ross Orogeny, the paleo-Pacific continental margin of Antarctica was blanketed by late-Neoproterozoic clastic sediment, interlayered with minor volcanic material, culminating in deposition of thick Lower Cambrian reef carbonates deposited on a mature continental platform during a period of global sea-level rise. Marine fauna in the carbonates suggest that East Antarctica resided in a low-latitude position and was geographically linked with other extant continents.

The western rift margin of East Antarctica coincided with the breakup of Rodinia, but formation of the Gondwana supercontinent transformed the TAM margin of Antarctica to an active convergent boundary. Subduction along this margin of Antarctica occurred in response to closure of the ancient Mozambique Ocean and collision within the East African Orogen beginning about 600–500 Ma (also known generally as the Pan-African Orogeny). The resulting Ross Orogeny in Antarctica refers to the period of latest Proterozoic and early Paleozoic tectonic activity related to continental-margin subduction like that occurring in the modern Andes Mountains. Initial deformation linked to Ross activity is preserved in deep-seated crystalline basement as well as in the older rift-margin deposits and can be traced to about 540 Ma. Some orogenic sedimentary deposits contain igneous detritus of similar age, suggesting erosion of a huge continental-margin batholith belt that is a central signature of Ross activity. The breadth and character of deformation, metamorphism, magmatism, and orogenic sedimentation suggest that the Ross Orogen was similar in scale to other large mountain belts, and it is well-exposed today as basement to the modern TAM. Orogenic features related to Ross shortening and magmatism can be traced from the Ellsworth and Pensacola Mountains to the Queen Maud and Queen Elizabeth mountains, then northward along the main spine of the TAM to Victoria Land; correlative tectonic features are found in the Delamerian Orogen in Australia.

The principal characteristics of the Ross Orogen are regional contractional deformation, emplacement of widespread granitoid magmas, and variable metamorphism of both high-temperature and high-pressure types. In detail, deformation was partitioned into both orogen-normal and orogen-parallel displacements, suggesting that convergence was oblique. The vast scale of magmatism forming the Ross batholith belt, including early alkaline compositions and main-phase calc-alkaline rocks, is most certainly a product of convergent-margin magmatism. As such, the calc-alkaline Ross-age igneous rocks represent significant primary magmatic additions to the Antarctic lithosphere. Evidence for eastward subduction of paleo-Pacific oceanic lithosphere beneath cratonic East Antarctica comes primarily from geochemical and isotopic variations in granitoid magmas, which show an eastward increase in continental signature. Ross-age igneous rocks span at least 80 million years during the orogenic cycle and include intrusions that predate deformation, are synchronous with it, or cut across deformation features. They intrude older metamorphic roots of the orogen, as well as young orogenic deposits. Ross metamorphism is highly variable in character, and includes high-temperature magmatic-arc metamorphism, high-pressure metamorphism due to crustal thickening and oceanic-arc collision, and low-grade metamorphism associated with seaward growth by plate-margin accretion. Regional metamorphism in pre-Ross sedimentary assemblages is typically of medium grade, but high-temperature rocks and migmatites that formed by local partial melting occur in the Miller Range (Nimrod Group) and Mountaineer Range (Wilson Group); eclogites, rocks formed at very high pressures, in northern Victoria Land attest to profound crustal thickening during Ross convergence. Thick accumulation of orogenic clastic sediments (mainly deposited in forearc basins in northern Victoria Land, the central TAM, and the Pensacola Mountains) reflect significant erosion within the mountain belt, consistent with thermochronologic evidence of rapid late-orogenic denudation.

Ross Orogen tectonic activity diminished through the Ordovician period (in most areas by about 480 Ma) and this region of Antarctica became tectonically quiet by the Early Devonian. Prolonged denudation reduced the Ross mountain belt to a continent-wide flat erosional surface, called the Kukri peneplain. This surface is well exposed in many places as an unconformity boundary separating basement rocks below from sedimentary and volcanic successions of the Beacon Supergroup above. It is an easily identifiable marker used to determine the magnitude of younger differential uplift. Some 2.5–3.0 kilometers of terrestrial sediment, mostly clastic sequences of quartz-rich fluvial conglomerate, sandstone, and mudstone, were deposited between Devonian and Triassic time (over 150 million years). This well-known upper Paleozoic and lower Mesozoic Gondwana sequence includes Devonian to Carboniferous shallow-marine and nonmarine clastics; Upper Carboniferous to Lower Permian glacial and glacial-marine rocks; Lower Permian marine, deltaic, fluvial, and lacustrine rocks; Upper Permian fluvial, lacustrine, and deltaic coal measures; and a thick succession of Triassic fluvial rocks. Correlative successions extend from South America to Australia, Africa, and India, suggesting a broad network of terrestrial basins.

Beacon strata contain rich plant, invertebrate, vertebrate, and trace fossil assemblages critical for paleogeographic and paleoenvironmental reconstructions marking the end of major glaciations on the Pangea supercontinent. These include Permian and early Triassic fluvial and lacustrine deposits containing extensive *Glossopteris* leaf-litter beds, petrified forests, and fossil crayfish and burrows, indicating a near-polar terrestrial environment. By Triassic time, Antarctica had drifted northward to lower paleolatitudes along with its African and Australian craton neighbors. Deposits of this age contain tetrapod fossils of *Lystrosaurus*- and *Cynognathus*-type reptiles and amphibians, and anatomically well-preserved fossil plants and pollens, some as silicified remnants in petrified forests. Antarctica reached its most northerly paleolatitude position at the end of Pangea time, and the uppermost Beacon deposits of the TAM contain recently discovered Jurassic vertebrates, both dinosaur and pterosaur faunas, suggesting a moderate-climate terrestrial ecosystem. Thus, the Gondwana sequence of the TAM records a progressive terrestrial climate shift from glacial conditions to subpolar, wet–temperate, and arid conditions.

Much of the present physiographic expression of the TAM can be traced to its Mesozoic history during early fragmentation of the Gondwana supercontinent, which resulted in continental rifting and separation of the Antarctic lithosphere from parts of present-day South America and Africa. In the TAM, the large-scale plate movements led to widespread Jurassic igneous activity and extensional deformation generally perpendicular to the modern trend of the mountain belt. Magmas collectively referred to the Ferrar Magmatic Province erupted as basaltic flows onto both wet and dry Beacon landscape surfaces and they were emplaced as individual subsurface intrusions. One of the most prominent of these, the Dufek intrusion, is similar to other mafic-layered intrusions worldwide except for a lack of known economic mineral occurrences. In many areas, Ferrar magmas were injected within Beacon strata as a swarm of laterally extensive sheet-like sills, enhanced in cliff exposures by glacial erosion. Geochronology shows that the Ferrar sills were emplaced over a geologically brief period about 175–180 Ma, yet they can be traced the entire length of the TAM. Individual sheets may be hundreds of meters thick and can be traced for tens and hundreds of kilometers. The Ferrar Magmatic Province extends over 3000 km along nearly the full length of the TAM and is contemporaneous with similar rocks in Australia, South America, and southern Africa. Ferrar magmas are thought to result from high-temperature melting of a mantle source, overlying mantle plumes or associated with back-arc spreading.

Jurassic magmatism was accompanied by crustal extension, which displaced some basement rocks westward toward Marie Byrd Land and contributed to differential uplift within the present-day intraplate mountain belt. Mesozoic extension is expressed mainly by distributed, relatively small-offset fault arrays, and did not result in complete rifting of Antarctica along its paleo-Pacific margin. The amount and timing of Mesozoic extension is poorly known, but appears to be of similar magnitude to the Basin and Range province of North America.

Extension continued episodically from Cretaceous into Cenozoic time, leading to crustal thinning and widening of the Ross Sea basin and movement along steep, orogen-parallel normal faults within the TAM.

With few exceptions, major range-front faults are covered by the Ross Ice Shelf at the base of the mountains, but they are inferred to mark the sharp geomorphic break. Mapped faults define an asymmetric pattern formed mainly by down-to-the-west normal faults. Displacement on individual structures defining this rift-shoulder extensional system is up to several hundred meters, with cumulative vertical displacement of 5 km. Uplift attributed to this displacement started by about 120 Ma, but a major period of extension beginning about 55 Ma produced as much as 4 km of denudation over just the past 30 million years (since Oligocene time). Cenozoic volcanism in the eastern Ross Sea region is thought to be an expression of this extensional setting. Contrasting geologic units along the edges of modern large outlet glaciers suggests that extension was accommodated by transverse structures reactivated along earlier rift-phase and Ross-orogen features. Geodetic data indicate that neotectonic uplift continues and active alkaline volcanism in the McMurdo area is attributed to residual intraplate extension between East and West Antarctica.

Cenozoic volcanism along the western and southwestern Ross Sea margin of the TAM is marked by Oligocene and younger alkali basalt centers, the largest of which is Mount Erebus. Volcanism of the McMurdo Volcanic Group began about 25 Ma, but many of the volcanoes in the region are Pliocene to recent age and now dormant. Mount Erebus (about 3800 m) on Ross Island is the world's southernmost historically active volcano. Its summit contains an active lava lake, contained within a composite caldera structure. Volcanic activity has been continuous since 1972, producing strombolian eruption of cinders and volcanic bombs on the crater rim.

The modern TAM form a nearly continuous ice barrier between East and West Antarctica. Ice flows generally away from the mountain belt, except where high-standing ice of the East Antarctic ice sheet drains through individual outlet glaciers into the Ross Sea. Katabatic-type polar winds ablate relatively stagnant ice dammed against the mountain buttress, leaving behind a lag of rocky debris, including numerous meteorites. Modern and recent climate patterns are controlled in part by the balance of ice present in the major ice sheets to either side of the mountain belt. Although the modern alpine features of the TAM reflect ongoing glacial erosion, some parts of the belt, particularly in the Dry Valleys of Victoria Land, contain glacial deposits and landscape surfaces that suggest polar desert conditions extending back at least 17 million years. Present research is directed to the question of whether the East Antarctic ice sheet has existed continuously at the edge of the TAM since Miocene time, or whether glaciation was episodic.

U

UKRAINE: ANTARCTIC PROGRAM

The State Program of Ukrainian Research in Antarctica for 2002–2010 is the integrated program that defines the strategy of Ukrainian activity in Antarctica. The main tasks of the program are fundamental and applied scientific Antarctic research in the field of global climate change, space weather, and ecosystem monitoring. The program's budget for science and infrastructure since 2000 equals US$1.3 million.

The Ukrainian Antarctic Center (UAC) provides research in Antarctica within the Ukraine Ministry of Education and Science as national operator. The UAC staff consists of fifty people. The scientific division includes the groups of scientific support, informational support, and the Antarctic Treaty supervising, publicity, and publishing section. The logistics division involves the groups of logistical procurement, technical services, communications, and personnel training. The network of UAC includes five scientific laboratories in conjunction with institutes of the National Academy of Sciences and universities

The Ukraine acceded to the Antarctic Treaty on September 1992, and in 1994 became a member of CCAMLR and an associate member of SCAR. In 2001 Ukraine adhered to the Protocol on Environmental Protection to the Antarctic Treaty. In May 2004 Ukraine became the twenty-eighth Consultative Party in the Antarctic Treaty System.

On 6 February 1996 the British Antarctic base Faraday was transferred to Ukraine and renamed Vernadsky station (65°15′ S, 64°16′ W). This event started Ukrainian Antarctic research as an independent state. At Vernadsky station, Ukrainian scientists carry out research in upper-atmosphere physics and geomagnetic field, total ozone observations, tide measurements, meteorology and climate, biology, glaciology, human biology and medicine, and ecology. The surface meteorology and hydrology observations, total ozone and tide measurements, ionosphere soundings, geomagnetic field registration, UV-B observation, electromagnetic signals observations in VLF, ELF, and HF bands (whistlers, Schumann and Alfven resonances, geomagnetic micropulsations, traveling ionosphere disturbances), and seismic–acoustic measurements are carried on year round to study the energy transfer processes from the Earth's surface to geospace. The geomagnetic data from Vernadsky have been sent to the INTERMAGNET network. The total ozone measurements are provided to study the ozone hole and atmospheric planetary wave dynamics. Mass-balance and glacier displacement in the Antarctic Peninsula region is the glaciology topic. In biology the research and monitoring of marine mammal and bird population conditions and the genetic structure of the krill population is carried out. The geophysical monitoring of West Antarctica to study deep processes in the lithosphere, its influence on the environment, and construction of the evolution of the geodynamic model of region is studied. In ecology the waste management and radioactive contamination-reducing processes in the human organism during winter are studied.

In logistics, R/V *Ernst Krenkel* was used for Vernadsky supply operation and scientific activity in 1997–1999, and R/V *Gorizont* sailed as the supply ship in 2000–2002. The Vernadsky supply scheme—air flight to Ushuaia and a ship charter across the Drake Passage—has been used since 2002. In 1997–2002 the UAC Bulletin was edited as a scientific journal in which the Ukrainian Antarctic research results are published. In 2003 the Bulletin was transferred to the multidisciplinary Ukrainian Antarctic Journal.

ULF PULSATIONS

During magnetic storms the geomagnetic field is greatly disturbed, and consequently at polar latitudes a compass needle can wander on a time scale of seconds to an hour or longer, for example during auroral substorms. Intense work during the International Geophysical Year in 1957–1958 established that small, periodic oscillations of the geomagnetic field occur virtually at all times and across the globe. These variations are called geomagnetic pulsations, and their occurrence and amplitude peak at high latitudes. In records from magnetometers, the pulsations are generally of two types. Regular, sinusoidal oscillations with periods between about 0.1 and 1000 sec are called continuous pulsations (Pc), and usually occur during local daytime. They last for minutes to hours and have amplitude typically around 1 nanoTesla (nT) for 30-sec pulsations, but they are much smaller at shorter periods (for comparison, the main background geomagnetic field has an intensity of 50,000–60,000 nT). At local night the pulsations usually have a more irregular, transient appearance (called Pi) and are associated with auroras and radio noise.

Geomagnetic pulsations have been extensively studied using arrays of high-precision magnetometers, using radars that reflect high-frequency radio signals from auroral features, and using magnetic and electric field measurements from spacecraft. It is now known that geomagnetic pulsations are the signature of ultra-low-frequency (ULF—frequency in the range of 1 mHz–10 Hz) waves that propagate through the magnetosphere of the Earth. These ULF waves result from the interaction of the solar wind with the geomagnetic field. The existence of such waves was first predicted in the theory of magnetohydrodynamics (MHD), developed by Hannes Alfvén, who was awarded the 1970 Nobel prize for this work. MHD describes electrically conducting gases in a magnetic field, such as the environment of the solar wind and the magnetosphere. These hydromagnetic waves propagate at what is called the Alfvén speed, which in the magnetosphere is around 1000–2000 km/sec. Thus ULF waves may travel through the entire magnetosphere to the earth in around 1 min.

There is strong evidence that ULF waves enter the magnetosphere from the upstream solar wind and are also generated at the magnetopause boundary when it undergoes rapid deformation under the action of the solar wind. The waves typically have dimensions comparable to the size of the entire magnetosphere, and may therefore establish oscillations along the geomagnetic field lines that map from the earth's surface into space like field lines from a bar magnet. Some waves are also generated locally within the magnetosphere, by gaining energy from charged particles orbiting the earth in the radiation belts. Finally, irregular ULF waves are associated with the transient magnetic fields generated by precipitating energetic particles responsible for auroras.

ULF waves carry energy from the solar wind throughout the magnetosphere but can also be used to monitor processes in space. This includes space weather effects that can, for example, degrade the performance of radio communications, surveillance radars, and satellites. Space telescope images show that auroras occur on Jupiter and Saturn, and spacecraft have recorded ULF waves in the magnetospheres of those planets.

UNITED KINGDOM: ANTARCTIC PROGRAM

Britain has a rich history of involvement in Antarctic affairs, which has shaped and set the context for how the programme is currently structured. The Scott Polar Research Institute (SPRI) was established, by public subscription, in 1920 within Cambridge University as a memorial to Captain Robert Falcon Scott and his four companions, who perished on their way back from the South Pole in 1912. It is now part of the Department of Geography of the University. The British Antarctic Survey (BAS), also located in Cambridge, developed from a secret military operation during World War II and is now a wholly owned component body of the UK Natural Environment Research Council (NERC). The Polar Regions Unit (PRU) of the UK Foreign and Commonwealth Office (FCO) has its roots in the British claim to Antarctic territory (the Falkland Islands Dependencies [FID]) lodged by Letters Patent in 1908, and more directly from the appointment of Dr. Brian Roberts (ex-British Graham Land Expedition) by the FCO in 1944 to deal with polar political problems and plan policy for the FID. The unit has been in existence in one form or another continuously since then. The Royal Navy has also had a long association with Antarctic affairs, extending back to the early explorations of James Cook and James Clark Ross, but in more modern times (since the Second World War) through the provision of an "Ice Patrol Vessel," currently HMS *Endurance,* which deploys annually to the South Atlantic.

The PRU is responsible for UK policymaking and representation in Antarctic matters in the international political arena. The PRU takes the lead at meetings of the Antarctic Treaty System (ATS), at the Council for Conservation of Antarctic Marine Living Resources (CCAMLR), and at the other subsidiary conventions of the ATS. It also represents UK interests at political fora concerned with Arctic affairs.

BAS provides the physical UK presence in Antarctica on behalf of the UK government. BAS has a dual mission: to undertake a world-class programme of science, and to sustain for the UK an active and influential presence and a leadership role in Antarctic affairs. BAS is funded from money provided by the British government for basic science that is channelled through the UK Research Councils. Since the funding is via this route the BAS science programme is not directly determined by government, and nowadays is set through a process of stakeholder and public consultation in the context of the broad strategic research aims of NERC, and subject to rigorous international peer review. The core programme is planned and resourced on a 5-year cycle between reviews. The BAS philosophy is to conduct research on global questions of concern to humankind using the opportunities offered to study the Earth system in the Antarctic setting. BAS also puts emphasis on maintaining key long-term observations of the environment and in continuing a programme of survey. It is enthusiastic about collaboration and maintains a strong programme of public engagement and outreach.

Although BAS is within a research council, its dual mission has meant that it is not possible for its strategy to be decoupled from the primary interests of government. Thus the long-term strategic planning for BAS is dealt with by an interdepartmental group that has representation from the FCO, Treasury, the Office of Science & Technology (of the Department of Trade & Industry), NERC, and BAS.

BAS is an integrated operation providing both the logistics and the scientific effort from within its own staff and resources, which makes it distinctly different from most other national operators. BAS operates two major year-round research facilities in Antarctica, at Rothera Point on Adelaide Island (Rothera Station) and on the Brunt Ice Shelf in the southern Weddell Sea (Halley Station). In addition, two smaller year-round research stations are maintained on the sub-Antarctic Island of South Georgia (at King Edward Point and on Bird Island), and a summer-only station is operated on Signy Island (South Orkney Islands). The BAS has two ice-capable vessels: the Royal Research Ships *Ernest Shackleton* and *James Clark Ross*. The former is primarily for logistical support whilst the latter provides a very sophisticated ocean research platform. BAS operates a fleet of four DHC-6 ski-wheel Twin Otter aircraft within the Antarctic and one DHC-7 (wheels only) aircraft whose primary role is to provide an intercontinental link between the Falkland Islands and Rothera Station. BAS provides expert advice to PRU for ATS and CCAMLR matters and is responsible for representation at the Council of Managers of National Antarctic Programmes (COMNAP). For 2005, the overall budget of BAS was circa £40M and the staff was circa 475 people.

The Royal Navy vessel HMS *Endurance* provides direct logistical support to BAS operations, primarily through the provision of her two helicopters. She is also engaged in a long-term programme of hydrographic survey around the Antarctic Peninsula, adjacent islands, and South Georgia.

Although most of the funding for research is channelled through BAS, the NERC also operates a responsive mode competitive scheme, known as the "Antarctic Funding Initiative," which provides funds for UK academics (and BAS staff) for Antarctic research using the BAS logistical capability.

SPRI does not have an in-house logistical capability, but has a broad portfolio of research in both the Antarctic and Arctic, and carries out postgraduate teaching in polar matters. It is also the home of one of the finest polar libraries in the world (the Shackleton Memorial Library), the Thomas H. Manning Polar Archives, and a comprehensive collection of polar maps. The secretariat for the Scientific Committee for Antarctic Research (SCAR) is based at SPRI, as are the World Data Centre for Glaciology and the International Glaciological Society. In addition, there is a museum of polar artefacts that is open to the public. There are also several other significant university groups in the UK carrying out research in, on, or related to Antarctica.

The Royal Society is the British national academy for science. It has taken an interest in Antarctic research since it sponsored the expedition that established the first Halley station in 1956 as part of the UK contribution to the International Geophysical Year. This interest continues through the its National Committee for Antarctic Research, the forum for coordinating the UK involvement in SCAR comprising leading scientists from BAS, SPRI, and the broader UK academic community.

UNITED NATIONS

In 2005, the sixtieth anniversary of the United Nations (UN) marked the organisation's enduring, frequently significant role in international affairs. For many, the UN represents the obvious mechanism for resolving, or at least managing, international problems. Unsurprisingly, Antarctica, a region characterised by uncertain, indeed disputed, ownership and a perceived conflict potential, has often been presented as a prime case for UN treatment, especially given concerns about economic exploitation and conservation alongside a growing awareness of the continent's integral role in global environmental systems. However, in practice, the UN has proven to be, and remains still, only a marginal player in Antarctic affairs. Instead, individual governments, acting both individually (e.g., through national scientific research programmes) and collectively through the Antarctic Treaty System (ATS), have performed the principal roles.

Despite occasional calls after 1945 for UN intervention, the governments active in Antarctica preferred a more direct approach, culminating in the 1959 Antarctic Treaty. Thenceforth, the region has been managed by the Antarctic Treaty parties (ATPs), working through the ATS. Nevertheless, in 1983, the Malaysian government and its supporters, guided by environmental NGOs, placed the "Question of Antarctica" formally on the UN's agenda. They argued the case for treating Antarctica, like the deep seabed, as the common heritage of humankind managed by a UN-based body in place of what was presented as the unaccountable, undemocratic, and nontransparent ATS. The participation of the apartheid South African government in the ATS was a further target for attack. By contrast, the ATPs asserted that Antarctica was managed by a valid, successful, and comprehensive regime open to accession by any UN member.

Sharp divisions between ATPs and their critics meant that the UN's initial consensus approach soon broke down in 1985. Restored in 1994, a consensus approach prevails still today. ATPs and non-ATPs, albeit still agreeing to differ about how to manage Antarctica, accept the need to work for change within the ATS framework. The UN remains seized of the "Question of Antarctica," but the critical campaign has lost much of its momentum. Thus, the topic is now placed on the UN agenda upon only a triennial basis—the last reference was in late 2005—and there is even growing speculation about Malaysian accession to the Antarctic Treaty.

Although the UN's post-1983 involvement in Antarctica has often been dismissed as somewhat ritualistic, the episode has encouraged a more informed appreciation upon the part of the broader international community of the nature and significance of Antarctica, the ATS, and polar science. Indeed, the UN Secretary-General's reports, produced to guide each UN session on Antarctica, offer a useful up-to-date reference source. At the same time, the UN-based challenge, though treated by ATPs as a low priority, has fostered a greater sense of purpose and unity between them alongside an awareness of the need to do more by way of selling the ATS's merits to a wider audience and the prudence of involving the UN's specialised agencies, like the United Nations Environment Programme (UNEP), in its work.

UNITED NATIONS CONVENTION ON THE LAW OF THE SEA (UNCLOS)

The United Nations Convention on the Law of the Sea was negotiated at the Third UN Conference on the Law of the Sea (UNCLOS III), held from 1973 to 1982. The convention was opened for signature at Montego Bay, Jamaica on 10 December 1982. On that day it attracted 119 signatures, yet it took 12 years—until 16 November 1994—for the convention to enter into force. In following years the convention secured an almost universal participation: to date (1 June 2006) there are 149 parties to the convention. This was facilitated by the adoption, on 28 July 1994, of the agreement relating to the implementation of Part XI of the Convention, on the international seabed area.

That aspect of the convention is related to the origin of the initiative for UNCLOS III and can be traced back to the 1967 UN General Assembly discussion of the concept of the common heritage of humankind and the seabed beyond the limits of national jurisdiction. However, when UNCLOS III eventually began in 1973, it started from a far broader platform: consciousness that the problems of ocean space are closely related and need to be considered as a whole.

The result was the convention, consisting of 320 articles and 9 annexes, containing both codification of customary norms and progressive development of international law. Included are rules on various maritime zones and areas: territorial sea, contiguous zone, straits used for international navigation, archipelagic waters, exclusive economic zone, continental shelf, high seas, and the international seabed area. The convention also devotes special parts to enclosed/semi-enclosed seas and the rights of land-locked states. Protection of the marine environment, scientific research, technology transfer, and settlement of disputes are all addressed. New institutions were established under the convention: the International Seabed Authority, the International Tribunal for the Law of the Sea, and the Commission on the Limits of the Continental Shelf. A meeting of states' parties to the convention has been held annually since 1994, while the UN Secretary-General has reported annually since 1984 on key law-of-the-sea developments.

Due to its features the convention is often referred to as the "Charter of the Oceans," a framework treaty that governs all major issues of the entire ocean space.

Part of that ocean space surrounds Antarctica. Here, however, the Antarctic Treaty and its related instruments also apply. Most of the current twenty-eight Antarctic Treaty consultative parties are simultaneously parties to the convention, with the exception of three states: the United States, Peru, and Ecuador. While in defining the limits of maritime zones the convention relies on the notion of a coastal state, the entire Antarctic Treaty System is built around a delicate balance of positions of sovereignty claimants and nonclaimants. There can be no doubt that the convention does apply to Antarctic waters, yet serious questions have been raised regarding various aspects of that application, including the extent of the high seas, the proclamation of coastal zones, the application of Part XI, and, more recently, the continental shelf beyond 200 nautical miles.

UNITED NATIONS ENVIRONMENTAL PROGRAMME (UNEP)

UNEP was established in 1972 to provide leadership and encourage partnership in caring for the environment by inspiring, informing, and enabling nations and peoples to improve their quality of life without compromising that of future generations.

UNEP's involvement in Antarctica and the Southern Ocean stems from the critical role they play in the global environmental system. Major processes of interaction between the atmosphere, oceans, ice, and biota affect the entire global system through feedbacks, biogeochemical cycles, circulation patterns, transport of energy and pollutants, and changes in ice mass balance. In addition, the region is of immense value for the conduct of research essential to understanding the global environment.

Through its various programmes, UNEP addresses assessment, management, and policy aspects of global and regional environmental issues, many of which are relevant to Antarctica and the Southern Ocean.

UNEP has closely linked global programmes on the conservation, management, and monitoring of the marine environment and its living resources. These programmes include the Global Plan of Action for the Conservation, Management and Utilization of Marine Mammals; the Global Programme of Action for the Protection of the Marine Environment from Land-Based Activities; and the Regional Seas Programme. Major periodic coordination meetings are organized among the regional seas to share experiences, to which the Convention for the Conservation of Antarctic Marine Living Resources is also invited.

The assessment programme of UNEP has responsibility for keeping under review the state of the environment. UNEP launched the fourth volume of the *Global Environment Outlook* series in 2004, where specific chapters are dedicated to the poles.

UNEP administers the secretariats of various global conventions dealing with subjects directly relevant to Antarctica and the Southern Ocean. They include the Vienna Convention for the Protection of the Ozone Layer and its Montreal Protocol on Substances that Deplete the Ozone Layer; the Stockholm Convention on Persistent Organic Pollutants; the Convention on Biological Diversity; the Convention on International Trade in Endangered Species of Wild Fauna and Flora; and the Convention on the Conservation of Migratory Species of Wild Animals, under which the recent Agreement on the Conservation of Albatrosses and Petrels was negotiated.

UNEP has the responsibility of preparing the report of the United Nations Secretary-General on the Question of Antarctica, which is submitted every 3 years to the General Assembly of the United Nations. To this end, UNEP is invited to attend the Antarctic Treaty Consultative Meetings as an expert organization. UNEP contributes to these meetings by the submission of technical papers that cover a range of issues including the practice of inspections, bioprospecting, and the status of conservation of Antarctic mammals and birds.

UNEP's involvement in polar areas requires policy guidance and coordinated inputs from UNEP substantive units, including UNEP's Key Polar Centre, GRID-Arendal in Norway. To this end, a Polar Task Force has been established that convenes on an *ad hoc* basis to discuss and decide upon policy issues and to a lesser degree on operational matters in the poles.

UNITED STATES: ANTARCTIC PROGRAM

The United States Antarctic Program is the principal expression of US interest in Antarctica and the Southern Ocean. Its purpose, as a presidential memorandum states, is to maintain an active and influential national presence responsive to US scientific, economic, and political objectives; the presence is stated to include science in major disciplines and year-round occupation of the South Pole and two coastal stations. A later presidential directive states that fundamental aims in the Antarctic are to protect the environment, preserve research opportunities, maintain the peace, and conserve marine living resources. The US Congress authorizes public funding for the program in response to annual requests made by the President.

The program helps the United States fulfill obligations under the Antarctic Treaty, to which the nation is signatory. Other international affiliations include the Council of Managers of National Antarctic Programs and the Scientific Committee on Antarctic Research.

The National Science Foundation (NSF), an agency of the US Government, manages the US Antarctic Program. Using the funds that the Congress has appropriated, it finances nearly all US research and operational support conducted in the Antarctic. Spending in fiscal 2004 was US \$265.56 million. Of this total, \$45.20 million was for research grants, \$152.29 million was for operations and science support, and \$68.07 million was for logistics. These annual levels are typical. The Congress occasionally allocates additional funds to the NSF for special projects such as the rebuilding of Amundsen-Scott South Pole Station.

The NSF is not an Antarctic institute and does not perform research. Scientists employed by universities and other institutions throughout the nation perform these functions, having submitted proposals to the NSF to do so. A major contractor to the NSF provides operational support in the Antarctic, and other contractors provide specialized services such as helicopter operations. The US military provides logistics including intercontinental airlift, sealift, icebreaking, operational weather forecasting, and LC-130 ski airplane operations.

While the United States has no central Antarctic institute, the NSF does fund specialized Antarctic facilities around the nation including an ice core laboratory, a marine geology research facility and core library, the Antarctic meteorite collection, a polar rock repository, and a center for maps, aerial photographs, and place names.

The NSF's web site (www.nsf.gov) provides information about the Antarctic program, and it lists and describes each research award. Regarding accomplishments, an NSF-funded organization compiles an online directory of data sources resulting from the NSF's Antarctic grants. Publication of Antarctic research results is the responsibility of grantees and occurs mainly in the standard refereed scientific literature. The NSF-funded online *Antarctic Bibliography,* which abstracts and indexes all the world's Antarctic research literature, contains grant numbers of listed publications that resulted from NSF support.

Early US Expeditions

US sealers were in the South Shetland Islands as early as 1819. The sealer Nathaniel B. Palmer, who worked in the Antarctic Peninsula area in 1820 and after whom Palmer Land is named, was one of the first to record a sighting of the Antarctic.

The first US scientist to work in the Antarctic was James Eights, who was naturalist aboard the United States Exploring Expedition of 1830, a voyage that the US Congress commissioned. Eights described some of the region's biota and studied the geology of sub-Antarctic islands, where he discovered fossil plants. The six Antarctic papers he published influenced the work of other naturalists, including Charles Darwin.

The United States Exploring Expedition, led by Lt. Charles Wilkes, US Navy, in 1839–1840, mapped 2500 km of the Antarctic coast south of Australia and proved thereby that Antarctica is a continent.

Richard E. Byrd's hugely popular expeditions in 1928–1930 and 1933–1935 investigated West Antarctica from a wintering station on the Ross Ice Shelf and included, in 1929, the first flight to the geographic South Pole. In the late 1930s, the US Government established the US Antarctic Service Expedition, intended to be permanent but stopped in 1941 because of World War II.

The 1946–1947 US Navy Antarctic Developments Project remains the largest Antarctic expedition, with 4700 personnel, 13 ships, and several aircraft; it made 15,000 mapping photographs. The US Navy Second Antarctic Developments Project and the privately financed Ronne Antarctic Research Expedition occurred the next season. These three expeditions yielded the region's first medium-scale maps and influenced placement of research stations for the 1957–1958 International Geophysical Year (IGY).

During planning for the IGY, the United States agreed to establish a research facility at the geographic South Pole. In December 1955 it began setting up Naval Air Facility McMurdo Sound on Ross Island as a seaport and base from which to fly supplies to the Pole. Amundsen-Scott South Pole and McMurdo stations have operated continuously, year round, since then. Five other US Antarctic stations built for the 18-month IGY are no longer used.

In 1959, the nation established its modern United States Antarctic Program.

Research

Much US Antarctic Program research involves phenomena that are global. Stratospheric chemists at McMurdo demonstrated that man-made chlorinated fluorocarbons cause the ozone hole; this evidence helped the world community in 1987 decide to phase out these and related chemicals. Now US year-round stations monitor the ozone hole for, among other things, the anticipated reduction in size as a result of the 1987 decision. Research also provides understanding of the harmful effects on living organisms of the increased ultraviolet radiation that penetrates the Antarctic atmosphere as a result of the ozone hole.

The West Antarctic Ice Sheet, which if melted would raise sea level some 5 m, is known to have disappeared millions of years ago, and portions now are changing rapidly. Scientists are using satellite data, surface sampling, seismic sensing, and other measures to try to predict future behavior of the West Antarctic Ice Sheet.

The annually deposited layers of the thick Antarctic ice sheet contain information about earlier climate change. Russia, the United States, and France collaborated from 1989 to 1998 to retrieve and study ice core from Vostok, the Russian station in East Antarctica. The coring yielded the longest continuous annual climate record extracted from ice—420,000 years.

Fossil discoveries by US scientists contributed to Antarctica's geologic history and its former connections to other continents. They include the terrestrial *Lystrosaurus,* discovered in 1969 (the dominant taxon of a cosmopolitan fauna of low diversity that survived the great extinctions at the end of the Permian); a fossil mammal discovered in 1982 with Argentine scientists (establishing that Antarctica and South America were connected as recently as 40 Ma); and a dinosaur in 1991, proving dinosaurs lived on every continent.

Research on the impact on biota of extreme cold and extended periods of light and dark is a focus. Some cold and dry areas of the Antarctic are studied as analogies to other bodies in the solar system and to the Late Precambrian Snowball Earth.

Maps ranging from single-sheet maps of the entire continent to large-scale maps of selected areas are produced and published by the US Geological Survey. The entire continent—except some featureless areas—has been mapped at a scale of 1:500,000 or larger.

Antarctica provides a platform for looking outward from Earth; astrophysics and astronomy are major emphases of the US Antarctic Program. Observations at South Pole Station through its cold, clean, dry atmosphere provide viewing in some wavelengths equal in quality to those made from space. Telescopes measure radiation emitted when the universe was young, before stars and galaxies began to form, providing clues about how the universe evolved into its present state.

An instrument array beneath Amundsen-Scott Station uses the homogeneous, clear ice sheet (2900 m deep) as the medium for detecting neutrinos from deep space. Neutrinos carry information very different from that obtained via light telescopes and radio telescopes, and observing them opens a new window to help detect and explain the universe's so-far-undetected forms of mass and energy.

Facilities and Operations

By 1965, the program had its present suite of three year-round stations: two on the coast (McMurdo, as mentioned, and Palmer, on Anvers Island off the west coast of the Antarctic Peninsula), and the interior station on the ice plateau at the South Pole.

In summer (October–February), the approximate population of the US Antarctic Program on the continent (not including ships) rises from winter's few hundred (349 in 2005) to about 1800. The approximate number of science projects rises from 10 in winter to over 125 in summer. About 2500 people a year participate.

Air transport generally takes place only in summer, but it is extensive then, enabling rapid deployment of scientists and support personnel to and from the Antarctic via McMurdo Station, providing almost the totality of transport to and from the South Pole, and making possible the establishment each summer of research camps.

Field camps away from the year-round stations are a major part of the US Antarctic Program, numbering in the dozens over summer, with their populations nearing 200. Camps are located as science requires throughout the Antarctic and vary in size from a tent to an installed facility with heated structures and even running water. The camps usually focus on geology and geophysics, glaciology, and biology. In a typical summer, aircraft flights to support these camps number in the hundreds.

Although airplanes bring to Antarctica the scientists, some research equipment, and fresh food, ships deliver most of the cargo and all of the fuel. McMurdo receives one tanker and one cargo ship, both ice-strengthened but requiring icebreaker escort, each year.

Palmer Station on Anvers Island by the Antarctic Peninsula is serviced entirely by ship (from southern South America) without icebreaker escort. Its location slightly north of the Antarctic Circle makes it accessible by ice-capable ship at any month of the year; the population varies from forty-five in summer to as low as ten in winter. The research emphasis is marine biology.

Year-round automated data collection takes place at remote sites throughout Antarctica. In 2002, a typical year, fifty-two weather stations and six geophysical observatories operated unattended except for brief visits for maintenance.

Southern Ocean research in marine geology and geophysics, marine biology, and oceanography has been extensive since the research ship USNS *Eltanin* (length 81.1 m) surveyed the region between 1962 and 1972, covering 410,000 nautical miles in an Antarctic circumnavigation of 55 cruises.

The program's present-day deep-water research ship is the purpose-built icebreaker *Nathaniel B. Palmer* (93.9 m), which entered service in 1992. This ship supports research in all parts of the Southern Ocean, with a focus on ice-infested areas.

R/V *Laurence M. Gould* (70.2 m), ice capable, transports personnel and cargo to and from Palmer

Station and supports oceanic research mainly along the western side of the Antarctic Peninsula and in the Drake Passage.

Ships of the US academic fleet also have worked in the Southern Ocean on particular research questions. The international Ocean Drilling Program *(Joides Resolution)* and its predecessor Deep Sea Drilling Project *(Glomar Challenger)* have taken deep-sea sedimentary cores south of 60° S, providing information regarding past climates obtainable in no other way. Findings include the 1988 discovery that a much larger Antarctic ice sheet existed 35 Ma.

Icebreakers in the US military fleet have participated in US Antarctic work since the beginning of the IGY, when *Glacier* (94.4 m) helped to establish McMurdo Station. While their primary role is to break channels in sea ice and to escort supply ships, the icebreakers also support research directly.

International Cooperation

International cooperation in research and research support occurs extensively in the US Antarctic Program. At its most straightforward, a US scientist joins a non-US research team or vice versa. Russia and the United States exchanged wintering scientists throughout much of the Cold War.

Other examples of international cooperation include joint research at a US Antarctic facility and entire projects planned from the beginning to be international, such as the Cape Roberts Project (seven nations, led by New Zealand), established to investigate and better understand climatic and tectonic history.

Shared use of facilities and operations has included jointly planned aircraft missions to McMurdo with New Zealand, Italy, and others. The intention always is that, over time, the participating nations contribute effort and derive benefit in commensurate measure.

UNITED STATES ANTARCTIC SERVICE EXPEDITION (1939–1941)

Early in 1939, with war threatening around the world, President Franklin D. Roosevelt decided that the United States must, at least temporarily, abandon its historic practice of neither making nor recognizing territorial claims in the Antarctic. Roosevelt was doubtless galvanized by the presence in the far south that austral summer of a German expedition that explored by air somewhere between 135,000 and 230,000 m^2 (350,000 and 600,000 km^2) of the Antarctic continent directly south of Africa. While the German effort seems to have been little more than an attempt to validate existing whaling rights (some whale products were vital in Germany), Roosevelt clearly believed that a German presence near the Antarctic Peninsula posed a threat to the solidarity and defense of the Western Hemisphere should a second world war occur.

At the same time, famed US polar explorer Admiral Richard Byrd was contemplating a third expedition south, as were several of his colleagues from former ventures. Indeed, Finn Ronne was on the verge of purchasing a ship, and Richard Black, working within the Department of the Interior, had aroused interest there in a US-sponsored expedition even before the president made his decision. Once Roosevelt signaled his intent, the elements of what would formally be designated the United States Antarctic Service Expedition of 1939–1941 (USAS) quickly fell into place. Byrd was first contacted by Department of the Interior and State Department officials in January 1939, and the following month he went to Washington, where he met with Roosevelt to lay preliminary plans. Ronne, Black, Paul Siple, Tom Poulter, and others from Byrd's two earlier private expeditions were swiftly recruited and got to work. Through aerial and ground exploration, Roosevelt wanted to reserve and confirm for possible claim the area stretching from Byrd's earlier Little America bases in the Bay of Whales in the Ross Sea over to the Antarctic Peninsula and adjacent areas eastward along the Weddell Sea. While the President initially suggested a new Little America together with a second base somewhere south of Africa's Cape of Good Hope (adjacent to Germany's newly claimed "Neue Schwabenland"), planners soon determined that fulfilling the basic mission objective would require establishment of an "East Base" somewhere on the peninsula.

Roosevelt's desire to keep the expedition a secret for as long as possible severely hindered both funding and development. When word at last leaked out in May 1939, Congress passed an initial US $10,000 funding bill, supplemented by a further $340,000 in July. This support proved so paltry that it was agreed to make the expedition part public and part private. The initial result was to pressure Byrd into contributing all personal resources to the venture, including the polar ship *Bear*. The Admiral and "his boys" soon ran afoul of public opinion as well. Byrd's popularity had waned during the depression-ridden 1930s. He was increasingly accused of being nothing more than a glory- and publicity-seeking hound who mounted expensive adventures while millions of fellow citizens remained bound in want. Congress's decision to transform the USAS into a mixed enterprise fanned public suspicion that the Admiral was looting both the government *and* the private sector for his own advantage.

When the expedition at last scrambled away aboard two small ships (*Bear* and the modern, 3500-ton, steel-hulled Alaska supply ship *North Star*) in the late autumn of 1939, war had come to Europe and public attention had shifted there. Accustomed to being sent off in a blaze of publicity, Byrd found his departure mentioned only in a brief squib at the bottom of page 38 of *The New York Times*.

Nonetheless, the expedition got off to a fine start. Byrd and his men managed to cram a giant, wheeled "snow cruiser" on board, together with three aircraft: a large, long-range Barkley-Grow seaplane, an equally big Curtis-Wright Condor, and a small Beechcraft "satellite" plane designed to operate from the snow cruiser. A firm program of scientific research was in place as a result of several earlier meetings between the newly formed USAS Executive Committee (including Byrd and chief scientist-designate Alton Wade) and members of the National Research Council of the National Academy of Sciences. And on the eve of Byrd's departure, Roosevelt had given him detailed instructions on objectives, centering around the making of claims, either by flags dropped from aircraft or by cairns on the ground. But, Roosevelt cautioned, neither Byrd nor any member of the expedition was to make any claim public without the express authorization of the Secretary of State.

Employing his traditional route, Byrd took his two ships through the Atlantic and Panama Canal, across the Pacific to Dunedin, New Zealand, and then down to the Bay of Whales, where West Base was established under Paul Siple. Once unloaded, *North Star* went back to Valparaiso, Chile for further supplies and, in March 1940, joined *Bear* off the Antarctic Peninsula, where, after a rough several days of exploration, a suitable site for East Base was found on tiny Stonington Island in Marguerite Bay.

Byrd (and apparently Roosevelt as well) contemplated that the two USAS bases would be occupied on a rotating basis for perhaps 5 or 6 years, despite (or perhaps because of) the fact that the world was at war. Roosevelt directed Byrd himself to return after establishing the bases in order to chair the executive committee overseeing the enterprise. In the event, the men were withdrawn and the bases shut down in March 1941 at the close of the austral summer. By this time, war was looming on the American horizon; fears that the Germans might exploit Antarctica for political or military purposes had proven baseless, and Congress could find many better places to spend money. Despite the widespread activities of the USAS in the "Pacific quadrant" of the Antarctic, the United States chose never to make claims, thus negating a major reason for the expedition.

Nonetheless, the USAS accomplished a great deal of valuable science. Despite the failure of the snow cruiser to perform, Byrd and his men mapped by both air and sea the ice-bound and often foggy, cloudy Antarctic coast between the Ross Sea and the Peninsula, which had defied earlier efforts at discovery. Employing dog sleds and light tractors, five small survey, seismic, and geological reconnaissance teams from Little America supplemented and expanded Byrd's aerial reconnaissance. Moving swiftly eastward across lands claimed by New Zealand, they explored much of the unclaimed Edsel Ford and Rockefeller ranges that lay inland from the coast. At Little America itself, Siple and his men did important research into frostbite and the wind-chill factor while performing valuable mid-winter auroral observations in temperatures that reached –60°F Siple later reported that aerial exploration of the Ross Sea area had resulted "in over a thousand useable aerial photographs."

Following severe weather, East Base commander Richard Black dispatched two field survey parties in the 1940–1941 summer. One was led by Finn Ronne and Carl Eklund and the other by Paul Knowles. These explored the base of the Antarctic Peninsula and the adjacent coast along the Weddell Sea. Although Knowles and his two companions never reached "the corner" where the Antarctic Peninsula turned into the Filchner (now Ronne) Ice Shelf, they reached farther south (71°51′ S) than any exploring party to date from that area. Ronne and Eklund walked 84 days and 1200 miles (1920 km) through some of the most treacherous crevasse fields in Antarctica. In several flights, Black subsequently supplemented, confirmed, and, in the case of the far southeastern Peninsula, somewhat extended his colleagues' ground treks and observations.

In November 1941, the American Philosophical Society devoted its monthly meeting to the scientific results of the USAS. Wade and Siple were the chief speakers, and Wade confirmed that the expedition had been terminated the previous spring due to "existing and impending hostilities." The USAS never formally expired. Meetings of its executive committee chaired by Admiral Byrd continued until allocated funds ran out in May 1942. But, smothered by wartime preoccupations, it was never revived.

As with the first two Byrd expeditions, neither the USAS nor its government or private sponsors published a formal account of its scientific endeavors, although a few papers did appear during the war. Nor are there any books or articles devoted exclusively to the expedition. However, several accounts have been written within broader contexts. They are clearly based on the formal records of the expedition (including many detailed daily radio reports from the "ice") now housed in Record Group 126, "Records of the US Antarctic Service," National Archives and Records Administration, in Suitland, Maryland, together with interviews with participants.

UNITED STATES (BYRD) ANTARCTIC EXPEDITION (1928–1930)

Fresh from his aerial feats over the North Pole in 1926 and the Atlantic Ocean in 1927, Richard E. Byrd turned his attention to organizing a major expedition to Antarctica. It was to have three goals. First was for Byrd to fly over the South Pole. Second was to explore the interior of Antarctica, especially the areas near Roald Amundsen's route to the South Pole. And third was to add to the scientific knowledge of Antarctica, in geography, geology, geomagnetism, and especially meteorology.

In planning for the expedition, Amundsen, Byrd's former rival for the North Pole, played an important role. Amundsen's knowledge of the area and conditions at the Bay of Whales persuaded Byrd to build his base near where Amundsen began his journey to the South Pole. Amundsen himself recommended that Byrd buy *Sampson,* a Norwegian whaler, as his flagship; this Byrd did, renaming it *City of New York*. Finally, Amundsen encouraged Martin Ronne, who had been on the 1912 expedition, to join Byrd and contribute his experience in the Antarctic as a resource.

The expedition challenged Richard Byrd as an organizer and a publicist. Costing more than a million dollars, this was the largest and most expensive expedition that had ever been mounted to Antarctica. Byrd purchased three airplanes and two ships, including a minesweeper, *Chelsea,* renamed *Eleanor Bolling,* in addition to *City of New York*. He contracted with two other ships to transport supplies and break through the ice. Besides recruiting volunteers, Byrd paid salaries for men with special and critical skills, such as pilots.

As he had done in his quest for the North Pole, Byrd organized the expedition as his own enterprise. He used his fame—what he called "the hero business"—to draw gifts of money, supplies, and equipment. Often, he received supplies from manufacturers in exchange for endorsements. Byrd also turned to people who had supported his North Pole expedition. John D. Rockefeller Jr. and Edsel Ford gave cash. News media paid for stories. *The New York Times* assigned a reporter, Russell Owens, to travel with the expedition and write stories that would be wired home for publication. Similarly, Paramount Pictures contracted with Byrd and sent two camera men on the expedition to film and create a documentary. Byrd named his base "Little America" and one of his airplanes *Stars and Stripes* to please the American public, even though Norwegians played important roles.

The massive expedition reached the Ross Sea and entered the Bay of Whales on December 28, 1928. Days of unloading supplies and building shelters followed. At first, the expedition tried to use Ford trucks to transport supplies from the shoreline to Little America. However, the trucks proved unreliable, and the expedition resorted to dogs and sleds. Three airplanes needed unloading and assembly. One was a three-engine Ford, which Byrd named *Floyd Bennett* in honor of his pilot of the North Pole flight, who had died in 1928. Because of its three engines, this was the plane that Byrd wanted to use for the long flight over the South Pole. Another one-engine Fokker, *Virginia,* was to be a plane for rescue and exploration. The third airplane, a one-engine Fairchild, named *Stars and Stripes,* had large windows for use in aerial photography. Captain Ashley McKinley, who had written a textbook about aerial photography in World War I, had charge of the camera to photograph the terrain over which the plane flew. To fly the planes, Byrd hired pilots Bernt Balchen, Harold June, Alton Parker, and Dean Smith.

Soon after landing on the ice, men began building Little America, a small town made of prefabricated buildings buried in the snow. Apart from an administration building and bunkhouse, the complex included three radio antenna towers, a mess hall, hangers for the airplanes, storage sheds, and a machine shop that contained the first generator of electricity in Antarctica. Telephone lines connected some of the buildings.

The base sheltered forty-two men of varying temperaments, skills, and backgrounds. Besides the four pilots, there were three aircraft mechanics, three radio operators, five dog drivers, a doctor, three surveyors, a tailor, a carpenter, news media experts, a cook, and general hands. Four scientists took part in the expedition. Leading the scientists was the geologist Dr. Larry Gould, who also was appointed second-in-command. William Haines and Henry Harrison had responsibility for meteorology, while Frank T. Davies was in charge of geomagnetism. In addition, Malcolm Hanson was the expert in radio studies. For meteorological studies and weather forecasts, the expedition relied on Haines. This expedition shaped the career of young Paul Siple. He had earned a place on the expedition by winning a national contest to have a Boy Scout on the expedition. Siple would join in Byrd's later expeditions and achieve prominence as a scientist.

Already in January 1930, airplanes served as instruments for geographical discovery. On January 27, Byrd and Bernt Balchen flew over Edward VII Land and discovered a mountain chain they named in honor of John D. Rockefeller Jr. Another flight in February enabled them to reach a new land that Byrd named Marie Byrd Land. Successful flights aside, danger and misfortune lurked. In March, the expedition lost *Virginia* when a windstorm destroyed the airplane while it was parked during a geological investigation of the Queen Maud Mountains.

During the Antarctic winter of 1930, attention focused on planning Gould's geological expedition to the Queen Maud Mountains and Byrd's related flight to the South Pole. Depots of supplies for the geological expedition, marked with bright orange flags, helped in finding the route south. Gould's party could radio news of the weather to Little America and could rescue the South Pole party in an emergency. Meanwhile, the plane would drop aerial photographs of the terrain in the distance to the ground party. Not until November 1929 did weather allow *Floyd Bennett* to drop the last depot of food and airplane fuel at the foot of Mount Nansen.

On November 4, 1929, Gould and five men with dogs and sleds set out for the Queen Maud Mountains. Two weeks later, Byrd, Balchen, June, and McKinley took off from Little America in *Floyd Bennett*. Loaded with the camera, food, and fuel, the airplane struggled to climb over the Liv Glacier. Frantically, the men threw bags of food off the plane and, aided by the lightening of the load and a fortunate updraft, lifted the plane safely. On November 29, *Floyd Bennett* circled the South Pole, dropped the flag of the United States, weighted with a stone from the grave of Floyd Bennett, and then returned to the depot at Mount Nansen for refueling. Gould and his men returned to Little America on January 19 after a journey of more than 2 months and 1500 miles (2400 km).

Exploratory flights and scientific investigations continued until the expedition left Antarctica on February 9, 1930. In the 13 months on the continent, the first Byrd Antarctic Expedition had carried out all of its objectives and more. Apart from the dramatic flight over the South Pole, Byrd and his men had made substantive achievements. They had proven that airplanes could fly to depots, refuel, and fly again. Their flights into the interior had found new mountains, which they named in honor of sponsors John D. Rockefeller and Edsel Ford. New land east of the 150° W longitude had been discovered and named after Marie Byrd. Using aerial cameras for the first time to develop maps, they had recorded nearly 150,000 m^2 (390,000 km^2). Gould and his party studied the geology of the Queen Maud Mountains and decided that they were related to the mountains of

Victoria Land. Meanwhile, at Little America, the men surveyed the outline of the Bay of Whales and conducted soundings for its depth. For 13 months, a continuous record of meteorological and magnetic observations had been maintained.

Probably the greatest accomplishment of this expedition was in sowing the seeds for the next. The news stories, the books, and the film *With Byrd at the South Pole,* which followed the expedition, stoked public interest in Antarctica. Byrd would depend on his own popularity and public interest in financing another expedition. Finally, Byrd and other explorers would draw on the lessons learned in using airplanes, radio, and motorized transport in the work of exploration and science.

UNITED STATES (BYRD) ANTARCTIC EXPEDITION (1933–1935)

The second Byrd Antarctic Expedition followed largely the model set by the Byrd Antarctic Expedition of 1928–1930. Both expeditions succeeded without governmental funding. Both used airplanes, motorized transport, and radio on an unprecedented scale. The second expedition resettled the base of the first, Little America, near the Bay of Whales at the Ross Ice Shelf. Like the first, the second expedition deliberately created stories for the mass media. The differences were that the second had more scientific investigations and a nearly fatal undertaking by Admiral Byrd to winter alone in the interior of Antarctica.

According to Byrd, the goal of his second expedition was to answer questions of science and geography raised during the first one. The expedition sought to apply twenty different sciences, including biology, geology, glaciology, astronomy, geophysics, meteorology, and oceanography, to the region. In addition, Byrd and his men planned to add to the geographical knowledge of Antarctica by further exploring areas such as the Rockefeller Mountains and Marie Byrd Land, which were discovered during the first expedition. Finally, Byrd and his men intended to test and employ motorized transports more than previously.

Fundraising proved more difficult for the second expedition than the first. Many Americans suffered financially in the Great Depression that had begun in 1929. A return to Antarctica, especially one that featured science so prominently, did not have the dramatic and popular appeal of the first flight to the South Pole. A wealthy few—Edsel Ford, William Horlick, Jacob Ruppert, Thomas Watson, and the National Geographic Society—gave significantly. However, most cash contributions were made in small amounts and amounted to only about $150,000, little more than one-tenth of the cost of the expedition. Companies granted equipment and supplies, and universities loaned scientific equipment.

As in the first expedition, news and entertainment media proved critical on the financial front. Major investors were the Columbia Broadcasting System and General Foods. In exchange for financial support, Byrd arranged regular radio broadcasts from Little America—relayed through Buenos Aires, Honolulu, Long Island, and San Francisco—to homes in the United States. General Foods paid $100,000 for the opportunity to air commercials during the broadcasts while Americans listened to news from Antarctica in their living rooms. Byrd's publicist, Charles Murphy, accompanied the expedition to make certain that good stories were ready for broadcast. In addition, Byrd persuaded a reluctant Paramount Studios, which doubted the commercial value of another film about Byrd and Antarctica, to invest by offering more flights and more drama.

Like Byrd's first expedition, the second proved to be a massive enterprise. Byrd leased for one dollar a year from the US Shipping Board a steel cargo vessel, *Pacific Fir,* which he renamed *Jacob Ruppert*. From the city of Oakland, California, Byrd bought at public auction an old icebreaker, *Bear,* which had been involved in the rescue of the Greeley expedition in 1884, for $1050. This he renamed *Bear of Oakland*. Airplanes were fundamental to all of Byrd's expeditions, and he bought three airplanes and an autogyro, an early helicopter. One of the airplanes, named *William Horlick,* had two engines and served as the chief plane for exploration; the other two had single engines for shorter flights. The helicopter was for short survey. For ground transport, the expedition had more than one hundred dogs. However, the ships also carried two light snowmobiles presented by Ford, a tractor from the Cleveland Tractor Company, and three Citroen tractors.

The second expedition had more people—fifty-six—winter in Antarctica than the first. Even as scientist Larry Gould had been second in charge in 1928, Byrd appointed another scientist, physicist Thomas C. Poulter, as second-in-command and chief of the scientific staff. Other scientists included two other physicists, two geologists, a geophysicist, two meteorologists, and three biologists. In addition, the wintering party had pilots, dog drivers, tractor drivers, a photographer, a motion picture photographer, a publicist, a surveyor, radio operators, carpenters, a cook, and a medical doctor. Paul Siple, who had been a Boy Scout on the first expedition, joined again as chief of the biologists. Roughly one-third of Byrd's team had been with him earlier. Among the new members was David Paige, who joined as the artist of the expedition.

Ice and weather severely delayed the expedition. Storms delayed the journey from New Zealand to Antarctica. On January 17, 1934, Byrd arrived at the Ross Ice Shelf and his former base, Little America. Ice from the shelf had broken into the sea. Through the years, pressure ridges had formed and made the trail—dubbed "Misery Trail"—from the shore to Little America difficult. Unloading took more time than expected. Meanwhile, ice began cracking on the Ross Ice Shelf, and the men feared that Little America could fall into the sea. To store supplies in an emergency, they built another base farther inland, "Retreat Camp."

These difficulties changed one of the primary goals of the expedition: to set up a camp in the interior of Antarctica. The expedition had brought a prefabricated hut designed for three men—Mountain House—to bury in the snow at the foot of the Queen Maud Mountains, some 400 miles from the coast. From here, a team would spend the winter and record meteorological data. Byrd hoped this adventure and scientific "first" would supply stories to the news media and persuade General Foods to renew its advertising contracts.

The delays at sea and in unloading, and the coming of winter, caused Byrd to change the plan. The expedition lacked time to transport enough supplies for three men or even to reach so far into the interior. Instead, Advance Base was built 123 miles from Little America. Byrd decided also that only one person—Byrd himself—would remain there. Many, including sponsors, questioned this decision. Isolated by distance and the Antarctic night, one person at Advance Base would have no help in an emergency. To have the leader of the expedition away for 6 months threatened administration and planning at Little America. Nevertheless, Byrd insisted. At parting, he ordered that no one risk his life to rescue him.

On March 22, 1934, Byrd flew to Advance Base and began his lonely adventure. He settled into routines of tending instruments that recorded winds, temperatures, and snowfall; viewing aurora; and freeing air ducts of snow and ice. Other routines included playing phonograph recordings, cooking, reading, and even taking walks in the Antarctic night by following poles connected with ropes. As promised, Byrd upheld a schedule of radio communications with Little America, using Morse code because his transmitter lacked the power to send his voice.

Catastrophe almost happened on May 31, 1934, when Byrd fainted from carbon monoxide fumes. Byrd credited this to faulty ventilation of his oil stove and used it sparingly. Nevertheless, the poison had entered his body and he suffered from the carbon monoxide as well as the cold in his hut. Byrd reduced his radio schedule to Little America and aroused concern there. In mid-June Byrd encouraged Poulter to undertake a field trip from Little America to Advance Base through the Antarctic night as an opportunity to view aurora. After three efforts through darkness and over dangerous crevasses, Poulter led a team of three and reached Byrd on August 11. Two months later, Byrd had recovered enough to fly back to Little America. The adventure at Advance Base resulted in scientific data and a work of literature. In 1938 the harrowing account of Byrd's experience appeared as *Alone,* which has remained one of the classic books of polar exploration.

Less dramatic but just as important were the many other accomplishments of this expedition. It was the first to use motorized transport successfully to move people and supplies into the interior for scientific investigation. Another success was to use seismic equipment for the first time to measure the thickness of ice of the Ross Ice Shelf and on the Rockefeller Plateau. Biologists discovered lichens on Scott Glacier and in Marie Byrd Land. They studied the life history of the Ross Sea at the Bay of Whales as well as bird life. Among the geographical discoveries were that no strait existed between the Ross and Weddell seas; new peaks of the Queen Maud Mountains, the Rockefeller Mountains, and the Rockefeller Plateau were also discovered. They also successfully sketched the eastern edge of the Ross Ice Shelf. Geologists on motorized transport garnered evidence that the Ford Ranges were related to the mountains of the Antarctic Peninsula.

In other ways, also, this expedition had significance. For Byrd, the experience had been so physically challenging that he would never winter again in Antarctica, even though he returned in 1947 and 1955. It would also be one of the last expeditions to Antarctica that would be privately financed. Apart from Finn Ronne's expedition in 1947, the United States government would take responsibility for exploration and investigation in Antarctica. Finally, the expedition had importance for such members of the expedition as Finn Ronne and Paul Siple, who would return to Antarctica and further develop their own careers as explorers and scientists.

UNITED STATES EXPLORING EXPEDITION (1838–1842)

Although the United States Exploring Expedition included Antarctica as only a part of its broad area of endeavor—it also surveyed the entire Pacific Ocean from Chile to Australia, as well as much of the Pacific Northwest—it nevertheless mapped 1,500 miles of previously unexplored Antarctic coastline and was the first to determine, based on its continuous line of sightings, that Antarctica is a continent.

Led by Lieutenant Charles Wilkes, a hotheaded, 40-year-old New Yorker nicknamed "Stormy Petrel," the six-ship squadron comprising the Exploring Expedition, or "Ex. Ex.," as it was widely known, sailed from Hampton Roads, Virginia, on August 18, 1838. Its primary object was the promotion of commerce, including the major industry of Pacific whaling, by improving navigation, but the expedition was also charged with extending the bounds of knowledge where practicable. It was the first voyage of discovery paid for by the US government and the last circumnavigation made solely under sail.

Wilkes commanded the flagship of the Ex. Ex., the 700-ton sloop of war *Vincennes,* with a complement of 190. The 559-ton sloop of war *Peacock* (commanded by Lieutenant William L. Hudson, second in command of the expedition) had a crew of 130, while the 224-ton brig *Porpoise* (commanded by Lieutenant Cadwalader Ringgold) carried 65. Two pilot schooners, the 110-ton *Sea Gull* (commanded by Lieutenant Robert E. Johnson, who was succeeded by Passed Midshipman James W. E. Reid) and the 96-ton *Flying Fish* (commanded by Lieutenant Samuel R. Knox, who was succeeded by Lieutenant William L. Walker on the Antarctic cruise from Tierra del Fuego), each had 15 crew members. The 75-ton storeship *Relief* (commanded by Lieutenant Andrew K. Long) had a complement of 75.

The naval expedition numbered 83 officers and 346 enlisted men—most of them quite young—but also included two civilian artists, Alfred T. Agate and Joseph Drayton, and seven civilian scientists, known as "the scientifics": botanists William D. Brackenridge and William Rich; conchologist Joseph P. Couthouy; geologist James D. Dana; naturalists Titian R. Peale and Charles Pickering; and philologist Horatio Hale.

After stopping in Rio de Janiero, the expedition explored Tierra del Fuego, made an initial foray into the Antarctic, then cruised north along the western coast of South America and transited the Pacific via Tahiti and Fiji to Australia. After a layover in Sydney, a second thrust south to Antarctica was followed by further exploration of Australia, New Zealand, Fiji, Hawaii, and the Pacific Northwest. The squadron then crossed the Pacific for a third time, to Manila and Singapore, before doubling the Cape of Good Hope and sailing the length of the Atlantic to New York City, reached on June 10, 1842.

The expedition covered a total of more than 87,000 miles, visited 280 Pacific islands, and produced 180 meticulously drawn charts, more than any previous surveying expedition. Some of the charts were still being used as recently as the Second World War.

First Southern Cruise

The first of Wilkes's two penetrations south into the Antarctic was begun on February 25, 1839, dangerously late in the Antarctic summer to be heading into icy, unknown waters.

Unfortunately, the Ex. Ex. ships were remarkably ill suited for polar work. Their open gunports constantly shipped seas, and their hulls were not reinforced or sheathed, leaving them unprotected from blows sustained in the pack ice. Other flaws of the hastily reconfigured ships were literally covered up with several coats of fresh paint by unscrupulous naval shipyards. The ships' crews were likewise extremely poorly provisioned, and the men suffered badly, often being reduced by their shoddy clothing and boots to wrapping their feet in blankets to stave off wetness and frostbite.

After a rendezvous at Orange Harbor, northwest of Cape Horn, Wilkes divided the squadron into three parts. *Vincennes* and *Relief* were dispatched to survey the coast of Tierra del Fuego. *Peacock*—carrying Peale, the only time any of the scientifics sailed on an Antarctic cruise during the entire expedition—and *Flying Fish* were directed to sail southwest in an attempt to better Captain James Cook's southing record of 71°10′ S, which he made at 106°54′ W. (Despite becoming separated in a gale and enduring great privation, *Peacock* reached 68°05′ S, while *Flying Fish* attained 70° S.)

Wilkes embarked upon *Porpoise,* which sailed with *Sea Gull* south across the Drake Passage toward the South Shetlands to see how far they could penetrate the pack ice. Icebergs and dense floes stopped them as they approached the northern reaches of the Weddell Sea around the northeastern tip of the Antarctic Peninsula but not before they deduced—catching a whiff of sulphur as they sailed to leeward—volcanic activity at Bridgeman Island.

Facing the inevitability of oncoming winter, Wilkes ordered *Sea Gull* to return to Orange Harbor via volcanic Deception Island, where its crew spent a week in Port Foster, the island's flooded caldera, collecting biological and volcanic specimens. *Porpoise,* surveying the eastern end of the South Shetland archipelago, narrowly escaped wrecking on Elephant Island in fog on March 7.

With the exception of *Sea Gull,* which was lost with all hands off the coast of Chile shortly after departing Orange Harbor at the end of April, the squadron rejoined company in Valparaiso on May 17. The sluggish *Relief* was detached from the expedition and directed to depot supplies at Hawaii and Australia. After surveying the South Pacific, the remaining Ex. Ex. ships reconvened in Sydney in November.

Second Southern Cruise

After a month's recuperation in Australia, the four ships sailed south again on December 26, 1839, with Wilkes commanding *Vincennes*. Aboard was one of the first canine visitors to the Antarctic, a Newfoundland dog Wilkes acquired in Sydney and named after that port. Despite some modifications to the three naval vessels, including closing up the gunports, nautical men in Sydney widely opined that the American ships would not survive their Antarctic voyage.

Once again the squadron quickly became separated, and in early February *Flying Fish* gave up its search for the others and returned to New Zealand alone.

The three larger ships managed to meet up, however, and on January 16, 1840, land was reported from *Peacock*'s masthead in the region of 157° E, although the sighting was, critically, not entered into the ship's log by Hudson. More landfalls were made in the following days.

Peacock narrowly escaped being wrecked on January 24 while on its own, when the ship was repeatedly blown backwards onto an ice floe, smashing its rudder. After pack ice floated in and trapped the ship, the crew was forced to drag *Peacock* through a narrow lead to open water, reached only after more than 24 hours of continuous effort. Upon return to Sydney for repairs in late February, it was found that the ice had battered parts of *Peacock*'s stem to a thickness of little more than an inch.

Aboard *Porpoise,* meanwhile, the tricolors of the two French exploration ships commanded by Dumont d'Urville were sighted on January 30. Due to a misunderstanding of intentions, however, the French and Americans failed to pass within hail, each side sailing away believing that the other had snubbed it.

After the American ships separated, *Vincennes* continued westward, sighting and charting discoveries until an icy barrier blocked his path. Wilkes named it Termination Land, marking as it did the end of his southern explorations; today it is known to be part of the Shackleton Ice Shelf.

Having followed the Antarctic coast for nearly 1500 miles, Wilkes announced the discovery of the Antarctic continent upon his return to Sydney on March 11.

Legacy

By the time the Exploring Expedition returned to New York in 1842 (minus *Flying Fish,* which was sold in Singapore, and *Peacock,* which foundered while trying to cross the bar at the mouth of the Columbia River in Oregon Territory), Wilkes' Antarctic discoveries were already being questioned. James Clark Ross, leader of the British Antarctic expedition of 1839–1843 in *Erebus* and *Terror,* to whom Wilkes gave a manuscript copy of his tracing of the Antarctic coastline, announced that he had sailed over positions that Wilkes laid down as land on his chart. Ross was equally dismissive of Wilkes' claim for an Antarctic mainland, but Wilkes insisted that he had indeed delineated a continent.

Subsequent investigations have proven the accuracy of most of the Exploring Expedition's delineation of the 1500 miles of Antarctic coastline it followed. Antarctic atmospheric conditions sometimes combine to create a phenomenon known as "looming" or superior mirage, in which geographic features beneath the horizon—as far as hundreds of miles distant—appear much closer than they are in reality. Wilkes was hardly the last Antarctic explorer to be misled by the occurrence, and aerial photo-mapping has confirmed the integrity of his Antarctic cartography.

The US Ex. Ex. represented a "coming of age" for science in the United States. Not only was the expedition federally funded, but it also gathered such a mass of material—in aggregate, some 40 tons (although very little was collected in the Antarctic)—that the government was forced to create an organized collection to manage it. The expedition's 4000 animal specimens, 50,000 botanical specimens, and thousands of shells, corals, fossils, and rock samples, along with 5000 ethnological and archaeological objects, became the foundation of the Smithsonian Institution, the national museum of the United States.

UNITED STATES NAVY DEVELOPMENTS PROJECTS (1946–1948)

"Operation Highjump," formally designated the United States Navy Antarctic Development Project of 1946–1947, was described by its nominal leader, Rear Admiral Richard E. Byrd, USN (ret.), as "the largest exploring expedition ever organized," and it remains so to this day. Between the end of December 1946 and early March 1947, 4700 men in 13 ships divided into three groups—each built around either an aircraft carrier or a seaplane tender—mounted a comprehensive and benign assault on what remained the world's last "secret land."

In the rapidly maturing Cold War environment of 1946, the US government stated flatly that Operation Highjump was to be "primarily of a military nature," its chief objective "to train naval personnel and to test ships, planes, and equipment under frigid zone conditions." As such, it would be the first officially sponsored US Antarctic expedition since Charles Wilkes had sailed south more than a century before. Soviet observers were quick to recognize Highjump's significance. The official naval journal *Red Fleet* asserted that "US measures in Antarctica testify that American military circles are seeking to subject the [polar] regions to their control..."

While the charge was far from precise, it was not baseless. The Pentagon, already thinking about and planning for a possible Third World War, realized that polar combat would be an important element in any conflict with the Soviets. The US Navy had already conducted carrier operations in the Davis Strait, west of Greenland, the previous summer. While the long-standing question of formal US claims to the Antarctic continued to be held in abeyance, the Navy was eager not only to keep itself before the American public through spectacular exploits, but also to try out wartime technologies, especially the trimetrogon camera capable of overlapping aerial photography that could readily be translated into accurate maps. Byrd and the polar community were no less eager than the Navy to apply this new technology to their Antarctic playground.

Penetrating the ice-choked Ross Sea with great difficulty, the Central Group under Admiral Richard Cruzen finally reached Byrd's old base at the Bay of Whales in the Ross Sea in mid-January and established Little America IV. Despite the presence of the icebreaker *Northwind,* the thin-hulled cargo and communications ships found the going so slow and rough through the ice pack that Cruzen at one point panicked, cabling Byrd that the entire operation should, in effect, be cancelled and all the ships withdrawn well before the end of the austral summer. Byrd overruled him, gently but firmly. At the end of January, with a temporary tent city well on the way to completion, Byrd and his party flew in from the carrier *Philippine Sea* in half a dozen R4D (DC-4) transport planes. Although small by contemporary standards, the aircraft would never have made it off a carrier deck or on and off an ice runway without special ski-wheel devices and JATO (Jet Assisted Take-off) bottles strapped to the wings. Once the foul weather cleared on February 7, the R4Ds began a frantic 200-hour aerial mapping campaign of the adjacent Marie Byrd and Victoria Land coastal and inland areas, together with flights down the Ross Ice Shelf to the Transantarctic Mountains and the polar plateau beyond. On February 15, Byrd himself made a nostalgic second flight to the South Pole, though it was not entirely frivolous because of the trimetrogon mapping cameras. Altogether, the R4Ds at Little America were able to make twenty-nine flights despite the increasingly chancy weather of a waning Antarctic summer and early fall.

Meanwhile, the Eastern Group (Captain George Dufek) and the Western Group (Captain Charles Bond), centered around the seaplane tenders *Pine Island* and *Currituck,* respectively, sailed around roughly 70% of the Antarctic coast. Despite one horrific crash of a big Martin seaplane from the Eastern Group very early—killing several crewmen and necessitating a dramatic rescue effort—Dufek and Bond together managed to get off a further thirty-five mapping flights. On one of the flights, Lieutenant Commander David Bunger of the Western Group, winging along the Queen Mary Coast of Wilkes Land, suddenly came upon what seemed a polar fairyland "of blue and green lakes and brown hills in an otherwise limitless expanse of ice." Other such areas—most notably the Dry Valleys west of McMurdo Sound—were either known or would later be found dotting Antarctica, but "Bunger Oasis" generated understandable awe.

In the midst of these flights, the Navy and a small cadre of civilian and military scientists, including such veterans of previous Byrd expeditions as Paul Siple, "Bud" Waite, and Vernon Boyd, conducted a variety of equipment tests and scientific observations. Several penguins were seized for leisurely research back home, and weather observations, oceanographic readings, and geological samples were taken while the Navy tested survival suits and amphibious tracked vehicles on both land and water. In the waning days on the ice, Boyd led a rushed and daring land excursion out to Mount Helen Washington in the Rockefeller Range, some 150 miles (240 km) east of Little America, using two 16-ton tracked vehicles. The very short stay, however, frustrated the scientists, who complained bitterly that naval and military requirements and desires constantly overrode invaluable polar science.

Deteriorating weather and ice conditions forced Byrd to order the cargo and communications vessels out of the Bay of Whales as early as February 6, even as the R4D flights continued. Little America was hastily evacuated by the icebreaker *Burton Island* 17 days later. The Eastern Group and Western Group, not having to worry about getting out of a vast, ice-filled bowl like the Ross Sea, were able to continue their work several weeks longer. By early March, however, they were gone.

Byrd and his commanders believed that their aerial photographic missions had taken giant strides in unlocking the geographical and geophysical structure of Antarctica, and in some ways they had. Doubtless the signal achievement was proving through comprehensive observation that the Transantarctic Mountains were a single system bending around in an arc from Victoria Land to the Horlick Mountains and eastward to the Thiel Mountains.

Quite soon, however, photo experts suggested that Highjump was not the success its commanders had hoped. Claims of the amount of territory actually seen and photo-mapped had to be dramatically scaled down; worse, what was actually seen and photographed and where it was often proved difficult to determine under careful analysis. Years later, it would become apparent to one alert observer that "Through lack of ground control, more than half the photographs were of no value." Further confirmatory on-site work would be required to establish a "ground truth" sufficiently precise to make authoritative maps.

Byrd and his colleagues, led by Paul Siple, immediately agitated for a Highjump II. In the event, the Navy settled for a far more modest "Second Antarctic Development Project" the following austral summer (1947–1948), informally known as "Operation Windmill." It was an apt description, for the Navy employed yet another new technology, the helicopter, in an attempt to salvage the Highjump photographic record. Embarked on the icebreakers *Edisto* and *Burton Island,* the small, crude, first-generation Bell choppers were a mixed success at best in putting survey parties ashore to carefully triangulate known points. Starting late in the season just west of Bunger Oasis, the vessels and their aircraft ran into frequent storms and heavy ice. Survey and geological parties did get ashore at several points. They dramatically lessened the importance of the Oasis, which on the ground proved to be almost lifeless, and they managed to complete some good survey work west of the Ross Sea. East of Little America (which the vessels visited briefly at the end of January), however, deteriorating conditions effectively ended the operation before it could confirm or modify more than a fraction of the Highjump aerial record. Only the kind of permanent and widespread occupation of the continent first undertaken during the International Geophysical Year a decade later and carried forward by Operation Deep Freeze and similar foreign programs would realize the ambitions first set forth in the US Antarctic Development Projects.

V

VEGETATION

The terrestrial vegetation of Antarctica comprises five major groups of organisms: phanerogams (seed-producing flowering plants); and the spore-producing bryophytes, lichens, algae, and blue-green algae or cyanobacteria. In the strict sense, lichens and cyanobacteria are microorganisms rather than plants. However, the severe climate and growing conditions, particularly with very low temperatures, critically during the summer, combined with oceanic isolation from the other Southern Hemisphere land masses, thereby reducing immigration, considerably restricts the diversity of the Antarctic flora. Despite the great land mass (c. 14 million km^2) of the continent and its offshore islands, barely 1% is ice free, and of this very little provides favourable habitat for plant colonization. Much of it comprises wind- and ice-blasted rock faces and boulder fields, mineral soils rendered unstable by freeze–thaw action and erosion, substrates that rarely receive liquid water, coastal areas colonized by huge populations of penguins, and, beyond the Antarctic Circle, increasingly cold, dry, and sunless (in winter) landscapes with increasing latitude. Comparable environments in the High Arctic do not experience such severe growing conditions. There, the short summers are relatively warm, the permafrost thaws, there is generally no shortage of water, and the landscapes are connected to more southerly continental land masses, allowing unrestricted migration of flora and fauna northwards. This has led to a wide range of ecosystems with diverse plant, mammal, bird, insect, etc., biotas, and complex food webs and ecological processes. The significance of climate and immigration potential in determining the differences in biodiversity of the two polar regions is perhaps best exemplified by the distribution of flowering plants. In the Antarctic there are only two species, the pearlwort *Colobanthus quitensis* (family Caryophyllaceae) and the hair grass *Deschampsia antarctica* (family Poaceae), both reaching 68°42′ S. By comparison, more than 1000 species exist at this latitude in the Arctic, with almost 100 species extending to the northernmost extremity of land at 84° N in Peary Land.

Phytogeographic Zones

The Antarctic has been variously divided into biological regions or zones. One of the most commonly used systems for terrestrial organisms is based on the distribution of plants, and in particular that of the phanerogams, which is a direct response to the prevailing summer climate. Thus the maritime Antarctic region comprises the western Antarctic Peninsula and island groups to the north (South Shetland, South Orkney, and South Sandwich islands, and Bouvetøya). Here the milder, wetter climate permits the occurrence of *Colobanthus* and *Deschampsia,* as well as a wide range of bryophytes, lichens, algae, and invertebrates, including the only two Antarctic higher insects. The colder, drier continent and the eastern Antarctic Peninsula together comprise the continental

Antarctic region where flowering plants are absent and the diversity of other flora is greatly reduced. The sub-Antarctic zone to the north of the maritime Antarctic includes those islands (South Georgia, Prince Edward Islands, Îles Crozet, Îles Kerguelen, Macquarie Island, Heard Island, and McDonald Islands) with a much richer flora and fauna (especially flowering plants and invertebrates), greater range of communities, and greater complexity of ecosystems processes (notably peat formation and microbial decomposition) and trophic levels. Here, depending on the area of the islands, extent of ice cover, distance from other land masses, climate, etc., the number of higher plants varies from about ten to about forty, excluding many introduced species that have persisted. Unlike the cool, temperate islands lying well to the north of the Polar Front (e.g., Gough, Amsterdam, Campbell, Auckland), the sub-Antarctic islands do not possess any arboreal vegetation.

Impact of Climate and Climate Change on Antarctic Vegetation

The biological groups and their species composition in the Antarctic are, to a large extent, dependent on the past and present climate. Those species that succeeded in reaching the southern polar regions had to be physiologically preadapted to colonize and survive the severe environmental conditions (notably low summer temperatures, long periods of desiccation, high levels of solar irradiance and ultraviolet radiation, long winters, a short summer growing season, long periods of winter darkness, and continual summer daylight south of 67° S). Such conditions become progressively more extreme with increasing latitude. Survival and spread are dependent on the physiological tolerance of the plants and on relatively stable environmental conditions. However, much of the Antarctic, like most other biomes of the planet, is experiencing climate change. From a biological point of view, particularly on land, the increasing air temperatures that have been occurring since the middle of the twentieth century have had a significant impact on the state of the environment, and hence of plant habitats. Regional climate change has been greatest in the maritime Antarctic, where the mean annual temperature is now 1°C–2°C higher than it was 50 years ago, much of this increase occurring since the mid-1980s. Although only a relatively small change, it has had a significant impact on the rate of melting in spring and summer, resulting in the break-up of ice shelves and the rapid retreat and thinning of glaciers and ice caps. On land this has created more extensive glacier forelands, and new surfaces are becoming exposed through permanent ice. On Signy Island, South Orkney Islands, for example, about one-third of the ice cover has disappeared, and the glaciers and ice cap have thinned by up to 15 m since about 1970. Such changes are much more localized in continental Antarctica. Loss of ice cover creates new surfaces for plant colonization.

Vegetation History and Immigration

The Antarctic flora and vegetation appear to have remained remarkably unchanged throughout the past c. 5000–10,000 years (i.e., since the end of the last major ice age). Palynological studies (analysis of pollen, spores, and fragments of plants in soil, peat, ice, and lake sediments) have so far indicated that no plants appear to have existed during the Holocene that do not occur there now. Nevertheless, it is likely that some species, especially the environmentally more sensitive bryophytes, may have become established and later extinct without leaving any trace of their existence. Many new immigrant species will have reached the isolated land mass of Antarctica and its offshore islands over the past few millennia to produce the diversity that now exists. Many species, including the two flowering plants, had colonized the maritime Antarctic by c. 5000 years ago. Radiocarbon dating of moss in peat deposits suggests that terrestrial peat-forming vegetation began development around 5500 years ago in the maritime Antarctic. Subfossil aquatic mosses of that age have also been found in maritime lake sediments (James Ross Island), while in continental Antarctica a sample has been dated at about 8500 years old (Clear Lake, Vestfold Hills). However, in many areas where no peat-forming vegetation ever developed, very sparse colonization by cold-adapted mosses and lichens probably occurred much earlier, shortly after ice-free habitats became available. Radiocarbon dating of the surface of moss turf in various sites exposed by receding ice on Signy Island, South Orkney Islands, has indicated that former vegetation was covered by advancing ice during several periods of colder climate over the past several thousand years. The vegetation was therefore exposed to several major climate-change events, lasting many centuries, which caused glacial advances and retreats. The last of these advances was the "Little Ice Age" that ended in the mid- to late 1800s, although there have been at least two minor advances in the twentieth century, lasting only a few years (1920s and 1940s). The gradual increase in species diversity with time is exemplified by two prominent moss species (*Polytrichastrum longisetum* and *Polytrichum piliferum*) that appeared on Signy Island in the mid-1980s. Both colonized newly exposed soil adjacent to a receding ice cap; neither was known from the archipelago previously, and one *(P. longisetum)* was new to the Antarctic. On Deception Island, South Shetland Islands, three species also previously unknown in the Antarctic (*Funaria hygrometrica, Leptobryum pyriforme,* and the liverwort *Marchantia polymorpha*) appeared on ash within a year of its being deposited by the 1967–1970 volcanic eruptions. All became extinct within a few years after the geothermal effect ceased, but *P. longisetum* colonized this ash at one site in the late 1990s.

The transoceanic immigration of plant propagules (any biological structure, spore, or seed capable of generating a new plant) is a continuous process and is dependent on atmospheric circulation patterns. Spores in particular are dispersed into the atmosphere at a source (southern South America, Australasia, or even farther afield). Under certain weather conditions they are swept to high altitude and carried over great distances. If such wind patterns reach Antarctica, dust particles and spores may be deposited over land, with only a very small proportion landing directly on an ice-free substrate suitable for colonization. However, most are inevitably deposited on ice and remain there in perpetuity, but some will eventually reach ice-free ground in melt water. Spores have a remarkable longevity and many are capable of germinating decades or even centuries after being preserved in ice or soil. The accumulation of viable propagules in the soil and ice is referred to as the propagule bank or reservoir, and occasionally propagules will germinate or develop to produce new plants if conditions are favourable for this. Very rarely a species new to the area or even to the Antarctic may appear. The composition of this reservoir of potential colonists can be shown by culturing soil at various temperatures in the laboratory and noting those species that grow. Larger, heavier propagules, such as seeds and viable plant fragments, cannot be transported by wind over long distances, but these are important in local distribution of species already established in the Antarctic. However, long-distance dispersal of these larger propagules does occur, if rarely, by their becoming attached to feathers and feet of some migratory birds, although few propagules ever reach the Antarctic by this means. Skuas and gulls, in particular, are believed to be responsible for much of the spread of the grass *Deschampsia antarctica* throughout the maritime Antarctic, as they often pull up rooted pieces of the plants for nesting material, sometimes from locations several kilometres from their nest. Skuas may also be responsible for introducing the liverwort *Clasmatocolea grandiflora* to its only known Antarctic location south of the South Sandwich Islands (Deception Island), where it is abundant over a few square metres at a geothermal site. Within this unique bryophyte stand is a skua's nest. The skuas probably make annual crossings of Drake Passage to and from Tierra del Fuego, where the liverwort is locally common.

Colonization, Succession and Community Development

Ice is an important repository of both propagules and nutrients, accumulated on and within it over long periods. As it melts, these are deposited along the receding ice margins, and, if the substrate is reasonably stable, colonizing organisms become established. This succession of organisms commences with imperceptible soil microorganisms (bacteria, cyanobacteria, unicellular algae, and fungi), followed within a few years by filamentous algae, bryophytes (principally mosses), and, at maritime Antarctic sites, occasionally the two flowering plants. Finally, after a decade or two (but much longer in dry continental locations), lichens become visible, although the complex process of the fungal component's "lichenizing" the algal component, or development from specialized vegetative propagules, will have been inconspicuously proceeding for many years before this stage is reached. During this microbial and plant succession an increasing diversity of invertebrates colonizes the soil as the amount of organic matter accumulates. Depending on the nature of the habitat these associations of organisms develop distinct communities, defined by the plant composition. Where several closely related communities develop, each differing because a specific environmental feature allows one or a few species to become predominant, the association of communities defines a particular ecosystem (e.g., fellfield, bog, moss turf bank, encrusting lichen, etc.). Recently created habitats resulting from ice recession are sparsely colonized in the early stages, but in time may become extensively covered by mosses and, in seepage areas, sometimes by mats of cyanobacteria (notably black *Nostoc commune* and pink-red *Phormidium* spp.). Wet, nutrient-enriched areas close to penguin colonies are typically colonized by stands of the green alga *Prasiola crispa*. As the terrain evolves, matures, and stabilizes, a range of ecosystems, each comprising several different but closely related plant communities, develops. Thus, wetter ecosystems (bog) support various moss-dominated communities, while drier ecosystems (fellfield) are typically dominated by various lichen-dominated communities.

Under a stable climatic regime, once the mature community typical of a particular suite of environmental conditions (soil or rock type, nutrient regime, water availability and drainage, microclimate, etc.) has developed, and one or a few species established as the dominants, the composition and status of the species is unlikely to change, unless some major circumstance happens to alter the equilibrium. Many species are sensitive to minor changes in the hydrological, geological, soil, and nutrient regime of their habitat. Thus, environmental changes result in ecological gradients, which are reflected in a sharp change from one community type to another, producing a series of narrow communities, often within a small area. Prominent examples in the maritime Antarctic include the abrupt change in vegetation from acid rock and soil (e.g., *Andreaea, Rhizocarpon, Usnea* spp., etc.) to calcareous marble and soil (e.g., *Schistidium, Syntrichia,* and *Caloplaca* spp.), and from the margin of melt streams (e.g., *Brachythecium austrosalebrosum, Bryum pseudotriquetrum, Sanionia uncinata, Warnstorfia sarmentosa*) through boggy seepage ground *(S. uncinata, W. sarmentosa, W. fontinaliopsis)* to dry fellfield (*Andreaea, Usnea,* and many crustose lichens). In continental Antarctica a common gradient from wet to dry substrata is accompanied by a sharp change from *Bryum* spp., *Ceratodon purpureus,* or *Schistidium antarctici* to a community dominated by the lichens *Buellia frigida, Pseudephebe minuscula, Umbilicaria decussata,* and *Usnea sphacelata*.

With the current trend of climate change, especially in the maritime Antarctic, new species may be expected to colonize and become components of established communities, while the status of some existing species may change, causing a shift in dominance. However, as yet there is little evidence of this.

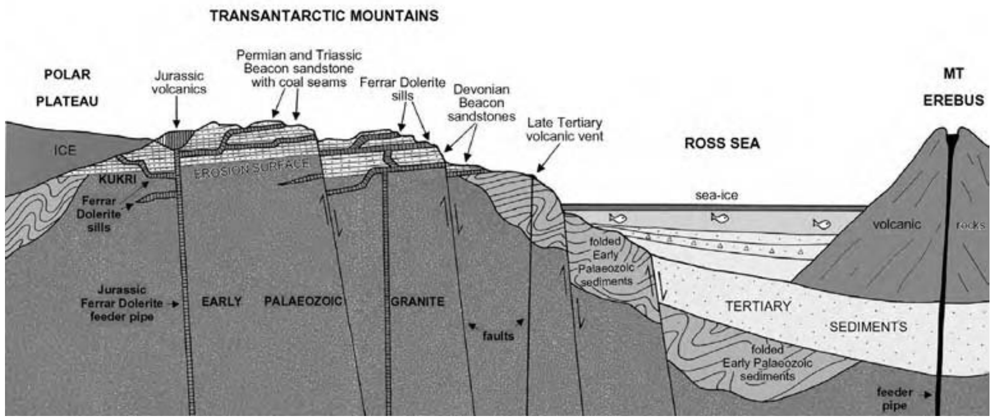
VICTORIA LAND, GEOLOGY OF

Introduction

Victoria Land straddles the northernmost segment of the Transantarctic Mountains adjacent to the Ross Sea. Uplifted in geologically young time, this mountain range provides one of the best-exposed geological sections in Antarctica. No wonder it was also among the first areas of Antarctica studied by geologists (David and Priestley 1914; Ferrar 1907).

Two rather different plate-tectonic events are responsible for the geological record in the area, the Paleozoic mountain-building process of the Ross Orogeny c. 500 Ma and the Cenozoic continental



Geological sketch map of Victoria Land. South Victoria Land and the Wilson Terrane (WT) of northern Victoria Land consist mainly of crystalline rocks and are of a similar character. The volcano-sedimentary Bowers Terrane (BT) and the turbiditic Robertson Bay Terrane (RBT) are unique to northern Victoria Land. The Rennick Graben (RG) is a geologically young feature related to the rifting of the Ross Sea.

split in the form of the Ross Sea rifting (40 Ma). In between, a tectonically quiet period is recorded by the deposition of terrestrial Gondwana sediments followed by extensive outpourings of plateau lavas.

The exposed rock sequence of the Transantarctic Mountains of southern Victoria Land (SVL) is thus comparatively simple, containing the following three subdivisions from bottom to top:

- A basement of metamorphic and granitic rocks of the Early Paleozoic Ross Orogen
- A flat-lying cover of the Devonian to Jurassic terrestrial Gondwana deposits
- A wide range of Cenozoic rift-related volcanic products

This simple sequence becomes more complicated in northern Victoria Land (NVL) because of additional low-grade fossiliferous terranes in the basement, an additional Mid-Paleozoic granite generation, and Cenozoic graben tectonics onshore.

On a geological map, the basement rocks of the Ross Orogen are exposed mainly on the lower slopes of the mountains in the form of a relatively narrow strip following the coast. In NVL, the exposed area is much wider. The cover rocks of the Gondwana sequence occur in a parallel strip further inland, mostly above 2000 m and close to the inland ice. These rocks show the regional tilt most clearly as the layers dip one or two degrees to the west. The young, rift-related volcanism occurs mainly on the Ross Sea coast with volcanic plateaus and small intrusions in NVL, stratovolcanoes around Terra Nova Bay and McMurdo Sound, and numerous small plugs in the areas in between. Some of the volcanoes are still active, like Mount Erebus on Ross Island.

The Basement Rocks of the Ross Orogen

During the Paleozoic, subduction processes similar to those under the present Andes formed a 3000-km-long mountain chain, the Ross Orogen of Antarctica. It consists of folded rock series that, under conditions of high temperature and low pressure, were metamorphosed (baked) to a varying degree and intruded by granitic bodies.

In SVL, the metamorphic rocks comprise a series of marbles, schists, metavolcanics, and intercalated gneisses with a general northwest strike and northwest-trending fold axes. These rocks are exposed east of the Skelton Glacier and in the foothills of the Royal Society Range and the southern Dry Valleys. Towards the north, they are replaced by gneisses. Granitic intrusions with generally calc-alkaline composition are present as local bodies in the entire area. The basement is made up completely of granitic rocks from Granite Harbour, which has given the name for the whole suite, northward into NVL.

In NVL, comparable basement rocks occur in the Wilson Terrane, the innermost of the three terranes (Bradshaw, Weaver, and Laird 1985) and the direct continuation of the SVL basement. In addition to shallow marine metasediments, there are also turbiditic deep-water series in the Wilson Terrane (e.g., in O'Kane Canyon, the Morozumi Range, and the Berg Mountains). High-grade gneisses and migmatites are present in the coastal areas from Terra Nova Bay to Mount Murchison (GANOVEX-ITALIANTARTIDE 1991) and along the west side of the Rennick Glacier from the Outback Nunataks to the Wilson Hills (GANOVEX Team 1987; Stump 1990). Granulite facies gneisses and migmatites are reported from the Campbell Glacier and the Wilson Hills. In the entire area of Victoria Land, the metamorphic rocks show two to four episodes of folding. Granite Harbour Intrusives in NVL are restricted to the Wilson Terrane.

The two outer terranes in NVL are of a very low metamorphic grade and contain fossils, the first Cambrian fossils found in Victoria Land (Laird et al. 1972).

The central Bowers terrane occurs in a narrow strip extending from the Pacific Coast to the Ross Sea. The exposed rocks form three major subunits (from bottom to top):

- A basal part of mainly submarine volcanics alternating with clastic marine sediments and partly volcanogenic turbidites
- Intermediate fossiliferous limestone–mudstone–sandstone–conglomerate sequences (Middle to Late Cambrian)
- A thick fluviatile to deltaic quartzite sequence at the top (Late Cambrian)

The top and bottom series are not directly dated. In suitable rock sequences the Bowers Supergroup is regularly folded (one episode), and the terrestrial quartzites form a box-like syncline more than 100 km long. The deformation in the basal volcanogenic sequence is more irregular.

The outer Robertson Bay Terrane contains a turbiditic sequence several kilometers thick. It is regularly folded around horizontal axes (one episode) and does not contain volcanic intercalations or coarse conglomerates. The turbidites are of distal character and contain sole marks and trace fossils. The base of the succession is nowhere exposed. The top may be present on Handler Ridge on the north side of Trafalgar Glacier, where large exotic blocks of limestone are found within the turbidite succession. These limestones have yielded a Lower Ordovician (Tremadocian) fauna of trilobites, conodonts, crinoids, brachiopods, and ostracods, so far the only occurrence of marine Ordovician sediments in Antarctica. The three terranes of NVL are separated by belts of schistose rocks several kilometers wide. The parent rocks in these schist belts can generally be correlated with rocks of the adjacent terranes. There is an additional phase of deformation in the schist belts. There is an ongoing discussion as to whether the outer terranes are far travelled or local products.

The Lanterman-Mariner suture forms one of the most interesting features in the basement geology of Victoria Land (Tessensohn and Ricci 2003). The suture as trace of an ancient subduction zone traverses NVL from the Lanterman Range to the Mariner Glacier and coincides with the Wilson-Bowers terrane boundary. It is accompanied by a number of peculiar features. A belt of high-pressure metamorphic rocks accompanies the boundary in the Wilson terrane. Flattened conglomerates in the Lanterman Range contain clasts of boninite, a rock type found in the vicinity of primitive oceanic island arcs. A belt of strongly sheared granitoids occurs in the Mariner Glacier area. Lenses of ultramafic rocks are found as tectonic slivers in both areas. Some of these lenses have an eclogitic core. All these features have been interpreted as being typical for a subduction zone. This was recently confirmed by the discovery of coesite (Palmeri, Talarico, and Ricci 2003) in samples from the eclogites. This high-pressure quartz modification requires a depth of formation of at least 90 km. The few other examples of coesite reported from a similar setting come from the Alps and the Himalayas.

The age of the metasediments in Victoria Land is poorly restricted. In the Skelton Glacier area, metasediments showing two phases of deformation are cut by a granite intrusion of 550 million years. This puts the parent rocks and an early deformation back in time before the Cambrian. In SVL, there are several other granites with a comparably early age. The main granite-forming igneous event in SVL and NVL took place around 500 Ma (510–480) at the boundary of the Cambrian and Ordovician periods. It was accompanied by widespread thermal metamorphism. A few late-stage bodies followed between 470 and 460 Ma.

Devonian–Carboniferous Admiralty Intrusives

These post-Ross, high-level intrusions with cooling ages of around 360 million years occur on all three terranes and also crosscut a terrane boundary (Mt. Supernal). The formation of this granite generation is not well understood, because in NVL there is no accompanying tectonic event. Similar rocks occur in Marie Byrd Land and Tasmania.

Gondwana Sequence

After the Ross period of mountain building, the rocks were eroded over a long period of time. The entire Silurian period is not represented. Erosion resulted in the formation of a peneplain cutting through the different units of the Ross orogen. The first new rocks laid down on this unconformity were Devonian sediments in SVL and subaerial volcanic rocks in NVL (Gallipoli Volcanics). The freshwater sediments containing fish remains and the first plants in Antarctica form the lowest horizon of the thick terrestrial Gondwana sequence that in Antarctica is called the Beacon Supergroup (Barrett 1971). The Gallipoli Volcanics in NVL are also associated with plant-bearing beds. The rocks are the surface equivalents of the coeval Admiralty Intrusives (360 million years).

The Carboniferous is missing in Victoria Land. The next sedimentary product in the sequence is a tillite (solidified moraine) of the Late Paleozoic glaciation, which, as fragments of Gondwana, affected all the southern continents.

The glacial beds are followed by mainly fluviatile sandstones with intercalated shaly horizons. The shales contain leaves of the *Glossopteris* flora represented on all southern continents. Large trees are preserved, sometimes in growth position. Coal seams several metres thick developed, sometimes very close above the glacial tillites.

The Triassic Beacon sequence does not differ fundamentally from the preceding Permian, but the *Glossopteris* flora are replaced by fernlike plants like *Dicroidium*.

Like on the other southern continents, the terrestrial Gondwana sequence provides a record of climate and environmental conditions for one of the largest land masses that ever existed on the planet.

The tectonically quiet sedimentation period lasted for a total of more than 200 million years. It came, however, to a rather abrupt end, when Gondwana started to break up in Jurassic times. An enormous event of lava production took place in southern Africa, Antarctica, and Tasmania. Lavas and pyroclastic rocks are particularly well exposed in the Rennick graben of NVL. In SVL, similar rocks occur at Carapace Nunatak. However, the main products preserved from this episode are the widespread Ferrar sills, horizontal sheets of lava intruded between the sandstone layers of the Beacon sequence. The sills are several metres to several hundreds of meters thick and are found across the entire continent, from Queen Maud Land to NVL.

Cenozoic Rifting

The extensional graben formation of the Ross Sea Rift during the Cenozoic is related to the final breakup process of Gondwana. The high Transantarctic Mountains can be regarded as the uplifted shoulder of the rift. With a summit elevation of c. 4000 m, they form the highest rift shoulder known on earth. With more than 10 km of sediments (Cooper and Davey 1987), the basins are also exceptionally deep.

The igneous activity related to the formation of the rift is alkaline in character, as in most other continental rifts on earth (e.g., the East African rift or the upper Rhine Graben) (Tessensohn and Wörner 1991). The volcanic Adare, Hallett, and Daniell peninsulas and Coulman Island were probably formed over the master faults along the northern Ross Sea coast in NVL. Stratovolcanoes are found where the coastline steps back to the west at Terra Nova Bay (Mt. Melbourne, Mt. Overlord) and McMurdo Sound (Mt. Erebus, Mt. Terror, Mt. Mourning, Mt. Discovery), probably due to the opening of transfer faults. Parallel to the northern one of these transfer faults, the Meander Intrusives form a series of alkali-granites, syenites, and gabbros, the only known Cenozoic intrusive rocks. The Malta Plateau north of Mariner Glacier consists of felsic peralkaline rocks. Other volcanic rocks occur in the coastal areas of Victoria Land in the form of small cones, vents, and plugs, on volcanic islands in the Ross Sea (Ross Island, Beaufort Island, Franklin Island, Possession Islands) and, as shown by geophysical surveys and in drill cores, in the western basin of the Ross Sea.

The oldest Cenozoic igneous rocks are the Meander Intrusives in NVL with ages from 25–38 million years. They are followed by peralkaline dikes (14–18 million years) and the peralkaline rocks of the Malta Plateau and other locations (7–11 million years). The basaltic plateaus are between 5 and 14 million years old, followed by the volcanic plugs and vents and the stratovolcanoes. However, all these age groups overlap each other to a certain extent. In SVL, volcanism starts around 19 Ma.

Structural Evolution

The Ross Orogen is the product of subduction of oceanic crust under the supercontinent Gondwana. Partial melting of the crust led to the formation of a magmatic arc, the Granite Harbour Intrusives. A pile of late Proterozoic sediments was deformed and metamorphosed during these processes. The former continent–ocean boundary is preserved in the form of a suture in NVL. On the oceanic side of this suture, two Cambrian terranes were accreted slightly later. After a tectonically quiet period, the first breakup event of Gondwana produced large volumes of plateau lavas and sills. Related to the final breakup split of Antarctica and Tasmania, the continental Ross Sea rift developed. A master fault between the Transantarctic Mountains and the Ross Sea led to down-faulting of the basins under the sea by more than 10 km and uplift of the Transantarctic Mountains by up to 4 km. The master fault and corresponding fault systems provided passageways for the young volcanism, which is still active today. A branch of the Ross Sea structures crosses NVL in the form of the Rennick Graben system, which has preserved the plateau lavas of the Mesa Ranges and brings down the Gondwana sequence almost to sea level.

VOLCANIC EVENTS

Antarctic volcanoes belong to the "Ring of Fire," a belt of volcanic systems surrounding the Pacific Ocean: Kamchatka, Japan, Philippines, New Zealand, Transantarctic Chain, Antarctic Peninsula, Andes, Galapagos, Central America, Rocky Mountains, and Alaska. The volcanic areas nearest to Antarctica are the South Sandwich Islands, South America, and New Zealand. Antarctic volcanic systems are located in the Antarctic Peninsula and in Victoria Land. The majority of the South Shetland Islands (Antarctic Peninsula) had a volcanic origin. Deception Island is a horseshoe-shaped caldera, still active (several eruptions occurred in 1967–1970), with several thermal springs, fumaroles, and steaming beaches. Mount Erebus (3790 m) is the largest of the four volcanic cones that form Ross Island. This volcano is fully active and the major historically known eruption occurred in 1984–1985. Mount Melbourne (2732 m, Northern Victoria Land) presently shows only weak geothermal activity.

Beyond local volcanism, Antarctica plays an important role in scientists' understanding of the climate–volcanism relationship, because the ice cap constitutes a natural archive of volcanic aerosols. The fact that the Antarctic ice sheet has a greater remoteness than even Greenland from active volcanic fields makes it more suitable for providing information on global events, potentially recording explosive volcanic eruptions that have occurred up to 20° N latitude. The explosivity of many volcanoes depends critically on the enrichment of volatile substances in near-surface magma reservoirs, where water (H_2O) and sulfur dioxide (SO_2) can form free gases at low pressure. During very explosive (Plinian) eruptions, more highly evolved derivative magmas are expelled with very high mass eruption rates (10^7–10^9 kg s^{-1}). Plinian eruptions form a spectacular column of the mixture of gas and particles, which forms a convective zone rising up to 40 km, because of the positive buoyancy in the atmosphere. Such eruptions inject ash and gases (mainly SO_2, HCl, and HF) directly into the stratosphere, where their residence time is up to 3 years, allowing their diffusion on a global scale. The photochemical reactions of SO_2 with H_2O and OH radicals in the stratosphere lead to the formation of micron- and submicron-sized sulphuric acid droplets. Depending on the geographical position of the source and the season of the year, volcanic aerosol layers form continuous veils (several km thick) at a height in the atmosphere of 20–30 km. Stratospheric sulphuric aerosol is a major forcing factor for climatic and environmental changes. It generally contributes to a cooling at the Earth's surface by solar radiation back-scattering and absorption. On the contrary, the absorption of sunlight and infrared radiation emitted by the Earth's surface causes a stratospheric warming. This radiative forcing results in massive changes in atmospheric circulation that, in turn, strongly affect tropospheric temperatures. Tropospheric and stratospheric temperature variations impact the climatic system by (1) changing midlatitude surface temperature with a possible seasonal pattern (summer cooling and winter warming) that depends on the eruption latitude, (2) causing differences in the temperature gradient between the equator and the poles and in the intensity and timing of the polar vortex, and (3) affecting climatic hemispheric conditions by variations of advective transport of air masses. Stratospheric sulphuric aerosol also changes the stratospheric chemistry, acting as a catalytic surface for heterogeneous reactions that change NOx into nitric acid and inactive anthropogenic chlorine reservoirs in the stratosphere ($ClONO_2$, HCl) into reactive chlorine (Cl, ClO). Such substances are effective in breaking up the O_3 molecule. The consequent ozone depletion constitutes a negative feedback of the surface cooling effect but heavily affects biota. A single volcanic eruption can perturb the climatic system with temperature changes on the same order of magnitude as other forcing factors, such as greenhouse gases and global anthropogenic sulphur emissions, but for shorter time periods. High-frequency volcanic activity could affect the climatic system for longer times (decennial to secular scale) and, if it occurs in climatically critical conditions, could act as a forcing factor, priming or speeding up climate mode changes via a positive feedback. In this view, the possibility of reconstructing a reliable volcanic history from ice-core stratigraphies of volcanic markers is highly relevant in assessing the climate–volcanism relationships.

Volcanic deposition the on Antarctic ice sheet can be revealed by detection of increased snow acidity, caused by deposition of acidic species such as H_2SO_4, HCl, and HF, or detection of sulphate levels anomalously higher than background values (tuned by biogenic emissions). In the former, conductivity measurements are carried out on melted (solution conductivity) or solid (electro-conductivity measurements [ECM]) ice-core sections, as well as by dielectric profiling (DEP) of solid ice. Specific measurements of sulphate (by ion chromatography) allow a better quantification of the volcanic deposition because sulphate is a conservative substance and is not affected by changes in snow acidity (e.g., neutralization processes with dust in glacial conditions) or interferences from other nonvolcanic conductive species. The direct measurement of sulphate allows a reliable estimation of the climatic impact of a volcanic eruption, independent of its explosivity. In fact, only the stratospheric sulphuric aerosol plays a relevant climatic role, ash having a short atmospheric residence time. The different sulphur concentration in the magmas is what is important, and small explosive events can inject more SO_2 into the atmosphere than large explosive eruptions. The El Chichon eruption (Mexico, 1982; 0.35 km^3 magma) emitted a very much larger SO_2 quantity than the Mount St. Helens eruption (USA, 1980; 0.5 km^3 magma), due to the larger concentration of sulphur in the magma (about 100 times larger).

Volcanism is recorded in ice cores up to a year after the relevant eruption, because of the time necessary for the sulphuric aerosol migration and deposition to the ice sheets. These peaks are correlated with temperatures deduced from oxygen isotope ratios in order to define climate connections.

The main advantages of a reliable reconstruction of the paleo-volcanism can be summarised as follows: (1) assessing the climatic and environmental impact of single major volcanic eruptions (mega-eruptions) and of high-frequency volcanic activity; (2) evaluating the stratosphere/troposphere interchange processes using stratospheric aerosol load as a marker; (3) using volcanic emissions to simulate other forcing factors, such as "nuclear winter" or meteoric impact; (4) setting and checking ice-core dating from seasonal marker stratigraphies or flow models by using volcanic signatures as known temporal horizons; and (5) synchronising the time scales of different ice cores (also in the different hemispheres) in order to understand whether climatic and environmental global changes occurred simultaneously in the two hemispheres or which hemisphere leads. This latest topic is very important in understanding driving forces and feedback factors of glaciation and deglaciation processes.

The cause–effect relationship between climate and volcanism is still controversial. On one hand, mega-eruptions or high-frequency volcanic activity seem to constitute a driving force for climate changes; on the other, the idea that the isostatic loading and unloading of the lithosphere, by accumulation and successive melting of the ice sheet, can generate instabilities in the Earth's mantle, and then volcanism, is an intriguing hypothesis.

VOLCANOES

Volcanoes are known from three areas within the Antarctic continent, and the oceanic islands in the surrounding Southern Ocean are mainly volcanic. Most of the volcanoes are extinct but there are a number that are considered active. The term "active volcano" usually applies to volcanoes that have erupted in historic times and have had their eruptions witnessed and recorded by people. As Antarctica was mainly unoccupied until the last 50 years, within Antarctica, active volcanoes are those that have had witnessed eruptions but also those showing evidence of recent eruptive activity. Evidence includes volcanic ash layers in the surrounding ice; very young ages (less than a few thousand years) determined on eruptive products; and geothermal features with temperatures above the ambient air. The following discussion is limited to the last 20 million years of geologic history, even though volcanism has occurred throughout the known geologic history of Antarctica.

In the Southern Ocean there are seventeen volcanic islands situated on the Antarctic tectonic plate. Big Ben volcano on Heard Island (53°06′ S, 73°30′ E) is active and lava was erupted on Marion Island (46°54′ S, 37°45′ E) in 1980. Eruptive columns were reported in the nineteenth century at the Balleny Islands (66°16′–67°38′ S, 162°15′–164°44′ E). St. Paul Island (38°43′ S, 77°33′ E) and Bouvetøya (54°25′ S, 3°21′ E) have fumaroles. Volcanic plumes were observed from the McDonald Islands (53°02′ S, 72°36′ E) during the 1990s and satellite images show a doubling of the size of the island between November 2000 and 2001.

Active volcanoes within the Antarctic continent occur in West Antarctica, the Antarctic Peninsula/ Ellsworth Land, and the western Ross Sea. Volcanoes in West Antarctica are found in Marie Byrd Land, where eighteen major and thirty small satellitic volcanic centers have been identified. The volcanoes occur in an intraplate tectonic setting and are on the flank of the West Antarctic Rift System, a region extending across West Antarctica through the Ross Sea in which the crust has been thinned by extension. Most of these impressive volcanoes are covered in snow and their bases are buried beneath the West Antarctic Ice Sheet. Mount Sidley (77° S, 126° W) is the tallest volcano in Antarctica at 4181 m high, rising 2200 meters above the surrounding ice level. Only Mount Berlin (76° S, 136° W) is considered active, as it has a steaming fumarolic ice tower and an underlying ice cave with elevated air temperatures. It is also the source of a 10,000-year-old and many older ash layers in ice on Mount Moulton (76° S, 135° W), a volcano 25 km to the east of Mount Berlin. Mount Takahe (76°15′ S, 112° W) has a youthful appearance, is 3460 m high, and appears to be the source of 7000-year-old volcanic ash in an ice core drilled at Byrd Station. There is also a possibility that an eruption is currently ongoing beneath the ice of the West Antarctic Ice Sheet. Airborne studies have shown a circular depression consistent with melting of the ice by a volcanic vent. The presence of a volcano beneath the depression is further evidenced by studies that show magnetic rocks typical of volcanoes.

In the western Ross Sea region, most volcanism occurs on or along the front of the Transantarctic Mountains and the volcanic rocks are known as the McMurdo Volcanic Group. Numerous magnetic anomalies detected beneath the Ross Sea are interpreted as small volcanic vents, but none of these vents is currently active. A very young-looking extrusive volcanic dome occurs among a group of volcanic cones and domes called The Pleiades (72°40′ S, 165°30′ E) on the Transantarctic Mountains in northern Victoria Land that probably erupted less than 1000 years ago. Fumaroles occur on a recently recognized active volcano, Mount Rittmann (73°28′ S, 165°37′ E), in north Victoria Land. Mt. Melbourne (74°21′ S, 164°42′ E), near Terra Nova Bay, has warm ground that steams near its summit, and an ash layer exposed in ice on the volcano's flank suggests that it erupted less than 200 years ago. Mount Erebus (77°32′ S, 167°10′ E) on Ross Island is the southernmost active volcano in the world and contains a persistent lake of molten anorthoclase phonolite magma. Small strombolian eruptions are common from the lake.

At the base of the Antarctic Peninsula and along the Ellsworth Land coast, eleven volcanic centers have been identified, but none of these volcanoes is currently active. Fourteen volcanic centers are known from the northern Antarctic Peninsula and adjacent offshore islands. Bridgeman Island (62°03′ S, 56°45′ W) has fumaroles and is here considered active. Seal Nunataks (65° S, 60°13′ W), on the east side of the Antarctic Peninsula, may be active but there are conflicting reports on the nature of the volcanic activity. Deception Island (63° S, 60°40′ W) lies at the southern end of Bransfield Strait, which is a marginal basin associated with subduction of the Pacific tectonic plate beneath the South Shetland Islands, which lie on the Antarctic tectonic plate. Deception Island is the second-most-active volcano in Antarctica, after Mount Erebus, and had significant eruptions in 1967, 1969, and 1970. The island is round, 14 km in diameter, and breached at the southeast end, allowing seawater to fill the large central caldera. Three new craters and an island were formed in the 1967 eruption. Volcanic ejecta were erupted from a fissure in ice on the caldera wall in February 1969 and resulted in significant meltwater and ice debris flows. A Chilean base was destroyed and a nearby British station severely damaged by the eruption. A chain of new craters was formed in August 1970 and the volcanic ejecta formed a strip of new land inside the caldera. Hot springs near the shoreline of the caldera provide a perfect location for swimming and bathing and have become a popular destination for tourists on tour ships.

VOSTOK STATION

Vostok Station, an inland station of the Russian Federation in Antarctica, was opened on December 19, 1957 to implement the USSR scientific program during the International Geophysical Year (IGY). The station was named after the sloop *Vostok*—one of the ships of the First Russian Antarctic Expedition of Fabian von Bellingshausen and M. Lazarev (1819–1821), and the first to see the Antarctic continent. The station is located on the Antarctic Plateau of East Antarctica at the point with coordinates 78°28′ S and 106°48′ E at a height of 3488 m above sea level. The distances from the coastal stations are: Mirnyy (Russia), 1410 km; Progress (Russia), 1350 km; Casey (Australia), 1360 km; Dumont d'Urville (France), 1705 km; Mario Zucchelli (Italy), 1470 km; and McMurdo (USA), 1305 km. The distance from Amundsen-Scott (USA) is 1250 km and from Dome C (Italy–France) is 620 km.

The choice of locality was determined by the plans for permanent helio-geophysical and aero-meteorological observations at the earth's South Geomagnetic Pole. The station coordinates corresponded to the pole position according to scientific knowledge of the time. The areas called "polar caps" in geophysics are situated around the geomagnetic poles in both hemispheres.

The magnetic field lines, along which the "solar wind" energy fluxes propagate, are directed towards the poles, leading to increased geomagnetic perturbation here. Organization of permanent observations of geomagnetism and the state of the ionosphere in "polar caps" make it possible to investigate the character of physical processes and internal relations in the "solar wind–magnetosphere–atmosphere" system. In the end, these data will explain the influence of solar activity and its variability on the formation of climate and weather conditions on Earth. The importance of these studies and a complicated character of cause–effect natural mechanisms of influence of the sun's physical state on the earth's atmosphere also necessitated continuation of research at Vostok station after the end of the IGY program. The choice of the station location proved to be especially successful, as in this area the largest of the known subglacial lakes on earth was discovered. It was also called Vostok.

Until 2005, Vostok and Amundsen-Scott stations remained the only year-round operating stations on the Antarctic continent. The annual logistics support of Vostok station (similar to its establishment in 1957) is by means of sledge-tractor traverses from Mirnyy station. Personnel, fresh products, and scientific equipment are delivered by airplanes from the coastal stations. An airstrip 3500 m long, which is suitable for receiving ski-equipped aircraft, including the LC-130 aircraft, is maintained at Vostok Station. In the late 1970s, the station was rebuilt. At present its structures include four buildings of aluminum panels, a glacial-drilling complex of veneer panels with heat insulation, an emergency electric power station (60 kW), and a base of fuel lubricants. Power supply is provided by three diesel generators with a capacity of 100 kW each. The station is capable of accommodating eighteen people in the wintertime and up to thirty in the summer. The telecommunications equipment is represented by satellite communication terminals and HF and UHF transceivers.

At Vostok, observations of geomagnetism, the state of the ionosphere, surface atmosphere, solar radiation, total ozone, and adaptation of the human organism are carried out on an annual basis. Until 1991, regular observations of the free atmosphere state (upper-air sounding) were conducted. During the seasonal period, the programs expand to include glaciological studies of ice cores from deep boreholes and snow–firn cover, study of the subglacial Lake Vostok parameters by geophysical methods (seismic sounding, seismology, radio-echo sounding), and geodetic methods (ice-cover dynamics, including drift and tidal motions), and studies of biodiversity of microorganisms at the station in the snow cover and ice cores. An important type of activity beginning from 1970 was deep ice-sheet drilling by specialists of St. Petersburg Mining Institute (SPMI). In 1998, drilling was stopped at a depth of 3623 m, as it was first necessary to develop an ecologically clean technology for penetrating the water layer of the subglacial lake. Such technology was jointly elaborated by specialists of SPMI and AARI and presented to the international community in 2002 and 2003 at XXVI and XXVII ATCM. As of June 2006, the borehole at Vostok station is the deepest of all boreholes drilled on the Earth's glaciers.

A complex of geophysical studies at Vostok is aimed at investigating the magnetosphere in the south polar cap of the planet. To assess its state, a universal PC-index was developed. Its application allowed derivation of a law that relates the PC-index value to the electric-field characteristics of "polar caps." A sharp increase in the PC-index shows the development of a magnetic substorm, making it possible to use it for operational prognostic purposes. It was determined that geomagnetic perturbations have a synchronous character at the magnetically conjugated points of the Southern and Northern hemispheres.

Thus, constant observations at Vostok Station allow a practical use of operational information in the northern regions of Russia.

The latitudinal and altitudinal location of Vostok Station determines its extremely severe climatic characteristics. Vostok is currently the "Pole of Cold" of our planet. The mean monthly air temperature ranges from –32.0°C (December) to –68.2°C (August), being above –60°C only for 4 months of the year (November–February), while its mean minimum values of below –70°C persist for 6 months (April–September). The absolute minimum air temperature ever measured on the planet was recorded at Vostok (–89.2°C on July 21, 1983). An absolute maximum of –12.2°C was observed on January 11, 2002. Relative air humidity throughout the year is close to 70%. Mean monthly atmospheric pressure varies between 618 mb (September) and 634 mb (January). Mean monthly wind speed is about 5 m s^{-1}, with the west-southwest direction predominating.

The discovery of the subglacial Lake Vostok resulted from comparison of the experimental data on seismic surveys, radio-echo sounding of the ice-sheet strata and the underlying surface character, and satellite altimetry of the glacial surface with theoretical thermodynamic models of the glacier. The outcome of this generalization was first presented at the SCAR Congress in Rome in 1994, and the first publication about this natural water body appeared in 1995. Beginning at this time, the RAE started comprehensive systematized studies of Lake Vostok. The lake presents an oblong knee-shaped water body elongated from north to south. Its length is 300 km, the width is 15 km, and the water table area is about 16,000 km^2. Its western shore is irregular, forming numerous bays and peninsulas, whereas the eastern shore is relatively rectilinear and precipitous. The southern lake area presents a deep water trough with a maximum water-layer thickness of 1200 m, while the northern area is shallow.

The maximum thickness of bottom sediments (up to 330 m) is observed in the deep-water trough. The ice-sheet thickness above the lake water layer changes from 3400 m in the southern part to 4350 m in the northern area. Directly beneath Vostok Station, the ice thickness is 3750 ± 25 m, the water layer thickness is 600 m, and the bottom-sediment thickness is 330 m.

W

WANDERING ALBATROSS

Wandering albatrosses *(Diomedea exulans)* are among the longest-winged flying birds with a wingspan of over 3 m. Wandering albatrosses weigh between 7 and 12 kg, with males about 20% heavier than females. Consistent with their feeding and flight characteristics, in addition to their long wings adapted for gliding flight, wandering albatrosses display massive pale bills and short tails. Adults have a characteristic white body and upper-wing plumage, the dark vermiculations diminishing with age. Juvenile birds have dark-brown plumage with white faces, their dark body plumage lightening with maturity.

Wandering albatrosses are a globally threatened species classified as "vulnerable" because of an overall decrease of 30% in numbers over three generations (70 years). Wandering albatrosses breed at five island groups (South Georgia, Prince Edward Islands, Îles Crozet, Îles Kerguelen, and Macquarie Island) with an estimated annual breeding population of 8500 pairs in this biennially breeding species. The total population is equivalent to about 28,000 mature individuals, with the Bird Island (South Georgia) and Crozet populations accounting for 30% of the species. These two populations indicated significant population decreases during the 1970s and 1980s, after which the Crozet population showed slight recovery before stabilising. The tiny population on Macquarie Island has recovered from precariously low levels to stabilise at the current level of about ten pairs breeding each year.

Wandering albatrosses return to their natal islands in November, about a month before egg laying. They are loosely colonial and breed in dispersed groups in open or patchy vegetation. The single egg is laid in a large truncated cone nest constructed of vegetation and mud. Laying occurs during December and February, and the parents share the 11-week incubation period. The chick hatches in March–April and is tended by the parents for 40 weeks before fledging occurs between November and February. The breeding season therefore for adults that successfully raise a chick extends over a 55-week period, requiring this species to be a biennial breeder, with no successful adults returning to breed the following year. Successful birds typically return to breed 2 years later, but some birds may elect not to return for 3–4 years. Unsuccessful birds usually attempt to breed in the successive year, but again some may defer for 2–3 years.

Most wandering albatrosses remain at sea for 5–7 years before returning to their natal island. Breeding generally commences between 8 and 11 years of age, although a decrease in the age of breeding has been reported for the decreasing Bird Island population. Birds from this population have also shown substantial reductions in both adult and juvenile survival rates, with longline fishing being implicated as the major source of the increased rates of mortality.

Wandering albatrosses forage widely over the Southern Ocean, and there is overlap in foraging distributions of birds from different colonies within the same ocean sectors. Typically, wandering albatrosses exploit sub-Antarctic and subtropical waters, and they forage over both neritic and shelf waters. Wandering albatrosses have minimal ability to dive and feed predominantly by surface-seizing their prey of fish and squid.

Wandering albatrosses are also prodigious scavengers and are perhaps the most aggressive of seabirds that forage on offal and discards behind fishing vessels. This propensity to scavenge during fishing operations makes them extremely susceptible to being drowned after ingesting baited hooks. Birds from South Georgia are likely to be most at risk from fisheries operating in the South Atlantic and Indo-Pacific Oceans, whereas the Îles Crozet, Prince Edward Islands, and Macquarie Island populations are likely to interact more with fishing operations in the Indian Ocean and Australian region. Widespread adoption of effective mitigation measures across a range of fleets is therefore required to safeguard the survival of this species.

WEATHER FORECASTING

Weather forecasting for the Antarctic is becoming much less of an art and very much more of a science as knowledge of the various physical processes that occur in the Antarctic environment develops and as our armoury of forecasting tools increases. This said, the relative paucity of weather observations over Antarctica and the Southern Ocean, and an ocean–ice–atmosphere environment that results in weather varying from calm and sunny conditions to howling blizzards, present the forecaster with considerable challenges.

Most of the twenty-nine or so National Antarctic Programs have subprograms related to meteorology (COMNAP 2005), with some Antarctic stations having a forecasting role, for example Marambio (Argentina); Casey and Davis (Australia); Frei (Chile); Great Wall (China); Neumayer (Germany); Terra Nova Bay (Italy); Mirnyy (Russia); SANAE IV (South Africa); Rothera (UK); Vernadsky (Ukraine); and McMurdo (USA). However, for most Antarctic stations there is no dedicated weather forecasting service available on a year-round basis. Occasionally, in "winter," a station might request *ad hoc* forecasts to support a traverse or a similar venture. Usually, however, station activities proceed on the basis of station management, insisting that expeditioners take all possible care when going about their outdoor tasks and in particular keep their own close watch on the weather. During the "summer" period many stations have their numbers increased due to an influx of scientific and maintenance personnel. Field camps are established from which scientists conduct their research, aircraft are ferrying people and cargo between stations, ships, and field camps, and there is an increase in recreational activity by staff enjoying a break. This increases the demand for weather forecasts, and some stations issue routine forecasts through the summer period.

In preparing weather forecasts, Antarctic meteorologists use a variety of forecasting techniques. The mean sea level (MSL) chart (showing lines of equal pressure at mean sea level) is still a key forecasting aid. It shows the positions of centres of low- and high-pressure systems, the air-pressure gradient between them, and the location of frontal systems (boundaries between air masses with different characteristics). While routine observations of air pressure, air temperature, and wind speed and direction are essential for the preparation of the MSL chart, such synoptic data are sparse over Antarctica and the Southern Ocean. However, data from satellites do provide invaluable information for the construction of weather charts. The MSL chart becomes of less use just a few kilometres inland of the coast of Antarctica, where the terrain rises steeply. Normalising pressure to sea level is problematical over such a depth of the atmosphere (the average elevation is around 2000 m). Here the forecaster might resort to using streamline charts, which show the direction along which the air is flowing.

The forecasting task is four-dimensional, with the prediction of weather elements at some time in the future for a location in an atmosphere that has vertical and horizontal extent. Increasingly, the simple MSL chart is being supplemented or replaced by the output from numerical weather prediction (NWP). This has become a prime forecasting tool in Antarctica, as indeed it has worldwide. In the Antarctic context, NWP gives guidance from the broad-scale synoptic environment down to local weather phenomena affecting Antarctic stations. Paradoxically, while there are fewer conventional weather observations available in the Southern Hemisphere compared to north of the equator, the vast expanses of southern oceans coupled with the effectiveness of satellite data and the relatively simple orography in the Southern Hemisphere means that the NWP output from most global models is now of similar quality for each hemisphere.

NWP over Antarctica and the Southern Ocean may have some skill up to a week ahead, but terrain plays an important role in defining the surface wind flow over the Antarctic continent, and many operationally available computer models do not adequately resolve topographic and orographic features. While the NWP output might provide good general synoptic guidance, the accurate prediction of individual weather elements over the Antarctic continent is often the province of local knowledge and "nowcasting" techniques (in which extrapolation of observed trends is limited to the very short term). This is particularly the case in areas of steep or complex terrain.

Whatever the forecasting technique used, the main aim is usually to provide information that will increase the safety of humans in what is often a very hostile environment. A "blizzard" (where blowing snow reduces visibility to 100 m or less, the air temperature is freezing, and the surface wind speed is gale force or greater) is the archetypal Antarctic weather phenomenon. With strong winds and low temperatures comes "wind chill," the cooling of a person's body due to the combined effects of cold surroundings and wind carrying the heat away from the body. Antarctic explorers Paul Siple and Charles Passel first attempted quantification of wind chill in 1939. Another, more insidious phenomenon is that of "white-out," which occurs in uniformly overcast conditions over a snow-covered surface. It is associated with diffuse, shadowless illumination that causes a lack of definition of features on a snow surface. The resulting lack of horizon definition can make it difficult for a person to even walk safely, let alone operate vehicles or land an aeroplane. The prediction of white-out might be achieved by using NWP output to predict potential for cloudiness, supplemented with satellite imagery or direct human observations of cloud bands to extrapolate the movement of actual cloud features in the short term. NWP might also be used as a guide to the general environment for windy conditions. Often forecasts of snow drift will depend on a nowcasting approach (by considering whether snow has fallen recently and whether the forecast wind is strong enough to raise that snow to a sufficient height). Some decades ago operators in the Antarctic might have been forgiven for looking at the latest Antarctic forecast with a jaundiced eye. Nowadays, while it still pays to "hope for the best but prepare for the worst," improvements in understanding of the relevant physical processes, satellite data, and NWP mean that weather forecasting skill for the Antarctic (even for phenomena such as blizzards, wind chill, and white-out) are on par with forecasting for lower latitudes.

WEDDELL, JAMES

Weddell was *primus inter pares* in the group of sealing captains who accomplished so much exploration of the Antarctic and sub-Antarctic in the early years of the nineteenth century, and whose achievements were recorded for posterity. During his great voyage of 1822–1824, he discovered the sea now named after him and penetrated it to the then-astonishing latitude of 74°15′ S.

As with so many of his contemporaries, much of Weddell's early life is obscure. His father was a prosperous Scottish-born upholsterer trading in London, and his mother, to whom he was deeply attached throughout his life, was a Quaker. Although it is known that he was born in 1787, his place of birth is uncertain. London would seem likely, but both Ostend and Massachusetts are possible. His father died early, and Weddell, following a brother into the Royal Navy, became a "boy, first class" on board HMS *Swan* on June 1, 1796. He was soon discharged and entered the merchant service, where he remained until he rejoined the Royal Navy in 1810 as an able seaman. Promotion then became rapid, as Weddell was a highly competent seaman. He was acting master within 1 year and received his warrant as master within 2. With the peace following the Napoleonic Wars, Weddell left the navy and reentered the merchant service.

After a few unremarkable years, Weddell arranged for the firm of Strachan & Gavin, of Leith, together with other investors—of whom one seems to have been Weddell himself—to outfit the brig *Jane* (160 tons) for sealing in southern waters, under his command. During his first voyage, in 1819–1820, Weddell—who, unusually for the time, carried a chronometer and knew how to use it—visited the South Shetland Islands, searched for and failed to find the "Aurora Islands," and wintered in the Falkland Islands, where he prepared detailed notes and charts of anchorages.

Encouraged by the success of the voyage, the investors purchased a diminutive vessel, *Beaufoy* (65 tons), to act as tender to *Jane,* and Weddell again set forth for the sealing grounds in 1821. He visited the Falklands, South Georgia, and the South Shetland Islands, and Michael McLeod, the captain of *Beaufoy,* reached the South Orkney Islands on a scouting mission a mere 6 days after their discovery by George Powell and Nathaniel Palmer. It seems to have been Weddell who named this archipelago when he visited it in *Jane* in February 1822. He charted the islands and, following his usual practice, made such scientific observations as he could.

By this time, Weddell was highly experienced in the sealing trade, and Strachan & Gavin, which seems to have had the same enlightened attitude as did the Enderby Brothers with regard to their captains engaging in exploratory and scientific work when possible, speedily decided on a third voyage. After a complete reequipping, *Jane* and *Beaufoy,* the latter under the command of Matthew Brisbane, who appears to have been an almost exact contemporary of Weddell, departed the Thames in September 1822. *Jane* sprang a leak on the voyage south, and this caused delays, as it was necessary to spend some time in a secure anchorage on the Patagonian coast in order to effect repairs. It became obvious to Weddell that it would not be profitable to head to the South Shetlands because of the lateness of the season and also because most of the seals in that archipelago had, by that date, already been slaughtered. He determined to aim for the South Orkneys, where they arrived after much bad weather, in mid-January 1823. Few seals were secured, but among them was one preserved by Weddell, which later became the type specimen of *Leptonychotes weddelli,* the Weddell seal. Unsatisfied, Weddell determined to seek new sealing islands and to examine the area between the South Shetlands and South Sandwich Islands. Failing in this, he decided to head south. For the first part of the passage the conditions were poor, but in mid-February, extraordinarily late in the season, and well to the south of the Antarctic Circle, the weather ameliorated and rapid progress was made in the desired direction. On February 18, the sea was completely clear of ice—in Weddell's words, "not a particle...was to be seen"—and these conditions continued with a favourable wind "light and easterly" enabling "all sail" to be kept. On February 20, the wind shifted to the south, causing Weddell to reverse course from his farthest south at 74°15′ S, 34°16′ W. No land was in sight.

It is important to appreciate the wisdom of Weddell's decision at this juncture. He was aware that a long and potentially difficult navigation northwards at an unpropitious time of the year awaited *Jane, Beaufoy,* and their crews. Even though further progress could have been made by altering course to southeast or west, Weddell appreciated that disaster loomed for his ships if the weather suddenly turned, as it could easily have done, and that, even if he did discover new sealing grounds, it was so late that most of the seals would already have left.

By mid-March both ships were in Undine Harbour in South Georgia, refitting and refreshing the crews, especially with regard to antiscorbutics, and continuing sealing. Weddell himself devoted much time on charting and making observations of wildlife and other natural phenomena. After wintering in the Falklands, Weddell set off, in October, on a renewed attempt to reach the South Shetlands. Although it was early in the season, this would have been at the optimal period for sealing, and the expedition had so far been woefully unsuccessful in its main aim. However, after a prolonged struggle with the pack, which was very far north, it proved impossible to land, and Weddell headed for Tierra del Fuego. During his sojourn there, he continued with his observations of wildlife, this time also experiencing the novelty of trying to establish relations with the inhabitants, in whom he appears to have had a good deal of interest.

By now anxious about the prospect of having to return home with no seal products, Weddell ordered that the two ships separate, and both thereafter ultimately had some success. *Jane* reached London in July 1824, to find that *Beaufoy* had arrived some weeks earlier.

Partly based on a desire to ensure that his record south be accepted by the maritime authorities, Weddell determined to prepare a book concerning his voyages. This appeared in 1825 under the ponderous title *A Voyage Towards the South Pole Performed in the Years 1822–1824; Containing an Examination of the Antarctic Sea to the Seventy-Fourth Degree of Latitude: and a Visit to Tierra del Fuego* and presented a distillation of his experiences, including comprehensive notes concerning navigation in the difficult waters. It also included his observations on wildlife and contained a proposal for the conservation of seals to ensure continuing future harvests. The book is a masterpiece, and recognition of his work came with his election to Fellowship of the Royal Society of Edinburgh.

Weddell's work at sea as captain of *Jane* continued but not as part of the sealing trade. *Jane* was deemed unfit for further use while at Horta in the Azores, and, after having been shipwrecked on the way home, Weddell became captain of *Eliza,* engaged in the Australia trade. One of the most celebrated coincidental meetings of polar "greats" took place in May 1831, on the Tasmanian coast, when Weddell and his men helped to moor John Biscoe's *Tula,* limping in with a sick crew after her great voyage.

For both Weddell and Brisbane, sad demises were in store. The latter was murdered by gauchos in the Falkland Islands on August 26, 1833. Weddell left the sea after returning from Tasmania in mid-1832. He resided in lodgings in London, where, despite being one of the greatest Antarctic sailors of all time, he died in poverty in September 1834.

WEDDELL, ROSS, AND OTHER POLAR GYRES

The large-scale circulation in the Antarctic Ocean is dominated by the Antarctic Circumpolar Current (ACC) and the subpolar gyres to its south. Whereas zonal flow prevails in the ACC, the large-scale cyclonic subpolar gyres induce meridional flow at their eastern and western rims, westward flow in the southern parts adjacent to the Antarctic continent, and eastward flow in the north. The subpolar gyres are elongated in shape, extending 3000–4000 km zonally and 1500–2000 km meridionally. There are three major gyres: the Weddell, the Ross, and the Kerguelen, which differ in size, flow intensity, and water mass properties. The Weddell and the Ross gyres are related to, but extend well beyond, the large embayments in the Antarctic continent for which they are named. The existence and shape of the Kerguelen Gyre is still a matter of debate.

Flow in the gyres has been determined at specific locations by measurements from ships, buoys and icebergs, or sea-ice drift, and to a lesser degree with current meters. A more comprehensive view of the shape of the gyres has been derived from water mass property distributions. Numerical models of sufficient horizontal resolution also provide useful information on the shape of the gyres and their currents. However, significant parts of the boundaries of the gyres are not fixed by topographical features but by variable water mass transition zones, leading to different estimates of area, depth, and transport from source to source. Further uncertainty results from the southern boundaries of the gyres, where related flows extend onto the continental shelves.

The Weddell Gyre is the largest of the three, extending eastward from the Antarctic Peninsula to about 30° E. It includes the entire Weddell Abyssal Plain and about half of the Enderby Abyssal Plain. Its northern limit is closely related to the southern slopes of the South Scotia Ridge and the Southwest Indian Ridges located between 55° and 60° S. The strong southward bend of the Antarctic Circumpolar Current west of Conrad Rise leads to a water mass transition zone near 30° E, separating the warmer, more saline waters of the ACC from the cooler and fresher Weddell Gyre. Limited by ice-shelf fronts in the south and the oceanic Weddell Front in the north, the Weddell Gyre extends over 7 million km^2, more than twice the size of the Weddell Sea. Its mean depth is near 3900 m, with a maximum near 5600 m in the Enderby Basin. Water mass property distributions and models indicate two embedded subgyres, divided near the Greenwich Meridian, each having volume transports of 50–55 Sv (1 Sv = 1 million m^3/sec). Mean currents in the interior of the Gyre are only on the order of 1 cm s^{-1} but increase to 10–50 cm s^{-1} in the boundaries. Superimposed on the mean flows are mesoscale eddies with comparable velocities. Tidal currents are small in the interior of the gyres but larger over the continental slopes and shelves.

The Ross Gyre extends from the coast of Victoria Land north and east of the Ross Sea into the Amundsen Abyssal Plain. To its northwest the Gyre is bounded by the slope of the Pacific Antarctic Ridge. Its eastern boundary is often located near 130° W, but models indicate a further eastward extension to 90° W, sometimes called the Bellingshausen Gyre. West of 130° W, the Ross Gyre covers an area of 2.4 million km^2 and has a volume transport modelled at 35 Sv. Current velocities are similar to those in the Weddell Gyre; the mean depth is near 3000 m and the maximum 4600 m.

The Kerguelen Gyre extends eastward from the Kerguelen Plateau at about 75° E across the Australian Antarctic Basin, with a northern boundary along the Southeast Indian Ridge. Northwestward flow along the eastern slope of the Kerguelen Plateau clearly shows up in the water mass distributions. Information on its northern and eastern rims results from models, which indicate a gyre flow of 45 Sv. Its area is 2.6 million km^2, mean depth 3900 m, and maximum depth 4700 km.

The origin of the gyres is a combination of wind and thermohaline forcing and the constraints of a bottom topography that has evolved since at least the Jurassic period. Since water mass stratification is normally weak in the polar oceans, currents vary little with depth, allowing bottom topography to exert a strong steering effect on the flow. Exceptions include dense bottom water plumes that can descend the continental slope. Atmospheric forcing of the gyre circulations is related to the transition from westerly winds in the north to easterly winds near the Antarctic coast. This induces opposite directions of flow in the northern and southern limbs of the gyres, and upwelling (Antarctic Divergence) in between. The winds result from the low-pressure belt around the Antarctic continental high-pressure system. The regionally variable wind stress induces sea-surface slopes in geostrophic balance with the ocean currents. While the bottom topography forces northward meridional flows in the west, southward return flows on the eastern limbs are less clear for all three gyres.

The southern limbs of the subpolar gyres sometimes include the Antarctic Coastal Current, and these two flow regimes are often not clearly separated. The bottom inclination at the continental slope often gives rise to a jet-like westward current, in geostrophic equilibrium with density gradients (Antarctic Slope Front) between different water mass characteristics on the shelf and in the deep sea. The northern boundaries of the gyres coincide with the southern boundary of the ACC, also identified by a frontal region. This front can have a double structure, as in the Weddell-Scotia Confluence at the northwestern boundary of the Weddell Gyre, where waters from the Antarctic peninsula continental shelf are injected between those of the Weddell Sea and ACC. Farther to the east the Southern Boundary of the ACC is often called the Weddell Front.

Within the gyres, water properties result from intrusions coming from the Antarctic Circumpolar Current and modifications due the ocean–atmosphere–ice interactions. Circumpolar Deep Water intruding at intermediate depths from the north is relatively warm and saline and rises toward the surface inside the gyres to replace surface water moving toward the boundaries. In winter the surface mixed layer is near freezing (~–1.9°C), and sea-ice formation results in salt release. That brine increases the density of the mixed layer, leading to vertical convection that entrains the Circumpolar Deep Water below. This warms the mixed layer, increasing heat flux to the sea ice and atmosphere. Melting sea ice reduces the mixed-layer density, in turn retarding convection and ice growth, a delicate balance in a region of low vertical stability.

Even more salt is released at the southern edges of the gyres, or their extensions onto the continental shelves, where offshore winds move newly forming ice away from the coastline. This results in the formation of high-salinity shelf water, which is dense enough to sink along the continental slope. There it mixes with colder shelf waters freshened by melting under the large ice shelves, entrains deep water from the gyres, and at some locations becomes dense enough to reach the floor of the abyssal plains. During these processes this dense water with recently "ventilated" components also becomes entrained in the larger gyre circulations, eventually exiting them as Antarctic Bottom Water or in the lowest layers of Circumpolar Deep Water, spreading into the deep basins of the world ocean. The formation of bottom water and the upwelling of deep water in the subpolar gyres are major components of the vertical overturning circulation of the global ocean. The properties and intensity of deep and bottom water formation vary from gyre to gyre.

Deep ocean convection occurred within the Weddell Gyre west of Maud Rise in conjunction with a large and persistent polynya that occurred there in the mid-1970s. However, most modern deep-water modification and bottom water formation is related to processes that take place on the Antarctic continental shelves and slopes. Water mass properties and circulation are subject to decadal variations, with freshening observed during recent decades in the Ross Sea, while bottom water in the Weddell Sea shows a trend of warming and salinity increase. Deep water in the Weddell Gyre increased in temperature until the mid-1990s and has cooled since then. It is not yet clear whether this is in response to decadal variability (e.g., related to El Niño in the form of the Antarctic Dipole) or to trends related to global warming.

The gyre structures impact the sea-ice cover, with the widest sea-ice belts in the Weddell and Ross Sea areas. In the boundary currents the sea-ice thickness of several meters is clearly larger than in the interior of the gyres, where only 50–100 cm are measured. Sea ice is transported out of the gyres toward the north, where it comes into contact with the waters of the ACC and melts. Icebergs also drift in and add freshwater to the gyre circulations. Their drift tracks depend both on the wind forcing and on the compactness of the sea ice.

Although less productive than oceanic frontal regions, the subpolar gyres are also home to a diverse sea life. Various species of whales, seals, and penguins are found, with fish less abundant than around the sub-Antarctic islands. In the Weddell Sea the dominant demersal fish is *Chionodraco myersi* and the pelagic *Pleuragramma antarcticum*. In particular the sea ice accommodates important biota like krill, which utilize the ice cover as an effective overwintering strategy. The gyre flows and upwellings influence the life cycles of plankton and fish larvae.

WEDDELL SEA, OCEANOGRAPHY OF

Discovered and named the George IV Sea in 1823 during a seal hunt on *Jane,* the Weddell Sea was renamed in 1900 for the master of that ship, James Weddell (1787–1834). Nearly 100 years later, Wilhelm Filchner reached the southern coast of the Weddell Sea onboard *Deutschland,* while attempting to determine if Antarctica was a single continent. The Weddell Sea is the southernmost extension of the South Atlantic, indenting Antarctica between the Antarctic Peninsula (~60° W) and Coats Land (10°–35° W). Its southern boundary extends beneath the Filchner-Ronne Ice Shelf, and its northern boundary follows the course of the South Scotia Ridge, extending along ~60° S from the tip of the Antarctic Peninsula to the South Sandwich Islands (30° W). If a line from there to Kapp Norvegia (10° W, 71° S) is taken as the eastern boundary, then the Weddell Sea covers an area of 2.8 million km^2, slightly larger than the Mediterranean Sea, and has a volume of 7.6 million km^3, ~0.5% of the world ocean. A boundary at the eastern end of the Weddell Gyre would encompass a greater area and volume.

At depths >4000 m, the Weddell Abyssal Plain is the deepest portion of the Weddell Sea. It is fringed by a relatively steep (15°–30°) continental slope, carved by numerous marine canyons connecting the abyss with the >500-m-deep continental shelf. This depth is greater than the 200 m typical for continental shelves worldwide and is caused by the load of the Antarctic Ice Sheet. The shelf width ranges from 0–50 km in the east and ~500 km in the south to ~100 km in the west, with a coastline running along the fronts (or grounding lines) of the Riiser-Larsen, Brunt, Filchner-Ronne, and Larsen ice shelves. Two major troughs (Filchner and Ronne) with maximum depths >1200 m have been cut into the southern continental shelf, marking the northward advance of the Antarctic Ice Sheet during glacial times. These troughs and a southward-sloping sea floor support the exchange of water masses between continental-shelf and ice-shelf cavities. Confined by the bottom relief, the ice-shelf base, and the continental margin grounding lines, the Filchner-Ronne cavity is the largest in the Southern Ocean, containing 0.14 million km^3 of water. The flow of waters of circumpolar origin into the Weddell Sea is disturbed by a 1600-m seamount, Maud Rise, centered at 65° S, 2.5° E. The chain of islands (South Shetland

Islands, South Orkney Islands, and South Sandwich Islands) along the South Scotia Ridge is interrupted by gaps as deep as 3000 m, allowing for the escape of dense Weddell Sea waters into the Scotia Sea.

The Weddell Sea climate is influenced by the northward flow of cold continental air and the transit of synoptic low-pressure systems (cyclones) with the westerly winds. Cyclone tracks are determined by a semiannual oscillation, which consists of a contraction and expansion of the circumpolar pressure trough, more southerly in March and September and more northerly in January and July. Sea-level pressures indicate that this oscillation has decreased since the 1970s. Southerly tracking cyclones tend to drift into the edge of the polar cell region, balancing the heat loss from negative net radiation on the elevated ice sheet. As one element of the three-cell structure of the global atmospheric meridional circulation, the southern polar cell is roughly located over the Antarctic continent. Along the coastline, katabatic (gravity) winds carrying cold surface air down from the Antarctic plateau interact with the low-pressure systems, initiating gale-force winds that drive sea-ice formation, sea-ice advection, and the maintenance of ice-free areas (polynyas). This simple picture of atmospheric circulation is strongly modified by the orography of the Antarctic continent, the ocean circulation, and the distribution of sea ice, which reduces the air–sea exchange of heat and moisture.

The annual mean near-surface air temperature in the Weddell Sea decreases southward from –4.3°C (South Orkney Islands) to –22.2°C (Coats Land) with monthly means (January and July) of +1°C and –10°C, and –8°C and –30°C, respectively, at these locations. Interannual variability and trends in near-surface air temperature decrease from north to south, although the significance of trends is difficult to determine because of the relatively short lengths of the time series. A 90-year (1904–1994) record from the South Orkneys reveals a temperature increase of 2°C, while a 40-year (1957–1997) record from Halley Station in the southeastern Weddell Sea shows a slight temperature decrease. It is not yet known whether climatic changes observed in the northwestern Weddell Sea result from local factors or broader-scale circulation changes, but in the latter case there are no obvious links to the enhanced anthropogenic emission of greenhouse gases. In addition to a strong seasonal cycle in all atmospheric properties, the Weddell Sea experiences interannual climate fluctuations characterized by anomalies in sea-level pressure, sea-surface temperature, and sea-ice extent that appear to move around Antarctica at about the speed of the mean ocean flow. Studies of these periodic phenomena, sometimes referred to as the Antarctic Circumpolar Wave, Antarctic Dipole, or Southern Annular Mode, often suggest links to extrapolar variability such as the El Niño Southern Oscillation.

The ocean circulation in the Weddell Sea is dominated by the cyclonic (clockwise-rotating) Weddell Gyre, which displays a double-cell subsurface structure with centers on both sides of the Greenwich Meridian. The southern branch of the gyre is part of the coastal or slope front currents, the latter near the continental shelf break and separating cold shelf waters (~–1.85°C) from warmer open ocean waters (0.5°C–0.7°C). The northern branch of the gyre is guided by the topography of the South Scotia and Mid-Ocean Ridge, and interacts with the southern edge of the Antarctic Circumpolar Current. Southward recirculation at the eastern end of the gyre is poorly defined but may lie near 20° E at the surface and 80° E at depth, where the Kerguelen Plateau is a natural eastern barrier for dense water masses newly formed in the Weddell Sea. The transport of the Weddell Gyre, from *in situ* observations and numerical model studies, is estimated to be ~50 million $m^2\ s^{-1}$, with an interannual variability of ~15%. On the broad southern continental shelf, additional cyclonic circulation cells centered over the Filchner and Ronne Troughs transport ten times less water. Those cells interact with a separate circulation beneath the Filchner-Ronne Ice Shelf, driven by thermohaline (density) differences between water masses on the continental shelf and within the deeper sub-ice shelf cavity.

The Weddell Sea is known for its severe sea-ice conditions, always a threat to the ships that penetrate into this remote region, from *Deutschland* and *Endurance* to *Magdalena Oldendorff,* forced to spend the 2002 austral winter in a sheltered bay near the Greenwich Meridian. Sea ice can be considered a thin blanket between ocean and atmosphere, one that both controls and is controlled by the fluxes of heat, moisture, and momentum across the interface. Sea-ice extent, concentration, and thickness are determined by growth/decay and drift of the ice cover, in turn linked to dynamic and thermodynamic processes in the ocean, ice, and atmosphere. Intensive atmospheric cooling of the ocean surface below the freezing temperature (~–1.9°C on the southern Weddell Sea continental shelf) initiates the formation of sea ice, which then drifts northward and melts near the fringes of the Weddell Sea. The sea-ice cover experiences large seasonal changes, increasing from ~1.5 million km^2 in February to ~7.5 million km^2 in July, when it extends to ~55° S. Due to its annual renewal, the average sea-ice thickness is only ~0.8 m, much less than in the Arctic Ocean. However, extremes range from >3 m for the multiyear ice that survives the summer melt, predominantly in the western sector, to a few centimeters in leads and coastal polynyas.

Polynyas and leads are open water areas in the sea ice field, maintained by tidal action and divergent winds. Near the coastline these often narrow regions are the sites of the strongest sea-ice formation, with rates up to 0.1 m/day (equivalent to 17 m/yr). A much larger polynya appeared in the mid-1970s in the eastern Weddell, covering an area of $\sim$0.25 million km^2 in successive winters. This region near Maud Rise is known for the sporadic occurrence of smaller polynyas or thinner sea ice and is the initial area for the disintegration of the winter sea-ice cover. Large polynyas over the deep ocean may result from a complex interplay between ocean currents and bottom topography, tidal action, and unusual atmospheric forcing. In contrast to coastal polynyas, where the oceanic heat loss to the atmosphere is mostly balanced by the latent heat of fusion of ice, deep-ocean polynyas gain heat by the upwelling of warmer deep water. Under some atmospheric conditions the upper ocean heat flux may exceed 100 Wm^{-2}, while the flux is as low as 3 Wm^{-2} beneath the perennial sea ice. The average ocean heat flux in winter for the entire Weddell Sea is less than 40 Wm^{-2}.

In a deep ocean polynya, densification of the surface layer due to extreme heat loss can initiate convection and cooling to depths of 4000 m. This has consequences well beyond the Weddell Sea (e.g., a colder bottom layer in the Argentine Basin in the late 1980s has been related to the cooling of the deep Weddell Sea during the polynya years of the mid-1970s). However, processes on and near the Weddell Sea continental shelf are generally believed to have larger influences on deep Southern Ocean properties, and ventilation of the abyssal world ocean. New bottom water that is formed in the Weddell Sea corresponds to 25%–60% of the total production of dense bottom water in the Southern Ocean. Outside the Weddell Sea this water mass has historically been referred to as Antarctic Bottom Water and is carried as far as 40° N in the North Atlantic by the global thermohaline circulation. Some of this water may have first been advected into the Weddell Sea from the Indian sector sources off Prydz Bay and Enderby Land. It transports natural and anthropogenic substances from the ocean surface into the deepest layers of the ocean, where they are effectively stored for centuries.

The growth rate of sea ice determines how much brine is expelled to the ocean, increasing its density and causing deep convection. Some of the resulting dense shelf water moves toward the continental shelf break, where it mixes with different open-ocean components of circumpolar origin, ventilating the deep water and forming new bottom water. Some of the salty shelf water also flows into the deep Filchner-Ronne cavity, where its temperature exceeds the *in situ* melting point. This water melts the deep ice-shelf base, acquiring distinctive oxygen-isotope and noble-gas signatures in the process, rising as a plume of Ice Shelf Water with temperatures below sea-surface freezing point. Where Ice Shelf Water exits the cavity and reaches the continental shelf break, mixing with open-ocean components again results in the formation of new bottom water. The sub-ice shelf circulation is subject to seasonal variations, and may be sensitive to climate shifts and related changes in the sea-ice cover, with consequences for ice shelf mass balance. The export of sub-ice melt water affects the vertical stability of the shelf water with consequences for deep convection and sea-ice thickness. The total sub-ice shelf freshwater flux in to the Weddell Sea has been modelled at $\sim$10 thousand $m^2\ s^{-1}$, slightly more than net precipitation, but most precipitation falls in winter as snow transported off the continental shelf on top of the sea ice. For comparison, iceberg calving results in a slightly higher freshwater flux but mainly affects the surface waters of the circumpolar current (i.e., remote from the continent).

Despite its hostile environment, the Weddell Sea is home to a variety of marine animals, including whales, seals, and penguins, even during the austral winter. Their survival depends on the existence of fish, squid, and (especially) krill *(euphausia superba)*, a pivotal organism in the Antarctic food web with a total biomass estimated to exceed the earth's human population. Gigantic krill swarms appear in the northwestern Weddell Sea along the South Scotia Ridge where cold, oxygen-rich waters meet relatively warm, nutrient-rich waters of circumpolar origin, supporting phytoplankton growth. This region coincides with the abundance of large colonies of marine animals on the adjacent islands. Additional feeding grounds exist around Maud Rise and the sill of the Filchner Trough, where relatively warm, nutrient-rich water is displaced upward by the bottom topography. The abundance of krill is also keyed to the presence of sea ice, from the base of which their feeding apparatus can scrape sea-ice algae. The irregular shape of the sea-ice base provides hiding places for the juveniles, from predators like fish, penguins, and seals. The movements of those predators, which can now be tracked with sophisticated, satellite-supported instrumentation, provide information about the temporal and spatial variability of biological production, along with oceanographic and sea-ice conditions. Elephant seals fitted with satellite-linked position recorders on the South Shetland Islands migrated more than 1000 km through the winter pack of the western

Weddell Sea to the northern Filchner Trough, against the flow of the coastal current. Their choice of this track may well be related to the strong current shear that crushes the pack ice, creating breathing holes. This example illustrates the complex interplay of processes in the polar environment, and the importance of interdisciplinary studies.

WEDDELL SEA REGION, PLATE TECTONIC EVOLUTION OF

Looking at the shape of present-day Earth it is difficult to imagine that the current distribution of the continents is just a snapshot of the crust's ongoing evolution. Earthquakes and volcanic eruptions, however, provide indications that the earth is still an active planet with moving continents.

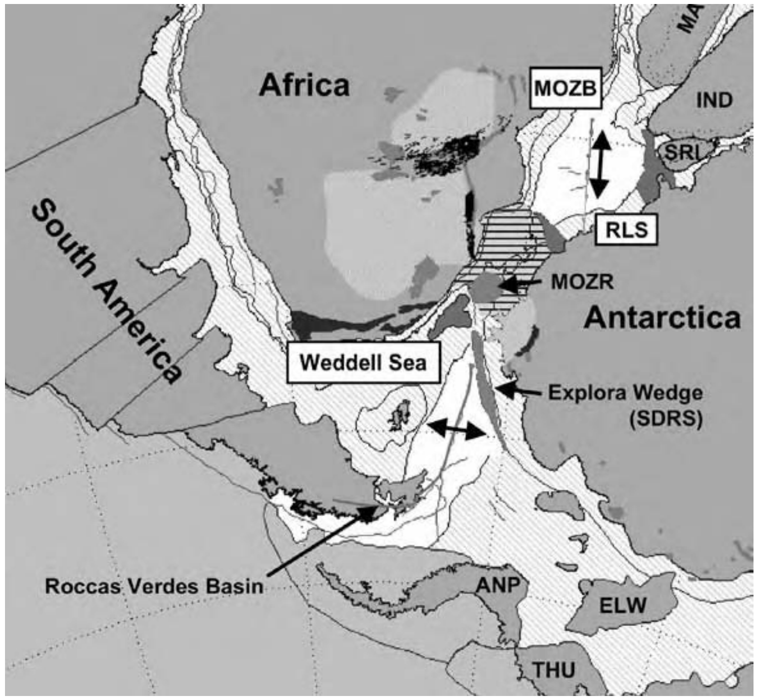
During Alfred Wegener's time (1826–1909), his theory of continental drift was hard for many scientists to believe. Today, we can measure the movements of the continents with high-precision GPS receivers and magnetic sensors. In order to look back in time at the history of continental drift, one has to investigate the magnetic field of the oceanic crust beneath the ocean basins. Here, information on the velocities and directions of the drift paths is stored in the differing magnetisation of the basaltic rocks in the oceanic crust, which results from numerous reversals of the earth's magnetic field during the past 200 Ma.

Marine and airborne magnetic investigations were carried out in the last 4 decades in order to unravel the drift history of the remote Antarctic continent. Combined with all the results from the world's oceans, these data provided a surprising image of the positions of the Southern Hemisphere continents at some 180 Ma. At that time, a large continent, Gondwana, existed in the Southern Hemisphere. South America, Africa, Madagascar, India, Australia, New Zealand, and, as its core, Antarctica, formed a huge land mass covered by widely varying landscapes, including forests. This general picture of the distribution of the continents, proven by magnetic measurements, has been quite well known for more than 3 decades.

Such huge land masses seem, for some reason, not to be stable configurations. At around 160 Ma, Gondwana started to separate step by step into the continental fragments that are known so well today. Although this general model has long been widely accepted, the details of the dispersal of South America, Africa, and India/Madagascar from Antarctica have ever since been the subject of controversy within the scientific community. One of the sources of this controversy is the pack ice around Antarctica, which prevented the investigation of critical parts of the ocean floor (e.g., the Weddell Sea). Special ice-strengthened research vessels are needed to operate in such "hostile" environments. Thus, most models were based on the combination of the sparsely distributed magnetic measurements and the onshore geology of the surrounding continents. Numerous strongly different geodynamic models existed that tried to describe the detailed separation of the southern continents. By the mid-1990s, one of these models proposed that the separation of Gondwana started in the western Weddell Sea at around 180 Ma. The more easterly basins of the Southern Ocean, like the Lazarev and Riiser-Larsen seas, are younger than 160 million years old and thus opened after the western Weddell Sea. In addition to this, the movements of microplates or small continents, and the presence of an extinct subduction zone in the western Weddell Sea, were proposed.

A renewed effort to close these gaps in knowledge started at the end of the 1990s with combined airborne and marine magnetic surveys in the Weddell, Lazarev, and Riiser-Larsen seas, in order to better constrain the early geodynamic evolution of the southern Atlantic and Indian oceans. The results of these detailed surveys were mostly surprising and significantly changed our view of Gondwana breakup.

The key problem in all older magnetic surveys of the South American (50°–08° W) to Indian (40°–70° E) sectors of the Southern Ocean was that the magnetic anomalies could not reliably be dated. A systematic pattern of aeromagnetic survey lines off the German base Neumayer, with a line spacing of 10 km, changed this situation. Clear magnetic lineations could be identified in the South American sector, and linked by a specific marine survey to a magnetic anomaly further north that dates unequivocally to 83 Ma. The oldest anomaly off Neumayer base could thus be dated to about 140 Ma. No clear magnetic anomalies were found in the Lazarev Sea, the western part of the African sector (10° W–40° E). A textbook example of magnetic lineations appeared



The configuration of the southern continents around 145 Ma. The oldest anomalies (thin lines) in the Weddell Sea (WS) and the Riiser Larsen Sea (RLS) are shown. According to the current knowledge in the Lazarew Sea, no spreading was active at this time. The hatched area west of Astrid Ridge indicates the location of a shallow sea or a still subaerial region (Jokat et al. 2003). However, the true sea floor spreading history for the Lazarew Sea is still under investigation. The interpretation shown here might change, if more details on the spreading history of the Mozambique Ridge is known. ANP: Antarctic Peninsula, ELW: Ellsworth-Whitmore Mountains, IND: India, MA: Madagascar, MOZB: Mozambique Basin, MOZR: Mozambique Ridge, RLS: Riiser-Larsen Sea, SDRS: Seaward dipping reflector sequences, SRI: Sri Lanka, THU: Thurston Island. Yellow: areas of old cratons, Red: volcanic material erupted before or during breakup.

again in the next basin to the east, the Riiser-Larsen Sea, the eastern part of the African sector. Here, magnetic anomalies dating back to 155 Ma were identified. These dates show that the opening of the ocean basins and, consequently, the dispersal of Gondwana was not as simple as previously thought; each ocean basin had a quite different history.

This new conceptual model for the region differs considerably in space and time from previous knowledge. In detail:

(1) The first deep-ocean basin to form as a consequence of Gondwana breakup was the Riiser-Larsen Sea, at around 160 Ma, and not the western Weddell Sea.
(2) The western Weddell Sea opened at around 147 Ma, much later than the previous prediction of 180–160 Ma.

As a consequence, these two basins were isolated from each other during their youth, and Africa was still connected to Antarctica in the region of the Lazarev Sea. This scenario is supported by rock samples drilled by the Ocean Drilling Program off Neumayer Base in 1987. Here, black shales were found at 500 m below sea floor, containing fossil fauna that point to an anoxic (oxygen-poor) shallow water environment. The age of the black shales ranges between 138 and 124 Ma.

(3) The detailed magnetic data off Neumayer base show that the young Weddell Sea opened by propagation towards the east.
(4) Finally, at some time between 140 and 135 Ma, Africa split from Antarctica and the Lazarev Sea started to form. Only since that time can a continuous ocean basin have existed from the Antarctic Peninsula to India, which was still attached to Antarctica. The southern polar ocean was born.
(5) All three continents, South America, Africa, and Antarctica, moved away from each other from the beginning of Gondwana breakup. At least 30 Ma of divergent stress finally resulted in the formation of new oceanic crust in the South Atlantic along the coasts of South Africa and Argentina from approximately 140 Ma on.

This prediction opposes all other models, which mainly deal with the South Atlantic independently.

(6) The extensive volcanism in South Africa and Antarctica dating from 183 Ma is not directly related to the formation of new oceanic crust. This strong magmatic activity is rather a precursor to the breakup event that took place 30 Ma later.

(7) The smooth and consistent northward movement of the South American plate in the Weddell Sea is in strong contrast to models that propose the movement of microplates, like the Ellsworth-Whitmore Mountains, in this region. In our current model, there is simply no room for such movements, and no geophysical information exists to support such a scenario.

Finally, it is worthwhile to note that the current model for the Gondwana breakup is consistent with all available geophysical data and most accepted geological interpretations. Despite the remaining problems, the new large magnetic data base provides strong constraints for the model. Research on this issue is ongoing, will further refine the model, and eventually will provide a better understanding on the deeper driving forces of supercontinent breakup.

WEDDELL SEAL

The Weddell seal (*Leptonychotes weddelli,* a member of the true seals, family Phocidae) is one of the largest of all seals, weighing 350–500 kg. Despite its large, rotund appearance, it has an exceptionally small head, characterized by a relatively short muzzle, and disproportionately large brown eyes. On each side of the muzzle there are mobile mystacial vibrissae (used in feeding); on the back of the muzzle are rhinal vibrissae (surfacing), and above each eye there are 5–7 supraorbital vibrissae. The supraorbital vibrissae may help seals squeeze their bodies into tight spaces (e.g., ice holes) without getting stuck. They have short (10 mm), thick fur that is mottled with large darker and lighter patches and dorso-ventrally shaded blue-black on the back grading to silver-white on the belly. At birth, pups have a lanugo of grey-brown hair that they molt 9–21 days postpartum. Adults molt from January through to March. Following pupping, molt is delayed until after that of males and other females.

Weddell seals breed on the fast ice surrounding the shores of Antarctica and are circumpolar in distribution. No other mammal breeds as far south. They are most abundant in the fast ice with breeding concentrations occurring at sites where major perennial (i.e., predictable) tide cracks form in the ice. The seals haul out on the ice surface adjacent to these cracks, and also at tidal cracks that form along the shoreline. Weddell seals maintain access to the surface throughout the winter by reaming the ice with their teeth, which keeps breathing holes open.

Weddell seals are also found in the pack ice, particularly outside of the breeding season. The fast ice is the normal breeding habitat, but there are a few small breeding populations on some of the sub-Antarctic islands. One notable colony of about one hundred seals exists at Larsen Harbour, South Georgia (55° S).

The total world population has been estimated at between 750,000 and 1 million, with major concentrations in the Weddell and Ross seas. The most intensively studied population of Weddell seals is at McMurdo Sound (77° S) in the southern Ross Sea.

Female Weddell seals show variable movements outside the breeding season. Satellite telemetry of females in the Ross Sea has shown that some females are relatively sedentary, not straying from their summer colonies, but most females from the eastern part of McMurdo Sound spend the winter in the middle and northern parts of the sound before the annual shore-fast ice has formed in those areas, or in the pack ice up to 50 km north of the sound. The most far-ranging seals may swim long distances, up to 1500 km, moving extensively across the western Ross Sea. Weaned pups from McMurdo Sound leave their natal area by the end of February and travel north along the Antarctic coastline but remain within the Ross Sea region.

The marine habitat of Weddell seals is relatively well known compared to most other species of Antarctic seal. In McMurdo Sound, seals use all parts of this deep fjord (maximum depth >850 m). Weddell seals are renowned for being deep divers, and in McMurdo Sound they usually dive between 100 and 350 m. They have been recorded diving to at least 760 m. Female Weddell seals appear to use the entire water column for feeding, with very little time spent at the bottom, although the types of prey captured suggest that most feeding occurs in the middle of the water column and near the bottom.

Pupping begins earlier in the year at lower latitudes; with the first pups born in late August at Signy Island, South Orkney Islands (60°43′ S) and at South Georgia (55° S). At their farthest south in McMurdo Sound (77° S), pregnant females do not arrive at breeding areas until early October and they give birth to a single pup in October or early November. Mothers stay with their pups on the sea ice for about the first 12 days and from then until the end of lactation (at about 45 days) spend increasing amounts of time in the water. As in other phocid seals, there is a postlactation estrous.

The mating system is one of slight to moderate polygyny with the most successful males mating with three to four females within any one season. Male territories are probably set up early in the breeding season, and male vocalizations that are thought to function as a breeding display are most common in October and November. Spermatogenesis is initiated in August and viable sperm are produced from October through December. Weddell seals mate under the ice during late November and throughout December. By January males become azoospermic. Males first show spermatogenesis at three years, but these males are still physically immature and will not attend breeding colonies until they reach 5–7 years of age. Successful males are generally older than 7 years and have been found holding territories at breeding colonies up to at least 13 years of age.

In McMurdo Sound, the average age of first reproduction is 6 (range 2–11) years, but further north the age of first reproduction is delayed, with the average age at Signy Island being 7 years and at the Vestfold Hills (68° S) 8 years. The annual reproductive rate is approximately 0.68, varying between 0.55 and 0.75. This variation occurs in a predictable 4- to 5-year cycle and may be correlated with the Antarctic Circumpolar Current. Once they have commenced breeding females continue to reproduce throughout their life (18 years or longer), and there is no evidence of reproductive senescence. Like many long-lived animals, it appears that experience counts. Pups have a higher chance of surviving if their mother is older or has had more pups in previous years.

Pups weigh 22–30 kg at birth and double their weight in the first 10 days as they feed on extremely high-fat (60%) milk. They are weaned at 6–7 weeks of age and at a weight of about 110 kg, which means that pups triple their weight during lactation. Pups enter the water from 2 weeks of age and start diving almost immediately. Over the first 3 months of life their skill at diving improves rapidly. The first dives by pups rarely exceed 20 m and 2 min, but by weaning they are diving to 50–70 m for 3–4 min and already capturing the notothenioid silverfish *Pleurogramma antarcticum;* by 12 weeks they regularly dive to 100 m for 5–6 min.

Preweaning mortality is low in Weddell seals, with a mean of 13% but varies significantly with the age of the mother. Survival from 0–1 years is on average 42.9%, from 1–2 years 63.5%, and from 2–6 years 80.6 %, which is comparable to adults. Juvenile survival overall (0–6 years inclusive) is lower for males at 9.3% than for females at 14.2% and is also a function of the mother's age and experience, as mothers aged 10 years and older are much more likely to successfully wean their pup. The minimum adult male (5 years and older) survival rate of Weddell seals in McMurdo Sound is 76.2%, with the oldest male surviving to 22 years. The survival rate of adult females is about 85% per annum but declines to 74% from 10 years and older. The oldest females recorded have been 25 years of age.

Female Weddell seals in McMurdo Sound range from 187 to 265 cm, nose to tail length. The weight of mothers immediately after pupping is highly variable with 14 postpartum mothers weighing between 342 and 524 kg and an average of 447 ± 52 kg. Like most phocid seals, females principally use stored blubber reserves during lactation. However, as the lactation period is particularly long in Weddell seals, many females must actively hunt during lactation. Despite this additional feeding, the large amount of high-fat milk fed to the pup is very costly, and mothers lose up to 250 kg or 59% of their body weight during lactation at an average rate of 4.5 kgd^{-1}. As a result, nonbreeding females may be larger than breeding females.

There is no sexual dimorphism, and males range from 201 to 293 cm in length. Like females, males vary considerably in mass between years, presumably as a result of variation in food availability between years. Males lose weight over the course of the breeding season, although less than females. For example, at Razorback Island in McMurdo Sound in 1986, males weighed between 283 and 414 kg (mean = 365 kg) at the beginning of the breeding season. By the end of the season these same animals weighed 185–332 kg (mean = 273 kg) with a mass loss of 2–3 kgd^{-1}. In 1997–1999 at Turtle Rock (also in McMurdo Sound), males weighed 315–465 kg (mean = 393 kg) at the beginning of the breeding season and 294–429 kg at the end (mean = 348 kg).

The sex ratio of females to males at colonies varies from 2.8:1 to 8.9:1 during the course of a breeding season. Adult males establish underwater territories and defend them against other males, with territories changing in size over the course of the breeding season and displacements occurring after repeated challenges to established males. Males share breathing holes, but the volume of individual male territories may vary fivefold.

Weddell seals are the most vocal of all seals, with twenty-one to forty-four vocalization types. The number and type of vocalizations varies both with season and the location around the Antarctic continent. During the breeding season males call almost continuously when in the water, and males are the only animals to emit low-frequency (1- to 6-kHz) trills (in McMurdo Sound) or songs (in the Vestfold Hills Fjords). These male calls may act in territorial defense or as a form of display to attract females.

Weddell seals feed principally on fish and cephalopods, although they are also known to eat crustaceans. Krill have not been found in Weddell seal stomachs or scats. The predominant prey species, both by frequency of occurrence and by weight, in McMurdo Sound, at Davis Station, and in the Weddell Sea, is the Antarctic silverfish, *P. antarticum*. The Antarctic silverfish makes up more than 90% of the fish biomass in McMurdo Sound. Other important fish prey species include the pelagic nototheniids *Pagothenia borchgrevinki* and benthic *Trematomus* spp. Weddell seals are renowned for hunting large Antarctic cod *Dissostichus mawsoni*. Weddell seals approach large prey from below, and they have also been observed blowing air bubbles to flush *P. borchvgrevinki* out of the platelet ice immediately below the fast ice. Yearling Weddell seals in McMurdo Sound show different foraging strategies according to their size. Larger yearlings make long, shallow dives and appear to forage on benthic species such as *Trematomus* spp., whilst smaller yearlings forage in the water column on similar prey species to adults'. Weddell seals have on occasion been observed killing and eating penguins including gentoos and chinstraps.

Adult Weddell seals suffer little from predation because they are relatively inaccessible in the regions of fast ice and heavy pack ice. However, some Weddell seals, especially younger seals, are preyed upon by killer whales and to a lesser extent by leopard seals, particularly in the spring and summer when the ice breaks up.

Weddell seals were mainly protected from commercial hunting by their inaccessibility. However, near research stations, seals were killed to provide food for sled dogs, until dogs were banned under the Madrid Protocol, with the last dogs removed from Rothera Station in February 1994. All killing of seals in the Antarctic region is regulated by the Convention for the Conservation of Antarctic Seals (CCAS) and the Antarctic Treaty.

There is a single isolated population at White Island (78° S), which is cut off from the main McMurdo Sound population by an 18-km-wide unbroken ice shelf that is 10–100 m thick. The thirty-odd seals in this population produce three to five pups per year and have a higher rate of neonatal and preparturient mortality than in the main McMurdo Sound population. The pups also often have congenital deformities, which may indicate a degree of inbreeding. White Island animals are larger than elsewhere, with females weighing up to 686 kg and males up to 554 kg.

WEST ANTARCTIC RIFT SYSTEM

The West Antarctic rift system encompasses all of West Antarctica except the Antarctic Peninsula. Topographically, it is dominated by a sub-sea-level trough that extends 3000 km from the Ross Sea, through the interior of West Antarctica to the Bellingshausen Sea. It is bounded along most of its length by the Transantarctic Mountains (TAM) and Ellsworth Mountains, which rise abruptly from –500 to –1000 m depths along the trough to summits of 4000–5140 m. This view of the rift system is deceptive, however. In addition to topography, the rift is defined by attenuated continental crust, block faulting, and alkaline volcanism. These features occur throughout coastal Marie Byrd Land (MBL) and Ellsworth Land. They indicate that the rift extends across the sub-sea-level trough to the coast, with no evidence for a northern boundary of unextended crust. It is thus highly asymmetrical, in contrast to many other rift systems. The MBL coastal highland is a volcano-tectonic dome that has risen within the rift system in late Cenozoic time, as described below. Early descriptions of the rift focused largely on the sub-sea-level trough and did not recognize the nature of the dome (Behrendt et al. 1991; LeMasurier 1978, 1990; Tessensohn and Wörner 1991).

Topographic Expression of Rifting

The earliest definitions of continental rifts were based on the distinctive topography of the "rift valley," or "graben," of East Africa (Gregory 1896; Seuss 1891), long before the tectonic significance of these features was understood. The West Antarctic rift is fully as large as those in East Africa, or the Basin and Range, but is unusual in the extensive sub-sea-level elevation of the main trough and the great depths of smaller ice-filled basins.

A north–south and east–west grain is expressed by the orientations of smaller basins within the trough. In the interior of MBL the Bentley subglacial trench and Byrd subglacial basin reach maximum depths of –2555 and –2000 m, respectively, and are oriented east–west. A narrow basin 250 km south of the Flood Range is more than 1500 m deep, and oriented north–south, and a trough of similar dimensions between the Crary Mountains and Mount Takahe is oriented west-northwest–east-southeast. The Ross Sea is underlain by three comparatively shallow (<1000 m) asymmetric basins, separated by rises (<500 m), all oriented roughly north–south. The thickness of the basin fill provides another perspective on these depths. The Byrd subglacial basin has only 0.5 km of sedimentary fill, whereas the Victoria Land basin, in the western Ross Sea, is filled with up to 14 km of late Mesozoic and younger strata (Cooper et al. 1991a).

Crustal Structure

During the International Geophysical Year (1957–1958), gravity surveys across West Antarctica revealed the large sub-sea-level trough, determined that it was underlain by continental crust ~30 km thick, and discovered the abrupt transition across the TAM front to crustal thicknesses of ~40 km (Bentley et al. 1960). Recent studies have largely confirmed these findings. Ritzwoller et al. (2001) found an average crustal thickness of ~27 km for the rift system, compared to ~40 km for East Antarctica. They show an area of low seismic wave velocities (reflecting high upper-mantle temperatures) that neatly defines the full area of the rift system from the Ross Sea to the Bellingshausen Sea, and from the TAM to the coast. They also show a well-defined asthenosphere (incipiently molten upper mantle layer) between ~55- and ~200-km depths, throughout the rift system. By contrast, seismic velocities in the Weddell Sea basin are significantly faster (cooler mantle), suggesting that this region is not now a part of the rift system. The Weddell Sea is underlain by oceanic crust that formed between ~155 and ~130 Ma (König and Jokat 2003).

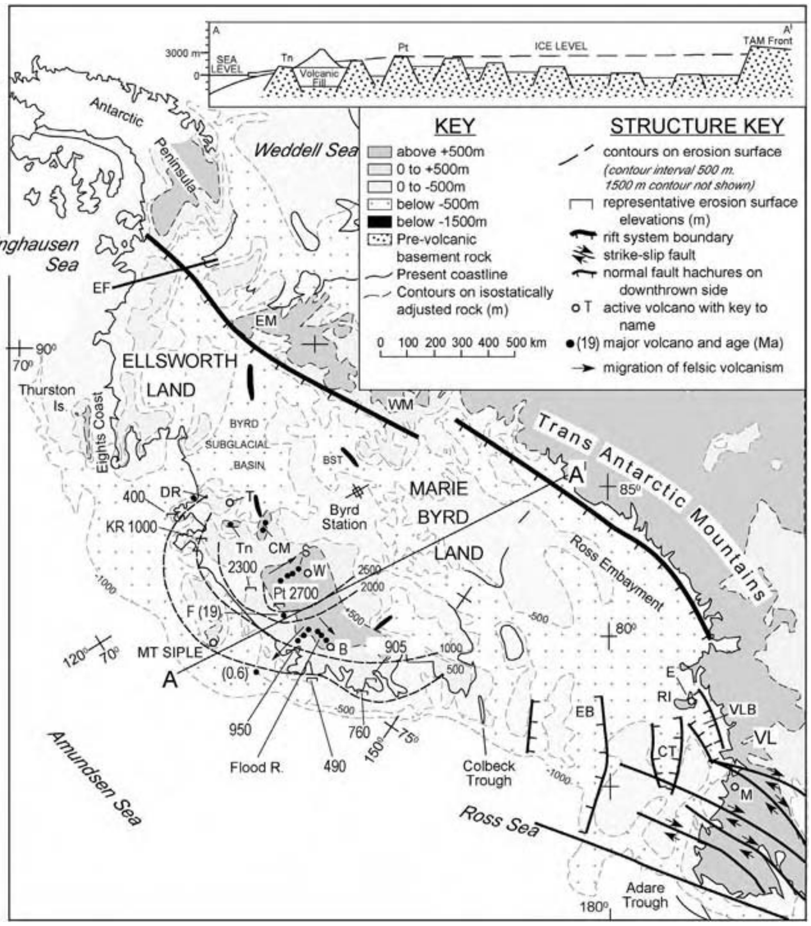
Winberry and Anandakrishnan (2004) found thicknesses of 21–31 km for the entire rift system, and only 34 km for East Antarctica. Their data also show a 21-km crust beneath the Bentley subglacial trench, a 25-km crust beneath the MBL dome, and faster mantle velocities in the rift interior compared to the dome region. Their crustal thickness beneath the dome is significantly less than previous estimates, implying that dome uplift is supported by low-density mantle. The thickness beneath the Bentley trench is one of the thinnest ever reported for the rift system, similar to estimates of ~20 km beneath the Ross Sea (Behrendt et al. 1991) and 19–23 km under the Victoria Land Basin (Cooper et al. 1991b).

The crust of West Antarctica is a collage of four continental blocks: the MBL, Thurston Island–Eights Coast, Ellsworth Mountains–Whitmore Mountains, and Antarctic Peninsula blocks. Each is characterized by somewhat different geologic assemblages and/or paleomagnetic pole positions, and each is separated from the other by deep subglacial troughs (Dalziel and Elliot 1982). Paleomagnetic data indicate that they moved relative to each other and to East Antarctica during the breakup of Gondwana in Mesozoic time (Grunow et al. 1987; Luyendyk et al. 1996). A conspicuous example is the 90° clockwise rotation of the Ellsworth Mountains, which was completed in early to mid-Cretaceous time (Grunow et al. 1987). Only two of these blocks, MBL and Thurston Island–Eights Coast, lie within the rift system, and the others lie on its flank. They do not define the rift in any sense but are simply components of crustal architecture.

Tectonic Structures

Ross Sea Sector

This is the "Ross Sea rift," as originally defined by Tessensohn and Wörner (1991). It is interesting to



Topography and structure of the West Antarctic rift system. Ice-free, isostatically adjusted bedrock topography is simplified from Drewry (1983). MBL dome structure is from LeMasurier (2005) and LeMasurier and Landis (1996). Victoria Land faults are simplified from Salvini et al. (1997). Ross Sea basins are simplified from Cooper, Davey, and Hinz (1991). The rift boundary between Ross Island and Adare trough has been omitted, to avoid clutter. B: Mount Berlin, BST: Bentley Subglacial Trench, CT: Central Trough, CM: Crary Mountains, DR: Dorrell Rock, E: Mount Erebus, EB: Eastern Basin, EF: Ellsworth Fault, EM: Ellsworth Mountains, F: Mount Flint, M: Mount Melbourne, RI: Ross Island, S: Mount Sidley, T: Mount Takahe, Tn: Toney Mountain, VL: Victoria Land, VLB: Victoria Land Basin, W: Mount Waesche, WM: Whitmore Mountains.

compare this sector with MBL, for an impression of different tectonic environments within the rift. The major structural features in the Ross Sea basin are three large north–south-trending grabens. Some narrow, deep basins that feed into the Ross embayment from the TAM (Drewry 1983) are clearly extensions of glacial valleys, overdeepened by erosion. However, seismic work in the Ross Sea has shown conclusively that the Victoria Land basin, Central basin, and Eastern basin are fault-controlled, asymmetric grabens (Cooper et al. 1991a). In the eastern Ross Sea, other north- to northwest-trending grabens (e.g., the Colbeck trough) have been mapped by Luyendyk et al. (2001).

The TAM front, which forms most of the southern rift boundary, is the most conspicuous structure in the entire rift system. Along the western Ross Sea, the boundary is marked by a series of northwest–southeast-trending, right-lateral, strike-slip faults, which are oblique to the mountain front (Wilson 1995). These structures are apparently inherited from the accretion of Proterozoic terranes in early Paleozoic time (Kleinschmidt and Tessensohn 1987). Salvini et al. (1997) propose that they are linked northwestward to transform faults along the Southeast Indian Ocean ridge, and southeastward to the Ross Sea basins. They suggest that extension and subsidence of the basins was driven by displacements along these faults. On the other hand, Fitzgerald and Baldwin (1997) argue that the asymmetric form of the Ross Sea grabens implies they were formed by displacements along low angle detachment faults. This mechanism also implies ~100% extension. Mylonitic gneisses dredged from the Colbeck Trough provide evidence of extension and fault displacement, around 98–95 Ma, and strain fabric analysis of the mylonites suggests 85%–100% extension (Siddoway et al. 2004).

Marie Byrd Land–Ellsworth Land

Coastal MBL is a largely ice-covered highland that appears to have experienced nearly continuous uplift and volcanism since the Eocene. It began with intrusion of the Dorrel Rock gabbro around 34 Ma, and was quickly followed by uplift and erosion of 3+ km of overlying rock, mainly in Oligocene time (Rocchi et al., in review). Around 29–27 Ma, the focus of uplift shifted 600 km westward, where dome uplift coupled with volcanism began at Mount Petras. The MBL dome is defined by elevations of a very low relief erosion surface exposed in block faulted nunataks, where it bevels mid-Cretaceous and older rocks. The elevations of these blocks rise from 400–800 m along the coast, and to 2700 m at Mount Petras, defining a dome ~800 km across, with perhaps 3 km of structural relief (LeMasurier and Landis 1996). Eighteen felsic volcanoes are distributed across the dome, mainly in north–south and east–west chains that appear to be fault controlled. The oldest volcano (19 Ma) is at the dome crest, and the others become younger toward the flanks, where all the active volcanoes are found. This pattern and the systematic increase in age with elevation of basalts that rest on the erosion surface demonstrate a very close association between dome growth and volcanism. The two patterns together suggest that the dome has been rising since 27–29 Ma, at ~100 m/my (LeMasurier and Landis 1996; LeMasurier and Rex 1989).

Farther east, the Ellsworth fault forms the southern boundary of the Antarctic Peninsula block, near the eastern boundary of the rift system. Kellogg and Rowley (1991) suggest that this fault is an on-land continuation of the Tharp fracture zone, a part of the Pacific–Antarctic ridge and transform fault system, that was active from ~85–50 Ma (Barker 1982). Other more westerly, sea-floor fracture zones trend southward toward the MBL coast, suggesting that the north–south and east–west fault systems, and perhaps the interior basins in MBL, may have been controlled by them during the MBL–New Zealand breakup, between 90 and 79 Ma (Larter et al. 2002).

Rift Volcanism

The earliest rift-related igneous activity is recorded by a 48-Ma gabbro in northern Victoria Land (Tonarini et al. 1997) and the 34-Ma gabbro in MBL. Volcanism has continued episodically to the present day, where it is represented by continuous activity at Mount Erebus, and by evidence of late Pleistocene activity at Mount Melbourne (northern Victoria Land) and Mounts Takahe, Berlin, Siple, and Waesche in MBL (McIntosh and Wilch 1995; Wilch, McIntosh, and Dunbar 1999; Wörner and Viereck 1990).

The largest of the well-exposed volcanoes are Mount Erebus (3795 m) and Mount Siple (3110 m), each with an exposed volume of ~1800 km^3 and more than 3000 m of relief (LeMasurier 1990). For comparison, the largest volcano in the Cascade Range, Mount Shasta, has a volume of 350 km^3 (Christiansen 1990). The highest volcano is Mount Sidley (4181 m), but like most MBL volcanoes it is partly buried beneath the continental ice sheet, and its total volume cannot be estimated. There are eighteen of these large volcanoes in MBL and a similar number along the Ross Sea coast. Many are composed largely or entirely of felsic rock (a rock like phonolite or rhyolite, composed of abundant light-colored minerals [Jackson 1997]); others are mainly basalt with a felsic cap. Small (<1 km^3) volcanic cones are much more abundant. These are mostly basaltic, and are distributed throughout the western Ross embayment and MBL provinces and in small volcanic centers on the coast of Ellsworth Land (LeMasurier 1990). Although felsic rocks are conspicuous, because they occur in large volcanoes, they appear to be subordinate in volume to basalt. In MBL, felsic rocks are believed to represent 10%–30% of the volume of volcanic rock (LeMasurier et al. 2003). Aeromagnetic data over the interior of West Antarctica have been interpreted to represent subglacial volcanic fields with a volume exceeding 1 million km^3 (Behrendt et al. 1994). This interpretation is supported by Ritzwoller et al. (2001) but is not consistent with cooler mantle in the interior (Winberry and Anandakrishnan 2004) or with the scarcity of volcanic rock in West Antarctic ice stream cores (Vogel 2004).

The alkaline volcanoes of the rift system include examples of a distinctive rock type called "rhomb porphyry," or "kenyte," first described from the Oslo rift and East African rift, respectively, and recognized by the presence of large (~5-cm), elongate feldspar crystals with rhombic cross-sections. Alkaline rocks are so named because they are relatively rich in the alkali elements sodium and potassium. This is expressed mineralogically by abundant alkali feldspars and by the common presence of green and blue alkali pyroxenes and amphiboles, normally visible only under a microscope. These rocks are geochemically indistinguishable from those found in oceanic island volcanoes, but the volume of felsic rocks in the rift system is large compared to oceanic volcanoes. Felsic rocks throughout the rift show little or no evidence of crustal contamination. They are essentially mantle-derived rocks produced by fractional crystallization of basalt at various levels in the crust (Kyle, Moore, and Thirlwell 1992; LeMasurier et al. 2003). Volcanoes found elsewhere in the Pacific "rim of fire" originate above subduction zones and are consequently more contaminated by the crust, more water-rich, and more explosive than those in the West Antarctic rift.

Rift History and Evolution

Our understanding of the evolution of the West Antarctic rift system is sketchy because so much of it lies beneath thick ice cover. The following outline is an attempt to briefly list major events that have been more or less agreed upon.

(1) *Jurassic*. Schmidt and Rowley (1986) used the distribution of late-Jurassic flood basalts, erupted during the separation of India and Africa from East Antarctica, to define a Jurassic "Transantarctic rift system" that formed along the TAM, from the Ross Sea to the Weddell Sea. The extension into the Weddell Sea was progressively blocked off by rotation of the Ellsworth Mountains, resulting in the present extension into the Bellingshausen Sea, which probably dates from the early Cretaceous.

(2) *Mid-late Cretaceous extension.* The interval from ~110–80 Ma, prior to and during the breakup of New Zealand and West Antarctica, is believed to be the main period of extension and crustal thinning in the rift system (Lawver and Gahagan 1994). Evidence for prebreakup extension includes (1) 90- to 110-Ma mafic dikes in MBL that trend east–west, parallel to the continental margin (Storey et al. 1999), (2) exhumation and rapid cooling of mid-crustal rocks in MBL between 105 and 94 Ma (Richard et al. 1994), (3) 98- to 85-Ma Ross Sea mylonites noted above, and (4) structural and stratigraphic evidence of rifting in New Zealand, extending back to ~100 Ma (LeMasurier and Landis 1996, and references therein).

(3) *Late Cretaceous breakup and subsidence.* Breakup began ~90 Ma, and New Zealand separated from MBL during the interval 83.0–79.1 Ma (Larter et al. 2002). The West Antarctic erosion surface, and a contemporaneous surface in New Zealand, record prolonged late-Cretaceous tectonic stability and erosional leveling, which extended across West Antarctica and contiguous portions of prebreakup New Zealand. After breakup, this was followed by subsidence to the –500-m to –1000-m levels that characterize most of the rift system today (LeMasurier and Landis 1996).

(4) *Cenozoic Transantarctic Mountain uplift and Ross Sea subsidence.* Apatite fission track analyses provide evidence for TAM uplift in the Early and Late Cretaceous and early Cenozoic (~55 Ma), with about 5 km of uplift since early Cenozoic time (Fitzgerald 1992; Fitzgerald et al. 1986; Stump and Fitzgerald, 1992). Episodic subsidence and extension of Ross Sea basins appears to have accompanied mountain uplift (Cooper, Davey, and Hinz 1991), but the main phase of uplift began around 55–50 Ma (Fitzgerald and Baldwin 1997), more than 30 m.y. after the main phase of extension. Cenozoic extension has been reported along the axial part of the Victoria Land basin ("Terror rift"), beginning in the Eocene (Cooper, Davey, and Behrendt 1991). Cande et al. (2000) report evidence for ~180 km of east–west extension across the Adare trough between 43 and 26 Ma. The great depth of the MBL interior basins implies that the ice is itself part of the basin fill, and that some extension has taken place there since the development of the ice sheet, probably in the early Miocene (Bart 2003; LeMasurier and Rocchi 2005). This is consistent with evidence for "locally extreme extension" beneath the Bentley subglacial trench (Winberry and Anandakrishnan 2004).

(5) *Mid-Cenozoic to recent volcanism; growth of the MBL dome.* Igneous activity has accompanied TAM uplift and Ross Sea subsidence since 48 Ma along the southern boundary of the rift. Rocchi et al. (2002) propose that this was initiated by plate motions that opened the Adare trough ~43 Ma, reactivated the northwest–southeast fault system, and induced decompression melting in the sublithospheric mantle. In MBL, 2000 km to the east, there is as yet no evidence for a plate-tectonic mechanism that could produce persistent dome uplift and volcanism since Oligocene time. Mantle plume support of the MBL dome has been proposed by LeMasurier and Landis (1996). This is consistent with the high elevation and

thinner crust over the dome (Winberry and Anandakrishnan 2004), and with seismic tomographic images that show vertical low-velocity structures extending down to the mantle transition zone beneath the MBL volcanic province (Sieminski et al. 2003). It is also consistent with the stationary plate environment of Antarctica that volcanism and uplift have remained focused at one spot since ~27 Ma, rather than producing the more familiar unidirectional volcanic chains associated with moving plates.

Summary

The West Antarctic rift system is similar to others in its attenuated crust, alkaline volcanism, and extensional fault structures. It is unusual in its pronounced asymmetry, largely sub-sea-level elevations, and the predominance of oblique strike-slip faults, rather than range-parallel normal faults, along the Victoria Land mountain front. The asymmetry seems to be a result of prolonged mid-Cretaceous extension that separated the northern rift flank (New Zealand) from Antarctica, leaving an ocean basin in between. This is one of the least-studied rifts on Earth, and much is still to be learned. Among the most vexing problems are (1) the cause and mechanism of TAM uplift, (2) the amount and timing of extension, and (3) what lies beneath the ice sheet. The latter is perhaps the most intractable problem, but it conceals evidence that bears on the total volume of rift-related volcanic rock, and hence the thermal context of rift evolution, and it conceals sedimentary basin fill that could elucidate the timing and magnitude of extension.

WHALES: OVERVIEW

Species Found in the Antarctic

The cetaceans, members of the order Cetacea (from the Latin "cetus," a large sea animal, and the Greek "ketos," a sea monster) are the most highly adapted of the aquatic mammals, spending their time exclusively in water. They comprise what are commonly known as whales, dolphins, and porpoises. However, the distinction between these is somewhat confused, with, for example, several members of the family Delphinidae having common names using the word "whale" (e.g., the killer whale, *Orcinus orca*) and some species generally known as "small cetaceans" that are larger than some known as "Great Whales" (e.g., Arnoux's beaked whale, *Berardius arnuxii*, is larger than the Antarctic minke whale, *Balaenoptera bonaerensis*).

This article focuses on the traditional Great Whales. Of the thirteen recognised species, eight spend a part of each year feeding in the Antarctic. All but one are members of the suborder *Mysticeti,* the baleen whales. There are six species of the family Balaenopteridae, the rorquals: the blue whale *(Balaenoptera musculus);* the fin whale *(B. physalus);* the sei whale *(B. borealis);* the Antarctic minke whale *(B. bonaerensis);* the dwarf form of the common minke whale *(B. acutorostrata);* and the humpback whale *(Megaptera novaeangliae)*. The blue whale comprises two subspecies, the "true" blue whale *(B. m. musculus)* and the pygmy blue whale *(B. m. brevicauda)*. There is also one member of the Balaenidae (*Eubaleana glacialis,* the southern right whale). The only member of the suborder Odontoceti or toothed cetaceans considered here is the sperm whale (family Physeteridae, *Physeter macrocephalus*). There are several populations of each of the species found in Antarctic waters.

Adaptations

Fossil whales go back to at least the Middle Eocene (c. 55 Ma). The most obvious adaptations from terrestrial mammals relate to changes in body shape as a result of their aquatic environment (e.g., streamlining). Power is provided by the large tail and horizontal flukes (fish tails operate in a vertical plane), whilst "steering" is provided by the flippers (adapted forelimbs); the rear limbs are vestigial. The skull has adapted in many ways, the most apparent being the presence of "blow holes" (paired in Mysticetes, single in Odontocetes) on top of the head. Whales have almost eliminated hair, and the skin is smooth (except where infested by parasites) and flexible to reduce resistance; the thermal function of hair is replaced by a thick layer of fatty tissue called "blubber." Bone structure has also been modified to improve buoyancy and take account of the denser aquatic environment. Other important adaptations include those related to diving (e.g., lung size, blood supply, and physiology).

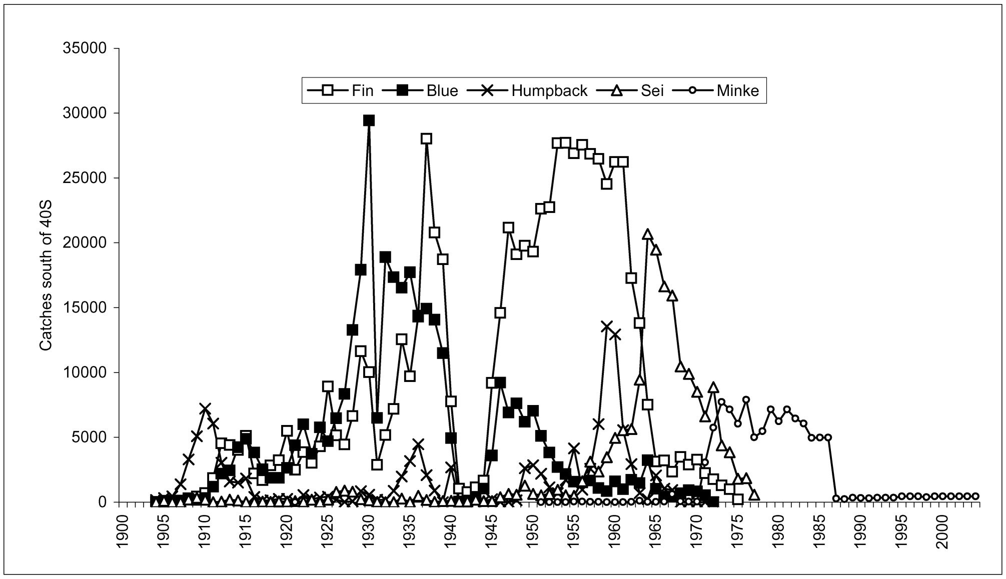
As noted above, baleen whales are called after their "baleen." They have several hundred elongated triangular baleen plates growing down on either side from their upper jaw. Although popularly called "whalebone," they are made of a horny material (keratin) and not bone. The baleen plates are 1–3 cm (1/2–1 inch) apart and fringed internally with fibres forming a sieve. The whale filters large mouthfuls of water containing the shrimps or other small crustaceans or fish on which it feeds. Female baleen whales are generally about 5% larger than males.

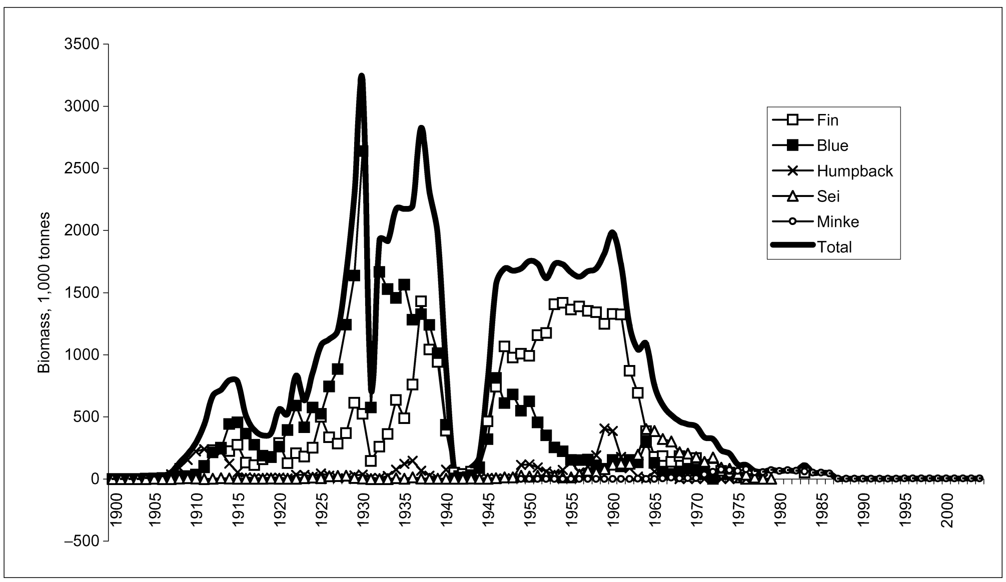
The rorquals (from the Norse for "grooves") are the most streamlined of the baleen whales. They are named after the grooves that run from the lower jaw to the abdomen, which allow the mouth to expand to dramatically increase the volume of water engulfed when feeding, whilst still allowing streamlined swimming when not feeding. The members of the genus *Balaenoptera* are the most streamlined and the most obvious difference between them is their size, ranging from the true blue whale (average 25–27 m) through the fin whale (average 21–22 m) and sei whale (average 15–16 m) to the Antarctic minke whale (average 10–11 m). The other rorqual, the humpback whale (average 13–14 m), is less streamlined and has much longer flippers. By contrast, the remaining Antarctic baleen whale, the southern right whale (average 14–15 m) has no grooves but a huge mouth framed by a bowed lower jaw. Consequently it is less streamlined and a much slower swimmer.

The sperm whale is easily recognised by its huge head (comprising about 1/3 of the body) containing the waxy spermaceti oil. This has been linked with both diving ability and sound production. Sperm whale males are considerably larger than females (c. 15–20 m versus 10–13 m).

Distribution and Migration

Whales are a migratory species, with baleen whales migrating between the summer feeding grounds in the





Top: Graph showing catches of the rorquals from 1904–2004 for the region south of 40° S. Bottom: Graph showing the approximate biomass removal for the rorquals that fed in the Antarctic from 1900–2004. It includes catches from throughout their range. Average weights for the species were assumed to remain constant throughout the time period (blue, 88 tonnes; fin, 50 tonnes; humpback, 27 tonnes; sei, 18.5 tonnes; minke, 9 tonnes).

Antarctic and the winter breeding grounds in tropical or semitropical waters (although the locations of the breeding grounds are only known for the humpback and southern right whales). Little or no feeding occurs outside the feeding grounds so the animals have to build up vast energy reserves (stored as blubber) during the feeding season. The sperm whale is somewhat different, with only older large males migrating to the Antarctic and no evidence that they do not feed at other times of the year.

In general, the whales found in the Antarctic spend only the austral summer there, taking advantage of the extremely high productivity at that time of the year, although there is increasing evidence (e.g., from acoustics) that some animals remain in the Antarctic much longer and may not migrate some years.

The timing of the migration into Antarctic waters differs somewhat by species. Whaling data suggest that blue whales reach the Antarctic before fin whales, with sei whales arriving last of all. Minke whales seem to spend the least time in the Antarctic, peaking in late December and leaving by late February. Humpback whales arrive about the same time as minke whales but leave later. Sperm whales peak between late December and mid-February. The length of time spent on the feeding grounds may be related to body size and reproductive condition. For baleen whales, there is also evidence of different reproductive classes migrating at different times. Pregnant females, for example, arrive earliest on the feeding grounds and leave latest, presumably to build up sufficient energy reserves for lactation.

There is also a general pattern of segregation of species, presumably related to prey availability and niche separation. For example, most true blue and minke whales are found in the high productivity waters near to the ice edge. Distribution of most fin and sei whales seems to be related to the Antarctic Convergence, with fin whales found between around 55°–62° S (i.e., just south of the convergence) and sei whales mainly on or near the convergence, although large adults can be found near the ice. Pygmy blue whales and dwarf minke whales tend to be found at similar latitudes to fin whales. Right whales and humpback whales have been found as far south as the ice edge, although they are thought to be more prevalent north of 55° and 60° S, respectively. Sperm whales are most commonly found south of around 64°–66° S.

Although all but pygmy blue whales have a circumpolar distribution, there is a general tendency for lower densities in the region between about 80° and 150° W. Sperm whale densities are highest from 90°–120° E and 150°–180° E.

Diet

The primary food source of all of the baleen whales (except the sei whale), and indeed many other species ranging from fish through birds to seals, is krill, *Euphausia superba,* a shrimp-like crustacean that is found throughout the Antarctic. Only very-high-density swarms of krill provide suitable food for whales, since the energetic costs of swimming through the water with an open mouth are high. This requirement will be reflected in the distribution of whales. In addition to some geographical segregation, different requirements for sizes of swarms may reduce competition between species found in the same areas, such as the smallest rorqual, the minke whale, and the largest, the blue whale, which are both found near to the ice edge. Sei whales feed on a wider range of species, including a different Euphausiid *(E. vallentini)* as well as copepods (e.g., *Calanus tonsus*) and amphipods (e.g., *Parathemisto gaudichaudii*).

In the Antarctic, sperm whales feed primarily on large squid, the main species being *Moroteuthis knipovitchi, Kondakovia longimana,* and *Mesonychoteuthis hamiltoni,* although other species including fish (e.g., *Ceratius holbolli* an angler fish) are eaten. Krill is the primary food of several squid species.

Life History and Social Structure

Whales are generally typical "K-selected" mammals, with low birth rates, slow growth, late maturation, and high survival rates.

Compared to odontocetes, baleen whales appear to have a relatively simple reproductive strategy and social structure, although little is known about the balaenopterids. There are no lasting male–female bonds, and males compete with each other for females. This can be either directly, as in humpback whales, where male fights can be quite violent, or indirectly, via sperm competition as in the southern right whales which have amongst the largest testes of any whales, species (the weight of both testes can exceed 900 kg, whereas the testes of the much larger blue whale weigh around 70 kg) or some combination of both. Humpback whales also exhibit "singing" behaviour to attract females. Large aggregations of feeding baleen whales can sometimes be seen in the Antarctic, although the degree of cohesion of these is unclear. Only for the humpback whale is there good evidence of cooperative feeding.

Gestation in the baleen whales is thought to be around 1 year. Almost exclusively, there is only one foetus, and there is no evidence of surviving twins. Neonates tend to be around 30% of the length of adults. There is some variation in calving rate by species, ranging from one per year in Antarctic minke whales to one every three years for southern right whales. The other rorquals generally have one calf every 2 years. The mother–calf bond is relatively short in baleen whales, with most weaned by the time they reach the feeding grounds (i.e., by about 4–7 months)—whale milk is extremely nutritious. The age at first calving is around 5–10 years. Longevity appears to be related to body size, with minke whales living to 50–60 years whilst fin and blue whales may reach up to 100 years.

Sperm whales have a much more complex matriarchal social structure. The basic social unit comprises 10–15 adult females and their young. Females give birth about once every 5 years and reach sexual maturity at about 9 years. These social groups remain in warm to temperate waters north of around 40° S. Males leave the family unit from about 5–15 years old, forming loose ''bachelor'' aggregations. The size of these aggregations decreases with age, the largest and oldest individuals usually being seen alone. It is the larger older animals that enter Antarctic waters. Only the large socially mature males (over about 25 years old) participate in mating, although they may spend only a few hours with the females. Teeth marks suggest considerable male–male competition.

The primary predator of whales is the killer whale *(Orcinus orca),* which is common in Antarctic waters (and indeed elsewhere) and has been known to attack both adults and calves of all species, even the blue whale. There have been some suggestions that killer whale predation may play an important role in Antarctic minke whale dynamics.

Status

The primary factor affecting the status of the whales that visit Antarctic waters has been whaling. The Antarctic was the scene of the heaviest modern whaling and several species were greatly reduced, despite the introduction of international regulations from 1946. However, whaling outside the Antarctic also had a major impact on some species. For example the southern right whale was severely reduced by whaling, largely on its breeding grounds, even before the advent of modern whaling. At least in terms of numbers, catches were relatively small in the Antarctic (over 3000 between 1951 and 1971 by illegal Soviet operations, compared to total Southern Hemisphere catches of up to 164,000 prior to 1920), although this would have been sufficient to impede recovery. The humpback whale was caught in both its feeding and its breeding grounds (again, in the latter case it had also been caught prior to modern whaling).

Antarctic whaling began in 1904 and expanded dramatically, particularly with the invention of the stern slipway, which allowed factory ships to operate in all Antarctic waters. The worst hit was the true blue whale, which was reduced to a tiny fraction of its original population size (although estimating preexploitation size is not easy), but the fin, sei, and humpback whales were also reduced to low levels. Only the Antarctic minke whale has been relatively unaffected by whaling operations.

The primary method for estimating abundance of cetaceans is by sightings surveys. These provide an estimate of a number of animals in a particular geographic area at a particular time. The International Whaling Commission has been conducting a series of sightings surveys in the Antarctic, mainly in waters south of 60° S, as they have been primarily directed at Antarctic minke whales. As the distribution of several of the species extends further north than this, the estimates for those species are only partial estimates. In addition, for certain species with appropriate natural markings (humpback, southern right, and sperm whales), estimates can be obtained from mark–recapture estimates based on photographs. Estimating abundance and trends for cetaceans is difficult, especially for such a vast area as the Antarctic. However, it is encouraging that for a number of species, there are signs that at least some populations are increasing.

Trophic Interactions

It seems inevitable that the exploitation of seals (especially crabeater seals, *Lobodon carcinophagus*) and whales must have had a major impact on the balance of the Antarctic ecosystem. It is questionable, even in the absence of human activity, whether the original balance can ever be restored. For example, if the unexploited population of blue whales in the Antarctic was around 200,000 and the present population is as many as 2000—then the reduction in blue whale biomass is some 16–20 million tonnes. Depending on a number of assumptions, this could amount to a reduction in krill consumption amounting to anything from 35 to 90 million tonnes of krill each year. Taking all marine mammal harvesting into account, estimates of as much as 55–165 million tonnes of ''surplus'' krill per year have been made for the exploited versus unexploited Antarctic, although such estimates are contingent on important and unverifiable assumptions.

The possible effects of this ''surplus'' are difficult to determine, and a number of different hypotheses have been proposed. From a baleen whale perspective, these include suggestions that there have been increases in Antarctic minke whales in response to the decline in blue whales that have inhibited the recovery of the latter. Others have suggested that it is unlikely that there is any interspecific competition at all between whales and that food has never been a limiting factor in whale dynamics in the Antarctic. To properly understand the true situation may never be possible. It will require sophisticated ecosystem modelling of all aspects of the past and present Antarctic. Even if appropriate models can be developed, it is

Crude Summary Information Relevant to Status of Some Whales Found in Antarctic Waters

Species	Approximate Total Catches (% S of 40° S)	"Original" Size	Present Abundance (and Year Applicable)	Evidence of Trend	Method	Area Covered
True Blue	358,000 (95%)	200,000–240,000	1700 (1996)	+2%–8%	Sightings	South of 60° S
Fin Whale	702,000 (97%)	200,000–400,000	5500 (1996)	Unknown; suggestions of increase in some areas	Sightings	Partial, south of 60° S
Sei Whale	203,000 (88%)	Unknown	Unknown	Unknown	n/a	
Antarctic Minke Whale	118,000 (88%)	Unknown	Analyses in progress; perhaps around 300,000	Unknown, but apparent decline Being investigated	Sightings	South of 60° S
Humpback Whale	164,000 (72%)	75,000–100,000	30,000 (recent)	+10% per year in Australia	Mark–recapture, sightings	Most areas, including outside Antarctic
Southern Right Whale	167,000 (2%)	60,000–100,000	7500 (1997)	+7%–8% per year	Mark–recapture	Primarily breeding areas off S. Africa, Argentina, and Australia
Sperm Whale	340,000 (63% since 1900)	Unknown	Unknown	Unknown	Mark–recapture	Only available for small local areas

There is considerable uncertainty in many of these estimates, especially of initial population sizes, which, where they exist, are based upon modelling exercises. Estimates of present abundance often have wide confidence intervals. The estimates are summed for the total circumpolar region and are not broken down by population, even where known. Catches are for the whole Southern Hemisphere, not just the Antarctic, and for the years 1904 to the present, except for southern right whales, the catch number of which includes figures from 1770.

questionable whether sufficient data exist or can be collected that will allow an unambiguous modelling exercise to occur, either in terms of explaining the past or predicting the future. Added to these difficulties are the potential effects of climate change and global warming on the Antarctic, and in particular krill and other krill predators. It is particularly important that efforts to monitor abundance be maintained or increased.

WHALING, HISTORY OF

Antarctic twentieth-century whaling was an industry very different from whaling in earlier times. It was "industrialized" and large-scale to a much greater extent than before. New whale species were chased on new whaling grounds. New whaling nations that had not taken part in world whaling before entered the business. On the other hand, the country that had completely dominated nineteenth-century whaling, the United States, almost disappeared from the industry. With New England as a base, the nineteenth-century industry had been global, with catching grounds in the Arctic, the North and South Atlantic, the Indian Ocean, and the North and South Pacific. It was only to a very limited extent that the American whalers ventured into Antarctic waters. Whales were chased around the sub-Antarctic islands, but the major catching grounds were farther north. Nineteenth-century economic exploitation of Antarctic resources was instead left to sealers. They were replaced by the new whaling industry in the early twentieth century.

The Antarctic Whaling Industry: Whales Killed 1909/1910–1979/1980

Year	Number of Whales killed
1909/1910	6099
1919/1920	5441
1929/1930	30,655
1939/1940	32,900
1949/1950	32,396
1959/1960	38,892
1969/1970	11,949
1979/1980	8074

The Exploratory Phase

Antarctic whaling had its origin in Norway, where so-called "modern" whaling was conceptualized in the 1860s by Svend Foyn. His system of whaling, using a powerful steam whale-catcher boat equipped with an explosive grenade harpoon gun, was distinctly different from old whaling, and made possible the catching of the large, fast swimming rorquals (blue whales, fin whales, humpback whales, and sei whales). The new industry grew in Norway towards the turn of the century. However, by the 1890s there were clear signs of depletion of the whale stocks, and the whalers started to look for new hunting grounds. This brought them to Iceland, Spitsbergen, and the Antarctic.

Both in Australia and in Scotland plans for whaling in Antarctic waters were discussed beginning in the 1870s. They were well known in Norway. In the early 1890s, four expeditions sailed south from Scotland and Norway in search of new whaling grounds. Two consecutive Norwegian expeditions with *Jason* became most important for the future development of the trade. They were initiated by the whaling and shipping owner Christen Christensen and captained by Carl A. Larsen. On the second trip, Larsen visited South Georgia and made his first plans for a whaling shore station there. His third Antarctic trip also was important. With the Swedish South Polar Expedition (1901–1904), he again visited South Georgia and saw Grytviken for the first time: a sheltered harbour that had earlier been used by American sealers. After the expedition, Larsen ended up in Buenos Aires, where he collected local support for the foundation of the first Antarctic whaling company, Compañia Argentina de Pesca. In 1904 Larsen and a group of Norwegian whalers arrived in Grytviken and set up a whaling shore station there.

The expeditions of the 1890s had been pursuing bowhead (southern right) whales. Larsen for the first time brought a small steam whale-catcher boat to southern waters to chase the rorquals, thus starting the era of modern whaling in Antarctica.

Early Antarctic Whaling Grounds

From the beginning in 1904, the industry expanded in two geographical areas, South Georgia and the South Shetland Islands. The industry was also from the beginning organised in two different ways: with a shore station or a floating factory ship as the base for the activity.

At South Georgia, many whalers followed in the wake of Larsen's establishment. In a matter of a few years, six whaling stations had been erected: Grytviken, Husvik Harbour, Stromness Harbour, Leith Harbour, Ocean Harbour, and Prince Olav Harbour. The companies were of several nationalities, but a majority of the whalers were recruited in Norway.

The year after Larsen established himself at Grytviken, Christen Christensen sent his floating factory ship *Admiralen* to the South Shetland Islands and started whaling in Admiralty Bay, King George Island. The next to appear in the South Shetlands was Adolf A. Andresen. He had already introduced modern whaling in Punta Arenas. Now he brought his new floating factory ship *Gobernador Bories* to Deception Island. This peculiar island was a perfect shelter from the rough Antarctic winds. Whalers Bay at Deception Island and Admiralty Bay at King George Island became the centres of whaling operations in the South Shetlands. In 1909 nine large factory ships moored along the shores of Whalers Bay—or "Factory Bay," as it was called at the time. Many factory ships also explored farther south along the Antarctic Peninsula. They came back year after year to sheltered bays and inlets such as Port Lockroy at Wiencke Island, Neko Harbour at Danco Coast, and many, many more. In the peak whaling season before World War I, twelve floating factory ships operated in the South Shetland whaling grounds.

Thus, while South Georgia became the center of shore station whaling, the South Shetland Islands became the center of whaling with floating factory ships. However, South Georgia was also visited by factory ships, and one shore station was erected in the South Shetlands—at Deception Island in 1912.

Shore station whaling also spread to other locations in the Antarctic area. At Îles Kerguelen (South Indian Ocean), a station was erected from 1908. At Signy Island in the South Orkney Island, where floating factories had been operating from 1912, a Norwegian company erected a small station in 1921.

Pelagic Whaling

In the mid-1920s a major transformation took place in the Antarctic whaling industry. The whalers had gradually diminished the whale stocks in the coastal waters of South Georgia and the South Shetlands. An expansion of the industry had also been restricted in these areas due to British sovereignty and concessions. The whalers therefore thought of ways to move their operations farther away from the shores into other parts of the Southern Ocean. Once again C. A. Larsen lead the way when he took a whaling expedition through the pack ice and into the ice-free Ross Sea in 1922.

Bringing the factory ships into the ice and moving them along the ice edge off shore demanded larger and better vessels. An important technological breakthrough was the whaling factory ship *Lancing,* which was equipped with a stern hauling-up slipway in 1925. The whales could then be hauled onto the ship's deck and processed in a much more efficient way than before—when the whales had been flensed along side as in the old whaling days.

The new whaling grounds and better technology led to a dramatic expansion in Antarctic whaling from the late 1920s. The industry had entered a new era, which has been characterized as "pelagic" whaling. The factory ships used for these operations were among the largest ships of the time. Some were rebuilt tankers or ocean-liners. Some were new, like *Kosmos* of 17,801 tonnes, built for Norwegian owners at Workman Clark, Belfast, in 1929. It signified a new design that from then on dominated the industry.

Pelagic whaling took the whalers away from the South Shetlands and the sub-Antarctic islands and all the way around the Antarctic continent. The whaling expeditions sailed along the northern extension of the ice and gradually moved south as the ice retreated throughout the southern summer. The main whaling grounds were in the Southern Ocean between South America and eastwards to Australia.

The industry grew towards the peak whaling season of 1930–1931. In that season forty-one floating factory ships and six shore stations operated, with about 200 catcher boats. The result was about 40,000 whales killed, producing more than 3 million barrels of oil. Never before or after were so many blue whales (29,410) killed in one season.

The whaling industry experienced the same turmoil as most other industries in the world economy in the early 1930s. In 1931 it was clear that the demand for whale oil could not match the record-high production, and most of the whaling fleet was left in the buoys for the 1931–1932 season. Shore stations closed down, and several companies permanently went out of business. With the exception of three stations at South Georgia (Grytviken, Leith Harbour, and Husvik Harbour), no Antarctic shore stations survived the economic crises. They were abandoned and left to decline.

The whaling industry revived in the late 1930s, and a record 46,000 whales were killed in the 1937–1938 season. But again the industry was brought to an almost complete standstill—this time by World War II. The whaling factory ships were used for the war effort on both sides as tankers and cargo ships. They faced heavy losses, and the world fleet of whalers was reduced by 1945 to less than half its prewar size. Many questioned whether the industry should be started up again. However, high demand and prices led to new expansion, and whaling again became a lucrative business for several countries. The result once more was an overexpansion, and collapse was inevitable. Diminishing catches and returns and increased international control gradually put an end to most commercial Antarctic whaling from the 1960s.

Whaling Nations

Norway was the pioneer nation of Antarctic twentieth-century whaling, and, together with Britain and Argentina, had the longest involvement in the industry. Argentina's activity was connected to one company that owned the Grytviken whaling station at South Georgia—a station primarily manned by Norwegian whalers. Norway and Britain, on the other hand, were the home countries of most of the major whaling companies. There were also strong ties between the two, and the period until the mid-1930s may be called the Norwegian–British hegemony of Antarctic whaling. From then on their dominance was challenged by new whaling nations, most importantly by Japan and Germany, which entered Antarctic whaling in the middle of the 1930s. Japan soon almost equalled the two whaling pioneers.

After World War II, the Netherlands (which had formerly been very active in Arctic whaling) went into the business. So did the Soviet Union, and, together with Japan, it took a leading role in Antarctic whaling in the 1950s and 1960s when British and Norwegian operations were gradually phased out. Several British and Norwegian floating factory ships and whale catcher boats were sold to Japanese whaling companies in the 1950s and 1960s.

Other countries that became involved in Antarctic whaling included Panama and the United States—but primarily as registries for whaling companies based in other countries. The United States, which had dominated global whaling in the nineteenth century, never became greatly involved in twentieth-century Antarctic whaling.

All nations except Japan and the Soviet Union abandoned Antarctic whaling in the 1960s. After the whaling moratorium of 1982, the Soviet Union gradually decreased its whaling, while Japan to this day has continued limited Antarctic whaling for small minke whales for scientific purposes. The Japanese, however, have announced intentions to increase their whaling activities.

Products

In old-style whaling, the main output was oil and whalebones (baleen). Oil from the blubber of the right whales and the case of the sperm whales was mainly used for lighting, lubrication, and producing soap. Whalebones were made into various products in the preplastic era. In the early days of Antarctic whaling, oil was still used for its traditional purposes, but the market had, to a large extent, been taken over by mineral oils. However, an important scientific discovery of the first decade of the twentieth century led to new uses of whale oil. The hydrogenation process allowed fluid oil to be transformed into solid fats. By this process, whale oil could be utilized as an edible fat and was able to be used for human consumption. It became an ingredient in several products. The main one was margarine, which became the single most important product of the industry during its heyday in the 1920s and 1930s, and again after World War II, when demand for edible fats was high in many countries.

In the initial years of Antarctic whaling, most expeditions primarily sought the oil-rich blubber. Soon, however, the remainder of the carcass, meat and bone, were also used to extract oil. This left remains that were ground and dried and made into the guano or whale meal used for animal food or as fertilizer. The shore stations, which had available space for such plants, particularly specialized in these products. A third product was frozen whale meat for human consumption. While this became a main product for the Japanese Antarctic whalers, European whalers only took up this product to a limited extent, especially after the 1950s, together with other so-called "byproducts" as meat-extracts.

How important in economic terms was the Antarctic twentieth-century whaling industry? Although whale oil never represented more than a fraction of the world supply of edible fats, it met a demand—particularly in Europe—in the interwar years and the early years after World War II, when there was a general shortage in supply. Whaling never became a very important industry of their home countries. The exception was Norway, a small economy with a disproportionately large share of the whaling companies and the employment, especially during the early industry and throughout the 1930s. Since most of the products went into the export markets, the currency income was of significance.

Work and Organization

A whaling expedition consisted of the floating factory ship or the shore station together with workers, crew, and catcher boats. In the early years, the number of catcher boats per expedition was not often more than two or three. After the Second World War, more than ten could be employed by one expedition. The crew likewise increased through the years as the vessels and stations grew larger, exceeding 300 per expedition. The whalers' payment was based on a lay system.

Antarctic whaling was, because of the climate, always undertaken on a seasonal basis—usually no longer than from October to April. Between the seasons, whalers left for their home countries. At the shore stations, a smaller maintenance crew usually stayed throughout the winter.

Whaling expeditions were dominated by men. Only on occasion did a few women (sometimes with children) stay at shore stations, usually accompanying the managers. The shore stations, especially the most developed ones at South Georgia, appeared as small industrial villages. The processing plant was the core of the station. There were also workshops, a small shipyard, living barracks, messes, storage facilities for provision and products, cinemas, cemeteries, soccer fields, and ski-jumps. The floating factory ships had, of course, more limited space, but basically performed the same core functions as the shore stations. The primary task was to process the whales that had been killed and towed in by the catcher boats. Blubber, meat, and bones were steam-cooked in different plants to extract the oil. Numerous methods were then used to purify the output, from clearing tanks to mechanical separators. The solids that remained were input in the production of the whale meal. Other plants took care of the byproducts. Whaling was indeed a sophisticated processing industry. If the expedition focused on frozen meat, as many of the Japanese whalers did, separate refrigerator vessels were employed.

Regulation and Control

For most of the period, Antarctic whaling faced regulations and control in one way or another. Almost from the beginning, the British government restricted the number of companies and the number of whale catchers that were allowed to operate in British territories. It also introduced legislation limiting the waste from the processed whales: full utilization was required.

The pelagic whaling of the late 1920s evaded these rules and led to a dramatic overexploitation. After the crises of the industry in the early 1930s, the two leading whaling nations, Britain and Norway, negotiated voluntary quota agreements between the whaling companies in an attempt to limit the catches. The number of expeditions was reduced. So was the size of the production. However, the expansion of the industry in the late 1930s, with new whaling nations entering the industry, undermined the regulations.

An important new phase of controlling the Antarctic whaling industry started with the establishment of the International Whaling Commission in 1946. From then on, restrictions on catches, season length, and catching areas were imposed. The commission decided on annual global quotas for the industry. In 1963 blue whales and humpback whales were protected. This was a long-overdue decision. The killings of blue whales had already peaked in 1931, indicating a diminishing of the stocks. After that time, whalers gradually shifted their attention to the smaller sei and fin whales—and in later years even to the small minke whales that no one had bothered to catch in the early years of Antarctic whaling.

Despite restrictions and reduced quotas, the exploitation of the whale stocks was too high even throughout the postwar years. The Antarctic whaling industry was finally more or less closed down, not because of restrictions but because of lack of whales and profitability for the companies involved.

The whaling industry—today and historically—has been criticised for lack of control and overexploitation. Whaling in Antarctica throughout the twentieth century obviously depleted the whale stocks to such an extent that it is uncertain whether they will ever recover. From this perspective, the history of whaling is a sad story. On the other hand, whaling was also an important industry of its day that generated useful products and employment. As in previous centuries, it was also a history of skills, exploration, and adventure.

WILD, FRANK

Frank Wild spent more time in Antarctica during the Heroic Age of Antarctic exploration than anyone else. Altogether he served on five Antarctic expeditions: the British National Antarctic Expedition of 1901–1904, under Robert Falcon Scott, Ernest Shackleton's British Antarctic Expedition of 1907–1909, Douglas Mawson's Australasian Antarctic Expedition of 1911–1914, Shackleton's Imperial Trans-Antarctic Expedition of 1914–1917, and the Shackleton-Rowett Expedition of 1921–1922. He also led the British government-sponsored mission to Spitsbergen in 1918–1919 after Shackleton, the original leader, was posted to northern Russia.

Wild's record is unique, yet there was nothing particular in his background to denote any special aptitude for or affinity with polar exploration. There was a belief in the family that Wild's mother was descended from Captain James Cook, and Wild was very proud of this relationship, although it proved untrue. The only other member of the Wild family to go on a polar expedition was Frank's younger brother Harry Ernest, who was a member of the ill-fated Ross Sea Party of the Imperial Trans-Antarctic Expedition.

John Robert Francis Wild was born on April 10, 1873, the second of thirteen children born to Benjamin and Mary Wild. Benjamin Wild was a school teacher, originally in Yorkshire, where Frank was born. In 1888 Wild joined the merchant navy, in which he served for 12 years. In 1900 he joined the Royal Navy, and soon after he saw the notice that Scott was looking for volunteers for the Antarctic expedition in *Discovery*. Wild was one of 6000 in the Royal Navy to apply and—as he was just under 5 feet 5 inches tall—was surprised to be accepted.

Wild made a number of significant contributions to the *Discovery* Expedition, including leading several of his comrades back to base in terrible weather and harrowing circumstances after one of them, George Vince, fell to his death. Scott spoke highly of Wild's service and recommended him for promotion, which followed with Wild's elevation to the rank of petty officer.

On that expedition, Wild had struck up a friendship with Shackleton, the third lieutenant. In 1907 Shackleton specifically asked Wild to join his British Antarctic Expedition in *Nimrod.* Wild was one of three men who accompanied Shackleton on the southern journey, attaining a point only 97 geographical miles (112 statute miles or 180 km) from the South Pole. It was that experience that made Wild "a Shackleton man." Upon his return home, Wild bought himself out of the Royal Navy. When Scott later asked Wild to join his second Antarctic expedition he declined. Scott, he felt, was "too much the navy man." Instead, he accepted Douglas Mawson's invitation to join his Australasian Antarctic Expedition, which was to explore as much as possible of the coastline of the "Australian Quadrant" of Antarctica, that area south of Australia.

Mawson wrote about his decision to take Wild in his book *The Home of the Blizzard:* "Wild had already distinguished himself in the south on both the Scott and Shackleton expeditions. He is now in the position of being, as it were, the oldest resident of Antarctica. Our sojourn together at Cape Royds, as fellow members of the Shackleton expedition, had acquainted me with Wild's high merits as an explorer and leader."

Wild was in command of the Western Base, which included seven other men, all either Australian or New Zealanders, none of whom had been to the polar regions before. Six of them were under the age of 26, and five were university educated. The party was landed from *Aurora* on an ice shelf (now named the Shackleton Ice Shelf) more than 1000 miles (1600 km) away from Mawson's main base at Commonwealth Bay. The shelf could have calved away and the party been swept out to sea, but Wild took full responsibility for the decision to land.

Wild's party was there for 1 year. They made six separate sledge journeys, mapped some 350 miles (560 km) of coast line, went inland onto the plateau, visited the extinct volcano Gaussberg, and made valuable meteorological, biological, and geological studies. There were no casualties, the party had no major internal strife, and all members spoke highly of Wild's leadership.

Shackleton then asked Wild to be second-in-command of his Imperial Trans-Antarctic Expedition, which was to cross Antarctica from Vahsel Bay in the Weddell Sea to the Ross Sea. Wild's participation was crucial: in the months spent on the ice while *Endurance* was trapped, in the boat journey to Elephant Island, and then, most important of all, for the 4 and a half months in 1916 when Wild was the leader of the remaining 21 men of the expedition waiting for rescue while Shackleton sought help. To maintain the health and morale of the disparate group of men for that period when they had no idea if Shackleton would ever return, were short of food, and had little chance of being able to achieve any rescue themselves, was an example of leadership second only to Shackleton himself.

On his return to England, Wild volunteered for war service. He was given a temporary commission in the Royal Naval Reserve, sent on a Russian language course, and posted to Archangel as RN transport officer during the time of the British intervention in the Russian Civil War. He was there for 1 year, and then Shackleton asked for him to join him on a mission to Spitsbergen to establish a British and Allied presence there and forestall any attempt by Germany to set up a base. Before they reached Spitsbergen, however, Shackleton was recalled to Murmansk, and Wild became the mission leader. He was in Spitsbergen for 12 months, most of the time searching for mineral deposits, as the Germans had already abandoned any idea of establishing a military presence there.

Wild went to Nyasaland in 1920 (with James McIlroy, one of the surgeons from *Endurance*). While there, he received a telegram from Shackleton asking him and McIlroy to join him on another Antarctic expedition, in a small ship, *Quest*. They did, but Shackleton died on board at South Georgia in January 1922 and Wild took command. The purpose of the expedition had never been hugely clear, but Wild got the assent of the other nineteen members to carry on. They went along the coast of Antarctica, landed on Elephant Island (although not the side where the *Endurance* party had spent 4 and a half months), visited several other Antarctic islands, and arrived back in England 12 months after they had left. With no coherent plan for the expedition, a small ship, bad weather, and inadequate equipment, it took both skill and firmness to ensure that the expedition achieved what it did.

Quest returned to England in September 1922. Five weeks later Wild married Vera Altman (whom he had met in Archangel after she had travelled across Russia from Vladivostok), and the following year they emigrated to Natal. Wild's attempts at farming there failed, and he took a variety of jobs in Rhodesia, on the border of Swaziland, and in the Transvaal. In 1928 he was divorced, but three years later he married Beatrice Rowbotham, a South African woman. He had little capital and at one point considered selling his Polar Medals and his other medals to raise money.

Eventually in 1939 the British government awarded him a small pension, but he died shortly afterwards of pneumonia, in Klerksdorp, Transvaal, on August 19, 1939. He was cremated at Braamfontein Cemetery in Johannesburg.

Most leaders and other major figures on Antarctic expeditions have been criticised (sometimes severely) in written accounts, diaries, or memoirs. Virtually never, however, was there any criticism of Wild's role, work, or leadership in any of the expeditions in which he participated: a unique tribute for a unique man.

WILKES, CHARLES

American naval officer Charles Wilkes (born April 3, 1798, in New York City) commanded the US Exploring Expedition of 1838–1842—the first voyage of discovery funded by the US government—which surveyed vast tracts of the Pacific Ocean, the Pacific Northwest of North America, and a 1500-mile stretch of Antarctic coastline fronting on the Indian Ocean, now known as Wilkes Land. Wilkes has also been credited as the first person to recognize Antarctica as a continent.

The youngest of four children of a successful businessman, Wilkes lost his mother before he was 3 years old. After attending several boarding schools, he became interested in following the sea. He made two transatlantic merchant voyages, then obtained a midshipman's warrant in the US Navy in 1818, rising to lieutenant in 1826.

On his early naval voyages, Wilkes developed skills in astronomy, geodesy, and hydrography, particularly during a survey of Narragansett Bay in 1832–1833. In 1833, he was put in charge of the Depot of Charts and Instruments, the forerunner of both the Naval Observatory and the Navy Oceanographic Office.

Wilkes sailed to Europe in 1836 to purchase instruments for the US Exploring Expedition, which Congress had authorized that May. While in Europe, he met and worked with many of the leading scientists of the day. Upon his homecoming in early 1837, however, the expedition was in disarray, so Wilkes spent that summer and fall surveying the Georges Bank and the spring of 1838 surveying the Savannah River area.

After several more senior officers had declined or been relieved of the command, Wilkes was offered leadership of the Exploring Expedition in March 1838. His brother-in-law, noted engineer James Renwick (Wilkes had married Jane Renwick, a childhood friend, in 1826), proved an important advocate for Wilkes within the political establishment and helped him gain the position.

Despite protests by many jealous senior officers, Wilkes was the best-suited officer in the US Navy for the task, thanks to his surveying expertise and his work with many prominent scientists. He moved quickly to prepare and outfit the squadron's six vessels, select the officers and men, and trim the overly large scientific staff.

The expedition sailed from Hampton Roads, Virginia on August 18, 1838. When it returned 4 years later, unfortunately, its many important accomplishments were overshadowed by a web of courts-martial between Wilkes and four of his officers. Wilkes was widely considered a vain, arrogant, and punitive leader, but he was convicted of just one charge: illegally flogging some of his men.

Although the expedition was greeted largely with indifference in the United States upon its return, Wilkes was awarded the Founder's Medal of the Royal Geographical Society in 1848. Promoted to rear admiral on the retired list in 1866, Wilkes died on February 7, 1877, at his home in Washington, D.C.

Wilkes' greatest legacy is the Exploring Expedition's nineteen reports, on which he worked indefatigably from 1844 to 1861, writing seven himself (the five-volume *Narrative* as well as the reports *Meteorology* and *Hydrography*), while overseeing production of the other dozen.

WILKINS, HUBERT

Sir George Hubert Wilkins (October 31, 1888–December 1, 1958), Australian polar explorer, photographer, cinematographer, pioneer aviator, balloonist, naturalist, newspaper reporter, navigator, submariner, and decorated war hero, was born at Mount Bryan East, South Australia. He studied engineering at the School of Mines in Adelaide but shifted fields entirely and became a cinematographer for the Gaumont Company and a reporter for the *Daily Chronicle* of London. Wilkins learnt to fly, and in 1912 was despatched by the Gaumont Company to film moving images of the war in the Balkans. In 1913 he took the post of cinematographer on Vihljalmur Stefanson's Canadian Arctic Expedition (he allegedly misread a telegram and mistakenly thought that it was an Antarctic expedition) and by early 1916 had returned to Australia to join the Australian Flying Corps as a lieutenant. His new role was to assist Captain Frank Hurley (photographer on Douglas Mawson's Australasian Antarctic Expedition and Ernest Shackleton's Imperial Trans-Antarctic Expedition) in filming hostilities in World War I France for use in newsreels. Despite his refusal to carry firearms, he twice earned the Military Cross, first for his attempts to rescue wounded men at the Third Battle of Ypres, and later for leading a company of American soldiers.

It was Wilkins' fascination for aviation and photography that inspired his first real brush with Antarctic exploration. Inspired by Hurley's achievements, he felt sure that a combination of aerial photography coupled with the great distances that could be travelled rapidly by aeroplane could significantly enhance the potential for Antarctic discovery and exploration. He participated in the British Imperial Expedition (1920–1922), organised by John L. Cope, which aimed to make a successful transpolar flight using two aircraft for the attempt with a further twelve support aircraft. The expedition began in the spring of 1920 but failed to secure adequate funding or the necessary aircraft, relegating its endeavours to a 4-month fact-finding trip in Andvord Bay and the west coast of Graham Land on the Antarctic Peninsula. Undeterred, Wilkins left the expedition early and approached the US representative for Junkers aircraft to secure the loan of three aircraft for a further expedition. However, his plans were shelved when Wilkins instead agreed to accompany Shackleton as naturalist on what was to be Shackleton's last Antarctic expedition. The expedition, which had scientific objectives, continued after Shackleton's death under the command of Frank Wild and afforded Wilkins the opportunity for further Antarctic experience and to photograph flora and fauna on South Georgia.

In 1925, Wilkins again tried to realise his dream of aerial exploration with the Australasian Polar Pacific Expedition. However, its aim to fly from the Ross Sea over King Edward VII land to Graham Land was again frustrated by lack of funds. With funding a recurring difficulty, Wilkins sought to raise his credibility and public profile between 1925 and 1928, by joining with Carl Ben Eielson (1897–1931) in a series of Arctic endeavours. Eielson's 2200-mile (3450-km) flight from the North Slope of Alaska over the polar ice cap to Greenland was the first flight from North America over the North Pole to Europe. Eielson was decorated with the Distinguished Flying Cross and won the Harmon Trophy for the greatest American aviation feat of the year. Wilkins received the Morse Medal from the American Geographical Society, the Patrons Medal from the Royal Geographical Society, and a knighthood from King George V. Armed with these new honours, Wilkins again tried to attract finance for an Antarctic expedition. With Eielson he had demonstrated the efficacy of aerial reconnaissance in the Arctic as a tool for exploration. Together they had charted hundreds of miles of new terrain and corrected existing maps to exclude phantom landmasses claimed by earlier explorers.

Initially Wilkins approached R. G. Casey, a major in the Australian army and an official at the London High Commission, but his argument for an Antarctic expedition to establish strategic weather stations on the Antarctic rim failed to secure funding. Instead, William Randolph Hearst, the millionaire American publisher, paid US$25,000 for exclusive media rights to an Antarctic expedition that consequently became known as the Wilkins-Hearst Antarctic Expedition.

The expedition's pilots once more comprised Wilkins and Eielson, with the addition of Joe Crosson, an experienced Arctic pilot who had been the first to fly an open plane between Fairbanks and Point Barrow, Alaska, and to land on a glacier. The trio used the same well-proven Lockheed Vega aircraft (with its name now changed to *Los Angeles*) as was flown during the Wilkins-Eielson Arctic endeavours of 1928. The seasoned Vega became the first plane to be flown in the Antarctic and was backed up by a second Vega dubbed *San Francisco*. In addition, the expedition received $10,000 of equipment from Australia's Vacuum Oil Company, while the Norwegian N. Bugge Hektor Whaling Company provided sea transport. Crucially, Heintz and Kaufman of San Francisco equipped the planes with shortwave radio equipment that furnished long-range communication and served as a radio distress beacon when the Morse key was depressed continuously.

Before leaving the Falkland Islands (their final port before Deception Island), Wilkins received instructions from the governor to make territorial claims to the Falkland Islands Dependency, which included Deception Island. From Deception Island, Wilkins hoped to explore Graham Land and the Palmer Peninsula (parts of what is now known as the Antarctic Peninsula) as far as fuel and weather permitted. However, his grand design was to fly to the Weddell Sea from Deception Island and then across the Antarctic continent (later achieved by Lincoln

Ellsworth) to the Ross Sea and Framheim, Roald Amundsen's base camp on the Ross Ice Shelf during his South Pole expedition. On December 20, 1928, Wilkins and Eielson flew *San Francisco* for 10 hours above Hughes Bay, across Gerlache Strait, and close to the Danco Coast before crossing the Peninsula from west to east. Beyond 67° S they discovered and named a series of channels and dropped a territorial claim on behalf of the British government. Running short of fuel, they then turned around at 71°20′ S. During their flight Wilkins took only 20 minutes to sketch 40 miles of unknown territory in addition to photographing their flight with a Kodak 3A folding autographic camera (using 122 roll film) and two movie cameras. In just 10 hours their 1300-mile (2100-km) flight charted nearly 1000 miles (1600 km) of terra incognita and marked the first time that undiscovered land was mapped from a plane. The expedition's final flight, on January 10, 1929, flew 250 miles (400 km) south to confirm their previous aerial sightings.

In November 1929, the second Wilkins-Hearst Expedition returned to Deception Island, aided by £10,000 from the Colonial Office and transported by the Discovery Committee's research ship, *William Scoresby*. The expedition pilots comprised Wilkins, Al Cheeseman, an experienced Arctic pilot, and Parker D. Cramer (1896–1931), pioneer of the "Great Circle" route. The expedition's final flight reached 73° S but made only one substantial new finding between December 27 and December 29, Wilkins' discovery that Charcot Land (as it was known) was an island, which Wilkins claimed for Britain.

In the 1930s, Wilkins organised three expeditions for American millionaire Lincoln Ellsworth (1880–1951). He participated in Ellsworth's attempts to fly across the Antarctic continent from 1933 until Ellsworth finally succeeded on November 22, 1935. In 1957 Wilkins made his last journey to Antarctica as a guest of Operation Deepfreeze. He died the following year and his ashes were scattered at the North Pole.

WILSON, EDWARD

Edward Adrian Wilson was born on July 23, 1872 at Cheltenham, the son of Dr. Edward Thomas Wilson, a well-known local physician, and his wife Mary Agnes, who wrote a popular textbook about poultry keeping. Educated at Cheltenham College and Cambridge University, he qualified as a Bachelor of Medicine from St. George's Hospital, London. As a boy, he showed a great interest in the flowers and wild creatures of the countryside, as well as an ability to draw. He was later inspired by the paintings of J. M. W. Turner and others in the National Gallery, so that, when appointed to the British National Antarctic Expedition (1901–1904), he not only took on a medical role and that of vertebrate zoologist but also that of artist. During the expedition in *Discovery,* he took part in the southern journey (the first major inland penetration of the continent) with Robert Falcon Scott and Ernest Shackleton. During this, despite being disturbed at points by snow-blindness, he sketched the length of the previously undiscovered range of mountains that flank the western edge of the Ross Ice Shelf. These panoramas and his observations of whales, seals, penguins, and seabirds were published in the volumes of scientific results. Before the departure of *Discovery* he had written up the collection of Antarctic seals from the *Southern Cross* expedition of 1898–1900 for the British Museum (Natural History).

On the expedition's return, Wilson was appointed to the Board of Agriculture's Grouse Disease Inquiry. He wrote one-third of the resulting report and illustrated it in its entirety. He sailed again for the Antarctic in June 1910 as head of the scientific staff during Scott's second and last expedition in *Terra Nova*. His nickname was "Uncle Bill." He inspired great respect and affection and was rarely too busy to advise or to help other members of the expedition. As during the British National Antarctic Expedition, he contributed himself—under the pseudonym "Zingiber" (Ginger, from the colour of his hair)—and illustrated most of the articles and poems by others for *The South Polar Times,* published in facsimile in 1907 and 1914. He also completed more fine watercolours, a selection of which was reproduced in the narratives of both expeditions and in the volumes of scientific results. His winter journey to Cape Crozier on the far side of Ross Island in June 1911, with Henry R. Bowers and Apsley Cherry-Garrard, to investigate the breeding habits of the emperor penguin, was made famous by the publication of Cherry-Garrard's book *The Worst Journey in the World.* Wilson was to die in the tent with Scott and Bowers in March 1912 during the desperate return journey from the South Pole. "I can do no more to comfort you," wrote Scott to Wilson's wife, Oriana, while the blizzard raged, "than to tell you that he died as he lived, a brave, true, man—the best of comrades and the staunchest of friends."

Bequeathed by his widow, the bulk of Edward Wilson's watercolours and sketches, as well as his *Discovery* diary, are in the Scott Polar Research Institute, Cambridge. There are still many admirers of his life and work.

WILSON'S STORM PETREL

Wilson's storm petrel *(Oceanites oceanicus)* is a small sooty-black storm petrel with a white rump, a pale upper-wing bar, and long black legs and feet with yellow webs. It is a member of the family of tube-nosed seabirds (Procellariiformes), which also includes albatrosses, shearwaters, and other petrels. They are completely dependent on marine prey and only return to land to breed. Other typical features of the family, which are shared by Wilson's storm petrels, are a long lifespan, with an adult mortality of less than 10%, and low reproductive rate. Wilson's storm petrels are the smallest endothermic animal of the Antarctic, only 18 cm long from bill to tail and 34–45 g in body mass, and thus must be particularly well adapted to withstand the frequent subzero temperatures at their breeding sites. In southern populations of the subspecies *O. o. exasperatus,* the body size and body mass are increased compared with the more northern subspecies, *O. o. oceanicus*.

Wilson's storm petrel has repeatedly been claimed to be the most numerous of all bird species worldwide. However, there seems no particular reason to believe this, as several other species also have a total population of several million pairs. Despite its abundance and familiarity to fishermen for centuries, the breeding grounds of Wilson's storm petrels were long unknown, until the first nests were found on sub-Antarctic Îles Kerguelen in 1874. Not until the era of Antarctic exploration at the beginning of the twentieth century was the extensive circumpolar breeding distribution revealed. The breeding sites for *O. o. exasperatus* include nunataks, snow-free coasts and islets around the whole of the Antarctic continent, and the islands of the Scotia Arc. In the sub-Antarctic, breeding grounds of *O. o. oceanicus* are found at South Georgia, the Falkland Islands, islands close to Cape Horn, Heard Island, Îles Crozet, and Îles Kerguelen. Estimates of the breeding populations at all sites are gross or incomplete, as surveys are extremely difficult, and few detailed estimates have been attempted. During the nonbreeding period, Wilson's storm petrels migrate north, visiting all major oceans except the Arctic. They reach the North Atlantic Ocean as far north as Newfoundland but are less numerous in the North Pacific Ocean, where they reach 30° N during the Southern Hemisphere winter.

Wilson's storm petrels feed at the sea surface, mainly while on the wing. During the breeding season, they frequent cold waters over the continental shelf or inshore and can detect food by smell. They prey on a wide variety of zooplankton including krill, amphipods, and small swarming fish, with smaller quantities of copepods, gastropods, and cephalopods. During the breeding season, krill (*Euphausia* spp.) is the most frequent prey. Chick-provisioning adults take more fish than incubating adults or nonbreeders, suggesting that adults selectively choose fish as an important source of nutrients for the growing chick. Because of their small size, Wilson's storm petrels have high energy requirements for maintenance and growth, and need to consume over 120% of their body mass in krill each day to meet their own demands and feed the chick.

Wilson's storm petrels may be encountered solitary or in feeding flocks of hundreds of birds. Their characteristic pattering flight consists in a series of short glides interspersed with fluttering and hovering to feed in one spot. Because they have very low wing loading, the flight is aerial, with frequent leaps several metres high. The bird has been named "skipjack bird" for this in Tristan da Cunha. Wilson's storm petrels may follow ships to seek organisms churned up by the propeller or scavenge scraps of fishing discards from vessels.

Like at sea, at the breeding grounds Wilson's storm petrels are both solitary and colonial, with single nests encountered and loose or dense colonies. Suitable snow-free and protected nest sites are typically in limited supply. The birds breed mainly in natural crevices such as cracks of cliffs and among boulders of rock slopes but have also been found to excavate burrows in soft soil and moss banks. Several studies of the breeding biology have been carried out since the pioneering study on the Argentine Islands in 1934–1937, but unfortunately no long-term data set is available from any of the study sites. An ongoing study at King George Island (South Shetlands) started in 1996.

Breeding starts in November to December, when adults between 3 and about 30 years of age return from the wintering grounds and reoccupy their burrows. At Antarctic colonies such as the South Shetland Islands, the nest chambers are still filled with ice when the first adults arrive. The ice beneath the rocks that form the breeding cavities melts during November and early December, when the temperatures exceed 0°C on most days. About 10 days before egg-laying, the female departs from the colony to feed intensively while the large egg (11 g, ~28% of adult body mass) is formed. The first eggs are laid in mid-December, and in January most of the breeding birds are incubating. The species has a socially and genetically monogamous mating system with intensive biparental care during incubation and chick-feeding. The single white egg is incubated in stints of c. 2 days but is often intermittently incubated if food abundance is not high. Remarkably, the egg can survive for several days if it cools to ambient temperature. The incubation time varies according to the number of days the egg is left unattended, from 39 to 59 days. Most chicks hatch in the first half of February. The hatchlings weigh only 6 g and are brooded for 1–4 days but left unattended in the burrow during the day when only a few days old. Both parents feed the chick with partly digested, regurgitated meals collected during feeding trips within a radius of over 200 km around the colonies. Each parent attends at a mean interval of 2 days until fledging, but in poor conditions, chicks may be fed more sporadically. Older chicks may fall into torpor and survive up to 1 week without food, while younger chicks starve quickly if not fed regularly. In good conditions, in contrast, chicks may accumulate subcutaneous fat and stomach oil and reach up to twice the body mass of adults.

The breeding adults visit the colonies, mate, and feed their chicks at night in order to reduce the chance of predation by skuas *Catharacta* spp. However, some skuas with established territories close to a colony of Wilson's storm petrels can become very skilled in catching birds on the wing even in poor light conditions and may leave their territory littered with pellets containing the remains of storm petrels.

The fledging period varies with latitude, taking between 48 days in southern colonies and 78 days farther north. The short fledging period in southern colonies indicates that the feeding rate is higher farther south, where there may be more abundant food supplies (or a shorter window for breeding). However, southern breeding places have another disadvantage. In Antarctic colonies, the nests are frequently snowed in, with snowstorms possible during all stages of the breeding season. Chicks with a good reserve of fat can survive entombment by snow, and parents dig tunnels through soft snow and feed the chicks. However, the snow frequently starts thawing during the day and subsequent frost results in a hard sheet of ice over the drifted snow, effectively blocking the nests.

For communication in the darkness of the breeding burrows at night, Wilson's storm petrels rely mainly on olfaction and calls. Adults use grating calls and male-specific chattering calls in mate attraction, mate recognition, and burrow defence, and peeping calls are uttered by both genders, especially in response to handling. Chicks call similarly to the peeping call of adults, especially while the parent is in the burrow, and these calls seem to play the role of an appeasement contact call. A second type of chick call is used exclusively for begging for food and is used at a greater rate by hungrier chicks. Parents respond to increased begging by regurgitating larger meals. Like other small burrowing petrels, Wilson's storm petrels have a characteristic musky smell, which is also apparent in the nesting material. Adult storm petrels use olfaction to locate their nest burrows, and chicks smell their way back to their individual burrows after excursions in the nights preceding fledging.

The breeding success of Wilson's storm petrels is highly variable and depends on the availability of prey and meteorological conditions. Krill forms the base of the feeding ecology of this bird; thus, competition with commercial fisheries is a potential threat, especially the large-scale exploitation of krill. Krill abundance may also be influenced indirectly by humans, for instance, if global warming leads to changes in oceanography and a reduction in the extent of Antarctic sea ice in winter. Sea ice is vital for the over-winter survival and reproduction of krill, and the storm petrels have low breeding success after low winter sea-ice cover. At the breeding sites, there are two potential threats: at some sub-Antarctic colonies (Îles Crozet, Îles Kerguelen, Falkland Islands), birds are subject to predation by introduced predators such as cats *Felis catus,* rats *Rattus* spp., and mice *Mus* spp., while in Antarctic colonies, snowstorms occur during the summer, burying burrows. In the South Shetland Islands, for example, the prevailing wind direction during the breeding season is westerly, whereas easterly winds are associated with snowstorms and may lead to entombment and complete breeding failure of entire colonies.

WIND

In Antarctica, the near-surface wind field is one of the most intensively studied meteorological elements. Early explorers acknowledged the strength and persistence of the wind. The extreme wind conditions largely restricted their field operations, as they still do today. During storms, snow is lifted into the air and deposited elsewhere. For this reason, field parties often need to dig out their transportation vehicles and tents in order not to be buried under a load of snow. The time-varying wind field determines not only the snow transport but also the transport of biological and chemical species and is therefore a meteorological element that is relevant to a wide range of studies.

Wind is the movement of air from areas of high pressure to areas of low pressure. There are several characteristic wind regimes in Antarctica. Extensively studied is the katabatic wind system, characterized by a low-level wind speed maximum and by a large directional constancy. Most landmasses on Earth gain heat during the day, leading to turbulence and convective activity, and they lose heat during the night, which suppresses the turbulence. In contrast, at high latitudes during winter, the radiational cooling of the surface lasts for the entire 24-hour period. The surface is colder than the overlying air. As a response, transfer of heat from near-surface air parcels towards the surface takes place. The density of the cooled air parcels is higher than the density of the surrounding warmer air. The parcels are heavier than their surroundings and, if a surface slope is present, the air will start to flow down the slope. In summary, the katabatic forcing occurs as a response to the transfer of heat from the near-surface layer due to radiational cooling of a sloping surface.

Pure katabatic winds occur when two forces balance, namely the katabatic forcing and the friction, a resistive force originating from the airflow over a rough surface. Pure katabatic winds are strong and blow parallel to the fall line on the steep slopes near the coast. Inversion winds occur when the katabatic force is balanced by the Coriolis force, which is related to the rotation of the earth. Inversion winds tend to be weaker and flow along the height contours on the gentle slopes in the interior. Often, all three forces mentioned above play a role, and the wind vectors are deviated to the left of the fall line by 20°–50°. In coastal regions, the piling up of cold air over the ice shelves and the sea ice can establish an opposing force, and in this case katabatic airflows do not penetrate far over the ice shelves and the sea ice.

Apart from the distinction between inversion and pure katabatic winds, there is also a distinction between ordinary and extraordinary katabatic winds. Regions where ordinary katabatics dominate are characterized by high wind speeds or gusts alternating with periods that are calm. In contrast, extraordinary katabatic winds blow uninterrupted for days or weeks. These winds are (in)famous due to the stories from early explorers, such as Sir Douglas Mawson, who wrote the well-known book *The Home of the Blizzard*. Extraordinary katabatic wind regimes are located in regions with upstream confluence of cold air into major drainage valleys, for example, upstream of Terra Nova Bay, Cape Denison, and Port Martin in Adélie Land, where the annual mean wind speed is about 20 m/s (eight on the Beaufort scale).

The katabatic circulation is so powerful and persistent that it affects the circulation in the entire free troposphere, roughly the first 8 km of the atmosphere above Antarctica. The katabatic outflow of mass in the lower atmosphere must be compensated for by downward motion (subsidence) and inflow of mass in the free troposphere.

Near-surface winds are not only driven by the katabatic forcing but also by pressure systems, such as depressions and synoptic weather systems. The circumpolar trough is a region of low pressure over the Southern Ocean (between 60° and 65° S), separating a zone of westerlies to the north from the polar easterlies to the south, close to the Antarctic continent. The eastward-migrating depressions in the circumpolar trough affect the weather at the coast profoundly and often cause strong winds. Near-surface winds related to pressure systems are largely affected by the orography and often flow along the orography. It is therefore very difficult to distinguish them from the winds generated by katabatic forcing. In the interior of the continent, the large-scale pressure gradient force is of equal importance to the katabatic force during the winter season, with both forces acting in the same direction.

Barrier winds occur when a cold airstream does not have sufficient kinetic energy to cross a barrier, and consequently flows parallel to the barrier. Barrier winds occur frequently along the Antarctic Peninsula and the Transantarctic Mountains. When the warm air overlaying the blocked cold air is able to flow over the barrier, warm downslope föhn winds occur at the lee side. During such events, the air is relatively warm and dry, and sublimation of blowing snow occurs.

Compared to other regions of the world, the history of measuring the near-surface winds in Antarctica is short. The first reports came in the beginning of the twentieth century from early explorers, who documented the extreme wind conditions in the regions where they traveled. During the first half of the century, measurements were made at sites scattered around the continent. Since the International Geophysical Year (1957–1958), which greatly contributed to our knowledge of Antarctic meteorology, more systematic measurements of the wind speed and direction became available. In the 1960s, a major step forward was made in producing an Antarctic-wide map of near-surface wind directions using sastrugi orientations. Sastrugi are sharp, irregular ridges formed on a snow surface by wind erosion and deposition and are therefore useful indicators of prevailing wind direction in remote regions. Aerial photographs of sastrugi fields provided the first broad-scale indication of the wind directions.

Most of our current knowledge of the near-surface wind field over land is from Automatic Weather Stations, consisting of a mast with arms on which wind direction (vane) and wind speed sensors are mounted. Information at higher levels is known from radiosonde balloon launches. Over the ocean, measurements have been made using drifting buoys. Apart from these *in situ* measurements, remote-sensing instruments have also been used in the last decades. The wind speed over the ice-free ocean is obtained from passive and active microwave instruments on different satellites. Satellite observing systems in the visible part of the spectrum have been used to estimate the upper-level wind by tracking clouds in images. Ground-based remote sensing instruments (Doppler Sodars and Radio Acoustic Sounding Systems) have been relevant to associate turbulence in the atmosphere to the near-surface wind system.

Another source of information on the wind field is from numerical models. Elegant one-layer models have shown that a steady-state wind develops when a sloping terrain is cooled, and these models have greatly contributed to our understanding of the katabatic wind system. Weather forecast models and climate models have been used to study the complex interaction between near-surface wind and a wide range of meteorological processes.

The winds interact strongly with other meteorological phenomena in the Antarctic region. During episodes of strong katabatic wind under clear sky conditions in winter, the turbulent exchange of heat between the surface and the overlying warmer atmosphere is large. Therefore the surface temperature is relatively high when compared to areas where winds are weak. The fast-flowing katabatic streams with their relatively high surface temperatures can be identified from satellite thermal infrared images. Also, the barrier and föhn winds have a strong effect on the local temperature, where barrier winds are generally cold due to the advection of continental air, and föhn winds are warm.

Winds are of major importance for the air–sea interaction. They are the major force for near-surface ocean currents. For example, the Antarctic Circumpolar Current in the Southern Ocean at about 40°–60° S is caused by the strong atmospheric westerlies in this region. When the ocean is covered with sea ice, leads or polynyas (areas of open water) form as a result of persistent offshore flow. In regions where the extraordinary katabatic winds prevail, like Terra Nova Bay, polynyas form every year at the same location. Also, the barrier and föhn winds in the Antarctic Peninsula have a large effect on the sea-ice distribution. Föhn winds force the ice away from the Larsen Ice Shelf and the barrier winds drive the ice northwards for a distance of 400 km, into the Antarctic Circumpolar Current.

The changes in sea-ice cover largely influence the exchange of heat and moisture between ocean and atmosphere, since sea ice acts as an insulator for the ocean. As very cold continental air flows over open water, exceptionally large heat fluxes cool the surface waters, leading to the formation of sea ice. This cooling brings about a destabilization of the water column and therefore induces downward convection. The associated changes in temperature and salinity affect the potential energy available in the oceans, which in turn drives the thermohaline circulation. In addition, leads or polynyas are believed to exert an important control over the ocean circulation beneath the ice shelves and hence the melting rate of the ice shelves.

Winds are of importance for the transport of chemical and biological species in the atmosphere. Depressions near the continent are associated with an influx of species from the ocean and from the neighboring continents. The atmospheric circulation pattern determines how a particle is transported from the source to the sink region and determines the deposition at the snow surface. Signals measured in ice cores have therefore often been used to obtain knowledge about the past state of the atmosphere. For example, increased dust content in the ice from the Last Glacial Maximum has been attributed to a more vigorous climate. The occurrence of pollen from non-Antarctic plants trapped in moss cushions and the presence of exotic plants and microorganisms on volcanically warmed Antarctic soils show that long-distance transfer of biological species takes place. Episodes of winds flowing off the high continental plateau toward the coast may inhibit transfer of species towards inland sites.

Strong winds that flow down the steep slopes towards the coast carry huge amounts of snow. Both this transport and the sublimation of blowing snow affect the net input of mass at the surface of the ice sheet (surface mass balance). Drifting snow is the transport of fine snow particles in the lowest layer above the surface, whereas blowing snow refers to conditions with a more vehement type of wind-driven snow, with a vertical extent of up to a couple hundred meters and strongly reduced visibility. At Mizuho, blowing snow occurs during 60% of the days in the winter season, and at another 30% drifting snow occurs.

Strong winds affect the heat loss of the body in inclement weather. For various combinations of wind speed and air temperature, the associated heat loss can be expressed as a wind-chill factor. In Antarctica, high winds are probably a limiting factor for outdoor activity more than low temperatures, as can be illustrated with a quote from C. T. Madigan (1929), participating in Mawson's expedition: "For nine months of the year an almost continuous blizzard rages and for weeks on end one can only crawl about outside the shelter of the hut, unable to see an arm's length owing to the blinding drift snow." The strong winds prevailing in the Antarctic can generate great problems for human activity in this region.

WISTING, OSCAR

Oscar Wisting was Roald Amundsen's most trusted and loyal expeditioner. Together, the two were the first to reach both the South Pole and the North Pole.

Wisting was born in Larvik, southern Norway, on June 6, 1871. He chose the navy as his career, but a meeting with Amundsen in Horten in 1909 partially changed this. Amundsen was testing kites as a possible aerial inspection platform for use in the ice, and he spontaneously invited Wisting to join his next expedition. When Wisting left on what became Amundsen's South Pole expedition, 1910–1912, he left behind a large family. He was more or less away from his family with Amundsen for 16 years, which resulted in bitterness amongst his children and a later bad conscience for him.

Wisting's attributes for the South Pole expedition were his all-round practical sense, endurance, and, not least, his loyalty. Amundsen needed men who obeyed without question. At the winter base Framheim, one of Wisting's jobs was to man the sewing machine in one of the snow caves that extended from the base hut. Here, among other jobs, he resewed the tents to make them lighter and more suitable for the sledge journey. He was one of the four men whom Amundsen chose for the South Pole journey, driving his own dog team. On December 14, 1911, the five men together held the Norwegian flag as it was planted at the Pole.

Wisting's merits on the South Pole expedition impressed Amundsen, who encouraged him afterwards to gain additional expertise for future expeditions. He obtained some training in elementary medicine and dentistry, took a diploma as a tinsmith, completed a cookery course, and studied navigation. In 1913–1914 he was in the group that fetched *Fram* back from South America, and in 1918–1925 he was away on Amundsen's *Maud* expedition. On this expedition Amundsen gave him increasing responsibility. He sledged with Helmer Hanssen on a 6-month journey to the nearest telegraph station and with the scientist H. U. Sverdrup on a long trip around the Chukchi Peninsula. When Amundsen left the expedition, Wisting was given major responsibilities, serving as captain during the last drift in the ice, 1922–1925. During the summer of 1923 he flew with Odd Dahl on what was probably the first flight over the Arctic Basin ice field.

Wisting was only home for a few days before he again was called out by Amundsen, this time to the flight in the dirigible *Norge* over the North Pole, with the job of manning the elevator. On the night of May 11–12, he and Amundsen shook hands as the two first to reach both Poles.

In 1928 he was scheduled to help Amundsen search for Umberto Nobile and his dirigible *Italia*. Fortunately for him, there was no room on the plane to Svalbard, and he thereby avoided disappearing with Amundsen. Wisting led an unsuccessful search expedition for his friend.

Wisting's last years were partially devoted to saving *Fram* for posterity, in a specially constructed museum in Oslo. During work at the museum on December 4, 1936, he had a heart attack and died alone in his cabin from the Antarctic expedition.

WOMEN IN ANTARCTIC SCIENCE

From the beginnings of Antarctic research, women scientists longed to participate, the first few finally gaining permission in the late 1950s. They now play a significant role in Antarctic science, in critical long-term monitoring, in new fields, and in international collaborative projects.

Those whose work is mentioned here are principal investigators for Antarctic scientific projects, or have worked long term in Antarctic fields. They come from seventeen nations.

Atmospheric Sciences

Women are not strongly represented in physics. An early woman physicist in the Antarctic was Nadezhda Kazakova, who led the Russian aerological team on five expeditions beginning in 1969. In 1970, Irene Peden studied properties of the lower ionosphere over the polar regions; Gisela Dreschhoff first surveyed the uranium resource potential of Antarctica in 1972, moving on to study cosmic radiation and its relevance to space exploration.

Middle atmosphere dynamics, using ground-based remote sensing, is a major interest of Susan Avery, former director of the University of Colorado Cooperative Institute for Research in Environmental Sciences (CIRES) and now Executive Vice Chancellor and Provost of the University of Colorado at Boulder. Her research encompassed mesospheric studies using a meteor echo detection and collection system, nonmigrating tides, coupling in the atmosphere through gravity waves, precipitation structure using wind profilers, and development of meteor radar systems. Pene Greet has also conducted long-term studies of the mesosphere. Her work on the design, calibration, operation, and analysis of Fabry-Pérot Spectrometer data, used to study atmospheric motions and temperature, has led to a significant series of observations, particularly on tidal variations. Elizabeth Essex studied the ionosphere, using techniques based on detecting signals transmitted from satellites. Kaoru Sato investigates the dynamics of the atmosphere, including wave dynamics, wave-mean flow interaction, instability, and the ozone hole.

Susan Solomon found key evidence of ozone destruction. An atmospheric chemist, she led the 1986 emergency expedition to investigate the formation of the ozone hole over Antarctica. She made some of the first measurements there that suggested chlorofluorocarbons as the cause of the ozone hole. In 2000 she received the National Medal of Science, the United

States's highest scientific honour, for "key insights in explaining the cause of the Antarctic ozone hole," among other honours and awards.

Anna Jones is another atmospheric chemist. Following the discovery that the chemistry of the polar boundary layer, where snow meets the atmosphere, is much more complex than previously thought, she organized and ran a major year-round measurement project during 2004 (Chemistry of the Antarctic Boundary Layer and the Interface with Snow [CHABLIS]). Involving research groups from six UK universities, this was the largest, longest, and most detailed measurement program of its kind yet carried out in Antarctica.

Irina Repina (Institute of Atmospheric Physics, Russian Academy of Science) has led several studies of Earth–atmosphere interactions.

Geosciences

Climate studies are significant in glaciology. Elisabeth Schlosser, a member of the all-women wintering team at Georg von Neumayer station in 1990, is a glaciologist–meteorologist working on snow accumulation. She uses long-term stable oxygen isotope data from ice cores to investigate past climate.

Recent climate history has been investigated by Elisabeth Isaksson, working since 1996 with the European Project for Ice Coring in Antarctica (EPICA). The last 10–100 years are the focus of Wendy Lawson's research into the response of ice masses to changing climatic inputs. Barbara Smith and Kumiko Azuma conduct studies of climate based on chemical analysis of ice cores, and Nelia Dunbar specializes in the volcanic ash record in Antarctic ice cores and the climate record of the West Antarctic ice sheet. The long-term ice-core work of multiple-award-winning Ellen Mosley Thompson is used in reconstructing the impact of climate on past environmental systems. She provided compelling evidence for contemporary global warming.

Ice mass balance and the dynamics of ice shelves and glaciers contribute to the study of climate change. Elizabeth Morris began her career with studies of the dynamics of ice shelves, moved on to study mass balance, and then became interested in providing ground data to validate and complement satellite data. She has developed an automatic, field-friendly version of the neutron probe for snow-density profiling. Another senior scientist who began studying snow and ice mass balance in 1978, is Julie Palais, now Antarctic Glaciology Program Manager at the US National Science Foundation (NSF). Brenda Hall is investigating the causes of ice ages through studies of the stability of ice sheets, especially the West Antarctic Ice Sheet, and the fluctuations of high-level lakes in the Dry Valleys. Cecilie Rolstad also works on glacier dynamics.

Basic sea-ice studies reveal its formation and thickness, biological significance, and role in climate change. Victoria Lytle, Kim Morris, and Pat Langhorne work in this field. Mary Albert (chair, US Committee to the International Polar Year) has been involved with the US International Trans-Antarctic Science Expedition (ITASE), analyzing firn cores for information on snow structure and air–snow transfer.

In geology, Lois Jones led a four-woman team in 1969 working on the origins of the saline lakes of the Dry Valleys. In 1971–1972 Elizabeth Truswell participated in the Deep Sea Drilling Project voyage to determine when the present ice sheet began to form. The research showed that the ice sheet was dramatically older than previously thought. Truswell works on fossil pollen preserved in off-shore sediments to unravel the nature and history of the early forests and how they were transformed with increasing cold. Focusing on understanding past climate change, paleobotanist Jane Francis investigates fossil woods and their use as tools for climate interpretation. Other Antarctic fossil studies are conducted by Edith Taylor (flora evolution and the use of fossil tree rings as proxy climate records) and Molly Miller (reconstructing benthic communities of freshwater ecosystems of the Phanerozoic period).

Margaret Bradshaw began Antarctic work in 1975, working primarily on rocks and fossils of the Devonian age in sedimentary rocks. Rosemary Askin's early Antarctic studies investigated the breakup of Gondwana. She now studies responses of land vegetation and phytoplankton to environmental and climatic changes and the causes of these changes. Vera Markgraf concentrates on climate change during times of transition, such as the late glacial. Subglacial bedrock is the subject of Terry Wilson's and Robin Bell's research. Bell participates in the investigation of subglacial Lake Vostok.

In structural geology, women are working on plate tectonics and plate boundaries (Joann Stock, Anne Trehu), seismic monitoring (Estella Weigelt, another member of the 1990 all-female German team), and the study of the Earth's magnetic field. This has led Carol Raymond from marine geophysics to the Jet Propulsion Laboratory and the Dawn mission to Mars. Ursula Marvin, now retired, also moved to space research, including the geological mapping of Ganymede, after field studies collecting meteorites in Antarctica (1978–1979, 1981–1982). She chaired the committee that allocates Antarctic meteorite samples to laboratories internationally.

Another geological pioneer is Janet Thomson. Following four reconnaissance expeditions, she compiled and published maps as a British Antarctic Survey mapping geologist, establishing and managing the BAS Mapping and Geographic Information Centre (MAGIC), 1989–2002. She considers her overriding achievement encouraging people to collaborate on projects leading to publications.

Marie Klenova was a pioneering female Antarctic oceanographer (1955), followed by Monica Grasselli and Lilja Ventajas (1979–1980). Now, Gisele Uenzelmann-Neben reconstructs depositional conditions and oceanic current systems from sedimentary structures, and Amy Leventer is chief scientist for the Coring Holocene Antarctic Ocean Sediments (CHAOS) study to develop a climate and oceanographic record for the Quaternary period. Janet Sprintall currently studies the seasonal variability and long-term change of the upper ocean structure of the Drake Passage.

Life Sciences

The ecology and physiology of marine organisms in the Southern Ocean have been studied by women since their first inclusion on marine science voyages (1959: Isobel Bennett and Hope Macpherson; 1962: Mary Alice McWhinnie; 1968–1969: Irene Bernesconi, Adela Caria, Elena Martínez Fonte, and Carmen Pujals). McWhinnie became a world expert on krill *(Euphausia superba)*. Monica Montu, leader of the second Brazilian Antarctic research expedition (1984), also studied krill, and Robin Ross (US) has just completed her twenty-fourth season in Antarctica studying the ecological physiology of zooplankton. She examines trends and cycles in the Antarctic food web, where krill, her special field, is the key species. Bettina Meyer manages a krill group, the work of which is embedded in the international Southern Ocean-Global Ocean Ecosystem Dynamic (SO-GLOBEC) program.

Greta Fryxell and Maria Vernet have specialised in phytoplankton ecology and physiology, and Corina Bruissaard examines phytoplankton viral ecology. Fiona Scott, a phytoplankton ecologist, currently focuses on marine protists. Salps, a very different planktonic grazer, are the subject of Laurence Madin and Patricia Kremer's collaboration. Mary Sewell works on meroplankton, the larval stages of marine invertebrates and fish, now part of the Latitudinal Gradient Project at Cape Hallett. Vonda Cummings, Stacy Kim, and Kathy Conlan all investigate biodiversity on the Antarctic sea floor.

Nadine Johnston (BAS) works with cephalopods. Antarctic fish studies by women began in the 1970s when Yuan Lin DeVries and Audrey Haschemeyer worked on fish antifreeze. Today, both field and laboratory studies of fish are being undertaken by Edith Fanta, head of the Science Committee of the Council for the Conservation of Antarctic Marine Living Resources (CCAMLR), and colleague Lucélia Donatti.

Margaret Clayton has made a long-term study of the reproductive biology of Antarctic macroalgae. In 2003 she conducted the most comprehensive study for nearly 100 years of Falkland Islands seaweeds. A student of Carmen Pujals, Liliana Quartino works on the ecology of Antarctic marine macroalgae. Colleague Gabriele Tosonotto is another marine biologist; María Eliana Ramírez specializes in Antarctic marine benthic flora, and Anne-Marie Schwarz studies plants in both marine and freshwater Antarctic aquatic systems.

The Southern Ocean is subject to intensive study today, especially investigations of the implications of climate change for living organisms. Margaret Clayton, Loes Gerringa, Liliana Quartino, Maria van Leeuwe, and Irene Schloss all work on aspects of ultraviolet B effects on ocean communities. Maria van Leeuwe and Anita Buma are doing pioneering work on iron–biota interactions, and oxidative stress on phytoplankton from solar ultraviolet radiation. Angelika Brandt is involved in scientific planning of the Antarctic Benthic Deep-Sea Biodiversity (ANDEEP): "colonisation history and recent community patterns" expeditions and coordinates biological sciences within the Antarctic Research Program of the German Science Foundation.

Antarctic freshwater aquatic systems have attracted some high-level female scientists. Johanna Laybourn-Parry has 16 years of Antarctic experience. Her projects have focused on carbon cycling in freshwater and saline lakes. Currently she works on bacterial and molecular diversity and the role of viruses in the Vestfold Hills saline lakes. Eleanor Bell also works in this field. Another limnologist, Diane McKnight, investigates the interactions between hydrological, chemical, and biological processes in controlling the dynamics of aquatic ecosystems, and is coprincipal investigator in the McMurdo Dry Valleys Long-Term Ecological Research. Gabriela Mataloni works with a group on the taxonomy and ecology of algae from Antarctic continental environments. Her current project is on the diversity and ecology of maritime Antarctic soil microalgal communities. Another experienced researcher, Kerrie

Swadling, has studied the ecology and biogeography of sea ice–associated organisms, while her lacustrine research centers on using faunal microfossils in the sediment record to describe the Holocene evolution of Antarctic lakes and their environs. Vivian Montecino has examined primary production in Antarctic lakes. The paleo-environment of the testate amoeba fauna of the late Holocene, reconstructed through peat core analysis, is Sofie Vincke's current project. Penny Greenslade has made extensive studies of invertebrate distribution and ecology, especially invasive introduced species.

Basic work on Southern Ocean sea birds began in the 1960s with Nelly Lafuente, Wanda Quilhot, and Christine Muller-Schwarze, and continued with Jeni Bassett in the 1970s. Long-term work on giant petrels is done by Donna Patterson. Rosemary Gales has worked on a range of species of marine birds and mammals, including penguins, albatrosses, and seals. Her research into the ecophysiology and foraging ecology of these species has been directed towards an understanding of their role in the marine environment and their interactions with fisheries and fishing operations.

The Adélie penguin is a biological indicator of Antarctic, especially krill-based, ecosystems. Scientists working on various Adélie programs include Judy Clarke, Silvia Olmastroni, Akiko Kato, Kerry Barton, and Gabrielle Nevitt. Barbara Wienecke and Akiko Kato have worked on emperor penguins.

Tracey Rogers has led programs for 15 years on the life history and population ecology of the leopard seal. As it is an apex predator, changes in its populations reflect changes within the ecosystem. Pam Yochem and Terrie Williams also monitor seal populations and behavior, and Deborah Thiele monitors whale populations.

In botany, two books by Vera Danilovna Aleksandrova are considered "musts" for students of cooler-region plant geography. In basic research, Marina Dorozhkina has worked for several summers investigating the composition of microflora (pollen and spores). The role of Antarctic yeasts in the accumulation and mobilisation of nutrients in polar desert food webs is Laurie Connell's long-term study.

The responses to environmental stress of plants as well as fauna are integral to the study of the impact of climate change. Botanist Sharon Robinson leads a group working from the molecular to the ecological levels. Aspects of this ecosystem interest are shared with Mary Skotnicki, and work on vegetation monitoring using remote sensing also involves Cath Lovelock. Following her earlier multidisciplinary work on the origins and evolution of six endemic, isolated sub-Antarctic island plant species, plant ecophysiologist Françoise Hennion is now investigating the effects of temperature variations on early plant growth.

The ecosystem and biodiversity are of major concern to terrestrial biologists. Patricia Selkirk is an outstanding leader here. Her Australian Antarctic Medal citation in 2004 noted that in more than 25 years of Antarctic service she has produced a substantial and influential body of work in the field of Antarctic and sub-Antarctic science, has acted as a pioneer and role model for women scientists in Antarctica, and has strongly advocated Antarctic science. A multidisciplinary scientist, her research has been broad ranging, from landscape-level geomorphology and vegetation history through to organism-level studies of plant reproduction and subcellular genetics. This research has formed much of the foundation for sub-Antarctic plant biology. She was part of the team that first discovered plant viruses in the sub-Antarctic and was the first researcher to value the sub-Antarctic region as the outer edge of the Antarctic Zone in monitoring climate change.

Dana Bergstrom, once Dr. Selkirk's graduate student, is chief officer for the SCAR Program Group on Regional Sensitivity to Climate Change (RiSCC) in the sub-Antarctic, has undertaken a vegetation history of Macquarie Island, and has worked on most sub-Antarctic Islands. Sieglinde Ott investigates developmental biological adaptations of maritime Antarctic lichens, the genetic diversity of lichen symbiotics, and Antarctic nunataks as model ecosystems. A spatial ecologist, Melodie McGeoch works on the quantification of the spatial variation across Marion Island of the keystone plant species *Azorella selago,* towards understanding the likely impacts of climate change on the system. Amanda Slager-Bastos is studying the genetic characterization of sub-Antarctic island fauna, and their biodiversity.

Soil biodiversity is Diana Walls's field, assessing the importance of this diversity to ecosystems. She has studied the impact of global change on soil species in the Antarctic Dry Valleys, with a major focus on the many ecosystem processes that are mediated by soil organisms.

Human Impacts

Conservation of the Antarctic is an obligation for Antarctic Treaty Members and often requires research to determine the best approach. One major concern is the cleanup of oil spills. Elizabeth Kerry's pioneering work demonstrated that it was possible to enhance the activity of oil-degrading organisms and therefore increase the rate of breakdown of oil spills in the Antarctic by the addition of fertilizer solutions to oil-contaminated soils. This procedure (bioremediation) has been investigated further as part of a major Australian program at Casey, established to determine the best way to clean up the Thala tip. Many women were and still are involved in this work.

Jackie Aislabie leads an interdisciplinary team to support environmental protection and management of ice-free areas of the Ross Sea region. She investigates the effects of hydrocarbon spills on Antarctic soils and is currently determining how to manipulate soil conditions to maximise hydrocarbon degradation. Other team members include Roberta Farrell, working on microbial biodiversity; Julia Foght, on enrichment of hydrocarbon-degrading bacteria with potential for bioremediation of spill sites; Megan Balks, on the impacts of human activities on soil environments; and Emma Waterhouse, on environmental management practices.

Another aspect of conservation is the identification of organisms present as a result of human activity, with a view to adapting management practices to reduce such introductions. Elizabeth Kerry identified fungal species in Antarctic soils in station areas, but not in natural ecosystems, considered likely to have been introduced via human activities.

Studies of sea-bed disturbance, especially the effects on crustacean communities of chemical toxins, are Kathy Conlan's work, and Sabine Duquesne has investigated ocean toxins. Simonetta Corsolini studies the bioaccumulation and toxicity risk assessment of persistent organic pollutants, and their distribution along the food webs. The response to stress of marine organisms is Doris Abele's main field, and she is organising an interdisciplinary exploration of the effect of the recent rapid warming at the western Antarctic Peninsula on terrestrial and marine coastal ecosystems. The effects of ultraviolet-induced damage on marine organisms have been Deneb Karentz's long-standing work, now applied to the ecological implications of Antarctic ozone depletion.

Emma Waterhouse works in the development and implementation of environmental management practices for Antarctic operations and edited a groundbreaking publication on Ross Sea environmental management. Jennie Whinam considers the highlight of 18 years of sub-Antarctic research to be the use of the results from their alien species project to fundamentally change the way that quarantine is viewed institutionally and in practice. Penny Greenslade, an entomologist, has also contributed to Australian quarantine and management practices.

The impact of tourism is of increasing concern in the Antarctic. Rosamunde Codling's 1980s research on the development and evaluation of tourism is considered seminal. Debra Enzenbacher undertook the first doctoral dissertation on Antarctic tourism policy. Melissa Giese's work on the impact of human activities on Antarctic wildlife has had policy implications.

Conservation

Lyn Goldsworthy, Janet Dalziell, Sabine Schmidt, and Liz Carr, all qualified scientists, have undertaken Antarctic conservation work through Greenpeace, including station monitoring and advocacy for the "World Park" proposal.

Archaeologists Estelle Lazer, Karen Townrow, and Angela McGowan have worked in projects to determine and preserve significant Antarctic historic sites. Janet Hughes investigated corrosion in Mawson's huts, while Roberta Farrell has studied microbial diversity and degradative fungi active in Scott's huts. Norwegian sites were surveyed by Susan Barr.

In cutting-edge research, Rosamunde Codling (UK) sought to define Antarctic "wilderness and aesthetic values," a concept enshrined in the Protocol on Environmental Protection to the Antarctic Treaty. She suggested methodologies for their identification and assessment, basic principles for assessment for area protection and management, and appropriate survey techniques.

One of the major focuses on research in the near future is the 2007–2009 International Polar Year, which will involve new multidisciplinary and collaborative work. Women are playing key roles in this Antarctic science and in related policymaking.

WOMEN IN ANTARCTICA: FROM COMPANIONS TO PROFESSIONALS

Antarctica attracts both women and men. Women have played important roles as supportive wives (e.g., Kathleen Scott and Paquita Mawson); as expedition fund-raisers and publicists (e.g., Dorothy Irving-Bell); as historians of expeditions (e.g., Ann Savours [UK], Gracie Delépine [France], and Helen Wright [US]); as curators of samples collected (e.g., Helen Bargmann [UK]), and in the development of the institutions and services central to the national Antarctic operations today. The Australian National Antarctic Research Expeditions (ANARE) were the first to include key female support staff on resupply voyages to Macquarie Island (scientific secretaries Susan Ingham, biologist, 1959; Ena Thomas, geographer, 1963–1964; and Elizabeth Chipman, 1967; Jutta Hösel, photographer, 1968; and the first female Antarctic journalist, Kirsten Ward, 1961–1962).

Female Companions

Women did accompany men to the far south on exploratory voyages and whalers' and sealers' ships (Chipman 1986). French woman Jeanne Baré (Baret) is the first one recorded, aboard Bougainville's Falkland Islands expedition in 1766–1777. As botanist/

valet, she was the first woman with a professional role in Antarctica. She was followed by country-woman Louise Séguin (Louison), a stowaway on board *Le Roland* on its 1773–1774 voyage to the Îles Kerguelen.

Some were captains' and officers' wives (Rose de Freycinet [France], aboard *Uranie,* 1817–1820; several Australian, American, and British women from 1842 onwards). The first woman accompanying a combined exploratory/whaling voyage was Norwegian Ingrid Christensen, the captain's wife, in 1927–1928. In 1931 she and Mathilde Wegger were aboard *Thorshavn* when it sighted the Antarctic continent, another first. Then in 1935 Captain Klarius Mikkelsen's Danish-born wife Caroline became the first woman to set foot on the Antarctic continent, near today's Davis station.

From the early 1800s women were present on the settlements on the sub-Antarctic islands. The first recorded marriage, birth, and death of females in the far south were in 1850 on the Auckland Islands. In 1890 Henry Charles Mellish managed the sealing gang on Macquarie Island, accompanied by his wife, who acted as cook; there was a New Zealand woman on her husband's whaling base on Campbell Island in 1911, and in 1913–1914 Klara Olette Jacobsen, from Norway, lived with her husband on South Georgia and gave birth to their daughter Solveig there.

Andrée Aubert de la Rüe accompanied her geologist husband on a private expedition to Îles Kerguelen in 1928–1929, the first of four summers and a winter (1952) for the couple. From 1944, women from France, the UK, and Norway came to Îles Kerguelen and South Georgia, as officials' or scientists' wives, and in 1953–1954 an American woman, Eleanor Rice Pettingill, summered with her ornithologist husband on the Falkland Islands. The first woman in the sub-Antarctic in her own right was G. L. Hammond, a New Zealand medical theatre sister on Campbell Island for the 1945–1946 summer.

In 1947 Finn Ronne led a private expedition to the Antarctic. Among the twenty-three members were his wife Edith (Jackie), who undertook recording duties, and a recently wed couple, Jennie and Harry Darlington. They were based at Stonington Island off the Antarctic Peninsula. Edith and Jennie, both in their twenties, were the first women to winter in the Antarctic.

During the 1947–1948 summer, Rosa Markmann de Gonzalez Videla and her daughters Rosa and Silvia, the family of the Chilean President, and Elena Cerda de Bulnes, whose husband was part of the presidential party, visited the South Shetland Islands and the Antarctic Peninsula. A second Chilean first lady visited in the 1968–1969 summer (Maria Ruiz-Tagle de Frei Montalva, along with her daughter, and with female journalist Carmen Marinoa de Ginesto), while another Chilean president's wife visited in 1976–1977 (Lucia Hirfiart de Pinochet).

Over a century after women began to accompany men to sub-Antarctic settlements, six women and their children joined the Argentine army base at Esperanza. The probable first marriage on the continent took place there during the 1978 winter.

Women in the Era of Antarctic Science

A new stage in Antarctic exploration began in 1947, with the establishment of national bases primarily for scientific work. Eight years later women began to travel south to undertake their own scientific work. For many, it was both the fulfillment of a dream and a very hard struggle to gain acceptance for Antarctic service. Sir Vivian Fuchs, then Director of the British Antarctic Survey, thought women could not handle the heavy cases of supplies and would require new facilities. Further, "their presence would change the whole psychological atmosphere of the bases" (Brisbane *Courier Mail,* July 12,1963). More bluntly, the US Commander of Operation Deepfreeze, Admiral Dufek, thought women would "wreck the illusion of being frontiersmen going into a new land and the illusion of being a hero" (*Sydney Morning Herald,* May 3, 1959). Such objections persisted even after women were included in official national expeditions. The facilities proved no barrier, since as one woman succinctly stated, "a lock for the toilet doors sufficed," but some doubts about their physical strength and many about their potentially disruptive social and psychological influence persisted well into the 1980s and even 1990s.

The desires to seek adventure, to test oneself in difficult conditions, to experience a small isolated community, and to work in this pristine land are shared by men *and* women, and some women were determined to break into Antarctic work. They repeatedly applied for advertised vacancies, and lobbied officials; they asked why they were rejected, did extra courses, and sought additional experience until it became very difficult to refuse their applications. They were highly selected and faced extra hurdles, such as a trial summer for the first Australian female continental station leader. And for several decades many women reported opposition from some male expeditioners. Women are now included in most national programs, though they still do not constitute half the station personnel even in summer, partly reflecting their underrepresentation in the professions in Antarctica and in senior positions in science.

At first women were ship based. Eminent professor and member of the Council for Antarctic Research of the USSR Academy of Sciences Maria V. Klenova, a marine geologist, was the first, working aboard the Russian vessels *Ob'* and *Lena* and at Mirnyy base, in the summer of 1955–1956. The expedition undertook mapping of uncharted areas of the Antarctic coastline, and her work contributed to the first Antarctic atlas. V. S. Korotkevich, hydrobiologist, and L. M. Nikolaeva were aboard *Ob'* the following summer, Korotkevich returning in 1962–1963. From then onwards Russian women also worked as ship's crew members.

Four women travelled to Macquarie Island with ANARE in December 1959 (Isobel Bennett, marine biologist; Mary Gilham, UK botanist; Susan Ingham, biological secretary; and Hope Macpherson, intertidal ecologist). Bennett and Macpherson returned the following summer, together with Ann Savours (historian, UK) and Elise Wollaston (botanist). Based on *Thala Dan,* under charter to the Australian program, Danish radio officer Inger Knudsen made her first visit to the continent in 1967–1968, the first female ship's officer.

Two French women spent the 1961–1962 summer on Îles Kerguelen: geophysicist Jeanne Baguette and an engineer specialising in the ionosphere, Dr. Genéviève Pillet, the latter returning in 1964–1965 and 1967–1968. In 1962–1963, another French engineer, Christiane Gillet, spent the first of many summers in Antarctica. As head of the technical bureau of the Expéditions Polaires Français, she has been responsible for provision and maintenance of technical equipment and machinery for the science programs at the stations. Journalist Yvonne Rebeyrol went south for the 1964–1965 season.

Four female American scientists were on board the USNS *Eltanin* for the first time in 1962–1963: Dr. Mary Alice McWhinnie, an established biologist, and Phyllis Marcinak, E. Figetti, and F. D. Frelen. After spending five more seasons in the south, in 1974 McWhinnie and Sister Mary Odile Cahoon became the first female scientists to winter on the continent. As chief scientist at McMurdo Station, McWhinnie was also the first woman in charge of that station.

In 1968–1969, four experienced Argentine scientists—Professors Irene Bernasconi (marine biologist), Adela Caria (microbiologist), Elena Martínez Fonte (marine biologist), and Carmen Pujals (botanist)—spent the summer conducting research on the continent.

Six women visited the South Pole for the first time in November 1969, linking hands to step off the plane together. Five were scientists, including New Zealanders Eileen McSaveney and Pam Young and Americans Lois Jones (first female scientific team leader), Kay Lindsay, and Terry Tickhill, plus journalist Jean Pearson. Finally, in 1979, medical doctor Michele Raney became the first woman to winter at Amundsen-Scott South Pole Station.

The first female summer scientist at McMurdo Station was psychologist Christine Muller-Schwarze, observing penguin behavior. Arriving just before Jones' team, she declined the brief South Pole trip. The following year two women worked at remote Byrd Station: electrical engineer Irene Peden, and field assistant Julia Vickers (New Zealand). In 1973, Lieutenant Ann E. Coyer became the first American woman to report for Antarctic duty with the US Navy. Female support staff Elena Ann Marty and Janet L. Boyd were included the next year. Twenty years later Trina Baldwin became the first woman to serve as wintering officer-in-charge at McMurdo Station.

Biologist Maria Darby and journalist Dorothy Braxton were the first New Zealand women to visit the Antarctic continent, on a tourist ship (1967–1968). Pam Young followed in 1969–1970 as a field assistant. The first New Zealand woman to undertake her own program was geologist Rosemary Askin, 21 years old when she arrived in Victoria Land in 1970. She continues her Antarctic work today, as does fellow New Zealand geologist Margaret Bradshaw, whose first season was in 1975–1976. Ann Chapman, biologist, and Barbara Spurr, limnologist, also began their research in the Antarctic in 1975–1976. Thelma Rodgers was the first technician at Scott Base in 1976–1977 and the first New Zealand wintering woman in 1979.

The first three Australian women to visit the continent were Elizabeth Chipman (information officer), Jutta Hösel (official photographer), and Shelagh Robinson (welfare officer), in 1975–1976. With them was British doctor Zoë Gardner, first woman to winter on an Australian station (1976, Macquarie Island). The first Australian woman to spend a full summer on the continent was Jeannie Ledingham (Cape Denison, 1977–1978), while in 1981 Louise Holliday, a medical doctor, was the first woman to winter at an Australian continental station (Davis). The first Australian female scientist to conduct a land-based scientific program on the Antarctic continent was biologist Elizabeth Kerry, in 1978–1979. She travelled to many locations around and remote from Casey station, collecting soil, moss, and lichen samples to isolate and identify fungi, as part of her study of the natural fungal flora of Antarctica.

Women soon occupied other positions with ANARE. Sarah Stephens was radio officer in 1977 at Macquarie Island; the next year Enid Borschmann wintered there as chef, and in 1983 Gay Woolley became the first female meteorology observer. The first female station leaders served in 1989: Alison Clifton at Macquarie Island and Diana Patterson at Mawson. Joan Russell followed (1990, Casey), then Louise Crossley (1991, Mawson). Crossley also led the summer Prince Charles Mountains field expedition in 1992. Meteorology observer Denise Allen was the first woman to winter at each of the Australian stations.

Other notable firsts for women include the all-female wintering team of nine at the German station Georg von Neumayer in 1990–1991 under the leadership of Monika Puskeppeleit (mixed wintering teams were allowed from 1995–1996). In 1987–1988 Heather Adamson conducted research at Casey; her daughter Erica was expedition biologist, staying over winter and the following summer. And in 1989–1990 Patricia Selkirk and daughter Jennifer pursued separate projects on Macquarie Island. The first wintering South African women were biologists Marianna Steenkamp and Marieta Cawood at Marion Island in 1987–1988.

By 1992 women were members of wintering teams for Argentina, Australia, New Zealand, Russia, the UK, and the United States, and in that year botanist Maria Agata Olech was base leader for the Polish station Arçtowski. Brazilian women were also taking leadership roles. The first black South African woman to be principal investigator for an Antarctic project was Law Professor Loretta Feris (2005–2006 season).

International cooperation is an integral part of the management of Antarctica, and women have been included in the expeditions of other nations, sometimes well ahead of permission to join their own national operations, or in lieu of national ones. Thus, in 1976–1977 British geologist Janet Thomson, the first British female scientist to undertake Antarctic fieldwork, joined an American expedition.

Women now play key roles in the management of national Antarctic programs. Gillian Wratt was director of the New Zealand Antarctic Programme from 1992–1996. From 1996 to 2002 she was chief executive of the newly created New Zealand Antarctic Institute (Antarctica New Zealand). Other positions she has held include chair of the Council of Managers of National Antarctic Programmes (COMNAP), 1998–2001; vice chair of the Antarctic Treaty Committee on Environmental Protection, 1998–2001; and chair of the Cape Roberts Project Operations Management Group, 1993–2002. Margaret Lanyon had a 36-year career as manager of the US New Zealand Antarctic Operations. For 15 of her 20 years with the British Antarctic Survey (BAS), Linda Capper has been head of press, publicity, and education. Carol Jacobs has been assistant director (liaison and administrative services) since 1995 with the South African National Antarctic Programme (SANAP) and the Prince Edward Islands Management Committee (PEIMC).

Women are now country members and observers on the three major scientific groups of the international Scientific Committee on Antarctic Research (SCAR). They serve as experts on Antarctic science selection panels, and three of the six Antarctic science program directors at the US National Science Foundation are currently women: Marie Bundy, Julie Palais, and Polly Penhale.

Honors for Women's Antarctic Service

Women have received UK awards for polar service. In 1986, Virginia Fiennes became the first woman to be awarded the Polar Medal, for her part in the Transglobe Expedition. New Zealand geologist Margaret Bradshaw received a Polar Medal in 1993, Jane Francis (a paleoclimatologist) received one in 2002, and Elizabeth Morris (a glaciologist) received one in 2003. An Order of the British Empire (OBE) was awarded to Morris in 2002, and a Member of the British Empire (MBE) to Linda Capper of BAS in 2003. Bradshaw has also received the Royal Society of New Zealand Science & Technology Medal in 1994.

Norwegian glaciologist Monica Kristensen-Solås received the Founder's Gold Medal of the Royal Geographical Society in 1989 as originator and leader of the 1986–1987 "90 Degrees South Antarctic Expedition." This expedition commemorated the seventy-fifth anniversary of Roald Amundsen's attainment of the South Pole. Using dogs, like Amundsen, Kristensen's party was 400 km short of the South Pole when forced to turn back to rendezvous with the ship, a hazard for many Antarctic expeditions.

BAS makes two awards. The Fuchs medal, in recognition of outstanding devotion to the Survey's interests and beyond the call of duty, has been received by Eleanor Honnywill (1975), Anne Todd (1987), Myriam Booth (1989), Janet Thomson (2001), and Alex Gaffikin (2001). The BAS Club Laws Prize for a young polar scientist was won in 2000 by Anna Jones.

The Australian Antarctic Medal has been awarded to six women: Denise Allen (1989, meteorological observer and deputy station leader); Lynn Williams (1989, medical officer, researcher, and field leader); Meredy Zwar (1995, outstanding chef and expeditioner); Judith Clarke (1996, veterinary biologist); Madeleine Wilcock (2000, doctor, for an emergency rescue), and Patricia Selkirk (2004, terrestrial biologist and mentor of many younger scientists).

Women have also been recognized in the awards of other nations.

Adventurers

Nancy Griffith was one of the crew of six aboard the yacht *Awahnee* that circumnavigated the Antarctic in 1971. Two private ventures in 1977–1978 included women. New Zealander Naomi James sailed to the Falkland Islands on the *Crusader,* and Australian-born Sally Poncet made her first venture south, with French husband Jérôme, aboard *Damien II*. The Poncets have subsequently wintered on the continent, settled in the Falklands with their three sons, and spend six months of each year studying bird populations on the islands surrounding Antarctica.

Virginia Fiennes was not only a key inspiration for her husband's 1979–1982 Transglobe Expedition, she was the radio operator, wintering at Ryvingen in Dronning Maud Land. She also designed the huts for the base camp. Jill McNicol was the cook for the sea portion of the expedition, and New Zealander Jeni Bassett was on board as seabird and mammal observer.

The Oceanic Research Foundation (ORF) undertook its first Antarctic expedition in 1977–1978 with Australian mountaineer Dorothy Smith aboard. Elizabeth Kerry, already a veteran of three summers on Macquarie Island, studied soil samples with that expedition. Smith participated in the second ORF venture in 1981–1982, a joint Australia–New Zealand expedition to Douglas Mawson's old base at Cape Denison that included Jeni Bassett, Margaret Huenerbein, Karen Keys, and Barbara Muhvich. An international group under the auspices of ORF froze their ship in for the 1983 winter. Mimi George, an American psychologist and deputy leader, studied reactions to the extreme conditions. British geographer Gillian Cracknell was also there. Pauline English and Meg Thornton were on William Blunt's 1983 expedition to Heard Island, where they both successfully climbed Big Ben, Australia's highest mountain. Thornton again visited Heard Island in 1984–1985. Blunt subsequently became involved with Project Blizzard, the attempt to restore Mawson's historic huts, which involved Julie Johnston and Estelle Lazer in 1984–1985, Angela McGowan in 1985–1986, and Lazer again in 1986–1987.

Further private visits have taken place since 1981–1982, often husband–wife couples, with women from Australia, France, Germany, and the United States. Margaret Werner made her first visit in 1988 as a crew member of an Australian Bicentennial team. Australian Brigitte Muir climbed Mt. Vinson Massif in 1991 and became the first woman to climb the highest peak on every continent.

The South Pole has become the goal of overland treks by ski and sail. The first two women to ski there were Americans Victoria Murden and Shirley Metz in 1988–1989, with a mixed team of eleven. An American all-female group reached the Pole in 1992–1993: Ann Bancroft (leader), Sue Giller, Anne Dal Vera, and Sunniva Sorby.

The first female solo, unsupported journey to the South Pole was made in 1994 by Norwegian Liv Arnesen, who covered 1200 km in 50 days. In 2001 she and Ann Bancroft made the first female attempt to cross the entire continent by ski and sail. Insufficient wind prevented them from reaching the opposite coast unaided by a few days. Three years after her solo trek to the South Pole in 1996, French alpinist Laurence de Ferrière left the South Pole to cross virgin territory to the coast at Dumont D'Urville Station. The French Polar Institute insisted on picking her up, 275 km short of her target, due to dangerous weather.

In 2000 five British women walked to the South Pole: Caroline Hamilton, Pom Oliver, Ann Daniels, Rosie Stancer, and Zoe Hudson. Rosie returned alone in 2004, the oldest woman to make it (43) and the second-fastest person. Two other British women walked to the South Pole in 2000: Fiona Thornewill (with husband Mike) and Catherine Hartley. Thornewill also trekked there alone in 2004, arriving 3 days ahead of Stancer.

WORDIE, JAMES

Sir James Mann Wordie was the elder statesman of polar exploration, whose 45-year career as explorer and academic linked the Heroic Age of Antarctic exploration with the mechanised and scientific era. He participated in nine polar expeditions, pioneered the concept of "summer expeditions," and greatly influenced a new generation of explorers.

Wordie was born in Glasgow on April 26, 1889, the youngest son of wealthy businessman John Wordie and his wife Jane (née Mann). He excelled as a student, first at the Glasgow Academy, then graduated from Glasgow University in 1910 with an honours degree in geology and attended St. John's College, Cambridge, as an advanced geology student.

Wordie met Raymond Priestley and Frank Debenham, veterans of Robert Falcon Scott's *Terra Nova* expedition (1910–1913), at Cambridge and volunteered to join Ernest Shackleton's Imperial Trans-Antarctic Expedition (1914–1917) as geologist. He was marooned on Elephant Island for four and a half months in 1916 and appointed chief of scientific staff on his return to the UK with responsibility for the publication of the expedition's official papers. Wordie joined the Royal Field Artillery in 1917 and was wounded near Armentieres in 1918.

Wordie travelled on two expeditions to Spitsbergen under William Speirs Bruce (1919 and 1920), and in 1921 ventured to Jan Mayen Island, where he made the first-ever ascent of Mt. Beerenberg. Wordie led five more voyages to the Arctic (East Greenland, 1923, 1926, and 1929; Baffin Bay, 1934; and Greenland and the Canadian Arctic, 1937) and was a mentor to the younger ranks of explorers, including Vivian Fuchs, Gino Watkins, and August Courtauld. He developed the private "university summer expeditions," which helped switch the focus of Arctic journeys from geographic discovery to scientific understanding. For 30 years he advised numerous Antarctic and Arctic expeditions, including the British Graham Land Expedition (1934–1937) and the Norwegian-British-Swedish Antarctic Expedition (1949–1952). By the 1930s, few expeditions left Britain without first consulting Wordie.

Wordie was a formidable administrator and was associated with creating the Scott Polar Research Institute (SPRI) in 1920, and he was chairman of the management committee of the institute for 18 years. He helped develop British policy towards the Antarctic regions, initially as a member of the Discovery Committee for 20 years from 1923. In 1943 he was the head of Operation Tabarin, the Naval Intelligence body responsible for the Antarctic, which later became the Falklands Islands Dependencies Survey (FIDS) and subsequently the British Antarctic Survey (BAS). Wordie was appointed honorary secretary of the Royal Geographical Society (RGS) in 1934 and president of it in 1951. He was vice-chairman of the Everest Committee, which was a major force behind the first successful ascent of Mount Everest. He was a close advisor to Fuchs and vice-chairman of Fuchs's Commonwealth Trans-Antarctic Expedition (1955–1958), which made the first crossing of Antarctica. He was also chairman of the British Mountaineering Council (1953) and chairman of the British National Committee for the International Geophysical Year (1957–1958). During his acclaimed academic career at St. John's College, Cambridge, Wordie was appointed lecturer and tutor of geology, president (1950), and master of the college (1952–1959).

Wordie's honours include the Silver Antarctic Medal (1917); Back Grant, RGS (1920); Bruce Medal, Royal Society of Edinburgh (1926); Founder's Medal, RGS (1933); Order of St. Olav, Norway (1943); Gold Medal, Royal Scottish Geographical Society (1944); Commander of the British Empire (1947); Charles Daly Medal, American Geographical Society (1952); and knighthood for services to polar exploration (1957). He died on January 16, 1962.

WORLD CLIMATE RESEARCH PROGRAMME (WCRP)

The World Climate Research Programme (WCRP) was established as a principal component of the World Climate Programme in 1980, with joint sponsorship from the World Meteorological Organization and the International Council for Science (ICSU). The Intergovernmental Oceanographic Commission (IOC) of UNESCO became a sponsor in 1993. WCRP has two major objectives: to determine the extent to which climate can be predicted, and to determine the extent of human influence on climate. A WMO/ICSU/IOC Joint Scientific Committee is responsible for formulating the overall scientific concepts and goals of the WCRP and for organizing the required international coordination of research efforts. The essence of WCRP science is understanding, observation, quantification, prediction, and projection of the climate system on a range of time scales, from intraseasonal through seasonal, yearly, and decadal to centennial. The economic, environmental, and social benefit of such forecasts is already significant and will grow as prediction skill improves.

Whilst WCRP research focuses on the physical system, it is increasingly concerned with the more complete climate system, which includes chemical and ecosystem interactions, and the interactions of human activities with global climate and the environment. Thus, the WCRP has joined with other global environmental programmes (IGBP, IHDP, and DIVERSITAS) to form the Earth System Science Partnership to further the integrated study of the earth system, the changes that are occurring, and the implications for global sustainability.

WCRP currently consists of four broad-based multidisciplinary core projects, all relevant to Antarctica. The Climate Variability and Predictability Project (CLIVAR) (http://www.clivar.org), a follow-on from the World Ocean Circulation Experiment and the Tropical Ocean–Global Atmosphere project, is focussed on climate variability, extending effective predictions of climate variation, and refining the estimates of anthropogenic climate change. CLIVAR is attempting particularly to exploit the "memory" in the slowly changing oceans and their interaction with the atmosphere and cryosphere.

The Climate and Cryosphere (CliC) Project (commenced in 2000) addresses the ice-covered regions of the Earth's surface (including the Antarctic Ice Sheet and the surrounding ice-covered Southern Ocean). CliC aims to assess the impacts of climatic variability and change on the cryosphere and its overall stability and to determine the consequences of such impacts on climate. CliC seeks to enhance monitoring of the cryosphere, to understand climate-related processes, and to model and understand the cryosphere's role in the climate system. Changes to the cryosphere are particularly important to sea-level change.

Climate processes in the Southern Ocean are important globally and are addressed by a combined CLIVAR–CliC–SCAR Southern Ocean Panel.

The Global Energy and Water Cycle Experiment (GEWEX) focuses on variability and potential change to the global hydrological cycle and energy budget processes. The Stratospheric Processes and Their Role in Climate (SPARC) project is concerned with coupling between the stratosphere and the lower atmosphere, including ozone depletion and its impacts.

The development of improved and comprehensive global climate models is an essential unifying theme running through WCRP. Such models are the fundamental tools for understanding and predicting natural climate variations and for providing reliable estimates of anthropogenic climate change. WCRP contributes to the design and implementation of a comprehensive, integrated, and sustained global climate observing system. WCRP also promotes multiyear model reanalyses of the global atmospheric circulation with state-of-the-art assimilation/analysis schemes. There is a growing need for similar reanalyses for the oceans and for special regions such as the Antarctic.

WORLD CONSERVATION UNION (IUCN)

History

IUPN, the International Union for the Protection of Nature, was founded in 1948 at a Conference at Fontainebleau, France, convened by the Government of France, UNESCO, and the Ligue Suisse pour la Protection de la Nature. It was planned as a world forum for nature conservation, threatened by postwar change. It became IUCN, the International Union for Conservation of Nature and Natural Resources, in 1956, and in 1990 adopted the descriptive title "The World Conservation Union."

Constitution and Programme

IUCN is a uniquely "hybrid" international organization, its 1036 members (in 2004) including 77 states, 114 government agencies, 77 international nongovernmental organizations (NGOs), and 735 national NGOs, spread across 144 countries. Its sovereign body is the General Assembly of all its members, now styled the World Conservation Congress and held every 4 years. The congress elects the president, treasurer, and council, and the chairs of six voluntary networks called Commissions. These latter are another unique feature linking over ten thousand individual conservationists to address the conservation of species, the protection of national parks and other areas, the management of ecosystems, environmental law, education and communication, and environmental economics and social policy.

The headquarters of IUCN is at Gland, in Switzerland, but the secretariat is decentralized, with thirty-two offices scattered around the world. The main programmes are concerned with ecosystems and their management, sustainable human livelihoods, global change and biodiversity, social policies, and environmental law. Many projects are undertaken in developing countries and in partnership with member organizations. The IUCN produces methodological handbooks, overviews of the status of species (notably the authoritative Red List of Threatened Animals), a United Nations List of National Parks and Protected Areas, and a diversity of action plans. IUCN has led in the production of two World Conservation Strategies (in partnership with the United Nations Environment Programme and the World Wide Fund for Nature) and has worked with many countries to prepare National Conservation Strategies.

IUCN and Antarctica

Each General Assembly or World Conservation Congress adopts resolutions and recommendations, and a number of these have called for action in the Antarctic. In 1960 IUCN urged that the new Antarctic Treaty set aside inviolate areas for the conservation of wildlife and supported SCAR's work on what became the Agreed Measures for the Conservation of Antarctic Fauna and Flora. In 1978 IUCN emphasised the need to conserve krill and other Antarctic marine resources, and in 1980 it participated in the negotiation of CCAMLR, the Convention on the Conservation of Antarctic Marine Living Resources. In 1981 the Union proposed that the Antarctic be specially designated as a protected area. In 1984 and 1988 concern was expressed over waste disposal, the depletion of some fish stocks, the rapid expansion of Antarctic tourism, and the possible exploitation of minerals (something most IUCN members strongly opposed).

IUCN itself published an Antarctic Conservation Strategy in 1991 and has held several joint symposia with SCAR. The union has observer status as an NGO at Antarctic Treaty consultative meetings and strongly supported the negotiation of the Protocol on Environmental Protection to the Antarctic Treaty. Its principal contribution is as the voice of the professional world conservation community, but it is significant that the majority of Antarctic Treaty consultative parties are also state members of IUCN.

WORLD METEOROLOGICAL ORGANIZATION

International cooperation in Antarctic meteorological and related sciences and services is underpinned by the activities of the World Meteorological Organization (WMO). Headquartered in Geneva, WMO is an intergovernmental organization that evolved in 1950 from its predecessor, the International Meteorological Organization. WMO is *the* specialized agency of the United Nations (UN) facilitating worldwide cooperation in meteorology, operational hydrology, and related geophysical sciences: 187 Member States and Territories participate (WMO 2004).

To fulfil this role, WMO undertakes a range of activities including the following:

(1) Facilitating the establishment of observational networks.
(2) Promoting the establishment and maintenance of (i) systems for the rapid exchange of meteorological and related information (primarily via the Global Telecommunication System [GTS]), and (ii) centres for the provision of meteorological and related services.
(3) Furthering the application of meteorology and operational hydrology to a range of human activities while encouraging close cooperation between meteorological and hydrological services.
(4) Encouraging research and training in meteorology and related fields.

The structure of WMO is based on an overarching body, The World Meteorological Congress, which is a quadrennial meeting of delegates of WMO Members to determine key policy, financial aspects, and regulatory aspects of WMO. The executive body of WMO is its Executive Council, comprising the directors of national meteorological or hydrometeorological services who meet annually to review the activities of WMO and to implement the programmes approved by the WMO Congress. There are eight technical commissions and ten major scientific and technical programmes, one of which is the cross-cutting Regional Programme (RP), which addresses relevant geophysical issues that are unique to, and of common concern within, a region.

Consistent with the spirit of cooperation that underpins globally based geophysical sciences, WMO has many interagency linkages; for example, oceanography and marine meteorology issues are dealt with through a joint technical commission in conjunction with the Intergovernmental Oceanographic Commission of the UN Educational Scientific and Cultural Organization.

In recognition that global issues may be better handled in subglobal units, there are six WMO Regional Associations (RAs): Africa, Asia, South America, North and Central America, South-West Pacific, and Europe. Each RA is composed of relevant WMO members, who coordinate meteorological and related activities within their respective regions.

The WMO Executive Council Working Group on Antarctic Meteorology (EC-WGAM) was established in 1964 to assume RA-type functions for the Antarctic (south of 60° S). The group's main task is to coordinate WMO's Antarctic Activities Programme (an RP) and in particular implement the World Weather Watch (WWW) basic components (especially observation and telecommunication networks) in the Antarctic. It also collaborates with other international organizations and programmes in operational and research activities in Antarctica, with, for example, the Scientific Committee on Antarctic Research and the Antarctic Treaty Consultative Meeting process.

EC-WGAM developed the Antarctic Basic Synoptic Network (ABSN), which is now an important element of the WWW Global Observing System: the operation and maintenance of the ABSN and the timely transmission of the observational data over the GTS are essential in the provision of meteorological data for global weather analysis and prediction and for climate research (WMO 2003).

WORSLEY, FRANK

If criteria for fame as an Antarctican included achievement on the continent itself, Frank Arthur Worsley would scarcely rate a mention, yet the captain of Sir Ernest Shackleton's ship *Endurance* left a powerful imprint.

Born in the New Zealand coastal settlement of Akaroa on February 22, 1872, Worsley went to sea as a teenager in the merchant navy, rounding Cape Horn on his first voyage. He served in both sail and steam, but sail was his passion, and he became a master navigator, learning about wind and wave, and of wildlife under and over the surface. He was eventually commissioned in the Royal Naval Reserve.

In 1914 Worsley joined Sir Ernest Shackleton's Imperial Trans-Antarctic Expedition (1914–1917) as the master of *Endurance,* the ship that was to deposit Shackleton and his party at the base of the Weddell Sea for a planned crossing of the Antarctic continent. Worsley and Shackleton shared many qualities and became good friends, brought together in peculiar circumstances. Shackleton selected him on hearing of "Worsley's Dream," in which Worsley saw himself navigating a ship through ice blocks down Burlington Street, London. He went there next day, found the expedition's headquarters, and met Shackleton, whose offer for being captain of the ship had recently been turned down by John King Davis.

After *Endurance* was crushed and the party drifted for months on the pack ice of the Weddell Sea, Worsley had his finest moments when three small boats were launched in April 1916. In charge of *Dudley Docker,* his navigation proved crucial in guiding the boats to the rocky dot of Elephant Island in a 5-day voyage that renewed hope for the men, some of whom were close to madness or death. That voyage was, in some senses, a more cruel and chilling experience than even the famed journey in the best of those small boats, *James Caird* (which had been built to Worsley's specifications).

Worsley was Shackleton's first choice for the six-man crew of *James Caird,* for his dead-reckoning skills and uncanny ability to snap sun-sightings and calculate positions in difficult conditions, as well as his proven small-boat sailing expertise. In the event, he navigated the small vessel about 800 miles (1300 km) from Elephant Island to South Georgia. The extraordinary 16-day journey—riding massive waves that hurtled endlessly around the boat—was possible only due to his seamanship, his navigating excellence, and the four sightings of the sun he managed under terrible conditions. At the end of the voyage, he brought *James Caird* back from disaster in a leeward storm to a safe landing.

After their arrival on the far side of South Georgia, from where help could be obtained at a whaling station, Worsley joined Shackleton and Tom Crean in crossing the virgin heights of the island, sealing their success. One sees in Worsley an extraordinary seaman with an explorer's heart.

Worsley commanded Q ships during World War I and was twice decorated for antisubmarine actions and while serving in the Russian theatre. He and Shackleton sailed together again on the Shackleton-Rowett Expedition of 1921–1922 on *Quest*. The two friends—notoriously bad money managers—dreamed of finding treasure, and they were hoping for a Pacific pearl lagoon as a finale to the expedition, a warmly anticipated period of pleasure sadly to end with Shackleton's untimely death at South Georgia.

In 1925 Worsley became joint leader of an expedition to Franz Josef Land, and a decade later he finally had his treasure hunt on Cocos Island, finding nothing. He retired from active work on the sea in 1939, becoming an instructor at the Royal Naval College, Greenwich. He died in England on February 1, 1943 from lung cancer, at the age of 70.

Y

YELLOW-NOSED ALBATROSS

Following a DNA study of all the world's albatrosses (order Procellariiformes) in the 1990s, the species previously known as the yellow-nosed albatross *Diomedea chlororhynchos* was placed, along with rest of the "mollymawks" (the smaller Southern Ocean albatrosses), in the genus *Thalassarche* and split into two species. As itsname suggests, the Atlantic yellow-nosed albatross *T. chlororhynchos* is found over the South Atlantic Ocean, and its close congener, the Indian yellow-nosed albatross *T. carteri,* occurs over the southern Indian Ocean.

Both yellow-nosed albatrosses are small and predominantly black and white, with the upper ridge of the black bill yellow with an orange tip in adulthood. The two species may be distinguished in the hand by the shape of the upper end of this yellow stripe: rounded in Atlantic birds and pointed in Indian birds. Additionally, and allowing for identification at sea when in adult plumage, Atlantic birds have a pale grey head, whereas Indian birds have a white head. Juveniles, with all-black bills and white heads, are difficult to identify to species at sea.

Individuals of the Atlantic yellow-nosed albatross breed only at the Tristan da Cunha group of islands (United Kingdom): Tristan, Inaccessible, Nightingale, and Gough Islands. A breeding population of c. 36,800 breeding pairs suggests a global population of 165,000–185,000 birds. However, recent accurate surveys of breeding numbers are unavailable for all islands. Evidence from Gough Island shows a decreasing population of c. 5300 pairs. Individuals of the Indian species breed on the Prince Edward Islands (South Africa) and the three French island groups of Île Amsterdam and Île St. Paul, Îles Crozet, and Îles Kerguelen. Its total population has been estimated as 36,500 breeding pairs, which is known to be decreasing at some studied breeding sites.

Birds of both species occur at sea in the southern Atlantic and Indian Oceans between South America and New Zealand, but not in the Pacific Ocean. It is likely that individuals of both species are largely restricted to their own oceans.

Birds of both yellow-nosed albatross species are annual breeders, nesting more or less colonially on pedestal nest mounds made of scraped-up mud, in which a single egg is laid. In the Tristan group, birds nest among thick vegetation (ferns and *Phylica* trees), whereas Indian Ocean birds may breed on exposed cliffs and slopes at their more southerly sites. Breeding commences after 5 years or more, with both parents sharing incubation and chick-rearing. Fidelity to mate and nest site are high, as in all mollymawks, but divorce does sometimes occur. The pedestal nest may be reused for many seasons. Breeding success is typically of the order of 60%–70% but in some years can approach zero, as when a disease outbreak, perhaps human-introduced, kills chicks.

Individuals of both species feed on squid and fish, less commonly crustaceans, taken by surface-seizing and shallow plunges. Scavenging from fishing vessels occurs, leading to mortality as birds drown on baited longline hooks. Because of this, and their decreasing populations, both species have been classified as Endangered (very high risk of extinction) by BirdLife International on behalf of the World Conservation Union.

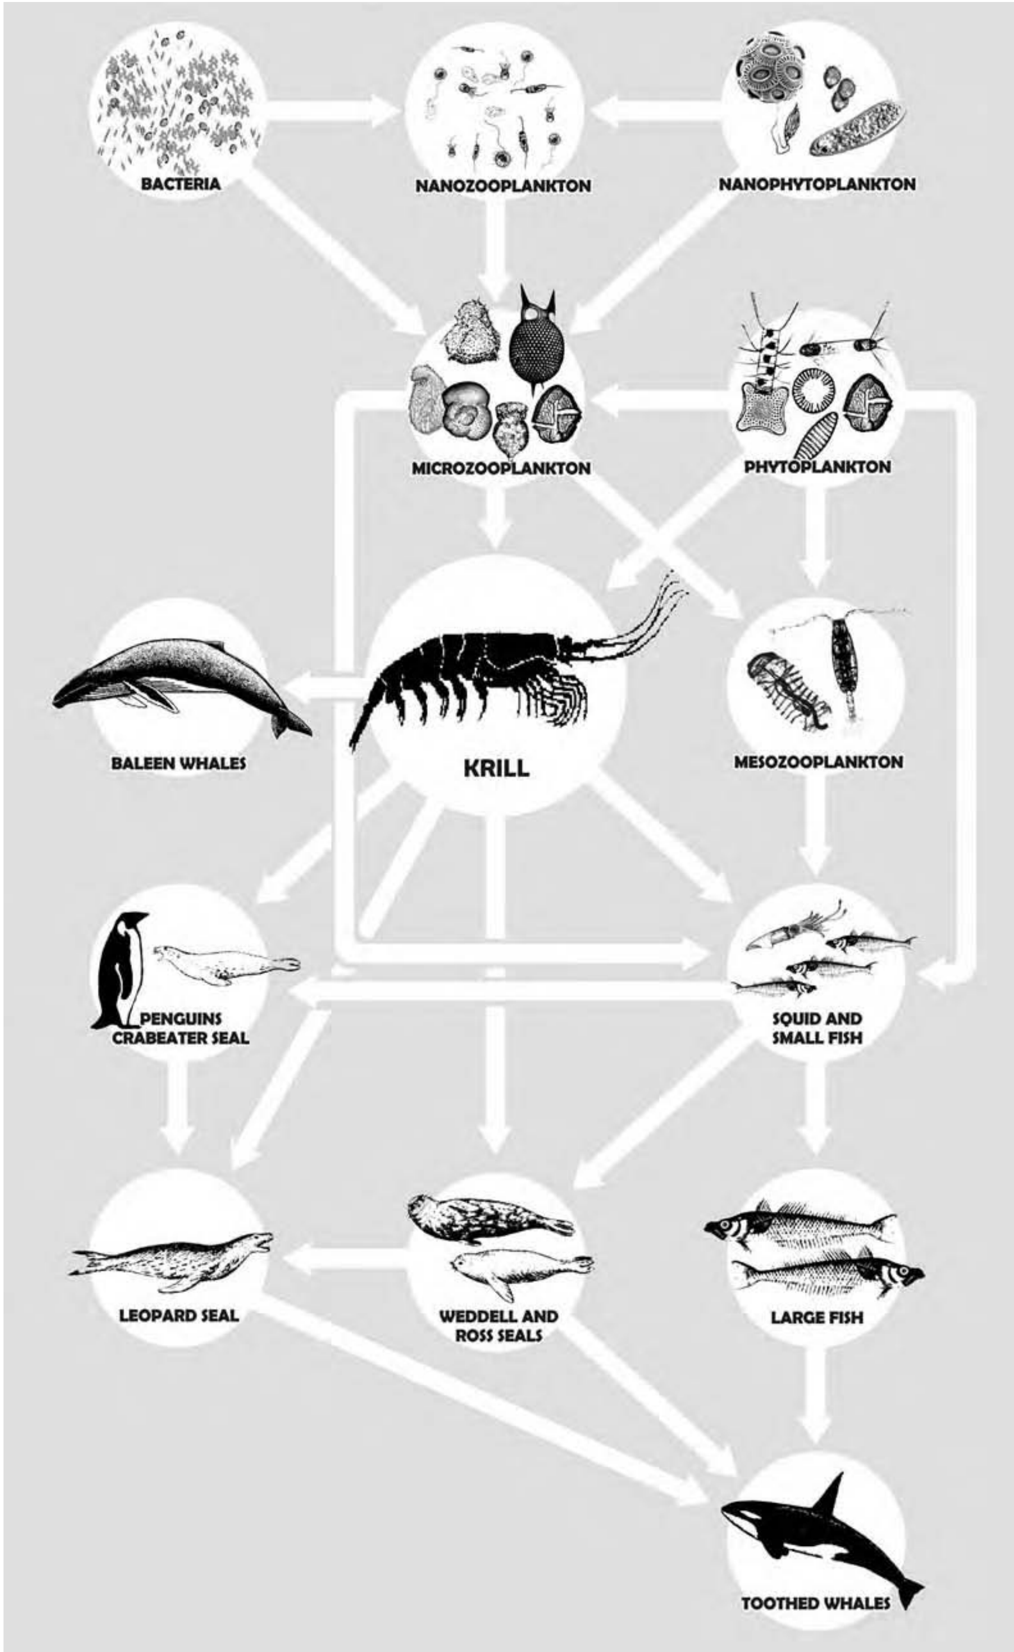
Z

ZOOPLANKTON AND KRILL

Zooplankton are marine or freshwater animals that live in suspension in the water column, from the surface to abyssal oceanic depths (>10,000 m). The swimming capabilities of these organisms are not strong enough to preclude their horizontal distribution from being governed by currents, but most are capable of maintaining a preferred depth range, and many can migrate vertically tens to hundreds of meters daily. Zooplankton include a diverse range of organisms: many single-celled organisms, often with elaborate calcareous or siliceous skeletons (Foraminifera, Radiolaria); gelatinous predatory (Hydromedusae, Siphonophorae, Scyphozoa, Ctenophora, Polychaeta, Chaetognatha) and particle-filtering forms (Pteropoda, Appendicularia, Salpidae); many crustaceans (Cladocera, Ostracoda, Copepoda); fish larvae; etc. The term "plankton," which encompasses plants (phytoplankton) and animals (zooplankton), is derived from the Greek "planktos," meaning wandering or drifting. Its first use is ascribed to the German biologist Viktor Hensen in 1887.

Zooplankton can be classified according to size, life-cycle traits, morphology, feeding mode, etc. Classifications based on size, most useful for methodological purposes (most plankton sampling gears are size-selective), recognize seven size categories, ranging from ultrananoplankton (below 2 µm; bacteria, viruses) to megaloplankton (>20 cm; many jellyfish). Holoplankters are those organisms that spend their entire life cycle in the water column, as opposed to meroplankters, which are nonplanktonic at some stage in their lives. For example, most marine benthic (bottom-dwelling) animals, like starfish, clams, mussels, snails, worms, and crabs, have a planktonic stage represented by their gametes (sperm and ova) and larvae. Also, the early stages of fish and squid are part of the plankton until they grow large enough to become strong swimmers, at which time they are considered to belong to the nekton.

In total, c. 7000 species of marine zooplanktonic animals have been described, distributed among approximately 30 groups. The most speciose holoplankters are the copepods, a group of small (around 1 mm) crustaceans for which over 2000 free-living marine planktonic species are known. A few groups have 300–600 species (e.g., other crustaceans like Mysidacea and Amphipoda, the Hydromedusae [a group of small jellyfish], and the single-celled Radiolaria and Tintinnina), with most others ranging around 50–100 described species worldwide. Although most zooplanktonic taxa have representatives south of the Polar Front, the numbers of Antarctic species are very variable between groups: some are almost absent from the area (like the single-celled Acantharia, or the Heteropoda [planktonic snails]), while others are very well represented. The most conspicuous zooplanktonic organisms are the crustaceans (Copepoda, with over 100 species; Euphausiacea; Amphipoda; Ostracoda), followed by Chaetognatha, Salpidae, Polychaeta, Phaeodaria, and Appendicularia. However, on average, the waters around Antarctica are relatively



Simplified scheme of Antarctic food web.

species poor, hosting some 1500 described holoplanktonic species (as compared with 5000–6000 for the Tropics and sub-Tropics).

Probably the most important Antarctic zooplankter is *Euphausia superba* or krill—a shrimp-like crustacean of the order Euphausiacea (the term "krill" is also applied to any of the c. eighty species of these planktonic crustaceans). Krill have an elongated head–trunk region (cephalothorax) where the food gathering, manipulating, and grinding limbs are inserted, and a muscular, segmented tail (abdomen) provided with five pairs of paddle-like swimming legs. Adult individuals are approximately 6 cm in length and weigh over a gram. Their body is reddish-transparent, with large black eyes and bioluminescent organs (photophores) on the lower side, but dead and preserved specimens are opaque. Krill feed mainly on phytoplankton, but planktonic animals are common in their diet as well.

The abundance of zooplankters in sea water is roughly inversely proportional to their size. Thus, bacteria, at less than 1 μm in diameter, are present in densities around 10^8–10^9 l^{-1}; protist concentrations (ciliates, Foraminifera, Radiolaria), whose size ranges from 10–100 μm, are usually around 10 to 10^3 l^{-1}; medusae (Hydromedusae), whose bodies measure around 5–15 mm, seldom reach densities over 0.05 l^{-1}; etc. But as opposed to diversity, abundance of zooplankton is not associated with latitude. The richest areas in numbers of individuals are located along the continental shelves. Antarctic waters have generally moderate to low zooplanktonic abundances, except during the short austral summer, when reproductive activity is concentrated. One notable exception is krill, which form huge swarms up to several hundreds of meters across, with densities of over 20 animals per liter and up to 15–20 kg per m^3. Stocks of krill around Antarctica are estimated at 300 to 1000 million metric tonnes, with a potentially sustainable harvest of 150 million metric tonnes a year (more than that of all other oceanic species of fish and shellfish throughout the world combined).

One of the most outstanding features of the Southern Ocean is its extreme seasonal cyclicity, whereby the scarcity of light in the ice-covered waters determines a strongly food-limited winter, which alternates with an ice-free season when phytoplankton growth is active in the water column. The life cycle of most Antarctic zooplankters is finely tuned to these changes.

Most herbivorous copepods (e.g., *Calanus propinquus, Calanoides acutus,* and many others) feed actively on the early-spring (October) phytoplankton bloom and shortly thereafter reproduce in the surface waters. Newborns graze vigorously in these upper phytoplankton-rich layers throughout the summer, and as they grow they sink in the water column. By May, when the pack ice starts waxing and food becomes scarce, they have reached an advanced larval stage and are located in deeper waters (250 to over 1000 m, depending on the species). Here they spend the winter in a dormant state, rising back to the surface in spring, where they feed, mature, and reproduce.

Other organisms, while also finely tuned to Antarctic seasonality, have a different reproductive strategy. *Euphausia superba* (krill) spawns in the upper layers (each female may lay up to 10,000 eggs at a time) and the fertilized eggs slowly sink; at 2000–3000 m the newborn hatch and start swimming upwards. They reach the surface in an early larval stage and start grazing. During their first year krill complete their nine-stage larval development, during the second year they graze and accumulate reserves, and by the third year of life they mature sexually and reproduce. During the summer, *E. superba* is an active filterer of the microplankton suspended in the water column, but during the winter, when food particles in the water are very scarce, it scrapes the undersurface of the ice pack, harvesting algae and other microorganisms.

Zooplanktonic organisms are key elements in marine food webs. They are active consumers of phytoplankton, and are in turn fed upon by other zooplankton, cephalopods, fish, and marine birds and mammals. In some areas, like the Southern Ocean, their importance is enhanced by the fact that the single-celled sarcodines and ciliates feed upon the abundant nanoplanktonic and ultrananoplanktonic particles (bacteria, autotrophic flagellates), and are in turn consumed by larger zooplankters, like copepods and euphausiids. The size of these bacteria and flagellates is too small for the larger zooplankters to efficiently feed on them; thus, the protists convert the organic matter into a size more easily available to higher levels of the food web. On the other hand, the grazing and predatory activity of some zooplankters can be so intense that they strongly affect the abundance and biomass of other plankton, including fish larvae, thus reducing fish populations. In the Southern Ocean, krill is a key component of food webs as it constitutes the major direct or indirect source of food of most of the larger Antarctic animals, such as fish, squid, seabirds, seals, and whales.

The abundance of krill has called the attention of scientists and fishers since its discovery, and in the early 1970s commercial fishing was started in Southern Ocean waters. Krill landings increased swiftly from 59 tonnes in 1973 to c. 50,000 tonnes in 1982–1986 (with a drop to c. 200,000 tonnes in 1983–1985, probably partly due to the Argentina–United

Kingdom war over the Falkland Islands). However, between 1987 and 1993, catches shrank to around 100,000 tonnes, remaining at those levels until the present (in the 2002–2003 season 116,866 tonnes of krill were caught by a total of five countries: Japan, South Korea, Ukraine, the United States, and Poland, with the first three accounting for over 80% of the catch). The main reason for this decline is the remoteness of the area. Profitability is also reduced by the fact that krill has powerful enzymes that break down its tissues soon after death, spoiling the catch, and the high concentrations of fluoride in the shell (which is toxic and has to be removed before the meat is fit for consumption). In addition, market demand for krill has decreased in the last decade in association with the strong worldwide increase in the production of farmed shrimp. In 1991, the Convention on the Conservation of Antarctic Marine Living Resources (CCAMLR) set a precautionary catch limit of about 10% of the biomass, but since 1993, catches have been far below these threshold values. Krill biomass, however, has also decreased considerably over the past century. In the southwest Atlantic sector, which contains >50% of Southern Ocean krill stocks, mean densities have declined significantly since the 1970s, probably as a response to waning winter ice coverage.

While krill has a circumpolar distribution, the highest concentrations are found in the area around South Georgia and the Antarctic Peninsula, which is where most of the fishing activities take place. Krill are caught by large freezer trawlers and processed on board into products for consumption by humans, domestic animals (cattle, poultry, pigs), and farmed fish, and for sport fishing bait. Krill are especially rich in vitamin A.

Appendix I: Chronology of Antarctic Exploration

Years	Expedition	Leader	Vessel
1487–88	**Portuguese Naval Expedition** Discovered and rounded Cape of Good Hope and reached southern limit of Africa at Cape Agulhas, opening a sea route to Indian Ocean	**Bartholomeu Diaz de Novaes**	
1497–99	**Portuguese Naval Expedition** Discovered sea passage around southern tip of Africa to India	**Vasco da Gama**	***São Gabriel* & 3 other ships**
1501–02	**Portuguese Maritime Voyage** Reported land at 52° S, possibly Patagonia	**Amerigo Vespucci (pilot)**	
1506	**Portuguese Naval Voyage** Discovered Tristan de Cunha group	**Tristão da Cunha**	***Santiago* & 13 other ships**
1519–22	**Spanish Maritime Voyage** Discovered Strait of Magellan and Tierra del Fuego; completed first circumnavigation	**Ferdinand Magellan**	***Vittoria* & 4 other ships**
1577–80	**English Maritime Voyage** Discovered Drake Passage and proved Tierra del Fuego was not part of "Terra Australis Incognita"; completed second circumnavigation	**Francis Drake**	***Pelican (Golden Hind)* & 4 other ships**
1592	**English Naval Expedition** Discovered Falkland Islands	**John Davis**	**HMS *Desire***
1615–16	**Netherlands Exploring Expedition** Discovered Cape Horn and Le Maire Strait	**Jakob Le Maire**	***Eendracht* & *Hoorn***
1617–18	**Netherlands Voyage** Discovered Île St. Paul	**Haevik Klaaszoon van Hillegom**	***Zeewolf***
1663	**Netherlands Voyage** Discovered what might have been Prince Edward Islands	**Barend Barendszoon Lam**	***Maerseveen***
1674–75	**English Mercantile Voyage** Discovered what was probably South Georgia	**Antonio de la Roche**	
1738–39	**French Exploring Voyage** Discovered Bouvetøya	**Jean-Baptiste Bouvet de Lozier**	***Aigle* & *Marie***
1768–71	**British Naval Expedition** Explored Tierra del Fuego and Drake Passage; made discoveries in Australia and New Zealand	**James Cook**	***Endeavour***
1771–72	**French Exploring Expedition** Discovered Îles Kerguelen	**Yves-Joseph de Kerguelen-Trémarec**	***Fortune* & *Gros-Ventre***
1771–73	**French Exploring Expedition** Discovered Îles Crozet	**Marc Macé Marion du Fresne**	***Mascarin***
1772–75	**British Naval Expedition** First crossing of Antarctic Circle; attained farthest south of 71°10′ S; claimed South Georgia; discovered South Sandwich Islands; completed circumnavigation in a high southern latitude	**James Cook**	***Resolution* & *Adventure***
1773–74	**French Naval Expedition** Revisited and charted Îles Kerguelen	**Yves-Joseph de Kerguelen-Trémarec**	***Rolland* & 2 other ships**
1776–80	**British Naval Expedition** Visited and named Prince Edward Islands; visited Îles Crozet and Îles Kerguelen	**James Cook**	***Resolution* & *Discovery***

Years	Expedition	Leader	Vessel
1805–06	**British Whaling Voyage** Discovered Auckland Islands	**Abraham Bristow**	***Ocean***
1809–10	**New South Wales Sealing Voyage** Discovered Campbell Island	**Frederick Hasselburg**	***Perseverance***
1810	**New South Wales Sealing Voyage** Discovered Macquarie Island	**Frederick Hasselburg**	***Perseverance***
1819	**British Mercantile Voyage** Discovered South Shetland Islands	**William Smith**	***Williams***
1819–20	**British Exploring Expedition** Surveyed South Shetland Islands; discovered Trinity Land; took possession of King George Island and Clarence Island	**Edward Bransfield (senior naval officer)**	***Williams***
1819–21	**Russian Naval Expedition** Circumnavigated Antarctic continent; made first confirmed sighting of Antarctic continent; discovered Peter I Øy and Alexander Island	**Fabian von Bellingshausen**	***Vostok* & *Mirnyy***
1820–21	**US Sealing Voyage** Nathaniel Palmer in *Hero* reported land that was later named Palmer Land	**Benjamin Pendleton**	***Frederick* & 5 other ships**
1820–22	**US Sealing Voyage** Made first confirmed landing on the mainland coast of Antarctica	**John Davis**	***Huron* & 2 other ships**
1821–22	**British Sealing Voyage** In company with Nathaniel Palmer *(James Monroe)*, discovered and charted South Orkney Islands	**George Powell**	***Dove* & *Eliza***
1821–22	**US Sealing Voyage** In company with George Powell, Nathaniel Palmer *(James Monroe)* discovered and charted South Orkney Islands	**Benjamin Pendleton**	***Frederick* & 6 other ships**
1822–24	**British Sealing Voyage** Established farthest south of 74°15′ S in Weddell Sea	**James Weddell**	***Jane***
1828–31	**British Naval Expedition** Visited South Shetland Islands to make pendulum and magnetic observations on Deception Island	**Henry Foster**	**HMS *Chanticleer***
1829–31	**US Sealing Voyage** First US government-sponsored Antarctic expedition	**Benjamin Pendleton**	***Seraph* & 2 other ships**
1830–33	**British Exploring Expedition** Discovered Enderby Land and Graham Land	**John Biscoe**	***Tula* & *Lively***
1833–34	**British Expedition** Discovered Heard Island and Kemp Land	**Peter Kemp**	***Magnet***
1837–40	**French Naval Expedition** Circumnavigation; explored much of Antarctic coast; discovered Terre Adélie; first saw Adélie penguins	**Jules-Sébastien-César Dumont d'Urville**	***Astrolabe* & *Zélée***
1838–42	**US South Seas Exploring Expedition** Discovered Wilkes Land and some 1500 miles of "coastline"; published expedition charts were first to use term "Antarctic Continent"	**Charles Wilkes**	***Vincennes* & 5 other ships**
1839–43	**British Naval Expedition** Circumnavigated continent; first to pass through pack ice to reach Ross Sea; discovered Victoria Land and charted 550 miles of it; discovered Ross Island, Ross Ice Shelf	**James Clark Ross**	**HMS *Erebus* & HMS *Terror***

1853–54	**British Voyage**	**William McDonald**	***Samarang***
	Discovered McDonald Islands		
1872–76	**British Naval & Scientific Voyage**	**George Strong Nares (1872–74)** **Frank Tourle Thompson (1875–76)**	**HMS *Challenger***
	Conducted oceanographic research while making circumnavigation; first steamship to cross the Antarctic Circle; visited many sub-Antarctic islands		
1873–74	**German Sealing & Exploring Expedition**	**Eduard Dallmann**	***Grönland***
	Visited South Shetland Islands and South Orkney Islands; charted coast and islands in region of Bismarck Strait		
1882–83	**German International Polar Year Expedition**	**Karl Schrader (Leader)**	
	Established scientific station and conducted scientific studies for more than a year		
1892–93	**Dundee Whaling Expedition**		**4 ships**
	Reconnaissance to investigate Antarctic whaling possibilities; W.S. Bruce and others conducted scientific programs		
1892–93	**Norwegian (Sandefjord) Whaling Expedition**	**Carl Larsen**	***Jason***
	Reconnaissance to investigate Antarctic whaling possibilities in Antarctic Peninsula region		
1893–94	**Norwegian (Sandefjord) Expedition**	**Carl Larsen**	***Jason* & 2 other ships**
	Exploratory and whaling and sealing expedition; discovered King Oscar II Coast, Foyn Coast, and Robertson Island; first use of ski in Antarctica		
1893–95	**Norwegian (Tønsberg) Whaling Expedition**	**Henrik Bull**	***Antarctic***
	Reconnaissance to investigate Antarctic whaling possibilities; landing at Cape Adare widely considered at the time to be the first landing on the continent		
1897–99	**Belgian Antarctic Expedition**	**Adrien de Gerlache**	***Belgica***
	International party discovered and mapped parts of the Antarctic Peninsula and nearby islands; first wintering south of the Antarctic Circle		
1898–1900	**British Antarctic Expedition**	**Carsten Borchgrevink**	***Southern Cross***
	First party to winter on Antarctic continent (Cape Adare); made pioneer scientific investigations; travelled south on Ross Ice Shelf		
1901–03	**German South Polar Expedition**	**Erich von Drygalski**	***Gauss***
	Wintered in ice pack; discovered Wilhelm II Land and Gaussberg		
1901–04	**Swedish South Polar Expedition**	**Otto Nordenskjöld**	***Antarctic***
	Conducted comprehensive scientific program; parties wintered at Snow Hill Island, Hope Bay, and Paulet Island; ship sank		
1901–04	**British National Antarctic Expedition**	**Robert Falcon Scott**	***Discovery***
	Conducted comprehensive scientific program; wintered at Hut Point on Ross Island; discovered King Edward VII Land; attained farthest south of 82°17′ S on Ross Ice Shelf		
1902–04	**Scottish National Antarctic Expedition**	**William Speirs Bruce**	***Scotia***
	Conducted comprehensive scientific program; first oceanographic investigation of Weddell Sea; established meteorological observatory on Laurie Island		
1903	**Argentine Relief Expedition**	**Julian Irîzar**	***Uruguay***
	Rescued members of the Swedish South Polar Expedition		
1903–04	**British Relief Expedition**	**William Colbeck** **Henry Duncan Mackay**	***Morning*** ***Terra Nova***
	Relieved *Discovery* and expedited return of British National Antarctic Expedition		
1903–05	**French Antarctic Expedition**	**Jean-Baptiste Charcot**	***Français***
	Explored and charted islands to west of Antarctic Peninsula; conducted comprehensive scientific program		

Years	Expedition	Leader	Vessel
1904–05	**Establishment of Whaling Base**	**Carl Larsen**	
	Compañia Argentina de Pesca established first Antarctic whaling station at Grytviken, South Georgia		
1907–09	**British Antarctic Expedition**	**Ernest Shackleton**	***Nimrod***
	Wintered at Cape Royds on Ross Island; made first ascent of Mount Erebus; discovered Beardmore Glacier; attained farthest south of 88°23′ S on Polar Plateau; reached region of the South Magnetic Pole		
1908–10	**French Antarctic Expedition**	**Jean-Baptiste Charcot**	***Pourquoi Pas?***
	Explored and charted west coast of Antarctic Peninsula and local islands; conducted comprehensive scientific program		
1910–12	**Norwegian South Polar Expedition**	**Roald Amundsen**	***Fram***
	Wintered on Ross Ice Shelf near Bay of Whales; party of five first to attain South Pole; explored King Edward VII Land		
1910–12	**Japanese Antarctic Expedition**	**Nobu Shirase**	***Kainan-Maru***
	Explored King Edward VII Land		
1910–13	**British South Polar Expedition**	**Robert Falcon Scott**	***Terra Nova***
	Wintered at multiple sites; conducted comprehensive scientific program; party of five second to attain South Pole, but all died on return		
1911–12	**German South Polar Expedition**	**Wilhelm Filchner**	***Deutschland***
	Discovered Filchner Ice Shelf; ship beset and drifted in pack for nine months		
1911–14	**Australasian Antarctic Expedition**	**Douglas Mawson**	***Aurora***
	Wintered at Macquarie Island, Cape Denison, and Shackleton Ice Shelf; conducted most comprehensive scientific program yet at the time, including oceanographic cruises; discovered and explored King George V Land and Queen Mary Land		
1914–16	**Imperial Trans-Antarctic Expedition, Weddell Sea Party**	**Ernest Shackleton**	***Endurance***
	Ship beset and drifted 10 months in Weddell Sea; ship crushed and sank; company reached Elephant Island; six men sailed to South Georgia to organise relief		
1914–17	**Imperial Trans-Antarctic Expedition, Ross Sea Party**	**Æneas Mackintosh**	***Aurora***
	Laid depots for Shackleton's proposed crossing of Antarctica; ship beset and drifted 10 months; land party relieved after three men had died		
1920–22	**British Imperial Expedition**	**John Cope**	
	Two men wintered at Waterboat Point, Antarctic Peninsula; conducted scientific program		
1921–22	**Shackleton-Rowett Antarctic Expedition**	**Ernest Shackleton; Frank Wild**	***Quest***
	Visited South Georgia (where Shackleton died), Weddell Sea, and a series of sub-Antarctic islands		
1923–24	**Norwegian Whaling Expedition**	**Carl Larsen**	***James Clark Ross***
	Initial whaling expedition to the Ross Sea		
1925–51	**Discovery Investigations**	**Neil Alison Mackintosh and others**	***Discovery, William Scoresby, & Discovery II***
	Series of expeditions engaging in long-term series of scientific programs		
1927–37	**Christensen Antarctic Expeditions**		
	Series of seven expeditions promoted by Lars Christensen; explored and claimed Norwegian sector of mainland; landed on and claimed Bouvetøya and Peter I Øy for Norway; made flights over coastal and inland areas; engaged in whaling		
1928–29	**Wilkins-Hearst Antarctic Expedition**	**Hubert Wilkins**	***Hektoria***
	First powered flight in Antarctica		

1928–30	**US Antarctic Expedition**	**Richard E. Byrd**	***City of New York* & 2 other ships**
	Wintered at "Little America" at Bay of Whales; explored various regions; first flight over the South Pole		
1929–30	**British Aerial Expedition**	**Hubert Wilkins**	
	Extended Wilkins' previous aerial reconnaissance of Antarctic Peninsula region		
1929–31	**British, Australian, New Zealand Antarctic Research Expedition**	**Douglas Mawson**	***Discovery***
	Discovered and charted various coasts, helping establish claim for Australian Antarctic Territory		
1933–34	**US Aerial Expedition**	**Lincoln Ellsworth**	***Wyatt Earp***
	Plan to fly across Antarctic continent from Ross Sea to Antarctic Peninsula postponed due to plane crash		
1933–35	**US Byrd Antarctic Expedition**	**Richard E. Byrd**	***Bear of Oakland* & *Jacob Ruppert***
	Wintered at "Little America II" at Bay of Whales; engaged in broad scientific and geographical research program		
1934–35	**US Aerial Expedition**	**Lincoln Ellsworth**	***Wyatt Earp***
	Plan to fly across Antarctic continent from Antarctic Peninsula to Ross Sea postponed due to bad weather; flight made along east coast of Peninsula		
1934–37	**British Graham Land Expedition**	**John Rymill**	***Penola***
	Conducted extensive scientific program; engaged in sledging and aerial geographical surveys		
1935–36	**Ellsworth Trans-Antarctic Flight**	**Lincoln Ellsworth**	***Wyatt Earp***
	Ellsworth & Herbert Hollick-Kenyon made first flight across Antarctic continent		
1938–39	**German Antarctic Expedition**	**Alfred Ritscher**	***Schwabenland***
	Conducted aerial reconnaissance and photography in Dronning Maud Land; claimed areas for Germany		
1939–41	**US Antarctic Service Expedition**	**Richard E. Byrd**	**USNS *North Star* & USS *Bear***
	Wintered at "Little America III" at Bay of Whales and at Stonington Island; conducted comprehensive scientific program and aerial reconnaissance		
1943–44	**British Naval "Operation Tabarin"**	**J. W. S. Marr**	
	Established permanent stations at Port Lockroy and Deception Island; carried out broad scientific program		
1944–45	**British Naval "Operation Tabarin II"**	**Andrew Taylor**	
	Established station at Hope Bay; built hut at Sandefjord Bay, Coronation Island; carried out broad scientific program		
1945–46	**Falkland Islands Dependencies Survey Expedition**	**Edward Bingham**	**3 ships**
	Officially took over responsibility for British stations from Operation Tabarin; established two new bases; conducted scientific and survey program		
1946–47	**US Navy Antarctic Developments Project ("Operation Highjump")**	**Richard E. Byrd**	**13 ships**
	Naval taskforce divided into three main groups with emphasis on naval training and aerial photographic reconnaissance; second flight over the South Pole; limited scientific program		
1947–48	**Australian National Antarctic Research Expedition**	**Stuart Campbell**	**HST *3501***
	Established research station on Heard Island and Macquarie Island and long-term scientific programs begun at both stations		
1947–48	**US Navy Antarctic Developments Project ("Operation Windmill")**	**Gerald L. Ketchum**	**USS *Burton Island* & USS *Edisto***
	Primary task to secure ground control for aerial photographs taken during Operation Highjump		

Years	Expedition	Leader	Vessel
1947–48	**Ronne Antarctic Research Expedition**	**Finn Ronne**	***Port of Beaumont***
	Wintered at Stonington Island; limited scientific and geographical programs; first two women to winter on Antarctic continent: Jennie Darlington and Edith "Jackie" Ronne		
1949–52	**Norwegian–British–Swedish Antarctic Expedition**	**John Giæver**	***Norsel***
	Established base of Maudheim; conducted comprehensive scientific program and extensive aerial survey		
1955–57	**Falkland Islands Dependencies Aerial Survey Expedition**	**Peter Mott**	***Oluf Sven***
	Program of vertical aerial photography of Falkland Islands, South Shetland Islands, and Antarctic Peninsula		
1955–58	**Commonwealth Trans-Antarctic Expedition**	**Vivian Fuchs**	**3 ships**
	First surface crossing of the Antarctic continent from "Shackleton base" on Filchner Ice Shelf to Scott Base on Ross Island via South Pole; comprehensive scientific program and aerial and surface reconnaissance and survey conducted		
1957–58	**International Geophysical Year**		
	World-wide cooperative research program involving 66 nations, of which 12 had bases in Antarctica, including during years immediately preceding and following the IGY		

Appendix II: The Antarctic Treaty

The Governments of Argentina, Australia, Belgium, Chile, the French Republic, Japan, New Zealand, Norway, the Union of South Africa, the Union of Soviet Socialist Republics, the United Kingdom of Great Britain and Northern Ireland, and the United States of America,

Recognizing that it is in the interest of all mankind that Antarctica shall continue for ever to be used exclusively for peaceful purposes and shall not become the scene or object of international discord;

Acknowledging the substantial contributions to scientific knowledge resulting from international cooperation in scientific investigation in Antarctica;

Convinced that the establishment of a firm foundation for the continuation and development of such cooperation on the basis of freedom of scientific investigation in Antarctica as applied during the International Geophysical Year accords with the interests of science and the progress of all mankind;

Convinced also that a treaty ensuring the use of Antarctica for peaceful purposes only and the continuance of international harmony in Antarctica will further the purposes and principles embodied in the Charter of the United Nations;

Have agreed as follows:

Article I

1. Antarctica shall be used for peaceful purposes only. There shall be prohibited, *inter alia,* any measure of a military nature, such as the establishment of military bases and fortifications, the carrying out of military manoeuvres, as well as the testing of any type of weapon.
2. The present Treaty shall not prevent the use of military personnel or equipment for scientific research or for any other peaceful purpose.

Article II

Freedom of scientific investigation in Antarctica and cooperation toward that end, as applied during the International Geophysical Year, shall continue, subject to the provisions of the present Treaty.

Article III

1. In order to promote international cooperation in scientific investigation in Antarctica, as provided for in Article II of the present Treaty, the Contracting Parties agree that, to the greatest extent feasible and practicable:

   a. information regarding plans for scientific programs in Antarctica shall be exchanged to permit maximum economy of and efficiency of operations;
   b. scientific personnel shall be exchanged in Antarctica between expeditions and stations;
   c. scientific observations and results from Antarctica shall be exchanged and made freely available.

2. In implementing this Article, every encouragement shall be given to the establishment of cooperative working relations with those Specialized Agencies of the United Nations and other technical organizations having a scientific or technical interest in Antarctica.

Article IV

1. Nothing contained in the present Treaty shall be interpreted as:

   a. a renunciation by any Contracting Party of previously asserted rights of or claims to territorial sovereignty in Antarctica;
   b. a renunciation or diminution by any Contracting Party of any basis of claim to territorial sovereignty in Antarctica which it may have whether as a result of its activities or those of its nationals in Antarctica, or otherwise;
   c. prejudicing the position of any Contracting Party as regards its recognition or non-recognition of any other State's rights of

or claim or basis of claim to territorial sovereignty in Antarctica.

2. No acts or activities taking place while the present Treaty is in force shall constitute a basis for asserting, supporting or denying a claim to territorial sovereignty in Antarctica or create any rights of sovereignty in Antarctica. No new claim, or enlargement of an existing claim, to territorial sovereignty in Antarctica shall be asserted while the present Treaty is in force.

Article V

1. Any nuclear explosions in Antarctica and the disposal there of radioactive waste material shall be prohibited.
2. In the event of the conclusion of international agreements concerning the use of nuclear energy, including nuclear explosions and the disposal of radioactive waste material, to which all of the Contracting Parties whose representatives are entitled to participate in the meetings provided for under Article IX are parties, the rules established under such agreements shall apply in Antarctica.

Article VI

The provisions of the present Treaty shall apply to the area south of 60° South Latitude, including all ice shelves, but nothing in the present Treaty shall prejudice or in any way affect the rights, or the exercise of the rights, of any State under international law with regard to the high seas within that area.

Article VII

1. In order to promote the objectives and ensure the observance of the provisions of the present Treaty, each Contracting Party whose representatives are entitled to participate in the meetings referred to in Article IX of the Treaty shall have the right to designate observers to carry out any inspection provided for by the present Article. Observers shall be nationals of the Contracting Parties which designate them. The names of observers shall be communicated to every other Contracting Party having the right to designate observers, and like notice shall be given of the termination of their appointment.
2. Each observer designated in accordance with the provisions of paragraph 1 of this Article shall have complete freedom of access at any time to any or all areas of Antarctica.
3. All areas of Antarctica, including all stations, installations and equipment within those areas, and all ships and aircraft at points of discharging or embarking cargoes or personnel in Antarctica, shall be open at all times to inspection by any observers designated in accordance with paragraph 1 of this Article.
4. Aerial observation may be carried out at any time over any or all areas of Antarctica by any of the Contracting Parties having the right to designate observers.
5. Each Contracting Party shall, at the time when the present Treaty enters into force for it, inform the other Contracting Parties, and thereafter shall give them notice in advance, of

   a. all expeditions to and within Antarctica, on the part of its ships or nationals, and all expeditions to Antarctica organized in or proceeding from its territory;
   b. all stations in Antarctica occupied by its nationals; and
   c. any military personnel or equipment intended to be introduced by it into Antarctica subject to the conditions prescribed in paragraph 2 of Article I of the present Treaty.

Article VIII

1. In order to facilitate the exercise of their functions under the present Treaty, and without prejudice to the respective positions of the Contracting Parties relating to jurisdiction over all other persons in Antarctica, observers designated under paragraph 1 of Article VII and scientific personnel exchanged under sub-paragraph 1(b) of Article III of the Treaty, and members of the staffs accompanying any such persons, shall be subject only to the jurisdiction of the Contracting Party of which they are nationals in respect of all acts or omissions occurring while they are in Antarctica for the purpose of exercising their functions.

2. Without prejudice to the provisions of paragraph 1 of this Article, and pending the adoption of measures in pursuance of subparagraph 1(e) of Article IX, the Contracting Parties concerned in any case of dispute with regard to the exercise of jurisdiction in Antarctica shall immediately consult together with a view to reaching a mutually acceptable solution.

Article IX

1. Representatives of the Contracting Parties named in the preamble to the present Treaty shall meet at the City of Canberra within two months after the date of entry into force of the Treaty, and thereafter at suitable intervals and places, for the purpose of exchanging information, consulting together on matters of common interest pertaining to Antarctica, and formulating and considering, and recommending to their Governments, measures in furtherance of the principles and objectives of the Treaty, including measures regarding:

   a. use of Antarctica for peaceful purposes only;
   b. facilitation of scientific research in Antarctica;
   c. facilitation of international scientific cooperation in Antarctica;
   d. facilitation of the exercise of the rights of inspection provided for in Article VII of the Treaty;
   e. questions relating to the exercise of jurisdiction in Antarctica;
   f. preservation and conservation of living resources in Antarctica.

2. Each Contracting Party which has become a party to the present Treaty by accession under Article XIII shall be entitled to appoint representatives to participate in the meetings referred to in paragraph 1 of the present Article, during such times as that Contracting Party demonstrates its interest in Antarctica by conducting substantial research activity there, such as the establishment of a scientific station or the dispatch of a scientific expedition.
3. Reports from the observers referred to in Article VII of the present Treaty shall be transmitted to the representatives of the Contracting Parties participating in the meetings referred to in paragraph 1 of the present Article.
4. The measures referred to in paragraph 1 of this Article shall become effective when approved by all the Contracting Parties whose representatives were entitled to participate in the meetings held to consider those measures.
5. Any or all of the rights established in the present Treaty may be exercised as from the date of entry into force of the Treaty whether or not any measures facilitating the exercise of such rights have been proposed, considered or approved as provided in this Article.

Article X

Each of the Contracting Parties undertakes to exert appropriate efforts, consistent with the Charter of the United Nations, to the end that no one engages in any activity in Antarctica contrary to the principles or purposes of the present Treaty.

Article XI

1. If any dispute arises between two or more of the Contracting Parties concerning the interpretation or application of the present Treaty, those Contracting Parties shall consult among themselves with a view to having the dispute resolved by negotiation, inquiry, mediation, conciliation, arbitration, judicial settlement or other peaceful means of their own choice.
2. Any dispute of this character not so resolved shall, with the consent, in each case, of all parties to the dispute, be referred to the International Court of Justice for settlement; but failure to reach agreement on reference to the International Court shall not absolve parties to the dispute from the responsibility of continuing to seek to resolve it by any of the various peaceful means referred to in paragraph 1 of this Article.

Article XII

1. a. The present Treaty may be modified or amended at any time by unanimous agreement of the Contracting Parties whose representatives are entitled to participate in the meetings provided for under Article IX. Any such modification or amendment shall enter into force when the depositary Government has received notice from all such Contracting Parties that they have ratified it.

b. Such modification or amendment shall thereafter enter into force as to any other Contracting Party when notice of ratification by it has been received by the depositary Government. Any such Contracting Party from which no notice of ratification is received within a period of two years from the date of entry into force of the modification or amendment in accordance with the provision of subparagraph 1(a) of this Article shall be deemed to have withdrawn from the present Treaty on the date of the expiration of such period.

2. a. If after the expiration of thirty years from the date of entry into force of the present Treaty, any of the Contracting Parties whose representatives are entitled to participate in the meetings provided for under Article IX so requests by a communication addressed to the depositary Government, a Conference of all the Contracting Parties shall be held as soon as practicable to review the operation of the Treaty.

   b. Any modification or amendment to the present Treaty which is approved at such a Conference by a majority of the Contracting Parties there represented, including a majority of those whose representatives are entitled to participate in the meetings provided for under Article IX, shall be communicated by the depositary Government to all Contracting Parties immediately after the termination of the Conference and shall enter into force in accordance with the provisions of para-graph 1 of the present Article

   c. If any such modification or amendment has not entered into force in accordance with the provisions of subparagraph 1(a) of this Article within a period of two years after the date of its communication to all the Contracting Parties, any Contracting Party may at any time after the expiration of that period give notice to the depositary Government of its withdrawal from the present Treaty; and such withdrawal shall take effect two years after the receipt of the notice by the depositary Government.

Article XIII

1. The present Treaty shall be subject to ratification by the signatory States. It shall be open for accession by any State which is a Member of the United Nations, or by any other State which may be invited to accede to the Treaty with the consent of all the Contracting Parties whose representatives are entitled to participate in the meetings provided for under Article IX of the Treaty.
2. Ratification of or accession to the present Treaty shall be effected by each State in accordance with its constitutional processes.
3. Instruments of ratification and instruments of accession shall be deposited with the Government of the United States of America, hereby designated as the depositary Government.
4. The depositary Government shall inform all signatory and acceding States of the date of each deposit of an instrument of ratification or accession, and the date of entry into force of the Treaty and of any modification or amendment thereto.
5. Upon the deposit of instruments of ratification by all the signatory States, the present Treaty shall enter into force for those States and for States which have deposited instruments of accession. Thereafter the Treaty shall enter into force for any acceding State upon the deposit of its instruments of accession.
6. The present Treaty shall be registered by the depositary Government pursuant to Article 102 of the Charter of the United Nations.

Article XIV

The present Treaty, done in the English, French, Russian and Spanish languages, each version being equally authentic, shall be deposited in the archives of the Government of the United States of America, which shall transmit duly certified copies thereof to the Governments of the signatory and acceding States.

The Antarctic Treaty
signed in Washington on 1 December 1959
entered into force on 23 June 1961

Appendix III: Signatories to the Antarctic Treaty

The Antarctic Treaty was signed in Washington on 1 December 1959 by 12 states, and entered into force for those states on 23 June 1961. Below are listed in chronological order the dates of ratification of the Treaty by the original signatories, the dates of accession or succession by other states, and the dates upon which acceding states became Consultative Parties.

Chronological Order

	State	Date	Status	Date when Acceding State Became Consultative Party
1	United Kingdom	31 May 1960	OS/CP	
2	South Africa	21 June 1960	OS/CP	
3	Belgium	26 July 1960	OS/CP	
4	Japan	4 August 1960	OS/CP	
5	United States of America	18 August 1960	OS/CP	
6	Norway	24 August 1960	OS/CP	
7	France	16 September 1960	OS/CP	
8	New Zealand	1 November 1960	OS/CP	
9	Russia[1]	2 November 1960	OS/CP	
10	Poland	8 June 1961	AS/CP	29 July 1977
11	Argentina	23 June 1961	OS/CP	
12	Australia	23 June 1961	OS/CP	
13	Chile	23 June 1961	OS/CP	
14	Czech Republic[2]	14 June 1962	AS	
15	Slovak Republic[2]	14 June 1952	AS	
16	Denmark	20 May 1965	AS

Appendix IV: SCAR Code of Conduct for Use of Animals for Scientific Purposes in Antarctica

Preamble

RECOGNIZING that Man has a moral obligation to respect all animals and to have due consideration for their capacity for suffering and memory:

ACCEPTING nevertheless that Man in his quest for knowledge has a need to use animals where there is a reasonable expectation that the result will provide a significant advance in knowledge or be of overall benefit for animals;

RESOLVED to limit the use of animals for experimental and other scientific purposes, with the aim of replacing such use wherever practical, in particular by seeking alternative measures and encouraging the use of these alternative measures;

DESIRING to adopt common provisions in order to protect animals used in those procedures which may possibly cause pain, suffering, distress or lasting harm and to ensure that where unavoidable they shall be kept to a minimum;

SCAR has adopted a code of conduct which is based on the international guiding principles for biomedical research involving animals as developed by the Council for International Organization of Medical Sciences.

Code of Conduct

I. The advancement of biological knowledge and the development of improved means to the protection of the health and well-being both of man and of the animals require recourse to experimentation on intact live mammals and birds of a wide variety of species.

II. Methods such as mathematical models, computer simulation and *in vitro* biological systems should be used wherever appropriate.

III. Animal experiments should be undertaken only after due consideration of their relevance for human or animal health and the advancement of biological knowledge.

IV. The animals selected for an experiment should be of an appropriate species and quality, and the minimum number required to obtain scientifically valid results.

V. Investigators and other personnel should never fail to treat animals as sentient, and should regard their proper care and use and the avoidance or minimization of discomfort, distress, or pain as ethical imperatives.

VI. Investigators should assume that procedures that would cause pain in human beings cause pain in other mammals and in birds.

VII. Procedures with animals that may cause more than momentary or minimal pain or distress should be performed with appropriate sedation, analgesia, or anesthesia in accordance with accepted veterinary practice. Surgical or other painful procedures should not be performed on unanesthetized animals paralyzed by chemical agents.

VIII. Where waivers are required in relation to the provisions of article VII, the decisions should not rest solely with the investigators directly concerned but should be made, with due regard to the provisions of articles IV, V and VI, by a suitably constituted review body. Such waivers should not be made solely for the purposes of teaching or demonstration.

IX. At the end, or, when appropriate, during an experiment animals that would otherwise suffer severe or chronic pain, distress, discomfort, or disablement that cannot be relieved should be painlessly killed.

X. The best possible living conditions and supervision should be maintained for animals kept for biomedical purposes.

XI. It is the responsibility of the director of an institute or department using animals to ensure that investigators and personnel have appropriate qualifications or experience for conducting procedures on animals. Adequate opportunities shall be provided for in-service training, including the proper and humane concern for the animals under their care.

Appendix V: Protocol on Environmental Protection to the Antarctic Treaty

Preamble

The States Parties to this Protocol to the Antarctic Treaty, hereinafter referred to as the Parties,

Convinced of the need to enhance the protection of the Antarctic environment and dependent and associated ecosystems;

Convinced of the need to strengthen the Antarctic Treaty system so as to ensure that Antarctica shall continue forever to be used exclusively for peaceful purposes and shall not become the scene or object of international discord;

Bearing in mind the special legal and political status of Antarctica and the special responsibility of the Antarctic Treaty Consultative Parties to ensure that all activities in Antarctica are consistent with the purposes and principles of the Antarctic Treaty;

Recalling the designation of Antarctica as a Special Conservation Area and other measures adopted under the Antarctic Treaty system to protect the Antarctic environment and dependent and associated ecosystems;

Acknowledging further the unique opportunities Antarctica offers for scientific monitoring of and research on processes of global as well as regional importance;

Reaffirming the conservation principles of the Convention on the Conservation of Antarctic Marine Living Resources;

Convinced that the development of a comprehensive regime for the protection of the Antarctic environment and dependent and associated ecosystems is in the interest of mankind as a whole;

Desiring to supplement the Antarctic Treaty to this end;

Have agreed as follows:

Article 1

Definitions

For the purposes of this Protocol:

(a) "The Antarctic Treaty" means the Antarctic Treaty done at Washington on 1 December 1959;

(b) "Antarctic Treaty area" means the area to which the provisions of the Antarctic Treaty apply in accordance with Article VI of that Treaty;

(c) "Antarctic Treaty Consultative Meetings" means the meetings referred to in Article IX of the Antarctic Treaty;

(d) "Antarctic Treaty Consultative Parties" means the Contracting Parties to the Antarctic Treaty entitled to appoint representatives to participate in the meetings referred to in Article IX of that Treaty;

(e) "Antarctic Treaty system" means the Antarctic Treaty, the measures in effect under that Treaty, its associated separate international instruments in force and the measures in effect under those instruments;

(f) "Arbitral Tribunal" means the Arbitral Tribunal established in accordance with the Schedule to this Protocol, which forms an integral part thereof;

(g) "Committee" means the Committee for Environmental Protection established in accordance with Article 11.

Article 2

Objective and Designation

The Parties commit themselves to the comprehensive protection of the Antarctic environment and dependent and associated ecosystems and hereby designate Antarctica as a natural reserve, devoted to peace and science.

Article 3

Environmental Principles

1. The protection of the Antarctic environment and dependent and associated ecosystems and the intrinsic value of Antarctica, including its wilderness and aesthetic values and its value as an area for the conduct of scientific research, in particular research essential to understanding the global environment, shall

be fundamental considerations in the planning and conduct of all activities in the Antarctic Treaty area.

2. To this end:

   (a) activities in the Antarctic Treaty area shall be planned and conducted so as to limit adverse impacts on the Antarctic environment and dependent and associated ecosystems;
   (b) activities in the Antarctic Treaty area shall be planned and conducted so as to avoid:

      (i) adverse effects on climate or weather patterns;
      (ii) significant adverse effects on air or water quality;
      (iii) significant changes in the atmospheric, terrestrial (including aquatic), glacial or marine environments;
      (iv) detrimental changes in the distribution, abundance or productivity of species or populations of species of fauna and flora;
      (v) further jeopardy to endangered or threatened species or populations of such species; or
      (vi) degradation of, or substantial risk to, areas of biological, scientific, historic, aesthetic or wilderness significance;

   (c) activities in the Antarctic Treaty area shall be planned and conducted on the basis of information sufficient to allow prior assessments of, and informed judgements about, their possible impacts on the Antarctic environment and dependent and associated ecosystems and on the value of Antarctica for the conduct of scientific research; such judgements shall take account of:

      (i) the scope of the activity, including its area, duration and intensity;
      (ii) the cumulative impacts of the activity, both by itself and in combination with other activities in the Antarctic Treaty area;
      (iii) whether the activity will detrimentally affect any other activity in the Antarctic Treaty area;
      (iv) whether technology and procedures are available to provide for environmentally safe operations;
      (v) whether there exists the capacity to monitor key environmental parameters and ecosystem components so as to identify and provide early warning of any adverse effects of the activity and to provide for such modification of operating procedures as may be necessary in the light of the results of monitoring or increased knowledge of the Antarctic environment and dependent and associated ecosystems; and
      (vi) whether there exists the capacity to respond promptly and effectively to accidents, particularly those with potential environmental effects;

   (d) regular and effective monitoring shall take place to allow assessment of the impacts of ongoing activities, including the verification of predicted impacts;
   (e) regular and effective monitoring shall take place to facilitate early detection of the possible unforeseen effects of activities carried on both within and outside the Antarctic Treaty area on the Antarctic environment and dependent and associated ecosystems.

3. Activities shall be planned and conducted in the Antarctic Treaty area so as to accord priority to scientific research and to preserve the value of Antarctica as an area for the conduct of such research, including research essential to understanding the global environment.
4. Activities undertaken in the Antarctic Treaty area pursuant to scientific research programmes, tourism and all other governmental and non-governmental activities in the Antarctic Treaty area for which advance notice is required in accordance with Article VII (5) of the Antarctic Treaty, including associated logistic support activities, shall:

   (a) take place in a manner consistent with the principles in this Article; and
   (b) be modified, suspended or cancelled if they result in or threaten to result in impacts upon the Antarctic environment or dependent or associated ecosystems inconsistent with those principles.

Article 4

Relationship with the Other Components of the Antarctic Treaty System

1. This Protocol shall supplement the Antarctic Treaty and shall neither modify nor amend that Treaty.

2. Nothing in this Protocol shall derogate from the rights and obligations of the Parties to this Protocol under the other international instruments in force within the Antarctic Treaty system.

Article 5

Consistency with the Other Components of the Antarctic Treaty System

The Parties shall consult and co-operate with the Contracting Parties to the other international instruments in force within the Antarctic Treaty system and their respective institutions with a view to ensuring the achievement of the objectives and principles of this Protocol and avoiding any interference with the achievement of the objectives and principles of those instruments or any inconsistency between the implementation of those instruments and of this Protocol.

Article 6

Co-operation

1. The Parties shall co-operate in the planning and conduct of activities in the Antarctic Treaty area. To this end, each Party shall endeavour to:
   (a) promote co-operative programmes of scientific, technical and educational value, concerning the protection of the Antarctic environment and dependent and associated ecosystems;
   (b) provide appropriate assistance to other Parties in the preparation of environmental impact assessments;
   (c) provide to other Parties upon request information relevant to any potential environmental risk and assistance to minimize the effects of accidents which may damage the Antarctic environment or dependent and associated ecosystems;
   (d) consult with other Parties with regard to the choice of sites for prospective stations and other facilities so as to avoid the cumulative impacts caused by their excessive concentration in any location;
   (e) where appropriate, undertake joint expeditions and share the use of stations and other facilities; and
   (f) carry out such steps as may be agreed upon at Antarctic Treaty Consultative Meetings.
2. Each Party undertakes, to the extent possible, to share information that may be helpful to other Parties in planning and conducting their activities in the Antarctic Treaty area, with a view to the protection of the Antarctic environment and dependent and associated ecosystems.
3. The Parties shall co-operate with those Parties which may exercise jurisdiction in areas adjacent to the Antarctic Treaty area with a view to ensuring that activities in the Antarctic Treaty area do not have adverse environmental impacts on those areas.

Article 7

Prohibition of Mineral Resource Activities

Any activity relating to mineral resources, other than scientific research, shall be prohibited.

Article 8

Environmental Impact Assessment

1. Proposed activities referred to in paragraph 2 below shall be subject to the procedures set out in Annex I for prior assessment of the impacts of those activities on the Antarctic environment or on dependent or associated ecosystems according to whether those activities are identified as having:
   (a) less than a minor or transitory impact;
   (b) a minor transitory impact; or
   (c) more than a minor or transitory impact.
2. Each Party shall ensure that the assessment procedures set out in Annex I are applied in the planning processes leading to decisions about any activities undertaken in the Antarctic Treaty area pursuant to scientific research programmes, tourism and all other governmental and non-governmental activities in the Antarctic Treaty area for which advance notice is required under Article VII (5) of the Antarctic Treaty, including associated logistic support activities.
3. The assessment procedures set out in Annex I shall apply to any change in an activity whether the change arises from an increase or decrease in the intensity of an existing activity,

from the addition of an activity, the decommissioning of a facility, or otherwise.

4. Where activities are planned jointly by more than one Party, the Parties involved shall nominate one of their number to coordinate the implementation of the environmental impact assessment procedures set out in Annex I.

Article 9

Annexes

1. The Annexes to this Protocol shall form an integral part thereof.
2. Annexes, additional to Annexes I-IV, may be adopted and become effective in accordance with Article IX of the Antarctic Treaty.
3. Amendments and modifications to Annexes may be adopted and become effective in accordance with Article IX of the Antarctic Treaty, provided that any Annex may itself make provision for amendments and modifications to become effective on an accelerated basis.
4. Annexes and any amendments and modifications thereto which have become effective in accordance with paragraphs 2 and 3 above shall, unless an Annex itself provides otherwise in respect of the entry into effect of any amendment or modification thereto, become effective for a Contracting Party to the Antarctic Treaty which is not an Antarctic Treaty Consultative Party, or which was not an Antarctic Treaty Consultative Party at the time of the adoption, when notice of approval of that Contracting Party has been received by the Depositary.
5. Annexes shall, except to the extent that an Annex provides otherwise, be subject to the procedures for dispute settlement set out in Articles 18 to 20.

Article 10

Antarctic Treaty Consultative Meetings

1. Antarctic Treaty Consultative Meetings shall, drawing upon the best scientific and technical advice available:

   (a) define, in accordance with the provisions of this Protocol, the general policy for the comprehensive protection of the Antarctic environment and dependent and associated ecosystems; and

   (b) adopt measures under Article IX of the Antarctic Treaty for the implementation of this Protocol.

2. Antarctic Treaty Consultative Meetings shall review the work of the committee and shall draw fully upon its advice and recommendations in carrying out the tasks referred to in paragraph 1 above, as well as upon the advice of the Scientific Committee on Antarctic Research.

Article 11

Committee for Environmental Protection

1. There is hereby established the Committee for Environmental Protection.
2. Each Party shall be entitled to be a member of the Committee and to appoint a representative who may be accompanied by experts and advisers.
3. Observer status in the Committee shall be open to any Contracting Party to the Antarctic Treaty which is not a Party to this Protocol.
4. The Committee shall invite the President of the Scientific Committee on Antarctic Research and the Chairman of the Scientific Committee for the Conservation of Antarctic Marine Living Resources to participate as observers at its sessions. The Committee may also, with the approval of the Antarctic Treaty Consultative Meeting, invite such other relevant scientific, environmental and technical organisations which can contribute to its work to participate as observers at its sessions.
5. The Committee shall present a report on each of its sessions to the Antarctic Treaty Consultative Meeting. The report shall cover all matters considered at the session and shall reflect the views expressed. The report shall be circulated to the Parties and to observers attending the session, and shall thereupon be made publicly available.
6. The Committee shall adopt its rules of procedure which shall be subject to approval by the Antarctic Treaty Consultative Meeting.

Article 12

Functions of the Committee

1. The functions of the Committee shall be to provide advice and formulate recommendations

to the Parties in connection with the implementation of this Protocol, including the operation of its Annexes, for consideration at Antarctic Treaty Consultative Meetings, and to perform such other functions as may be referred to it by the Antarctic Treaty Consultative Meetings. In particular, it shall provide advice on:

(a) the effectiveness of measures taken pursuant to this Protocol;
(b) the need to update, strengthen or otherwise improve such measures;
(c) the need for additional measures, including the need for additional Annexes, where appropriate;
(d) the application and implementation of the environmental impact assessment procedures set out in Article 8 and Annex I;
(e) means of minimising or mitigating environmental impacts of activities in the Antarctic Treaty area;
(f) procedures for situations requiring urgent action, including response action in environmental emergencies;
(g) the operation and further elaboration of the Antarctic Protected Area system;
(h) inspection procedures, including formats for inspection reports and checklists for the conduct of inspections;
(i) the collection, archiving, exchange and evaluation of information related to environmental protection;
(j) the state of the Antarctic environment; and
(k) the need for scientific research, including environmental monitoring, related to the implementation of this Protocol.

2. In carrying out its functions, the Committee shall, as appropriate, consult with the Scientific Committee on Antarctic Research, the Scientific Committee for the Conservation of Antarctic Marine Living Resources and other relevant scientific, environmental and technical organizations.

Article 13

Compliance with This Protocol

1. Each Party shall take appropriate measures within its competence, including the adoption of laws and regulations, administrative actions and enforcement measures, to ensure compliance with this Protocol.
2. Each Party shall exert appropriate efforts, consistent with the Charter of the United Nations, to the end that no one engages in any activity contrary to this Protocol.
3. Each Party shall notify all other Parties of the measures it takes pursuant to paragraphs 1 and 2 above.
4. Each Party shall draw the attention of all other Parties to any activity which in its opinion affects the implementation of the objectives and principles of this Protocol.
5. The Antarctic Treaty Consultative Meetings shall draw the attention of any State which is not a Party to this Protocol to any activity undertaken by that State, its agencies, instrumentalities, natural or juridical persons, ships, aircraft or other means of transport which affects the implementation of the objectives and principles of this Protocol.

Article 14

Inspection

1. In order to promote the protection of the Antarctic environment and dependent and associated ecosystems, and to ensure compliance with this Protocol, the Antarctic Treaty Consultative Parties shall arrange, individually or collectively, for inspections by observers to be made in accordance with Article VII of the Antarctic Treaty.
2. Observers are:

   (a) observers designated by any Antarctic Treaty Consultative Party who shall be nationals of that Party; and
   (b) any observers designated at Antarctic Treaty Consultative Meetings to carry out inspections under procedures to be established by an Antarctic Treaty Consultative Meeting.

3. Parties shall co-operate fully with observers undertaking inspections, and shall ensure that during inspections, observers are given access to all parts of stations, installations, equipment, ships and aircraft open to inspection under Article VII (3) of the Antarctic Treaty, as well as to all records maintained thereon which are called for pursuant to this Protocol.
4. Reports of inspections shall be sent to the Parties whose stations; installations, equipment, ships or aircraft are covered by the

reports. After those Parties have been given the opportunity to comment, the reports and any comments thereon shall be circulated to all the Parties and to the Committee, considered at the next Antarctic Treaty Consultative Meeting, and thereafter made publicly available.

Article 15

Emergency Response Action

1. In order to respond to environmental emergencies in the Antarctic Treaty area, each Party agrees to:

   (a) provide for prompt and effective response action to such emergencies which might arise in the performance of scientific research programmes, tourism and all other governmental and non-governmental activities in the Antarctic Treaty area for which advance notice is required under Article VII (15) of the Antarctic Treaty, including associated logistic support activities; and
   (b) establish contingency plans for response to incidents with potential adverse effects on the Antarctic environment or dependent and associated ecosystems.

2. To this end, the Parties shall:

   (a) co-operate in the formulation and implementation of such contingency plans; and
   (b) establish procedures for immediate notification of, and co-operative response to, environmental emergencies.

3. In the implementation of this Article, the Parties shall draw upon the advice of the appropriate international organisations.

Article 16

Liability
Consistent with the objectives of this Protocol for the comprehensive protection of the Antarctic environment and dependent and associated ecosystems, the Parties undertake to elaborate rules and procedures relating to liability for damage arising from activities taking place in the Antarctic Treaty area and covered by this Protocol. Those rules and procedures shall be included in one or more Annexes to be adopted in accordance with Article 9 (2).

Article 17

Annual Report by Parties

1. Each Party shall report annually on the steps taken to implement this Protocol. Such reports shall include notifications made in accordance with Article 13 (3), contingency plans established in accordance with Article 15 and any other notifications and information called for pursuant to this Protocol for which there is no other provision concerning the circulation and exchange of information.
2. Reports made in accordance with paragraph 1 above shall be circulated to all Parties and to the Committee, considered at the next Antarctic Treaty Consultative Meeting, and made publicly available.

Article 18

Dispute Settlement
If a dispute arises concerning the interpretation or application of this Protocol, the parties to the dispute shall, at the request of any one of them, consult among themselves as soon as possible with a view to having the dispute resolved by negotiation, inquiry, mediation, conciliation, arbitration, judicial settlement or other peaceful means to which the parties to the dispute agree.

Article 19

Choice of Dispute Settlement Procedure

1. Each Party, when signing, ratifying, accepting, approving or acceding to this Protocol, or at any time thereafter, may choose, by written declaration, one or both of the following means for the settlement of disputes concerning the interpretation or application of Articles 7, 8 and 15 and, except to the extent that an Annex provides otherwise, the provisions of any Annex and, insofar as it relates to these Articles and provisions, Article 13:

   (a) the International Court of Justice;
   (b) the Arbitral Tribunal.

2. A declaration made under paragraph 1 above shall not affect the operation of Article 18 and Article 20 (2).
3. A Party which has not made a declaration under paragraph 1 above or in respect of which a declaration is no longer in force shall be deemed to have accepted the competence of the Arbitral Tribunal.
4. If the parties to a dispute have accepted the same means for the settlement of a dispute, the dispute may be submitted only to that procedure, unless the parties otherwise agree.
5. If the parties to a dispute have not accepted the same means for the settlement of a dispute, or if they have both accepted both means, the dispute may be submitted only to the Arbitral Tribunal, unless the parties otherwise agree.
6. A declaration made under paragraph 1 above shall remain in force until it expires in accordance with its terms or until three months after written notice of revocation has been deposited with the Depositary.
7. A new declaration, a notice of revocation or the expiry of a declaration shall not in any way affect proceedings pending before the International Court of Justice or the Arbitral Tribunal, unless the parties to the dispute otherwise agree.
8. Declarations and notices referred to in this Article shall be deposited with the Depositary who shall transmit copies thereof to all Parties.

Article 20

Dispute Settlement Procedure

1. If the parties to a dispute concerning the interpretation or application of Articles 7, 8 or 15 or, except to the extent that an Annex provides otherwise, the provisions of any Annex or, insofar as it relates to these Articles and provisions, Article 13, have not agreed on a means for resolving it within 12 months of the request for consultation pursuant to Article 18, the dispute shall be referred, at the request of any party to the dispute, for settlement in accordance with the procedure determined by Article 19 (4) and (5).
2. The Arbitral Tribunal shall not be competent to decide or rule upon any matter within the scope of Article IV of the Antarctic Treaty. In addition, nothing in this Protocol shall be interpreted as conferring competence or jurisdiction on the International Court of Justice or any other tribunal established for the purpose of settling disputes between Parties to decide or otherwise rule upon any matter within the scope of Article IV of the Antarctic Treaty.

Article 21

Signature

This Protocol shall be open for signature at Madrid on the 4th of October 1991 and thereafter at Washington until the 3rd of October 1992 by any State which is a Contracting Party to the Antarctic Treaty.

Article 22

Ratification, Acceptance, Approval or Accession

1. This Protocol is subject to ratification, acceptance of approval by signatory States.
2. After the 3rd of October 1992 this Protocol shall be open for accession by any State which is a Contracting Party to the Antarctic Treaty.
3. Instruments of ratification, acceptance, approval or accession shall be deposited with the Government of the United States of America, hereby designated as the Depositary.
4. After the date on which this Protocol has entered into force, the Antarctic Treaty Consultative Parties shall not act upon a notification regarding the entitlement of a Contracting Party to the Antarctic Treaty to appoint representatives to participate in Antarctic Treaty Consultative Meetings in accordance with Article IX (2) of the Antarctic Treaty unless that Contracting Party has first ratified, accepted, approved or acceded to this Protocol.

Article 23

Entry into Force

1. This Protocol shall enter into force on the thirtieth day following the date of deposit of instruments of ratification, acceptance, approval or accession by all States which are Antarctic Treaty Consultative Parties at the date on which this Protocol is adopted.

2. For each Contracting Party to the Antarctic Treaty which, subsequent to the date of entry into force of this Protocol, deposits an instrument of ratification, acceptance, approval or accession, this Protocol shall enter into force on the thirtieth day following such deposit.

Article 24

Reservations

Reservations to this Protocol shall not be permitted.

Article 25

Modification or Amendment

1. Without prejudice to the provisions of Article 9, this Protocol may be modified or amended at any time in accordance with the procedures set forth in Article XII (1) (a) and (b) of the Antarctic Treaty.
2. If, after the expiration of 50 years from the date of entry into force of this Protocol, any of the Antarctic Treaty Consultative Parties so requests by a communication addressed to the Depositary, a conference shall be held as soon as practicable to review the operation of this Protocol.
3. A modification or amendment proposed at any Review Conference called pursuant to paragraph 2 above shall be adopted by a majority of the Parties, including ¾ of the States which are Antarctic Treaty Consultative Parties at the time of adoption of this Protocol.
4. A modification or amendment adopted pursuant to paragraph 3 above shall enter into force upon ratification, acceptance, approval or accession by ¾ of the Antarctic Treaty Consultative Parties, including ratification, acceptance, approval or accession by all States which are Antarctic Treaty Consultative Parties at the time of adoption of this Protocol.
5. (a) With respect to Article 7, the prohibition on Antarctic mineral resource activities contained therein shall continue unless there is in force a binding legal regime on Antarctic mineral resource activities that includes an agreed means for determining whether, and, if so, under which conditions, any such activities would be acceptable. This regime shall fully safeguard the interests of all States referred to in Article IV of the Antarctic Treaty and apply the principles thereof. Therefore, if a modification or amendment to Article 7 is proposed at a Review Conference referred to in paragraph 2 above, it shall include such a binding legal regime.
   (b) If any such modification or amendment has not entered into force within 3 years of the date of its adoption, any Party may at any time thereafter notify to the Depositary of its withdrawal from this Protocol, and such withdrawal shall take effect 2 years after receipt of the notification by the Depositary.

Article 26

Notifications by the Depositary

The Depositary shall notify all Contracting Parties to the Antarctic Treaty of the following:

(a) signatures of this Protocol and the deposit of instruments of ratification, acceptance, approval or accession;
(b) the date of entry into force of this Protocol and any additional Annex thereto;
(c) the date of entry into force of any amendment or modification to this Protocol;
(d) the deposit of declarations and notices pursuant to Article 19; and
(e) any notification received pursuant to Article 25 (5) (b).

Article 27

Authentic Texts and Registration with the United Nations

1. This Protocol, done in the English, French, Russian and Spanish languages, each version being equally authentic, shall be deposited in the archives of the Government of the United States of America, which shall transmit duly certified copies thereof to all Contracting Parties to the Antarctic Treaty.
2. This Protocol shall be registered by the Depositary pursuant to Article 102 of the charter of the United Nations.

Additional texts

Schedule to the Protocol: Arbitration

Annex I: Environmental Impact Assessment
Annex II: Conservation of Antarctic Fauna and Flora
Annex III: Waste Disposal and Waste Management
Annex IV: Prevention of Marine Pollution
Annex V: Area Protection and Management
Annex VI: Liability for Environmental Emergencies

Note: The complete text of the Protocol on Environmental Protection to the Antarctic Treaty is reproduced here. In addition, there is a "Schedule to the Protocol," and there are six annexes that are listed at the end. The full texts of the "Schedule" and the annexes may be seen at: http://ww.cep.aq/default.asap?casid=5074

Appendix VII: Antarctic Academic Journals

Analysis of the *Antarctic Bibliography* shows that scientific papers on Antarctica are now published in more than one thousand journals. There are few journals devoted entirely to the polar regions and only six—*Antarctic Science, Antarctic Research Series, Antarctic Record, CCAMLR Science, Terra Antartica,* and *Byuleten' Ukrains'kogo Antarktichnogo Tsentru*—are committed just to the continent and its surrounding seas.

Bipolar journals include *Polar Biology* and *Polarforschung* from Germany, *Polar Record* from the UK, *Arctic Antarctic and Alpine Research* from the United States, and journals from China and Poland.

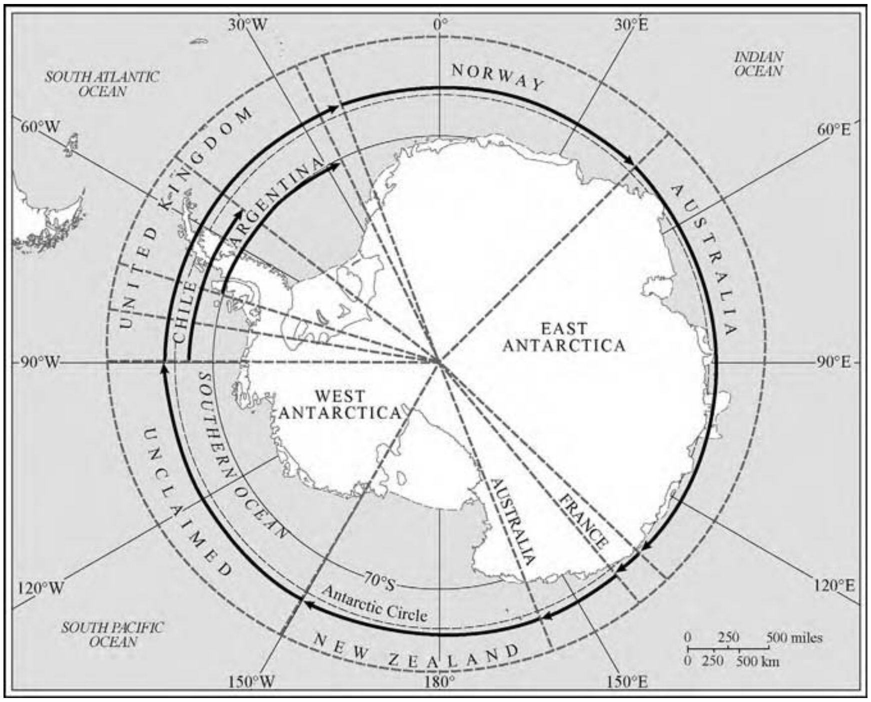
The most significant disciplinary journals for Antarctic science include *Journal of Geophysical Research, Geophysical Research Letters, Deep Sea Research, Annals of Glaciology,* as well as *Nature* and *Science*.

The top twenty-two journals, in terms of the numbers of Antarctic science papers published over the last 6 years, are (in alphabetical order):

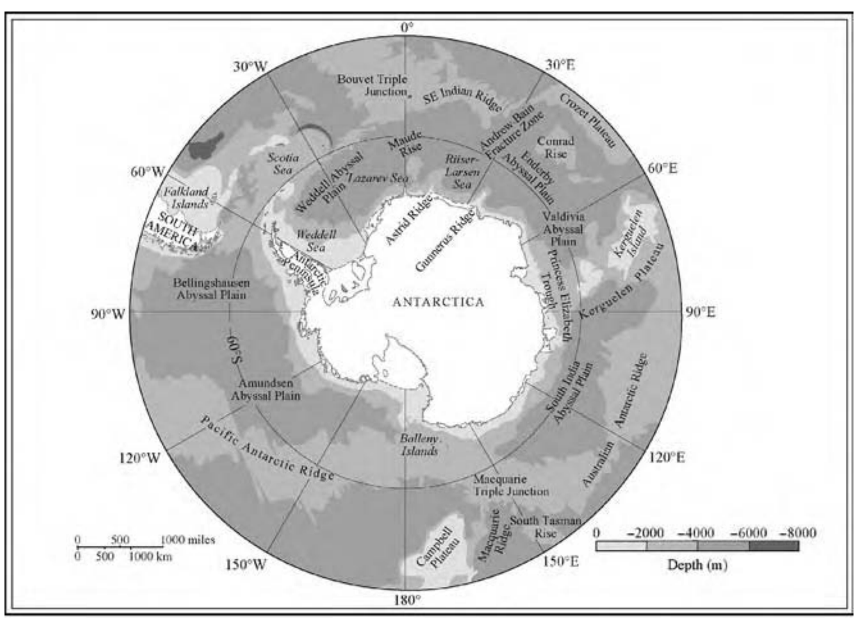
Antarctic Research Series
Antarctic Science
Berichte zur Polar- und Meeresforschung (formerly Berichte zur Polarforschung)
Bulletin—Royal Society of New Zealand
Byuleten' Ukrains'kogo Antarktichnogo Tsentru
Chinese Journal of Polar Science
Deep-Sea Research. Parts I and II
Geografiska Annaler. Series A: Physical Geography
Geophysical Research Letters
Global and Planetary Change
Jidi Yanjiu = Chinese Journal of Polar Research
Journal of Climate
Journal of Geophysical Research
Journal of Glaciology
Nankyoku Shiryo = Antarctic Record
Nature
Polar Biology
Polish Polar Research
Science
Terra Antartica
Terra Antartica Reports

D. W. H. Walton

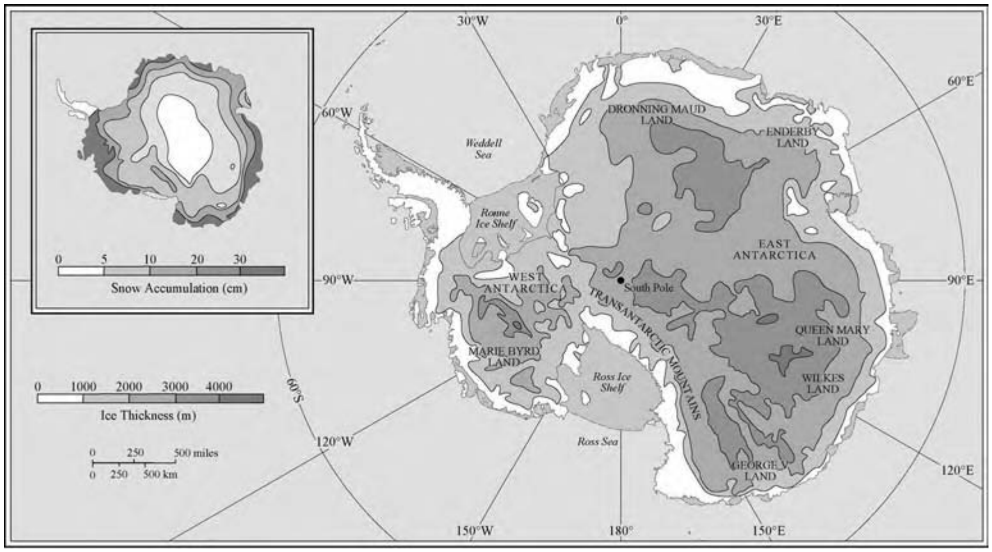
Maps



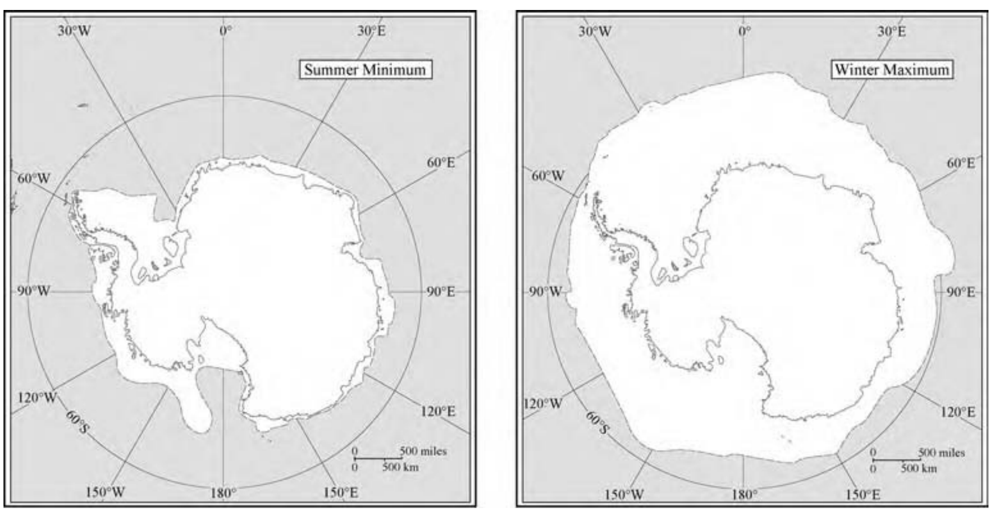
Antarctic territorial claims.



Bathymetry of the Southern Ocean region. The Southern Ocean is delineated by the 60° S latitude and the Antarctic coast. Depths are color-coded according to the scale bar at the base of the figure, with contours drawn at 2000 m intervals.

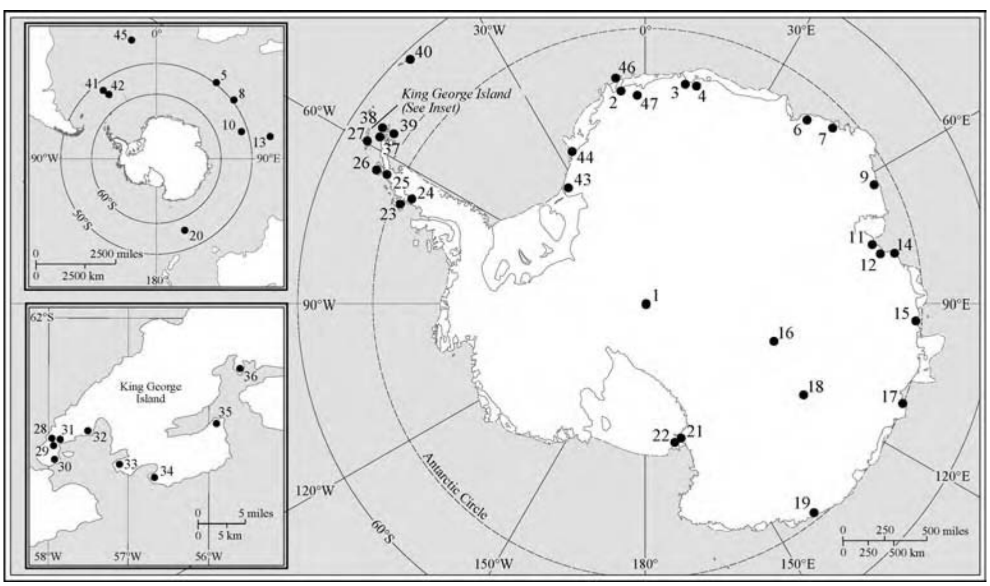


Antarctic ice sheet thickness and mean annual snow accumulation. Note that the areas of greatest ice thickness are not the same as those of maximum snow accumulation.

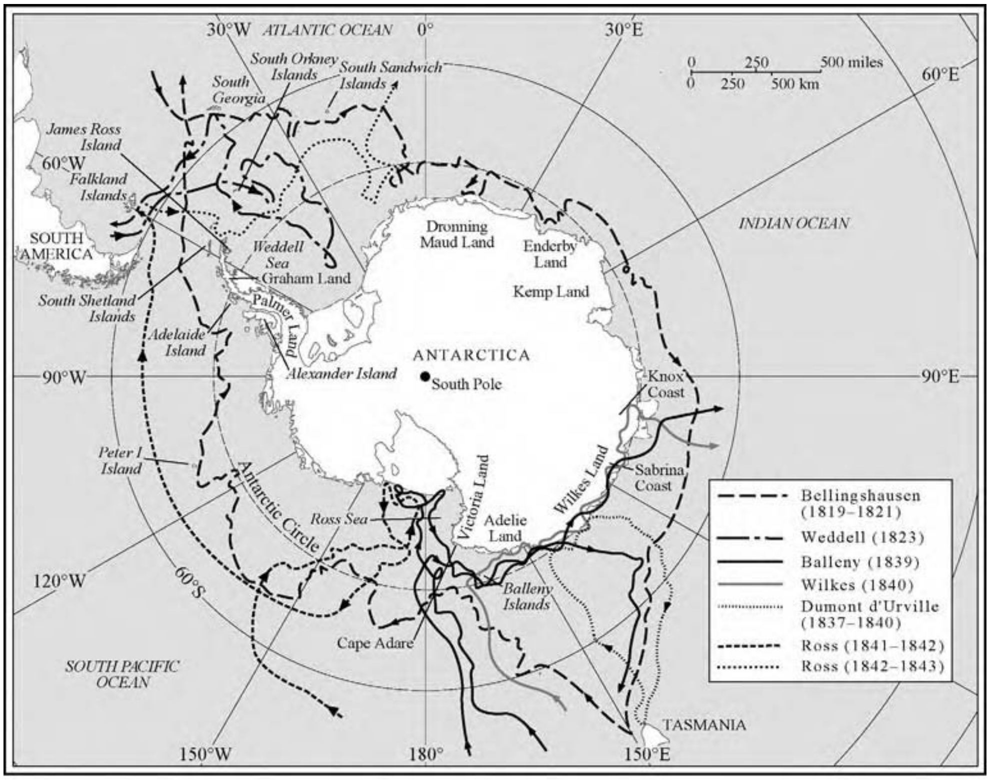


Sea ice extent. Left: minimum, during February, when only the Weddell, Bellingshausen, and Amundsen seas have much ice cover. Right: maximum, during September, when the ice cover increases at least five times over its minimum.

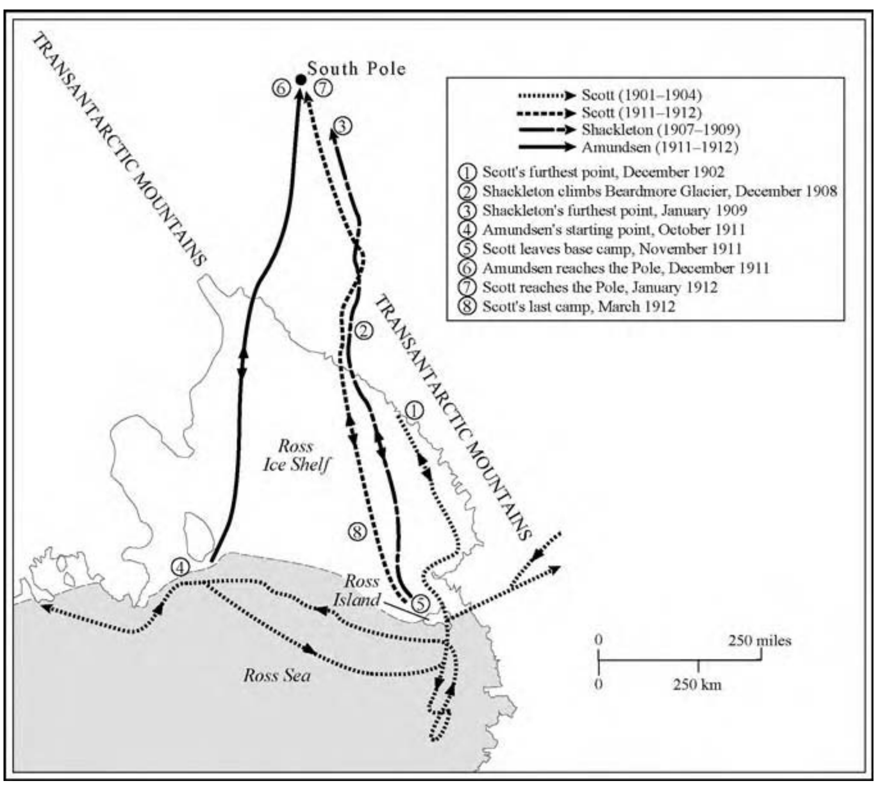
The Antarctic Plate. The continent sits well in the middle of it, surrounded by five other plates.



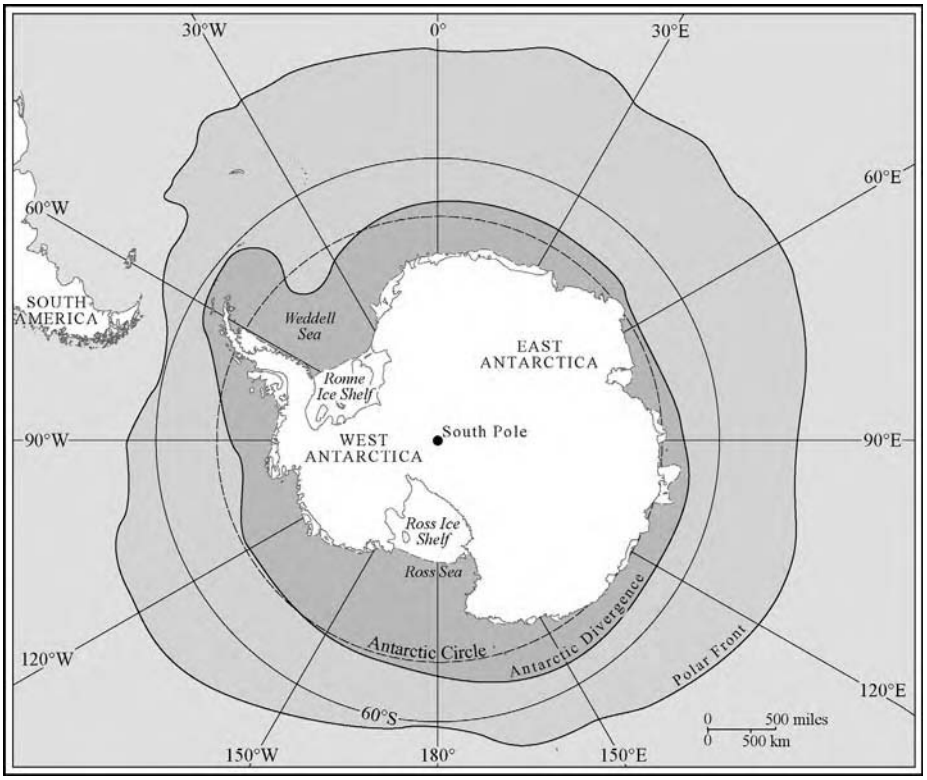
Scientific research stations in the Antarctic, austral winter 2005. Information about the numbered bases can be found in Appendix VI.



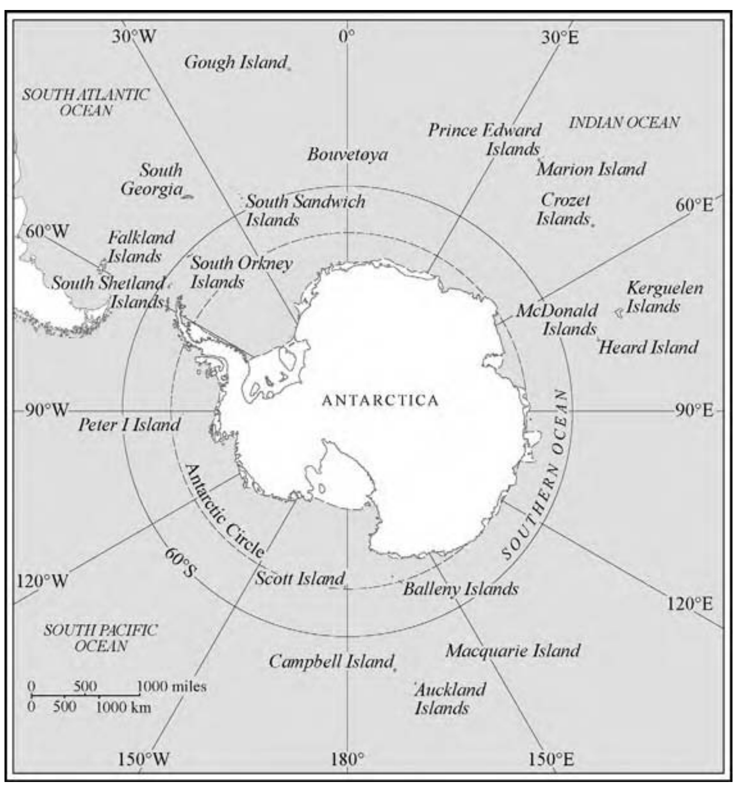
The maritime routes of Antarctic expeditions in the first half of the nineteenth century.



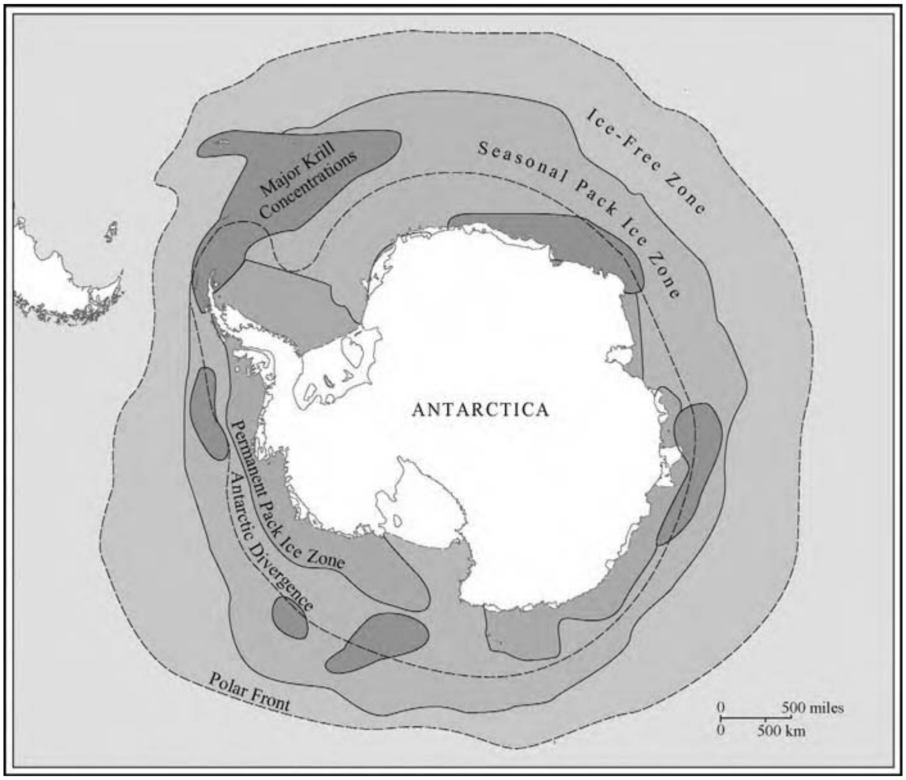
The race for the South Pole.



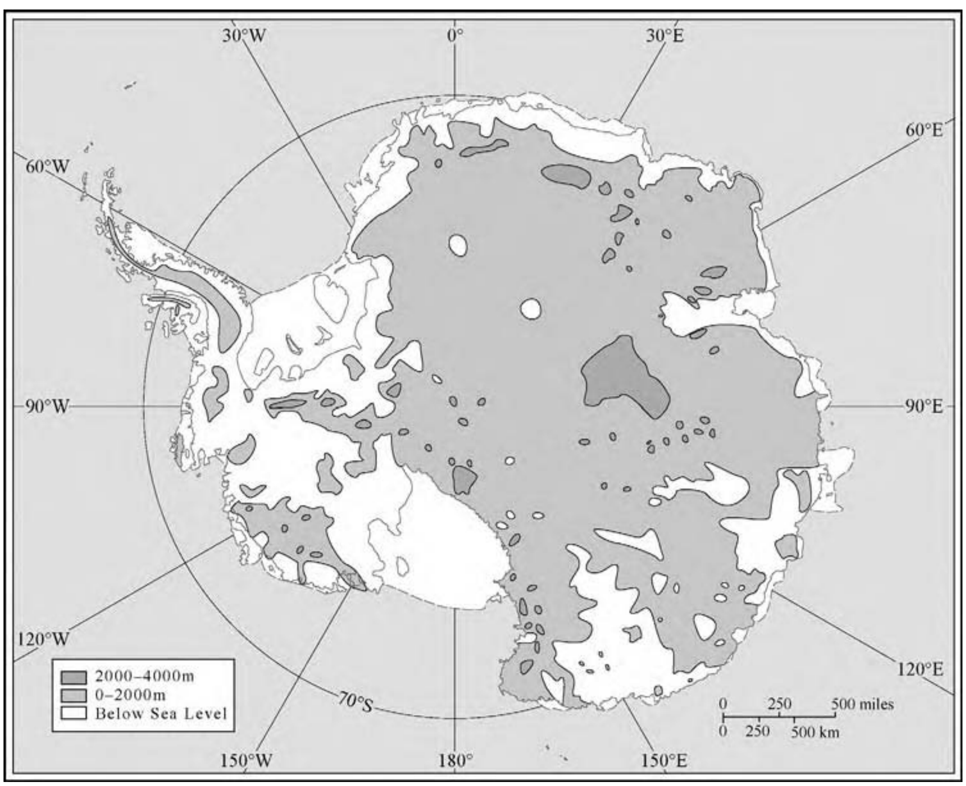
The major oceanographic fronts: the Polar Front (formerly the Antarctic Convergence) and the Antarctic Divergence.



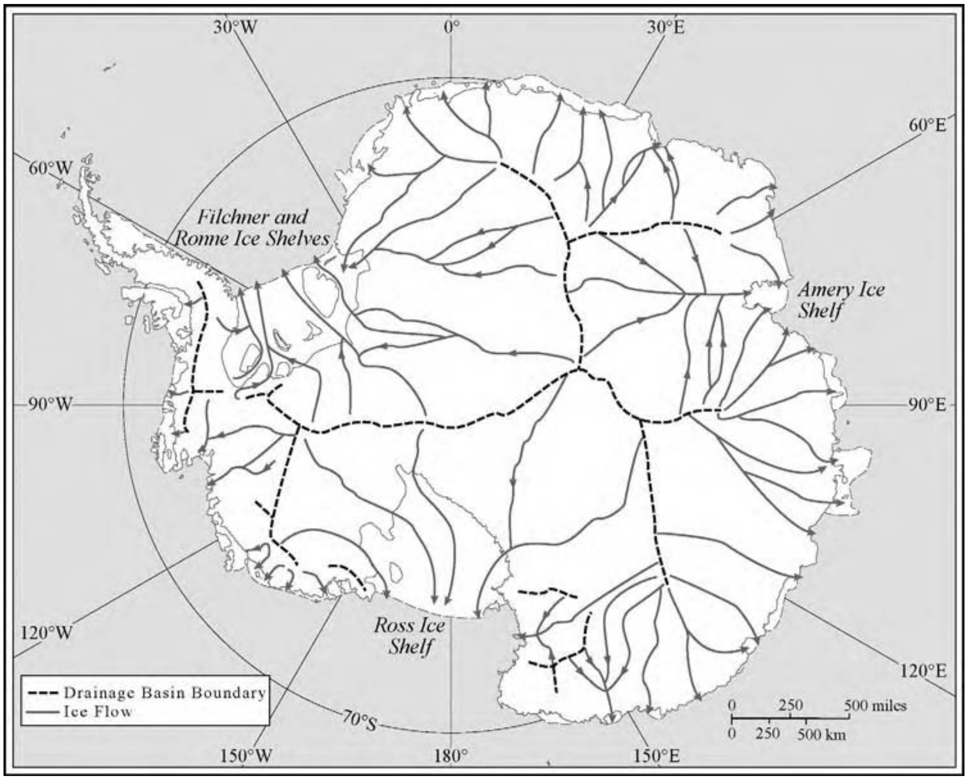
The sub-Antarctic islands.



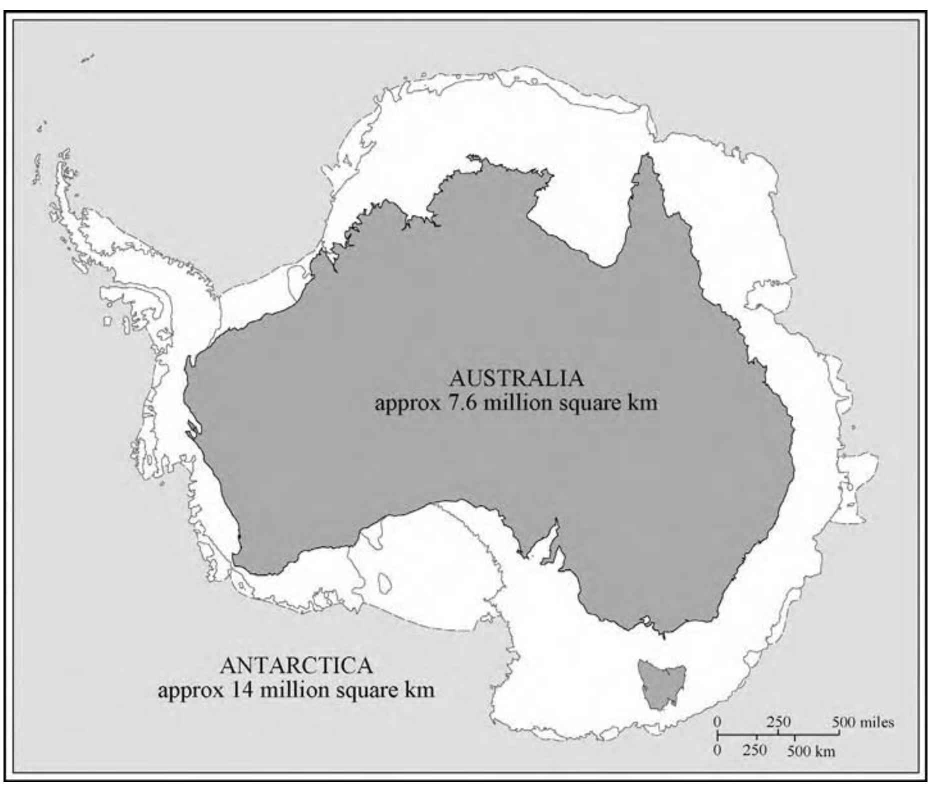
Krill abundance in the Southern Ocean. The major concentrations of krill occur within the seasonal pack ice zone.



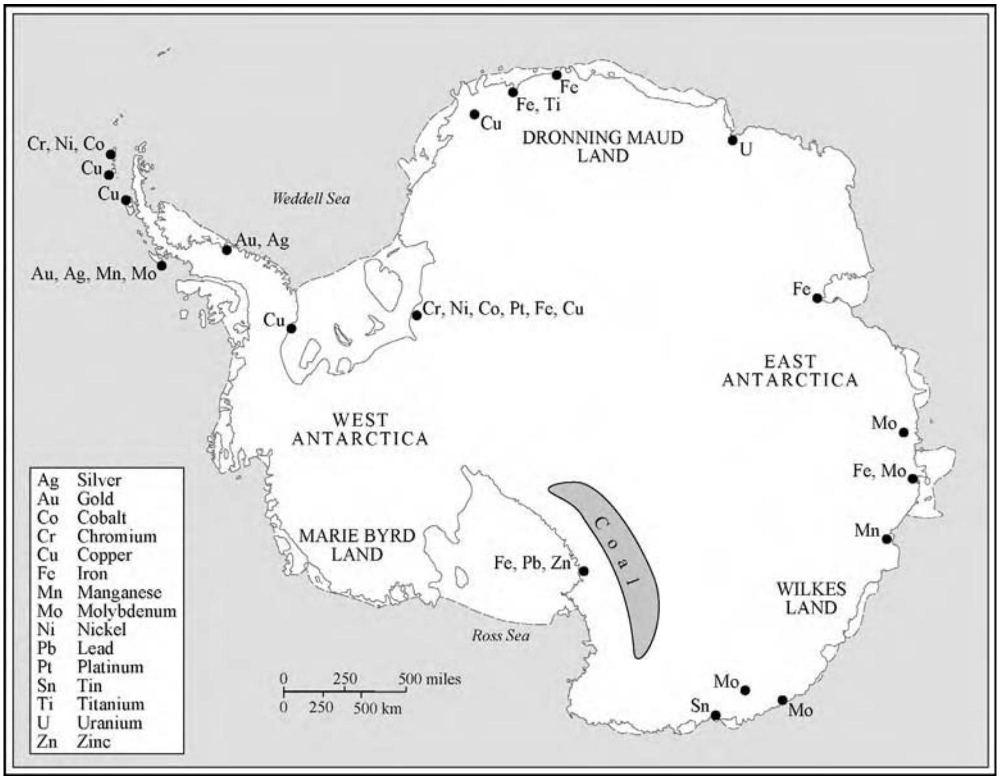
Bedrock of continental Antarctica, as it would be if the overlying ice were removed and isostatic rebound had caused it to rise.



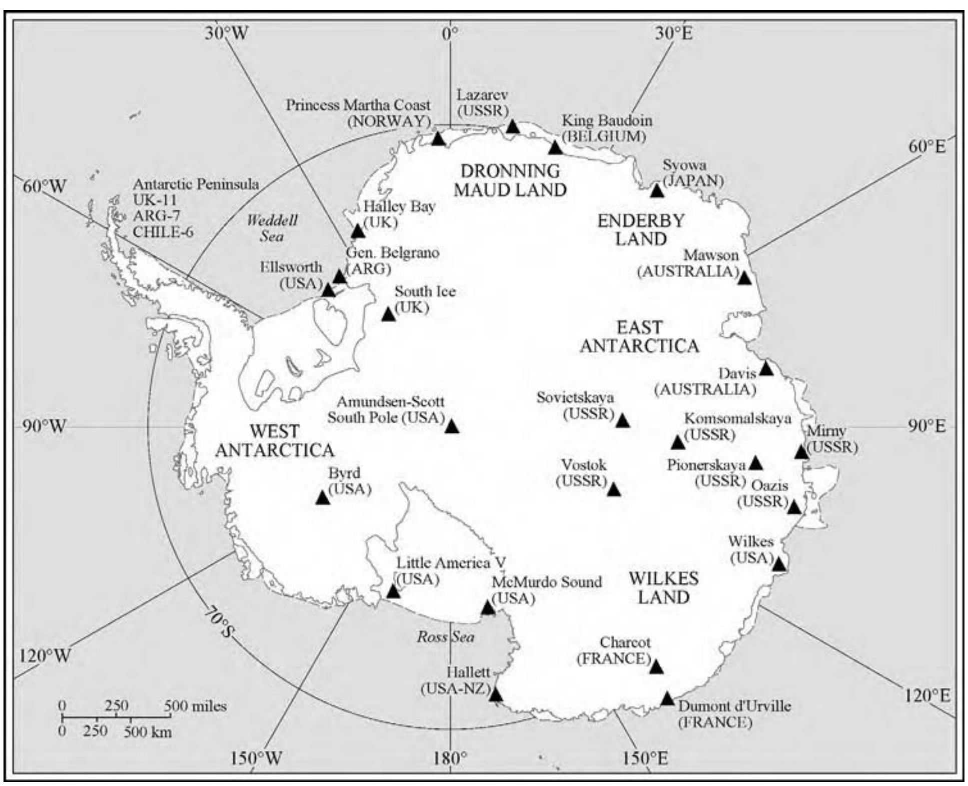
The movement of the Antarctic Ice Sheet as it flows downhill towards the coast through drainage basins. There are three major drainage areas—forming the Ross Ice Shelf, the Filchner-Ronne Ice Shelf, and the Amery Ice Shelf—as well as other areas around the entire continent.



The continent of Antarctica is almost twice as large as Australia. The size of the former is approximately 14 million square km, while of the latter approximately 7.6 million square km.



Minerals found in the Antarctic. Most of these are inaccessible.



Stations of the International Geophysical Year. A dozen different nations set up 50 different stations for the largest scientific project ever undertaken. Many of these stations or successors at the same locations are still in use today.
